The basis for our investigation is an annotated dataset created by Petersen (2020) and subsequently updated by us to include more examples and senses. The examples are extracted from the Corpus of Contemporary American English (CoCA; Davies 2008). We focus on a subset of 1,042 sentences that have been annotated for, among other things, the core semantic class of the reading and the construction type (‘unergative’, ‘unaccusative’, ‘causative’). Petersen assigns a single semantic class to each example. However, as mentioned in Section 3, we believe that, in some cases, *break* can be said to simultaneously express more than one meaning. We use our experiment in Section 5.3 to identify examples with this property.

We rely primarily on the meaning class distinctions and make secondary use of the constructional annotations. Petersen’s annotation scheme uses 72 semantically rich meaning classes, which have a highly skewed distribution. The full distribution is given in Appendix E.

5.2 Probing Experiments

We want to explore the LLM representations in a fluid way that will lead us to identify new readings. Our tools for doing this are supervised probe models applied to the column of representations above the *break* token in each of our examples. We probe for meaning-class and construction-type (see also Papadimitriou et al. 2021). These probes serve as a quantitative evaluation of the extent to which these *break* representations encode these important properties, and they are also tools for heuristically finding new uses and readings.

For our construction-type probing work, we can use all 1,042 sentences, since there are only three classes and all have substantial representation in the

data (causative: 673 examples, unaccusative: 197, unergative: 172). For the meaning-type work, there are 72 classes, many with only a few instances. Thus, we limit attention to just the classes with at least 10 examples (Appendix E).

Our probe models are L2-regularized classifiers with a cross-entropy loss. Our core metric is the macro F1 score, which assigns equal weight to each class’s F1 score regardless of the class size. Following Hewitt and Liang (2019), we report *selectivity* scores, which are the probe scores minus the performance on a control task, which here is random assignment of *break* representations to meaning classes. We report selectivity scores averaged across 20 random 80%/20% train/test splits.

The probe results show a clear pattern: the lowest layers are not very robust when it comes to this probing work, but higher layers are very robust in this sense (see also Reif et al. 2019; Ethayarajh 2019). We see similar results for other LLMs in the class we are focused on, as reported in Appendix D. For this reason, we focus on layer 24 of RoBERTa-large from now on.

5.3 Discovering New Example Types

Our primary goal is to see whether it is possible to use LLMs to gain new insights about lexical semantics. Our probing results suggest that LLM representations are systematic enough to make this plausible, but they are very high-level. We need an investigative technique that is more free-form and that can bring to our attention new kinds of theory-relevant examples.

A natural choice is visualization. We provide t-SNE visualizations (van der Maaten and Hinton, 2008) in Appendix G, and we find that they are indeed useful: where an example of meaning class *a* is nestled among examples of class *b*, the *a*-class example is often an interesting blend of *a*-class

Sentence	Meaning		Construction	
	Gold	Predicted	Gold	Predicted
1. Patients will sometimes break out in a spontaneous recitation of the rosary	break_out_start	break_out_start	unacc.	unerg.
2. It was like you knew something, like you knew the story was getting ready to break again.	reveal	appear	unacc.	unacc.
3. @(Soundbite-of-music)@!Mr-GELB: (Singing) Tell me who’s going to pick up the pieces when you start to break down.	break_down_separate_into_parts	break_down_succumb	unacc.	unacc.
4. People have so many problems overcoming the disputes that occur when families break up	break_up_end_relationship	break_up_separate_into_parts	unacc.	unacc.
5. “So why tell the whole story now? Somebody, some male, has got to be willing to break this code of silence,” he says.	violate	end	unacc.	unacc.
6. So they forwarded the pictures to Madrid, where another officer noticed some printing on a towel that helped break the case.	decipher	end	causative	causative
7. Then too, stress can also work to break down the immune system, increasing the likelihood of respiratory and creating gastrointestinal and nervous disorders.	break_down_render_inoperable	break_down_destroy	causative	causative
8. Wind, naturally acidic rain, and physical processes such as freezethaw cycles also break down rock.	break_down_separate_into_parts	break_down_destroy	causative	causative
9. It didn’t take being an ICU exec to break the code: trade secret.	decipher	violate	causative	causative

Table 6: A curated sample of theoretically informative examples.

and *b*-class meanings, and such examples seem genuinely worthwhile to study further. However, these visualizations introduce known distortions resulting from compressing high-dimensional spaces into two dimensions (Wattenberg et al., 2016), and they can even vary in qualitatively substantive ways across models and runs.

For something more stable, we return to our probe models. The selectivity scores for both are conservative if we think of them as tools for finding new examples: the meaning-class probes achieve results above 80% macro F1, and the construction-type probes are nearly perfect in their performance (where chance is around 33%). Thus, we decided to extract and review the errors made by these models, with the expectation that many of these examples could inform lexical semantic theory itself.

Table 6 is a selection of examples that we extracted in this way for further analysis. This is a small curated set of (so-called) errors, though these examples do not look like errors to us, but rather like instances in which multiple senses and multiple construction types emerge in the same example.

Example 1 is predicted unergative, whereas the gold label is unaccusative. For us, this raises a new

question: what is the role of *spontaneous* in the overall agentivity of the subject, and should this play into how we characterize the syntactic frame?

Example 2 looks like a clear case where multiple senses can be activated and different utterance contexts might favor different readings. Is the breaking of a news story an agentive act of revealing information (the gold label), or can it be (or be described as) something more like a natural process of appearing (the predicted label)? Both readings seem available, and individual uses might blend them for a particular rhetorical effect.

We also find cases where both the gold meaning and the predicted meaning are in principle available, and the choice between them depends on whether we would like to focus on the metaphorical or the literal meaning of the expression. This can be seen in examples 3 and 4.

Example 4 also reveals a common pattern we found in our examples: in many cases where multiple senses are present, there is a contextual entailment relation between them. In example 4, should we focus on the direct and perhaps metaphorical reading (gold) or the more literal likely consequence (predicted)? In example 5, violating the

code of silence entails ending it. In example 6, deciphering a case entails solving or ending it. In example 7, the process of breaking down the immune system, which we paraphrased as rendering it inoperable (gold meaning), could culminate in its destruction (predicted meaning). And example 8 reveals that the event structure of *break* examples can be very complex. When a rock is broken down by natural forces, we can think of this as a process of breaking down into smaller parts (gold meaning) with the end state being total destruction (predicted meaning). Many examples in which the breaking event leads to the fragmentation of the theme participant can show similar blends.

We also see cases where there seems to be genuine uncertainty about which of the two senses is intended. Example 9 illustrates this. Depending on the meaning of the word *code* (‘encryption’ vs. ‘norm’), *break* can either mean ‘decipher’ (gold) or ‘violate’ (predicted). This example further evinces the importance of our contextual modulation tenet: sometimes we have to go even beyond full sentences to be able to determine the meaning of *break* in a particular case.

These are just a few examples of a much larger set of interesting cases that emerge from studying the interaction between our LLM-based probe models and our linguistic annotations. Appendix F provides a larger sample with brief annotations about potential theoretical relevance. We close this paper by reflecting on how best to incorporate these insights into the linguistic theory itself.

6 Discussion

The fact that linguistic theory and LLMs agree on the core tenets of high dimensionality and contextual modulation is a striking alignment of theoretical ideas with engineering success.

The fact that LLMs do not use discrete features, but rather derive dense, real-valued representations from data seems like an opportunity for linguists to reflect on the role of discreteness. As we noted in Section 3, it seems unlikely that purely analytic work and traditional corpus work will lead to an exhaustive hand-built representation for any lexical items. With LLMs, we can mine the existing representations while considering the LLM architecture and learned parameters to be a reflection of the core tenets of the theory.

The deep contextual modulation countenanced by linguistic theory and operationalized by LLM

embeddings invites a further question: do lexical items exist outside of their tokens of use? Even for the hand-built feature representations in Table 3, the rows could in principle vary based even on usage information, which would suggest a theory that is actually more about tokens (instances of use) than types. Similarly, for LLMs, though they do contain type-level representations (in the form of an embedding for the vocabulary), these play a minor role, and all the representations we have considered in this paper were in terms of representations that are more like token-level representations.

Overall, then, a theory of lexical semantics that draws heavily on LLMs as investigative tools, and even as ways to state theoretical ideas, is likely to become more usage-based than traditional theories would assume. This could lead them to focus less on pure representation and more on what is actually communicated between people when they use language. Traditional questions are likely to take on new forms in this setting, and exciting and relevant new questions – and new pieces of evidence – are likely to arise.

7 Limitations

Our general thesis is that LLMs are valuable tools both for conducting lexical semantic analyses and for providing valuable perspectives for lexical semantic theory design in general. Although we think this thesis is widely supported by prior literature, our own case study is limited to just a partial analysis of a single verb. This creates the risk that our general conclusions may be more specific to this verb, or to English, than we would like. The prior literature inherits many of our English-only biases as well (but see [Papadimitriou et al. 2021](#)).

Our main results use RoBERTa-large, and our appendices report on parallel analyses with different versions of BERT and DeBERTa. These models share core architectural features and were optimized in largely similar ways using very large – and largely uncontrolled – datasets. This means that these artifacts are certainly biased in ways that are relevant for lexical semantics. However, we are unlikely to be able to identify, isolate, and factor out these biases with the methods used in our paper. Our core methods are reasonably simple and lightweight, and we have released all our code. We hope that these steps allow easy reproduction of our core analyses whenever newer LLMs are released, so that we can begin to understand better how LLM

biases can affect linguistic theorizing in the mode we are advocating for.

Our current approach also has an analytic limitation: though we fit probe models and use them as devices for finding potentially relevant examples, the final step in our analysis involves inspection of those examples by linguists like ourselves. This means that the final step is not as reproducible as the others, and it means that any analytic biases that the linguists involved might have are likely to make their way into the analyses. We do not see a way to avoid these analytic steps entirely, since linguistic analysis favors this kind of low-level work, but we do think that we can mitigate the concerns about analyst bias by making all our data available for others to inspect, as a way of opening up many perspectives on the data and the associated theoretical questions.

Supplementary Materials

A WordNet-based Features

The feature-based analyses of Section 3 are easily extended with features obtained using more approximate, data-driven techniques. To illustrate this potential, we looked to WordNet (Fellbaum, 1998), which has a very rich picture of *break*. The lemma *break* participates in 59 SynSets in WordNet. We built a graph of these SynSets based on the hypernym relation. The resulting graph has 29 connected components (29 subgraphs). Figure 1 depicts the largest connected components as subgraphs. If we label these subgraphs with their most-specific shared hypernym, we get potentially new meaning dimensions like “Cause to change; make different; cause a transformation” and “undergo a change; become different in essence; losing one’s or its original nature”. These are similar, but only the first conveys agency. Both seem like plausible latent semantic dimensions that we could add to Table 3, either as primitive features or as sets of more basic meanings. And of course this is only a single example of many that WordNet would support, and additional features could be extracted from FrameNet (Baker et al., 1998; Baker and Sato, 2003; Ruppenhofer et al., 2006).

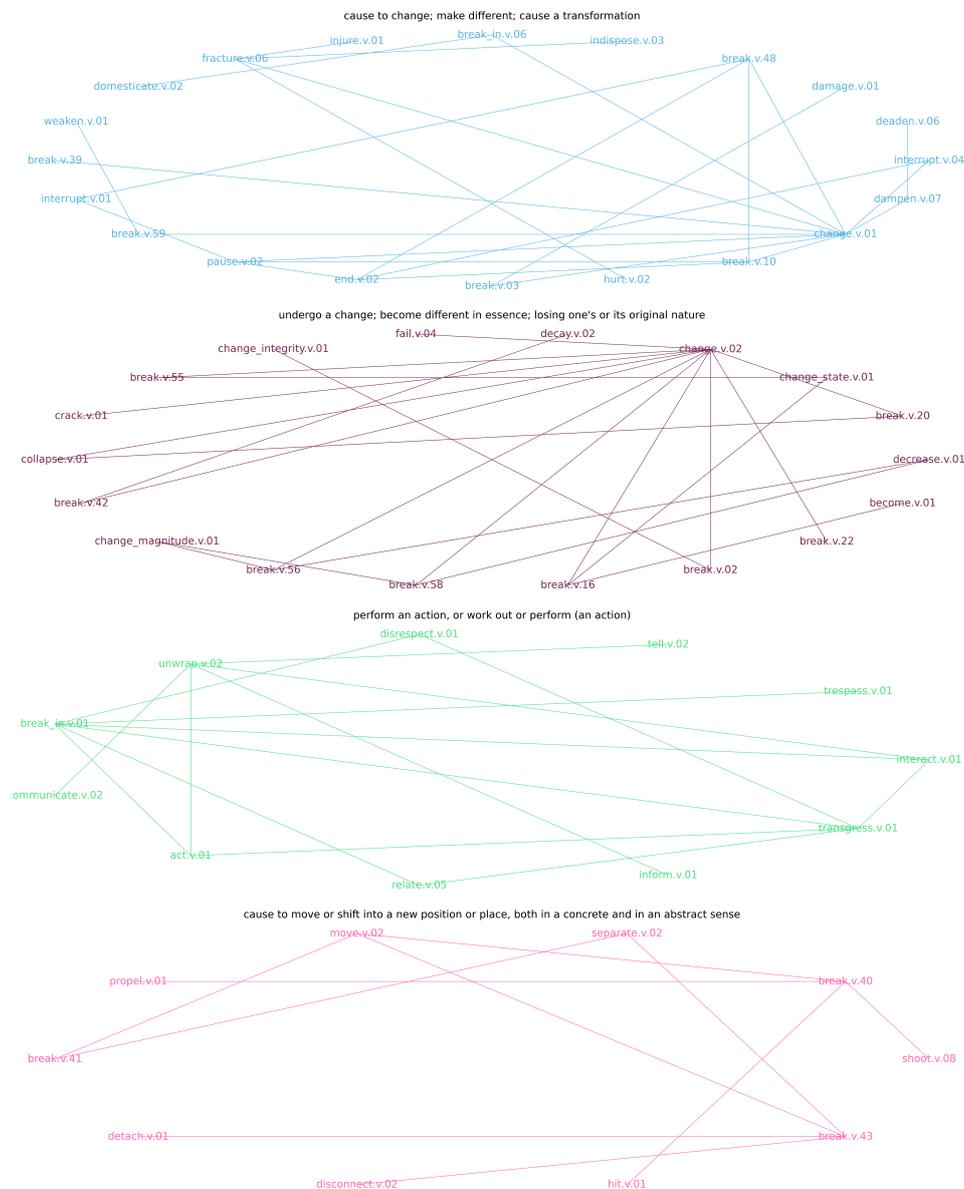

Figure 1: Largest WordNet connected components for *break* labeled with the name of their most specific shared hypernym. These hypernym labels suggest interesting abstract meaning dimensions for these senses.

B Additional Static Vector Analyses

Table 7 extends Table 4 from the main text with additional variants of word2vec, fastText, and GloVe. The overall picture seems consistent across these variants. For the main text, we simply chose the variant of each model that looked the best to us in terms of capturing meaning dimensions of *break*.

C LLM Structure

The input to the LLMs we consider is always a sequence of tokens $[x_1, \dots, x_n]$. Each token may correspond to a full word type or a word piece, depending on the tokenization method. For instance, whereas *the* is tokenized as a single unit, *breakage* is likely to be analyzed as two pieces, *break* and *##age*, where the *##* prefix indicates a word-internal piece. This is a detail we set aside in our analyses, since we consider only examples involving *break* and all the models we use analyze *break* as a single token.

The elements of the input sequence are looked up in a static embedding space. The result is a sequence of vectors $[\mathbf{x}_1, \dots, \mathbf{x}_n]$, where each \mathbf{x}_j has dimension d . These are akin to the static representations from models like those in Section 4: there is one vector per word piece and thus no contextual modulation.

The static embeddings are additively combined with one or more separate embeddings that record aspects of each token’s position in the sequence. In the simplest case, there is a single positional embedding that is used to create a sequence of vectors $[\mathbf{p}_1, \dots, \mathbf{p}_n]$, each of dimension d , and we obtain positionally enriched representations as $H_0 = [\mathbf{x}_1 + \mathbf{p}_1, \dots, \mathbf{x}_1 + \mathbf{p}_n]$. Thus, already at this point in the model, a single word will have different representations depending on where it appears in the input sequence.

The positionally-enriched embeddings are fed into the Transformer architecture itself. This creates numerous interactions between the representations. Each Transformer block $i > 0$ results in a sequence $H_i = [\mathbf{h}_{i,1}, \dots, \mathbf{h}_{i,n}]$ of hidden representations, each one of dimension d . The models we consider have between 12 and 24 of these layers.

We focus on models that are trained in the manner of the BERT model. The core of that training regime is *masked language modeling*, in which elements of the input sequence are randomly masked out or replaced with randomly chosen tokens from the vocabulary, and the task of the model is to learn to assign high likelihood to the actual token, using the entire surrounding sequence. This is a very advanced form of distributional learning, but the core intuition is very similar to that of the single vector models: we are learning linguistic properties entirely from co-occurrence patterns in corpus data.

In our main text, we report results for RoBERTa (Liu et al., 2019), which is ‘**Robustly optimized BERT approach**’. We focus on the ‘large’ variant, which has 24 hidden layers. In Appendix D, we report parallel experiments with the case-sensitive version of the original BERT model as well as two variants of the new DeBERTa model: version 1 and version 3 (which introduces some modifications to the pretraining regime compared to version 1). DeBERTa is potentially interesting from the perspective of lexical semantics, because it more fully separates the traditional static embeddings $[\mathbf{x}_1, \dots, \mathbf{x}_n]$ from the positional embeddings $[\mathbf{p}_1, \dots, \mathbf{p}_n]$. This might be taken to reify word types (as separate from token occurrences) more than the other models do. Like RoBERTa, BERT and the DeBERTa variants have ‘base’ (12-layer) and ‘large’ (24-layers) instances. For our main text, we chose to focus on RoBERTa-large because it seems slightly better overall than the rest, but our findings indicate that all these models perform about the same in our evaluations, suggesting that all of them can support lexical semantic investigation.

D Additional Probing Results

Table 8a gives meaning-class probing results for all of the models described in Appendix C, and Table 8b provides a parallel set of results for the construction-type probes. The models are very consistent with each other in terms of layer-wise trends and overall performance. Only the DeBERTa variant stands out as showing differences that may be truly substantive.

The past few days had consisted of a simple routine of drinking melted snow to stay hydrated and sleeping while waiting for the storm to break.	appear	end	unacc.	unacc.	Model prediction may be correct.
A small pair of scissors will easily break the seal, but bringing those scissors in your carry-on bag may no longer be permitted.	separate_ into_parts	decipher	causative	causative	The decipher prediction seems sensible given that a seal is like a lock or (easy) code that needs to be overcome.
Patients will sometimes break out in a spontaneous recitation of the rosary	break_out_ start	break_out_ start	unacc.	unerg.	The modifier "spontaneous" seems to affect agentivity and perhaps also argument structure.

Millennial darlings began to break down like virus-ridden websites, from the supercharged (Qualcomm, Oracle) to the superhyped (Amazon, Yahoo!) to the just plain super (Sun, Lucent, AOL).	<u>break_</u> <u>down_</u> succumb	<u>break_</u> <u>down_</u> render_	unacc.	unacc.	There is a comparison of "millennial darlings" with "virus-ridden websites". The gold meaning may apply to "millennial darlings" and the predicted meaning to "virus-ridden websites".
I felt disappointed, but I waited, hoping the clouds would break.	separate_ into_parts	appear	unacc.	unacc.	Weather events are persistently uncertain about whether they describe the start or end of something. Here, the clouds are leaving and other things are presumably appearing.

G Visualizations

Figure 2 uses t-SNE to visualize *break* embeddings from layer 1 of RoBERTa-large, and Figure 3 shows the embeddings from layer 24. We use color to distinguish the top 10 meaning classes (and the rest are gray). Underlined examples are unergative and boxed examples are unaccusative. The layer 24 visualization has much more structure than the layer 1 visualization. By layer 24, the model seems strikingly well-aligned with the meaning categories and construction types, as evidenced by how examples with the same color cluster together, and how the construction type annotations also cluster within those spaces. The other models we consider show effectively these same patterns.

SWING : Balancing Coverage and Faithfulness for Dialogue Summarization

Abstract

Missing information is a common issue of dialogue summarization where some information in the reference summaries is not covered in the generated summaries. To address this issue, we propose to utilize natural language inference (NLI) models to improve coverage while avoiding introducing factual inconsistencies. Specifically, we use NLI to compute fine-grained training signals to encourage the model to generate content in the reference summaries that have not been covered, as well as to distinguish between factually consistent and inconsistent generated sentences. Experiments on the DIALOGSUM and SAMSUM datasets confirm the effectiveness of the proposed approach in balancing coverage and faithfulness, validated with automatic metrics and human evaluations. Additionally, we compute the correlation between commonly used automatic metrics with human judgments in terms of three different dimensions regarding coverage and factual consistency to provide insight into the most suitable metric for evaluating dialogue summaries.¹

1 Introduction

Dialogue summarization is a text generation task that aims to produce a compact summary given a piece of conversation. Conventional approaches to dialogue summarization rely on features of conversation data (Goo and Chen, 2018; Li et al., 2019; Oya et al., 2014). Recently, the rise of large pre-trained language models (LMs) has enabled coherent and fluent summaries to be generated without these features. However, low coverage and factual inconsistency remain two pressing issues as studies have shown that the summaries generated from these pre-trained LMs often do not fully cover the reference (Liu and Chen, 2021; Tang et al.,

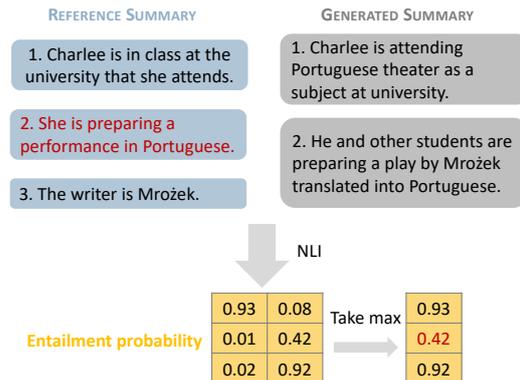

Figure 1: An illustration of how NLI can help determine whether a reference sentence is covered by the generated summary. We compute the entailment probability from each reference sentence (i.e. premise) to each generated sentence (i.e. hypothesis). By taking the max value along the row dimension, the resulting vector denotes the probability that each reference sentence entails a sentence in the generated summary. In this example, the entailment probability for the second reference sentence is low, indicating that this sentence is likely not covered by the generated summary.

2022) and that the generated summaries are often not factually consistent with the inputs (Zhang et al., 2020b; Maynez et al., 2020; Cao and Wang, 2021). If an unfaithful dialogue summarization model with low coverage is deployed for public use, it could spread misinformation and generate misleading content that only covers partial facts of a conversation. Hence, we are urgently in need of a solution to improve coverage without negatively impacting faithfulness for dialogue summarization.

Relatively little work addresses coverage and factual inconsistency for dialogue summarization. Some work addresses the issue of unfaithfulness with a controllable generation framework guided by person named entities (Liu and Chen, 2021) or summary sketches (Wu et al., 2021). Tang et al. (2022) categorize factual inconsistencies for dialogue summarization into different types of errors,

^{*}Work done while interning at Amazon.

¹We release our source code for research purposes: <https://github.com/amazon-science/AWS-SWING>.

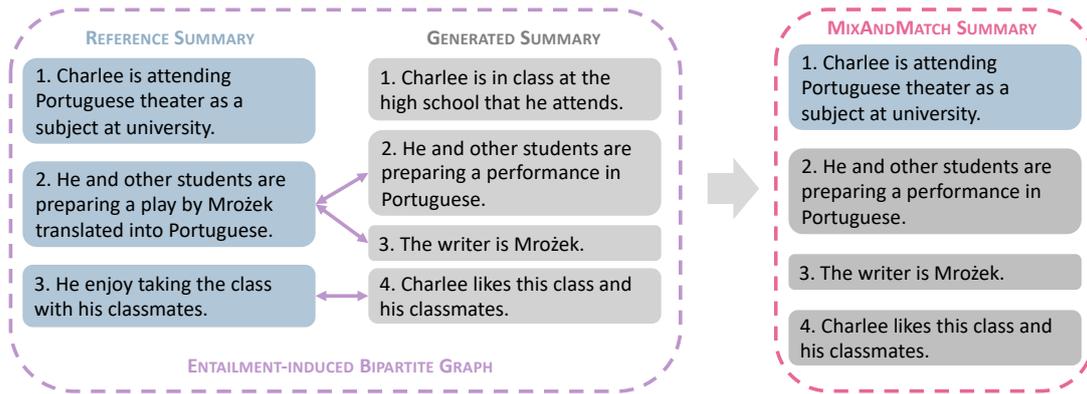

Figure 2: Illustration of how an entailment-induced bipartite graph is built and how a MIXANDMATCH summary is derived. With the NLI model, we determine which sentences from each summary contain equivalent information by computing the entailment probabilities between pairs of generated sentences and reference sentences, as indicated by the purple edges. Based on the graph, we determine that the generated summary does not cover the first reference sentence and that the first generated sentence is not faithful. Hence, the MIXANDMATCH summary is formed by combining the first reference sentence and the second to the fourth generated sentence.

such as missing information and wrong reference. Their framework integrates a contrastive loss and a self-supervised loss to reduce multiple types of errors. However, a great portion ($> 40\%$) of their outputs does not cover the full content of the reference summary. Thus, it is important to address coverage and factual consistency synergistically in dialogue summarization. The issue where the content in the reference does not occur in the generated summary is known as the missing information issue (Liu and Chen, 2021; Tang et al., 2022). In this work, we aim to mitigate missing information in the summary while being faithful to the dialogue.

We propose SWING , Summarizing Dialogue With NLI Guidance. Our approach samples a summary from the model and utilizes natural language inference (NLI) to determine (1) the faithfulness of each generated sentence and (2) whether each reference sentence has been covered by the generated summary. An example is shown in Figure 1. Based on the results computed by NLI, two losses are proposed to encourage the model to generate missing information and distinguish between factually consistent and inconsistent generated sentences.

Our contributions can be summarized as follows:

- We propose SWING, a dialogue summarization framework that effectively addresses missing information through two losses computed using NLI. The first loss encourages the model to recover content missing from the reference summaries. The second loss instructs the model to differentiate between factually consistent and inconsistent

generated sentences.

- Our approach achieves the best performance in mitigating missing information on two public dialogue summarization datasets, DIALOGSUM (Chen et al., 2021b) and SAMSUM (Gliwa et al., 2019), as validated by automatic metrics and human judges.
- We measure the correlation of human judgments with conventional and recently developed automatic metrics to provide intuition for future research on evaluating the faithfulness and coverage of dialogue summaries.

2 Method

Upon analyzing the dialogue summaries in SAMSUM, we observe that dialogues are often summarized linearly, consistent with the findings of Wu et al. (2021). Therefore, we segment the summaries into sentences and use a natural language inference (NLI) model to provide finer-grained training signals at the sentence level for two goals: (1) encourage generating sentences in the reference summaries that have not been covered by the generated sentences and (2) differentiate factually consistent generated sentences from inconsistent ones. To achieve these goals, we first determine the faithfulness of each sentence using an entailment-induced bipartite graph (§2.1). Then, we propose two new losses addressing each challenge in turn: an **Uncovered Loss** that encourages the model to recover missing information (§2.2) and a **Contrastive Loss** that brings closer the representations of the reference summary and the generated sentences that

Algorithm 1: Entailment-induced Bipartite Graph

Input: A reference summary $S^* = \{s_1^*, \dots, s_n^*\}$, a generated summary $S = \{s_1, \dots, s_m\}$;
Output: The bipartite mapping ϕ between sentences in S^* and S ;

- 1 Initialize ϕ as a zero matrix of size $n \times m$ where $n = |S^*|$ and $m = |S|$;

- 28 $\phi(i, j) \leftarrow 1$;
- 28 Return ϕ ;

contain equivalent information to some sentences in the reference summary (§2.3). For the rest of this paper, we use *reference sentence* and *generated sentence* to refer to a sentence in the reference summary and the generated summary, respectively.

2.1 Entailment-induced Bipartite Graph

To determine which reference sentence has not been covered by the generated summary and which generated sentence is not faithful to the reference summary, we construct a bipartite graph that links sentences between a reference summary and a generated summary. An edge indicates the linked sentences contain equivalent information. If no edge connects to a reference sentence, we consider this sentence not covered by the generated summary. Similarly, if a generated sentence is not linked in the bipartite graph, this sentence is likely not

faithful to the reference summary. We use the entailment probabilities computed by an NLI model to determine whether a pair of sentences contain equivalent information. The procedure of constructing the bipartite graph is shown in Algorithm 1.

The NLI model takes in two sentences, a premise (P) and a hypothesis (H), and computes whether P entails, contradicts, or is neutral to H . Here, we only focus on the entailment probability from the i -th reference sentence to the j -th generated sentence $p_{\text{ent}}(s_i^*, s_j)$. We use the ROBERTA-LARGE model² trained on the MNLI dataset, achieving an accuracy of around 91%, which is on par with the performance of state-of-the-art models.

Let $\phi(i, j)$ denote the mapping between the i -th reference sentence and the j -th generated sentence. $\phi(i, j) = 1$ if a link exists between s_i^* and s_j ; otherwise, $\phi(i, j) = 0$. We first consider a simplified setting by assuming each reference sentence can be mapped to at most one generated sentence, and vice versa (i.e. $0 \leq \sum_j \phi(i, j) \leq 1$). In this setting, we can determine whether two sentences contain equivalent information by checking the entailment relation from both directions (lines 26-27).

$$\phi(i, j) = \begin{cases} 1, & p_{\text{ent}}(s_i^*, s_j) > \tau \wedge p_{\text{ent}}(s_j, s_i^*) > \tau \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

Here, τ is a hyperparameter that indicates the entailment threshold.

However, one reference sentence may contain information equivalent to multiple generated sentences (one-to-many mappings) and vice versa (many-to-one mappings). In Figure 2, for example, the second reference sentence contains information equivalent to the second and the third generated sentences combined. This relation cannot be discovered if we only check the entailment relation between pairs of individual sentences.

Therefore, we must resolve one-to-many and many-to-one mappings before checking one-to-one mappings. To find one-to-many mappings, for every reference sentence s_i^* , we look for consecutive generated sentences $\{s_j, s_{j+1}, \dots, s_{j+k}\}$ s.t. $\max_i p_{\text{ent}}(s_i^*, s_m) > \tau \forall m \in \{j, \dots, j+k\}$ (lines 6-8). We only check for consecutive sentences based on our previous observation that dialogues are often summarized linearly. For every match, we concatenate the generated sentences $s_{j:j+k} = \{s_j, s_{j+1}, \dots, s_{j+k}\}$ and

²<https://huggingface.co/roberta-large-mnli>

check whether $s_{j:j+k}$ entails the reference sentence s_i^* (lines 8-9). If the entailment holds, we let $\phi(i, m) = 1 \quad \forall m \in \{j, \dots, j+k\}$ (lines 11-12). The same approach is used to address many-to-one mappings (lines 14-22). Following Algorithm 1, a bipartite graph is built between the generated summary and the reference summary. Henceforth, we denote the reference sentences that have not been covered as $\underline{S}^* = \{s_i^* | \forall j \phi(i, j) = 0\}$ and generated sentences that can be mapped to some of the reference sentences as $\underline{S} = \{s_j | \exists i \phi(i, j) = 1\}$.

2.2 Uncovered Loss

The objective of the uncovered loss is to encourage the model to generate information from the reference summary that the generated summary has not covered. To this end, we train the model with MIXANDMATCH summaries, which are constructed by combining reference sentences that are not covered by the generated summary and generated sentences that contain information equivalent to some of the reference sentences. An example is shown in Figure 2.

The MIXANDMATCH summary \hat{S} is constructed by taking the union of \underline{S} and \underline{S}^* and sorting the sentences by their index,

$$\hat{S} = \text{SORT}(\underline{S} \cup \underline{S}^*). \quad (2)$$

The uncovered loss is effectively maximum likelihood estimation (MLE) with MIXANDMATCH summaries being the decoding targets:

$$\mathcal{L}_{\text{Uncovered}} = - \sum_t \log p(\hat{S}_t | \hat{S}_{<t}, \mathcal{D}), \quad (3)$$

where \mathcal{D} is the original dialogue and \hat{S}_t denotes the t -th token in the MIXANDMATCH summary.

The main advantages of constructing MIXANDMATCH summaries over other positive sample construction approaches, such as back translation and paraphrasing, are the two desired properties of this formulation. First, the model already has a high probability of generating sentences in \underline{S} . Therefore, the loss function (Equation (3)) does not penalize the model much for generating these sentences. Second, the penalty for generating sentences \underline{S}^* is larger since the model has a lower probability of generating those sentences.

2.3 Contrastive Loss

In the early stage of our experiment, the original goal was to discourage the model from generating

factually inconsistent sentences. We adopt unlikelihood training (Welleck et al., 2020) to decrease the probability of sampling these sentences from the model. However, we found that this objective causes the model to generate nonsense sequences. This phenomenon was also observed when we experimented with CONSEQ (Nan et al., 2021), which also incorporates such a loss function into its training process, as shown in §4.1. We hypothesize that it resulted from the fact that sentences in dialogue summaries share similar structures. Hence, using the unlikelihood training objective would confuse the model.

Instead, we pivoted our focus on differentiating factually consistent sentences from their inconsistent counterparts with the proposed contrastive loss. For each summary, we use the factually inconsistent sentences as negative samples (i.e. $s_j \notin \underline{S}$) and consistent sentences as positive samples (i.e. $s_j \in \underline{S}$). The contrastive learning objective takes a similar form as the InfoNCE loss (Oord et al., 2018):

$$\mathcal{L}_{\text{Contrastive}} = - \sum_{s_i \in \underline{S}} \frac{\exp(\cos(h_i, h_{S^*}))}{\sum_{s_j \in \underline{S}} \exp(\cos(h_j, h_{S^*}))} \quad (4)$$

, where h_i and h_j denote the representations of the generated sentences, h_{S^*} means the representations of the reference summary, and $\cos(\cdot, \cdot)$ denotes cosine similarity. The main difference between our contrastive objective and the other work (Cao and Wang, 2021; Tang et al., 2022) is granularity. Equation (4) operates at the sentence level rather than the summary level; therefore, it provides finer-grained training signals.

2.4 Training

The final loss function that our model is optimized with is a weighted sum of the two aforementioned loss functions and MLE,

$$\mathcal{L}_{\text{Final}} = \mathcal{L}_{\text{MLE}} + \alpha \mathcal{L}_{\text{Uncovered}} + \beta \mathcal{L}_{\text{Contrastive}}, \quad (5)$$

where \mathcal{L}_{MLE} is:

$$\mathcal{L}_{\text{MLE}} = - \sum_t \log p(S_t^* | S_{<t}^*, \mathcal{D}). \quad (6)$$

3 Experiments

3.1 Datasets

Experiments are conducted on two English-language dialogue summarization datasets: SAMSUM (Gliwa et al., 2019) and DIALOGSUM (Chen

Model	DIALOGSUM								SAMSUM

Table 1: Performance comparison on DIALOGSUM and SAMSUM. - $\mathcal{L}_{\text{Uncovered}}$ and - $\mathcal{L}_{\text{Contrastive}}$ denote variants of SWING by ablating the corresponding loss. RL denotes ROUGE-L (%), BS denotes BARTSCORE, FC denotes FACTCC (%), QS denotes QUALS, and QFE denotes QAFACTEVAL. The subscripts F and R denote F1 score and recall, respectively. The proposed method outperforms previous systems on both DIALOGSUM and SAMSUM in most metrics, especially on the recall measures. Statistical significance over previous best systems computed with the permutation test (Fisher et al., 1937) is indicated with * ($p < .01$).

et al., 2021b). SAMSUM contains 16,369 online chitchat dialogues with an average of around 94 tokens per dialogue. DIALOGSUM is a spoken dialogue dataset that consists of 13,460 samples in total. With an average token count of about 131, the dialogues in DIALOGSUM are under real-life scenarios with clear communication patterns and intents. Details of the dataset statistics can be found in Appendix A.

3.2 Metrics

Our evaluation focuses on measuring the factual consistency, particularly the missing information challenge, of the summarization models. Therefore, we adopt recently developed metrics that have been shown to correlate well with human judgments in terms of faithfulness. BARTScore (Yuan et al., 2021) computes the semantic overlap between the generated summary and the reference summary by calculating the logarithmic probability of generating each summary conditioned on the other one. Since our goal is to assess how well the model reduce information missing from the reference summary, we consider the *Recall* (R) setting where we assess $p(S^* | S, \theta)$, the likelihood of generating the reference summary S given the generated summary S^* . FactCC (Kryscinski et al., 2020) is an entailment-based metric that predicts the faithfulness probability of a claim w.r.t. with the source texts. Similar to BARTScore, we use FactCC in the *Recall* setting where the claim is a reference sentence and the source text is the generated summary. We report the mean of the average CORRECT probability of each sentence within a generated summary.

In addition, we report the ROUGE-L metric (Lin, 2004), which has been also shown to better reflect

faithfulness compared to ROUGE-1 and ROUGE-2 (Pagnoni et al., 2021). For these metrics, we also consider the *F1* setting, where we compute each metric in the reverse direction ($S^* \rightarrow S$) and then take the average of both directions, to validate that the model is not generating too much redundant information. Finally, two recently introduced QA-based metrics that have demonstrated close approximation to human judgements in terms of factuality, QUALS (Nan et al., 2021) and QAFACTEVAL (Fabbri et al., 2022a), are also used for evaluation.

3.3 Implementation Details

We choose BART (Lewis et al., 2020) as the backbone seq2seq model as it has demonstrated better dialogue summarization performance than other pre-trained language models (Tang et al., 2022), such as PEGASUS (Zhang et al., 2020a) and T5 (Raffel et al., 2020). The proposed models are optimized using AdamW (Loshchilov and Hutter, 2019) with learning rate $3e-5$ and weight decay $1e-3$. The maximum input sequence length is set to 1024. For all baseline models, we use the best hyper-parameters reported in their papers. We fix τ to be 0.5 throughout all our experiments. α and β are both 1.0.

3.4 Baselines

We compare SWING with the following competitive baseline systems. **TextRank** (Mihalcea and Tarau, 2004) is a graph-based ranking algorithm that performs extractive summarization. **BART** (Lewis et al., 2020) is a seq2seq language model pre-trained on various denoising objectives. **CTRLDIASUMM** (Liu and Chen, 2021) and **CODS** (Wu et al., 2021) are controllable generation frameworks that generate summaries guided by named entity

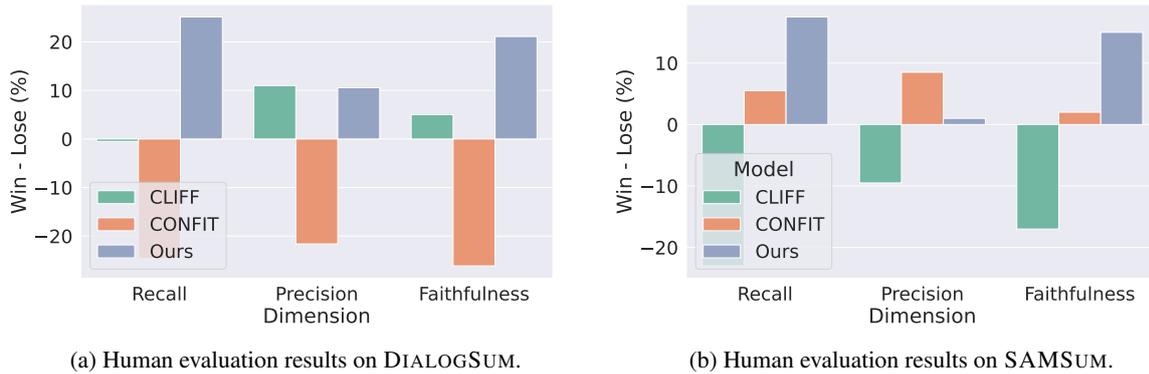

Figure 3: Human evaluation results. SWING achieves the highest RECALL and FAITHFULNESS scores on both datasets, suggesting the advantages of our approach in reducing missing information and improving the overall faithfulness of the generated dialogue summary.

planning and sketches, respectively. **CONSEQ** (Nan et al., 2021) learns a contrastive objective based on unlikelihood training, where positive and negative samples are selected by QUALS. **CLIFF** (Cao and Wang, 2021) and **CONFIT** (Tang et al., 2022) are trained with a similar contrastive learning loss that takes the form of the InfoNCE loss (Oord et al., 2018), except that CONFIT is optimized with an additional self-supervised loss that aims to reduce reference errors. BART-LARGE is used across all experiments that involve pre-trained language models for fair comparison.

4 Results

4.1 Main results

Table 1 summarizes the main results on DIALOGSUM and SAMSUM. SWING outperforms previous approaches in almost all metrics, especially recall measures. This result reflects that the proposed approach generates summaries that cover more content in the reference summaries lexically and semantically. One interesting observation was the deficient performance of CONSEQ on both datasets. We hypothesize that poor performance was the use of the unlikelihood training objective in their loss, as mentioned in §2.3. Since sentences of dialogue summaries often share similar structures, adopting such an objective could confuse the model. We verified this hypothesis by running a small experiment by training BART-LARGE with MLE and negative samples determined by QUALS, similar to CONSEQ. The resulting model also produces significantly lower performance than training with MLE alone. The finding confirms that the poor performance of CONSEQ is caused by the unlikelihood training and that such a loss function is unsuitable for dialogue summarization.

4.2 Human Evaluation

To further validate the effectiveness of SWING, we use Amazon’s Mechanical Turk (AMT) to recruit workers to conduct human evaluations on three methods: CLIFF, CONFIT and SWING. We sampled 100 dialogues from the test set of DIALOGSUM and SAMSUM, respectively. For each dialogue, human judges are presented with a pair of summaries produced by two different approaches and asked to select the better one with respect to three dimensions. **RECALL** assesses the portion of information in the reference summary covered by the generated summary. **PRECISION** considers whether all the content in the generated summary occurs in the reference summary. **FAITHFULNESS** examines whether the generated summary is factually consistent with the dialogue. "Tie" is selected if the judges consider the two summaries to be of equal quality. The final score of each system is calculated as the percentage of times the system is selected as the better one minus the percentage of times the system is not. To evaluate the annotation quality, we compute the inter-annotator agreement. The average Cohan’s Kappa (Cohen, 1960) is 54.35%, indicating a moderate agreement. Details of the human evaluation setup can be found in Appendix B.

The human evaluation results are demonstrated in Figure 3. We have the following observations. First, SWING achieves the highest RECALL scores on both datasets, indicating that our approach is the best in addressing the missing information issue for dialogue summarization. Second, while SWING does not score the highest on PRECISION, we achieve the highest scores on FAITHFULNESS. This implies that even though our approach often generates summaries with extra information,

Reference Summary	CONFIT	SWING
Mike took his car into garage today. Ernest is relieved as someone had just crashed into a red Honda which looks like Mike’s.	Mike took his car to the garage today. Someone crashed into his car.	Mike took his car into the garage today. Someone just crashed into a red Honda looking like Mike’s.

Table 2: Qualitative analysis on the outputs of SWING and CONFIT. The two rows demonstrate the *missing details* and the *missing sentences* issue of the summaries generated by CONFIT, respectively. The extra information in the outputs of CONFIT that also occurs in the reference summaries is highlighted in blue. In both cases, SWING is able to cover more content presented in the reference summaries.

the additional content is likely still faithful to the input. To measure the amount of additional information produced, we compute the average number of tokens per summary for each model. As seen in Table 3, the summaries generated by SWING is only slightly longer than those produced by CLIFF and CONFIT. This suggests that SWING achieves significantly higher faithfulness and coverage than CLIFF and CONFIT while maintaining conciseness.

Model	DIALOGSUM	SAMSUM
CONFIT	29.46	22.45
CLIFF	27.34	22.30
BART-LARGE	28.03	23.19
SWING	31.32	24.23

Table 3: Average token count per summary generated by different models.

4.3 Qualitative Analysis

To provide better insight into the effectiveness of the proposed method, we conduct a qualitative analysis using the 100 dialogues randomly sampled from the SAMSUM dataset. Specifically, we further categorize missing information errors into two sub-types: (1) *missing details* where partial information of a sentence in the reference summary is missing in the generated summary and (2) *missing sentences* where the model fails to generate an entire sentence in the reference summary. An example of each sub-type is shown in Table 2. By comparing the test sets outputs of CONFIT and SWING, we see that there are 10 improved cases with less *missing details* and 6 cases where *missing sentences* is mitigated by SWING. Meanwhile, our

proposed approach only introduces *missing details* error and *missing sentences* error in 1 and 2 examples, respectively. This implies that our approach is effective in alleviating both sub-types of missing information error while particularly advantageous in reducing *missing details* errors.

4.4 Correlation with Human Judgements

Although recently proposed metrics have been shown to be highly correlated with human judgements on news summarization in terms of factuality (Kryscinski et al., 2020; Yuan et al., 2021), no previous work has studied the transferability of these metrics to dialogue summarization. We seek to answer this question by computing the correlation of the automatic metrics in Table 1 with the human annotations discussed in §4.2. Using Kendall’s Tau (Kendall, 1938) as the correlation measure, the results are summarized in Table 4. We observe that: (1) $BARTSCORE_R$ is the most consistent and reliable metric across the three dimensions. It performs the best in RECALL on both datasets, indicating that $BARTSCORE_R$ is most suitable for measuring how well a model resolves the missing information issue in dialogue summarization. (2) Although a large number of invalid questions and answers are generated, QUALS is the best metric for assessing PRECISION overall. (3) $FACTCC_F$ and $FACTCC_R$ are two of the worst metrics in general. This could be explained by the fact that FACTCC constructs negative samples with some semantically variant transformations. However, these transformations may not be comprehensive enough to cover all cases. Hence, the poor transferability of FACTCC on these two datasets.

Metric	DIALOGSUM			SAMSUM		
	RECALL	PRECISION	FAITHFULNESS	RECALL	PRECISION	FAITHFULNESS
ROUGE-L _F	23.50	24.21	10.29	6.07	10.24	-0.75
ROUGE-L _R	23.46	2.51	4.24	29.52	9.61	17.88
BARTSCORE _F	18.35	25.94	3.17	15.50	8.00	10.69
BARTSCORE _R	26.48	14.87	9.25	32.10	9.68	24.11
FACTCC _F	6.15	6.93	1.19	-3.43	5.12	-2.28
FACTCC _R	4.79	6.86	10.56	4.13	10.32	-1.43
QUALS	14.23	23.61	-0.83	1.55	15.35	4.50
QAFACTEVAL	14.06	16.20	16.80	5.03	2.83	6.26

Table 4: Correlation (%) of automatic metrics with human judgements. We first convert human evaluation results and automatic metric scores into a scale of $\{-1, 0, 1\}$, which corresponds to $\{\text{LOSE, TIE, WIN}\}$. Then, Kendall’s Tau (Kendall, 1938) is used to compute the correlation between two sequences.

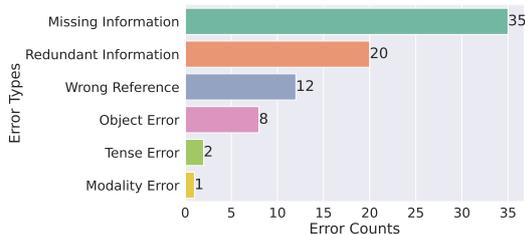

Figure 4: Remaining challenges.

4.5 Remaining Challenges

We analyzed the remaining errors by comparing 100 generated summaries with corresponding reference summaries on the SAMSUM datasets using the categories of factual errors defined in Tang et al. (2022). The results are shown in Figure 4. We observe that missing information still accounts for the largest portion of factual errors, even though our approach significantly exceeds prior methods in mitigating this issue. This reflects that this issue is challenging to tackle and that there is still a great opportunity to improve the reduction of missing information. As a comparison, we manually inspected outputs of BART-LARGE using the same 100 dialogues as input. We found 42 cases where information is missing from the dialogue summaries produced by BART-LARGE. This observation further confirms the effectiveness of SWING in addressing insufficient coverage. In addition, redundant information is another major source of errors. Although we have shown in §4.2 that the additional information generated by SWING is likely still faithful to the input dialogue, compactness is one of the important qualities of a summary. This can be improved by using NLI to guide the model to avoid generating extra information. Other common mistakes are wrong reference and object errors, both of which can be addressed with the self-supervised

loss discussed in Tang et al. (2022).³

5 Related Work

Dialogue Summarization Early work on dialogue summarization focus on the AMI meeting corpus (McCowan et al., 2005) due to the lack of dialogue summarization data. These studies enhance summarization performance by leveraging features of conversational data, such as dialogue act (Goo and Chen, 2018), visual features (Li et al., 2019), and the relationships between summary and dialogue (Oya et al., 2014). Later, Gliwa et al. (2019) released the SAMSUM dataset, the first large-scale dialogue summarization dataset, enabling abstractive summarization research on casual chat dialogue. With the rise of large language models (LMs), recent work focuses on improving the controllability of sequence-to-sequence models built upon large LMs. For instance, Wu et al. (2021) proposes to utilize a summary sketch to control the granularity of the summary generated. Liu and Chen (2021) conditions the generators with person name entities to control which people to include in the generating summary. Chan et al. (2021) improves controllability by formulating the summarization task as a constrained Markov Decision Process.

Factual Consistency Enhancement While factuality has been widely explored in the field of fact-checking and fake news detection (Thorne et al., 2018; Wadden et al., 2020; Huang et al., 2022b; Shu et al., 2018; Pan et al., 2021; Huang et al., 2022a), factual inconsistency remains a major challenge for abstractive summarization. One line of work attempts to improve the faithfulness of

³This analysis is not comparable to results reported in Tang et al. (2022) due to differences in the sampled examples.

the generated summary with a separate correction model that corrects the errors made by the summarization model (Dong et al., 2020; Cao et al., 2020; Fabbri et al., 2022b) or directly fix factual inconsistencies in the training data (Adams et al., 2022). Another line of work employs auxiliary loss functions to improve models’ representations or discourage the model from generating unfaithful outputs (Cao and Wang, 2021; Chen et al., 2021a; Nan et al., 2021; Tang et al., 2022). The main advantage of these approaches is the efficiency in inference time.

Some studies have attempted to use NLI to detect factual inconsistency in generated summaries. Early approaches rely on out-of-the-box NLI models, which did not yield satisfactory results (Falke et al., 2019). Barrantes et al. (2020) improved the detection accuracy by using an NLI model fine-tuned on the Adversarial NLI dataset (Nie et al., 2020). Laban et al. (2022) addresses the mismatch issue in input granularity between NLI datasets and inconsistency detection by passing sentence pairs as inputs instead of document-summary pairs. Kryscinski et al. (2020) and Yin et al. (2021) trains document-sentence entailment models to address the granularity mismatch issue. Utama et al. (2022) introduces a controllable generation framework that generates document-level NLI training data for identifying factual inconsistency. Our work leverages an NLI model to guide the dialogue summarization model to recover missing information.

6 Conclusion

We have proposed SWING, a dialogue summarization framework that generates summaries with mitigated missing information and improved faithfulness. To instruct the model to generate missing content from the reference summaries and to differentiate factually consistent generated sentences from their inconsistent counterparts, we propose two losses based on NLI. Experimental results on the DIALOGSUM and SAMSUM datasets showed that our approach achieves significantly higher faithfulness and coverage, while still maintaining conciseness, compared to prior methods. In addition, we measure the correlation between the reported automatic metrics and human judgments to provide insight into the most suitable metric for evaluating the coverage and factuality of dialogue summaries for future research.

7 Ethical Considerations

We acknowledge that the use of large language models pre-trained on the Web could lead to biased outputs. We did find out that our model may sometimes generate the incorrect pronouns for neutral names. For example, in Figure 1, Charlee is being referred to as a male in the generated summary, while Charlee is actually a female as shown in the reference summary. Such an issue is often caused by under-specified context (e.g. Charlee’s gender is not mentioned in the input dialogue). Fortunately, we found that such an error accounts for < 1% of the total outputs from our framework and the issue can be largely alleviated when enough context is provided.

8 Limitations

While our proposed approach is effective in mitigating missing information, this issue is still far from resolved, as shown in Figure 4. Significant effort is needed to ensure dialogue summarization models produce completely factual content. In addition, our method works as we found that most of the reference summaries in the two datasets we used are faithful to the corresponding dialogue. The proposed method may not work on other summarization datasets, such as XSum, which contains hallucinations in about 70% of the reference summaries (Maynez et al., 2020).

9 Acknowledgments

We would like to extend our gratitude to the reviewers for their valuable feedback and insights, which greatly contributed to the improvement of this paper. We would also like to thank the human evaluators for their time and effort in assessing the performance of our model. Their contributions have been essential in ensuring the quality of our research.

A Dataset Statistics

We present the detailed statistics of DIALOGSUM and SAMSUM in Table 5.

Dataset	# Dialogues	Avg. Dialogue Words	Avg. Summ. Words
DIALOGSUM	13,460	187.5	31.0
SAMSUM	16,369	124.1	23.4

Table 5: Statistics of DIALOGSUM and SAMSUM. We use the NLTK tokenizer to compute word counts for both datasets.

B Human Evaluation Details

In this section, we describe the details of our human evaluation. We recruit AMT workers from the United States for ensuring language fluency. Qualification requirements are set such that only workers who have an acceptance rate greater than 99% and have more than 10,000 accepted HITs in the past are allowed to work on our annotation task. To further ensure annotation quality, we conducted two rounds of annotations. In the first round, we launched 100 HITs to select high-quality annotators in the first round. 8 qualified annotators are selected to enter the second round to conduct the remaining evaluation. We set the reward to \$0.8 per HIT to encourage experienced annotators to participate. Our annotation interface is displayed in Figure 5.

For each HIT, annotators are provided with a piece of dialogue and a corresponding reference summary as well as two summaries generated from different systems, demonstrated on the left segment of the interface. Based on the summaries and the dialogue, annotators are tasked to answer three questions shown on the right segment of the interface, each of which corresponds to RECALL, PRECISION, and FAITHFULNESS. They need to determine which summary is better with regard to each prompt.

C Comparison with Other Data Augmentation Methods

We compared our MIXANDMATCH summary construction technique with other data augmentation methods, including back translation (BACKTRANSLATE) and paraphrasing (PARAPHRASING). For back translation, we use mBART-50 (Tang et al., 2020) to translate a summary from English to German and then back to English. For paraphrase generation, we use this open

source package⁴. The experimental results are summarized in Table 6. Training with MIXANDMATCH summaries achieves the highest scores on most metrics, indicating that our proposed method is the most effective in improving the factuality of the generated summaries.

D Hardware and Software configurations

All experiments are conducted on a Linux machine with NVIDIA V100. We use PyTorch 1.11.0 with CUDA 10.1 as the Deep Learning framework and utilize Transformers 4.19.2 to load all pre-trained language models.

E Validation Set Performance

We report the validation set performance of our proposed model in Table 7.

F Number of Parameters

We do not introduce additional parameters to the backbone language model, BART-LARGE. During training time, the number of parameters equals to the sum of the number of parameters in BART-LARGE and ROBERTA-LARGE. In inference time, since we do not need the NLI component, the number of parameters is the same as that of BART-LARGE.

G Scientific Artifacts

The licenses for all the models and software used in this paper are listed below in parentheses: BART (MIT License), FACTCC (BSD-3-Clause License), QAFACTEVAL (BSD-3-Clause License), BARTSCORE (Apache License 2.0), QUALS (MIT License), py-ROUGE (Apache License 2.0), NLTK (Apache License 2.0).

Language-Aware Multilingual Machine Translation with Self-Supervised Learning

Haoran Xu[♣], Jean Maillard[♡], Vedanuj Goswami[♡]

[♣]Johns Hopkins University, [♡]Meta AI

hxu64@jhu.edu
{jeanm, vedanuj}@meta.com

Abstract

Multilingual machine translation (MMT) benefits from cross-lingual transfer but is a challenging multitask optimization problem. This is partly because there is no clear framework to systematically learn language-specific parameters. Self-supervised learning (SSL) approaches that leverage large quantities of monolingual data (where parallel data is unavailable) have shown promise by improving translation performance as complementary tasks to the MMT task. However, jointly optimizing SSL and MMT tasks is even more challenging. In this work, we first investigate how to utilize **intra-distillation** to learn more *language-specific* parameters and then show the importance of these language-specific parameters. Next, we propose a novel but simple SSL task, **concurrent denoising**, that co-trains with the MMT task by concurrently denoising monolingual data on both the encoder and decoder. Finally, we apply **intra-distillation** to this co-training approach. Combining these two approaches significantly improves MMT performance, outperforming three state-of-the-art SSL methods by a large margin, e.g., 11.3% and 3.7% improvement on an 8-language and a 15-language benchmark compared with MASS, respectively¹.

1 Introduction

Multilingual machine translation (MMT) (Aharoni et al., 2019; Arivazhagan et al., 2019) comes with the problem of designing architectures where certain parameters are shared and certain parameters are more language-specific. In order to mitigate negative interference across languages, recent studies have investigated language-specific parameters, including searching for more language-specific parameters (Lin et al., 2021), or adding extra language-specific components to the original

¹Work done during an internship at Meta AI Research

¹Code is released at https://github.com/felixxu/CD_ID_MMT.

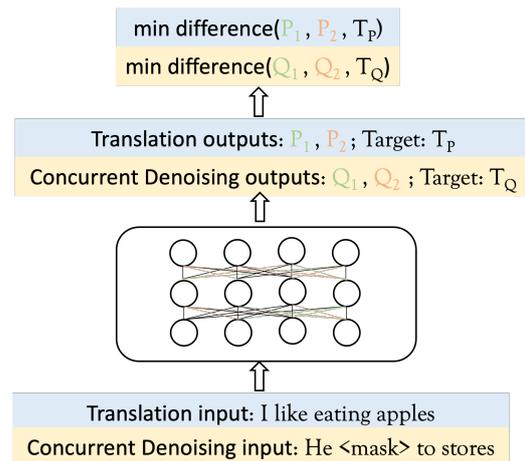

Figure 1: Concurrent denoising is a complementary task to the MMT task. Both tasks are applied with intra-distillation, where we forward pass model twice for the translation and masked inputs and each time we disable different subsets of parameters (illustrated by different colors). Then, for each task, we not only minimize the difference between the target and two outputs (e.g., minimize $\text{difference}(P_1, T_P)$ and $\text{difference}(P_2, T_P)$ in the MMT task), we also minimize the difference between two translated outputs as well as two denoised outputs (e.g., minimize $\text{difference}(P_1, P_2)$ for MMT).

model (Zhang et al., 2021; NLLB Team et al., 2022), or even utilizing language-specific pre-trained language models (Xu et al., 2021; Yarmohammadi et al., 2021). All these studies indicate the importance of language-specific parameters. *In this work, we first want to encourage parameters to have more language-specific attributes given a fixed model size.*

The difficulty of scaling MMT to low-resource and long-tail languages arises due to the scarcity of abundantly available parallel aligned data. Previous works (NLLB Team et al., 2022; Siddhant et al., 2022; Kim et al., 2021; Wang et al., 2020; Siddhant et al., 2020) try to tackle this by collecting massive amounts of monolingual data and using various types of self-supervised learning (SSL)

objectives, such as denoising AutoEncoder (DAE) (Liu et al., 2020) or Masked Sequence to Sequence (MASS) (Song et al., 2019) as auxiliary tasks to co-train with the MMT task, to compensate for the scarcity of parallel data for low-resource languages. *Following this line, we secondly aim to propose a more effective SSL objective.*

With the goal of learning language-aware MMT models and designing more effective SSL methods for MMT, we introduce two approaches. The first approach is **Intra-Distillation (ID)** (Xu et al., 2022), which performs a forward pass through the model K times², and in each pass disables a different set of parameters. This enforces consistent contributions between these disabled parameters by minimizing the difference between the K outputs. ID was originally proposed by Xu et al. (2022) to achieve a balanced parameter contribution in a model. Here, we study the effectiveness of ID in learning language-specific parameters for MMT models. Next, we introduce **Concurrent Denoising (CD)** which is an auxiliary self-supervised task jointly trained with the MMT task. CD predicts the same masked sentences both on the encoder and decoder side with a shared projection layer to facilitate the consistent understanding between encoder and decoder representations. We show that CD outperforms several state-of-the-art SSL methods for translation. Finally, we apply ID to our co-training scheme to further improve the MMT performance by learning more language-specific parameters. The overall framework is illustrated in Figure 1 and we summarize our main contributions below.

- We propose a method to quantify the degree of language-specificity of all parameters (Section 2) and perform a thorough analysis to demonstrate that intra-distillation helps the model learn more language-specific parameters. These parameters contribute more towards a specific language to improve the overall model generalization performance (Section 3).
- We propose the **concurrent denoising** SSL method and demonstrate its improvements over other existing SSL objectives for MMT. Moreover, we introduce a co-training method of MMT and CD with the help of intra-

distillation and shows the strong effectiveness of ID in improving MMT+SSL multi-task optimization (Section 4).

- We conduct extensive experiments on a 8-language dataset and a larger 15-language multilingual dataset, and demonstrate that MMT with concurrent denoising and intra-distillation outperforms multiple strong state-of-the-art methods (Section 5).

2 Preliminary

2.1 Quantify Language-Specific Parameters

Parameter sensitivity is a measure of the impact on the loss when a specific parameter of a model is zeroed-out. It is widely used in pruning as importance score (Ding et al., 2019; Molchanov et al., 2019; Lubana and Dick, 2021). A parameter can express different sensitivities depending on the language of the input data. Those parameters that have high sensitivity to a specific language but low sensitivity to others, are language-specific parameters. We define the i^{th} parameter in a model parameterized by Θ as $\theta_i \in \mathbb{R}$. We further define $\Theta_i = [0, \dots, 0, \theta_i, 0, \dots, 0] \in \mathbb{R}^{|\Theta|}$ and $\Theta_{-i} = [\theta_1, \dots, \theta_{i-1}, 0, \theta_{i+1}, \dots, \theta_{|\Theta|}] \in \mathbb{R}^{|\Theta|}$. The sensitivity of the i^{th} parameter given input batch b_l from language l is formulated as

$$\mathcal{S}(\theta_i, b_l) = |\mathcal{L}(\Theta, b_l) - \mathcal{L}(\Theta_{-i}, b_l)|, \quad (1)$$

where $\mathcal{L}(\cdot)$ is the loss function given the input batch and parameters. Then, we use a first-order Taylor decomposition to approximate the sensitivity of any arbitrary parameters. Equation 1 then becomes

$$\mathcal{S}(\theta_i, b_l) \approx |\Theta_i^T \nabla_{\Theta} \mathcal{L}(\Theta, b_l)|, \quad (2)$$

where $\nabla_{\Theta} \mathcal{L}(\Theta, b_l)$ is the gradient of the loss with respect to the model parameters. In our implementation, we randomly pick 500 batches and feed them to the model to retrieve the gradients and compute the average sensitivity. We then have

$$\mathcal{S}(\theta_i, \mathcal{B}_l) \approx \frac{1}{|\mathcal{B}_l|} \sum_{b_l \in \mathcal{B}_l} |\Theta_i^T \nabla_{\Theta} \mathcal{L}(\Theta, b_l)|, \quad (3)$$

where \mathcal{B}_l is a set containing 500 random b_l batches.

Now, we propose to quantify the degree of language-specificity of θ_i with respect to language l by measuring the relative sensitivity difference between language l and the other languages as

$$D(\theta_i, l) = \frac{\mathcal{S}(\theta_i, \mathcal{B}_l) - \mathcal{S}(\theta_i, \mathcal{B}_{-l})}{\mathcal{S}(\theta_i, \mathcal{B}_{-l}) + \sigma}, \quad (4)$$

²We use $K = 2$ in this work.

where \mathcal{B}_{-l} represents the set composed of mixed batches from all training languages except for the language l , and σ is a very small positive constant³. The larger $D(\theta_i, l)$ is, the more language-specific θ_i is to language l .

2.2 Intra-Distillation

A model with more balanced parameter sensitivity distribution shows better generalization (Liang et al., 2022). Xu et al. (2022) propose intra-distillation (ID) as an effective task-agnostic training method, aiming to encourage all parameters to contribute equally, which improves performance when model size is fixed. However we argue that, in the multilingual setting, ID actually helps the model learn more language-specific parameters resulting in improved performance. Given an input batch, ID needs to forward pass the model K times to obtain K outputs and each time a random subset of parameters is zeroed out. The core idea of ID is to minimize the difference of these K outputs to approximate minimizing the contribution gap of the parameters that are zeroed-out, because the K outputs are forced to be the same with different zeroed parameters. Let $\{p_1, \dots, p_i, \dots, p_K\}$ denote the K outputs. Note that the outputs are probability distributions in the translation and denoising task. The ID loss is then formulated by the X-divergence (Xu et al., 2022) to minimize the difference of K outputs as

$$\mathcal{L}_{id} = \frac{1}{K} \sum_{i=1}^K \text{KL}(p_i \parallel \bar{p}) + \text{KL}(\bar{p} \parallel p_i) \quad (5)$$

$$\text{where } \bar{p} = \frac{1}{K} \sum_{i=1}^K p_i$$

Let the original task loss be \mathcal{L}_i for the i^{th} pass. Then, the total loss is a combination of the original task losses and ID loss, given as

$$\min \frac{1}{K} \sum_{i=1}^K \mathcal{L}_i + \alpha \mathcal{L}_{id} \quad (6)$$

where α is a hyper-parameter to control the strength of ID. Similar to Xu et al. (2022), we use dropout to simulate *zeroed-out* parameters in all experiments.

Although the explanation for better performance after using ID is that the model parameters become more balanced, it is unclear how parameter contributions to different languages change after

³ σ is 1e-8 in our implementation.

applying ID in a multilingual (multitask) setting. For instance, do parameters become more language-agnostic and shareable across all languages, or do they become more language-specific? We investigate this in more details in Section 3.2.

3 Language-Aware MMT Models

In this section, we study how parameters can be prompted to be more language-specific by applying **intra-distillation**, which improves the model generalization performance. Specifically, certain parameters become more language-specific and tend to contribute more to their specific language and less to others. We demonstrate the importance of language-specific parameters by showing how much they can contribute in pruning experiments. We begin our analysis from a case study on MMT experiments with an 8-language dataset (M8), and then scale up our experiments to 15 languages (M15) with larger data size in Section 5. Here, we show results and analysis on $\text{xxx} \rightarrow \text{eng}$ directions. Similar discussions for $\text{eng} \rightarrow \text{xxx}$ directions are shown in Appendix A.

3.1 Experiments on Intra-Distillation

Dataset and Training We train MMT models with and without ID on the M8 dataset⁴. M8 is composed of Nigerian Fulfulde (fuv, 18K parallel sentences), Kimbundu (kmb, 82K), Ganda (lug, 278K), Chewa (nya, 693K), Swahili (swh, 2.1M), Umbundu (umb, 193K), Wolof (wol, 9K) and Zulu (zul, 1.2M). Datasets are extracted from the primary bitext used by the NLLB-200 model (NLLB Team et al., 2022). For ID, we pass the model twice ($K = 2$) considering the computational cost, and set α as 5 suggested by Xu et al. (2022). We use FLORES-200 as our dev and test sets (NLLB Team et al., 2022). Our model training is based on the Transformer_{big} architecture (Vaswani et al., 2017) with 32K vocabulary jointly trained by SentencePiece (Kudo

⁴The languages were selected in order to have a realistic dataset reflecting a specific use case. Multilingual training is crucial for languages that are low-resource, as is the case for many languages of Africa. We chose two different language groupings from the African continent: Benue-Congo languages (Kimbundu, Ganda, Chewa, Swahili, Umbundu, Zulu) and North-Central Atlantic languages (Nigerian Fulfulde, Wolof). While these languages may all belong to the Atlantic-Congo family, this is an extremely large, varied, and under-researched family, with Glottolog recording over 1,400 languoids in it – compare this to under 590 languoids recorded for the Indo-European family.

and Richardson, 2018). We report sacreBLEU scores (spm tokenizer) (Post, 2018).

Results Following NLLB Team et al. (2022), we categorized a language as *low-resource* if there are fewer than 1M parallel sentences, and as *very low-resource* if fewer than 100K (very low-resource is not the subset of low-resource). Otherwise, the language is considered as *high-resource*. We report the average BLEU scores for each of the three categories. In Table 1, we show that MMT with ID outperforms the regular MMT model by a large margin on all three categories by +1.21 BLEU averaged across all languages.

Method	High	Low	Very Low	All
Regular	31.70	12.57	6.92	15.94
Intra-Distillation	33.30	13.63	8.05	17.15

Table 1: M8 results on $\text{xxx} \rightarrow \text{eng}$ comparing regular MMT and MMT with ID. We observe that MMT with ID outperforms regular MMT by a significant margin.

3.2 Language-Specific or Language-Agnostic?

Next, we study whether parameter contributions are more language-specific or just shareable across all languages after ID. Given the i^{th} language l_i , we compute the sensitivities (Equation 3) of all parameters and flatten them into a list. Then, we calculate the Pearson correlation coefficients (PCC) p_{ij} between sensitivity lists of any arbitrary pair of languages l_i and l_j . A lower p_{ij} indicates that there are more contribution (sensitivity) disagreements between languages l_i and l_j . We plot a heat map to visualize p_{ij} for every language pair. Taking into account that the top 10% parameters usually dominate the contribution (Xiao et al., 2019; Sanh et al., 2020), we consider the performance of two groups of parameters, high-sensitive (top 10% most sensitive) and low-sensitive (the remaining 90%) parameters, respectively. Figure 2 shows that all p_{ij} in both groups become lower, indicating there is lower sensitivity similarity between different languages for the same parameters, which means the model becomes more language-specific after ID. For instance, sensitivity similarity between `zul` and `wol` drops from 0.67 to 0.57 in the low-sensitive group. However, the p_{ij} of low-sensitive parameters drops much more than high-sensitive ones, and high-sensitive parameters still hold high similarity (over 0.9). Thus, low-sensitive parameters mostly have language-specific properties while high-sensitive parameters

tend to play ‘language-agnostic’ roles. Overall, parameters are more language-specific after ID⁵. In fact, learning more language-specific parameters through ID in MMT leads to better performance as seen in Section 3.1. These findings align with the results of recent studies which investigate language-specific parameters (Lin et al., 2021; Zhang et al., 2021; NLLB Team et al., 2022), indicating the importance of language-specific parameters.

3.3 The Importance of Language-Specific Parameters

Here, we study the reason *why language-specific parameters are important and how much they contribute*. To investigate this, we first measure the degree of language-specificity of all parameters based on Equation 4. We explore the contribution of language-specific parameters with respect to the BLEU scores. Then, we conduct one-shot unstructured pruning with respect to BLEU scores in order of the degree of language-specificity for both models with and without ID, starting with the least language-specific parameters⁶. As more parameters are pruned, a slower performance drop means that a higher contribution comes from the remaining more language-specific parameters. Figure 3 shows the average BLEU drop across 8 languages versus the percentage of parameters pruned. After pruning the less language-specific parameters, the rest of the more language-specific parameters in the model with ID are able to preserve better performance, indicating the importance of more language-specific parameters.

4 Proposed Self-Supervision Method

We extend our study of language-awareness to MMT models co-trained with self-supervised objectives that have been shown to improve translation performance. We first propose a simple but effective self-supervised learning objective, **concurrent denoising** (CD), and then investigate the effectiveness of ID in helping improve multi-task optimization challenges of co-training CD and

⁵The overall parameter contribution is still more balanced as claimed in Xu et al. (2022). We leave further discussion on this to Appendix B.

⁶Note that, as shown in Figure 2b, the 10% most sensitive parameters are highly language-agnostic. They are easy to classify as less language-specific and can be pruned, but pruning them would lead to near-random performance ($\text{BLEU} \approx 0$), making it hard to evaluate the importance of more language-specific parameters. Thus, we keep the top 10% sensitive parameters and prune the rest of parameters that display a more language-specific behavior.

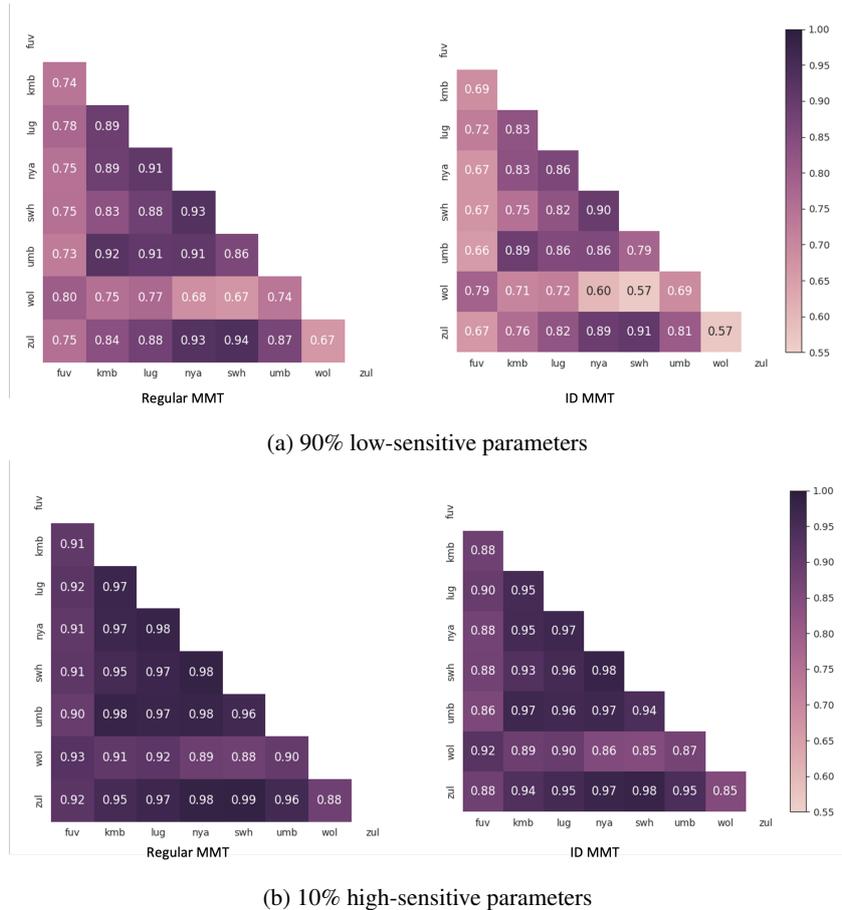

Figure 2: PCC between the lists of parameter sensitivity of every language (left for regular MMT and right for MMT with ID). We show contribution similarity of two groups of parameters, i.e., top 10% high-sensitive parameters and the remaining 90% parameters. The lower score between two languages represents the less similarity of parameter contributions for these two languages, which means more contribution disagreements and parameters are more language-specific.

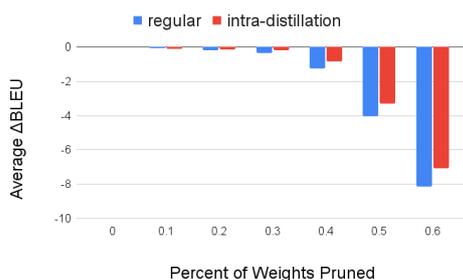

Figure 3: Change in average $xxx \rightarrow eng$ translation performance across 8 languages versus pruning ratio. Models are pruned starting with the least language-specific parameters.

MMT tasks together by learning more language-specific parameters.

4.1 Concurrent Denoising

Self-supervised learning objectives usually involve sentence denoising either on the encoder side, such

as MLM (Devlin et al., 2019), or on the decoder side, such as DAE (Liu et al., 2020). Jointly denoising sentences on both the encoder and the decoder sometimes is better than a single denoising objective (Wang et al., 2020; Kim et al., 2021) for MMT, but the training cost is doubled as we need to calculate the loss for the same monolingual sentence twice (masked in two different ways). We propose **concurrent denoising**, a self-supervised task that denoises a single masked sentence both on the encoder and decoder sides, which not only reduces the training time but also improves the language understanding of the model to result in better MMT performance.

We add noise to the monolingual data by whole-word masking (Devlin et al., 2019), where we randomly replace $r_m\%$ words with the special token `<mask>`. During the replacement process, each word has a 10% chance not to be masked, and another 10% chance to be replaced with other

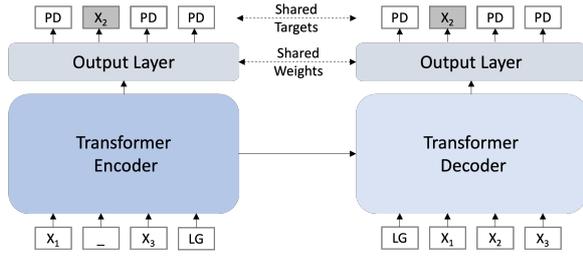

Figure 4: Concurrent denoising. In the example input sentence ‘ $X_1 X_2 X_3$ ’, the token X_2 is masked. The encoder and decoder share the same output projection layer and target tokens to predict the masked token. We only calculate the loss for the masked token prediction. PD represents the target token loss padding and LG is a special language token.

random tokens. The encoder and decoder use a shared output layer to reconstruct the original sentence. The loss for the encoder and decoder side are denoted as \mathcal{L}_e and \mathcal{L}_d respectively⁷. The total training loss combining translation loss \mathcal{L}_{MMT} and two self-supervised losses is

$$\mathcal{L} = \mathcal{L}_{MMT} + \mathcal{L}_e + \mathcal{L}_d. \quad (7)$$

Concurrent denoising is illustrated in Figure 4. Two key differences between our concurrent denoising method and regular MLM or DAE methods are worth highlighting.

Shared Output Projection Since the decoder has an output projection layer while the encoder does not, Wang et al. (2020) train the encoder with MLM by using an additional projection layer. However, we utilize the decoder projection layer as a shared layer for both encoder and decoder to reconstruct the sentence, which significantly reduces model parameters. This is because the projection layer is usually large when we have a large vocabulary size. We show the effect of using a shared projection layer in Appendix C.

Shared Target Tokens Since the output representations of the encoder and decoder are fed to the same projection layer, we want them to predict the same target token at the same position for the stability of the projection layer training. To achieve this, we carefully design our language token positions. Instead of only prepending a special language token at the beginning of the source sentence (Johnson et al., 2017), we append

⁷Unlike DAE training on the decoder side, we zero out the losses which predict non-masked tokens.

the special language token on the source side and also prepend it on the decoder side (As shown in Figure 4). This design also applies to MMT. In this way, we can avoid the encoder and decoder from predicting the same token at different positions.

4.2 Concurrent Denoising with Intra-Distillation

We investigate whether ID helps concurrent denoising to improve overall performance. We apply ID to the co-training of CD and MMT tasks. Following Equation 6 and 7, our final loss is

$$\mathcal{L} = \frac{1}{K} \left(\sum_{i=1}^K \mathcal{L}_{MMT_i} + \sum_{i=1}^K \mathcal{L}_{e_i} + \sum_{i=1}^K \mathcal{L}_{d_i} \right) + \alpha (\mathcal{L}_{id_MMT} + \mathcal{L}_{id_e} + \mathcal{L}_{id_d}), \quad (8)$$

where \mathcal{L}_{id_MMT} , \mathcal{L}_{id_e} and \mathcal{L}_{id_d} respectively represent the ID loss for translation, encoder denoising and decoder denoising (i.e., \mathcal{L}_{id_e} minimizes the difference of the K encoder outputs based on Equation 5, etc.). The i index in \mathcal{L}_{e_i} , \mathcal{L}_{MMT_i} and \mathcal{L}_{d_i} indicates that these losses are for the i^{th} forward pass.

5 MMT+SSL Experiments

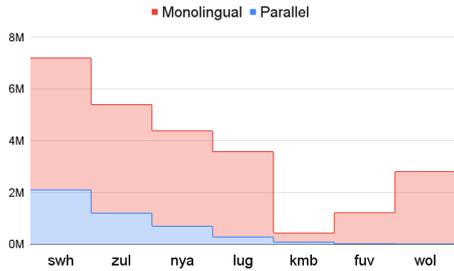

5.1 Baselines

We consider three strong baselines. All baselines are our own implementation following the settings from the original papers.

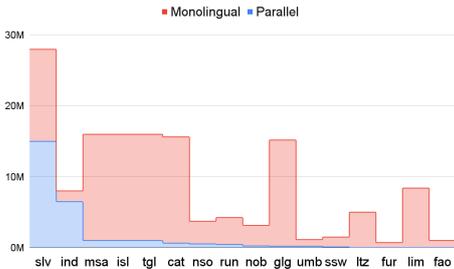

DAE NLLB Team et al. (2022) learn the effects of the causal language modeling (LM) and DAE objectives (Liu et al., 2020). Since they find that DAE performs better than LM or LM+DAE, we only compare our methods with the DAE objective.

DAE+MLM Wang et al. (2020) study a multi-task learning framework which jointly trains the MMT, MLM and DAE objectives, where MLM and DAE reconstruct sentences noised by different masking methods. Kim et al. (2021) also investigate the effectiveness of ELECTRA (Clark et al., 2020). They conclude that DAE+MLM is better than DAE+ELECTRA.

MASS Siddhant et al. (2020) and Siddhant et al. (2022) utilize MASS (masked sequence to sequence pre-training) (Song et al., 2019) to improve the MMT performance. Similar to MLM which predicts masked tokens on the encoder side, MASS masks a fragment of a sentence and predicts the masked fragment but on the decoder side.

(a) M8 dataset

(b) M15 dataset

Figure 5: The statistics of monolingual and parallel data for M8 and M15 are presented. The languages are arranged in descending order of parallel data size.

5.2 Datasets

In addition to the M8 dataset described in Section 3.1, we also build a larger dataset (M15), covering 15 languages. In composing this dataset, we take into account linguistic diversity and data size. The resulting dataset has languages from 6 linguistic families and a balanced number of high-resource, low-resource and very low-resource languages. Detailed information on this dataset is in Appendix D. We randomly sample at most 3M monolingual samples per language for M8, and 15M for M15. The distribution of monolingual data and parallel data for M8 and M15 is shown in Figure 5. Note that we also use parallel data for self-supervised learning, so the true monolingual data size includes bitext data. We use the FLORES-200 dataset for evaluation. All datasets come from the primary bitext and monolingual data used for the NLLB-200 model (NLLB Team et al., 2022).

5.3 Data Sampling

We use a data sampling temperature of $T = 1$ suggested by NLLB Team et al. (2022) to train on the MMT objective. For monolingual data, we use a temperature of $\frac{10}{7}$ to balance the SSL training, as suggested by Liu et al. (2020). During co-training, we mix the two sources in an equal ratio (50% monolingual data (including bitext used for SSL

training) with self-supervision and 50% parallel data).

5.4 Training and Evaluation Details

All experiments consider both the $eng \rightarrow xxx$ and $xxx \rightarrow eng$ directions and use the Transformer architecture (Vaswani et al., 2017). We use Transformer_{big} (242M parameters, 6 layers, 16 heads, 1,024 hidden dimension, 4,096 FFN dimension) for M8 experiments. For M15 experiments, we double the layers of Transformer_{big} (418M parameters). We use a vocabulary of size 32k for both M8 and M15 with SentencePiece (Kudo and Richardson, 2018). The batch size is 30K tokens. We warm-up for the first 8K steps. We set the total training steps to 100K and 300k for M8 and M15 respectively, with patience set to 10 for early stopping. We forward pass the model twice ($K=2$) to conduct ID. We set the ID weight $\alpha = 5$. During concurrent denoising, the masking ratio is set to $r_m = 30\%$. We also show the effect of masking ratio in Appendix E. During generation, we use beam search with a beam size of 5 and a length penalty of 1.0. All models are evaluated with sacreBLEU (spm tokenizer).

Table 3: Overall $eng \rightarrow xxx$ BLEU for M8 and M15.

5.5 Results

The overall results for the $xxx \rightarrow eng$ and $eng \rightarrow xxx$ directions are shown in Tables 2 and 3. For both M8 and M15, and both translation directions, concurrent denoising is better than all aforementioned baselines, and combining it with ID further improves upon the baselines by an even larger margin. For instance, our method outperforms MASS by 11.3% and 3.7% on M8 and M15 respectively, averaged across all languages and directions. We also show the effectiveness of ID on other objectives like DAE in Section 6.1, but the results are subpar compared to CD+ID.

Aligned with the findings of Wang et al. (2020); Kim et al. (2021), we observe that DAE+MLM is better than DAE alone in M8 $xxx \rightarrow eng$, but the improvements become very minor when it comes to M8 $eng \rightarrow xxx$ or when scaling to 15 languages. MASS performs similarly or better than DAE in the $eng \rightarrow xxx$ but worse in the $xxx \rightarrow eng$.

In M15, high-resource languages perform slightly worse with SSL methods compared to the MMT only baseline, but improves other categories, similar to the observations of NLLB Team et al. (2022). It does not occur on M8, possibly due to the smaller dataset size allowing for sufficient model capacity to learn from additional monolingual data.

Note that the effectiveness of SSL such as DAE and MASS is not as pronounced as reported by Wang et al. (2020) and Siddhant et al. (2022). However, it is necessary to consider the for domain mismatch between the training and evaluation data. As demonstrated by Siddhant et al. (2022), a significant decline in performance can occur when either monolingual or bitexts diverge from the evaluation domain. In our study, the training data is sourced from NLLB-200 and FLORES-200, which encompasses a wide range of domains. we hypothesize that this contributes to the observed lessened effectiveness of SSL techniques in our experiments.

6 Analysis

6.1 Ablation Study

The final loss, described in Equation 8, has 6 loss terms. Except for the translation loss, we ablate the relative contribution of all the other 5 loss terms to the translation task performance. In Table 4, we show the results of this ablation study on M8 $xxx \rightarrow eng$ directions. Method ① is the regular MMT model and method ② is ID training only for

MMT (the same result as in Section 3.1). Method ③ is the same as the MMT+DAE method. With the help of ID for the decoder denoising (method ④) and an additional ID for translation (method ⑤), translation performance can respectively obtain +0.41 and +0.98 BLEU on average compared to ③. Note that method ⑤ is the MMT+DAE+ID method. Compared to our MMT+CD+ID method, it substantially underperforms our method (17.73 vs. 18.69), which shows that our method could better stimulate the potential of ID. The results for methods ⑥, ⑦ and ⑧ indicate the effectiveness of encoder denoising with CD and applying ID. Overall, the translation performance improves by including all the loss terms.

Method	Avg. BLEU
① \mathcal{L}_{MMT}	15.94
② $\mathcal{L}'_{MMT} + \mathcal{L}_{id_MMT}$	17.15
③ $\mathcal{L}_{MMT} + \mathcal{L}_d$	16.75
④ $\mathcal{L}'_{MMT} + \mathcal{L}'_d + \alpha \mathcal{L}_{id_d}$	17.16
⑤ $\mathcal{L}'_{MMT} + \mathcal{L}'_d + \alpha(\mathcal{L}_{id_d} + \mathcal{L}_{id_MMT})$	17.73
⑥ $\mathcal{L}_{MMT} + \mathcal{L}_e + \mathcal{L}_d$	17.29
⑦ $\mathcal{L}'_{MMT} + \mathcal{L}'_e + \mathcal{L}'_d + \alpha(\mathcal{L}_{id_d} + \mathcal{L}_{id_e})$	17.59
⑧ $\mathcal{L}'_{MMT} + \mathcal{L}'_e + \mathcal{L}'_d + \alpha(\mathcal{L}_{id_d} + \mathcal{L}_{id_e} + \mathcal{L}_{id_MMT})$	18.69

Table 4: Ablation study on loss terms. For simplicity, we use \mathcal{L}' to represent the mean loss of K forward pass, e.g., $\mathcal{L}'_e = \frac{1}{K} \sum_{i=1}^K \mathcal{L}_{e_i}$.

6.2 Language-Specific Parameters for SSL

In Section 3, we observed that ID helps MMT learn more language-specific parameters and improve model generalization. We are also interested in understanding 1) whether the model also learns more language-specific parameters for the SSL task (here we investigate CD), and 2) what is the relationship of parameter contribution between MMT and SSL tasks for the same language. We use the $xxx \rightarrow eng$ direction of the M8 dataset as an example to study these questions.

In Figure 6, we plot a heat map to illustrate the PCC of all parameter sensitivities between every language pair. As expected, parameter sensitivity similarity becomes lower for all languages, which means there are more language-specific parameters when we train SSL methods with ID. For the second question, in Figure 7 we show the parameter sensitivity similarity between the MMT and CD tasks for each language. The contribution similarity becomes higher between the two tasks for every language with ID. This is expected, since the losses of MMT and CD have the same objective on the decoder side, i.e., text generation conditioned on

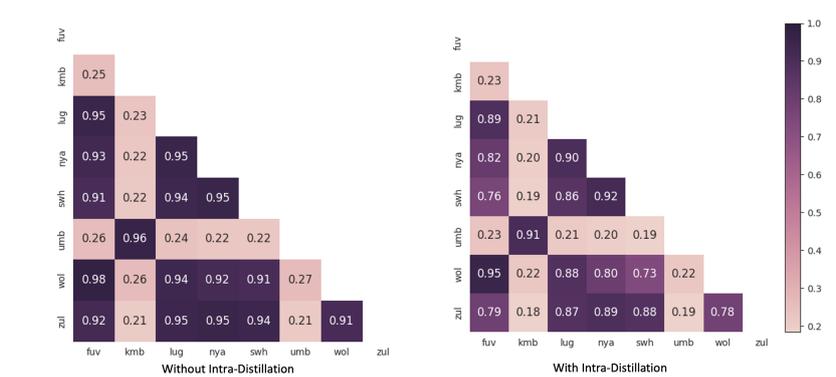

Figure 6: Parameter contribution similarity among all language pairs, evaluated by PCC for the CD task before (left) and after (right) ID.

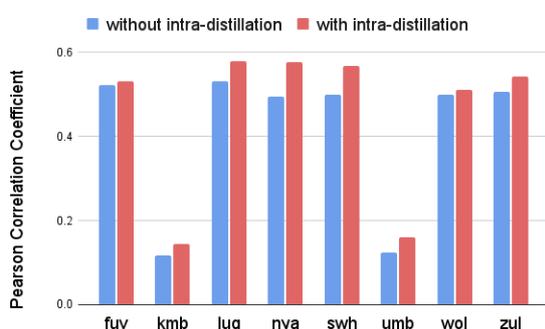

Figure 7: Parameter contribution similarity between MMT and CD for each language with and without ID.

another text. This is also another reason why SSL tasks can help multilingual translation.

7 Conclusions

We show extensive analysis that intra-distillation training helps multilingual translation by learning more language-specific parameters. We propose concurrent denoising, improving upon multiple state-of-the-art self-supervised learning methods. Moreover, we demonstrate that applying intra-distillation to the above co-training scheme offers further improvements to translation performance.

Limitations

Although we show improvements using our methods on multiple languages from diverse language families on multilingual machine translation, it should be noted that the generalizability of our findings to other multi-task learning settings, such as those involving the combination of tasks such as named entity recognition, part-of-speech tagging, and question answering, remains uncertain. This is due to

the fact that our study primarily focused on the utilization of intra-distillation to learn task-specific parameters on multilingual machine translation and did not investigate the aforementioned tasks. Furthermore, with intra-distillation we need to perform more than one forward pass, leading to a trade-off between higher performance and increased training time – which, for many use-cases, could be arguably acceptable.

Regular	34.14	11.47	5.75	15.71
Intra-Distillation	35.05	13.79	5.69	16.07

Table 5: M8 $\text{eng} \rightarrow \text{xxx}$ results of regular MMT and MMT with intra-distillation.

Similar to Section 3, the model with intra-distillation outperforms the regular MMT model by a large margin in the $\text{eng} \rightarrow \text{xxx}$ direction, as shown in Table 5. We still use a heat map to visualize the PCC of parameter sensitivity lists among every language pair in the $\text{eng} \rightarrow \text{xxx}$ direction. In Figure 8, we show that contribution similarity becomes lower as well, which means that the model also learns more language-specific parameters.

Figure 8: PCC between the list of all parameter sensitivities across every language in the M8 $\text{eng} \rightarrow \text{xxx}$ experiments. We compare the similarity between MMT with and without intra-distillation.

We also evaluate the importance of these language-specific parameters by following the same settings in Section 3.3. We conduct one-shot unstructured pruning, starting with the least language-specific parameters. We again see that the average BLEU scores of 8 languages from the model trained with intra-distillation drop slower after more parameters are pruned, indicating that these language-specific parameters learned by intra-distillation are able to preserve more performance.

B More Balanced Parameter Contribution

We compute the sensitivity of all parameters by feeding a set of batches \mathcal{B} that contains all language data in the M8 $\text{xxx} \rightarrow \text{eng}$ experiment. We illustrate parameter sensitivity distribution in Figure 10. Aligned with the findings in Xu et al.

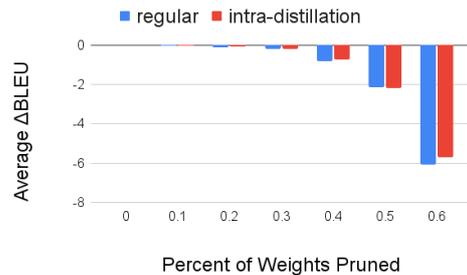

Figure 9: Change of model performance averaged across 8 languages against increasing pruning ratio for the $\text{eng} \rightarrow \text{xxx}$ translation task. Models are pruned starting with the least language-specific parameters.

(2022), the distribution of parameter sensitivity becomes more balanced after using ID.

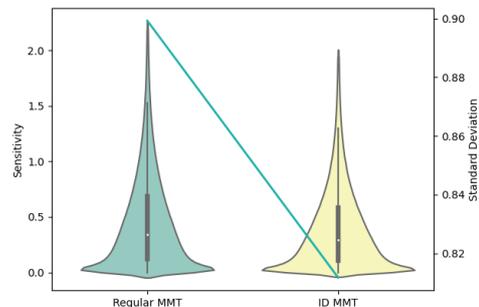

Figure 10: Sensitivity distribution (violin plots aligned with left y-axis) along with their standard deviation (green curve aligned with right y-axis, lower means more balanced parameter contribution). Note that we also remove the top 1% highest-sensitive parameters to ease the illustration.

C Ablation Study on Shared Projection Layer

Since we use a shared projection layer for both encoder and decoder denoising as well as for translation to reduce the model size and save memory, we investigate whether this sharing leads to a performance drop. We conduct experiments on M8 $\text{xxx} \rightarrow \text{eng}$ dataset. Table 6 shows that our method with shared layer slightly outperforms the one with separate output projection layers on average.

D M15 Language Information

We give a full account of the 15 languages in the M15 dataset in Table 7.

Method	High	Low	Very Low	All
CD+ID (shared layer)	35.16	15.18	9.23	18.69
CD+ID (NOT shared layer)	35.09	15.04	9.28	18.61

Table 6: Comparison of concurrent denoising + intra-distillation with and without using a shared projection layer.

E Effect of Masking Ratio

We take MMT+CD+ID as our study case to investigate the effect of masking ratio $r_m\%$ on the MMT performance. We conduct experiments on M8 $\text{xxx} \rightarrow \text{eng}$. Figure 11 shows that there is no big performance change when we set mask ratio between 0.3 and 0.6.

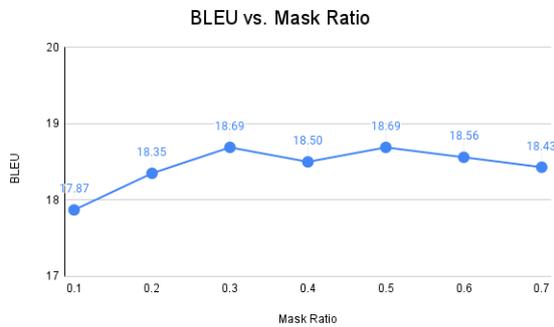

Figure 11: MMT performance change along with masking ratio on the MMT+CD+ID method.

Language	Language id	Parallel Data Size	Resource Level	Language family	Monolingual Data Size

Abstract

Cloze tests play an essential role in language assessment and help language learners improve their skills. In this paper, we propose a novel task called Cloze Quality Estimation (CQE) — a zero-shot task of evaluating whether a cloze test is of sufficient “high-quality” for language assessment based on two important factors: reliability and validity. We have taken the first step by creating a new dataset named CELA for the CQE task, which includes English cloze tests and corresponding evaluations about their quality annotated by native English speakers, which includes 2,597 and 1,730 instances in aspects of reliability and validity, respectively. We have tested baseline evaluation methods on the dataset, showing that our method could contribute to the CQE task, but the task is still challenging.¹

1 Introduction

A cloze test (Taylor, 1953) is an efficient and comprehensive tool in language assessment, and thus it is widely used in language proficiency tests (Passage and Questions in Table 1), which measure multiple language abilities of examinees simultaneously, for example, grammatical knowledge (Rye, 1982; Alderson, 1979) and reading comprehension ability (Raymond, 1988; Klein-Braley, 1997). The most widespread format of the cloze test is the multiple-choice word-level cloze test, which consists of an incomplete passage with several blanks and a series of questions, where each question includes several options (four options in the usual setting), requiring examinees to fill the blanks by selecting words (or phrases) from options that make the passage coherent.

The significantly high price of creating cloze tests by experts has prompted automatic cloze generation methods (Goto et al., 2010; Sakaguchi

et al., 2013; Hill and Simha, 2016; Panda et al., 2022). However, automatically generated cloze tests do not always contribute well to language assessment and suffer from low quality. In language assessment, a reliable and valid cloze test shows a high ability to measure examinees’ language level (Bachman, 1985). Cloze question creation has two steps, word deletion and distractor generation, with the latter greatly affecting the ability to measure language level. As indicated by (Xie et al., 2018), some cloze tests, particularly automatically generated cloze tests, are created coarsely and cause two fatal issues in language assessment: (1) these tests do not guarantee that the answer is not ambiguous, which means there is a risk that multiple options fit almost equally well into the blank; (2) the test creation process considers less about which aspect of the language phenomenon is measured in the test; hence, such tests cannot measure the examinee’s language level. These two issues make the cloze test unsuitable for measuring examinees’ language level. The first issue makes the test unreliable (e.g., Question 4 in Table 1), which means even if an examinee has enough language knowledge to answer the test, the test might report a wrong score to indicate that the examinee lacks such knowledge. In other words, an unreliable cloze test cannot present the examinee’s language level. The second issue makes the test invalid (e.g., Question 3 in Table 1). An invalid test cannot identify the aspect in which an examinee lags in terms of language knowledge, which indicates that educators cannot identify the knowledge that the examinee has not acquired.

In this paper, we tackle the issues of evaluating the appropriateness of cloze tests for language assessment focusing on distractors. By following the test design principle (ALTE, 2011), we define a zero-shot task to evaluate cloze tests for language assessment considering two aspects: reliability and validity, which is called Cloze Quality Estimation

¹The CELA dataset and code of baselines are available at <https://github.com/zz-zhang/cloze-quality-estimation>.

Passage:

A policeman was walking along the street. In the doorway of a shop, a man was standing in the 1 light, with an unlighted cigar in his mouth. The policeman slowed down and then walked up to the man. "I'm just waiting for a friend here," the man said "It's an appointment 2 twenty years ago." The man struck a match and 3 his cigar. The light 4 a pale face with a little white scar near his right eye. "Twenty years ago tonight, when I said goodbye to Jimmy Wells, my best friend to start for the West to make my fortune ...

Questions:

- | | | | |
|------------------|-----------------------|---------------|------------------|
| 1. A. dark | B. bright | <u>C. dim</u> | D. colorful |
| 2. A. make | B. makes | C. making | <u>D. made</u> |

Evaluation:

(reliable, valid_grammar)
(reliable, valid_reading)
(reliable, not_valid)
(not_reliable, not_valid)
...

Table 1: Example of cloze test and qualities for each question in CELA. The input consists of a **passage** with multiple blanks and a series of **questions** (tuples of options). The expected output is **evaluation** tuples to indicate whether the questions are reliable and valid (and what language ability is tested if valid). Underlined options are the correct answers, which fit passage perfectly.

(CQE). In CQE, each question in a cloze test is asked to be estimated, whether it is reliable and valid. CQE provides a cloze as input (**Passage** and **Questions** in Table 1) and requires estimation of each question as output (**Evaluation** in Table 1). We introduce a new test set called the **Cloze Estimation dataset for Language Assessment (CELA)** which includes a variety of cloze tests and corresponding annotations. These cloze questions are specifically designed for junior high-school students in China. We prepared diverse English cloze tests including expert-designed and rule-generated tests and asked native English speakers to solve them and annotate the quality of each question in the two aspects of reliability and validity.

We also introduce baseline methods for the CQE task: we designed option-aware methods that evaluate cloze questions by analyzing their options. We tested the baseline methods with the CELA and compared them against option-agnostic baselines. We found that detection of unreliable questions is challenging and that all our baseline methods were wary to label a question as unreliable. The framework of our option-aware methods contributed to the validity evaluation, particularly when implemented by DNN-based approaches, which outperformed option-agnostic baselines significantly and showed potential for improvement.

The main contributions of this work are summarized as follows:

- We propose a new task of quality estimation

of cloze tests (CQE) for language assessment. We design two sub-tasks: reliability evaluation and validity evaluation.

- We create a new CQE dataset (CELA) for English learners, including annotations for both expert-designed and automatically generated cloze tests.
- We propose the first CQE methods considering the options of cloze questions. We report the experimental results using rule-based and DNN-based approaches.

2 Related Work

Language educators are capable of creating cloze tests rationally; they select words to be blanked and design distractors by their experience in language education to improve reliability and validity. CLOTH (Xie et al., 2018), SCDE (Kong et al., 2020), and CEPOC (Felice et al., 2022) are collections of human-created cloze tests, which are highly evaluated by experts in terms of measuring the English ability of examinees. However, designing cloze tests by experts is costly and difficult to generalize.

Automatic cloze generation methods could decrease the cost of creating cloze tests. To avoid generating useless tests in language assessment, these methods focus on distractor generation, which affects the quality of tests significantly. Previous works have conducted trials designing good rules or

machine learning models. Sakaguchi et al. (2013) described a method of generating distractors for assessing an English as second language (ESL) learner’s ability to distinguish semantic nuances between vocabulary words. They could generate valid questions, but these questions are domain-limited, which is not easy to generalize to cloze tests for human language assessment. The Children’s Book Test (CBT) (Hill et al., 2016) deletes named entities, common nouns, verbs, and prepositions and then designs distractors having the same part of speech (POS) as the deleted words to measure abilities in reading comprehension and vocabulary. Because of the naive distractor creation, the CBT method has the risk of generating unreliable questions. Coniam (1997); Goto et al. (2010); Correia et al. (2012); Hill and Simha (2016); Jiang et al. (2020) explore cloze test generation with various features, such as n -gram frequency and POS tag, and attempt to select deleted words and create distractors by using discriminative models including conditional random fields and support vector machine. Advanced distractor generation methods (Panda et al., 2022) that employ large pre-trained language models (LMs) can provide more valid distractors. These LMs produce better text representation that captures rich semantic information, and better text representation allows generation methods to produce more plausible distractors, which could measure language abilities better. However, designing good rules or models to improve the quality of cloze tests is not that easy. Furthermore, these works claimed they could generate better distractors, but it is difficult to perform comparisons to previous work. All the works performed human evaluations using their own metrics.

Crowdsourcing has been used to evaluate the quality of cloze tests and explore factors that affect quality (Skory and Eskenazi, 2010); workers were required to fill appropriate words in an open cloze-style sentence (a sentence with a blank, but without providing options). Answers from workers were used to calculate Cloze Easiness (Finn, 1977) to indicate whether the sentence is usable for the testing an examinee’s vocabulary. The Association of Language Testers in Europe provides a manual for developing a language test (ALTE, 2011), which specifies that the statistics of a test’s results reflect its reliability and validity. It asks various examinees to answer a test and analyzes the statistics of a question such as the accuracy and the answer

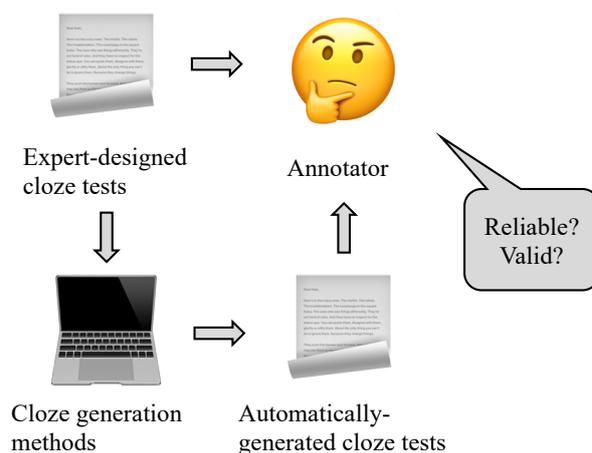

Figure 1: Flow of creating CELA. Cloze generation methods use passages and blanks from expert-designed tests to eliminate the effect of the word deletion strategy.

distribution. However, these evaluation methods require human resources or experts, which is time-consuming and sometimes difficult to obtain.

3 Cloze Quality Estimation

Motivated by related work, we propose the task of evaluating the quality of the cloze test. We introduce the definition of CQE task and CELA, our new dataset designed specifically for the CQE task. Figure 1 shows the flow of creating CELA. We collected expert-designed and automatically generated cloze tests and asked native English speakers to annotate whether these tests are reliable and valid.

3.1 Task Definition

First, we define a CQE task as follows. In a CQE task, given an incomplete passage with blanks and a series of questions with tuples of options, a quality estimation model should predict the quality of the questions and return tuples to indicate whether these questions are reliable and valid for language assessment. Here, we formalize a CQE task as two classification sub-tasks: *reliability evaluation* and *validity evaluation*.

Reliability. In the reliability evaluation, given a cloze passage with multiple questions (tuples of options), we perform a binary classification of whether the questions are reliable (*reliable*) or not (*not_reliable*). In terms of reliability, if a cloze question has more than one option that fits the context perfectly, there is no guarantee that the question can report a stable test score even when taken by the same examinee. Thus, in the reliability evaluation, we define that if a cloze question has more

than one correct answer, it is not reliable.

Validity. In the validity evaluation, we perform a three-class classification of either the question is valid for measuring grammatical knowledge (*valid_grammar*), valid for measuring reading comprehension ability (*valid_reading*), or invalid (*not_valid*). In terms of validity, a valid question should require examinees to use their language ability to distinguish the correct answer option from distractors. If a question measures more than one language ability, the question is considered to be too simple to measure the language ability of the examinee (Rankin, 1976). Thus, in the validity evaluation, we define that if a question requires the examinee’s single language ability (grammar or reading comprehension) to distinguish the answer option, the question is valid, otherwise it is invalid.

3.2 CELA data preparation

We collected English cloze tests from Chinese senior-high-school examinations (Xie et al., 2018) called CLOTH, which is expert-designed. To explore whether automatically generated cloze questions are sufficient for language assessment, we also employed four automatically generated cloze tests using previous generation methods: Randomized, Hill, Jiang, and Panda. All generated tests were based on the same cloze passages from expert-designed tests, that is, these five settings share the passages, blanks, and correct answers but have respective distractors in questions.

Randomized is generated using a random sampling method. In this method, we built vocabulary from CLOTH and randomly selected words from the vocabulary as distractor options.

Hill is generated using the same method of the CBT dataset (Hill et al., 2016), which selects words that have the same POS tag with the answer from the vocabulary as distractors.

Jiang employs the method of Jiang et al. (2020), which also selects words from the vocabulary but considers more factors including POS tag, word frequency, and spelling similarity. Their method is designed for the Chinese cloze test, but we adapted it to the English test.

Panda employs the method of Panda et al. (2022), which uses round trip translation to paraphrase a passage and align the paraphrased passages with the original one. They use aligned words to the answer as distractor candidates and select a distractor from candidates considering the syn-

onym and POS tag.

As a result, we collected and generated 150 cloze tests including 3,000 questions².

3.3 CELA annotation

We hired Amazon Mechanical Turkers to annotate the 3,000 questions. To ensure annotation quality, we required annotators to have approval rates over 98% and be native English speakers living in the United States. We also added attention checks to avoid bots and irresponsible annotators. Each question was annotated by three different annotators. Table 2 shows examples of our annotation task. As a reward, we paid each annotator \$1.5 for a test, which included 20 questions and took 5 to 7 minutes for completion.

We performed inter-annotator analysis on the annotations using Fleiss’ kappa score (Fleiss, 1971). Kappa scores were 0.67 and 0.45 for reliability (binary) and validity (3-class), respectively. Moderate kappa scores indicate that the annotation task was well-defined and the annotation result was trustable. Furthermore, to improve the annotation quality, we discarded all disagreed annotations. The majority of annotations that were rejected on the grounds of reliability pertained to long-term reasoning questions. These questions necessitated the integration of information from multiple sentences, and without taking into account this information, the distractors appeared to be equally plausible. This led to a divergence of opinions among some annotators and ultimately resulted in the determination that these questions were unreliable. The reasons for rejection in terms of validity were more varied. One pattern that emerged was the use of prepositions, where some annotators classified questions regarding preposition usage as *valid_reading* instead of *valid_grammar*, despite our explicit instructions on this matter. We posit that this may have been due to the fact that certain questions involving prepositions necessitate contextual information in order to deduce the correct answer (e.g., prepositions of location), causing some annotators to consider them as reading comprehension questions.

The processed data statistics are shown in Table 3. Because most blanks in CLOTH are content words and corresponding questions are designed to measure reading comprehension ability, there are few questions that measure grammatical knowledge.

²The cloze tests are collected/generated in five ways, each accounting for one-fifth of the total.

Passage	... He wished to find a good job. One day, he went to a company to ____ for a job.
Example 1	
Question	A. apply B. vote C. prepare D. wait
Explanation	In this question, only option A fits the passage perfectly, so please select “One” in Number of answer; options B, C, and D don’t fit the passage logically, and you will eliminate them by the knowledge (ability) of reasoning, so please select “Reading” option in Measured ability.
Example 2	
Question	A. apply B. applied C. look D. has applied
Explanation	In this question, both option A and C fit the passage perfectly, so please select “More than one” in Number of answer; except correct answers (option A and C), options B and D don’t fit the passage grammatically, and you will eliminate them by the knowledge (ability) of grammar, so please select “Grammar” option in Measured ability.
Example 3	
Question	A. apply B. vote C. applying D. waiting
Explanation	In this question, only option A fits the passage perfectly, so please select “One” in Number of answer; option B doesn’t fit the passage logically, option C doesn’t fit the passage grammatically, and you will eliminate them by the both of knowledge (abilities). So please select the “None” option in Measured ability. Also, since option D fits the passage neither logically nor grammatically, you will eliminate it by any of knowledge (abilities). So you can select the “None” option in Measured ability only considering option D.

Table 2: Example of annotation. We used following instructions: “Please select an option in the Number of answers list to indicate whether there is more than one option that fits the passage perfectly; please select what kind of language ability the question measures in the Measured ability list. You can refer to Table 2 for examples.”

Type	#
Reliability questions	2,597
reliable	2,324
not_reliable	273
Validity questions	1,730
valid_grammar	86
valid_reading	921
not_valid	723

Table 3: Statistics of the processed data. Because reliability is easier to annotate, it has higher agreement, and more annotations are retained than validity.

3.4 CELA analysis

We observed that the five types of cloze tests have various qualities. Figure 2 shows the quality statistic in CELA according to generation methods.

In reliability, Jiang is the most reliable and only includes 3.9% of unreliable questions, and Panda has 22.1%, which is the most unreliable. Surprisingly, CLOTH and Panda, which are expert-designed and generated by an advanced generation method, respectively, are not as reliable as the oth-

ers. We conjecture that these two types of tests tend to produce more plausible distractors that break only little coherence of the context. Plausible distractors are good at measuring learners’ language ability but have a higher risk of making the question unreliable. In particular, the Panda system utilizes round-trip translation and alignment to generate distractor candidates, which limits the scope of possible candidates and tends to produce more credible options compared to those generated by other systems. Furthermore, the Panda system does not impose strict limitations on eliminating distractors that are also suitable for the blank, which increases the likelihood of generating unreliable questions. On the other hand, the Randomized system selects distractors from the vocabulary without any constraints, which reduces the chance of selecting distractors that are also appropriate for the blank.

In validity, meeting our conjecture, there are fewer invalid questions in CLOTH and Panda, which means these two test types are better at measuring language ability than others. For automatic distractor generation methods, Panda has the strictest

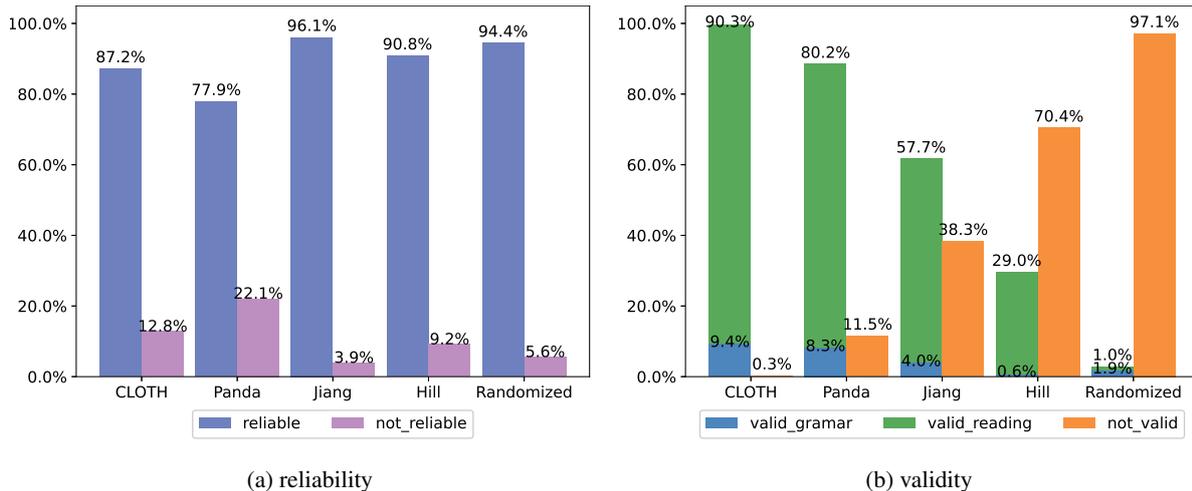

Figure 2: Quality statistics of cloze tests in CELA. The left and right buckets represent the ratio of high-quality and low-quality questions, respectively.

restrictions on distractor selection and produces the fewest invalid questions. Jiang has more filters for eliminating distractor candidates than Hill and could generate more valid questions. Randomized does not have any restrictions and is difficult to produce valid questions for language assessment.

We provide an example of the CELA dataset in Table 1. In the CELA dataset, each instance includes an incomplete passage with blanks and corresponding sets of options as input (questions). In a question, at least one option can be filled into the corresponding blank to make the passage coherent both grammatically and semantically. The label for each question is a tuple that denotes whether the question is reliable and valid, and if the question is valid the tuple also indicates which aspect of language ability the question measures.

4 Option-aware CQE Method

We propose two methods to tackle the CQE task, which analyze all options of cloze questions as baseline methods for the CQE task.

4.1 Intuition

We designed an option-aware CQE method considering how options in the question affect reliability and validity. We followed the definition in Subsection 3.1 and considered that the reliability and validity of a question is decided by its options. Thus, to tackle two sub-tasks in CQE, we need to inspect each option in terms of (1) whether it can be regarded as the sole answer to the question, and (2) what language ability it measures.

For the former (reliability), we consider that if an option breaks neither grammatical nor semantic coherence of the context, it fits the context perfectly and can be regarded as an answer option. For the latter (validity), if a distractor option only breaks grammatical (or semantic) coherence, examinees will use grammatical knowledge (or reading comprehension ability) to eliminate it, and in these cases, we say the distractor option is a grammatical (or reading) option; if a distractor option breaks both coherence, because it is too simple to measure one’s ability, we say it is a purposeless option.

For example, given a context: *I remember sitting in that dark hall listening to Mr. Zigler _____ everyone’s spirits up to the ceiling.* and options: *[raise, rise, educate, disappointed]*, the option *raise* does not break neither grammatical nor semantic coherence, so it is an answer option; the option *rise* breaks the grammatical coherence because the blank requires a transitive verb, so it is a grammatical option; the option *educate* obeys the grammatical rule but does not fit context semantically, so it is a reading option; the option *disappointed* is a purposeless option because it breaks both grammatical and semantic coherence of context.

Based on this intuition, we implement two functions, *BreakGrammar(·)* and *BreakSemantics(·)*, to judge whether an option breaks grammatical or semantic coherence. See Appendix A for a detailed description of the overall framework. To realize these two functions, we designed two different approaches: a rule-based approach and a DNN-based approach.

4.2 Rule-based approach

The rule-based approach is straightforward. It compares options with the answer to a question. The answer to a question can fit the context perfectly and does not break either grammatical or semantic coherence. Thus, we consider that if an option has the same grammatical/semantical feature as the answer, it does not break corresponding coherence either. In this case, functions *BreakGrammar(.)* and *BreakSemantics(.)* require one more parameter *answer*.

Given an answer option *answer* and an option *opt*, we fill *answer* and *opt* into context and obtain POS tags for them. If *opt* has the same POS tag as *answer*, we consider that it does not break grammatical coherence, otherwise it breaks grammatical coherence. For the implementation, we employed POS tagger in the Stanza library³.

Similarly, we use a synonym dictionary to judge if the option breaks grammatical coherence. If *opt* is a synonym of *answer*, *opt* does not break the semantic coherence, otherwise it breaks semantic coherence.

4.3 DNN-based approach

We also designed a DNN-based approach to implement these two functions. By using pretrained DNN models, we can plug in both grammatical and semantic knowledge into the CQE model. Unlike the rule-based approach, the DNN-based approach does not use *answer* but *opt* information for CQE.

We employ an English grammatical error corrector that can detect both grammatical and semantic errors and output the error types. We fill each option into context as input of the corrector and check the output. If the output indicates that there is no grammatical/semantic error, we regard that the option does not break grammatical/semantic coherence; otherwise, we think it breaks such coherence. We need to distinguish grammatical and semantic errors which affect the output of *BreakGrammar(.)* or *BreakSemantics(.)*. We design such a filter based on error types. To recognize the error type, we use the output tag of an error annotation toolkit.

5 Experiment

We conduct experiments to determine whether option-aware CQE methods (§4) can be a good baseline to estimate the quality of cloze tests,

³<https://github.com/stanfordnlp/stanza>

by comparing them with option-agnostic baseline methods (§5.2).

5.1 Configurations

To implement an option-aware baseline with a rule-based approach, we built an English synonym dictionary⁴. Considering that the word inflection or tense do not affect the meaning, we lemmatized both *answer* and *opt* into their basic form to judge if they were synonyms. The word lemmatization was implemented by employing the NLTK library⁵ and using the lemmatizer based on WordNet (Miller, 1998). We also employed POS tagger in the Stanza library to assign POS tags to *answer* and *opt*.

As for a DNN-based approach, we employed GECToR (Omelianchuk et al., 2020), a grammatical error corrector, that provided trained parameters and achieved a considerable performance on both CoNLL-2014 and BEA-2019 shared task (Ng et al., 2014; Bryant et al., 2019). We used GECToR which was implemented by RoBERTa (Liu et al., 2019). We fed original and corrected sentences into the Error ANnotation Toolkit (ERRANT)⁶ to obtain ERRANT tags. If the detected error’s ERRANT tag is one of **ADJ**, **ADV**, **NOUN**, and **VERB**, we considered the error to be a semantic one and not a grammatical one. Furthermore, we observed that the tag **OTHER** might contain both grammatical and semantic errors; therefore, we set two configurations for errors with tag **OTHER** as either grammatical or semantic errors.

5.2 Option-agnostic baselines

We employed the following *random* baseline and *majority prediction* baseline to show how well option-agnostic methods could perform on the CELA. Option-agnostic baselines can also be regarded as weak baselines.

Random baseline The random baseline predicts random class in reliability and validity classification. We chose the output class from the uniform distribution.

Majority prediction baseline The majority prediction baseline predicts the majority class in each classification sub-task. According to our CELA dataset, it always predicts *reliable* and

Table 4: Performance of CQE baseline methods on the CELA dataset. $r.F_1$, $g.F_1$, and $n.F_1$ represent binary F_1 score for *valid_reading*, *valid_grammar*, and *not_valid* questions, respectively. **Bold** and underline indicate the best and second-best result, respectively. \bar{O} and O indicate we regard errors from GECToR with tag **OTHER** as grammatical and semantic errors, respectively.

valid_reading in the sub-task of reliability and validity classification, respectively.

5.3 Meta-evaluation metrics

To demonstrate the efficiency of CQE methods in estimating the quality of cloze tests, we provide baseline meta-evaluation metrics for the CQE task. Specifically, in the reliability evaluation, we used F_1 , precision, and recall score. Because unreliable cloze tests are harmful to language assessment, we must focus on how well CQE models can recognize unreliable tests; thus we set *not_reliable* as the positive label. For the validity evaluation, we used the micro-averaged and macro-averaged F_1 score. To indicate how well models perform in each class, we also split the overall F_1 score into three parts: F_1 for *valid_reading*, *valid_grammar*, and *not_valid*.

5.4 Result

The performance of the baselines on the CELA dataset is presented in Table 4. For option-agnostic baselines, because of imbalanced data distribution, the majority prediction baseline was not able to detect the *not_reliable* questions. Both baselines of random and majority prediction did not perform well on reliability compared with validity. Moreover, unreliable question detection is important to language assessment. In future work, improving the performance on reliability should be considered preferentially.

The option-aware baseline implemented by the rule-based approach performed worse than random baselines on some metrics. Although it achieved a moderate recall value, the precision was nearly zero, which denotes it tends to assign *reliable* to all questions. On the validity performance, it outperformed option-agnostic baselines on some metrics,

but it is still insufficient for evaluating the quality of cloze tests. One reason is that rules using the POS tag and synonym list are so naïve that they only consider partial cases of the option type. For example, given a context *This music made everyone want to _____. It was an early form of jazz.* and options [*dance, sing, laugh, ...*], though options *sing* and *laugh* are not the synonyms of the answer *dance*, they also fit the context semantically and should have not been classified into the reading option.

In most cases, the option-aware method using the DNN-based approach outperformed option-agnostic baselines. The DNN models utilized in this paper were straightforward and rudimentary, and there is potential for further improvement to make them more suitable for widespread use. Regarding reliability, errors with **OTHER** as grammatical or semantic errors have little effect on the performance. In terms of validity, when we regard **OTHER** errors as semantic errors, the micro F_1 value increased because the model could predict more *not_valid* questions correctly, which accounted for a significant proportion in CELA.

Except for hyperparameters, the mis-prediction caused by the underlying DNN models also leads to errors. GECToR did not perform well on long-term reasoning; thus, it was not able to detect some semantical errors. For example, given a context *I was ____ of flying, ... In order to get rid of my fear I decided to try a helicopter ride*, when filling word *proud* into the blank, we expect GECToR to correct the sentence with some words similar to *afraid*, but GECToR did not report any error.

6 Conclusion and Future Work

We proposed a novel task for evaluating cloze questions for human language assessment (CQE), which involved two important factors that affect the quality of cloze questions, reliability and validity, and also provided the CELA dataset. In addition, we explored automated CQE methods that can estimate the quality of cloze tests, by designing option-aware methods. Our experimental results on the CELA dataset showed that imbalanced data bring challenges.

In future work, we would like to investigate more factors that affect the quality of cloze questions and expand the CELA dataset. For example, given the context *The sun also ____.* and two different sets of options [*raises, rises, lifts, elevates*] as well as [*raises, lives, runs, lefts*], although these two sets of options both measure reading comprehension ability, answering the question with the former set of options is more difficult than the latter and requires a higher language level. Improving the performance of DNN models and optimizing implementation of *BreakGrammar(.)* and *BreakSemantics(.)* can improve the evaluation performance. For example, designing more detailed filters in the grammatical error corrector to filter out potential semantic errors or using fine-designed data to train different language models for grammatical and semantic error detection separately may boost the performance of DNN models.

We hope that the task and our resource will encourage further exploration from both computational linguistics and language education.

Limitations

The first limitation of this study is the coverage. In this study, the CQE task is defined to evaluate cloze tests that are generated by distractor generation methods. Cloze tests in this study are all based on expert-designed blanks. However, word deletion methods, which decide which word to be blanked, affect the quality of cloze tests, too. Investigation of how blanks influence the quality of cloze tests is necessary.

The second limitation of this study is the scalability of the annotation. In this study, the annotation of question quality is done by experts, which makes creating a large-scale dataset not that easy. This limitation could be mitigated by alternative choice of target data, i.e., there is room to replace native speakers with non-native speakers by selecting tar-

get data that do not require English knowledge at high-level proficiency (e.g., CEFR-A).

Finally, the CQE task and corresponding corpus are designed specifically for the English language. However, we are interested in exploring the possibility of adapting the task and dataset to other languages. The principles of test design, such as reliability and validity, apply to other languages as well, but the specific details may vary based on the language. For example, questions for a hieroglyph-based language may require learners to identify glyphs, which must be taken into consideration when defining reliability and validity. Adapting the CQE task to a new target language and creating a corresponding dataset requires a publicly available cloze question dataset or effective cloze question generation techniques in the target language, as well as experts in the language to evaluate question quality. In the future, we hope to develop an automatic adaptation method to transfer our task and dataset to multiple languages.

Abstract

While pre-trained language models (PLMs) have become a de-facto standard promoting the accuracy of text classification tasks, recent studies (Kong et al., 2020; Dan and Roth, 2021) find that PLMs often predict over-confidently. Although various calibration methods have been proposed, such as ensemble learning and data augmentation, most of the methods have been verified in computer vision benchmarks rather than in PLM-based text classification tasks. In this paper, we present an empirical study on confidence calibration for PLMs, addressing three categories, including confidence penalty losses, data augmentations, and ensemble methods. We find that the ensemble model overfitted to the training set shows sub-par calibration performance and also observe that PLMs trained with confidence penalty loss have a trade-off between calibration and accuracy. Building on these observations, we propose the **Calibrated PLM (CALL)**, a combination of calibration techniques. The CALL complements the drawbacks that may occur when utilizing a calibration method individually and boosts both classification and calibration accuracy. Design choices in CALL’s training procedures are extensively studied, and we provide a detailed analysis of how calibration techniques affect the calibration performance of PLMs.

1 Introduction

Trustworthy deployment of machine learning applications requires accurate and calibrated predictions to instill their reliability and help users be less confused about models’ decisions (Xiao and Wang, 2019; Liu et al., 2020).

However, modern deep neural networks (DNNs) produce miscalibrated predictions, i.e., a mismatch between a model’s confidence and its correctness. One of the reasons is that an over-parameterized

*Corresponding author. This work is partially done at UNIST.

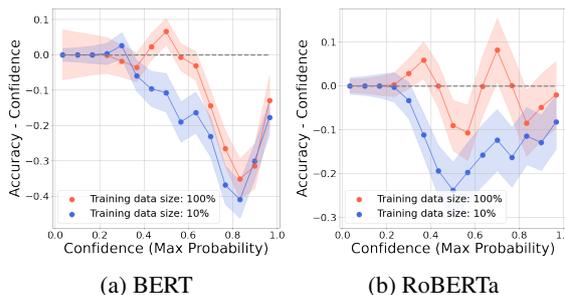

Figure 1: Reliability diagrams (DeGroot and Fienberg, 1983) on TREC (Li and Roth, 2002) with PLMs. A dashed line implies a perfect calibration while PLMs generally show over-confident predictions.

classifier typically produces over-confident predictions (Guo et al., 2017). Moreover, the miscalibration can be exacerbated when DNNs make predictions on test data different from the training distribution, i.e., distribution shift (Ovadia et al., 2019).

To obtain the well-calibrated predictions, many pioneering studies have shown the calibration effect of ensemble and regularization techniques focused on computer vision benchmarks. Ensemble learning has become one of the standard approaches to reduce calibration errors (Lakshminarayanan et al., 2017; Bonab and Can, 2019). Pereyra et al. (2017) propose the entropy regularized loss which penalizes confident output distributions in order to reduce overfitting. Hongyi Zhang (2018); Hendrycks et al. (2020) demonstrate that DNNs trained on diverse augmented data are less prone to produce over-confident predictions, leading to the calibration benefit under the distribution shift.

Intense research effort has focused on improving the calibration performance of vision models on image datasets. However, exploration of existing calibration methods with pre-trained Transformers (PLMs) has received less attention. Moreover, recent studies show that PLMs such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) pro-

duce miscalibrated predictions introduced by over-parameterization (Kong et al., 2020). Therefore, it is necessary to investigate how modern calibration techniques affect PLMs’ calibration.

In this paper, focused on PLMs in multi-class classification tasks, we explore widely used calibration families, including (1) confidence penalty loss functions that can be used instead of cross-entropy loss, (2) data augmentations, and (3) ensemble methods. We consider a low-resource regime since the small size of the training dataset amplifies the miscalibration of models (Rahaman et al., 2021). We also observe PLMs especially produce unreliable predictions in the data scarcity setting (see Figure 1).

Contributions. We conduct a comprehensive empirical study for the effectiveness of the above calibration methods. In this study, our findings are as follows:

- A PLM trained with imposing a strong penalty on the over-confident output shows significant improved calibration performance, but its accuracy can slightly deteriorate.
- For ensemble methods, Deep Ensemble (Lakshminarayanan et al., 2017) and MIMO (Havasi et al., 2021) increase the diversity of predictions, resulting in the well-calibrated predictions in the data scarcity setting. However, the ensemble methods show insufficient calibration when each ensemble member is overfitted to negative log-likelihood for the training dataset.
- Data augmentation methods that can expose diverse patterns such as MixUp (Hongyi Zhang, 2018) and EDA (Wei and Zou, 2019) are more effective for calibration in PLMs compared to weak text-augmentation methods (Kolomiyets et al., 2011; Karimi et al., 2021).

Building on our findings, we present Calibrated PLM (CALL), a blend of the discussed calibration methods. Numerical experiments demonstrate that the components of CALL complement each other’s weaknesses. For instance, data augmentation and ensemble methods offset the accuracy decline caused by the confidence penalty loss, while data augmentation and the confidence penalty loss counteract overfitting in the ensemble model. Through our extensive experiments, we show the CALL’s competitiveness on several text classification benchmarks.

2 Related Work

The calibration of machine learning models has been mainly studied for the trustworthy deployment of image recognition applications (Lakshminarayanan et al., 2017; Hongyi Zhang, 2018; Guo et al., 2017). Beyond the computer vision fields, research on the calibration ability of language models in the NLP domain has also recently been attracting attention (Desai and Durrett, 2020; Dan and Roth, 2021).

Desai and Durrett (2020) investigate the calibration ability of PLMs, and they demonstrate that RoBERTa produces more calibrated predictions than BERT. They also show that temperature scaling (Hinton et al., 2014) and label smoothing (Szegedy et al., 2016) improve the calibration performance of PLMs for language understanding tasks. Dan and Roth (2021) conduct an empirical study of the effects of model capacity on PLMs and show that smaller pre-trained transformers provide more reliable predictions. Moon et al. (2020) find that PLMs tend to produce over-confident outputs based on in-distribution (ID) keywords rather than contextual relations between words. They demonstrate that keyword-biased predictions can be over-confident even in out-of-distribution samples with ID keywords.

Kong et al. (2020) suggest two regularizers using generated pseudo-manifold samples to improve both ID and out-of-distribution calibration for PLMs. They use MixUp (Hongyi Zhang, 2018) as a regularization technique for BERT calibration and show that mixed training samples on the data manifold improve the calibration performance. Similarly, Park and Caragea (2022) propose a variant of MixUp utilizing saliency signals and also analyze the impact of combining additional calibration methods with MixUp. However, they only consider temperature scaling and label smoothing as additional calibration methods.

3 Why Re-assess Calibration Methods?

Guo et al. (2017) observe that a larger DNN tends to be more poorly calibrated than a smaller one. As the size of the parameters for modern DNNs continues to increase, the miscalibration issues need to be addressed more than ever.

At the same time, the unique character of PLMs raises concerns about whether previous findings on calibration obtained from standard convolutional neural networks (CNNs) can be successfully ex-

tended to PLM. For example, PLMs with ensemble learning may have different behavior compared to randomly initialized CNNs because naive PLMs have a massive amount of parameters and are initialized with pre-trained weights in the fine-tuning stage.

On the other hand, for the data augmentation, because image transformations (e.g., flipping, translation, and rotating) can not be directly applied to text-based samples, thus, it is also necessary to investigate the effect of text-specific augmentations on the calibration of PLMs.

4 Calibration Strategies

In this section, we review the existing literature used in our experiments and how we applied each method to PLMs. Calibration methods we explore are denoted by **bold**.

4.1 Preliminaries

Notation. Let $\mathcal{D} = \{x_i, y_i\}_{i=1}^N$ be a dataset consisting of N samples, where $x_i \in \mathcal{X}$ is an input and $y_i \in \mathcal{Y} = \{1, \dots, K\}$ is a ground truth label. We denote by $\bar{p}_i = f(y|x_i)$ the predicted distribution of a classifier f . Class prediction and associated confidence (maximum probability) of f are computed as $\hat{y}_i = \operatorname{argmax}_{k \in \mathcal{Y}} \bar{p}_i$ and $\hat{p}_i = \max_{k \in \mathcal{Y}} \bar{p}_i$, respectively.

In the BERT-style architecture, output of embedding layer, L attention blocks, and the output dense layer (with softmax function) are denoted by z_{embed} , $g = \{g_1, \dots, g_L\}$, and h , respectively.

Calibration Metrics. A calibrated model provides reliable predictive probability whose confidence aligns with its expected accuracy, i.e. $\mathbb{E}_{\hat{p}}[|\mathbb{P}(\hat{y} = y|\hat{p}) - \hat{p}|]$. Given a finite dataset, *Expected Calibration Error* (ECE; Naeini et al., 2015) is widely used as a calibration performance measure. ECE can be computed by binning predictions into T groups based on predictions of f and then taking a weighted average of each group’s accuracy/confidence difference:

$$\sum_{t=1}^T \frac{|B_t|}{N} |\operatorname{acc}(B_t) - \operatorname{conf}(B_t)|, \quad (1)$$

where B_t is the group of samples and their corresponding confidences belonging to the $(\frac{t-1}{T}, \frac{t}{T}]$. The $\operatorname{acc}(B_t)$ and $\operatorname{conf}(B_t)$ denote average accuracy and confidence of predictions for B_t , respectively.

Model calibration also can be measured using proper scoring rules (Gneiting and Raftery, 2007)

such as Brier score (Brier et al., 1950) and negative log likelihood (NLL).

4.2 Confidence Penalty Losses

We explore an alternative loss functions that can be used instead of cross-entropy (CE) loss.

Brier Loss (BL; Brier et al., 1950) is one of the proper scoring rules, defined as the squared error between the softmax output and the one-hot ground truth encoding. BL is related to ECE in that it is an upper bound of the calibration error by the calibration-refinement decomposition (Bröcker, 2009; Liu et al., 2020).

Entropy Regularized Loss (ERL; Pereyra et al., 2017) penalizes confident output distributions by adding the negative entropy:

$$\mathcal{L}_{\text{ERL}} = \mathcal{L}' + \beta \sum_{k=1}^K \bar{p}_k \log \bar{p}_k, \quad (2)$$

where \mathcal{L}' can be an arbitrary classification-based objective function (e.g., CE and BL), and β is the hyperparameter that controls the strength of the confidence penalty.

Label Smoothing (LS; Szegedy et al., 2016) is a commonly used *trick* for improving calibration that generates a soft label by weighted averaging the uniform distribution and the hard label.

4.3 Data Augmentations

Data augmentations have been widely used to improve the model’s calibration performance in computer vision fields (Hongyi Zhang, 2018; Hendrycks et al., 2020; Wang et al., 2021). However, text augmentations are often overlooked in the literature on the calibration in NLP tasks. To the best of our knowledge, we are the first to extensively study how text augmentation techniques such as Synonym Replacement (SR; Kolomiyets et al., 2011), Easy Data Augmentation (EDA; Wei and Zou, 2019), and An Easier Data Augmentation (AEDA; Karimi et al., 2021) affect calibration performance. We also investigate the recent variant of MixUp (Zhang and Vaidya, 2021).

SR randomly choose n words from the input sentence except for stop words and then replace each of these words with one of its synonyms chosen using WordNet (Miller, 1995).

EDA is a token-level augmentation method that consists of four random transformations: SR, Random Deletion, Random Swap, and Random Insertion.

AEDA only use Random Insertion operator that insert punctuation marks (i.e., “.”, “;”, “!”, “?”, “:”, “:”) into a input sentence.

MixUp (Hongyi Zhang, 2018) is a data augmentation strategy using convex interpolations of inputs and accompanying labels. Guo et al. (2019) investigate word- and sentence-level MixUp strategies to apply MixUp to recurrent neural networks. Zhang and Vaidya (2021) propose MixUp-CLS, that performs MixUp on the pooled [CLS] token embedding vector for a last attention layer of PLM. MixUp-CLS shows improved accuracy for natural language understanding (NLU) tasks compared to word-level MixUp. Unless otherwise specified, we use MixUp-CLS in our experiment.

4.4 Ensembles

Ensemble techniques utilize M models by combining them into an aggregate model and then average the predictions to produce calibrated outputs: $\frac{1}{M} \sum_{m=1}^M f_m(y|x)$. We compare the deterministic model with three ensemble approaches, and the computational cost of the ensemble methods used in the experiment is reported in Appendix A.

Deep-Ensemble (DE; Lakshminarayanan et al., 2017) consists of M randomly initialized models and provides a calibration effect leveraging the predictive diversity of ensemble members. When applying DE to PLMs, M independent models have different initialization weights only in a penultimate layer since PLMs are initialized with pre-trained weights.

Monte Carlo Dropout (MCDrop; Gal and Ghahramani, 2016) interprets Dropout as an ensemble model, leading to its application for uncertainty estimates by sampling M times dropout masks at test time.

Multi-Input and Multi-Output (MIMO). To alleviate the high computational cost and memory inefficiency of DE, Havasi et al. (2021) propose the multi-input and multi-output architecture by training M sub-networks inside a CNN.

In original MIMO, the M inputs (images) $\{x^m\}_{m=1}^M$ are sampled from $\mathcal{D}_{\text{train}}$. MIMO concatenates multiple inputs per channel before the first convolution layer and produces multiple outputs using M independent output dense layers. The feature extractor of CNN remains unchanged. For the training procedure, all ensemble members have the same mini-batch inputs with probability p , and the inputs are randomly sampled from the training

dataset with probability $1 - p$.

For applying MIMO to the PLMs, the following consideration arise; When multiple inputs are connected before the embedding layer, the length of tokens is M times longer. Thus, applying MIMO to PLMs in this manner is inefficient for a dataset that consists of long sentences.

Instead, we modify the original configuration of MIMO so that it can be applied to various NLP tasks. For PLM, the output of the first attention layer \bar{z} is calculated by averaging multiple outputs of M independent first attention blocks $\{g_1^m\}_{m=1}^M$:

$$\bar{z} = \frac{1}{M} \sum_{m=1}^M g_1^m(z_{\text{embed}}). \quad (3)$$

To produce multiple predictions, we use M modules that consist of the last attention blocks $\{g_L^m\}_{m=1}^M$ and dense layer h . The ensemble prediction is calculated by:

$$\bar{p} = \frac{1}{M} \sum_{m=1}^M h(g_L^m(g'(\bar{z}))), \quad (4)$$

where $g' = \{g_2, \dots, g_{L-1}\}$ is the shared attention blocks.

	# train	# dev	# test	l_{avg}	# classes

5 Experiments

This section presents the experimental results of the calibration methods. We describe experimental datasets and settings (Section 5.1 and 5.2), followed by empirical results for the low-resource regime (Section 5.3), overall calibration result (Section 5.4), and detailed analysis (Section 5.5). We then introduce the training procedure of CALL in Section 6. In our experiments, we set RoBERTa trained with CE as a baseline. Unless otherwise specified, ensemble and augmentation methods are applied to the baseline.

5.1 Datasets and Metrics

Dataset. Following Zhou et al. (2021), we use the following three text classification datasets. Data statistics are described in Table 1.

Acc \uparrow / ECE \downarrow / NLL \downarrow	TREC	SST2	20NG
RoBERTa (baseline)	94.04 / 4.08 / 24.86	91.23 / 7.42 / 43.08	76.58 / 11.37 / 90.40
CE+ERL	93.72 / 4.05 / 24.20	91.04 / 6.62 / 38.77	<u>76.79</u> / 11.21 / 90.32
CE+LS	93.84 / 3.37 / <u>23.71</u>	91.16 / 6.03 / 30.26	76.39 / 11.36 / 90.90
BL	93.24 / 2.69 / 26.55	89.48 / 7.15 / 36.02	75.74 / 7.21 / <u>86.02</u>
BL+ERL	93.84 / 2.48 / 24.78	90.32 / 5.68 / 29.61	76.13 / 6.62 / 86.11
BL+LS	93.52 / <u>2.32</u> / 25.16	91.15 / <u>5.56</u> / <u>29.37</u>	75.83 / <u>6.57</u> / 86.31
SR	94.24 / 3.37 / 22.24	90.54 / 7.22 / 38.03	76.45 / 10.54 / <u>87.64</u>
AEDA	93.76 / 4.68 / 28.36	91.45 / 6.69 / 37.67	76.41 / 11.49 / 91.21
EDA	93.40 / 2.83 / 23.46	91.56 / <u>5.01</u> / <u>29.86</u>	76.01 / <u>10.52</u> / 88.89
MixUp	<u>94.76</u> / 2.23 / <u>22.02</u>	90.86 / 6.46 / 31.89	<u>76.74</u> / 11.22 / 90.65
MCDrop	94.20 / 4.16 / 24.45	91.04 / 6.84 / 39.55	76.63 / 10.18 / 87.52
MIMO	94.88 / 3.13 / 20.38	91.26 / 6.21 / 32.78	76.25 / 5.61 / 81.43
DE	95.03 / <u>2.89</u> / 19.02	<u>91.44</u> / 4.88 / <u>29.51</u>	78.09 / 7.51 / 78.96

Table 2: Results for the low-resource regime. For each dataset, all methods are trained with 10% of training samples. The best results in each category are indicated in underline and the best results among all methods are indicated in **bold**. Accuracy is a percentile. We report ECE and NLL multiplied by 10^2 .

- Stanford Sentiment Treebank (SST2; Socher et al., 2013) is a sentiment analysis dataset that consists of sentences from movie reviews.
- 20 Newsgroups (20NG; Lang, 1995) is a topic categorization dataset which contains news articles with 20 categories.
- TREC (Voorhees and Tice, 2000) is a dataset for question classification, and we use its coarse version with six classes.

To evaluate the effectiveness for calibration methods in the data scarcity setting, we use 10% of the training set.

Metrics. We measure ECE and NLL for each calibration method. For ECE, we bin the predictions into $T = 15$ equidistant intervals. We report ECE and NLL multiplied by 10^2 in all experimental results for the convenience.

5.2 Training Configurations

We implement our framework upon Huggingface’s Transformers (Wolf et al., 2020) and build the text classifiers based on RoBERTa (roberta-base) in the main experiment. All models are optimized with Adam optimizer (Kingma and Ba, 2017) with a weight decay rate of 0.01, warmup proportion of 0.1, batch size of 16, a dropout rate of 0.1, and an initial learning rate of $1e-5$. We fine-tune the RoBERTa for 10 epochs. For each calibration method, hyper-parameters are tuned according to the classification performance, and the detailed hyper-parameter setting is described in Appendix B. We also provide empirical results for BERT

(bert-base-cased) in Appendix C. We report the averaged performance over 5 runs using different random seeds and implementation results are available at https://github.com/kimjeyoung/PLM_CALL.

5.3 Result for Low-resource Regime

Table 2 represents the classification accuracy and calibration performances for each dataset in the low-resource regimes. Most calibration strategies perform better than the baseline, even in cases where the baseline calibration results were already good, e.g., TREC. These results demonstrate that the existing methods can enhance PLM’s calibration ability when the annotation budget is small, as in many real-world settings.

Interestingly, augmentation methods except for AEDA also result in the calibration benefit. For example, MixUp and EDA show improved calibration performances for all datasets compared to the baseline.

Among confidence penalty losses, BL significantly reduces ECE for the three datasets. Moreover, the calibration performance is further improved when BL is combined with an additional regularization method (i.e., BL+ERL and BL+LS). However, BL+LS and BL+ERL underperform the baseline with respect to accuracy, and this performance drop is also observed when applied to BERT (Appendix C).

DE not only shows the most remarkable improvement of NLL but also improves accuracy for all datasets. MIMO also consistently outperforms the baseline for ECE. In summary, DE and MIMO are

Acc \uparrow / ECE \downarrow / NLL \downarrow	TREC	SST2	20NG
RoBERTa (baseline)	97.40 / 2.41 / 15.24	94.35 / 4.13 / 26.36	86.00 / 9.51 / 68.26
CE+ERL	97.24 / 2.44 / 14.64	94.05 / 4.05 / 26.94	86.13 / 9.41 / 70.18
CE+LS	97.28 / 2.06 / 13.11	94.21 / 3.75 / 20.17	86.14 / 9.81 / 70.16
BL	97.04 / 1.80 / 12.23	94.48 / 2.95 / 17.25	86.06 / 7.06 / 58.37

BL+LS	96.92 / 1.41 / 12.54	94.34 / <u>2.78</u> / 17.74	<u>86.15</u> / 6.76 / 58.17
SR	97.04 / 2.19 / 12.18	94.31 / 3.48 / 20.81	85.97 / 9.31 / 64.84
AEDA	<u>97.24</u> / 2.35 / 12.99	94.45 / 3.70 / 23.27	85.89 / 9.85 / 69.41
EDA	97.16 / 1.87 / 11.54	94.21 / <u>2.95</u> / 19.27	85.74 / <u>8.69</u> / <u>60.90</u>
MixUp	97.20 / <u>1.55</u> / 11.58	<u>94.57</u> / 3.61 / <u>19.04</u>	<u>86.21</u> / 8.72 / 64.48
MCDrop	97.56 / 2.37 / 13.84	94.01 / 3.64 / 24.02	85.97 / 8.61 / 64.49
MIMO	97.32 / 2.30 / 12.86	94.32 / 2.68 / <u>17.51</u>	85.80 / 8.68 / <u>60.92</u>
DE	97.32 / <u>2.09</u> / <u>12.83</u>	<u>94.64</u> / 3.10 / 19.15	86.81 / <u>7.90</u> / 62.31

Table 3: Overall calibration results for calibration techniques. For each dataset, all methods are trained with 100% of training samples.

more effective than the other calibration methods when considering both accuracy and calibration in the low-resource regime.

5.4 Overall Result

Overall performance result is reported in Table 3. Similar to the results in Table 2, most of calibration methods show better calibration performance compared to the baseline. In this setting, RoBERTa trained with BL+ERL works best. For example, BL+ERL shows NLL results of 17.31 and 58.02 in SST2 and 20NG, respectively, but DE obtain 19.15 and 62.31. In the data augmentation category, EDA and MixUp improve ECE and NLL compared to SR. AEDA underperforms the baseline for 20NG.

5.5 Analysis

Our empirical results raise the following questions: (1) Why do EDA and MixUp show better calibration performance than SR or AEDA? (2) How can we improve the accuracy of BL+ERL? (3) Why are ensemble methods more efficient than regularization methods in the low-resource setting, whereas BL+ERL is most effective for the full-data available setting? We further conduct a detailed analysis focusing on the above questions.

Role of Data Augmentation. Although the PLM trained on the proper scoring rule reduce calibration error for the training dataset, minimizing calibration errors for all unseen ID samples is challenging because we use finite training data (Liu et al., 2020). As an alternative, if models trained with augmented samples learn diverse representations, we expect to match the distribution of training data with the distribution of unseen ID data.

Distance	TREC	SST2	20NG
SR	11.56 / 17.44	7.12 / 12.01	15.54 / 23.02
AEDA	11.57 / 16.95	6.87 / 12.09	16.37 / 22.36
EDA	14.16 / 17.08	8.09 / 10.99	17.27 / 22.24
MixUp	14.52 / 15.44	7.69 / 11.18	16.65 / 21.62

Table 4: (Left) Distance between original and augmented sentences for the training samples. Higher is better. (Right) Distance between augmented training sentences and original test samples. Lower is better. The distance are computed at the last attention layer of RoBERTa.

Acc / ECE	TREC	SST2	20NG
BL+ERL	93.84 / 2.48	90.32 / 5.68	76.13 / 6.62
+SR	92.60 / 2.93	91.75 / 4.57	76.40 / 5.49
+AEDA	93.84 / 2.84	91.32 / 5.21	75.83 / 6.14
+EDA	93.40 / 2.83	90.76 / 4.97	76.45 / 5.18
+MixUp	94.76 / 2.23	90.89 / 4.52	76.25 / 6.39

Table 5: Comparison result for augmentation methods. Each method is trained with 10% of training data.

We analyze the distance between unseen and training data distribution, assuming that the augmentation scheme that pulls the distribution of training data towards the unseen data distribution will be effective for calibration.

To measure the distance between the two distributions, we use Hausdorff-Euclidean distance. In Table 4, RoBERTa trained with MixUp shows the closest distance between training data and test data, followed by EDA. In addition, the augmented data generated by MixUp and EDA are far away from the training data. It can be interpreted that EDA and MixUp generate more diverse patterns of

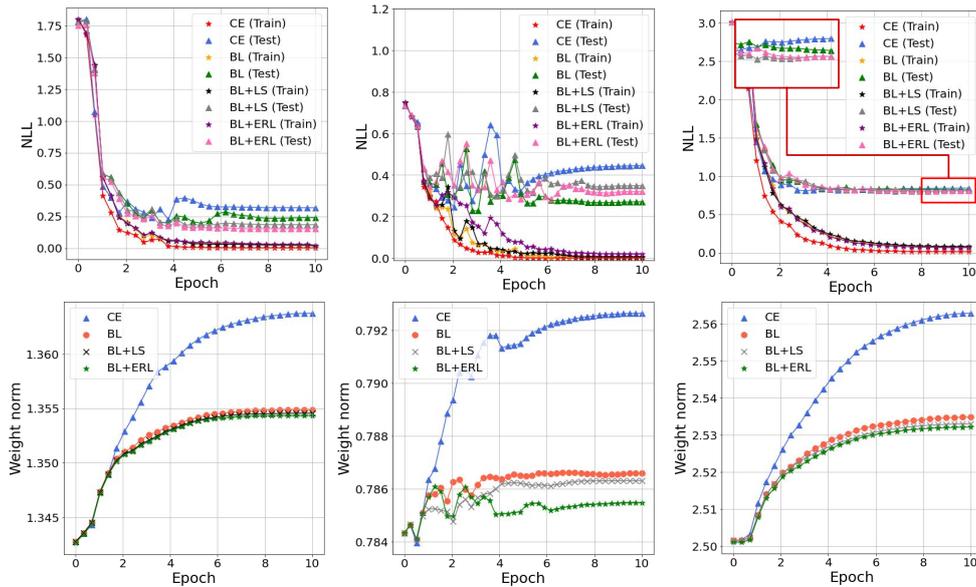

Figure 2: The plot of the NLL (Top) and the norm of weights (Bottom) while training RoBERTa on TREC (Left), SST2 (Middle), and 20NG (Right), respectively. The weights are extracted from the penultimate layer of RoBERTa and we use 10% of samples for training.

representations. Hence, matching the distribution of observed data with the distribution of unseen data by adopting a proper augmentation method that generates diverse patterns may help the model produces calibrated predictions.

On the other hand, since data augmentation generally helps to improve accuracy, we investigate whether augmentation methods improve the accuracy of BL+ERL. In Table 5, MixUp improves not only classification accuracy but also calibration performance on all datasets compared to the naive BL+ERL.

Role of Regularization. A crucial empirical observation by Guo et al. (2017) is that overfitting the NLL during training appears to be associated with the miscalibration of DNNs.

To better understand the role of strong regularization, we visualize the NLL during the training process of PLM. In Figure 2, training and test NLL are reduced at the beginning of training regardless of regularization methods. However, as training progresses, the test NLL of RoBERTa trained with CE increases¹. On the other hand, other regularization methods show an inhibitive effect on overfitting compared to CE.

A DNN can produce over-confident predictions if the network increases the norm of its weights, which results in the high magnitudes of the logits

¹Note that we use weight decay and dropout for training in order to alleviate overfitting.

(Mukhoti et al., 2020). Figure 2 (Bottom) shows that the RoBERTa trained with CE also has a larger norm than the regularized models.

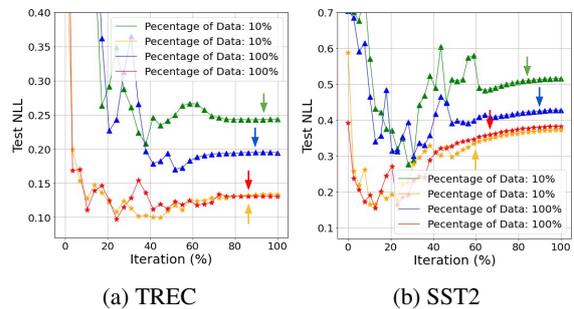

Figure 3: The test NLL for DE. Each arrow denotes the point at which the validation accuracy is the maximum.

Diversity Analysis in Ensembles. Diversity of predictions in ensemble is one of the key factor of determining calibration performances (Havasi et al., 2021). However, in the presence of overfitting, the diversity of predictions between ensemble members may decrease because the trained individual members would produce similar predictions that are overfitted to the same training data distribution (Shin et al., 2021).

We hypothesize ensemble members of DE applied to PLMs may also suffer from overfitting. Thus, we investigate whether the ensemble members are overfitted to NLL. In Figure 3, DE trained with 10% of the training data shows a different test NLL for each ensemble member, while DE trained

Acc \uparrow / ECE \downarrow / NLL \downarrow	TREC	SST2	20NG

Table 6: CALL_{MIMO}: BL+ERL+MixUp+MIMO. CALL_{DE}: BL+ERL+MixUp+DE. The best and second best results are indicated in **bold** and underline, respectively.

with 100% of the training data results in a closer NLL for the ensemble members as the training progresses.

According to our experimental result, members within the ensemble often fail to produce different predictions due to the overfitting, indicating that additional effective regularization schemes can be adopted to prevent overfitting when applying the ensemble to the PLM. This finding also explains why ensemble techniques shows sub-par calibration performance compared to the regularization methods in the setting where full-data available.

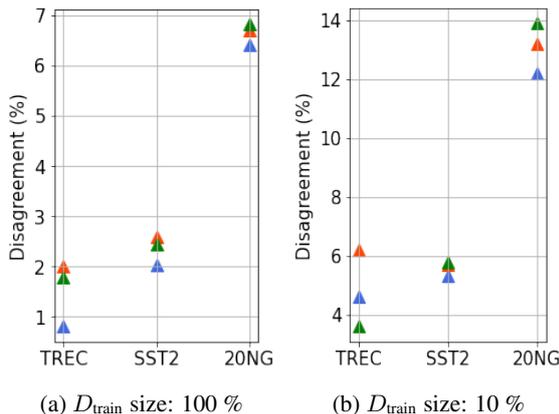

Figure 4: The diversity of predictions in ensemble with respect to the regularization methods. **Blue**: DE; **Orange**: DE+MixUp; **Green**: DE+BL+ERL. Results for MIMO and MCDrop are reported in Appendix D. A higher disagreement means that the models within the ensemble make different predictions.

We investigate whether BL+ERL and MixUp methods can compensate for the aforementioned

limitation of the ensemble method. We measure disagreement score (see Havasi et al., 2021) to analyze the degree of diversity for predictions. As shown in Figure 4, DE shows a high disagreement score in the low-resource regime. When full-data are available, the disagreement score of DE is consistently the lowest for all datasets. However, we observe that MixUp and BL+ERL significantly mitigate the reduction of predictive diversity for DE.

6 Calibrated PLMs

Through extensive analyses, we find that (1) MixUP that generate more diverse patterns helps improve the accuracy of BL+ERL, and (2) the reduced predictive diversity in the ensemble can be mitigated by BL+ERL and MixUp.

To this end, we report the calibration performance incrementally applying BL+ERL, MixUp, and ensemble techniques to the naive RoBERTa. Specifically, we denote BL+ERL+MixUP+DE, and BL+ERL+MixUP+MIMO by CALL_{DE}, and CALL_{MIMO}, respectively.

In Table 6, overall, CALL_{DE} achieves remarkable performance compared to DE on SST2 and 20NG datasets. CALL_{MIMO} shows competitive performance with DE with respect to ECE and NLL. This experiment shows that the calibration performance can be improved by the combinations using the ensemble, data augmentation, and confidence penalty losses in NLP tasks based on PLM, and each calibration method complements each other to further improve calibration performance without compromising accuracy.

7 Conclusion

In this work, we investigate the calibration effect of PLMs with various calibration methods applied. As a result of a comprehensive analysis of how calibration methods work in PLMs, we find that (1) the confidence penalty losses have a trade-off between accuracy and calibration, and (2) ensemble techniques lose predictive diversity as training progresses, resulting in reduced calibration effectiveness. To address these findings, we propose CALL, a combination of BL, ERL, MixUp, and ensemble learning. CALL reduces the risk of accuracy reduction through its data augmentation and ensemble techniques, and enhances the predictive diversity of ensemble methods by incorporating strong regularization and data augmentation. On multiple text classification datasets, CALL outperforms established baselines, making it a promising candidate as a strong baseline for calibration in text classification tasks.

Limitations

Although the proposed framework achieves significantly improved calibration performance compared to the baselines, CALL still has room for performance improvement and may require more diverse approaches (Zadrozny and Elkan, 2001; Hinton et al., 2014; Mukhoti et al., 2020; Liu et al., 2020). Another limitation is that we only address the ID calibration issue for PLMs. Therefore, whether CALL could work well for out-of-distribution detection and generalization tasks is unclear. We leave these questions for future research.

Ethics Statement

The reliability of deep-learning models is crucial to the stable deployment of real-world NLP applications. For example, the computer-aided resume recommendation system and neural conversational AI system should produce trustworthy predictions, because they are intimately related to the issue of trust in new technologies. In this paper, through extensive empirical analysis, we address diverse calibration techniques and provide a detailed experimental guideline. We hope our work will provide researchers with a new methodological perspective.

A Computational Cost for Ensemble Methods

Latency ↓ (s) (Train / Test)	TREC	SST2	20NG
RoBERTa	725.9 / 3.0	1031.9 / 8.2	1494.7 / 29.5
MCDrop (M=2)	725.9 / 5.8	1031.9 / 15.6	1494.7 / 58.8
MIMO (M=2)	840.7 / 3.5	1178.3 / 9.1	1720.0 / 34.0
DE (M=2)	1438.2 / 5.8	2060.7 / 15.6	3026.8 / 58.8
CALL _{MIMO}	841.9 / 3.5	1180.2 / 9.1	1721.5 / 34.0
CALL _{DE}	1440.3 / 5.8	2062.1 / 15.6	3028.4 / 58.8

Table 7: Comparison of training/test time for ensemble approaches. We measure the computational time on an NVIDIA-V100 single GPU.

Table 7 includes computational costs for ensemble methods on a single GPU. CALL_{DE} (RoBERTa+BL+ERL+MixUP+DE) is almost the same as DE since only the regularization term in the loss function and data augmentation process are added. Similarly, the computation cost of CALL_{MIMO} is almost the same as MIMO, and CALL_{MIMO} achieves a significant speedup in training/test time compared to DE.

B Hyperparameter Setting

Selected hyperparameters are highlighted in bold. **ERL**. Strength of the confidence penalty $\beta \in \{0.001, 0.005, 0.01, 0.1\}$. Empirically, PLMs trained with high beta (e.g., 0.1) showed sub-par classification accuracy. We set the low beta as 0.001 for all experiments.

LS. ϵ -smoothing parameter $\epsilon \in \{0.01, 0.05, 0.1\}$.

EDA. We follow the parameters recommended by the authors. Full-data setting: $\alpha = 0.1$. Data scarcity setting: $\alpha = 0.05$. α is a parameter that indicates the percent of the words in a sentence that are changed.

AEDA. For each input sentence, $p = \{5, 10, 15\}$ percentage of the words are changed for low-resource regime, otherwise $p = \{5, 10, 15\}$ words are changed.

SR. $p = \{5, 10, 15\}$ percentage of the words are changed for low-resource regime, otherwise $p = \{5, 10, 15\}$ words are changed.

MixUp. $\alpha \in \{0.1, 0.5, 1.0\}$ (strength of interpolation).

MCDrop. $p \in \{0.01, 0.02, 0.03, 0.04, 0.05, 0.1\}$ is the Dropout rate. $M \in \{2, 3, 4, 5\}$. We choose the hyperparameters when the validation accuracy is best in each experiment.

MIMO. $M \in \{2, 3, 4, 5\}$. Validation accuracy tends to decrease when M is increased.

We choose input repetition parameter $p \in \{0.1, 0.2, 0.3, 0.4, 0.5\}$ when the validation accuracy is best in each experiment. Overall, $p = 0.2$ is best.

DE. Full-data setting: $M \in \{2, 3, 4, 5\}$. Data scarcity setting: $M \in \{2, 3, 4, 5\}$.

C Empirical Result for BERT

We report empirical results for BERT in Table 8 and Table 9.

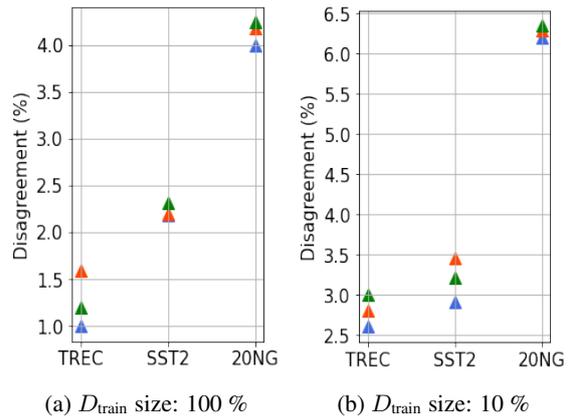

Figure 5: Effect of regularization with respect to diversity of predictions in ensemble. **Blue**: MCDrop; **Orange**: MCDrop+MixUp; **Green**: MCDrop+BL+ERL.

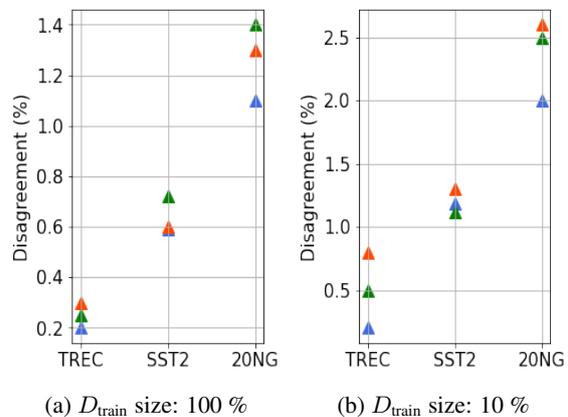

Figure 6: Effect of regularization with respect to diversity of predictions in ensemble. **Blue**: MIMO; **Orange**: MIMO+MixUp; **Green**: MIMO+BL+ERL.

D Analysis Diversity

We report diversity measure for MCDrop and MIMO in Figure 5 and Figure 6, respectively.

Abstract

Detecting out-of-distribution (OOD) inputs is crucial for the safe deployment of natural language processing (NLP) models. Though existing methods, especially those based on the statistics in the feature space of fine-tuned pre-trained language models (PLMs), are claimed to be effective, their effectiveness on different types of distribution shifts remains underexplored. In this work, we take the first step to comprehensively evaluate the mainstream textual OOD detection methods for detecting semantic and non-semantic shifts. We find that: (1) no existing method behaves well in both settings; (2) fine-tuning PLMs on in-distribution data benefits detecting semantic shifts but severely deteriorates detecting non-semantic shifts, which can be attributed to the distortion of task-agnostic features. To alleviate the issue, we present a simple yet effective general OOD score named GNOME that integrates the confidence scores derived from the task-agnostic and task-specific representations. Experiments show that GNOME works well in both semantic and non-semantic shift scenarios, and further brings significant improvement on two cross-task benchmarks where both kinds of shifts simultaneously take place. Our code is available at <https://github.com/lancopku/GNOME>.

1 Introduction

The pre-training and fine-tuning paradigm based on Transformers (Vaswani et al., 2017) has achieved tremendous success in various natural language understanding (NLU) tasks (Devlin et al., 2019; Liu et al., 2019; Qiu et al., 2020). However, fine-tuned pre-trained language models (PLMs) notoriously suffer from over-confident predictions on out-of-distribution (OOD) inputs (Hendrycks et al., 2020). As this issue threatens the reliability of NLP models deployed in the open world, textual OOD detection has attracted great attention recently (Podolskiy et al., 2021; Zhou et al., 2021, 2022; Duan et al.,

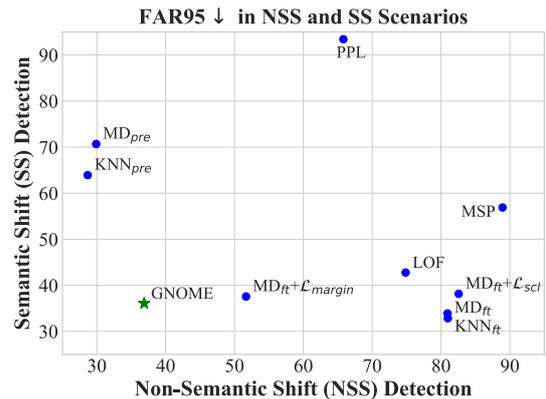

Figure 1: OOD detection performance (FAR95↓, lower is better) in non-semantic and semantic shift scenarios. No single existing method works well in both scenarios, but our proposed GNOME mitigates the trade-off.

2022, etc.), which aims to enable the model to abstain from making unreasonable predictions on OOD data and resort to human intervention.

Nonetheless, almost all of the current approaches are assessed under certain assumptions about the type of OOD texts. One line of works creates in-distribution (ID) and OOD pairs from arbitrary datasets for different tasks (Hendrycks et al., 2020), while another line assumes that OOD data belong to classes in the ID task but unseen during training, e.g., in intent recognition (Podolskiy et al., 2021). Arora et al. (2021) reveal the inconsistency among the evaluation protocols and category the distribution shifts to non-semantic shifts (NSS) and semantic shifts (SS), but a thorough comparison of existing methods in different settings is missing as later works either focus on either detecting NSS (Duan et al., 2022) or SS (Zhou et al., 2022).

In this work, we systematically evaluate the mainstream textual OOD detection methods on a comprehensive suite of benchmarks covering both NSS and SS scenarios. As shown in Figure 1, no single method wins across the board. Notably, the detec-

tors based on the pre-trained features, e.g., the Mahalanobis distance detector MD_{pre} (Xu et al., 2021), excel at detecting non-semantic shifts but fail in detecting semantic shifts. In contrast, when the PLM is fine-tuned on annotated ID data, the detectors based on fine-tuned features, e.g., MD_{ft} (Podolskiy et al., 2021), perform well in the SS scenario but disastrously fail in the NSS setting. These observations uncover an intriguing trade-off: *fine-tuning contributes to the detection of semantic shifts but impairs the detection of non-semantic shifts*. This trade-off raises two critical research questions:

RQ1: *Why does fine-tuning undermine the detection of non-semantic shifts?* It is relatively easy to attribute the positive effect of fine-tuning in the SS setting to the learned class-discriminative features (Fort et al., 2021), but it remains unknown why fine-tuning plays a negative role in the NSS setting. We empirically find that the adverse effect comes from the fact that fine-tuning gradually destructs the pre-trained task-agnostic knowledge about general linguistic properties, which are useful cues for the detection of non-semantic shifts.

RQ2: *How to develop a general textual OOD detection method?* Since the type of distribution shifts is unknown in practice, our findings suggest that a practical method able to detect different kinds of OOD texts is yet to be developed. To this end, we aggregate the distance scores estimated in the feature space of both pre-trained and fine-tuned models to derive a **GeNeral textual OOD Measurement scorE** (GNOME) capable of detecting both NSS and SS. On the suite of benchmarks covering both NSS and SS settings, GNOME (the green star in Figure 1) surpasses the previous SOTA by 8.13 FAR95 points on average; on two cross-task benchmarks where both kinds of shifts happen simultaneously, GNOME reduces the average FAR95 by 4.88 points. Note that GNOME is not meant to be a SOTA method in all settings but rather a simple, principled way to get reasonable detection performance under various kinds of distribution shifts—we hope our analysis inspires better approaches for general textual OOD detection.

2 Related Work

OOD detection aims to detect abnormalities coming from a different distribution from the training data so that the model can refuse to make predictions on them (Amodei et al., 2016; Yang et al.,

2021). Since it is essential for the security of machine learning models deployed in the open-world environment, OOD detection has gained great attention, first in computer vision (CV). We categorize the mainstream OOD detection methods into three groups by way to derive confidence scores: (1) *confidence-based methods* using the output probabilities of classifiers trained on in-distribution (ID) data (Hendrycks and Gimpel, 2017; Lakshminarayanan et al., 2017; Liang et al., 2018; Liu et al., 2020); (2) *density-based methods* using density scores derived from generation models (Zong et al., 2018; Ren et al., 2019; Xiao et al., 2020); (3) *distance-based methods* using the distance statistics in the feature space of neural networks (Lee et al., 2018; Huang et al., 2021; Sun et al., 2022).

Following the progress in CV, textual OOD detection based on PLMs has also attracted increasing attention. Hendrycks et al. (2020) show that the maximum softmax probability (MSP) score (Hendrycks and Gimpel, 2017) is a strong baseline for PLMs, followed by a group of works on confidence-based textual OOD detection (Li et al., 2021; Shen et al., 2021; Yilmaz and Toraman, 2022). As for the density-based branch, Gangal et al. (2020) and Arora et al. (2021) apply the idea to textual OOD detection by leveraging language models such as LSTM (Hochreiter and Schmidhuber, 1997) and GPT-2 (Radford et al., 2019). Regarding the distance-based methods, Podolskiy et al. (2021) revisit the Mahalanobis distance-based detector (Lee et al., 2018) for textual OOD detection based on fine-tuned PLMs and achieve performance gains over confidence-based methods, which is then further improved by introducing contrastive regularization (Zhou et al., 2021), utilizing nearest-neighbor distance (Zhou et al., 2022), and leveraging intermediate features (Chen et al., 2022).

Nonetheless, the NLP community lacks uniform evaluation criteria for OOD detection. Generally, ID/OOD pairs for evaluation are constructed in three ways: (1) *the non-semantic shift (NSS) setting* (a.k.a., the background shift setting) (Li et al., 2021; Arora et al., 2021; Duan et al., 2022), where ID and OOD data consist of the same semantic classes but differ in background information,¹ e.g.,

¹Although the model can also make predictions on the samples with only non-semantic shifts, the accuracy tends to significantly drop. As the cost of wrong predictions is great in safety-critical scenarios, a conservative method for handling these samples by rejecting them is practical.

tweets as ID and Wikipedia comments as OOD in toxicity detection; (2) *the semantic shift (SS) setting* (Podolskiy et al., 2021; Zhou et al., 2022), where OOD data are composed of unseen classes belonging to the ID task, e.g., new classes in intent classification; (3) *the cross-task setting* (Hendrycks et al., 2020; Zhou et al., 2021), where the ID and OOD data are from datasets for different tasks and both semantic and non-semantic shifts happen, e.g., sentiment analysis data as ID and news classification data as OOD. Arora et al. (2021) first notice the inconsistency and compare confidence-based and density-based methods in NSS and SS settings, but they neglect the crucial branch of distance-based methods and the cross-task setting. In this work, we fill in this gap by presenting a comprehensive evaluation and developing a general textual OOD score motivated by our observations.

3 Observations and Explanations

In this section, we first give preliminaries in § 3.1. Then we introduce our benchmark for evaluating textual OOD detection (§ 3.2) and the evaluated methods (§ 3.3). Finally, we present the evaluation results (§ 3.4) and our interpretation of the observed trade-off between NSS and SS scenarios (§ 3.5).

3.1 Preliminaries

Problem Formulation The OOD detection problem can be formulated as a binary classification problem to decide whether an input example \mathbf{x} belongs to the training data distribution \mathcal{P}_{in} (ID) or not (OOD). An OOD detector D makes decisions for the input \mathbf{x} based on the following formula:

$$D(\mathbf{x}) = \begin{cases} \text{ID} & \text{if } S(\mathbf{x}) \geq \gamma \\ \text{OOD} & \text{if } S(\mathbf{x}) < \gamma \end{cases}, \quad (1)$$

where $S(\mathbf{x})$ is the confidence score output by the detector and γ is the threshold chosen by the user.

Metrics We adopt two widely-used metrics AUROC and FAR95 following prior works (Podolskiy et al., 2021; Zhou et al., 2021). AUROC can be interpreted as the probability that the model ranks a random ID sample higher than a random OOD sample, and FAR95 is the proportion of negative samples (OOD) wrongly judged as positive (ID) when the true positive rate is 95%. Higher AUROCs and lower FAR95s indicate better performance.

Notations Assume M_θ is a PLM where θ denotes its parameters and $\mathbf{z} = M(\mathbf{x})$ denotes the feature

Setting	Task	ID	OOD
Non-Semantic Shift	Sentiment Analysis	SST-2 IMDB	IMDB SST-2
	Toxicity Detection	Twitter Jigsaw	Jigsaw Twitter
Semantic Shift	News Categorization	AGNews NC	AGNews _{OOD} NC _{OOD}
	Dialogue Intent Classification	ROSTD CLINC	ROSTD _{OOD} CLINC _{OOD}

Table 1: The architecture of the constructed suite of benchmarks categorized as either non-semantic shift (NSS) or semantic shift (SS). NC is short for the News Category dataset.

vector for the input sample \mathbf{x} derived from M (e.g., the last-layer CLS embedding in Transformers). For a classification task with C classes, the user fine-tunes M together with a classification head h and get the fine-tuned model $F_{\theta^*,h} = h \circ M_{\theta^*}$ where θ^* denotes the fine-tuned parameters. The output of F is $F_{\theta^*,h}(\mathbf{x}) = (p_1(\mathbf{x}), p_2(\mathbf{x}), \dots, p_C(\mathbf{x}))^T$, which denotes the predicted probabilities.

3.2 Benchmark Construction

We aim to build ID/OOD pairs where either the non-semantic shift (NSS) or the semantic shift (SS) dominates so that we can fairly compare existing methods on the ability to detect these two kinds of shifts separately. (1) For NSS, we choose SST-2 (Socher et al., 2013) and IMDB (Maas et al., 2011) for sentiment analysis, and Twitter (Founta et al., 2018) and Jigsaw² for toxicity detection. Among the four, any two datasets from the same task can be regarded as an ID/OOD pair. (2) For SS, we use four datasets: New Category (NC) (Misra and Grover, 2021; Misra, 2022), AGNews (Corso et al., 2005), ROSTD (Gangal et al., 2020), and CLINC (Larson et al., 2019). For each dataset, we use some classes as ID and the remaining classes as OOD. We show the architecture of the constructed suite of benchmarks categorized as either non-semantic shift (NSS) or semantic shift (SS) in Table 1 and more details can be found in Appendix A. Compared with Arora et al. (2021), we additionally include toxicity detection data for NSS and intent recognition data for SS, which make the suite of benchmarks more representative of real-world scenarios.

²Available at this [link](#).

3.3 Evaluated Baselines

OOD Detection Methods We evaluate the mainstream methods as follows. (1) For *confidence-based methods*, we test the MSP baseline ($S(\mathbf{x}) = \max_{y \in \{1, 2, \dots, C\}} p_y(\mathbf{x})$) (Hendrycks and Gimpel, 2017) and its three variants: Scaling (Liang et al., 2018), Energy Score (Liu et al., 2020), and D2U (Yilmaz and Toraman, 2022); (2) For *density-based methods*, we evaluate the PPL method (Arora et al., 2021) using the GPT-2 model for language modeling ($S(\mathbf{x}) = 1/\text{PPL}(\mathbf{x})$); (3) For *distance-based methods*, we test the LOF method (Lin and Xu, 2019) that trains a local outlier detector on fine-tuned features of ID data, and the basic variants of the Mahalanobis detector (MD): MD_{pre} (Xu et al., 2021) built on pre-trained features ($\mathbf{z} = M_\theta(\mathbf{x})$) and MD_{ft} (Podolskiy et al., 2021) built on fine-tuned features ($\mathbf{z} = M_{\theta^*}(\mathbf{x})$). Also, we evaluate two variants of MD built on features derived from PLMs fine-tuned with supervised contrastive and margin-based auxiliary targets (Zhou et al., 2021), namely $\text{MD}_{\text{ft}} + \mathcal{L}_{\text{scl}}$ and $\text{MD}_{\text{ft}} + \mathcal{L}_{\text{margin}}$. Generally, the confidence score in MD is formulated as:

$$\text{MD}(\mathbf{x}) = \min_{c \in \{1, 2, \dots, C\}} (\mathbf{z} - \mu_c)^T \Sigma^{-1} (\mathbf{z} - \mu_c), \quad (2)$$

$$S(\mathbf{x}) = -\text{MD}(\mathbf{x}),$$

where μ_c is the class centroid for class c and Σ is the global covariance matrix (μ and Σ can be estimated on ID training data). Besides, we evaluate the nearest-neighbor detectors (Sun et al., 2022) based on pre-trained (KNN_{pre}) and fine-tuned features (KNN_{ft}). We refer readers to Appendix C for more details about the baselines.

Model Configuration For the methods based on fine-tuned PLMs, we build text classifiers by fine-tuning the RoBERTa_{base} (Liu et al., 2019) model (110M parameters) on annotated ID data. For MD_{pre} , we use the pre-trained RoBERTa_{base} model. For the PPL method, we fine-tune the GPT-2_{small} model (117M parameters) for language modeling on ID data. More details can be found in Appendix B.

3.4 Evaluation Results and Findings

We display the main evaluation results in Table 2. As shown, the confidence-based methods underperform the density-based method PPL in the NSS setting, while they outperform PPL in the SS setting, in line with the observations in Arora et al. (2021). Notably, we notice that the distance-based methods achieve the best results in both NSS and SS

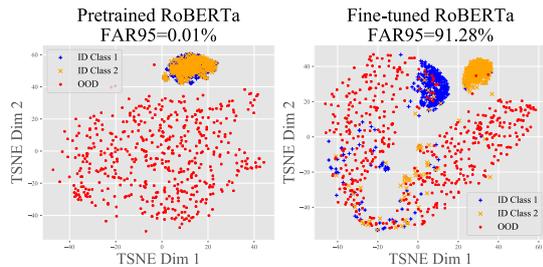

Category	Method	Avg.	NSS	SS
Confidence	MSP	71.63/72.92	65.47/88.94	77.78/56.89
	Scaling	71.96/71.62	65.45/88.94	78.47/54.30
	Energy	71.75/71.63	64.90/89.05	78.61/54.20
	D2U	71.99/71.49	65.47/88.94	78.52/54.04
Density	PPL	67.65/79.61	74.28/65.81	61.03/93.42
Distance	MD_{ft}	80.39/57.42	72.25/80.95	88.54/33.89
	$\text{MD}_{\text{ft}} + \mathcal{L}_{\text{scl}}$	82.22/60.36	76.71/82.57	87.73/38.15

	KNN_{ft}	81.02/56.91	72.58/80.99	89.47/32.84
	KNN_{pre}	85.69/46.29	92.66/ 28.67	78.72/63.92

Table 2: The performance (AUROC \uparrow /FAR95 \downarrow values in percentage) of the evaluated approaches. All results are averaged over five random seeds, and best results are highlighted in **bold**. We report results averaged on the ID/OOD pairs in NSS and SS setting in the last two columns, respectively, and report the results averaged on all eight benchmarks in the third column. See full results on each benchmark in Table 4 and Appendix E.

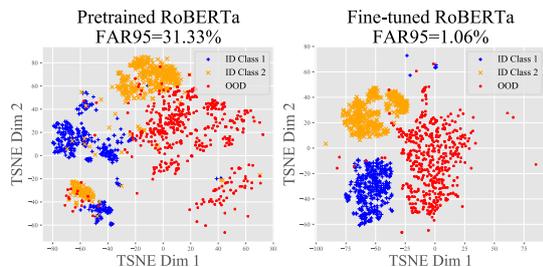

settings. Concretely, MD_{pre} and KNN_{pre} built on pre-trained features are the best in the NSS setting, while MD_{ft} and KNN_{ft} built on fine-tuned features are the best in the SS setting. However, no single method wins across the board. Thus, we draw an intriguing trade-off: *In textual OOD detection, fine-tuning PLMs on ID data boosts semantic shift detection but impairs non-semantic shift detection.*

To intuitively understand the effect of fine-tuning, we visualize the features using t-SNE (Van der Maaten and Hinton, 2008) in both settings. As plotted in Figure 2, before fine-tuning, the ID and OOD samples are sharply separated in the NSS setting, but show a significant overlap in the SS setting; after fine-tuning, the ID samples are well clustered on class in both settings and unseen classes (OOD) in the SS setting are also pulled away from the ID data, but OOD samples in the NSS setting become almost indistinguishable from the ID data.

The observed benefits of fine-tuning in the SS setting match the observation in the near-OOD image detection (Fort et al., 2021), suggesting that the fine-tuned task-specific representations are more suitable for detecting unseen classes belonging to the ID task. Regarding the negative effect of fine-tuning in the NSS setting, we speculate that it can be explained in this way: task-agnostic features important for detecting non-semantic shifts are learned during pre-training but discarded in the fine-tuning stage, for which we will present empirical evidence in § 3.5. To our knowledge, we are the first to study the impact of fine-tuning on the de-

(a) Non-Semantic Shift: SST-2 (ID) vs. IMDB (OOD)

(b) Semantic Shift: ROSTD (ID) vs. ROSTD_{OOD} (OOD)

Figure 2: T-SNE visualizations for the features derived from pre-trained and fine-tuned RoBERTa models and the corresponding FAR95 of the Mahalanobis detector.

tection of different kinds of OOD texts and reveal the trade-off between the NSS setting (fine-tuning harms) and the SS setting (fine-tuning helps).

In addition, we notice that when the model is fine-tuned with margin-based contrastive auxiliary targets ($\mathcal{L}_{\text{margin}}$) (Zhou et al., 2021), the MD detector ($\text{MD}_{\text{ft}} + \mathcal{L}_{\text{margin}}$) substantially surpasses MD_{ft} in the NSS setting with marginal sacrifice in the SS setting, thus it achieves the best performance on average. However, it still falls far behind MD_{pre} in the NSS setting. *As no single existing method behaves well in both settings, a general textual OOD detection method capable of detecting different kinds of OOD texts is yet to be developed, given the broad range of distribution shifts in realistic scenarios.*

3.5 Empirical Explanations

Probing Analysis. From the view of the oracle, the OOD data in the NSS setting can be easily distinguished from the ID data by certain task-agnostic linguistic features. For example, the IMDB data are long movie reviews with an average length of 230 tokens, which can be well distinguished by length from the SST-2 reviews with an average length of 19 tokens. Therefore, we speculate that the negative effect of fine-tuning arises from the deletion of general linguistic features during fine-tuning. To test the conjecture, we evaluate the sentence em-

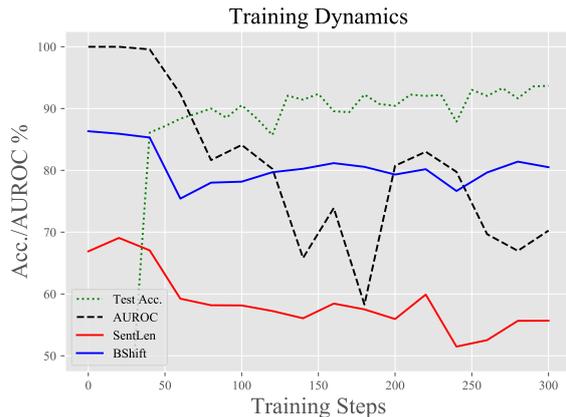

Figure 3: The dynamics of test accuracy, probing accuracies of *SentLen* and *BShift*, and the performance (AUROC \uparrow) to detect IMDB as OOD in the fine-tuning process of the RoBERTa model on SST-2. We have seen similar trends on other datasets in the NSS setting.

Methods	Avg.	NSS	SS
MD_{pre}	50.29	29.90	70.68
MD_{ft}	57.42	80.95	33.89
$\text{MD}_{\text{ft}} + \text{RecAdam}$	55.76	78.39	33.13
MD_{ft} (head lr $\times 10$)	53.90	76.18	31.63
$\text{MD}_{\text{ft}} + \text{LP-FT}$	50.92	60.26	41.59

Table 3: The performance of MD_{ft} coupled with regularization techniques on textual OOD detection. We report the FAR95 \downarrow values on average.

beddings produced by the model checkpoints in the fine-tuning process on SST-2 on two classic probing tasks designed by Conneau and Kiela (2018): *SentLen* (sentence length) and *BShift* (bigram shift). They are general linguistic features irrelevant to the class labels in downstream classification tasks, so the probing accuracies can be regarded as indicators of the preservation of task-agnostic features (see details in Appendix A.3). We show the tendency of the probing accuracies along with corresponding OOD detection performance (IMDB as OOD) and test accuracy in Figure 3. We find that as fine-tuning goes on, although the classification performance on ID test data shows an upward trend, the OOD detection performance (AUROC) gradually declines along with the probing accuracies. The observed correlations between the OOD detection performance and the probing accuracies on *SentLen* and *BShift* empirically indicate that fine-tuning impairs NSS detection by distorting the task-agnostic features in pre-trained models.

Does Regularization Help? As stated, fine-tuning may destruct the pre-trained features and

thus harm NSS detection. If the cause-effect holds, the negative effect can be alleviated by regularization techniques for preserving pre-trained features. To verify this deduction, we investigate three regularization approaches: (1) the RecAdam optimizer (Chen et al., 2020); (2) a 10× larger learning rate for the head (Prabhu et al., 2021); (3) the linear-probing then fine-tuning approach (LP-FT) (Kumar et al., 2022). As shown in Table 3, the regularization techniques applied to MD_{ft} bring moderate improvements in the NSS setting, but they still fall far behind MD_{pre} that exploits the original pre-trained features. The results provide further empirical support for our reasoning about the demerits of fine-tuning. Moreover, they suggest that effectively preserving pre-trained task-agnostic features suitable for NSS detection in fine-tuned PLMs is challenging. A plausible solution is to decouple task-agnostic and task-specific features in a single fine-tuned model, which we leave for future study. Another possible solution is to directly leverage the pre-trained model, which we will introduce next.

4 GNOME for Textual OOD Detection

In view of the observed trade-off, we are motivated to combine the strengths of task-agnostic and task-specific representations to obtain a confidence score capable of modeling both non-semantic shifts and semantic shifts. A straightforward way is to take the mean of MD_{pre} and MD_{ft} scores.³ However, given that the norm of features can fluctuate and thus the distance scores are not comparable across different spaces, simple averaging may cause the integrated score to be skewed towards the side with the larger norm. To alleviate the issue, we normalize MD_{pre} and MD_{ft} before aggregation:

$$\begin{aligned} \text{Norm}(\text{MD}_{\text{pre}}(\mathbf{x})) &= \frac{\text{MD}_{\text{pre}}(\mathbf{x}) - \mu_{\text{pre}}}{\sigma_{\text{pre}}}, \\ \text{Norm}(\text{MD}_{\text{ft}}(\mathbf{x})) &= \frac{\text{MD}_{\text{ft}}(\mathbf{x}) - \mu_{\text{ft}}}{\sigma_{\text{ft}}}, \end{aligned} \quad (3)$$

where μ and σ are the mean and standard deviation of Mahalanobis distance scores, respectively, which can be estimated on ID validation samples. Then we obtain the integrated score GNOME (GeNeral textual OOD Measurement scoreE):

$$S_{\text{GNOME}}(\mathbf{x}) = -\text{Agg}(\text{Norm}(\text{MD}_{\text{pre}}(\mathbf{x})), \text{Norm}(\text{MD}_{\text{ft}}(\mathbf{x}))), \quad (4)$$

³Our core idea is orthogonal to the distance-based scoring function, so we can also combine KNN_{pre} and KNN_{ft}. We have tested in this way and got similar results to those obtained by combining MD_{pre} and MD_{ft}.

where Agg is the aggregation operator (such as the mean or max). We use the mean operator for aggregation in our main experiments. Note that We do not use a weighted average because it is not possible to tune the weights when OOD data is unknown, which follows the mainstream setting in OOD detection. If the user has prior knowledge about the type of OOD data, he/she can train the weights to aggregate the scores.

5 Experiments

5.1 Experimental Setup

Benchmarks Besides the eight benchmarks introduced in § 3.2 that are categorized as either NSS or SS, we also evaluate GNOME and baselines in the cross-task setting (Hendrycks et al., 2020; Zhou et al., 2021) where both kinds of shifts happen simultaneously. Following Zhou et al. (2021), we choose SST-2 (Socher et al., 2013) and 20 News-groups (Lang, 1995) as ID data, and regard a series of datasets from different tasks as OOD data: TREC-10 (Li and Roth, 2002), WMT-16 (Bojar et al., 2016), Multi30k (Elliott et al., 2016), RTE (Dagan et al., 2005), and SNLI (Bowman et al., 2015). Refer to Appendix A for more details.

Models and Metrics We follow the same model configuration as that in § 3.3 in main experiments and report FAR95 values in the main text (the trend of AUROC results in Appendix E is similar).

5.2 Results and Analysis

GNOME works well in both SS and NSS settings and significantly surpasses baselines in terms of average performance. As shown in Table 4, GNOME is competent in both settings (close to MD_{pre} for NSS and MD_{ft} for SS) and achieves the best performance on average. The average FAR95 is 36.50%, 8.13% lower than the previous SOTA MD_{ft}+ $\mathcal{L}_{\text{margin}}$ requiring extra margin-based targets.

GNOME also achieves superior performance in the cross-task setting. As results in Table 5, GNOME outperforms all baseline methods (4.88% FAR95 reduction on average) in the cross-task setting, demonstrating the power of integrating task-agnostic and task-specific representations when non-semantic shifts and semantic shifts happen simultaneously. Note that among existing methods, MD_{pre} and KNN_{pre} are the best on the 20 News-groups benchmark, suggesting that non-semantic shifts dominate there; MD_{ft}+ $\mathcal{L}_{\text{margin}}$ is the best on

Methods	Avg.	Non-Semantic Shift (NSS)				Semantic Shift (SS)			
		SST-2	IMDB	Twitter	Jigsaw	NC	AGNews	ROSTD	CLINC

KNN _{pre}	20.79	41.57	0.01
GNOME (ours)	13.02	26.02	0.01

Table 5: OOD detection performance in the cross-task setting. For each ID dataset, we report the macro average of FAR95↓ on all corresponding OOD datasets, averaged over five random seeds.

the SST-2 benchmark, indicating that both kinds of shifts matter there. Without any prior knowledge about the type of distribution shifts, GNOME yields the best performance on both benchmarks.

5.3 Ablation Study

We examine the rationality of the key components of GNOME here. As shown in Table 6, when the normalization operation is absent, the performance in the SS setting is slightly enhanced ($\sim 3\%$ FAR95 reduction), but the performance in the NSS and cross-task settings drops by around 7% FAR95 points, which suggests that the normalization operation helps strike a balance between the two scenarios and thus achieve better performance on average. These results also empirically verify that the mean operator is more suitable than the max

Norm.	Agg.	Avg.	NSS	SS	CT
✓	mean	28.67	36.88	36.12	13.02
	max	30.08	38.33	37.90	14.01
✗	mean	32.61	44.00	33.32	20.52
	max	34.67	45.31	33.88	24.83

Table 6: The performance (FAR95↓) corresponding to different normalization choices and score aggregators in GNOME. CT denotes the cross-task setting.

operator for the score aggregation step in GNOME. We have also tested other common normalization methods such as min-max and found that they underperform the standardization normalization employed in GNOME.

Besides the score-level fusion in GNOME, we have also tested feature-level fusion (concatenating or averaging pre-trained and fine-tuning features), but they lead to a significant drop in the SS setting ($+20\%$ FAR95) while only a slight improvement in the SS setting. Thus we argue that the score-level fusion by the mean operator is better.

6 Further Discussion

6.1 Comparison with Ensemble Methods

On the top of MD_{fit} based on the fine-tuned PLM, GNOME is free of modification to the model architecture or training, and only requires an extra inference of the off-shelf PLM to obtain pre-trained features, thus being practical for real-world deployment. For a strictly fair comparison under the same inference overhead constraint, we compare GNOME with previous ensemble meth-

Methods	#Passes	Avg.	NSS	SS
<i>Single Pass</i>				
MSP	1	72.92	88.94	56.89
MD _{fit}	1	57.42	80.95	33.89
MD _{pre}	1	50.29	29.90	70.68
<i>Model Ensemble</i>				
MSP	2	70.25	88.45	52.05
MD _{fit}	2	56.09	81.35	30.82
MSP	5	68.59	88.37	48.80
MD _{fit}	5	55.35	80.64	30.11
<i>Dropout Ensemble</i>				
MC Dropout	2	72.68	88.41	56.95
MC Dropout	5	70.75	85.88	55.62
GNOME	2	36.50	36.88	36.10

Table 7: Comparison with ensemble methods on the developed benchmark. We report FAR95 values averaged on the ID/OOD pairs in both SS and NSS settings.

ods, which can be divided into two groups: (1) *Model ensemble* (Lakshminarayanan et al., 2017): summing confidence scores derived from models trained over different random seeds (we apply it to MSP and MD_{fit}); (2) *MC Dropout* (Gal and Ghahramani, 2016): summing the probabilities output by multiple inferences with dropout on.

As the results shown in Table 7, previous ensemble methods that require 2× or 5× forward passes only slightly raise the performance compared with their single-pass counterparts, and fall far behind GNOME in terms of the average detection performance. These results also substantiate the power of integrating pre-trained and fine-tuned features. We do not compare with the *k*-Folden method (Li et al., 2021) that needs $(C - 1)$ sub-models (C is the number of ID classes) because it does not apply to binary classification problems and is expensive for large-scale problems where C is large.

6.2 The Choice of Pre-Trained Features

In the main experiments, we adopt the last-layer CLS embeddings as the pre-trained features for simplicity and fair comparison between MD_{pre} and MD_{fit}. As works on unsupervised textual OOD detection (Xu et al., 2021) and unsupervised sentence embedding (Su et al., 2021) show, pooling operations such as token-level and layer-level averaging produce better pre-trained features. We then alternatively use *last-avg* (the average of token embeddings in the last layer) and *first-last-avg* (the average of token embeddings in the first and last layers) embeddings as pre-trained features in MD_{pre} and GNOME. As shown in Table 8, when

Pre-trained Features	Methods	Avg.	NSS	SS
-	MD _{fit}	57.42	80.95	33.89
<i>last-cls</i>	MD _{pre}	50.29	29.90	70.68
	GNOME	36.50	36.88	36.10
<i>last-avg</i>	MD _{pre}	46.28	36.14	56.41
	GNOME	35.88	38.33	33.43
<i>first-last-avg</i>	MD _{pre}	41.77	36.00	47.54
	GNOME	35.89	37.93	33.85

Table 8: The OOD detection performance (FAR95↓ in percentage) of different pre-trained features.

Backbone	Methods	Avg.	NSS	SS
BERT _{base-uncased}	MD _{pre}	67.81	60.61	75.01
	MD _{fit}	59.06	85.05	33.08
	GNOME	50.98	65.42	36.55
RoBERTa _{base}	MD _{pre}	50.29	29.90	70.68
	MD _{fit}	57.42	80.95	33.89
	GNOME	36.50	36.88	36.10
RoBERTa _{large}	MD _{pre}	71.17	58.72	83.60
	MD _{fit}	58.98	83.33	34.62
	GNOME	44.92	54.08	35.76

Table 9: Textual OOD detection performance (FAR95↓ values on average) with different pre-trained backbones.

the *last-cls* embeddings are replaced with the *last-avg* or *first-last-avg* embeddings, MD_{pre} is moderately degraded in the NSS setting (~7% FAR95 increase), but it is drastically improved in the SS setting (~14% or ~23% FAR95 reduction). Notably, the trade-off before and after fine-tuning still holds when the *last-avg* or *first-last-avg* is used to get pre-trained features. However the pre-trained features are derived, GNOME consistently brings improvements to the average detection performance.

6.3 Generalization on Other PLMs

To demonstrate the generality of GNOME, we also test on another two PLMs: BERT_{base-uncased} (Devlin et al., 2019) (110M parameters) and RoBERTa_{large} (Liu et al., 2019) (355M parameters). As shown in Table 9, we observe that: (1) The NSS-SS trade-off is prevalent on different PLMs and GNOME brings consistent gains over baselines in terms of average performance. (2) RoBERTa_{base}, which uses more diverse pre-training data, beats BERT_{base-uncased}, suggesting that pre-training on diverse data boosts textual OOD detection; RoBERTa_{large} underperforms RoBERTa_{base}, indicating that larger models are not necessarily better at OOD detection.

7 Conclusion

Aware of the lack of a fair and comprehensive evaluation of current textual OOD detection methods, we take the first step to systematically assess them under different distribution shifts. Interestingly, we find that no single method works well in both the non-semantic shift setting and the semantic shift setting, and there exists a trade-off: fine-tuning pre-trained language models on in-distribution data benefits detecting semantic shifts but undermines detecting non-semantic shifts. After presenting empirical explanations for the trade-off from the perspective of feature distortion, we are then motivated to fully utilize both the pre-trained and fine-tuned features to obtain an efficient measurement score GNOME for better detecting diverse distribution shifts. Extensive experimental results demonstrate the efficacy and generality of GNOME. Overall, GNOME is a first step in leveraging the intuition from our observations and analysis, and we hope that this work sheds light on the behavior of pre-trained language models upon detecting different kinds of distribution shifts and inspires new methods for general textual OOD detection.

Limitations

Although our approach GNOME yields the best overall performance on the suite of benchmarks where either NSS or SS dominates and also performs best in the cross-task setting where both kinds of shifts take place, it slightly underperforms MD_{pre} and KNN_{pre} in the NSS setting and marginally lags behind MD_{ft} and KNN_{ft} in the SS setting. This is comprehensible because it is challenging for a single method to function perfectly for arbitrary OOD data without priors on the type of distribution shifts as analyzed in visual OOD detection works (Ahmed and Courville, 2020). Note again that we do not intend to present a perfect textual OOD detector capable of tackling all kinds of distribution shifts; instead, our core contributions are that we discover the trade-off between NSS and SS settings, present an empirical analysis to explain the phenomenon and provide insights to mitigate the trade-off for general textual OOD detection.

Ethical Considerations

We believe that our work leads to a better understanding of the behavior of pre-trained language models on OOD texts. We also believe that the

proposed method will facilitate the reliable deployment of NLU models since a model may face various types of OOD inputs in the wild and our method contributes to the detection performance on unknown OOD data in the average sense. All experiments in this work are conducted on open datasets and all pre-trained models that we investigate are publicly available. We do not anticipate any negative social consequences to our work and we hope to continue to build on our method and develop more effective textual OOD detectors in the future.

A Dataset Introduction and Statistics

A.1 The Constructed Suite of Benchmarks

We show the included datasets in Table 10 and give an introduction to them as follows.

For the NSS setting, we consider two tasks: sentiment analysis and toxic detection. For sentiment analysis, we choose SST-2 (Socher et al., 2013) and IMDB (Maas et al., 2011). SST-2 contains short

Dataset	# Classes	# Train	# Dev	# Test	L
SST-2	2	6,920	872	1,821	19
IMDB	2	23,000	2,000	25,000	230
Twitter	2	69,632	7,737	8,597	17
Jigsaw	2	143,614	15,957	63,978	68
AGNews	4	115,778	3,994	3,993	23
NC	5	68,859	8,617	8,684	30
ROSTD	12	30,521	4,181	8,621	7
CLINC	150	15,000	3,000	4,500	8
AGNews _{OOD}	-	-	-	3,600	21
NC _{OOD}	-	-	-	11,402	29
ROSTD _{OOD}	-	-	-	3,090	7
CLINC _{OOD}	-	-	-	1,000	9

Table 10: Statistics of the datasets used for the constructed suite of benchmarks. **L** denotes the average length of each sample.

movie reviews by the audience, while IMDB contains longer and more professional movie reviews. Therefore, the two datasets can regard each other as OOD data representing a non-semantic shift. For toxic detection, we choose Twitter (Founta et al., 2018) and the Jigsaw dataset from a Kaggle challenge.⁴ The Twitter dataset consists of short comments on Tweet, while the Jigsaw dataset consists of longer Wikipedia comments, so they can regard each other as OOD data of the NSS type.

For the SS setting, we consider two tasks where newly emerging classes are common: news topic categorization and dialogue intent classification. For news topic categorization, we choose the AGNews (Corso et al., 2005) and News Category datasets (Misra and Grover, 2021; Misra, 2022) to construct ID/OOD pairs. Specifically, we choose four classes from AGNews and five classes from News Category as ID data and regard the remaining classes from the original datasets as OOD data. For dialogue intent classification, we use the ROSTD (Gangal et al., 2020) and CLINC (Larson et al., 2019) datasets as ID data and regard the annotated unknown intents from the original datasets as OOD data.

A.2 Cross-Task Benchmarks

For the cross-task setting, we follow Zhou et al. (2021) to use SST-2 and 20 Newsgroups (20 NG) (Lang, 1995) as ID data. 20 NG is a news categorization dataset containing 10,182 training samples, 1,132 validation samples, and 7,532 test samples. The average sample length in 20 NG is 289. Naturally, SST-2 and 20 NG can regard each other as

⁴Available at this [link](#).

Dataset	# Test	L
TREC-10	500	10
Multi30k	1,014	13
WMT16	2,000	22
RTE	3,000	48
SNLI	2,000	21

Table 11: Statistics of OOD datasets in the cross-task setting. **L** denotes the average length of each sample.

Dataset / Loss	\mathcal{L}_{ce}	$\mathcal{L}_{ce} + \mathcal{L}_{scl}$	$\mathcal{L}_{ce} + \mathcal{L}_{margin}$
SST-2	93.96	94.23	93.69
IMDB	94.56	94.53	94.21
Twitter	93.67	93.64	93.81
Jigsaw	81.82	82.08	82.43
NC	95.39	95.21	95.43
AGNews	91.28	91.03	91.18
ROSTD	99.23	99.21	99.26
CLINC	96.21	96.16	96.08
20 NG	84.52	84.65	84.53

Table 12: Accuracies / F1 scores on the test set of in-distribution data (averaged over five random seeds). We report F1 scores for Twitter and Jigsaw toxic detection and accuracies for other tasks.

OOD data. Besides, we use five additional datasets from different datasets as OOD test data for each ID dataset: TREC-10 (Li and Roth, 2002), WMT-16 (Bojar RTE (Dagan et al., 2005), and SNLI (Bowman et al., 2015)). TREC-10 is a question classification dataset; Multi30k (Elliott et al., 2016) and WMT16 (Bojar et al., 2016) are parts of the English side data of English-German machine translation datasets; RTE (Dagan et al., 2005) and SNLI (Bowman et al., 2015) are the concatenations of the precise and respective hypotheses from NLI datasets. The statistics of the OOD datasets are listed in Table 11.

A.3 Probing Benchmarks

To probe the linguistic information contained in pre-trained and fine-tuned features, we use two probing tasks designed by Conneau et al. (2018). Each probing dataset contains 100k training samples, 10k validation samples, and 10k test samples. We use the SentEval toolkit (Conneau and Kiela, 2018) along with the recommended hyperparameter space to search for the best probing classifier according to the validation accuracy and report test accuracies.

B Performance on In-Distribution Data

We fine-tune the RoBERTa_{base} model on the ID training data to build text classifiers in our main experiments. The model is optimized with the

Adam (Kingma and Ba, 2015) optimizer using a learning rate of $2e-5$. We use a batch size of 16 and fine-tune the model for 5 epochs. We evaluate the model on the ID validation set after every epoch and choose the best checkpoint as the final model. The setting is the same for other pre-trained Transformers studied in the paper (BERT_{base-uncased} and RoBERTa_{large}). The performance of fine-tuned RoBERTa_{base} models is given in Table 12, where \mathcal{L}_{ce} denotes the vanilla cross-entropy loss, \mathcal{L}_{scl} denotes the supervised contrastive loss (Khosla et al., 2020), and \mathcal{L}_{margin} denotes the margin-based contrastive loss (Zhou et al., 2021). We report the F1 scores on the test set for toxic detection on Twitter and Jigsaw and test accuracies for other tasks.

C Details of OOD Detection Baselines

C.1 Confidence-Based Baselines

Notations In a classification problem with C classes, assume the input is \mathbf{x} , we denote $f_i(\mathbf{x})$ is the output logit of class i , and the predicted softmax probability of class i is defined as:

$$p_i(\mathbf{x}) = \max_i \frac{\exp(f_i(\mathbf{x}))}{\sum_{j=1}^C \exp(f_j(\mathbf{x}))}. \quad (5)$$

Confidence-based methods obtain the OOD score based the output logits and softmax probabilities.

MSP Hendrycks and Gimpel (2017) propose the maximum softmax probability (MSP) baseline, in which the confidence score is defined the predicted maximum softmax probability among C classes:

$$S(\mathbf{x}) = \max_i p_i(\mathbf{x}). \quad (6)$$

Scaling In the ODIN paper (Liang et al., 2018), temperature scaling is applied to the scoring function:

$$S(\mathbf{x}) = \max_i \frac{\exp(f_i(\mathbf{x})/T)}{\sum_{j=1}^C \exp(f_j(\mathbf{x})/T)}, \quad (7)$$

where T is the temperature term. Following Hsu et al. (2020), we fix $T = 1000$ in our experiments. Note that ODIN (Liang et al., 2018) also propose an input pre-processing step adding adversarial perturbation to the input image, while we do not use it because it is not directly applicable for discrete inputs in NLP.

Energy Score (Liu et al., 2020) propose to use the free energy function for OOD detection, which

is formulated as follows:

$$E(\mathbf{x}) = \sum_{i=1}^C e^{f_i(\mathbf{x})}, \quad (8)$$

$$S(\mathbf{x}) = -E(\mathbf{x}).$$

D2U Yilmaz and Toraman (2022) propose to improve out-of-scope detection by exploiting the shape of the entire output distribution. Specifically, the distance of the output distribution $P(\mathbf{x}) = (p_1(\mathbf{x}), \dots, p_c(\mathbf{x}))$ to the uniform distribution U as the OOD score:

$$S(\mathbf{x}) = \text{dst}(P(\mathbf{x}), U), \quad (9)$$

where dst is the distance function. We use the KL divergence as the distance function as recommended in Yilmaz and Toraman (2022) in our experiments. Note that Yilmaz and Toraman (2022) also propose to use D2U for loss calculation when out-of-scope training data is available, while we do not use it in the training because we follow the mainstream setting in OOD detection works where OOD data is not available for training.

C.2 Density-Based Baselines

PPL Arora et al. (2021) propose to use the token perplexity (PPL) score derived from the GPT-2 language model (Radford et al., 2019) as the OOD score. Following the implementation of Arora et al. (2021),⁵ we fine-tune the GPT-2_{small} model (117M parameters, similar to RoBERTa_{base} in size) for language modeling on the ID training data and use the inverse of the PPL score as the OOD score. Formally, for an input text sequence $\mathbf{x} = \{x_1, \dots, x_t\}$,

$$\text{PPL}(\mathbf{x}) = \exp \left\{ -\frac{1}{t} \sum_{i=1}^t \log p_{\theta}(x_i | x_{<i}) \right\}, \quad (10)$$

$$S(\mathbf{x}) = 1/\text{PPL}(\mathbf{x}),$$

where t is the number of tokens in \mathbf{x} .

C.3 Distance-Based Baselines

Local Outlier Factor (LOF) Lin and Xu (2019) propose to identify unknown user intents by feeding feature vectors derived from LSTM models to the density-based novelty detection algorithm, local outlier factor (LOF) (Breunig et al., 2000). In our implementation, we use the last-layer CLS vector embeddings by the fine-tuned RoBERTa models as the input and train a LOF model following the

⁵Available at this Github repository.

implementation details of Lin and Xu (2019) on the ID training set. Finally, we use the local density output as $S(\mathbf{x})$.

Mahalanobis Distance Detector The Mahalanobis distance detector (MD) (Lee et al., 2018) is a classical distance-based OOD detection method that exploits the sample distance to the nearest ID class in the embedding space to obtain the OOD score. Formally, for a given feature extractor ψ , the Mahalanobis distance score is defined as:

$$S(\mathbf{x}) = -\min_{c \in \Upsilon} (\psi(\mathbf{x}) - \mu_c)^T \Sigma^{-1} (\psi(\mathbf{x}) - \mu_c), \quad (11)$$

where $\Upsilon = \{1, 2, \dots, C\}$ is the label space containing C classes in the ID task, $\psi(\mathbf{x})$ is the embedding vector of the input \mathbf{x} , μ_c is the class centroid for a class c , and Σ is the covariance matrix. The estimations of μ_c and Σ are defined as:

$$\begin{aligned} \mu_c &= \frac{1}{N_c} \sum_{\mathbf{x} \in \mathcal{D}_{in}^c} \psi(\mathbf{x}), \\ \Sigma &= \frac{1}{N} \sum_{c \in \Upsilon} \sum_{\mathbf{x} \in \mathcal{D}_{in}^c} (\psi(\mathbf{x}) - \mu_c) (\psi(\mathbf{x}) - \mu_c)^T, \end{aligned} \quad (12)$$

where $\mathcal{D}_{in}^c = \{\mathbf{x} \mid (\mathbf{x}, y) \in \mathcal{D}_{in}, y = c\}$ denotes the training samples belonging to the class c , N is the size of the training set, and N_c is the number of training instances belonging to the class c . As for textual OOD detection based on pre-trained language models, when the feature extractor ψ is the off-the-shelf pre-trained model, i.e. detecting anomalies in the pre-trained feature space (Xu et al., 2021), it is called MD_{pre} in our paper; when ψ is the fine-tuned model, i.e. detecting anomalies in the fine-tuned feature space (Podolskiy et al., 2021), it is called MD_{fit} in our paper.

Contrastive Fine-Tuning Targets Coupled with the MD Detector Zhou et al. (2021) propose to use two forms of contrastive losses to boost textual OOD detection, i.e., the supervised contrastive loss (\mathcal{L}_{scl}) and the margin-based contrastive loss (\mathcal{L}_{margin}). For a classification task containing C classes, given a batch of training examples $\{x_i, y_i\}_{i=1}^M$, where x_i is the input and y_i is the label, the supervised contrastive loss term \mathcal{L}_{scl} and the final optimization target \mathcal{L} can be formulated as:

$$\begin{aligned} \mathcal{L}_{scl} &= \sum_{i=1}^M \frac{-1}{M|P(i)|} \sum_{p \in P(i)} \log \frac{e^{z_i^T z_p / \tau}}{\sum_{a \in A(i)} e^{z_i^T z_a / \tau}}, \quad (13) \\ \mathcal{L} &= \mathcal{L}_{ce} + \mathcal{L}_{scl}, \end{aligned}$$

where $A(i) = \{1, \dots, M\} \setminus \{i\}$ is the set of all anchor samples, $P(i) = \{p \in A(i) : y_i = y_p\}$ is the

set of anchor samples from the same class as i , τ is a temperature hyper-parameter, z is the L2-normalized CLS embedding before the softmax layer, \mathcal{L}_{ce} is the cross-entropy loss, and λ is a positive coefficient. Following the implementation of Zhou et al. (2021),⁶ we use $\tau = 0.3$ and $\lambda = 2$.

The margin-based loss term \mathcal{L}_{margin} and the final optimization target \mathcal{L} is formulated as:

$$\begin{aligned} \mathcal{L}_{pos} &= \sum_{i=1}^M \frac{1}{|P(i)|} \sum_{p \in P(i)} \|\mathbf{h}_i - \mathbf{h}_p\|^2, \\ \mathcal{L}_{neg} &= \sum_{i=1}^M \frac{1}{|N(i)|} \sum_{n \in N(i)} (\xi - \|\mathbf{h}_i - \mathbf{h}_n\|)^2_+, \\ \mathcal{L}_{margin} &= \frac{1}{dM} (\mathcal{L}_{pos} + \mathcal{L}_{neg}), \\ \xi &= \max_{i=1}^M \max_{p \in P(i)} \|\mathbf{h}_i - \mathbf{h}_p\|^2, \\ \mathcal{L} &= \mathcal{L}_{ce} + \lambda \mathcal{L}_{margin}, \end{aligned} \quad (14)$$

where $N(i) = \{n \in A(i) : y_i \neq y_n\}$ is the set of anchor samples from other classes than y_i , $\mathbf{h} \in \mathbb{R}^d$ is the unnormalized CLS embedding before the classification head, ξ is the margin, d is the number of dimensions of \mathbf{h} , and λ is a positive coefficient. We use $\lambda = 2$ following Zhou et al. (2021).

Except for the optimization target, we use the same hyper-parameters for the two tuning methods as vanilla tuning.

Nearest-Neighbor-Based Detector Sun et al. (2022) explore the efficacy of non-parametric nearest-neighbor distance for OOD detection and show its advantages over the Mahalanobis distance detector on visual OOD detection benchmarks. Specifically, it takes the minus of the average distance from the test sample to the k -nearest training samples in the normalized feature space. We reproduce two variants, i.e., KNN_{pre} using the pre-trained features and KNN_{fit} using the fine-tuned features. We set the neighborhood size $k = 10$ in our experiments.

D Software and Hardware Requirements

We implement our code based on the PyTorch (Paszke et al., 2019) and HuggingFace Transformers (Wolf et al., 2020) Python libraries. All experiments (training and inference) in this paper can be conducted on a single NVIDIA TITAN RTX GPU (24 GB memory), except that the fine-tuning of the RoBERTa_{large} model needs 4 TITAN RTX GPUs.

E Additional Experimental Results

We display the AUROC results of GNAME and the baselines on the constructed suite of benchmarks in Table 13. The overall trend is consistent with that of the FAR95 results reported in Table 4 in the main text.

A Question of Style: A Dataset for Analyzing Formality on Different Levels

Elisabeth Eder and Ulrike Krieg-Holz and Michael Wiegand

Universität Klagenfurt, Klagenfurt, Austria

{elisabeth.eder | ulrike.krieg-holz | michael.wiegand}@aau.at

Abstract

Accounting for different degrees of formality is crucial for producing contextually appropriate language. To assist NLP applications concerned with this problem and formality analysis in general, we present the first dataset of sentences from a wide range of genres assessed on a continuous informal-formal scale via comparative judgments. It is the first corpus with a comprehensive perspective on German sentence-level formality overall. We compare machine learning models for formality scoring, a task we treat as a regression problem, on our dataset. Finally, we investigate the relation between sentence- and document-level formality and evaluate leveraging sentence-based annotations for assessing formality on documents.

1 Introduction

Textual style can be approached from various points of view. We focus on its inherent formality dimension stretching from informal to formal language use. See these two sentences, for example:

- (1) We gave thorough thought to an adequate example.
Wir haben gründlich über ein adäquates Beispiel nachgedacht.
- (2) racked our brains about a niice example... :D
haben uns den kopf über ein schöönes beispiel zermartert... :D

While both sentences transport the same content, they differ in their degree of formality. (2) is less formal than (1). It may be suitable only for more informal discourse contexts and inappropriate in formal settings. Understanding these different nuances of formality is crucial for effective communication. Consequently, striking the right tone is relevant not only for humans but also for various NLP applications. May it be machine translation in need to transfer expressions of formality between different languages adequately (Niu and Carpuat, 2020; Anastasopoulos et al., 2022), chatbots aiming to produce contextually appropriate language to increase user satisfaction (Chaves et al., 2019;

Elsholz et al., 2019), or writing assistance systems altering content to be more formal (Saber et al., 2020). Hence, intra-lingual formality style transfer, which deals with generating a formal phrase given its informal version and vice versa, has recently also received increased attention (e.g., Shang et al., 2019 or Zhang et al., 2020).

Our paper addresses a prerequisite for this task: **assessing linguistic formality**. Rating the transferred style strength is necessary for evaluating formality style transfer models. Further, parallel corpora with formal and informal language pairs, often the basis for style transfer, are commonly built by automatically grading and extracting informal sentences first (Rao and Tetreault, 2018; Briakou et al., 2021b). For facilitating such formality assessments and analyzing linguistic formality in general, we make the following **contributions**:

1. We present the **first dataset of sentences from a wide range of genres with human formality assessments on a continuous informal-formal scale**. We ensure a comprehensive perspective on formality by collecting sentences from diverse domains. Formality annotations are obtained via a comparative annotation variant (annotators compare items to each other), which is not only more reliable than the rating scale method (Kiritchenko and Mohammad, 2017) but also satisfies the principle that a “continuum of formality” (Heylighen and Dewaele, 1999) exists rather than categorical distinctions. The dataset is the **first** to target **German** sentence-level formality unrestrictedly overall.

2. We **evaluate several machine learning models** for formality scoring on our dataset, which we treat as a **regression task**. Regression models have been found to be more suitable than classifiers for evaluating formality style transfer models since they grasp the broad spectrum of linguistic formality (Briakou et al., 2021a). Besides fine-tuning transformers on our dataset, we examine utilizing formality-informed corpora from different lan-

guages with coarser or narrower representations of formality. Further, we employ feature-based approaches for formality scoring and analyze linguistic properties that constitute formality. For such analyses, we provide a tool with a variety of features for profiling characteristics of registers, genres, and author styles for various languages.

3. We investigate the applicability of sentence-level formality annotations for the formality assessment of documents. Lately, [Jin et al. \(2022\)](#) proposed extending formality style transfer, which so far exclusively focuses on the sentence level, to stylistically more complex documents. However, datasets targeting formality on this scope are rare and limited in size, probably because obtaining annotations is more expensive. Therefore, we analyze how sentence formality contributes to the formality of documents.

2 Related Work

With their continuous formality score based on frequencies of parts of speech, [Heylighen and Dewaele \(1999\)](#) established a milestone for the definition of formality. [Lahiri et al. \(2011\)](#) adapted this measure from the document to the sentence level. Most approaches targeting the lexical dimension of formality also regarded formality as a continuum ([Brooke et al., 2010](#); [Brooke and Hirst, 2014](#); [Pavlick and Nenkova, 2015](#); [Eder et al., 2021](#)).

To the best of our knowledge, datasets comprising sentences with human formality assessments on a continuous informal-formal scale have not been constructed before. [Pavlick and Tetreault \(2016\)](#) built an English dataset collecting formality annotations on a 7-point Likert scale for sentences from only four sources (compared to the twelve in our dataset). They introduced formality detection as a regression task using features based on analyzing human perceptions of formality for a ridge regression model. Other datasets targeting sentence-level formality have binary labels since they primarily serve as parallel data for formality style transfer and contain formal and informal language pairs. They cover English ([Rao and Tetreault, 2018](#); [Cheng et al., 2020](#)), Brazilian Portuguese, French and Italian ([Briakou et al., 2021b](#)), and Hindi, Bengali, Kannada and Telugu ([Krishna et al., 2022](#)).

Work on formality style transfer mainly used classification for measuring style strength and a handful of different classifiers (e.g., [Lai et al. \(2021\)](#) employed a CNN, [Wang et al. \(2019\)](#) an

LSTM, and [Krishna et al. \(2020\)](#) transformers). Evaluating the style strength as a regression task, [Rao and Tetreault \(2018\)](#) borrowed the approach from [Pavlick and Tetreault \(2016\)](#), and [Briakou et al. \(2021b\)](#) relied on fine-tuning transformers.

For the German language, not yet considered for intra-lingual formality style transfer, two sentence collections with binary formality annotations based on formal and informal direct address exist ([Faruqui and Padó, 2012](#); [Nadejde et al., 2022](#)). (Since these formality levels do not exist in English, they pose a problem for machine translation ([Nadejde et al., 2022](#).) Hence, these datasets target a very constrained view of formality only.

Focusing on the document level, several works used traditional machine learning models for binary formality classification based on linguistic features. As training data, [Abu Sheikha and Inkpen \(2010\)](#) assumed binary labels for formality from the text genre, and [Peterson et al. \(2011\)](#) manually annotated emails from the English *ENRON* corpus ([Klimt and Yang, 2004](#)) with four formality classes. Treating formality assessment on documents as a regression task, [Chhaya et al. \(2018\)](#) employed linguistic features for formality scoring on *ENRON* emails, which have been rated on a 5-point Likert scale, whereas [Eder et al. \(2021\)](#) evaluated word formality scoring on emails from the German corpus *CodE Alltag* ([Eder et al., 2020](#)) based on continuous formality annotations. All these manually labeled document collections are small in size ($\sim 1k$) and built from a single domain only, i.e., emails. None of these works leverages formality-annotated sentences nor fine-tunes transformer models to assess the formality of documents.

3 Data

To build our dataset, we collected 3,000 German (DE) sentences from different domains and let crowdworkers assess their formality on a continuous formality scale via comparative annotations.

3.1 Collecting Sentences

We chose twelve different text sources, which we assumed to be related to diverse levels of formality, to cover the broad spectrum of linguistic formality best possible. From each source, we took 250 sentences. We picked these sentences randomly, but they had to consist of at least one word. Additionally, we attempted to enhance language variety by selecting a minimum number of sentences per au-

thor. We also tried spreading the data over different topics whenever such information was available.¹

We utilized the following sources:

Tweets. We rehydrated tweets from a German *Twitter* snapshot (Scheffler, 2014).

Reddit. We extracted posts from the *GeRedE* corpus, which contains German communication on *Reddit* (Blombach et al., 2020).

Subtitles. To account for spoken language, we included German sentences from the *OpenSubtitles* collection of parallel corpora with movie and TV subtitles (Lison and Tiedemann, 2016).

Comments. 250 sentences were collected from the *One Million Posts Corpus*, which comprises comments on news articles (Schabus et al., 2017).

Emails. We took sentences from *Code Alltag*, a corpus with German emails (Eder et al., 2020).

Blogs. Using the *DWDS* platform (Geyken et al., 2017), we obtained sentences from a blog corpus (Barbaresi and Würzner, 2014).

Fiction. Due to the lack of accessible corpora covering contemporary fictional texts, we reverted to an archive that, besides fan fiction, contains original work from nonprofessional writers.² We extracted 250 sentences from their short stories.

News. We gathered sentences from the German news corpus from 2020 provided in the *Leipzig Corpora Collection* (Goldhahn et al., 2012).

Wikipedia. From the *Leipzig Corpora Collection*, we also used sentences from the German *Wikipedia* corpus from 2021.

Political. For potentially more formal spoken language examples, we extracted sentences from German political speeches that are included in the parallel corpus *EuroParl* (Koehn, 2005).

Legal. We gained sentences from the legal domain by utilizing a dataset with German court decisions (Leitner et al., 2019).

Science. We used *Springer Link*³ to manually collect sentences from scientific journals, proceedings, and books published between 2000 and 2022 under open access.

3.2 Human Assessment

We gathered human formality assessments for the resulting 3,000 sentences using Best-worst scaling (BWS) (Louviere et al., 2015), a form of comparative annotation. BWS delivers more reliable an-

notations than the rating scale method mitigating issues such as a scale region bias or inconsistent annotations (Kiritchenko and Mohammad, 2017). Further, it complies with the notion of formality as a continuum (Heylighen and Dewaele, 1999).

For BWS, annotators are presented with n items at a time (typically $n = 4$). They have to decide which item from the n -tuple is the *best* and which is the *worst* (i.e., the highest and the lowest regarding the property of interest). To get real-valued scores from these BWS annotations, the percentage of times the term is chosen as worst is subtracted from the percentage of times the term is chosen as best (Counts Analysis (Orme, 2009)). Thus, each item receives a score between +1 (most formal) and -1 (most informal).

We randomly generated $2N$ 4-tuples (where N denotes the number of sentences) under the premise that each term occurs only once in eight different tuples and each tuple is unique.⁴ For the annotation process proper, we chose crowdsourcing to ensure the heterogeneity of annotators. Using the crowdsourcing platform *Clickworker*⁵, German native speakers assessed each of the 6,000 tuples five times. Thus, we collected 30,000 annotations from 1,084 different annotators, with an average of 27.7 annotations per annotator.

All five annotators agreed in 19% of the annotations. In two-thirds, three or four annotators chose the same item, while only in 15% just two of the answers matched. The higher the difference between the real-valued formality scores of two sentences, the higher the agreement of the crowdworkers. For a score difference of just 0.1, the agreement is 64%. It rises to over 70% for higher score differences, with over 80% for differences higher than 0.4 and at least 90% for differences over 0.7.

We computed the split-half reliability⁴ for our formality-assessed dataset by randomly splitting the annotations of a tuple into two halves, calculating scores independently for these halves, and measuring the correlation between the resulting two sets of scores. We got an average Spearman's ρ of 0.919 (± 0.002) over 100 trials, which indicates a high reliability of the annotations.

3.3 The Final Dataset

Figure 1 displays the distribution of human-assessed formality scores for each of the twelve

¹For some corpora, we subsumed subreddits, blogs, genres, or articles, to which comments refer, in place of topic.

²<https://www.fanfiktion.de/>

³<https://link.springer.com/>

⁴We employed scripts developed for emotion scaling by Kiritchenko and Mohammad (2016, 2017).

⁵<https://www.clickworker.de>

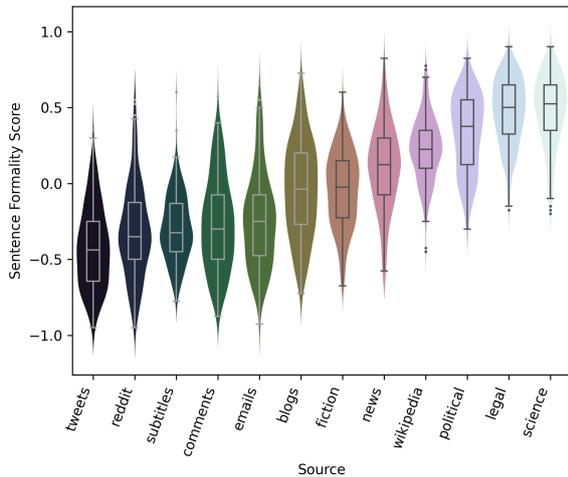

Figure 1: Distribution of formality scores for our 3,000 sentences per each of the twelve sources ordered by the average formality score of the source.

sources of the 3,000 sentences in our dataset. As expected, sentences from online communication or sources with more spontaneous language use, e.g., *tweets* or *comments*, tend to be linked to lower scores, while sentences with more elaborated language use, e.g., *legal* or *scientific* texts, have higher scores. However, sources scatter broadly, and assuming the same degree of formality per genre seems inappropriate.

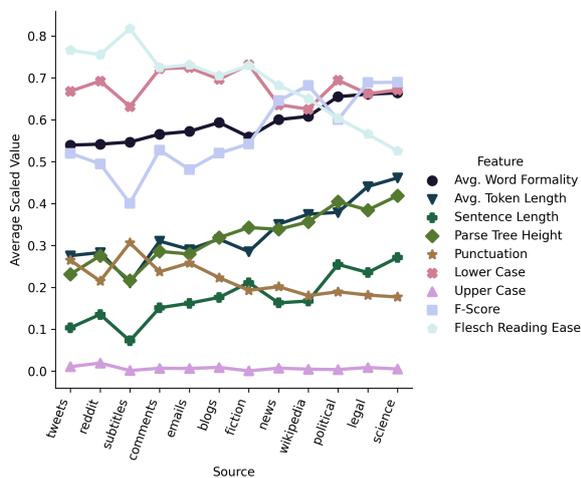

Figure 2: Averages of simple linguistic characteristics (scaled to a range between 0 and 1) of sentences for each source; sources ordered by their mean formality.

In Figure 2, we plot some simple linguistic features, which have been studied in relation to formality (Heylighen and Dewaele, 1999; Pavlick and Tetreault, 2016, i.a.) for each source. The mean word formality, token length, sentence length and parse tree height rise for sources with higher av-

erage sentence formality scores. The proportion of punctuation characters tends to sink, whereas the ratios of upper- or lower-case tokens are more stable. Heylighen and Dewaele’s (1999) F-score indicates a higher formality and the readability score Flesch Reading Ease (Flesch, 1948) signals a lower readability for sources with higher mean formality.

In the following, we explore such properties for scoring the formality of the individual sentences.

4 Formality Scoring on Sentences

We compared different models for predicting formality scores for sentences on our dataset.

4.1 Within-Dataset Experiments

Transformers. We experimented with fine-tuning transformer models on our dataset. For that, we employed GBERT-base (Chan et al., 2020), a German BERT language model.⁶ For all transformer-based experiments, we used the NLP library *FLAIR* (Akbi et al., 2019) as a framework.

Feature-based Models. We evaluated two feature-based models, which allowed us to examine the influence of linguistic characteristics more directly. The first ridge regression model employs eleven different feature groups and was developed for scoring the formality of English sentences (Pavlick and Tetreault, 2016). The second was created for English documents, more precisely emails (Chhaya et al., 2018). It borrows features from the first model and extends them with affect-based features. We adapted these feature sets to German and adjusted them to work on sentences and documents. We also employed a ridge regression model. Table 5 in the Appendix contains a detailed breakdown of the features we implemented.

4.2 Cross-Dataset Experiments

Learning from Other Languages. We examined using English sentences with formality scores determined via averaging over individual annotations on a 7-point Likert scale (Pavlick and Tetreault, 2016). This dataset (*PT16* in the following) contains about 11k sentences from four sources: news and blogs from Lahiri (2015) extended by emails and Q&A sites. We evaluated three different settings. We fine-tuned GBERT-base transformers on *PT16* translated to German and tested them on

⁶Other German transformers (Chan et al., 2020; Minixhofer et al., 2022) either yielded no significant difference or performed worse (see Table 3 in the Appendix).

Training		Testing		Model	Spearman's ρ
sentences	ours (de)	sentences	ours (de)	GBERT	0.919 (± 0.009)
	ours (de)		ours (de)	feature-based (\sim Pavlick and Tetreault, 2016)	0.857* (± 0.007)
	ours (de)		ours (de)	feature-based (\sim Chhaya et al., 2018)	0.830* (± 0.018)
	<u>PT16 (de)</u>		ours (de)	GBERT	0.877* (± 0.018)
	PT16 (en)		ours (de)	XLM-RoBERTa	0.847* (± 0.017)
	PT16 (en)		ours (<u>en</u>)	BERT	0.844* (± 0.022)
	XFORMAL (br-pt+fr+it)		ours (de)	XLM-RoBERTa	0.768* (± 0.020)
	GYAFC (en)		ours (de)	XLM-RoBERTa	0.716* (± 0.023)
	FP12 (de)		ours (de)	GBERT	0.595* (± 0.042)

Table 1: Evaluation of different models for formality scoring on our sentences; “*” stands for a statistically significant difference of $p < 0.005$ with respect to **best** model (using two-sided Wilcoxon signed-rank test on Spearman’s ρ); language(s) of datasets in brackets, translated data underlined.

our dataset. Consequently, we utilized BERT-base (Devlin et al., 2019) for fine-tuning on the original English *PT16* and testing on the English translation of our dataset. Further, we fine-tuned multilingual XLM-RoBERTa-base transformers (Conneau et al., 2020) on the English *PT16* and tested them on our German sentences. For the translations in both directions, we employed the models from Edunov et al. (2018) via the *fairseq* toolkit (Ott et al., 2019).

Formality Classifiers. Since there are huge datasets with binary formality annotations, we evaluated binary formality classifiers leveraging these data. We used the probability of the class determined by the classifiers as a prediction of a formality score. For the informal class, we took the probability as a negative number, thus ending up with scores from -1 to $+1$. Lacking more comprehensive German data, we experimented with a dataset from Faruqui and Padó (2012) that comprises 60k German sentences with binary formality annotations based only on formal and informal direct address (unmarked in English yet explicitly marked in German). We fine-tuned GBERT on this dataset, *FP12* in the following, for binary classification. As *FP12* is limited to this particular case of formality, we further utilized parallel datasets with formal and informal language pairs from languages other than German. These parallel datasets, containing informal sentences from a Q&A forum and their formal rewrites, are *GYAFC* with 110k English sentences (Rao and Tetreault, 2018) and *XFORMAL* with 23k Brazilian Portuguese, French and Italian sentences (Briakou et al., 2021b). We employed binary XLM-RoBERTa-based classifiers fine-tuned on *GYAFC*⁷ and *XFORMAL*⁸.

⁸https://huggingface.co/SkolkovoInstitute/xlmr_formality_classifier

4.3 Evaluation

Table 1 reports the average Spearman’s ρ for the different setups. Evaluated in a 10-fold cross-validation manner, the two feature-based models yielded high results. To explore their relation to formality, Figure 3 shows several linguistic features used by these models per the formality score of the sentences. While sentiment seems to be a relatively constant feature across the formality scale, other factors correlate better with formality. The punctuation ratio and the Flesch readability score tend to sink, whereas word formality, token length, constituency tree height, and the number of tokens rise with increasing sentence formality. According to *SHAP* (Lundberg and Lee, 2017)⁹, among the most important features of the approach by Chhaya et al. (2018) are indeed the sentence length, the average word formality, the Flesch score and the average token length (already achieving 0.8 Spearman’s ρ on their own). This shows that such simple linguistic properties are good indicators of formality, at least at the sentence level.

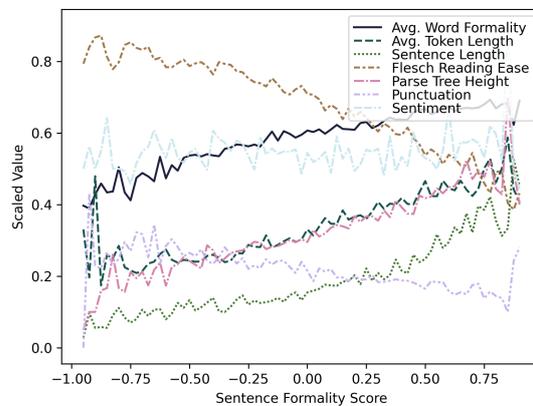

Figure 3: Relation between several linguistic features (scaled values) and the formality scores of the sentences.

⁹*SHAP* is a game theoretic approach that facilitates interpreting predictions of machine learning models.

However, fine-tuning transformers significantly outperformed the feature-based approaches (Table 1). In Figure 4, we plot the predictions of GBERT transformers fine-tuned on our dataset versus the human-assessed formality scores. The errors are lower on both ends of the scale. Sentences nearer to the scale’s middle are more difficult to predict for the model since they carry fewer linguistic markers than sentences with extreme (in)formality scores. But in general, predictions are relatively accurate.

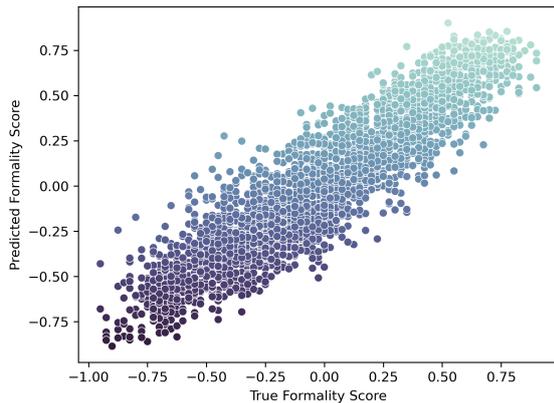

Figure 4: Predictions of the best model versus gold formality scores (brighter colors mean higher predictions).

Table 1 also shows that from the settings utilizing the *PT16* dataset, the model fine-tuned on *PT16* translated to German performed best. The formalization effect of machine translation (informal sentences get more formal through translation (Briakou et al., 2021b)) seems to influence the models using translated data since they tended to predict higher formality scores, especially for more neutral sentences. However, the results indicate that this is less critical when compared to the cross-lingual regression model fine-tuned on English and tested on German data. Contrasted to fine-tuning and testing on our dataset, the *PT16* models were still significantly worse, although *PT16* comprises over three times more sentences than our dataset. This may also be ascribed to its narrower scale of formality. *PT16* models tended to yield lower results on more formal domains of our dataset (*science*, *legal* and *Wikipedia*). Scoring these genres seems more challenging for those models since *news*, the most formal source in *PT16* (Pavlick and Tetreault, 2016), has only the fifth-highest average formality score in our dataset (see Figure 1).

The probabilities for being either formal or informal from the binary formality classifiers fine-tuned on *GYAFC* and *XFORMAL* in a cross-lingual set-

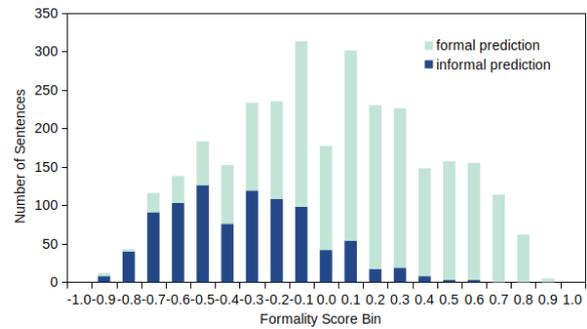

Figure 5: Formal and informal predictions of the *GYAFC* model per formality score bin of our sentences.

ting also showed a correlation to the human assessments (Table 1). However, these models performed worse than regression models. Figure 5 exemplifies the class predictions of the binary formality classifier fine-tuned on *GYAFC* per formality score bin (formality scores rounded to one decimal place) on our dataset. It shows that sentences with lower formality scores tended to be classified as informal and sentences with higher scores as formal. However, formal and informal sentences were predicted in nearly every formality score bin. From that, we infer that a binary separation of formality into formal and informal sentences is not reasonable.

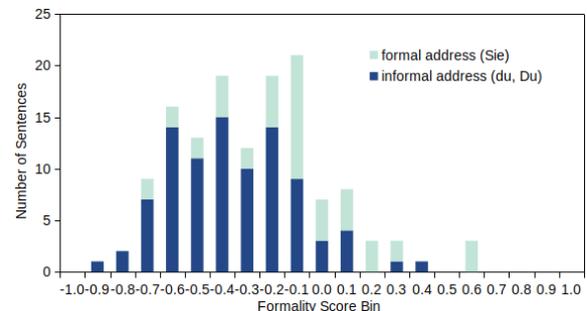

Figure 6: Distribution of formality scores of sentences with formal and informal address.

The monolingual binary classifier fine-tuned on *FP12*, which includes only formal and informal address sentences, performed significantly worse than all other setups. Figure 6 shows the number of sentences with formal and informal address in our dataset (only 137 in total) per formality score bin. Although they lean towards the lower end, even these sentences scatter broadly over the formality scale (average formality scores are -0.10 (± 0.30) for formal and -0.36 (± 0.25) for informal address). Formality is not only expressed via these different forms of address. (3) shows a sentence from our dataset with formal address but a

Table 2: Results for formality scoring on documents; statistically significant differences (calculated with the two-sided Wilcoxon signed-rank test) are marked with ‘*’ for $p < 0.005$ with respect to the **best** models; language(s) of datasets in brackets, translated data underlined.

low formality score because of other indicators. Consequently, formality is a much broader concept, and restricting it to this use case is insufficient for comprehensive formality analysis.

 Don’t *you* want to *have a look*?

5 Formality Scoring on Documents

Documents may assemble an even more diverse range of clues for degrees of formality than sentences. Only recently, Jin et al. (2022) proposed extending style transfer to the more complex document level, but manual formality annotations of documents are more expensive to obtain than sentence-level assessments. Therefore, this section investigates how single sentences and linguistic properties contribute to the overall document formality. We examine if sentence-level formality annotations are useful for assessing formality on documents.

5.1 Evaluation on German Documents

We conducted experiments and analyses on German documents. For that, we utilized 800 emails with continuous formality scores (Eder et al., 2021). Sentences from emails show the highest standard deviation of formality of all domains in our dataset and the corpus from Pavlick and Tetreault (2016). Thus they possess a high stylistic variability. We denote the dataset *E21* in the following.

We compared transformers and feature-based approaches trained on our formality-informed sentences with transformer models fine-tuned on *E21* for predicting formality on this document collection. The upper half of Table 2 presents the average Spearman’s ρ for these models. Fine-tuning GBERT on *E21* itself (10-fold cross-validation) performed best, but there is no statistically significant difference between utilizing the documents

or our formality-assessed sentences as training data. The transformer models grasped the concept of formality more comprehensively since the feature-based ridge regression models yielded significantly worse results. It seems that linguistic features do not generalize well. Figure 7 shows some of the most predictive linguistic features for formality scoring on the sentence level for the documents. The average word formality and the Flesch Reading Ease correlate with document formality in a similar way than with sentence formality (Figure 3). However, the average sentence length and average token length are comparably more static across the formality scale of documents and thus less suitable features.

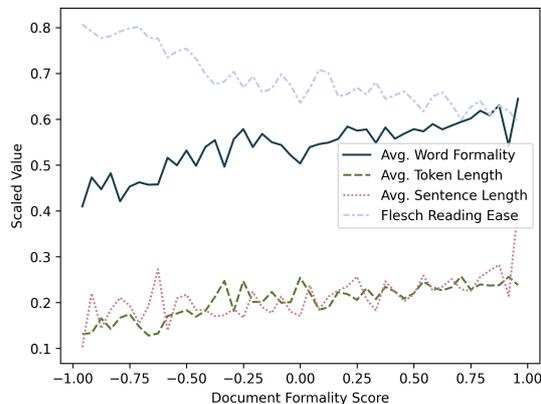

Figure 7: Linguistic characteristics (scaled values) of the documents per their formality scores.

To further understand how the formality of a document is affected by its sentences, we split the documents of *E21* into separate sentences. Then, we ran the GBERT model fine-tuned on our dataset on these sentences to determine their formality. Taking the average of the calculated scores as document score still returned a Spearman’s ρ of 0.801. Although this result is significantly worse

($p < 0.01$) than running the model on the documents directly, it still shows a strong correlation between the scores of the sentences and the document formality score. In Figure 8, we plot the number of sentences per calculated formality score bin for each formality score bin of the corresponding documents. The sentence and document formality scores show some overlap. Nevertheless, the sentences in the documents have quite a range of formality scores.

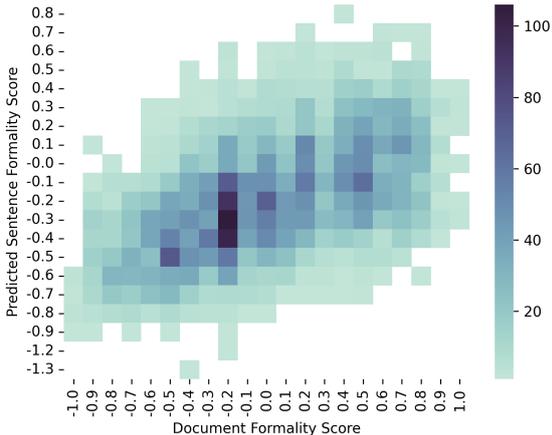

Figure 8: Frequency of calculated formality scores of sentences per formality score bin of documents.

How the formality of sentences changes throughout a document is shown in Figure 9, which depicts the mean sentence formality by position in the documents. The formality tends to decrease with increasing position in the text. This observation is in line with the assumption of Heylighen and Dewaele (1999) that formality is higher at the beginning of a text because of the lack of previous discourse to relate to. For threaded online discussions, Pavlick and Tetreault (2016) reported congruent findings.

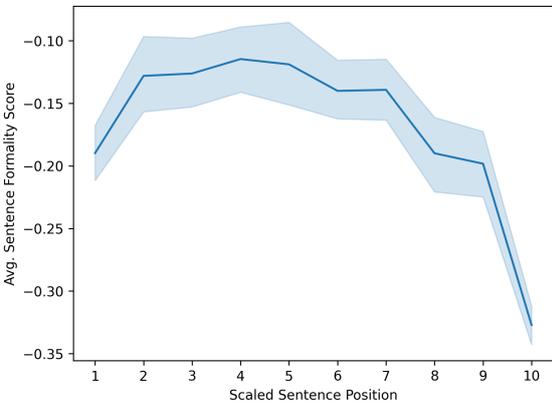

Figure 9: Average sentence formality score by position in documents; sentence positions are scaled to ten bins.

Concluding, fine-tuning transformers on sentences is applicable for assessing the formality of documents, as our results show. However, due to the variety of sentence formality scores, it may not be helpful to map formality assessments of documents to their sentences to save annotation efforts or assume mono-style documents regarding the formality dimension.

5.2 Evaluation on English Documents

To investigate the applicability of transformer models fine-tuned on our sentences for other languages, we evaluated them on English documents. We used 960 emails (*C18* in the following) with formality annotations obtained via averaging over individual assessments on a 5-point Likert scale (Chhaya et al., 2018). The lower half of Table 2 shows the results. Fine-tuning on the documents (10-fold cross-validation) significantly outperformed sentence-based models. We ascribe this performance decline also to the manual annotations of *C18* since we only calculated an average split-half reliability of $0.573 (\pm 0.015)$ Spearman’s ρ over 100 trials. Given these conditions, a BERT model fine-tuned on our translated dataset still achieved a high correlation also compared to the English *PT16* model. Hence, we assume our dataset is beneficial for formality assessment of English-language documents too.

6 Conclusion

We presented the first dataset of sentences with highly reliable human formality assessments on a continuous informal-formal dimension obtained via Best-worst scaling. Our dataset comprises 3,000 sentences evenly distributed over twelve different domains to cover the broad spectrum of formality best possible. It is the first for the German language with a comprehensive perspective on sentence-level formality altogether.

We evaluated various machine learning models for the regression task of assessing formality on our dataset. We found that a transformer model fine-tuned on an existing German dataset including only sentences of formal and informal address (*Sie* vs. *Du/Du*) yielded the worst results. Hence, this restricted view on formality is insufficient to capture a more comprehensive concept of formality. Cross-lingual settings utilizing transformer-based classifiers pre-trained on huge datasets with formal and informal language pairs not restricted

to a particular form of formality performed better. However, a binary categorization of formality strikes as inappropriate since ridge regression models employing simple linguistic features outperformed them. Fine-tuning transformers for regression on an English dataset produced similar (for the cross-lingual setting or the English translation of our dataset) or higher (for the German translation of the training data) results. In comparison, a transformer model fine-tuned on our dataset with its broader formality scale outperformed all other settings significantly.

Expanding the scope to longer texts, a requested future research direction of style transfer (Jin et al., 2022), we investigated the influence of the formality of sentences on a document’s formality. We observed that the sentences included in the documents cover a wide spectrum of formality with higher formality scores at the beginning. Our results indicate that a transformer model fine-tuned for formality scoring on our sentences generalizes better across text levels than linguistic features and can be used to predict the degree of formality of German and English documents. We anticipate our dataset to facilitate future work on German formality style transfer and formality analysis in general on both the document and the sentence level. It may also be valuable for other languages.

Our **dataset** and a **tool** for analyzing styles with a wide range of linguistic features are **available** under https://github.com/ee-2/in_formal_sentences and <https://github.com/ee-2/register>.

Limitations

This work assesses the formality of texts in isolation, excluding any conventional and situational contexts. However, for different genres and situations different expectations have to be met. For example, an expression regarded as formal in one genre may be perceived as too informal in another. We also do not take forms of formality beyond the pure text level into account. Properties that contribute to formality besides the text itself may include the structure of a text (e.g., blank lines in emails (Chhaya et al., 2018)) or the volume, the pitch, the speech rate, or the rhythm of speech (Labov, 1972). For future research and downstream applications, it might be helpful to consider the contextual circumstances and non-textual varieties of formality too.

Our experiments on the document level include only emails due to the lack of other corpora with formality annotations on this text level. With their composition, often including greeting, signoff, and signature, emails present a particular genre. Potentially, the greeting provides already a good indication of the formality of the text that follows (e.g., ‘Dear Mrs. Doe’ vs. ‘Hi Jane’). Although we anticipate congruent findings, future work should experiment with other types of documents, possibly more challenging to assess. Further, extending the cross-lingual experiments on the document level to languages other than English (e.g., languages with multiple forms of honorifics, such as Japanese) will be required.

Ethical Considerations

We ensured that our dataset can be made publicly available (sentences from *comments* are restricted to non-commercial use only). Since our data originates from several different domains, we gave careful consideration to finding a balance between copyright and data privacy regulations. Finally, we pseudonymized text spans containing personal information in user-generated content where necessary (*tweets*, *Reddit* posts, *comments* and *blogs*). This means we replaced sensitive text with automatically generated substitutes, e.g., female names with other female names or locations with other locations. We only release the IDs for *tweets*, *Reddit* posts and *comments*. For *blogs*, we follow the license requirements and publish the respective reference. The corpora with *emails* and *legal* texts had been pseudonymized already, no information on authors is available. For less-privacy-sensitive text sources, such as *subtitles*, *political* speeches, *news* and *Wikipedia*, we report all information shared in the original corpus, e.g., URLs. The sentences from *fiction* and *science*, which we collected ourselves, are cited appropriately in order to acknowledge intellectual property rights. People involved in creating our dataset were compensated at least following minimum wage requirements.

Acknowledgments

This work was partially funded by the Faculty of Humanities of the University of Klagenfurt. Further, we especially thank Udo Hahn for valuable input and discussions.

A Appendix

A.1 Models for Formality Scoring

Fine-tuned Transformer Models. For fine-tuning transformers, we used the recommended and default parameter settings of the *FLAIR* framework (Akbik et al., 2019) (version 0.10):

- learning rate = 5.0e-5
- maximal epochs = 10
- optimizer = AdamW
- scheduler = linear scheduler with warmup
- warmup fraction = 0.1
- mini batch size = 4

Table 3 shows the results for fine-tuning different transformers on our dataset in a 10-fold cross-validation setting. We experimented with the German transformer models GBERT-base, GBERT-large, GELECTRA-base, GELECTRA-large (all from Chan et al. (2020)), and WECHSEL-RoBERTa-base-german (Minixhofer et al., 2022). The large models possess a high fluctuation in performance. Therefore, we chose the best-performing

Model	Spearman’s ρ
GBERT-base	0.919 (± 0.009)
GELECTRA-base	0.918 (± 0.011)
GBERT-large	0.109* (± 0.274)
GELECTRA-large	0.322* (± 0.426)
WECHSEL-RoBERTa-base	0.912* (± 0.009)

Table 3: Results for different transformer models on our dataset (10-fold cross-validation); significant differences (at least $p < 0.05$) are marked with ‘*’.

(and less expensive) GBERT-base model for our experiments on German data.

Table 4 displays the performances of transformer models used in a cross-dataset setting on the original data. We report results for fine-tuning regression models on our dataset and *PT16* in a 10-fold cross-validation setting. For the formality classifier we fine-tuned ourselves, the GBERT model fine-tuned on *FP12*, we achieved perfect accuracy on the original test split of this dataset.

Feature-based Models. For the feature-based models, we used *spaCy* (3.3) (Honnibal et al., 2020) and its language model *de_core_news_sm* for basic NLP processing routines. We utilized the *benepar* library (Kitaev and Klein, 2018; Kitaev et al., 2019) (version 0.2) for constituency parsing and scored the formality of a word given its word embedding as proposed by Eder et al. (2021). Emotional features are based on the lexicon by Buechel et al. (2020), whereas sentiment was determined with the German *TextBlob* module (0.4.3).¹⁰ We used *scikit-learn.org* (1.0.2) for the ridge regression implementation with the default parameters. We compared two sets of features adapted from Pavlick and Tetreault (2016) and Chhaya et al. (2018). In Table 5, we list the concrete features we employed per setting.

A.2 Annotation

We restricted the pool of crowdworkers to German native speakers from Germany, Austria, and Switzerland who were older than 18 years. No further information on the demographics of the annotators is accessible. The crowdworkers were compensated following the minimum wage defined by the German government (€ 9.60 per hour at the time of annotation). *Clickworker*, the crowdsourcing platform we used, does not provide separate qualification tests. Rather it ensures the qualification

of the crowdworkers by their own filtering methods (e.g., project-independent online tests/training or evaluation of the work results). The German annotation guidelines can be found in the project repository alongside the dataset.

A.3 Computing Details

We carried out our experiments on a NVIDIA RTX A40 GPU with 48GB RAM. We estimate a total computational budget of 72 GPU hours. Fine-tuning GBERT-base, BERT-base, or XLM-RoBERTa-base on our dataset took under 15 minutes per model. Fine-tuning these models on *PT16* required about 45 minutes per model. Fine-tuning GBERT on *FP12* took about two hours, and fine-tuning models on German or English documents needed under five minutes. Training ten ridge regression models for 10-fold cross-validation was completed in under two minutes for the feature set based on Chhaya et al. (2018) and in under 15 minutes for the feature set based on Pavlick and Tetreault (2016).

Task-specific Compression for Multi-task Language Models using Attribution-based Pruning

Abstract

Multi-task language models show outstanding performance for various natural language understanding tasks with only a single model. However, these language models utilize an unnecessarily large number of model parameters, even when used only for a specific task. This paper proposes a novel training-free compression method for multi-task language models using a pruning method. Specifically, we use an attribution method to determine which neurons are essential for performing a specific task. We task-specifically prune unimportant neurons and leave only task-specific parameters. Furthermore, we extend our method to be applicable in low-resource and unsupervised settings. Since our compression method is training-free, it uses few computing resources and does not destroy the pre-trained knowledge of language models. Experimental results on the six widely-used datasets show that our proposed pruning method significantly outperforms baseline pruning methods. In addition, we demonstrate that our method preserves performance even in an unseen domain setting.

1 Introduction

Various pre-trained language models with large-scale data and parameters have emerged (Devlin et al., 2018; Lewis et al., 2019; Raffel et al., 2019; Brown et al., 2020). Specifically, pre-trained language models like T5 (Raffel et al., 2019) and GPT-3 (Brown et al., 2020) have shown outstanding performance on many natural language understanding tasks. These language models can perform various tasks with a single model by treating every text processing problem as a text generation problem. However, these language models may utilize unnecessary large-scale model parameters even when performing only a specific task. Previous works have introduced various compression methods for language models such as pruning (Chen et al., 2020; Goyal et al., 2020; He et al., 2021),

knowledge distillation (Sanh et al., 2019; Hou et al., 2020; Mao et al., 2020; Sun et al., 2020), quantization (Shen et al., 2020), and low-rank factorization (Liu et al., 2021). However, these studies have (1) not compressed the language models task-specifically or (2) demanded an additional training process like the case of knowledge distillation. This additional training process requires excessive computing resources and a massive training dataset. Furthermore, this training process can destroy inherent pre-trained knowledge in language models since it updates the model’s pre-trained parameters (Toneva et al., 2018). Due to the catastrophic forgetting (McCloskey and Cohen, 1989) caused by pre-trained knowledge destruction, models which are compressed and trained for a specific task, tend to show degraded performance on solving other pre-trained tasks (Kirkpatrick et al., 2017; Ritter et al., 2018). Also, additional memory space is required to store the trained parameters separately.

In this paper, we propose a novel training-free attribution-based task-specific pruning method that enables more efficient compression and inference by extracting only task-specific parameters from multi-task language models. We can determine which neurons are essential to derive a specific output for each neural network layer by using attribution so that we can extract only task-specific parameters from the entire model, as shown in Figure 1. We can efficiently process input data while preserving the model’s task performance by selecting only the important neurons determined by the attribution method. Furthermore, we extend our method to be applicable in two challenging scenarios: low-resource and unsupervised scenarios. The former alleviates insufficient labeled data situations, and the latter handles settings when labels are unavailable. Both methods can relieve the cost of obtaining labeled datasets, which requires excessive human resources and is time-consuming. Especially under the low-resource setting, our attribution-based task-

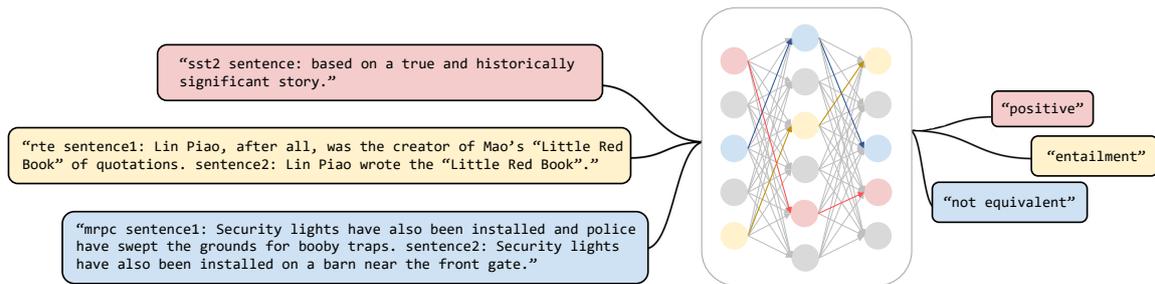

Figure 1: Task-specific Knowledge of Multi-task Language Models. Not all parameters in a language model behave as important parameters when performing a single task. For example, in this figure, when a language model receives SST-2 data, sentiment analysis data, only the parameters expressed in red color behave as essential parameters.

specific pruning requires only a single forward and backward propagation computation for few-shot data samples (e.g., only ten samples) to derive attribution of each neuron. Since this pruning process does not update the model’s parameters, it does not destroy the pre-trained knowledge of the language models. Therefore, it is irrelevant to the various disadvantages that arise during an additional training process. Since our method is model-agnostic, it can be applied to any neural network model broadly and generally. Even we can use it to extract only task-specific knowledge after other compression methods are applied.

Experimental results on the six widely-used natural language understanding tasks show that our proposed method significantly outperforms baseline training-free pruning methods. Furthermore, we demonstrate that our method shows robust performance in both low-resource and unsupervised settings. Also, we reveal that our proposed method shows outstanding knowledge preservation even for an unseen related domain, which suggests that our method can preserve task-specific knowledge effectively. We additionally investigate to offer a guideline for our task-specific compression method by analyzing which types of layers are significant for processing task-specific knowledge.

2 Related Works

2.1 Efficient Language Models

As transformer-based (Vaswani et al., 2017) language models (Devlin et al., 2018; Radford et al., 2018; Raffel et al., 2019; Liu et al., 2019; Yang et al., 2019) have become state-of-the-arts on many NLP tasks in the last few years, deep neural network model compression methods have been vastly applied to large-scale language models. Fan et al. (2019) randomly drops layers at training time, which enables structured pruning on transformer

layers at inference time. Michel et al. (2019) prunes less important attention heads at inference time. Other works (Goyal et al., 2020; Kim et al., 2021) focus on pruning less important tokens and progressively remove them during inference. However, many of the pruning methods (Goyal et al., 2020; Kim et al., 2021; Chen et al., 2020) require a following fine-tuning step of the model parameters after fixing the configuration of a pruned network, which makes such methods undesirable for efficient task-specific compression.

On the knowledge distillation side, Sun et al. (2019); Jiao et al. (2019); Sanh et al. (2019) employ teacher-student framework (Hinton et al., 2015) to transfer knowledge from an original large model (teacher), to a lightweight shallow model (student). They differ in how the student network is initialized and to which components knowledge distillation is applied. On the other hand, Shen et al. (2020) uses the mixed precision group-wise quantization based on Hessian information to compress BERT.

There are other streams of works that explore efficient language models by solving the bottleneck of the Transformer-based model computation. Beltagy et al. (2020) and Zaheer et al. (2020) sparsify the attention matrix to make transformer-based language models more efficient and Wang et al. (2020) applies low-rank approximation to increase inference speed. However, such works sparsify the full self-attention matrix according to attention score, which does not directly reduce the dimension of the matrices in the model such as query, key, value, and feed-forward matrices.

2.2 Network Pruning

One of the ways to categorize network pruning is to compare structured pruning to unstructured pruning. For structured pruning (Li et al., 2016; Hu et al., 2016; Wen et al., 2016), groups of weight con-

nections are removed from a network together, such as entire channels or filters in CNN-based networks and layers or attention heads in transformer-based networks. For unstructured pruning (Han et al., 2015a,b), weight connections are removed from a network individually. However, unstructured pruning methods produce large sparse weight matrices which are computationally inefficient unless equipped with a specifically designed hardware. In this paper, we utilize the structured pruning method to propose a compression method that enables efficient weight matrix multiplication computation.

2.3 Attribution Method

We utilize an attribution method (Shrikumar et al., 2016) to extract the importance of neurons from the pre-trained language models. Attribution methods are mostly used to derive important features (*i.g.*, *pixel*, *token*) to extract interpretability from deep neural networks (Baehrens et al., 2010; Springenberg et al., 2014; Shrikumar et al., 2016). Specifically, attribution methods are used to compute the importance of each feature for performing a specific task. Formally, suppose we have a function $\mathcal{P} : \mathbb{R}^d \rightarrow [0, 1]^m$ that represents deep neural networks for multi-class classification. The contribution of the i -th feature in x to the prediction of c -th class using \mathcal{P} is defined as follows:

$$A_i^{(x,c)}(x) = x_i \times \frac{\partial \mathcal{P}(c|x)}{\partial x_i} \quad (1)$$

where $\partial \mathcal{P}(c|x)/\partial x_i$ is the gradient of $\mathcal{P}(c|x)$ with respect to the i -th feature.

3 Methodologies

In this section, we describe our attribution-based pruning method for extracting only the task-specific knowledge from a multi-task language model T5 (Raffel et al., 2019), where attribution is obtained using gradient information. Furthermore, we extend our method to low-resource and unsupervised settings to alleviate insufficient labeled data situations. We select T5 because it is a multi-task solving model and can be used in any natural language understanding setting by treating every text processing problem as a text generation problem. For our problem setting, suppose we have input text $x = \{x_1, \dots, x_n\}$ and output text $y = \{y_1, \dots, y_m\}$ mapped as $(x, y) \in \mathcal{D}$, where each text corresponds to a sequence of tokens, and an input text contains a prefix task description. We

can represent a standard conditional language modeling objective to maximize the following likelihood:

$$\mathcal{L}(x, y) = \sum_i \log \mathcal{P}(y_i|x, y_1, \dots, y_{i-1}; \Theta) \quad (2)$$

where the conditional probability \mathcal{P} is modeled using a neural network with parameters Θ .

3.1 Task-specific Knowledge Extraction

Applying Pruning for Transformer variants

Deep neural networks can be compressed by pruning unimportant i -th neurons of the layer representation h (Han et al., 2015a,b). The architecture of Transformer-based models mainly consists of multi-head attentions and fully connected feed-forward networks as follows.

$$\begin{aligned} MultiHead(Q, K, V) &= Concat(head_1, \dots, head_h)W^O \\ head_i &= Attention(QW_i^Q, KW_i^K, VW_i^V) \\ FFN(x) &= \sigma(xW_1 + b_1)W_2 + b_2 \end{aligned} \quad (3)$$

where $W_i^{Q,K,V} \in \mathbb{R}^{d_{model} \times d_{q,k,v}}$ and $W_i^O \in \mathbb{R}^{d_v \times d_{model}}$ are the projection matrix parameters for multi-head attentions. For the fully connected feed-forward network (FFN), two linear transformations, denoted with the projection matrix parameters W_1 and W_2 and biases b_1 and b_2 , with an activation function are used. Transformer (Vaswani et al., 2017) variants can be compressed by pruning $W^{Q,K,V,O}$, $W_{1,2}$, and $b_{1,2}$ for each transformer block.

Deriving Attribution for Language Models

Language models generate text outputs by iteratively selecting a word-piece from the vocabulary dictionary. Therefore, the text generation process can be seen as a classification task dealt with in the attribution methods, and we can apply the attribution methods to compute the importance of features for language models. However, the purpose of this study is to derive the importance of each neuron h_i in the layer representation $h \in \mathbb{R}^d$, rather than deriving the importance for the input feature x_i . Hence, the attribution formula is adapted to compute a neuron attribution $A_i^{(x,y_j)} \in \mathbb{R}$ as follows:

$$A_i^{(x,y_j)}(h) = h_i \times \frac{\partial \mathcal{P}(y_j|x, y_{1:j-1})}{\partial h_i} \quad (4)$$

If the target output text consists of multiple word-pieces rather than a single word-piece, language

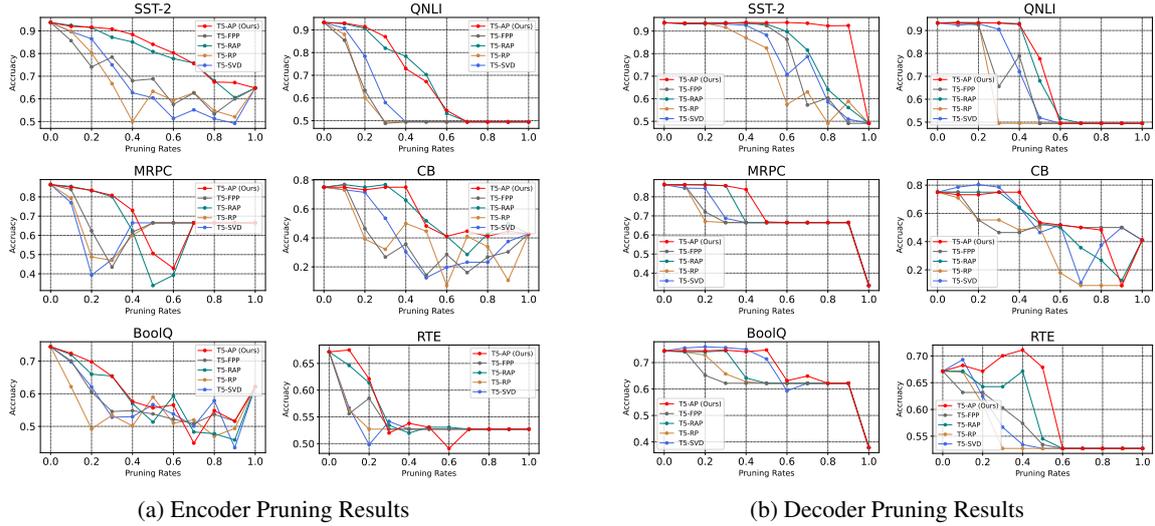

Figure 2: Module-specific Pruning Results. Our proposed attribution-based pruning significantly outperforms the other pruning methods in most cases. Especially, our task-specific pruning is more effective on decoder compression; these results suggest that most task-specific knowledge exists in the decoder of language models. The standard deviations of T5-RP and T5-RAP are shown in appendix B.

models must derive the multiple word-piece output distributions. Therefore, we change the attribution formula to handle multiple word-piece outputs as follows:

$$A_i^{(x,y)}(h) = h_i \times \sum_{j=1}^{|y|} \frac{\partial \mathcal{P}(y_j|x, y_{1:j-1})}{\partial h_i} \quad (5)$$

Since $A_i^{(x,y)}$ is attribution for one sample data x , we obtain the final neuron attribution by summing attributions for multiple sample data as shown in the following formula:

$$A_i^{(\mathcal{D})}(h) = \sum_{(x,y) \in \mathcal{D}} A_i^{(x,y)}(h) \quad (6)$$

where \mathcal{D} means the entire task-specific dataset. In low-resource environments, few-shot samples can be used for \mathcal{D} (e.g., only ten samples), which are sufficient to derive a precise importance score for each neuron. Experimental results for low-resource setting are described in section 4.3.

Attribution-based Layer Pruning We focus on applying attribution-based pruning on the Transformer encoder and decoder, more specifically on multi-head attention and fully connected feed-forward networks. We use neuron attribution $A_i^{(\mathcal{D})}$ as the importance for each neuron of a specific layer. We sort the importance of each neuron in order of magnitude at each layer, and we can compress the model by pruning neurons with lower importance.

$$\text{argsort}_i(A) = |\{j | (A_i < A_j) \cup (A_i = A_j, j < i)\}| \quad (7)$$

where $i, j \in \{1, \dots, k\}$

Once neurons are sorted according to the importance score, we prune neurons from each layer with the pruning rate p by constructing a set \mathcal{M} of neuron indices to be secured.

$$\mathcal{M} = \{i | \text{argsort}_i(A) < \lfloor k \times p \rfloor\} \quad (8)$$

where $i \in \{1, \dots, k\}$

The algorithm for deriving a set \mathcal{M} is shown in appendix A. Suppose $W \in \mathbb{R}^{d \times k}$ is a linear matrix multiplication parameter we want to prune, the matrix after pruning is denoted as $\tilde{W} = (W_{ij})_{\substack{1 \leq i \leq d \\ j \in \mathcal{M}}}$.

If the bias term $b \in \mathbb{R}^k$ is added to the operation for an affine transformation, the bias term can also be compressed by performing the $\tilde{b} = (b_i)_{i \in \mathcal{M}}$ operation similarly. The compressed parameters are used to compute the new representation by performing the transformation operation $h\tilde{W}$ or $h\tilde{W} + \tilde{b}$.

More specifically, for W_i^Q , W_i^K , and W_i^V from eq. (3), second dimension (the number of columns) of the matrix is pruned and for W_i^O , W_1 , and W_2 , the first dimension (the number of rows) is pruned to preserve the original architecture by matching shape with input processed from the previous layer. After pruning, multi-head attention and fully connected feed-forward network computations are precisely the same as before but with the pruned weight matrices:

$$\begin{aligned}
MultiHead(Q, K, V) &= Concat(head_1, \dots, head_h) \tilde{W}^O \\
head_i &= Attention(Q \tilde{W}_i^Q, K \tilde{W}_i^K, V \tilde{W}_i^V) \\
FFN(x) &= \sigma(x \tilde{W}_1 + b_1) \tilde{W}_2 + \tilde{b}_2
\end{aligned} \tag{9}$$

Note that attribution scores are sorted locally within each layer, and the pruning rate p is applied to each prunable layer uniformly.

Our proposed compression process utilizes a structured pruning without any training process. Therefore, our method can conduct on-demand real-time task-specific compression and inference for each task while preserving pre-trained parameters. The detailed algorithm for on-demand real-time task-specific compression and inference is shown in appendix A.

3.2 Unsupervised Pruning

Obtaining labeled data usually requires excessive human resources and is time-consuming. Therefore, we propose an additional method to derive attributions in an unsupervised setting to mitigate this problem. If the label for the dataset is given, we can simply compute attribution by summing the gradients values for the word-piece set composing the label. However, when the label is not given, the target word-piece set is ambiguous. To resolve this problem, we compute task-specific importance by summing the absolute values of attributions for all candidate labels as follows:

$$A_i^{(x, \mathcal{Y})}(h) = \sum_{y \in \mathcal{Y}} |h_i| \times \sum_{j=1}^{|y|} \left| \frac{\partial \mathcal{P}(y_j | x, y_{1:j-1})}{\partial h_i} \right| \tag{10}$$

where \mathcal{Y} is the candidate label set. The above importance computation formula does not require supervision for any data. Hence, we may not reflect definite label information when computing each neuron’s importance under our unsupervised compression setting. However, this setting is helpful for a resource-constrained environment, where obtaining labeled data is challenging.

4 Experiments

4.1 Experimental Setup

Datasets We conduct experiments on six downstream tasks (Wang et al., 2018, 2019). Specifically, we utilize SST-2 (sentiment analysis); MRPC

(semantic textual similarity); BoolQ (question answering); and QNLI, CB, RTE (natural language inference).

Implementation Details We select pre-trained *T5-base*¹ as a backbone for the following experiments. *T5-base* consists of 12 encoder and 12 decoder layers. Each encoder layer contains 6 prunable matrices: 4 for the multi-head self-attention networks and 2 for the feed-forward networks. Each decoder layer contains 10 prunable matrices: 4 for the multi-head self-attention networks and 2 for the feed-forward networks, and 4 for the cross-attention networks. *T5-base* used in our experiments has been fine-tuned by multi-task learning using the six datasets above. We experiment with pruning rates ranging from 0.1 to 1.0, and a pruning rate is applied to each prunable layer uniformly.

4.2 Task-specific Pruning Efficiency

In this section, we validate the effectiveness of our task-specific attribution-based pruning by comparing the performance with other pruning methods. We collect compressed models using various pruning methods and evaluate the model’s performance on testset for all six datasets.

Baselines We select four other training-free pruning methods to compare with our task-specific **T5 Attribution Pruning (T5-AP)**.

- **T5 Forward Propagation Pruning (T5-FPP)** derives the importance of each neuron with the absolute value of the forward propagation value of each neuron. This method is widely used to compress model in various studies (Han et al., 2015b; Hu et al., 2016; Li et al., 2016). Previous studies using FPP generally fine-tune the compressed model to increase the model’s performance. However, we eliminate the fine-tuning process to maintain a fair evaluation scenario since we focus on studying training-free compression.
- **T5 Low Rank Factorization (T5-SVD)** prunes weight matrices of neural networks using Singular Value Decomposition (SVD). SVD is commonly used as a main matrix compression idea in various researches (Wang et al., 2020; Noach and Goldberg, 2020). Specifically, SVD is used to compress a ma-

¹<https://huggingface.co/t5-base>

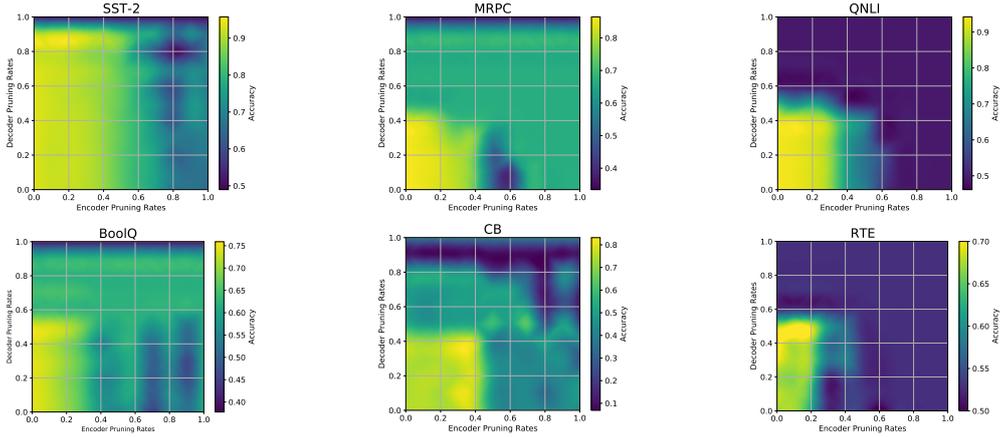

Figure 3: Module-integrated Pruning Results. These results reveal that compressing the whole architecture of the model does not additionally degrade the model’s performance compared to module-specific pruning. We experiment with the combinations of ten pruning rates for the encoder and decoder, and plot the interpolated results.

trix based on low rank factorization formula as follows:

$$W = U\Sigma V \approx \sum_{j=1}^r \sigma_j \times (U_j \times V_j) \quad (11)$$

where $W \in \mathbb{R}^{d \times k}$ is a matrix to compress, and $U \in \mathbb{R}^{d \times r}$ and $V \in \mathbb{R}^{r \times k}$ are the decomposed matrices. $\Sigma = \text{diag}(\sigma_1, \sigma_2, \dots, \sigma_r)$ is a diagonal matrix consisting of the singular values σ_i , where $r \leq \min(d, k)$ is the matrix rank. U_j is the j -th column of U and V_j is the j -th row of V . We can compress the matrices of T5 by determining the rank $r = \lfloor \frac{d \times k \times p}{d+k+1} \rfloor$ to have the same number of parameters as T5-AP, where p is the pruning rate defined in formula 8.

- **T5 Random Attribution Pruning (T5-RAP)** randomly selects word-pieces that are not label, and uses them to compute attribution. RAP does not derive appropriate task-specific importance for each neuron since this method randomly selects word-pieces output. We calculate the final performance of T5-RAP by averaging the accuracy derived from five trials of random word-pieces selection.
- **T5 Random Pruning (T5-RP)** randomly selects which neuron to prune. This method can achieve the lower-bound performance of overall training-free pruning methods since it randomly selects which neuron to prune without any knowledge. We calculate the final performance of T5-RP by averaging the accuracy derived from five trials of random pruning.

Module-specific Pruning For each dataset, we separately compressed the encoder and decoder at varying pruning rates to reveal the effect of our method on the encoder and decoder, respectively. Figure 2 shows the experimental results for five compression methods, including our proposed method. Experimental results show that our method outperforms other compression methods in most cases. Specifically, there is almost no performance difference between the T5-RP and T5-FPP. These results suggest that the T5-FPP does not extract task-specific knowledge. In addition, T5-SVD performs not badly in some cases, but generally performs similarly to T5-RP. It is because the low-rank approximation of T5-SVD does not work task-specifically. Surprisingly, T5-RAP sometimes performs similarly to T5-AP, probably due to the use of partial gradients information calculated from model parameters. Our experiments show that the decoder part of T5 has the robustness for task-specific compression than the encoder part of T5. These results demonstrate that T5 decoder processes more task-specific information than T5 encoder.

Module-integrated Pruning To maximize the compression efficiency of a language model, we should compress the whole model instead of compressing the encoder or decoder, respectively. Therefore, we also validate our method by compressing the whole architecture of T5. Figure 3 shows the experimental results of simultaneously compressing both the encoder and decoder using our method. These experimental results reveal that compressing the whole architecture of the model, not compressing each encoder or decoder sepa-

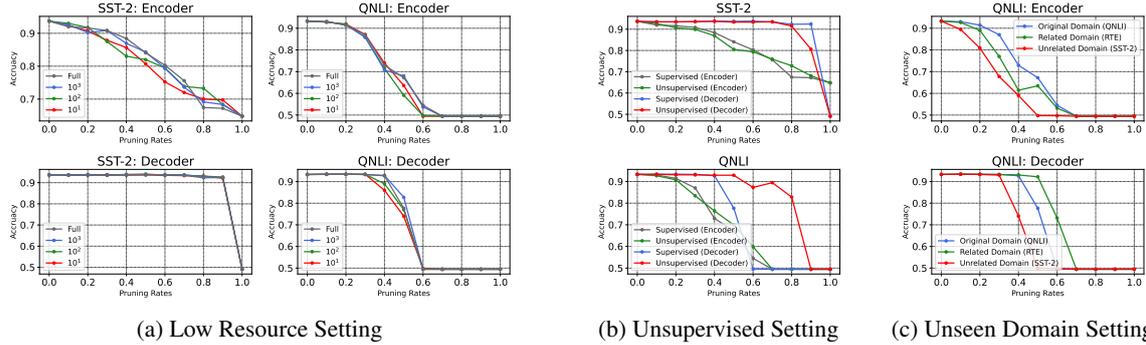

Figure 4: Experimental results extending our pruning method to challenging settings: (a) Low-resource setting experiment results. (b) Unsupervised setting experiment results. (c) Unseen domain setting experiment results. These extensions make our method more practical for use in a real-world setting.

rately, does not degrade the model’s performance additionally.

Our method focuses on compressing a multi-task language model without any additional training process in a model-agnostic way. Therefore, it is difficult to compare our method with previous compression research due to the inconsistent experimental setting since previous studies have treated training-based and model-specific compression methods. Since our method is model-agnostic, it can be utilized broadly and generally to prune multi-task language models containing only task-specific knowledge after applying other compression methods.

4.3 Low-resource Setting

In this section, we demonstrate the results for compressing language models based on the attribution computed from only few-shot. Specifically, we compute neuron importance using only 10^3 and 10^2 , and 10^1 samples of SST-2 and QNLI datasets and prune the T5 model with the computed importance, where we balance the number of samples for each class when sampling a subset of the whole dataset. All results are reported by averaging five trials of random sampling. Figure 4-(a) represents the pruning results in low-resource setting. For SST-2 dataset, we find that compression using only 10^1 data samples yields comparable performance to the results of using the entire training dataset. The total number of data samples of SST-2 is 67k, and 10^1 of data samples corresponds to about 10^{-4} of the whole dataset. For the QNLI dataset, we demonstrate that compression using only 10^3 data samples of the labeled training dataset yields comparable performance to the results of using the entire training dataset. Furthermore, the performance degradation is also insignificant when using only

10^1 samples of the labeled QNLI training dataset. The total number of data samples of QNLI is 105k, and 10^3 and 10^1 data samples correspond to about only 10^{-2} , 10^{-4} of the whole dataset, respectively. These results suggest that most of the task-specific knowledge is derived from computing gradients for only the candidate outputs. We can effectively reduce the time consumption in this low-resource setting by using a few labeled instances to compute the attribution, and it is the most significant advantage over other training-based compression methods.

4.4 Unsupervised Setting

We suggest an additional method to compute attributions using an unlabeled text dataset in section 3.2. We present the pruning results by computing attributions for an unsupervised setting in Figure 4-(b). Results of encoder compression with the unsupervised setting for both SST-2 and QNLI datasets show competitive scores to that of labeled data. For the decoder, the performance of SST-2 decreases slightly, but the performance of QNLI rather increases. The experimental result on SST-2 reveals that the compression in an unsupervised setting shows robust performance maintenance. In the QNLI result, we observe that computing attributions using information from all output candidates enhances the model’s performance.

4.5 Unseen Domain Setting

In this section, we validate the effect of our task-specific compression on unseen domains. We compress the T5 using related and unrelated datasets, and then compare the performance preservation for the original dataset. Specifically, we compress the T5 using attribution computed with SST-2 and RTE, respectively. And then, we evaluate the compressed models with the QNLI dataset. QNLI and RTE are

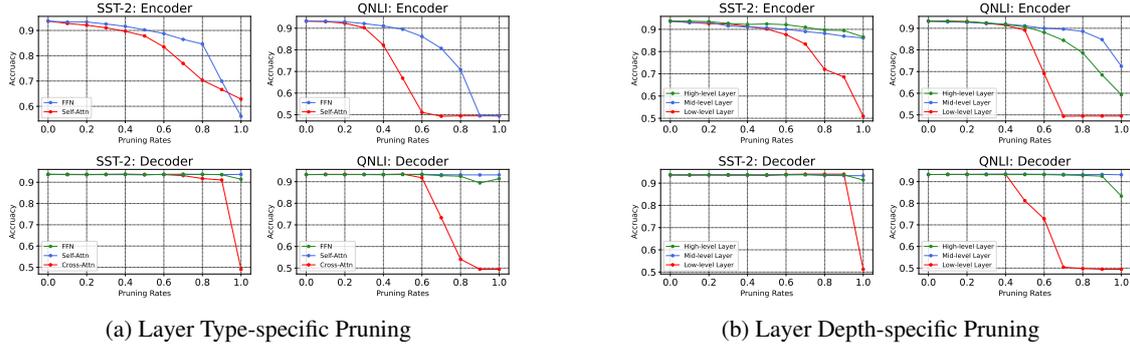

Figure 5: Layer types analysis: (a) Layer architecture experiment results. (b) Layer depth experiment results. The higher the degradation, the more essential layers are.

related domains since both are natural language inference datasets, and SST-2 is an unrelated domain built for sentiment analysis. Figure 4-(c) shows the evaluation results of the compressed model for related and unrelated domains. Experimental results reveal our method’s robust performance maintenance for the related domain. Surprisingly the case of decoder compression shows even better performance maintenance in the related domain than in the original domain.

4.6 Layer-specific Pruning Analysis

This section further investigates the pruning effect per layer type. We select two pruning settings: (1) Layer type-specific and (2) Layer depth-specific.

Layer Type-specific Pruning Analysis Layer type-specific pruning analysis focuses on understanding how the performance of the model varies depending on the type of compressed layers. The encoder investigates pruning results for feed-forward neural networks and self-attention networks, and the decoder focuses on feed-forward neural networks, self-attention networks, and cross-attention networks.

Layer Depth-specific Pruning Analysis Layer depth-specific pruning analysis investigates how the performance of the model changes depending on the depth of the compressed layers. We select SST-2 for experiments and separate each encoder and decoder into three parts: (1) Low-level layer, (2) Mid-level layer, and (3) High-level layer. Since *T5-base* consists of 12 layers for each encoder and decoder, each depth consists of 4 layers.

Layer-specific pruning results are shown in Figure 5. For the encoder, self-attention networks are more critical for preserving the performance than feed-forward neural networks. For the decoder, cross-attention networks are more important than

feed-forward neural networks and self-attention networks. For each layer-depth, we can conclude that the low-level features are more crucial to preserving the model’s performance. Especially, experimental results reveal that the model’s performance is preserved even if the pruning rate of a specific layer is 1.0. These results demonstrate that there is redundant information processing between layers for performing a specific task. Note that although the pruning rate is 1.0 for a layer, the representation propagated through the pruned layer does not lose every knowledge completely. It is because transformer variants have residual connections to preserve the knowledge of previous layers.

5 Conclusion

This paper proposes a novel training-free attribution-based task-specific knowledge extraction method for multi-task language models. Specifically, we use attribution to determine which neurons are important to derive a specific output for each task. Then, we prune task-specific unimportant neurons to extract only task-specific knowledge from the entire model. We further propose a method for computing attributions in low-resource and unsupervised settings. We demonstrate that our method outperforms the other pruning methods on the widely used text datasets. In addition, we examine that our task-specific language model pruning method shows outstanding performance in the unseen domain, especially when the unseen domain is related to the dataset used to configure the compressed version. Our compression method does not update the pre-trained parameters of the language models, which enables efficient on-demand compression and inference. Also, our proposed method is valuable because it can be universally applied to any neural network-based model architecture.

Limitations

To the best of our knowledge, this is the first work to compress a multi-task language model without extra training on the target task. Due to insufficient prior work on these training-free compression methods, we couldn't include a thorough comparison with other baseline algorithms. Also, our work focused on analyzing the results of six widely-used natural language understanding datasets among GLUE benchmark. We believe that extra experiments on various challenging natural language understanding tasks will show our work's generalization performance. We have conducted experiments on various settings; varying layer types, layer depth, low resource, unsupervised, and unseen domain. However, there are still extra room for improving this work, such as exploring and applying layer-specific pruning rates, which we leave for future work.

A Algorithms

Our pruning method consists of two stages: (1) Derivation of task-specific neuron indices per layer for a specific task (2) Real-time task-specific inference with previously pruned layers.

Algorithm 1 Deriving task-specific neuron indices per layer for a task t

Input: task-specific dataset \mathcal{D}^t ; model \mathcal{P} ; pruning rate p
Output: list \mathcal{M}^t with task-specific neuron indices per layer

- 1: Initialize all \mathcal{M}_i^t as an empty set and all $A_i^{(\mathcal{D}^t)}$ to zero
- 2: $\mathcal{B} \leftarrow$ split \mathcal{D}^t into mini-batches of size β
- 3: **for** each batch $b \in \mathcal{B}$ **do**
- 4: **for** each layer $l \in \mathcal{P}$ **do**
- 5: **for** $i = 1$ to k^l **do**
- 6: compute neuron importance $A_i^{(b)}(h^l)$
- 7: $A_i^{(\mathcal{D}^t)}(h^l) \leftarrow A_i^{(\mathcal{D}^t)}(h^l) + A_i^{(b)}(h^l)$
- 8: **for** each layer $l \in \mathcal{P}$ **do**
- 9: **for** $i = 1$ to k^l **do**
- 10: **if** $\text{argsort}_i(A^{(\mathcal{D}^t)}(h^l)) < \lfloor k^l \times p \rfloor$ **then**
- 11: $\mathcal{M}_i^t \leftarrow \mathcal{M}_i^t \cup \{i\}$

return \mathcal{M}^t

In the first stage, we sort neuron indices in descending order by computed attribution scores, leaving high-importance neurons by $(1 - p)$ ratio.

Algorithm 2 Real-time task-specific inference with pruned layers

Input: task t ; text inputs x ; indices container \mathcal{M} ; model \mathcal{P}
Output: text outputs y

- 1: For task t , load corresponding \mathcal{M}^t
- 2: **for** each layer $l \in \mathcal{P}$ **do**
- 3: $W^l \leftarrow (W_{ij}^l)_{\substack{i \in \mathcal{M}_i^t \\ j \in \mathcal{M}_i^t}}$ ▷ match rows with a previous layer l'
- 4: **if** bias b^l exists in layer l **then**
- 5: $b^l \leftarrow (b_i^l)_{i \in \mathcal{M}_i^t}$
- 6: compute outputs y with x using the pruned model $\tilde{\mathcal{P}}$

return y

In the second stage, we prune task-specifically unimportant neurons when given a user request for a specific task. We task-specifically compress a model in real-time and conduct an inference with the pruned model.

B Statistic of Pruning Results

We compute the pruning results of the baselines of T5-RP and T5-RAP through five random trials. The standard deviations of the accuracy for the two baselines are shown in Table 1.

		SST-2	MRPC	QNLI	RTE	CB	BoolQ
T5-RP	Encoder	0.0202	0.0046	0.0143	0.0426	0.0168	0.0020
	Decoder	0.0241	0.0108	0.0003	0.0580	0.0010	0.0060
T5-RAP	Encoder	0.0082	0.0080	0.0119	0.0165	0.0099	0.0061
	Decoder	0.0159	0.0089	0.0029	0.0123	0.0027	0.0063

Table 1: Standard deviations of Pruning results.

We calculate the standard deviations by averaging the values derived by all pruning rates. These results reveal that the variances of T5-RP and T5-RAP are not significant.

Zero-shot Transfer of Article-aware Legal Outcome Classification for European Court of Human Rights Cases

Abstract

In this paper, we cast Legal Judgment Prediction on European Court of Human Rights cases into an article-aware classification task, where the case outcome is classified from a combined input of case facts and convention articles. This configuration facilitates the model learning some legal reasoning ability in mapping article text to specific case fact text. It also provides an opportunity to evaluate the model's ability to generalize to zero-shot settings when asked to classify the case outcome with respect to articles not seen during training. We devise zero-shot experiments and apply domain adaptation methods based on domain discrimination and Wasserstein distance. Our results demonstrate that the article-aware architecture outperforms straightforward fact classification. We also find that domain adaptation methods improve zero-shot transfer performance, with article relatedness and encoder pre-training influencing the effect.

1 Introduction

Legal Judgment Prediction (LJP) has recently gained considerable attention in the mainstream NLP community (e.g., Aletras et al. 2016; Chalkidis et al. 2019, 2021, 2022b; Santosh et al. 2022, 2023). In LJP, the outcome of a case should be classified/predicted based on a textual description of case facts. In actual legal reasoning, legal practitioners (e.g., advocates, judges) determine relevant rules from the sources of law (e.g., statutes, regulations, precedent) that are relevant to the case at hand. They then carry out an analysis to determine which rules apply to the case at hand, and deduce the outcome of the case by applying them. Subsuming case facts under elements of rules given in legal sources plays a critical role in this process. Many current LJP approaches (e.g., Aletras et al. 2016; Chalkidis et al. 2019, 2022b; Santosh et al. 2023) tackle this as a straightforward classification problem with the textual descriptions of case fact as

the sole input. This reliance on the model learning statistical correspondences from case fact descriptions directly to outcomes neglects the role of legal sources in this relationship. As a consequence, the model may learn sub-optimal fact-outcome patterns that are informed by the case distribution in the data rather than learning to align facts with the legal source text containing applicable rules. The models may also attend to outcome-correlating distractors present in the dataset rather than engage in the legal fact-vs-law reasoning that is required of legal practitioners for a proper justification of the outcome (Santosh et al., 2022).

This work seeks to remedy this incomplete inference and enable the model to learn more authentic reasoning between rules and case facts by casting LJP into an article-aware classification setting and subjecting it to a zero-shot transfer challenge. Article-aware classification has been explored on Chinese criminal case corpora (Wang et al., 2018, 2019b; Yue et al., 2021; Chen et al., 2022). Similarly, Holzenberger et al. 2020 has modeled statutory reasoning by classifying US tax law provisions concatenated with textual case descriptions. We build on this prior work in two ways. First, we develop and evaluate our model on a public dataset (Chalkidis et al., 2022b) of cases by the European Court of Human Rights (ECtHR), which hears complaints by individuals about possible infringements of their rights enshrined in the European Convention on Human Rights (ECHR) by states. To the best of our knowledge, this is the first work applying article-aware case outcome prediction setting to human rights adjudication. Our approach pairs case fact descriptions with candidate ECHR articles and assigns a binary target label depending on whether the article has been alleged/deemed to have been violated, or not. Our results show that the article-aware classification model outperforms the traditional classification setup by a small but consistent margin.

Second, we subject the model to a zero-shot transfer task. Models trained on case facts alone cannot produce inferences about convention articles they did not observe during training. By contrast, human judges can conduct outcome analysis with new/amended legal provisions because they are trained to understand the rules they contain and apply them to case facts in an expertise-informed way, even in the absence of secondary sources (e.g., commentaries to the rule, etc.). Article-aware classification allows an emulation of this process by means of a zero-shot benchmarking task on articles unseen at training time. We compare two conditions where (1) the model either has no access to the target articles, or (2) it is allowed to ‘read’ the target articles but is not given any prediction outcome labels for case-target article pairs.

We experiment with domain adaptation by means of a domain discriminator (Ganin et al., 2016) and Wasserstein distance (Shen et al., 2018). Our results show that this improves performance on unseen articles compared to a vanilla model. We study the impact of law-specific pre-trained encoders on this zero-shot transferability compared to the standard language pre-trained one. Intuitively, we observe that our models perform better in zero-shot transfer if the target/unseen articles are semantically related to articles seen at training time.

It should be noted that, despite these tasks being typically referred to as instances of ‘legal judgment prediction’, ECtHR fact statements are typically not finalized until the decision outcome is known, making the task effectively one of retrospective classification rather than prediction (Medvedeva et al., 2021). While this does lead to distracting and confounding phenomena (see our prior work in Santosh et al. 2022), the dataset remains a useful resource for the development of NLP models that analyze these fact statements for text patterns that correspond to specific convention articles as drafted by the court. Consequently, in this paper we hence speak of our models as engaging in *case outcome classification (COC)*.

Our main contributions in this paper are¹:

- We cast LJP/COC on ECtHR cases as an article-aware classification task by pairing case fact descriptions with candidate articles. Assuming a frozen pre-trained encoder network, our article-aware prediction model out-

performs straightforward fact classification.

- We conduct zero-shot transfer benchmarking of article-aware COC models. We find this to be a difficult testing task for the generalization of COC models. We show that domain adaptation using a domain discriminator and a Wasserstein distance method improves generalization.
- We conduct auxiliary experiments validating that article relatedness positively affects transfer performance and show an interaction between domain adaptation and domain specific encoder pre-training.

2 Related Work

Legal Judgement Prediction: LJP/COC as an NLP task has been studied using corpora from different jurisdictions, such as the ECtHR (Chalkidis et al., 2019, 2021, 2022b; Aletras et al., 2016; Liu and Chen, 2017; Medvedeva et al., 2020; SAYS, 2020; Medvedeva et al., 2021; Santosh et al., 2023) Chinese Criminal Courts (Luo et al., 2017; Zhong et al., 2018; Yang et al., 2019; Yue et al., 2021; Zhong et al., 2020), US Supreme Court (Katz et al., 2017; Kaufman et al., 2019), Indian Supreme Court (Malik et al., 2021; Shaikh et al., 2020) the French court of Cassation (Şulea et al., 2017b,a), Brazilian courts (Lage-Freitas et al., 2022), the Federal Supreme Court of Switzerland (Niklaus et al., 2021), UK courts (Strickson and De La Iglesia, 2020) and German courts (Walzl et al., 2017)

Early works (Aletras et al., 2016; Şulea et al., 2017a,b; Virtucio et al., 2018; Shaikh et al., 2020; Medvedeva et al., 2020) used bag-of-words features. More recent approaches use deep learning (Zhong et al., 2018, 2020; Yang et al., 2019). Large pre-trained transformer models have since become the dominant model family in COC/LJP (Chalkidis et al., 2019; Niklaus et al., 2021), including legal-domain specific pre-trained variants (Chalkidis et al., 2020; Zheng et al., 2021) that have been employed for the benchmark ECtHR corpus we use in this paper (Chalkidis et al. 2021, 2022b).

Prior work on Chinese criminal case corpora case extends fact-based classification by providing the text of legal source articles as additional input. Luo et al. 2017 used an attention-based neural network which jointly models charge prediction and relevant article extraction in a unified framework whose input includes the text of legal articles. Sim-

¹Our code is available at <https://github.com/TUMLegalTech/zeroshotLJP>

ilarly, Wang et al. 2018, 2019b; Chen et al. 2022; Yue et al. 2021 employ matching mechanism between case facts and article texts. To the best of our knowledge, ours is the first work to adapt article-aware prediction to the ECtHR corpus, which is situated in the in human rights litigation domain. Going beyond previous works, we further benchmark the zero-shot transfer performance of such models, providing a test bed to evaluate their capability to process article texts they have not seen during training time and applying them to case facts towards classifying allegations/outcomes.

Domain Adaptation (DA): In transfer learning, the field of domain adaptation (DA) addresses the covariate shift between source and target data distributions (Ruder, 2019). It is tackled under three different settings: (1) Semi-supervised DA (Bollegala et al., 2011; Daume III and Marcu, 2006) where labels for the source and a small set of labels for the target domain are available, (2) unsupervised DA (Ganin et al., 2016; Blitzer et al., 2006) where only labels for the source domain and unlabelled target data are given, and (3) Any Domain Adaptation / Out of Distribution generalization (Ben-David et al., 2022; Volk et al., 2022) where only labeled source data is given. In this work, we distill the existing public LexGLUE ECtHR dataset into a new benchmark on more challenging unsupervised and any domain adaptation settings for COC to emulate legal reasoning involving previously unseen convention articles.

DA variants have been benchmarked for various NLP tasks, such as Question answering (Yu et al., 2018), duplicate question detection (Shah et al., 2018), sentiment analysis (Li et al., 2017; Ganin et al., 2016), dependency parsing (Sato et al., 2017), relation extraction (Wu et al., 2017), POS tagging (Yasunaga et al., 2018), named entity recognition (Jia et al., 2019), event trigger identification (Naik and Rose, 2020), machine reading comprehension (Wang et al., 2019a), and machine translation (Yang et al., 2018). To the best of our knowledge, this work is the first to benchmark domain adaptation in COC/LJP. While previous works typically involve short text, COC on ECtHR data involves case facts and articles, both of which typically are long documents.

Methods proposed for domain adaptation can be categorized into four types: (a) Instance-based data selection methods (Jiang and Zhai, 2007; Remus, 2012) which employ similarity metrics to

sample source data points to match the distribution of the target domain and train models based on obtained subsamples from the source domain, (b) Pseudo-labeling approaches (Ruder and Plank, 2018; Rotman and Reichart, 2019) which train a classifier based on source data initially and use it to predict labels on unlabeled target data towards further adapting the model, (c) Pivot-based methods (Blitzer et al., 2006; Ziser and Reichart, 2017) which aim to map different domains to a common latent space (where the feature distributions are close) by employing auto encoders and structural correspondence learning, and (d) Loss-based methods (Ganin and Lempitsky, 2015; Shen et al., 2018) which employ domain adversaries aiming to minimize the discrepancies between source and target data distributions. In this work, we employ loss-based approaches using a domain discriminator (Ganin et al., 2016) and Wasserstein distance (Shen et al., 2018) to enable domain adaptation for our COC models.

3 Dataset, Tasks & Settings

We use the LexGLUE ECtHR dataset provided by (Chalkidis et al., 2022b), which consists of 11k case fact descriptions along with target label information about which convention articles have been alleged to be violated (task B), and which the court has eventually found to have been violated (task A). The dataset is chronologically split into training (2001–2016), validation (2016–2017), and test set (2017–2019) with 9k, 1k, and 1k cases, respectively. The label set includes 10 prominent ECHR articles, which forms a subset of all the rights contained in the convention and its protocols. In both the ECtHR A and B benchmarks, it is assumed that the model classified the target from the fact description alone, which we refer to as the **fact classification variant**.

For our article-aware classification settings, we augment the dataset with the texts of the 10 articles copied from the publicly available ECHR convention document². We formulate the **article-aware prediction variant** for both tasks: Given both the case fact statements and a particular article information, the model should classify the binary outcome of whether an article has been alleged to be violated by the claimant (task B) or found to have been violated by the court (task A).

²https://www.echr.coe.int/documents/convention_eng.pdf

Our zero-shot transfer task then involves determining violation/allegation from case facts with respect to articles which are not seen during training time. We consider a ‘domain’ to be a particular convention article (i.e., 10 convention articles form 10 domains). The objective is to train a model on a source domain (seen articles) with the goal of performing well at test-time on a target domain (unseen articles). Following (Yin et al., 2019; Ramponi and Plank, 2020), we propose two settings under zero-shot COC:

Zero-Shot Restrictive / Unsupervised Domain Adaptation (UDA): In this setting, the model is given a pair of case facts and the text of training set articles (i.e., the source domain) along with their corresponding violation/allegation outcome label. In the target domain, it is provided with case facts and article text pairs as well, but the outcome label is withheld. The goal of UDA is to learn an outcome classifier from the outcome labelled source domain which should generalize well on the target domain by leveraging outcome-unlabelled target data. This setting is legally realistic, as the text of new or modified written legal sources is typically known for a given task and available for domain adaptation (e.g., a public administration decision support tool receives an update after relevant legislation has changed).

Zero-shot Wild / Any Domain Adaptation (ADA) / Out of Distribution Generalization: In this setting, the model never sees any article data from the target domain during training, yet should be able to generalize to it. In the legal setting, this corresponds to a model which is required to work with texts of sources only available at query time (e.g., complex retrieval settings where multiple legal sources potentially apply).

We reorganize the dataset to evaluate our zero-shot transfer/adaptation models by splitting the 10 ECHR articles into two non-overlapping groups, such that both contain articles of various frequencies (common, moderate, rare).

- *split_0*: 6, 8, P1-1, 2, 9
- *split_1*: 3, 5, 10, 14, 11

We evaluate UDA and ADA on *split_0* as source and *split_1* as target, and vice-versa.

4 Method

We employ a hierarchical neural model which takes the case fact description x along with the article

a as input and outputs a binary outcome (allegation in Task B and violation in Task A) for case x with respect to article a . Our architecture is a modified version of the Enhanced Sequential Inference Model (ESIM) (Chen et al., 2017) incorporating conditional encoding (Augenstein et al., 2016; Rocktäschel et al., 2016) that has been adapted to deal with long input sequences following hierarchical attention networks (Yang et al., 2016). We experiment with two domain adaptation components based on adversarial training: (1) a classification-based domain discriminator and (2) a Wasserstein-distance based method which aims to reduce the difference between the source and the target domain distributions.

4.1 Article-aware prediction Model

Given the facts of the case $x = \{x_1, x_2, \dots, x_m\}$ where $x_i = \{x_{i1}, x_{i2}, \dots, x_{in}\}$ and the article $a = \{a_1, a_2, \dots, a_k\}$ where $a_j = \{a_{j1}, a_{j2}, \dots, a_{jl}\}$, the model outputs a binary label. x_i / a_i and x_{jp} / a_{jp} denote the i^{th} sentence and p^{th} token of the j^{th} sentence of the case facts / article, respectively. m/k and n/l denote the number of sentences and tokens in the i^{th} sentence of case facts / article, respectively. Our model contains an encoding layer, followed by an interaction layer, a post-interaction encoding layer, and a classification header. See Fig. 1 for an overview of our architecture.

4.1.1 Pre-interaction Encoding Layer

Our model encodes the facts of the case x sentence-wise with LegalBERT (Chalkidis et al., 2020) to obtain token level representations $\{z_{i1}, z_{i2}, \dots, z_{in}\}$. These are aggregated into sentence level representations using token attention:

$$u_{it} = \tanh(W_w z_{it} + b_w) \quad (1)$$

$$\alpha_{it} = \frac{\exp(u_{it} u_w)}{\sum_t \exp(u_{it} u_w)} \quad \& \quad f_i = \sum_{t=1}^n \alpha_{it} z_{it} \quad (2)$$

where W_w, b_w and u_w are trainable parameters. The sentence level representations $\{f_1, \dots, f_n\}$ are passed through a GRU encoder to obtain context-aware sentence representations of the facts $h = \{h_1, h_2, \dots, h_m\}$. The analogous article encoder takes a as input and outputs $s = \{s_1, s_2, \dots, s_k\}$.

4.1.2 Interaction Layer

Interaction between the sentences of the case facts and articles is done via dot product attention between the two sequences of sentences as follows:

$$e_{ij} = h_i^T s_j \ \& \ h'_i = \sum_{j=1}^k \frac{\exp(e_{ij})}{\sum_{l=1}^k \exp(e_{il})} s_j \quad (3)$$

$$s'_j = \sum_{i=1}^m \frac{\exp(e_{ij})}{\sum_{l=1}^m \exp(e_{lj})} h_i \quad (4)$$

where e_{ij} represents the dot product interaction score between the context-aware representations of the i^{th} sentence of the case facts and the j^{th} sentence of the article. h'_i and s'_j represent article-aware representations corresponding to the i^{th} sentence of the case facts and the fact-aware representation corresponding to the j^{th} sentence of the article, respectively. Finally, we obtain interaction-aware sentence representations of the facts $h' = \{h'_1, h'_2, \dots, h'_m\}$. Similarly for the article, we obtain $s' = \{s'_1, s'_2, \dots, s'_k\}$

4.1.3 Post-Interaction Encoding Layer

The article-dependent final representation of the case facts is obtained in two steps: (i) we compute the final representation of the article text and (ii) use it as a conditional encoding (Augenstein et al., 2016; Rocktäschel et al., 2016) to obtain the final article-dependent fact representation.

Final representation of article: We first combine the pre-interaction sentence encodings and fact-aware sentence representations of the article:

$$p_i = [s_i, s'_i, s_i - s'_i, s_i \odot s'_i] \quad (5)$$

where \odot denotes element-wise product. This representation aims to capture high-order interaction between the pre- and post- interaction elements (Chen et al., 2017). The sentence representations p_i are passed over a non-linear projection and a GRU (as in the pre-interaction encoder) to perform context-level modelling among sentence sequences. The final article representation A is obtained via sentence attention analogous to eq. 2.

Final Representation of Case Facts: Similarly, we pass the combined representation of case facts using pre- and post- interaction similar to Eq. 5 over a non linear projection, a GRU layer, and sentence level attention to the obtain article-dependent final representation of case facts. To ensure conditioning, we initialize the GRU hidden state with the final representation of the articles A . This facilitates capturing the salient case fact information with respect to the specified article.

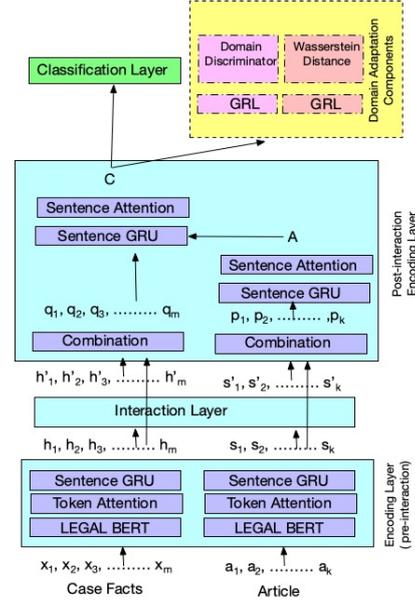

Figure 1: Our article-aware prediction model architecture

4.1.4 Classification Layer

We pass the article-dependent final representation of the case facts through a nonlinear projection to classify the outcome.

4.2 Domain Adaptation Components

Domain Adaptation aims to make models generalize well from a source to a target domain. Both domains are mapped to a common latent space, reducing differences between their distributions and facilitating domain invariant feature representations. In our case of article-aware COC, we regard reasoning with respect to every ECHR article as a domain and seek to learn article-invariant case facts representations. Put differently, we want our model to learn how to read two texts and interrelate them towards an outcome determination (as lawyers do) with minimal encoding of the information contained in the texts into the model itself. This way, the models can achieve generalization capability to adapt and perform reasoning with regard to articles not seen during training time.

4.2.1 Domain Discriminator

We employ a two layer feed forward network as a discriminator which takes the article-dependent case fact representation as input to predict the article (i.e., the domain). We train the discriminator in an adversarial fashion to maximize the model’s ability to capture information required for the outcome task while minimizing its ability to

predict the article. This guides the model to generate article-invariant feature representations and improves transferability. Following (Ganin and Lempitsky, 2015; Ganin et al., 2016), we perform a min-max game adversary objective optimization using a gradient reversal layer (GRL) between the feature extractor and discriminator. It acts as the identity during the forward pass but, during the backward pass, scales the gradients flowing through by $-\lambda$, making the feature extractor receive the opposite gradients from the discriminator. The overall objective function reduces to:

$$\arg \min_{\theta_F, \theta_C, \theta_D} [L_c(C(F(x, a)), y_e) + \lambda L_d(D(\text{GRL}(F(x, a))), y_a)] \quad (6)$$

where L_c, L_d represents the loss function corresponding to classifier and domain discriminator, respectively, λ is the GRL hyperparameter, x is the input, y_e is the outcome label, y_a is the class-id of the article, F, C and D represents feature extractor, classifier, and discriminator with parameters θ_F, θ_C and θ_D , respectively. In case of UDA (where the model has access to the text of target domain articles), we discriminate among all the source and target articles. While in case of ADA, we discriminate among source articles only.

4.2.2 Wasserstein Method (Distance based)

Our second method aims to reduce the Wasserstein distance (Shen et al., 2018) between different domain feature distributions. In a given batch, the final feature representations will be fed into the domain critic (Arjovsky et al., 2017), which is a feed-forward network whose output is a single scalar for each batch element. These scalars are then averaged per domain in the batch, resulting in two numbers representing source and target domains, respectively. Their difference can be considered an approximation of the Wasserstein distance between the two feature distributions and becomes the Wasserstein loss component of the network. If the domain critic neural network satisfies the constraint of the Lipschitz-1 continuous function, we calculate the approximate empirical Wasserstein distance by maximizing the following domain critic loss:

$$L(X_p, X_q) = \frac{1}{n_p} \sum_{x_p \in X_p} f_w(F(x_p)) - \frac{1}{n_q} \sum_{x_q \in X_q} f_w(F(x_q)) \quad (7)$$

where f_w, F denote the Wasserstein domain critic and feature extractor, respectively, X_p and X_q de-

Table 1: Fact Classification vs Article-aware prediction Performance on Task A and Task B. mic. and mac. indicates micro-F1 and macro-F1 scores, respectively.

Model	Task B		Task A	
	mac.	mic.	mac.	mic.
Fact Classification	71.96	77.40	61.21	72.21
Article-aware pred.	74.14	78.49	67.09	74.77

note datasets from two domains p and q with n_p and n_q samples, respectively.

During optimization, a gradient reversal layer (Ganin et al., 2016) between the feature extractor and domain critic ensures that (a) the domain critic weights are updated such that the Wasserstein loss becomes maximal, while the encoder weights are updated towards minimizing it. Through this procedure, we encourage the model to learn feature representations that are invariant to the covariate shift between the source and the target domain. Since the Wasserstein distance is continuous and differentiable everywhere, we can train the domain critic end-to-end. In case of UDA, we minimize the distance between the source and the target domains, while in case of ADA, we minimize among the different source domains. To enforce the Lipschitz constraints, we clip the weights of the domain critic within a compact space $[-c, c]$ after each gradient update following (Arjovsky et al., 2017).

5 Experiments & Discussion

5.1 Baseline

For the **fact classification variant**, we employ an architecture similar to the article-aware prediction model but reduced to the case fact based encoding without the interaction mechanism. The output layer is modified to 10 classes and trained against a multi-hot target vector using a binary cross entropy loss. Notably, we freeze the weights in the LegalBERT sentence encoder, both to save computational resources and to reduce the model’s susceptibility to shallow surface signals and ensure the comparability of our domain adaptation methods. We describe the detailed hyperparameters for the article-aware prediction model in Appendix Sec. A

5.2 Does Article-aware Classification Perform Better than Fact-only Classification?

Micro-F1 and macro-F1 scores for both tasks A and B with regard to the 10 target articles are given in Table 1. The article-aware model performs better than fact-only classification across the board. In

Table 2: Task B F1 performance of baseline and domain adaptation models

Setting	Model	Transfer 0 → 1				Transfer 0 ← 1			
		source : <i>split_0</i>		target : <i>split_1</i>		source : <i>split_1</i>		target : <i>split_0</i>	
		mac.	mic.	mac.	mic.	mac.	mic.	mac.	mic.
Baseline	Source only	73.45	75.63	7.32	7.37	70.26	77.10	8.49	9.08
UDA	Domain Disc.	73.81	76.95	13.92	14.94	70.63	77.43	22.50	26.27
	Wasserstein	69.63	74.86	13.17	18.16	66.89	75.21	20.78	30.30
ADA	Domain Disc.	73.76	76.13	9.62	10.77	69.71	76.85	9.30	10.45
	Wasserstein	70.17	74.80	9.14	9.89	67.46	75.25	9.26	10.38

particular, we notice a greater improvement in the macro-F1 score, indicating the article-aware classification approach helps the model to improve performance for sparser articles which are not prominently represented in the case distribution. We conjecture that this performance difference can be explained with article-aware classification being subjected to a different training regime. In fact-only classification, a given case’s fact text will always be associated with the same multi-hot outcome vector. By contrast, in the fact-aware setting, it will occur multiple times alongside different article texts and the model is forced to predict a single binary outcome variable. This seems to lead the model away from shallow signals towards capturing fact-article correspondence, resulting in a better model. Additionally, the beneficial effect is greater for the harder task of violation classification.

5.3 Does Domain Adaptation Help to Improve Zero Shot Transferability ?

We evaluate UDA and ADA on both Task A and Task B with the two article splits. A baseline *source only* model is trained without domain adaptation using the labelled source data only and tested on the target test data directly. Tables 2 and 3 show the performance of different models with our two splits on task B and A, respectively.

Baseline vs Domain Adaptation: From both tables, we observe that the performance of the *source only* model on target data is lower compared to their domain adaptation counterparts with a significant margin. This indicates that, intuitively, models trained on source data without any adaptation do not generalize to unseen articles. This also highlights the need to have domain adaptation components to achieve a generalizable model.

UDA: Under unsupervised domain adaptation, we observe that the Wasserstein distance method performs better on target data than the Domain Discriminator in micro-F1 by a significant margin. It also improved macro-F1 marginally in Task A tar-

get data, but is inferior in Task B. Most strikingly, however, Wasserstein performance on source data is lower than the source only baseline across the board, especially with respect to macro-F1. These observations also indicate that the Wasserstein distance method is able to transfer well to certain articles more than others. This can be attributed to the method influencing feature representations towards a reduction of the mean difference across articles. The distribution of target articles which are closer to the source articles distributions might have gained well. We further validate this hypothesis using an experiment illustrated in sec 5.5. On source data, the Domain Discriminator performed better than the source only model, albeit by very small margins but consistent across the tables.

ADA: On target data, both the Domain Discriminator and Wasserstein distance are comparable across the tables in both metrics. With respect to source data, in task B, the Domain Discriminator performed better than the Wasserstein distance method in both micro and macro F1. Strikingly, in Task A, Wasserstein performance on source data picks up in micro-F1 (slightly even better than source only baseline) but stays behind in macro-F1.

ADA vs UDA: Unsurprisingly, the performance on target data under ADA tends to be lower compared to UDA due to no access to target article information in this setting compared to UDA.

The absolute performance levels on the target data immediately suggest that the zero-shot transfer task we propose is very difficult and the discrepancy of performance between source and target data is still large, even in the case of domain adaptation components. This indicates ample opportunity for further research on neural models capable of reasoning with legal text in a way that transfers well to unseen legal domains. Some of the source-target performance divergence can likely be attributed to the model falling prey to spurious correlations that exist in the data, which is especially prominent in the ECtHR datasets that suffer from fact statements

not being finalized until the case outcome is known (see our prior work in Santosh et al. 2022). Given this limitation, our zero-shot framework serves as a challenging benchmark in the development of legal NLP models that learn to interrelate case facts and legal source text towards supporting domain experts.

5.4 How does Encoder Pre-Training influence Zero-Shot Transferability?

We conduct an additional experiment on Task A with *split_1* as source and *split_0* as target, where we replace LegalBERT embeddings used in the encoding layer with BERT base embeddings (Kenton and Toutanova, 2019), and report its performance in Table 4. Comparing it to Transfer 0 \leftarrow 1 in Table 3, we observe that the BERT base model performs worse on target data than the LegalBERT encoder. In particular, the best performing Wasserstein domain adaptation model drops from 26.2 to 16.36, much more than the Domain Discriminator. We leave an exploration of this asymmetric effect of the pre-training regime across different domain adaptation strategies to future work.

Base BERT performs similarly on the source domain. This indicates that even a non-legally pre-trained encoder can be harnessed to reach comparable in-domain performance. However, to generalize to unseen target articles, domain specific pre-training is beneficial. It should be noted that LegalBERT (Chalkidis et al., 2020) has been pre-trained on a collection of ECtHR decisions that may include cases from LexGLUE’s test partition, thereby possibly injecting domain-specific information about the target articles into the encoding.

5.5 How does Article Relatedness Affect Zero-Shot Transferability?

To test whether article relatedness between source and target domains affect performance, we experiment with Article P1-1 (Article 1 of Additional Protocol 1 - The Protection of Property) as the target domain. This simulates the realistic scenario of our zero shot setting where the convention is amended with an additional protocol. We then constructed one related and one unrelated source domain based on the suggestion provided by a legal expert (the second author) while ensuring training sets of similar size. The related domain consists of articles 6 (right to a fair trial) and 8 (right to respect for private and family life). The unrelated domain articles comprise articles 2 (right to life), 3

(prohibition of torture, and 5 (right to liberty and security).

We report the performance on Task A for target P1-1 in Table 5. We observe that the related source domain is able to perform better across the board, confirming the intuition that relatedness between source and target is an important factor to be considered when training a model for transferability. As before, we observe that UDA achieves higher performance overall as it has the chance to see article P1-1 during training. Interestingly, we observe the Wasserstein method outperforming the Domain Discriminator for the related source, but vice versa for the unrelated source. We believe this is owed to related articles forming similar feature distributions and thereby making it easy for the Wasserstein distance to facilitate adaptation. This case study suggests the design of domain adaptation components which derive information more from related articles than unrelated ones when transferring to a target article. This raises a related question of how article relatedness could be determined by the model itself rather than a priori by an expert.

6 Conclusion

We cast case outcome classification on ECtHR data into an article-aware architecture. This configuration is inspired by realistic legal reasoning involving both the case facts and convention articles to determine possible allegations/violations. Assuming non-finetuned pre-trained encoders, we observe a performance improvement over a simple fact-only classification model. It also enables us to conduct experiments in zero shot transfer COC with and without access to unlabeled target data during domain adaptation. While we show that domain adaptation techniques are in principle suitable to facilitate generalization, the divergence between source and target domain performance is large and this task variant is very difficult. We further observe that the effectiveness of domain adaptation interacts with law-specific pre-training of transformer-based encoders and with the relatedness of the source and target domains. Overall, this zero-shot COC task formulation opens up new research opportunities towards legal NLP models that are more aligned with expert reasoning.

Limitations

We cast the legal judgment prediction task into an article-aware classification setting and create a

Table 3: Task A F1 performance of baseline and domain adaptation models

Setting	Model	Transfer 0 → 1				Transfer 0 ← 1

zero-shot benchmark on a corpus of ECtHR cases. Matching between the text of legal sources and case fact descriptions varies greatly between different legal systems and subdomains, and is highly dependent on the textual nature of the case fact and legal sources. Specific to our context, for example, we have discussed the ECtHR fact statements as being influenced by the eventual case outcome and not suitable for prospective prediction in sec 1. COC as article-aware classification in other jurisdictions will likely lead to different levels of task difficulty, absolute performance, and zero shot transferability. In particular, many legal areas require multiple sources to be applied in conjunction to a set of case facts.

Technically, a major hurdle dealing with corpora related to the legal domain is their lengthy nature. We resort to hierarchical models, which are inherently limited in that tokens across long distances cannot directly attend to one another. This restriction of hierarchical models is still underexplored (but see preliminary work in, e.g. Dai et al. 2022; Chalkidis et al. 2022a). Additionally, we freeze the weights in the LegalBERT sentence encoder, both to save computational resources and to reduce the model’s susceptibility to shallow surface signals

and ensure the comparability of our domain adaptation methods, in particular with respect to the impact of domain-specific pre-training. We leave an exploration of COC as article-aware classification with fine-tuned encoders for future work.

Ethics Statement

We experiment with a publicly available datasets of ECtHR decisions, which has been derived from the public court database HUDOC³. These decisions contain real names of the parties involved without any anonymization. We hence do not consider our experiments to produce any additional harmful effects relating to personal information.

The task of legal judgment prediction raises ethical, civil rights, and legal policy concerns, both general and specific to the European Court of Human Rights (e.g., (Fikfak, 2021) on system bias and court caseload). The main premise of this work is to make incremental technical progress towards enabling systems to work with case outcome information in a way that is aligned with how human experts analyze case facts through an interplay with complex legal sources. We do not advocate for the practical application of COC/LJP systems by courts, but rather explore how their core functionality of processing legal text can be made as expert-aligned as possible. Our research group is strongly committed to research on such models as a means to derive insight from legal data for purposes of increasing transparency, accountability, and explainability of data-driven systems in the legal domain.

We are conscious that, by adapting pre-trained encoders, our models inherit any biases they contain. Similarly, the ECtHR case collection as historical data may contain a data distribution in which sensitive attributes of individuals (e.g., applicant gender) may have some predictive signal for the allegation/violation variable (see, e.g., (Chalkidis et al., 2022c)). We believe the results we observe

³<https://hudoc.echr.coe.int>

in our COC experiments to not be substantially related to such encoded bias. However, legal NLP systems leveraging case outcome information and intended for practical deployment should naturally be scrutinized against applicable equal treatment imperatives regarding their performance, behavior, and intended use.

All models of this project were developed and trained on Google Colab. We did not track computation hours.

The sentence level GRU encoder dimension is 200 (i.e. 400 bidirectional), and the sentence level attention vector dimension is 200. The entailment classifier hidden layer also has size 200. Domain discriminator and critic have two layered networks with hidden layers of size 200 and 100. The entailment classifier is trained with a binary cross entropy loss while the domain discriminator is trained with cross entropy loss over a one-hot domain vector. The model is optimized end-to-end using Adam (Kingma and Ba, 2015). The dropout rate (Srivastava et al., 2014) in all layers is 0.1. To handle data skewness in the entailment setup, we employ a custom batch sampler which ensures every batch contains 4 different articles as well as 2 positive and 2 negative instances per article. Our batch size is 16. We employ a learning rate scheduler based on loss plateau decay. For adversarial training using GRL, following (Ganin and Lempitsky, 2015), we set the λ in gradient reversal to be $\lambda = \frac{2}{1+\exp(-\gamma p)} - 1$ where $p = \frac{t}{T}$, where t and T denote current training step and total training steps. γ is determined using a grid search over [0.05, 0.1, 0.15, 0.2]. We employ a 10 class domain discriminator (5 from source and 5 from target) in the case of UDA and a 5 class discriminator in the case of ADA. We reduce the mean between instances of a particular article of source and target in the case of UDA. In the case of ADA, we reduce the mean between instances of different articles in the source domain.

A Implementation Details

We employ a maximum sentence length of 256 and document length (number of sentences) of 50. Our word level attention context vector size is 300.

Abstractive Document Summarization with Summary-length Prediction

Abstract

Recently, we can obtain a practical abstractive document summarization model by fine-tuning a pre-trained language model (PLM). Since the pre-training for PLMs does not consider summarization-specific information such as the target summary length, there is a gap between the pre-training and fine-tuning for PLMs in summarization tasks. To fill the gap, we propose a method for enabling the model to understand the summarization-specific information by predicting the summary length in the encoder and generating a summary of the predicted length in the decoder in fine-tuning. Experimental results on the WikiHow, NYT, and CNN/DM datasets showed that our methods improve ROUGE scores from BART by generating summaries of appropriate lengths. Further, we observed about 3.0, 1.5, and 3.1 point improvements for ROUGE-1, -2, and -L, respectively, from GSum on the WikiHow dataset. Human evaluation results also showed that our methods improve the informativeness and conciseness of summaries.

1 Introduction

Current abstractive summarization models mostly utilize pre-trained language models (PLMs) (Liu and Lapata, 2019; Dou et al., 2021; Liu and Liu, 2021; Narayan et al., 2021; Liu et al., 2022a). Abstractive document summarization requires an encoder to determine the important parts in an input text and a decoder to output a non-redundant summary of the appropriate length relevant to the input. Thus, the characteristics required for an abstractive summarization model differ from those required as a language model, and are not usually considered in the pre-training for PLMs (Devlin et al., 2019; Zhang et al., 2019; Lewis et al., 2020). Hence, we need to fine-tune a PLM with a summarization dataset to treat it as an abstractive summarization model. Unlike training a randomly initialized model, this fine-tuning maintains and inherits the

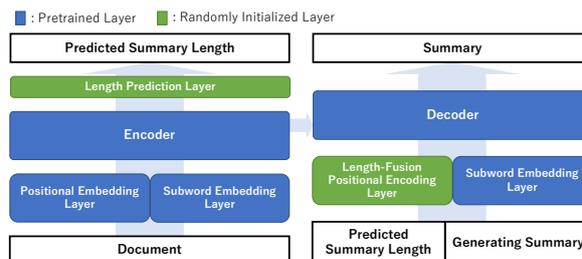

Figure 1: Overview of our methods. The length prediction layer predicts the summary length. The length-fusion positional encoding layer controls the decoder to generate a summary of the appropriate summary length.

parameters learned as an original language model. Therefore, to learn an abstractive summarization model by fine-tuning a PLM, it is necessary to suppress its characteristics as a language model while enabling it to learn the unique properties of abstractive summarization.

For this purpose, we propose two regularization methods for fine-tuning a PLM to learn abstractive summarization. Figure 1 shows an overview of our methods. The first method is a regularization method that uses the encoder’s hidden states to predict the length of an output summary. When the length is not given for a summary to be generated, we believe it is difficult to determine what volume of important key contents to select from the original document. Thus, fixing the length for a summary can make it easier to select key contents for it. We think humans can also create more informative and concise summaries when a summary length is given. The system should also be better trained for selecting key contents in the original document for a summary in case when it can be provided with the length of the summary.

The second method provides the decoder with the length predicted by the first method and enables it to learn to output a summary of the length. In addition to regularizing the training of the decoder, this method reduces the search space by searching

only for summaries of the appropriate length during generation, and so it is expected to produce a concise and informative summary. Although there have been studies on adjusting the output length of summaries, they have focused on controlling the output length for a given desired length (Kikuchi et al., 2016; Liu et al., 2018; Takase and Okazaki, 2019; Makino et al., 2019; Saito et al., 2020; Yu et al., 2021).¹ We incorporate a target-length prediction task to the encoder side and then inject the predicted length to the decoder side to generate the final summary.

In an evaluation on the WikiHow, NYT, and CNN/DM datasets, our methods improve the ROUGE scores of BART with appropriate lengths of summaries. On the WikiHow dataset, the performance improvement reached about 3.0, 1.5, and 3.1 points for ROUGE-1, -2, and -L, respectively, from GSum. Human evaluation results also showed that our methods enable the fine-tuning for a PLM to generate informative and concise summaries.

Our contributions are as follows: (1) We propose a regularization method that uses the encoder’s hidden states by predicting the length of a summary. (2) We propose a regularization method that reduces the search space by injecting the predicted length of a summary. (3) Both automatic and human evaluation results show that our novel model that combines (1) and (2) can generate a summary closer to its gold summary length by improving informativeness.

2 Our Methods

We apply our regularization methods to a transformer-based (Vaswani et al., 2017) PLM to generate a summary from a given document.

2.1 Predicting Summary Length

We impose summary-length prediction on the encoder during fine-tuning to make it easier for the encoder to determine how much important information the given document contains. The encoder converts a sequence of n tokens in a document $\mathbf{x} = \{x_1, x_2, \dots, x_n\}$ into hidden states $\{h_1, h_2, \dots, h_n\}$. Note that h_n is a hidden state of an end-of-document symbol x_n .

Then, we propose the length-prediction layer by using h_n and a 2-layer feed-forward neural network u to predict the summary length, which is the

number of subwords in the summary, as follows:

$$\ell_{pred} = u(h_n). \quad (1)$$

After that, by using the root-mean-square error (RMSE), the regularization loss for the encoder \mathcal{L}_{len} is calculated as follows:

$$\mathcal{L}_{len} = \sqrt{(\ell_{pred} - \ell_{gold})^2}, \quad (2)$$

where ℓ_{gold} is the gold length of the target summary.

2.2 Generating a Summary with the Predicted Length

We provide the decoder with the predicted summary length to generate a concise summary of the appropriate length relevant to the given document.

To encode the information of the predicted length into the decoder while keeping its pre-trained information, we insert our Length-Fusion Positional Encoding layer (LFPE), which is a transformer layer, before the decoder. Our LFPE consists of the length-ratio positional encoding (LRPE) (Takase and Okazaki, 2019) and a transformer layer. LRPE converts the position information of an output token y_t at time t to a continuous vector p_t with considering the predicted length ℓ_{pred} as follows:

$$p_t = \begin{cases} \sin(t/\ell_{pred}^{2i/dim}) & (i \equiv 0 \pmod{2}) \\ \cos(t/\ell_{pred}^{2i/dim}) & (i \equiv 1 \pmod{2}), \end{cases} \quad (3)$$

where dim is the dimension size of the embedding.

Then, the transformer layer converts $\{p_1, p_2, \dots, p_t\}$ into $E_t = \{e_1, e_2, \dots, e_t\}$ at a decoding time-step t . When adopting LFPE, we replace the original sinusoidal positional encoding of the pre-trained decoder with E_t . After that, the decoder calculates the output probability of y_t as $P(y_t|y_{t-1}, \dots, y_1, \mathbf{x}, \ell_{pred})$.

Finally, the regularization loss for the decoder \mathcal{L}_{gen} is calculated as follows:

$$\mathcal{L}_{gen} = -\sum_{t=1}^m \log P(y_t|y_{t-1}, \dots, y_1, \mathbf{x}, \ell_{pred}), \quad (4)$$

where m is the number of tokens in the target summary. Note that we replace ℓ_{pred} with ℓ_{gold} in the decoder during training.

¹Previous work assumes the desired length is given.

Dataset	Training	Valid	Test
WikiHow	168,126 (47.2)	6,000 (45.2)	6,000 (45.4)

Table 2: Experimental results on WikiHow, NYT, and CNN/DM. † indicates the improvement is significant ($p < 0.05$) compared with the best baseline score (underlined) on each dataset. * indicates the reported score in the original paper. AVG indicates the average generated summary length.

2.3 Objective Function

To balance the encoder and decoder regularization, we sum the two losses through a hyperparameter λ for calculating the final loss as follows:

$$\mathcal{L} = \mathcal{L}_{gen} + \lambda \cdot \mathcal{L}_{len}. \quad (5)$$

3 Experiments

3.1 Experimental Settings

Datasets: We used WikiHow (Koupae and Wang, 2018) in the knowledge base domain and NYT² (Sandhaus, 2008) and CNN/DM (Hermann et al., 2015) in the news domain. Table 1 shows the dataset statistics.

Evaluation Metrics: We used F-scores of ROUGE-1 (R-1), -2 (R-2), and -L (R-L) in our experiments. To evaluate the quality of the predicted length and the length-controllability, we employed

²Detailed pre-processing steps are described in Appendix A.

the length variance (VAR): $\text{VAR} = 0.001 \times \frac{1}{n} \sum_{i=1}^n |y_{\text{pred}} - y_{\text{gold}}|$, where y_{pred} is the length of the generated summary and y_{gold} is the length of the reference summary in word level, respectively.

Compared Methods: We used BART-large (Lewis et al., 2020) for constructing baselines and our models by following the previous work (Dou et al., 2021). The proposed models are as follows. **BART w/ R_{enc}** employs our method only for the encoder in §2.1. **BART w/ R_{enc+dec}** employs our methods both for the encoder and the decoder. The baseline models are as follows. **BART** and **PEGASUS** (Zhang et al., 2019) are the original pre-trained BART and PEGASUS. **GSum** (Dou et al., 2021) is a BART-based combination model that utilizes extracted sentences as a guidance signal to consider extractive aspects for a summary. For the guidance signal, it uses the MatchSum model (Zhong et al., 2020).

We followed the hyperparameters of **BART** and **GSum** for training and testing the baselines and our models. We set λ to 0.1, 0.05, and 0.05 for WikiHow, NYT, and CNN/DM, respectively, on the basis of validation performances.³

3.2 Automatic Evaluation

The results are shown in Table 2. We can see that both of our models, BART w/ R_{enc} and BART w/ R_{enc+dec}, showed significant improvement in ROUGE scores over BART on WikiHow. These scores were higher than the combination model of GSum and PEGASUS (Zhang et al., 2019), which yields the current best results reported on WikiHow. We analyzed relations between lengths and ROUGE scores. When our BART w/ R_{enc+dec} predicted summary lengths closer to gold summary lengths than BART, 95.4% of generated summaries from ours obtained higher R-1 scores than BART. In addition, VAR and AVG scores show that our models can generate summaries closer to the gold summary lengths and can actually reduce the search space in decoding steps. These results indicate that the proposed methods enable BART to generate highly abstractive summaries of appropriate lengths.

We can also confirm that the proposed methods improved summarization performance over BART on NYT⁴ and CNN/DM. We can also see that

³Further details are described in Appendix B.

⁴There is no reported result for PEGASUS on NYT. For GSum, since the pre-processing could not be made identical, the reported and our scores were a bit different.

Model	WikiHow		CNN/DM	
	Info	Con	Info	Con
GSUM	-	-	3.97	4.02
BART	4.00	4.22	3.98	4.02
BART w/ $R_{enc+dec}$	4.09 [†]	4.19	4.05 [†]	4.07

Table 3: Human evaluation results. The notations are the same as in Table 2.

our model BART w/ $R_{enc+dec}$ showed significant improvement in ROUGE scores over GSUM on NYT. Although GSUM outperformed our BART w/ $R_{enc+dec}$ in ROUGE scores on CNN/DM, it could generate summaries closer to the gold summary lengths.

Thus, we tried to investigate what types of datasets our methods can work better on and found that the variance of reference summary lengths might be related to the performance of our models. Based on the observations from Tables 1 and 2, our BART w/ $R_{enc+dec}$ can largely improve performances on summarization datasets with a high variance of summary lengths, such as WikiHow and NYT.

3.3 Human Evaluation

For human evaluation, we sampled 100 documents each from WikiHow and CNN/DM. By using Amazon Mechanical Turk, we assigned 40 evaluators who obtained both US high school and US bachelor’s degrees to each dataset for grading the results with scores from 1 to 5 (5 is the best) in terms of informativeness (Info) and conciseness (Con).

Table 3 shows the results. These results indicate that BART w/ $R_{enc+dec}$ generated more informative summaries than BART, that is consistent with the results from the automatic evaluation. In some cases, the generated summaries with BART are just short summaries on WikiHow due to a high variance of reference summary lengths, and so the Con score is slightly lower than the one for BART w/ $R_{enc+dec}$. However, BART w/ $R_{enc+dec}$ yields the best overall Info and Con scores, which shows our regularization methods are essential for fine-tuning a PLM to learn abstractive summarization models. We also evaluated GSUM together. BART attained a 0.01 better score for Info than GSUM even on CNN/DM since GSUM focuses on generating faithful summaries with injecting outputs from an extractive summarization model.

We investigated the tendency of the length of generated summaries. Figure 2 shows the relation-

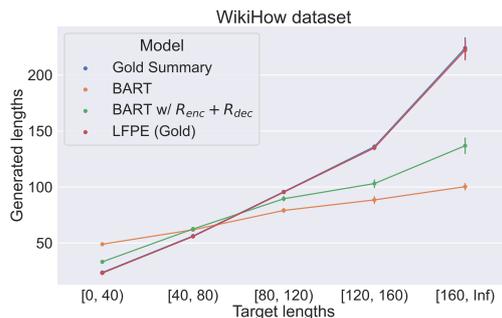

Figure 2: For x-axis, we divided the gold target lengths into 5 bins with 40 words interval. Y-axis indicates the length of generated summaries.

BART use this method if you have a digital multimeter with a diode check function. set your multimeter to resistance mode. plug the leads into the correct ports. disconnect the diode from the circuit. touch the leads in the forward-bias direction. lower the resistance range if the result is 0. test the resistance in the reverse direction. test a new diode or a working diode.

BART w/ $R_{enc+dec}$ set your multimeter to resistance mode. plug the leads into the multimeter. disconnect the diode from the circuit. touch the leads in the forward-bias direction. test in the reverse direction. try a new diode.

Gold use this method when necessary. set your multimeter to resistance mode. plug in the leads. disconnect the diode. measure the forward bias. measure the reverse bias. compare to a working diode.

Table 4: Example summaries generated from BART w/ $R_{enc+dec}$, BART, and gold summaries on WikiHow.

ship between gold and generated summary lengths for each model. We used WikiHow because it contains various target summary lengths. When we injected the gold summary length, the length of generated summaries from LFPE (Gold) was almost the same as the gold summaries. These results indicate that LFPE can precisely control various output lengths.⁵ In addition, generated summary lengths from BART w/ $R_{enc+dec}$ show that the length-prediction layer can also predict various target summary lengths.

Table 4 shows example generated summaries with BART w/ $R_{enc+dec}$, BART, and gold summaries on WikiHow. The summary length prediction is essential for creating an informative and concise summary that is closer to the gold summary length.

4 Related Work

In summary length control, previous work mostly focuses on controlling models for generating summaries with a predefined length (Kikuchi et al.,

⁵Further details are described in Appendix C.

2016; Liu et al., 2018; Takase and Okazaki, 2019; Makino et al., 2019; Saito et al., 2020; Yu et al., 2021). Our work is novel because it enables a model dynamically predicts the appropriate summary length from the input text without relying on any predefined length.

From the viewpoint of regularization, we can see such a regularization term like L_{len} in recent works of summarization tasks. Kamigaito et al. (2018); Kamigaito and Okumura (2020) in sentence compression and Ishigaki et al. (2019) in extractive document summarization incorporate dependency tree information into the attention (Kamigaito et al., 2017). Hsu et al. (2018) integrate extractive and abstractive summarization. MatchSum (Zhong et al., 2020) considers the semantic similarity between a document and its extracted summary. BRIO (Liu et al., 2022a) takes multiple similar abstractive summaries into account by contrastive learning in sequence-to-sequence (Edunov et al., 2018). Different from these works, our approach focuses on summary lengths through L_{len} and can be incorporated into these works by adding L_{len} to their loss function.

5 Conclusion

To fine-tune a pre-trained language model for abstractive document summarization, we proposed a regularization method that uses the encoder’s hidden states to predict the length of an output summary. We also proposed LFPE, that focuses on generating a summary with a given target length while keeping pre-trained information of the transformer-based model. We used LFPE to regularize the decoder during training to generate a summary with the predicted length.

Automatic evaluation results showed that the proposed methods enable BART to generate summaries of appropriate lengths while improving ROUGE scores. Human evaluation results also showed that the proposed methods enable BART to generate more informative and concise summaries.

6 Limitations

Although our models can largely improve performances on datasets with a high variance of summary lengths, the gain was small for datasets with a low variance of summary lengths. In the future, we will consider external resources to predict a summary length for the datasets with a low variance of target summary lengths. We plan to form document

clusters based on each topic since different topics may have different reference lengths. We believe this may improve performances for the datasets with a low variance of summary lengths.

A Statistics of the datasets

NYT dataset consists of articles from the New York Times and the associated summaries.⁶ we followed the previous preprocessing step and splitting (Kedzie et al., 2018). There are two types of the reference summaries, which are archival abstracts and online teaser means. From this collection, we take all articles that have a concatenated summary length of at least 100 words.

B Model details

We introduce the detailed information of the baseline and our models.

We used Fairseq⁷ (Ott et al., 2019) for the model implementation. As the pretrained weight, we used bart-large in huggingface⁸. We used the original implementation for GSum⁹. We ran training for the models on two NVIDIA Tesla V100 with the multi-GPU setting. As described in the experimental settings, all hyperparameters were the same as for the large-scale BART in Lewis et al. (2020). Hyperparameter λ was set to 0.1, 0.05 and 0.05 for the WikiHow, CNN/DM, and NYT datasets, respectively, on the basis of validation performances.

Model	R-1	R-2	R-L	VAR
GOLC* (Makino et al., 2019)	38.27	16.22	34.99	5.13
PALUS* (Yu et al., 2021)	39.82	17.31	36.20	0.01
LPAS* (Saito et al., 2020)	43.23	20.46	40.00	-
PtLAAM* (Liu et al., 2022b)	44.17	20.63	40.97	-
BART	44.48	21.41	41.19	0.78
LRPE (Takase and Okazaki, 2019)	<u>45.67</u>	22.11	<u>42.20</u>	0.03
LFPE (Our)	45.93[†]	22.30	42.44[†]	0.03

Table 5: Experimental results on CNN/DM with using the gold summary length information. The notations are the same as in Table 2.

Δ	Generated Summary
+1	She and her husband are celebrating their 10th wedding anniversary.
0	She and her husband are celebrating their 10th anniversary.
-1	She and her husband are now married 10 years.

Table 6: Example summaries generated from BART with LFPE for different lengths on CNN/DM. $\Delta = +1/-1$ indicates the injected length is larger/smaller than the gold summary.

C Length-controllability

We investigated the length-controllability of our LFPE in §2.2 by comparing it with the original BART and LRPE. We also compared these methods with the previously reported scores of GOLC, PALUS, LPAS, and PtLAAM. We used CNN/DM and gave the gold summary length to the models by following the previous work. The results in Table 5 show that LFPE outperformed other methods in terms of ROUGE scores and VAR. Thus, our LFPE can control the output summary length while keeping ROUGE scores and outperform the state-of-the-art length-controllable methods.

Next, we analyzed the effect of length-controllability in actually generated summaries in CNN/DM. Table 6 shows example generated summaries with injecting different lengths into LFPE. In this example, when there is no possibility of dropping a subword, our model paraphrases “10th” to “10” while maintaining the informativeness and grammaticality. From this observation, we can understand that our LFPE controls the summary length through subword-based paraphrasing, which is supported by the decoder’s ability of abstraction.

Hierarchical Label Generation for Text Classification

Abstract

Hierarchical text classification (HTC) aims to assign the most relevant labels with the hierarchical structure to an input text. However, handling unseen labels with considering a label hierarchy is still an open problem for real-world applications because traditional HTC models employ a pre-defined label set. To deal with this problem, we propose a generation-based classifier that leverages a Seq2Seq framework to capture a label hierarchy and unseen labels explicitly. Because of no available social media datasets that target at HTC, we constructed a new (**Blog**) dataset using pairs of social media posts and their hierarchical topic labels. Experimental results on the **Blog** dataset showed the effectiveness of our generation-based classifier over state-of-the-art baseline models. Human evaluation results showed that the quality of generated unseen labels outperforms even the gold labels.

1 Introduction

Hierarchical text classification (HTC) aims to assign the most relevant labels with their structure for a given document. Because real-world applications categorize documents into a structured class hierarchy sequence (Silla and Freitas, 2011), such as patent collections (Tikk et al., 2005), web content collections (Dumais and Chen, 2000), and medical record coding (Cao et al., 2020), it is needed to capture the label hierarchy for better categorization.

To solve the HTC task, recent work has focused on enhancing label embeddings with a taxonomic hierarchy (Cao et al., 2020; Zhou et al., 2020; Wang et al., 2021) or considering a sequential classification approach (Rivas Rojas et al., 2020; Yang et al., 2018, 2019) that leverages a Seq2Seq framework to capture the label hierarchy. Despite the previous methods being successful, their approaches classify labels sequentially by choosing them from the pre-defined label set in the training dataset. It is still an open problem for real-world applications to handle

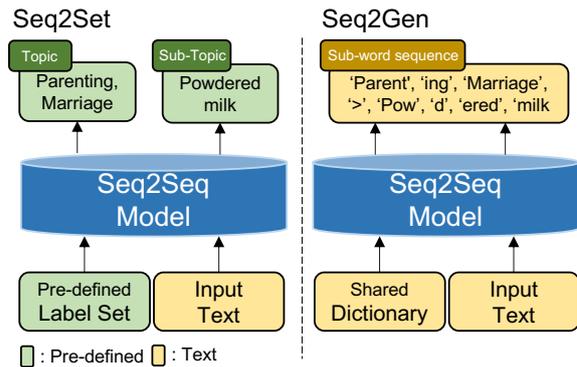

Figure 1: Different from previous Seq2Set (Rivas Rojas et al., 2020), our Seq2Gen can handle unseen labels with sub-word level generation.

unseen labels that do not appear in the pre-defined label set from the training dataset (Banerjee et al., 2019; Aly et al., 2019; Xu et al., 2021). Due to severe deficiencies in annotating data for labels in a hierarchy and handling unseen labels for real-world applications (Liu et al., 2021), we need a general modeling framework for handling unseen labels while explicitly incorporating a label hierarchy to overcome the restriction of the pre-defined label set for the development of real-world text classification applications.

For this purpose, we propose a generation-based classifier that can generate unseen labels in sub-word level. Our method can directly predict labels within a hierarchical structure by considering the label hierarchy as the order of the labels in a sequence. Because all labels are represented as sub-word strings in a shared vocabulary between labels and words, our method can predict unseen labels through generation (Sennrich et al., 2016). To expand unseen labels considerably, we also propose a method to extract knowledge of hierarchical labels from a pre-trained encoder-decoder by semi-supervised learning.

Since there are no available social media datasets

for HTC, we constructed a new blog dataset in Korean that includes a hierarchical label structure. The dataset contains up to three levels with a document. To evaluate the treatment of unseen labels in detail, we additionally constructed cross-lingual datasets, consisting of Japanese and English social media posts from the Kyoto (Hashimoto et al., 2011) and Reddit (Kim et al., 2019) datasets.

Comparisons between our generation-based and traditional classifiers on the Blog dataset showed that our method outperforms state-of-the-art models for both rank-based and ROUGE metrics. Human evaluation results showed that the quality of our generated unseen labels outperforms even the gold labels. In addition, we confirmed our generation-based classifier can handle unseen labels even on the cross-lingual datasets in a zero-shot setting, that shows the potential for tagging labels with considering a label hierarchy in unseen languages.

2 Problem Formulation

We introduce the task of traditional HTC and formulate how we solve it in our generation-based framework. The traditional HTC has been formalized as choosing labels one-by-one from a pre-defined label set in the training dataset, for example, with a sequential classification method (Seq2Set). However, handling unseen labels with considering a label hierarchy is important in designing models for real-world applications.

To solve this problem, we formulate the task as topic generation using a Seq2Seq model (Seq2Gen), such as pre-trained BART (Lewis et al., 2020). Figure 1 shows the Seq2Seq framework to generate target labels. It generates labels for an input text as a sequence of label tokens, and thus the label hierarchy can be directly considered through the Seq2Seq model. Because all the labels are represented as sub-word strings in a shared vocabulary between labels and words (Xiong et al., 2021), our model is permitted to generate even unseen labels, that are not included in the pre-defined label set (Sennrich et al., 2016). Due to the lack of diverse labels with considering their hierarchy in HTC datasets (Kowsari et al., 2017; Sinha et al., 2018), we utilize semi-supervised learning to draw the pre-trained knowledge in the pre-trained Seq2Seq model.

Topic Label	Hierarchical Template
$L = \{l_1\}$	l_1 is a topic.
$L = \{l_1, l_2\}$	l_2 is a sub-topic of l_1 .
$L = \{l_1, l_2, l_3\}$	l_2 is a sub-topic of l_1 and l_3 is a sub-topic of l_2 .

Table 1: Hierarchical template to map labels into a target topic sequence.

3 Generation-based Classifier

Considering HTC as a language generation task, we use a multi-lingual BART (mBART) (Liu et al., 2020), which is an extended version of a transformer-based pre-trained BART for multiple languages, as our Seq2Seq framework.

3.1 Seq2Seq-based Model

Our generation-based classifier can directly consider a label hierarchy. For learning, we append “>” as a special symbol representing a hierarchy between topics, $\mathbf{L} = \{l_1, l_2, l_3\}$, and concatenate them as a target topic sequence. Let w_i be the i -th token in a document $\mathbf{D} = \{w_1, w_2, \dots, w_n\}$. \mathbf{D} is fed into the encoder of the mBART, and then the generated hidden representations with the previous output token, c_{i-1} , are fed into the i -th step of the decoder. Finally, we use the cross-entropy loss between the decoder’s output and the label sequence to fine-tune the model, as follows:

$$H^{Enc} = \text{Encoder}(D), \quad (1)$$

$$H^{Dec} = \text{Decoder}(H^{Enc}, c_{i-1}), \quad (2)$$

$$\text{Loss} = - \sum_{i \in m} \log(\text{Softmax}(H^{Dec}W + b)), \quad (3)$$

where W and b indicate a learnable weight and bias, respectively, and m indicates the target length.

To show the effectiveness of directly considering a label hierarchy, we additionally consider a template-based Seq2Seq model. For learning, we manually create a hierarchical template, which has slots to map topic labels into a target topic sequence, instead of \mathbf{L} . Table 1 shows the hierarchical template to map topics into slots.

3.2 Augmentation with Semi-supervision

Since BART is a pre-trained Seq2Seq model learned with massive text corpora, we assume that we can draw pre-trained knowledge (Petroni et al., 2019) from BART to enhance the label hierarchy and expand labels considerably for dealing with unseen labels. For this purpose, we augment the

Training	Valid	Test
13,705 (1,011)	761 (254)	761 (292)

Table 2: Statistics of Blog. The number in parentheses indicates the number of different labels in each data.

dataset with a *silver* dataset, an automatically annotated dataset by using a model’s generation in a manner of semi-supervised learning. As demonstrated by He et al. (2020), we first train a model only with the *silver* dataset, generated by a model trained with the gold dataset, and then fine-tune it with the gold dataset.

4 Blog Dataset

We created a new HTC dataset (Blog) by collecting posts and their topic label sequences from Naver blogs,¹ that contain a large number of different labels compared to the previous HTC datasets (Kowsari et al., 2017; Sinha et al., 2018). The topic label sequences contain up to three hierarchical topic levels. Extracted topic label sequences can be noisy because a blogger can choose only the topic (the top-level class) from 32 classes, and the remaining topic sequence was automatically generated by the Naver blog system. Therefore, we hired experts on social media to annotate a relevance score from 0 to 3 (3 is the best) for a post and its topic label sequence. We filtered posts with scores less than 2 to ensure high quality. Then, we divided them into three parts (training: 90%, valid: 5%, and test: 5%). Table 2 shows the statistics of the created dataset.

To evaluate unseen label generation in cross-lingual few- and zero-shot settings, we additionally created Japanese (Kyoto) and English (Reddit) datasets from publicly available social media post datasets (Hashimoto et al., 2011; Kim et al., 2019). For Kyoto and Reddit, we extracted 249 and 500 posts, respectively. For each post, five human experts annotated a topic label sequence. After pre-processing, we obtained 234 and 400 posts with their label sequences for Kyoto and Reddit, respectively, and divided them into three parts (training: 10%, valid: 5%, and test: 85%). Blog, Kyoto, and Reddit are available upon request.²

¹<https://section.blog.naver.com/>

²Detailed explanations for the datasets are in Appendix A.

5 Experiments

5.1 Experimental Settings

Datasets: Blog, Kyoto, and Reddit were used to compare our generation-based and previous classification methods. To obtain silver data for semi-supervised learning, we additionally extracted 21,520 Naver blog posts. We also evaluated our models on the public HTC dataset, Web of Science (WOS) (Kowsari et al., 2017). It contains 46,985 instances with two levels, where each level consists of 7 and 134 different labels. We divided them into three parts (training: 60%, valid: 20%, and test: 20%).

Evaluation Metrics: Previous studies used a short ranked list of potentially relevant labels to evaluate the classification quality: the precision at top k ($P@k$) and the Normalized Discounted Cumulative Gain at top k ($NDCG@k$), where $k = 1, 2, 3$ (Xun et al., 2020; Zhang et al., 2021). However, these rank-based evaluation metrics could not evaluate the quality of a hierarchical label sequence, and thus, we also used ROUGE-1-F and ROUGE-2-F, that can evaluate the quality of hierarchical label sequences by taking into account label n -grams.

Compared Methods: Our methods are as follows: **Template** uses the proposed hierarchical templates to generate a topic label sequence with mBART.³ **Seq2Gen** directly generates a topic label sequence with mBART. **Self-Template** and **Self-Seq2Gen** use **Template** and **Seq2Gen** by expanding unseen labels with semi-supervised learning, respectively.

The baselines, which include state-of-the-art models that employ a tree structure of labels, are as follows: **CorNet** utilizes BERT (Devlin et al., 2019) by incorporating a feed-forward layer to consider a label hierarchy (Xun et al., 2020). **MATCH** utilizes BERT by incorporating hypernymy regularization in a loss function to consider hierarchical structures (Zhang et al., 2021).⁴ **Seq2Set** is a variant of the state-of-the-art HTC model that sequentially classifies a topic label sequence from a pre-defined label set with mBART. We replaced Bi-GRU with mBART for a fair comparison to our Seq2Gen (Rivas Rojas et al., 2020).

³Results using different templates are in Appendix B.

⁴For both CorNet and MATCH, we used a multilingual BERT instead of the original BERT for the cross-lingual setting.

⁵The paired-bootstrap-resampling (Koehn, 2004) was used ($p < 0.05$).

Model	P&N@1	P@2	P@3	N@2	N@3	R1-F	R2-F	Unseen
CorNet	77.79	50.72	36.88	70.03	72.76	47.77	8.76	-

Table 5: Experimental results on WOS. The notations are the same as in Table 3.

5.2 Automatic Evaluation

Table 3 shows the results on Blog. Generating topic labels using the mBART-based models consistently outperformed classifying them using the mBERT-based models. Specifically, the gain was large in the ROUGE metrics. In addition, our generation-based methods, Template and Seq2Gen, outperformed the sequential classifier Set2Set. The proposed Seq2Gen outperformed Template, where the improvement in R2-F was larger than that in R1-F, that indicates Seq2Gen can capture a hierarchical sequence directly compared with the hierarchical template. Moreover, Self-Template and Self-Seq2Gen, that use the *silver* dataset to fine-tune the models, consistently improved the performances. This is because we succeeded in enhancing the label hierarchy with diverse unseen labels. For 21,520 posts in the *silver* dataset, our Seq2Gen

Model	Relevance	Taxonomy	Best
Seq2Set	2.29	2.17	0
Self-Seq2Gen	2.59	2.56 [†]	23
Gold	2.51	<u>2.46</u>	13

Table 6: Human evaluation results. The notations are the same as in Table 3.

Input: Yoon Restaurant’s Kimchi pancake. How to make kimchi pancake, recipe for kimchi pancake. It’s been a few days since spring rain has been so moist, so the air is very fresh:) ...
Gold: Cooking, Recipe
Self-Seq2Gen: Cooking, Recipe > Kimchi pancake
Input: I can’t go to the gym, I can’t exercise outside, watch diet YouTube at home. ... The problem with Home Training is that all the exercise moves go by so quickly. ...
Gold: Health, Medicine
Self-Seq2Gen: Sports > Home Training

Table 7: Examples of generated unseen labels from Self-Seq2Gen in the Blog dataset.

could generate 4,385 different unseen labels.

Table 4 shows the cross-lingual results. The R2-F scores for Seq2Gen, trained with Blog, in the zero-shot setting show that it can generate even cross-lingual unseen labels.⁶ Table 5 shows the results on WOS. We can confirm that the generation-based method outperformed the sequential classification method. Thus, our Seq2Gen can work better even for a smaller number of different labels. However, we think the improvements and the number of generated unseen labels are smaller than the ones on Blog due to the smaller number of different labels.

5.3 Human Evaluation and Analysis

We conducted a human evaluation for 50 randomly sampled posts that contain generated unseen labels from our Self-Seq2Gen. Five human annotators graded them with scores from 1 to 3 (3 is the best)

⁶Results including rank-based metrics are in Appendix C.

in terms of Relevance and Taxonomy.⁷ We additionally asked the annotators to select the best label sequence from Seq2Set, Self-Seq2Gen, and Gold label sequences. Best indicates the number of cases where the majority among the annotators judged the best. Table 6 shows the human evaluation results. The generated unseen labels from Self-Seq2Gen achieved a higher preference than the Gold labels.

Table 7 shows example generated unseen labels from Self-Seq2Gen. As we expected, our Self-Seq2Gen frequently generated unseen labels with considering the label hierarchy. In the first example, the generated unseen label, “Kimchi pancake”, can be considered as a sub-topic of “Cooking, Recipe” because the “Kimchi pancake” is a food name. In the second example, “Home training” can be considered as a sub-topic of “Sports”.

6 Conclusion

We proposed a generation-based classifier for HTC. It could handle unseen labels with considering their label hierarchy. In addition, we constructed cross-lingual HTC datasets from social media posts. Automatic evaluation results showed that our generation-based classifier could outperform state-of-the-art models. We confirmed our classifier could handle unseen labels by human evaluation.

7 Ethical Considerations

We created the new datasets of Blog, Kyoto, and Reddit for the HTC task. The created datasets have been collected in a manner which is consistent with the terms of use of any sources and the intellectual property and privacy rights of the original authors of the texts. Please note that we have confirmed by our legal team and the datasets will be available upon request for only research purpose.

8 Limitations

Although our Seq2Gen could generate unseen labels on cross-lingual datasets in the zero-shot setting, that shows the potential of tagging labels with considering their label hierarchy, it was difficult to outperform the few-shot setting. In the future, we plan to incorporate cross-lingual label trees for the zero-shot setting.

⁷Relevance and Taxonomy indicate how much the generated label sequences are related to the input context and the quality of the label hierarchy, respectively.

A 32 Topics for Naver blog System

Table 8 shows 32 topic classes (top-level) from Naver blog system.

For Kyoto and Reddi t, to establish the same setting as for Blog, the experts first annotated the topic label (the top-level class) from given 32 classes. Then, they annotated hierarchical label sequences up to three-levels if they consider subsequent labels are required. We deleted posts with no majority for the topic label. We obtained 234 and 400 posts with their label sequences for Kyoto and Reddi t, respectively, and divided them into three parts (training: 10%, valid: 5%, and test: 85%).

For Reddi t and Kyoto, each input text is not one-to-one matching for target labels, which is different from the **Blog** dataset. For training, we considered all different target label sequences. For the evaluation, we selected maximized scores by regrading them as multiple references. To assess the agreement between the participants for the datasets, we used Fleiss’ Kappa (L. Fleiss, 1971). We obtained Kappa scores of 0.55 for Kyoto and 0.23 for Reddi t, indicating moderate and fair agreements, respectively.

B Results using different templates.

We study the various manually created hierarchical templates using valid Blog because different hierarchical templates can express the same meaning. Table 9 shows the performance using different templates. On the basis of the valid results in terms of average ROUGE-F scores, we use the top performing template in our experiments.

C Results on Kyoto and Reddit datasets

Active Learning for Multilingual Semantic Parser

Zhuang Li*, Gholamreza Haffari

Openstream.AI

{zhuang.li, reza.haffari}@openstream.com

Abstract

Current multilingual semantic parsing (MSP) datasets are almost all collected by translating the utterances in the existing datasets from the resource-rich language to the target language. However, manual translation is costly. To reduce the translation effort, this paper proposes the first active learning procedure for MSP (AL-MSP). AL-MSP selects only a subset from the existing datasets to be translated. We also propose a novel selection method that prioritizes the examples diversifying the logical form structures with more lexical choices, and a novel hyperparameter tuning method that needs no extra annotation cost. Our experiments show that AL-MSP significantly reduces translation costs with ideal selection methods. Our selection method with proper hyperparameters yields better parsing performance than the other baselines on two multilingual datasets.

1 Introduction

Multilingual semantic parsing converts multilingual natural language utterances into logical forms (LFs) using a single model. However, there is a severe data imbalance among the MSP datasets. Currently, most semantic parsing datasets are in English, while only a limited number of non-English datasets exist. To tackle the data imbalance issue, almost all current efforts build MSP datasets by translating utterances in the existing datasets from the resource-rich language (e.g. English) into other languages (Duong et al., 2017; Li et al., 2021a). However, manual translation is slow and laborious. In such cases, active learning is an excellent solution to lower the translation cost.

Active learning (AL) is a family of methods that collects training data when the annotation budgets are limited (Lewis and Catlett, 1994). Our work proposes the *first* active learning approach

for MSP. Compared to translating the full dataset, AL-MSP aims to select only a subset from the existing dataset to be translated, which significantly reduces the translation cost.

We further study which examples AL-MSP should select to optimize multilingual parsing performance. Oren et al. (2021) demonstrated that a training set with diverse LF structures significantly enhances compositional generalization of the parsers. Furthermore, our experiments show that the examples with LFs aligned with more diversified lexical variants in the training set considerably improve the performance of multilingual parsing during AL. Motivated by both, we propose a novel strategy for selecting the instances which include diversified LF structures with more lexical choices. Our selection method yields better parsing performance than the other baselines. By translating just 32% of all examples, the parser achieves comparable performance on multilingual GEO-QUERY and NLMAP as translating full datasets.

Prior works obtain the hyperparameters of the AL methods by either copying configurations from comparable settings or tuning the hyperparameters on the seed evaluation data (Duong et al., 2018). However, the former method is not suitable as our AL setting is unique, whereas the second method requires extra annotation costs. In this work, we provide a cost-free method for our AL scenario for obtaining optimal hyperparameters.

Our contributions are i) the first active learning procedure for MSP that reduces the translation effort, ii) an approach that selects examples for getting superior parsing performance, and iii) a hyperparameter tuning method for the selection that does not incur any extra annotation costs.

2 Background

Multilingual Semantic Parsing. A multilingual semantic parser is a parametric model $P_\theta(\mathbf{y}|\mathbf{x})$ that estimates the probability of the LF $\mathbf{y} \in \mathcal{Y}$ condi-

*Most of this author’s work was completed during his internship at Openstream.AI.

tioned on the natural language utterance $\mathbf{x} \in \mathcal{X}_l$ in an arbitrary language from a language set $l \in \mathcal{L}$. The model is trained on the utterance-LF pairs $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^N \in \mathcal{X}_L \times \mathcal{Y}$ where $\mathcal{X}_L = \bigcup_{l \in \mathcal{L}} \mathcal{X}_l$ includes multilingual utterances.

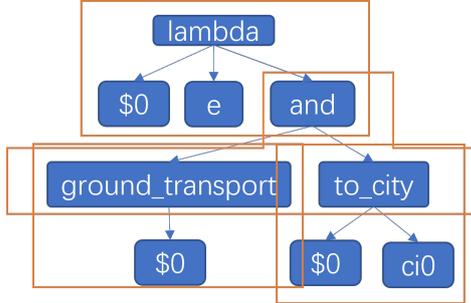

Figure 1: The example of the compounds in an LF tree, $(\text{lambda } \$0 \text{ e } (\text{and } (\text{ground_transport } \$0) (\text{to_city } \$0 \text{ ci0 })))$.

Atoms and Compounds. Each logical form sequence can be represented as a semantic tree, $\mathbf{y} = \tau_{\mathbf{y}}$. Oren et al. (2021); Shaw et al. (2021) define the nodes and sub-trees in $\tau_{\mathbf{y}}$ as the *atoms* and *compounds*, respectively. Increasing the diversity of the atoms and compounds in the training set improves the parser’s compositional generalization (Oren et al., 2021; Li et al., 2021b). For example, an LF “ $(\text{lambda } \$0 \text{ e } (\text{and } (\text{ground_transport } \$0) (\text{to_city } \$0 \text{ ci0 })))$ ” can be expressed as a tree as in Fig. 1. The atoms are nodes such as “*lambda*”, “*\$0*”, “*e*” in the LF tree. In this work, the compounds are defined as two-level sub-trees such as “ $(\text{ground_transport } \$0)$ ”, “ $(\text{to_city } \$0 \text{ ci0 })$ ”, “ $(\text{and } \text{ground_transport } \text{to_city })$ ”, and “ $(\text{lambda } \$0 \text{ e } \text{and })$ ” in the LF tree.

Data Collection for MSP. Prior data collection or active learning works annotates the LFs for the utterances (Duong et al., 2018; Sen and Yilmaz, 2020) or vice versa (Duong et al., 2018; Wang et al., 2015). But most MSP works (Susanto and Lu, 2017; Li et al., 2021a) obtain data by translating existing datasets from high-resource languages into low-resource languages, which is less costly since it does not need annotators’ expertise in LFs. Following the same annotation paradigm, our AL does not annotate LFs for multilingual utterances, but instead chooses the utterances to be translated.

3 Active Learning for MSP

AL-MSP considers only a bilingual scenario for the proof of concept, while extending our AL method to more than two languages is easy. The

goal of AL-MSP is to minimize the human effort in translating utterances while the semantic parser can still achieve a certain level of performance on the bilingual test sets. Starting from a semantic parser initially trained on the dataset $D_s = \{(\mathbf{x}_i^s, \mathbf{y}_i)\}_{i=1}^N$ whose utterances are in the high-resource language s , AL-MSP selects K_q examples $\tilde{D}_s = \{(\mathbf{x}_i^s, \mathbf{y}_i)\}_{i=1}^{K_q}$ from D_s , followed by manually translating the utterances in \tilde{D}_s into a target language t , denoted by $\tilde{D}_t = t_{s \rightarrow t}(\tilde{D}_s)$, where $\tilde{D}_t = \{(\mathbf{x}_i^t, \mathbf{y}_i)\}_{i=1}^{K_q}$. The selection criterion is based on our proposed *acquisition* function $\phi(e_s)$ scoring each example, $e_s = (\mathbf{x}_s, \mathbf{y})$. The parser is re-trained on the union of \tilde{D}_t and D_s . There will be Q iterations of selection and re-training until the re-trained parser reaches a good performance on the bilingual test sets T_s and T_t . Algorithm 1 describes our experimental settings in detail.

Algorithm 1: AL-MSP

Input : Initial training set $D^0 = D_s^0$, budget size K_q , number of the selection rounds Q
Output : A well-learned multilingual parser $P_\theta(\mathbf{y}|\mathbf{x})$
 Train the parser $P_\theta(\mathbf{y}|\mathbf{x})$ on the training set D^0
for $q \leftarrow 1$ **to** Q **do**
 Estimate the acquisition $\phi(\cdot)$
 Select a subset $\tilde{D}_s^q \in D_s^{q-1}$ of the size K_q based on the acquisition function $\phi(\cdot)$
 Translate the utterances in \tilde{D}_s^q into the target language, $\tilde{D}_t^q = t_{s \rightarrow t}(\tilde{D}_s^q)$.
 Combine the training sets, $D^q = D^{q-1} \cup \tilde{D}_t^q$
 Exclude the selected examples \tilde{D}_s^q from $D_s^q = D_s^{q-1} \setminus \tilde{D}_s^q$
 Re-train the parser $P_\theta(\mathbf{y}|\mathbf{x})$ on D^q
 Evaluate parser performance on test sets T_s, T_t
end

3.1 Selection Acquisition

Our selection strategy selects the untranslated examples which maximize the acquisition scores. The acquisition comprises two individual terms, LF Structure Diversity and Lexical Choice Diversity.

LF Structure Diversity (LFSD). We give a simple technique to diversify the LF substructures (atoms and compounds) in the instances. At q th iteration, let $D_s^l = \bigcup_{i=1}^{q-1} \tilde{D}_s^i$ denotes all the translated examples and $D_s^u = D_s^{q-1}$ be the untranslated ones. We partition their union $D_s^u \cup D_s^l$ into $|D_s^l| + K_q$ clusters with Incremental K-means (Dataiku Lab, 2022). Each example $e_s = (\mathbf{x}_s, \mathbf{y})$ is featurized by extracting all the atoms and compounds in the LF tree $\tau_{\mathbf{y}}$, followed by calculating the TF-IDF (Salton and McGill, 1986) value for each atom and com-

pound. Incremental K-means considers each example of D_s^l as a fixed clustering centroids and estimates K_q new cluster centroids. For each of the K_q new clusters, we select one example closest to the centroid.

Such selection strategy is reformulated as selecting K_q examples with the highest acquisition scores one by one at each iteration:

$$\phi_s(\mathbf{e}_s) = \begin{cases} -\|f(\mathbf{y}) - \mathbf{c}_{m(\mathbf{y})}\|^2 & \text{if } m(\mathbf{y}) \notin \bigcup_{\mathbf{e}_s \in D_s^l} m(\mathbf{y}) \\ -\infty & \text{Otherwise} \end{cases} \quad (1)$$

where $f(\cdot)$ is the feature function, $m(\cdot)$ maps each LF into its cluster id and \mathbf{c}_i is the center embedding of the cluster i . As in Algo. 1, when a new example is chosen, none of its cluster mates will be selected again. The incremental mechanism guarantees the newly selected examples are structurally different from those chosen in previous iterations. Since we use batch-wise AL, we just estimate the clusters once per iteration to save the estimation cost.

Lexical Choice Diversity (LCD). LCD aims to select examples whose LFs are aligned with the most diversified lexicons. We achieve this goal by choosing the example maximizing the average entropy of the conditional probability $p(x_s|a)$:

$$\phi_c(\mathbf{e}_s) = -\frac{1}{|A_{\mathbf{y}}|} \sum_{a \in A_{\mathbf{y}}} \lambda_a \sum_{x_s \in V_s} p(x_s|a) \log p(x_s|a) \quad (2)$$

$$\lambda_a = \begin{cases} 1 & \text{if } a \in A_l \\ \beta & \text{Otherwise, } 0 \leq \beta < 1 \end{cases} \quad (3)$$

where a is the atom/compound, $A_{\mathbf{y}}$ is the set of all atoms/compounds extracted from \mathbf{y} , V_s is the vocabulary of the source language, A_l is the set of atoms/compounds in all selected examples until now, and $p(x_s|a)$ is constructed by counting the co-occurrence of a and x_s in the source-language training set. To prevent selecting structurally similar LFs, the score of each selected atom or compound is penalized by a decay weight β .

Our intuition has two premises. First, the parser trained on example pairs whose LFs have more lexical choices generalizes better. Second, LFs with more source-language lexical choices will have more target-language lexical choices as well.

LF Structure and Lexical Choice Diversity (LFS-LC-D). We eventually aggregate the two terms to get their joint benefits, $\phi(\mathbf{x}_s, \mathbf{y}) = \alpha\phi_s(\mathbf{x}_s, \mathbf{y}) + \phi_c(\mathbf{x}_s, \mathbf{y})$, where α is the weight that balances the

importance of two terms. We normalize the two terms using quantile normalization (Bolstad et al., 2003) in order to conveniently tune α .

Hyperparameter Tuning. Because our setup is unique, we can not copy hyperparameters from existing works. The other efforts (Duong et al., 2018) get hyperparameters by evaluating algorithms on seed annotated data. To tune our AL hyperparameters, α and β , a straightforward practice using seed data is to sample multiple sets of examples from the source-language data, the target-language counterparts of which are in seed data, by varying different hyperparameter configurations and reveal their translations in the target language, respectively. The parser is trained on different bilingual datasets and evaluated on the *target-side* dev set. We use the one, which results in the best parsing performance, as the experimental configuration.

Such a method still requires translation costs on the seed data. We assume if the selected examples help the parser generalize well in parsing source-language utterances, their translations should benefit the parser in parsing target languages. Given this assumption, we propose a *novel* cost-free hyperparameter tuning approach. First, we acquire different sets of source-language samples by varying hyperparameters. Then, we train the parser on each subset and evaluate the parser on the *source-side* dev set. Finally, we use the hyperparameters with the best dev set performance.

4 Experiments

Datasets. We experiment with multilingual GEOQUERY and NLMAP. GEOQUERY utterances are in English (EN), German (DE), Thai (TH), and Greek (EL); NLMAP utterances are in English and German. Neither corpora include a development set, so we use 20% of the training sets of GEOQUERY and NLMAP in each language as the development sets for tuning the hyperparameters. To simulate AL process, we consider English as the resource-rich language and others as the target languages. After the examples are selected from the English datasets, we reveal their translations in the target languages and add them to the training sets. **AL Setting.** We perform six iterations, accumulatively selecting 1%, 2%, 4%, 8%, 16% and 32% of examples from English GEOQUERY and NLMAP. **Baselines.** We compare four selection baselines and the oracle setting: i) *Random* picks English utterances randomly to be translated, ii) *S2S*

(*FW*) (Duong et al., 2018) selects examples with the lowest parser confidence on their LFs, iii) *CSSE* (Hu and Neubig, 2021) selects the most representative and diversified utterances for machine translation, iv) *Max Compound* (Oren et al., 2021) selects examples that diversify the atoms and compounds in the LFs, v) *ORACLE* trains the parser on the full bilingual training set.

Evaluation. We adopt the exact match accuracy of LFs for all the experiments. We only report the parser accuracy on the target languages as we found the influence of new data is negligible to the parser accuracy on English data (See Appendix A.2).

Base Parser. We employ BERT-LSTM (Moradshahi et al., 2020) as our multilingual parser. Please see Appendix A.1 for its detailed description.

4.1 Hyperparameter Tuning

Table 1 displays the experiment results with the hyperparameters tuned using only English data (EN) and the hyperparameters tuned using seed data on i) English data plus a small subset (10% of train data plus development data) in the target language (EN + 10%), ii) the full bilingual data (EN + full), iii) the same dataset in a different pair of languages from our experiment languages (Diff Lang), iv) a different dataset in the same languages as our experiment (Diff Data).

	GEOQUERY			NLMAP
	DE	TH	EL	DE
EN (Ours)	73.86	74.57	77.57	69.43
EN + 10%	73.86	74.57	77.57	69.02
EN + full	73.86	74.57	77.14	69.43
Diff Lang	73.86	74.04	77.57	-
Diff Data	71.36	-	-	67.72

Table 1: The parsing accuracies on GEOQUERY and NLMAP test sets in various target languages after translating 16% of the English examples selected by LFS-LC-D with the optimal hyperparameters obtained by different tuning approaches.

From Table 1, we can see our approach takes significantly fewer annotation resources than others to find optimum hyperparameters. Adding more target-language data does not help obtain better hyperparameters, validating our assumption that English data is enough for LFS-LC-D to obtain good hyperparameters. Surprisingly, the hyperparameters tuned on a different language pair do not significantly worsen the selection choices. However, tuning hyperparameters from other datasets results in inferior parsing performance, which is anticipated as different datasets include different

LFs, but the performance of LFS-LC-D is closely related to the LF structures.

4.2 Active Learning Results

Effectiveness of AL-MSP. Fig. 2 shows that only a small amount of target-language data significantly improves the parsing performance over the zero-shot performance. For example, merely 1% of training data improves the parsing accuracies by up to 13%, 12%, 15% and 6% on GEOQUERY(DE), GEOQUERY(TH), GEOQUERY(EL) and NLMAP(DE), respectively. With the best selection approach LFS-LC-D, translating 32% of instances yields parsing accuracies on multilingual GEOQUERY and NLMAP that are comparable to translating the whole dataset, with an accuracy gap of less than 5%, showing that our AL-MSP might greatly minimize the translation effort.

Effectiveness of LFS-LC-D. LFS-LC-D consistently outperforms alternative baselines on both multilingual datasets when the sampling rate is lower than 32%. In contrast, S2S(FW) consistently yields worse parser performance than the other baselines. Our inspection reveals that the parser is confident in instances with similar LFs. MAX COMPOUND diversifies LF structures as LFS-LC-D, however it does not perform well on GEOQUERY(TH). CSSE diversifies utterances yet performs poorly. We hypothesize that diversifying LF structures is more advantageous to the semantic parser than diversifying utterances. RANDOM also performs consistently across all settings but at a lesser level than LFS-LC-D.

Individual Terms of LFS-LC-D. We also inspect each individual term, LFS and LCD, in LFS-LC-D. As in Fig. 3, both terms have overall lower performance than LFS-LC-D, indicating the combination of two terms is necessary. Specifically, LFS performs poorly on NLMAP at the low sampling region. We inspect that NLMAP includes 5x more compounds than GEOQUERY. Therefore, it is difficult for the small number of chosen examples to encompass all types of compounds. LCD performs poorly on GEOQUERY(TH). We notice that Thai is an analytic language linguistically distinct from English, German or Greek, so the entropy values of the probability $p(x_s|a)$ over lexicons in Thai ($p=0.03$) is statistically more different to the ones over English than German ($p=5.80e-30$), and Greek ($p=1.41e-30$)¹. Overall, the two terms could

¹We use the Student’s t-test (Demšar, 2006).

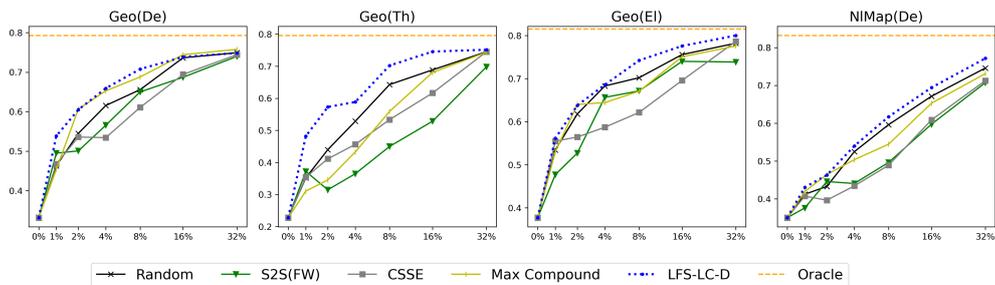

Figure 2: The parsing accuracies at different iterations on the test sets of GEOQUERY and NLMAP in German (De), Thai (Th), and Greek (El) using different selection approaches. All experiments are run five times with different seeds.

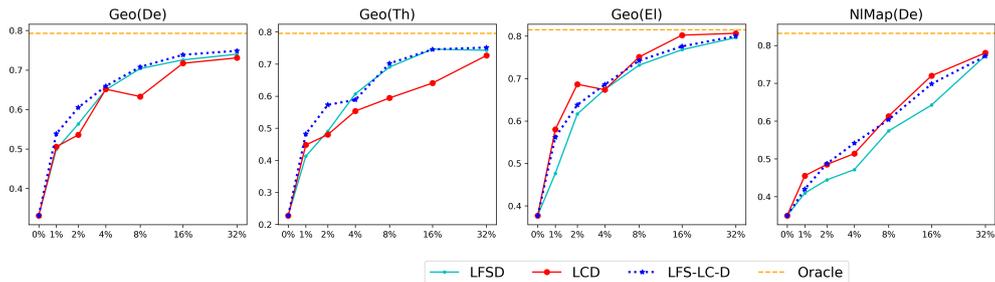

Figure 3: The parsing accuracies at different iterations on the test sets of GEOQUERY and NLMAP in German (De), Thai (Th) and Greek (El) using LFS, LCD, and LFS-LC-D, respectively.

benefit each other, so LFS-LC-D performs steadily across different settings.

Comparison with Machine Translation. We also evaluate the parsers that utilize machine translation services. The parsers are trained on a combination of English data and data translated into the target language by Google Translation (Wu et al., 2016). The accuracy of parsers evaluated on test sets of Geo(De), Geo(Th), Geo(EI), and NIMap(De) was 49%, 58%, 75%, and 75%, respectively. These parsing accuracies are significantly lower than those attained by parsers trained on data provided through human translation, which achieved 80%, 80%, 81%, and 83%, respectively. This suggests that the performance of the parser is tightly correlated to the quality of the employed machine translation system. Clearly, human translation delivers a greater output quality compared to machine translation. In addition, the results reveal that parsers employing AL methods can easily outperform those employing machine translation methods, particularly when the sampling rate for AL is more than 1%, 4%, 8%, and 32% in the four data settings.

5 Conclusion

We conducted the first in-depth empirical study to investigate active learning for multilingual seman-

tic parsing. In addition, we proposed a method to select examples that maximize MSP performance and a cost-free hyperparameter tuning method. Our experiments showed that our method with the proper hyperparameters selects better examples than the other baselines. Our AL procedure with the ideal example selection significantly reduced the translation effort for the data collection of MSP.

Limitations

To reduce annotation costs, existing data collection methods for MSP also utilize machine translation (Moradshahi et al., 2020). Despite the generally lower quality of machine-generated translations compared to human translations, the cost of machine translation services is notably more economical. Our study pioneers the investigation into the feasibility of reducing annotation costs by manually translating only selective portions of the utterance pool. In our work, we provide an initial evaluation of parsers using machine translation versus those using AL methods. Further research is necessary to thoroughly compare these cost-reduction approaches, highlighting their respective advantages and limitations, which we intend to pursue as part of our future work.

A Appendix

A.1 Implementation Details

BERT-LSTM BERT-LSTM is a Sequence-to-Sequence model (Sutskever et al., 2014) with the XLM-RoBERTa-base (Liu et al., 2019) as its encoder and an LSTM (Hochreiter and Schmidhuber, 1997) as its decoder.

Hyperparameters of the Parsers We tune the hyperparameters of BERT-LSTM on English data. For a fair comparison, we fix the hyperparameters of the parser while evaluating the active learning methods. Specifically, we set the learning rate to 0.001, batch size to 128, LSTM decoder layers to 2, embedding size for the LF token to 256, and epochs to 240 and 120 for the training on GEOQUERY and NLMAP, respectively.

Hyperparameters of AL For tuning the hyperparameters of the active learning method, we grid search the decay weight β in 0, 0.25, 0.5, 0.75 and the weight balance rate α in 0.25, 0.5, 0.75, 1. The optimal hyperparameters are 0.75 and 0.75 for all language pairs of GEOQUERY and 0.75 and 0.25 for multilingual NLMAP.

In the Diff Lang setting, we assume we can access the data in a language pair other than the experimental one. For selecting English utterances to be translated into German, Thai, and Greek, we tune the hyperparameters on the data of En-Th, En-EL, and En-De pairs, respectively.

In the Diff Data setting, we assume we can access the data in the same language pair as our experimental one but in a different domain with a different type of LF. For selecting English utterances in GEOQUERY for translation, we tune the hyperparameters on the bilingual NLMAP. For selecting utterances in NLMAP, we tune the hyperparameters on the GEOQUERY in the language pair, En-De.

A.2 Parser Accuracies on English Test Sets

As in Fig. 4, training the parser on the data in the target language does not significantly influence the parser’s performance on the English test sets. Therefore, in Sec. 4, we only report the experimental results on the test sets in the target languages.

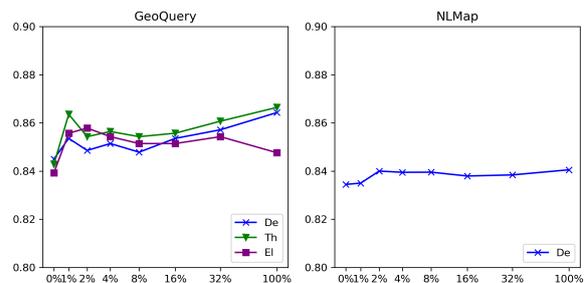

Figure 4: The parsing accuracies at different iterations on the English test sets of GEOQUERY and NLMAP after selecting data in German (De), Thai (Th) and Greek (El) using LFS-LC-D, respectively.

Joint Word and Morpheme Segmentation with Bayesian Non-Parametric Models

Abstract

Language documentation often requires segmenting transcriptions of utterances collected on the field into words and morphemes. While these two tasks are typically performed in succession, we study here Bayesian models for simultaneously segmenting utterances at these two levels. Our aim is twofold: (a) to study the effect of explicitly introducing a hierarchy of units in joint segmentation models; (b) to further assess whether these two levels can be better identified through weak supervision. For this, we first consider a deterministic coupling between independent models; then design and evaluate hierarchical Bayesian models. Experiments with two under-resourced languages (Japhug and Tsez) allow us to better understand the value of various types of weak supervision. In our analysis, we use these results to revisit the distributional hypotheses behind Bayesian segmentation models and evaluate their validity for language documentation data.

1 Introduction

In computational language documentation, unsupervised segmentation into words or morphemes¹ aims to identify boundaries between units in sequences of symbols, typically corresponding to a phonetic or orthographic transcription of an unsegmented utterance. These tasks are fundamental, as they help to identify and analyse possible dictionary entries. There is a long tradition to handle these tasks with generative probabilistic models (Brent, 1999; Venkataraman, 2001) initially designed to model the acquisition of speech by children. The most successful approaches to date rely on non-parametric Bayesian models based on Dirichlet Processes (Goldwater et al., 2006, 2009; Godard et al., 2016) and Adaptor Grammars (Johnson et al., 2007; Eskander et al., 2016; Godard et al., 2018;

¹In this paper, our position regarding the notions of ‘words’ and ‘morphemes’ is entirely empirical, as we mainly try to reproduce annotations performed by field linguists.

Eskander et al., 2019). An interesting property of these generative models is their ability to accommodate existing resources (e.g. partial list of word types) (Sirts and Goldwater, 2013; Ruokolainen et al., 2016), which are often available in actual documentation settings (Bird, 2020).

We study here a scenario where we automatically generate a two-level segmentation,² identifying simultaneously both word and morpheme boundaries. Figure 1 illustrates such a segmentation, where whitespaces separate words, while morphemes are joined with hyphens. Our main task is thus to identify two types of boundaries from the unsegmented stream of symbols (first line) to form the two-level segmented sentence (penultimate line). In this work, we only focus on *surface segmentation* (e.g. eat+ing) as opposed to *canonical segmentation* (e.g. hike+ing for hiking) (Cotterell et al., 2016).

Segmentation	Sentence
Unsegmented	uɪzokuatɕupuwɪsumtoa
Word	uɪzo kwi aɕwi puɪwɪsumtoa
Morpheme	uɪzo-kwi-a-tɕwi-puɪ-wɪ-suɪ-mto-a
Two-level	uɪzo kwi a-tɕwi puɪ-wɪ-suɪ-mto-a
Translation	He let me see my son.

Figure 1: Example of two segmentation levels in Japhug: words are separated by whitespaces (‘ ’) and morphemes by hyphens (‘-’). Extract from (Jacques, 2021)

The motivation for this task is two-fold: (a) to evaluate our ability to obtain annotations such as Figure 1 in an unsupervised way; (b) to see how much the two-level model can disambiguate word from morpheme boundaries, thus improving word segmentations. Note that in actual documentation settings, the annotation of morpheme boundaries

²This ‘two-level segmentation’ is unrelated to the ‘two-level morphology’ (Koskenniemi, 1983), which describes the association between surface forms and underlying representations using the formalism of extended rational expressions.

is usually performed on utterances that are already segmented into words, hence the need to optimise this step.

A baseline for this task is a two-pass approach: first, identify putative word boundaries, then iterate the segmentation procedure on the corresponding set of word types. As we discuss below, unsupervised word segmentation procedures tend to generate units that are often halfway between morphemes and words (see e.g. (Goldwater et al., 2009) or (Godard et al., 2016) who report oversegmentation for words). This means that the first pass often delivers units that are too short and inadequate for the latter processing step. This remains true even with partial supervision information at the word level (Okabe et al., 2022).

We therefore study models that explicitly distinguish between words and morphemes, considering both the fully unsupervised and the minimally supervised settings. The research questions that we address are the following:

- RQ1: Bayesian segmentation models identify units based solely on distributional properties, identifying units that are often in between words and morphemes. Can we improve both segmentations through an explicit modelling of these two levels?
- RQ2: a simple baseline is to first segment sentences into words, then to segment each *word type*³ identified in the first step into morphemes. A second question is how much a single joint segmentation model can mitigate the error propagation of this two-step baseline.
- RQ3: there are multiple ways to implement and supervise joint segmentation models, an important distinction being between linear (flat) and hierarchical segmentation models. A third question relates to the strengths and weaknesses of these approaches, both in the presence and absence of supervision.
- RQ4: Bayesian segmentation models primarily rely on distributional properties of characters in morphemes and words, and embed specific assumptions regarding these distributions. We last question the validity of these assumptions in a low-resource language documentation context.

³Types denote unique words, as opposed to *tokens*, which encompass all running occurrences of types in a corpus.

More generally, our main goal in this study is to assess *whether statistical cues alone are sufficient to identify two distinct segmentation levels*. To answer this question, we analyse several simple joint segmentation models introduced in Section 2 and experiment with two under-resourced languages, briefly presented in Section 3. Our main results and analyses are in Section 4. From a practical perspective, our objective is *not* to devise directly-usable models for field work but to observe the effect of introducing a subword level of segmentation in Bayesian non-parametric models, especially in very low-resource situations as in language documentation: will it improve the (original) word-level segmentation quality? How can additional resources help?

2 Segmentation models

2.1 One-level segmentation

For this work, we use our own Python implementation⁴ of the unigram version of Goldwater et al.’s (2009) model: dpseg. This model relies on Dirichlet Processes to evaluate the probability of a word sequence, as we briefly recall below. In dpseg, the probability of a new occurrence w , based on the observed past words, is expressed through Equation (1) where w denotes a word $w = c_1 \dots c_L$ comprising L characters:

$$P(w|h^-; \alpha) = \frac{n_w^{(h^-)} + \alpha P_0(w|h^-)}{n^- + \alpha}. \quad (1)$$

Here, h^- denotes the rest of the text (w excluded), $n_w^{(h^-)}$ the frequency of word w in the text, and n^- the total number of words. α is the concentration parameter and P_0 , the *base distribution*, is defined by Equation (2):

$$P_0(w) = p_{\#}(1 - p_{\#})^{(L-1)} * \prod_{l=1}^L P_c(c_l), \quad (2)$$

with $p_{\#}$ the probability to terminate a word and P_c a distribution over the set of characters, assumed uniform in the dpseg model.

Observing an unsegmented character string $c_1 \dots c_T$, word segmentation can be formalised with a latent variable model, introducing unobserved boundary variables $b_1 \dots b_T$, where $b_t = 1$ (resp. $b_t = 0$) respectively denotes presence or absence of a boundary after c_t . The inference is typi-

⁴Available at <https://github.com/shuokabe/pyseg>.

cally performed with Gibbs sampling, using Equation (1) to iteratively resample the latent boundary variables values. To speed up convergence, Goldwater et al. (2009) additionally use simulated annealing.

We chose to explore dpseg over alternative segmentation models such as SentencePiece (Kudo and Richardson, 2018) or Morfessor (Creutz and Lagus, 2002; Smit et al., 2014) because of its better performance in similar language documentation contexts. It is also well suited to small data conditions and enables weak supervision (Okabe et al., 2022). Furthermore, preliminary experiments showed no major difference between using a Dirichlet process (DP), as we do, and a variant based on a Pitman-Yor process (PYP), known to better capture the underlying power-law distribution. Overall, we believe that using more sophisticated variants or faster implementations of dpseg would not substantially alter our main observations.

2.2 Pipeline model: two-step segmentation

We now turn to models computing a segmentation in words and morphemes. Our baseline two-level model combines in a pipeline two dpseg models: the first inputs unsegmented text and yields a word-level segmentation. The *word types* in this segmentation are then collected and processed by a second dpseg to get the morpheme-level segmentation. By design, in this approach, a word type is always associated with a unique morphological analysis.⁵

2.3 Flat segmentations with coupling

Two-level segmentation can also be formalised with latent variables, using two sets of variables, denoted as $\{b_1^w \dots b_T^w\}$ (resp. $\{b_1^m \dots b_T^m\}$) for word (resp. morpheme) boundaries. Obviously, using the same dpseg model to independently sample these variables will produce indistinguishable segmentations. It is, however, possible to get two-level segmentations by introducing interactions between these two models, so that the values of variables b_t^w and b_t^m are no longer independent. Deterministic interactions can be introduced in two ways which both ensure that word and morpheme segmentation hypotheses always remain consistent: by imposing either i) that word boundaries also correspond to morpheme boundaries, or ii) that morpheme internal positions are also considered word internal.

⁵This hypothesis corresponds to what we observe in our corpora, where only a few dozen words occur with more than one segmentation in morphemes.

In strategy i), we first sample boundary variables for words and then for morphemes, yielding the parallel-w approach. If a word boundary is detected ($b_t^w = 1$), then we deterministically identify a morpheme boundary at that position ($b_t^m = 1$). Otherwise ($b_t^w = 0$), we sample the value for b_t^m as usual. The net effect is to make morpheme boundaries more likely than in an independent model and generate shorter units at the morpheme level; no change is expected at the word level. In strategy ii), denoted parallel-m, morpheme variables are sampled first: if a boundary is detected ($b_t^m = 1$), an extra sample decides the value of b_t^w ; else, we readily assign $b_t^w = 0$. Here, the effect is reversed and makes word boundaries less likely, forcing the word model to generate longer units; the morpheme-level segmentation remains unchanged.

2.4 Hierarchical segmentations

Inspired by (Mochihashi et al., 2009), we also implement hierarchical segmentation models for the two-level segmentation task. These models aim to explicitly represent the structured aspect of the double segmentation process. Here, the word model is nearly identical to the basic version of dpseg, with a change in the base distribution P_0 of Equation (1). The character model (P_c) is replaced by a second non-parametric model for morphemes (hence the hierarchical nature of the model), also based on dpseg. This morpheme model has a base distribution that is, as for the original dpseg, a unigram character model.

Considering a word w (of length L) made of K morphemes, $w = m_1 \dots m_K$, by analogy to Equation (2), P_0 is therefore changed to:

$$P_0^w(w|h^-) = p_{\#}(1-p_{\#})^{(L-1)} * \prod_{k=1}^K P^m(m_k|h^-), \quad (3)$$

where $P^m(m_k)$ is the probability of morpheme m_k according to the morpheme model (the standard dpseg model), which is written as follows:

$$P^m(m_k|h^-; \alpha^m) = \frac{n_{m_k}^{(h^-)} + \alpha^m P_0^m(m_k)}{n_{\bar{m}} + \alpha_m}, \quad (4)$$

where α^m and P_0^m are, respectively, the concentration parameter and the base distribution for morphemes—the latter being a uniform character model. Sampling in this model is implemented as follows: each time a new word is hypothesised, a morpheme segmentation is obtained from the morpheme model; for words that are actually retained,

this segmentation is recorded and used for further occurrences of the same word form. A basic version of this approach (denoted *hier-type*) thus samples boundary variables for morphemes only once for each word type.⁶ Two variants are considered: in the *hier-iter* model, morpheme boundaries are iteratively resampled for all existing word types every k iterations of the word-level Gibbs sampler; in *hier-final*, this process is only performed once after convergence of the word model, to make a fair comparison with the pipeline model of Section 2.2. As in the pipeline model, these approaches ensure that all occurrences of a given word type will have the same morphological decomposition.

2.5 Unsupervised Adaptor Grammars

Another hierarchical baseline is based on the Adaptor Grammar (AG) model of (Johnson et al., 2007). This is a strong unsupervised word segmentation model that can also capture morphological structure to some extent. We use the *colloc* grammar in (Johnson, 2008), which considers the following levels: a Sentence is made of Collocations, which are made of Words, themselves composed of Characters. In the same manner as (Johnson, 2008, Section 3.2), we considered the Collocation tier to correspond to words and the Word tier to morphemes.⁷

2.6 Weak supervision

Following (Okabe et al., 2022), we further consider two types of realistically available resources that can supervise the segmentation process. The first takes the form of a small number of segmented sentences (e.g. from previously annotated texts), where the corresponding boundary variables are observed. During Gibbs sampling, we skip these positions and simply use the observed values (0 or 1). This type of supervision, which gives information at the *token* level, is denoted *sentence*.

A second type of resource corresponds to lists of lexical units (words and/or morphemes). We use them to replace in P_0 the uniform model with a bigram model, thus increasing the likelihood of known units. This supervision method which uses knowledge about *types* is denoted *dictionary*.

Observed word segmentation or the word dictionaries will be used to compute $P^w(w|h^-, \alpha)$

⁶This is slightly more subtle, as the same word can be created then deleted during the Gibbs sampling iterations.

⁷Appendix C details the hyperparameter values.

(Equation (1)). Likewise, observed morpheme boundaries or morpheme lists will be taken into account at the morpheme level (e.g. in Equation (4) for the hierarchical model). In all our experiments, we assume that weak supervision is available simultaneously at the word and morpheme levels.

2.7 Full supervision

An even more favourable situation is when boundaries are fully observed for a sufficiently large set of sentences, warranting the use of supervised learning techniques such as Conditional Random Fields (Lafferty et al., 2001). This situation is studied notably by (Moeller and Hulden, 2018; Kann et al., 2018). Our experiments with this setting show that this procedure is sample efficient. It is, however, also subject to the same confusion between word and morpheme boundaries and does not significantly outperform the weak supervision setting. Full results are reported in Appendix D.

3 Experimental protocol and material

3.1 Evaluation metrics

Following (Goldwater et al., 2006), the segmentation outputs are evaluated with F-scores on the two levels of segmentation (word and morpheme) at three tiers: BF at the boundary level obtained by comparing predicted and actual boundary values (0 or 1), WF for the token level, which focuses on the correspondence between each unit in the sentences, and LF for the lexicon level, counting the matches between unit types collected on the whole text. For finer analyses, we also report the precision and recall for all three levels in Appendix D.

In addition, some basic statistics regarding the texts will be presented for both segmentation levels. N_{utt} , N_{type} , and N_{token} respectively denote the number of utterances, unit types, and tokens in the text. We also report the inferred average token (WL) and type (TL) lengths.

3.2 Linguistic material

This work studies two low-resource languages: Japhug and Tsez.

Japhug is a Sino-Tibetan language from the Gyalrong family spoken in the Sichuan province in China. It notably has a rich morphology for both nouns and verbs. For example, verbs can use several prefixes to express tense or aspect features on top of suffixes. Japhug is currently being documented: recordings, annotated corpora, and dictio-

naries are available in Pangloss.⁸ Jacques (2021) comprehensively describes the language. The corpus is composed of all the Japhug examples from the L^AT_EX source files of this grammar book.⁹ The extraction of those sentences is made easier thanks to the `\gll` command before the Japhug sentences.

Tsez is a Caucasian language part of the Nakh-Daghestanian language family, spoken in the Republic of Dagestan in Russia. It is officially an unwritten language, transcribed and transliterated through the Avar writing system (Comrie and Polinsky, forthcoming). Nouns and verbs are mainly inflected with a variety of combined suffixes. Moreover, Tsez features a set of clitics that are merged with the words. The latest grammar is currently in the process of being published. The only substantial dictionary of the language contains around 7,500 entries. The Tsez corpus contains sentences from the Tsez Annotated Corpus of (Abdulaev and Abdulaev, 2010), used in (Zhao et al., 2020) to study the generation of interlinear glosses.

language segment	Japhug		Tsez	
	word	morph.	word	morph.
N_{utt}	3628	3628	2000	2000
WL	4.73	2.90	5.61	2.81
TL	7.30	5.41	6.93	5.21
N_{type}	6739	2731	5732	1603
N_{token}	28579	46632	20153	40229
$N_{super.}$	664	493	867	455

Table 1: Statistics for the Japhug and Tsez corpora. Both are segmented into words and morphemes (morph.).

Table 1 describes the two language corpora, reporting statistics at the two segmentation levels. Japhug word types have an average number of 2.48 morphemes, while in Tsez, that value is 2.37.

For weak supervision, the first 200 sentences of each corpus are selected as training material, used as is for boundary supervision (sentence method) or as a list of unique (word or morpheme) types for lexical supervision (dictionary method). $N_{super.}$ above summarises the number of supervision units.

3.3 Experimental settings

In our experiments, the results are obtained after 20,000 iterations of Gibbs sampling, with 10 in-

crements of simulated annealing, for quicker convergence as detailed in (Goldwater et al., 2009). The last iteration of a run returns the final boundary prediction that is considered to be the model output. To account for the variability of the sampler, we report below the average of three runs. We find that this segmentation procedure is stable with an average standard deviation of less than 1 for all metrics.

We use the default values of the base dpseg for hyperparameters: $p_{\#} = 0.5$ and $\alpha = \alpha^m = 20$. We set the same initial value of the concentration parameter for the two levels in both categories of model. Following Teh (2006) and Mochihashi et al. (2009), the two concentration parameters, which both have a Gamma posterior distribution, are re-sampled after each iteration on the corpus—thus, upon convergence, we observe $\alpha \neq \alpha^m$.

For the hierarchical models, hier-final re-segments word types into morphemes with 1,000 iterations of Gibbs sampling, while hier-iter carries out 5 iterations of morphological segmentation every 100 iterations of word segmentation.

4 Experimental results

4.1 RQ1: unsupervised two-level models

Table 2 reports segmentation results for the Japhug corpus. The corresponding results for Tsez are in Table 6 in Appendix D. As briefly stated in the introduction, the one-level dpseg segments into units that are too short for words (cf. average unit lengths WL and TL) and seems to segment units that are closer to morphemes, with higher morpheme F-scores for all three evaluation tiers. This motivated our work on two-level segmentation models, which, contrarily to the basic dpseg, make a distinction between the two types of boundaries. The more sophisticated AG model shows a similar trend, outputting words and morphemes that are too short, insufficiently diverse (low LF), and result in too many tokens (excessive N_{token}).

The pipeline approach only differs from the one-level dpseg at the morpheme level, where we see worse F-scores, with a massive drop in LF score. For the ‘parallel’ models, the expected improvements are observed: better morpheme boundaries for parallel-w, better word boundaries for parallel-m. However, these two models deliver units that remain quite close in average length, and the F-score improvements remain rather limited in magnitude. In those experiments, the hierarchical

Table 2: Results on the Japhug corpus for unsupervised one-level (*) and two-level dpseg models. The reference contains 6,739 words and 2,731 morphemes (N_{type}). **Bold** numbers represent the best result per metrics.

models make a stronger distinction between the two types of units, yielding well-differentiated average lengths (WL and TL). Overall, almost all two-level models but the simple-minded pipeline improve the baseline scores for at least one level of segmentation, with the unsupervised parallel-w flat model delivering the best results on average.

While our answer to RQ1 is positive, we note that the score differences between approaches are often small and that all models keep oversegmenting words, leading to a too low number of word types and yielding poor LF scores. The same trend is observed for the hierarchical models at the morpheme level: they find too few morphemes (cf. N_{type}) and result in poor type-level scores.

4.2 RQ2: error propagation

Compared to the baseline, the unsupervised pipeline approach obtains poor LF score at the morpheme level (Table 2). As the two approaches have almost identical BF and WF scores, this means that pipeline performance is mostly due to its ability to detect frequent morphemes at the expense of rarer ones. This is also reflected by the very small number of morpheme types found by this model.

This is because the pipeline model uses the word types computed by the regular dpseg to detect morpheme boundaries. As this first step obtains poor results ($WF \approx 20$), cascading errors accumulate. Wrong detections at the word level are thus counted twice: once at the word level, once at the morpheme level. The use of joint models slightly remedies this state of play, yielding improvements in the word dictionary, which then turn into improved morpheme dictionaries. This allows us to answer RQ2 positively, even though the recall for morpheme types still remains far from satisfactory. To progress on that front, the surest way seems to improve word segmentation, if only because many word types are made of one single morpheme.

4.3 RQ3: flat and hierarchical models

This section compares the flat (parallel) and hierarchical models, first analysing the differences between variants of the same family, before comparing these two approaches.¹⁰

Parallel models As explained in § 2.3, each ‘parallel’ model only improves the baseline for one type of unit: morpheme boundaries for parallel-w and word boundaries for parallel-m (Table 2). This remains true when using weak supervision. A first comparison is between the parallel models, where we see better scores for parallel-w, which outperforms parallel-m on almost all accounts and all weak supervision settings. In fact, even with the help of supervision, parallel-m obtains lower BF and WF scores at the word level than parallel-w: more word types are generated, the average length is increased, but these hypotheses are often wrong. We do not see the reverse for parallel-w, which generates fewer morphemes: the decrease in recall is almost balanced by the increase in precision, with little negative impact on the morpheme segmentation quality.

Hierarchical models First, for all three F-scores at the morpheme level, in any experimental situation, the hier-type model is consistently worse than the hier-final model, which carries out additional Gibbs sampling steps for the morpheme variables once the word boundaries have stabilised. This model finds longer units (cf. WL) with the additional iterations, which leads to significant improvements (+20 points in WF).

The hier-iter variant achieves a fair trade-off between the boundary and token F-scores on the one hand, and the type F-score on the other hand: this model is better when evaluated at the type level, while hier-final reaches better scores on the other two levels. As the hier-final model

¹⁰Full results in Appendix D.

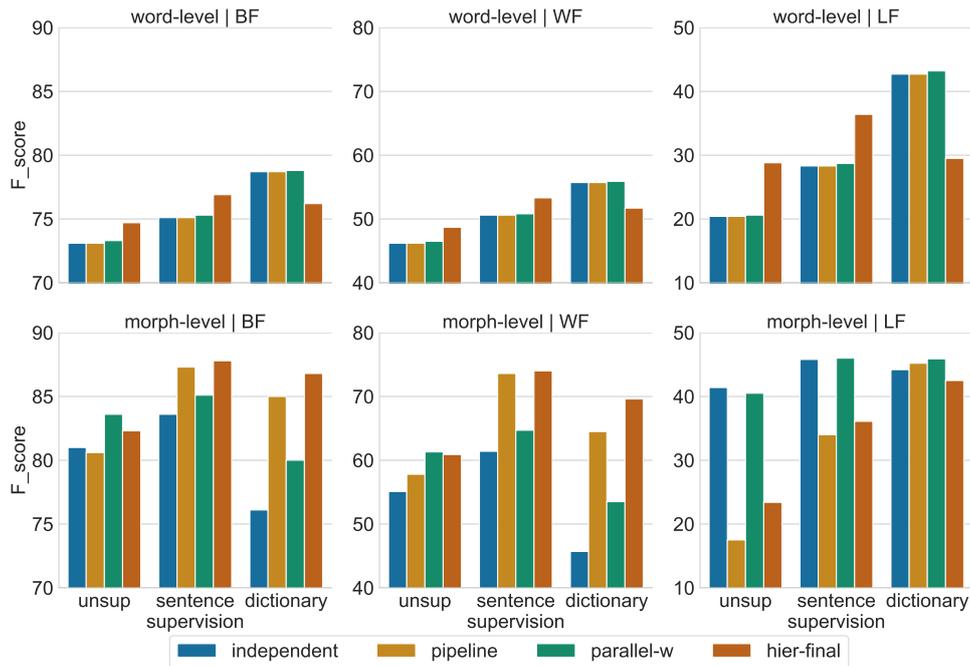

Figure 2: Results in Japhug without supervision on the left, with sentence supervision in the middle, and dictionary supervision on the right of each subplot (row: segmentation level, column: F-score). We use a different y-axis scale for each F-score.

attains a similar but higher aggregated F-score on average, we chose it to represent the hierarchical models for the following sections. This model is also slightly less computationally involved than hier-iter, another reason for choosing it in practical settings.

Comparing two types of models Figure 2 displays the results for the baselines and best performing flat and hierarchical models on Japhug with and without supervision, illustrating the impact of resources. Four models are compared: pipeline, parallel-w, hier-final, and independent. The latter corresponds to *two distinct* dpseg models, one trained for word boundaries, the other for morpheme boundaries, each supervised and evaluated at the corresponding level. It can produce inconsistent segmentations.

By design, independent, pipeline, and parallel-w generate similar word-level segmentations and improve a lot from dictionary supervision. At the morpheme level, the latter model strongly improves its LF score, equally benefiting from both weak supervision strategies.

The hierarchical model has the best results for word-level scores with sentence supervision, whereas, with dictionary supervision, it lags behind the other methods. At the morpheme level, results are less clear. When unsupervised,

hier-final is better than the baselines but worse than parallel-w; however, it always gets a strong boost from supervision, more so than its contenders. In short, sentence is more beneficial for the hierarchical model, while dictionary rather improves the others. Still, these increments remain small; we conclude that weak supervision does not seem to help the models better differentiate the two types of units. Overall, when aggregating F-scores across settings and languages, models rank as follows, from worst to best: independent, pipeline, parallel-w, and hier-final. This answers RQ3.

4.4 RQ4: distributional assumptions

4.4.1 Word distributions in CLD

The parallel and hierarchical models both rely on the same fundamental assumption: the distribution of word tokens in a natural corpus follows a power law, which was a motivation for using Dirichlet processes in (Goldwater et al., 2006). As described in (Goldwater et al., 2011), such distributions derive from the use of a two-stage model: a *generator* which focuses on creating word types (this is P_0 in the dpseg model) and an *adaptor* that produces the ‘rich-get-richer’ effect (Equation (1)).

To check how well our data matches this assumption, in Figure 3, we look at type/token curves, which display the number of word types in texts

of increasing lengths. We deem this ratio to be a reasonable proxy to observe the ‘rich-get-richer’ effect on word types. We compare the Japhug and Tsez texts, their automatic segmentations (‘dp-’), as well as their English translation (‘-en’) (as in (Godard et al., 2016)), with five languages of varying morphological complexity: English, French, Finnish, German, and Turkish. For these, we use the 2020 news data from the Leipzig corpus (Goldhahn et al., 2012), keeping only the first 2,000 sentences for comparison.

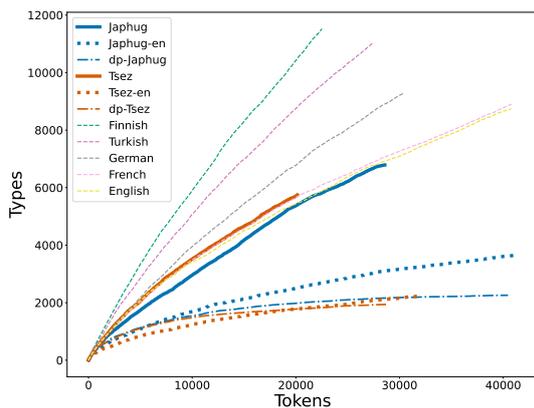

Figure 3: Type-token curves for several languages

We see that the curves for Japhug and Tsez follow the French and English trends, reflecting a lesser lexical variation than for German, Turkish, and Finnish. Looking at their English translations confirms this trend and hints that the number of word types in our corpora does not correctly mirror the actual morphological complexity of these languages. Indeed, corpora collected for language documentation may present distributional biases: sentences are often chosen to illustrate relevant linguistic properties, as in our Japhug corpus extracted from a grammar book. This reduced lexical variety is amplified in automatically segmented texts, where we fail to identify most rare words. For example, 97% of the words occurring only once are not found by the unsupervised hier-final model. See Appendix A for another view of the same phenomena.

4.4.2 Modelling morpheme distributions

Where the parallel and hierarchical versions differ is how they estimate morpheme models: parallel-w assumes a power law of morphemes in running texts, while hier-final assumes it on word types. We see the impact of these assumptions in Figure 4. This graph is based on an esti-

mation of the parameter of the Zipf distributions of words in the Tsez corpus and of morphemes in the Tsez word types (see details in Appendix A). While these parameters strongly depend on the corpus size, they are typically in the range $[-1, -1.2]$ (Baayen, 2001) — the lower value computed for the reference Tsez word distribution again hints at the peculiarity of this distribution, whereas the corresponding parameters for morpheme are in the right ballpark.

All inferred segmentations at the word level behave similarly, with values steeper than for the reference, reflecting the effect of using a power-law model. Once more, we see that supervision is hardly helping. We observe sharper differences at the morpheme level, where the hierarchical model gets much closer to the reference, further boosted by sentence supervision. This is in line with (Virpioja et al., 2011), which notes the better morpheme segmentations obtained when modelling types rather than tokens.

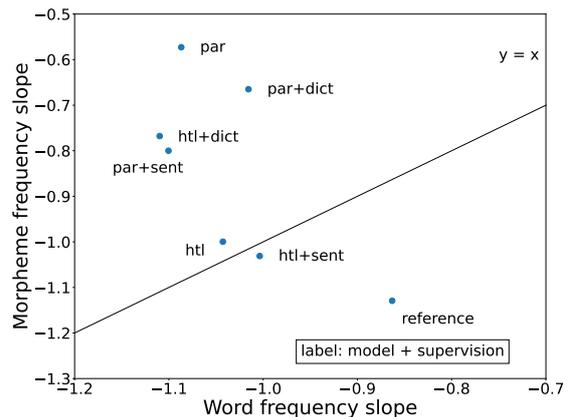

Figure 4: Zipfianity of various segmentations of Tsez. par is based on parallel-w, htl on hier-final.

5 Related work

Word segmentation and morphological segmentation are related tasks; however, both segment only at a single level. We focus here on methods or objectives of approaches comparable to ours.

Word segmentation with Bayesian non-parametric models, on the one hand, benefits from models based on Dirichlet Processes (Goldwater et al., 2006, 2009), extended with the more general Pitman-Yor Processes and a hierarchical structure (Teh, 2006; Mochihashi et al., 2009). In language documentation settings, unsupervised methods are applied (Godard et al., 2016). Morphological segmentation, on the other hand, usually focuses

on the *surface* segmentation of word *types* (Cotterell et al., 2016), with models such as Morfessor (Creutz and Lagus, 2002). Ruokolainen et al. (2016) extensively survey the task for supervised conditions. In low-resource settings, recent works include (Kann et al., 2018; Liu et al., 2021; Moeng et al., 2021).

For both tasks, the Adaptor Grammar (AG) (Johnson et al., 2007), capable of modelling hierarchical structure in sequences with trees, often yields strong results (Johnson, 2008; Eskander et al., 2016; Godard et al., 2018), especially thanks to its flexibility in incorporating minimal supervision. For instance, Sirts and Goldwater (2013) explicitly model words as a compound of one or more morphemes in their AG.

6 Conclusion

By extending a Bayesian non-parametric segmentation model, dpseg, we have proposed two models to simultaneously segment into words and morphemes: one segmenting in parallel and the other in a hierarchical manner. Using corpora of two low-resource, morphologically complex languages, we have observed improved performance with respect to the baselines. These two approaches have been contrasted in various ways, leading us to favour the hierarchical approach when supervision is available. The observed improvements are, however, modest, partly due to modelling assumptions that are not fully matched in our data. It remains that sorting words from morphemes based solely on distributional cues is difficult, if possible at all, even with the supervision considered in this work.

Further studies will need to consider other signals of ‘wordness’. Some can be extracted from the way units combine with their neighbours, using contextual word models; some will require new sources of supervision, e.g. at the phonological level. Another extension will be to distinguish between lexical and grammatical morphemes, which tend to occur and behave differently.

Limitations

The main limitation comes from the use of the unigram dpseg model. Although it has strong and stable performance on the word-level segmentation task, comparable to its bigram version in our settings (Godard et al., 2016), some weaknesses inherent to the unigram assumption appear as in Appendix B. Moreover, such an assumption at the

morpheme level means that, for example, adding a distinction between lexical and grammatical morphemes, as suggested in conclusion, will be of little use since the probability of a morpheme does not affect that of others in the word for unigram models. Nevertheless, in our language documentation setting, we deem this unigram assumption to have a small impact on the overall results due to data size.

For some of our two-level models (pipeline and hierarchical), we also relied on the assumption that a word can only have a single morphological decomposition, as stated in Sections 2.2 and 2.4. Although it may not apply in other situations, this reasonably holds in our two corpora (as briefly explained in footnote 5) since we found 51 word types with several morphological analyses in Japhug and 14 in Tsez.

Besides, our work and observation only rely on two languages. However, the two-level segmentation for very low-resourced languages, as we displayed, needs a reference text segmented with distinct boundaries for words and morphemes for evaluation in particular. Since word segmentation usually focuses on tokens in sentences and morpheme segmentation on word types, texts explicitly segmented in two levels are difficult to obtain, even so of good quality.

Finally, we reckon that our current implementation of the Gibbs sampler is not particularly optimised. For actual deployment, these models should be designed and implemented in a more computationally-efficient way or even another language than Python.

A Word and morpheme distributions

According to Zipf’s law, for a unit of rank R , its normalised frequency f ($f = \frac{F}{N}$ with F the frequency of the unit and N the total number of units in the corpus) is computed as follows in Equation (5):

$$f = \frac{c}{R^a}, \quad (5)$$

with c a normalising constant and a the parameter of the distribution (Baayen, 2001). Hence, the relationship between the log-(normalised) frequency and the log-rank is:

$$\log(f) = -a \log(R) + \log(c) \quad (6)$$

To visualise the linear relationship shown in Equation (6), we hence fit a (least square) linear regression. Thus, Figure 4 plots the value of the slope $-a$ for words (x-axis) and morphemes (y-axis).

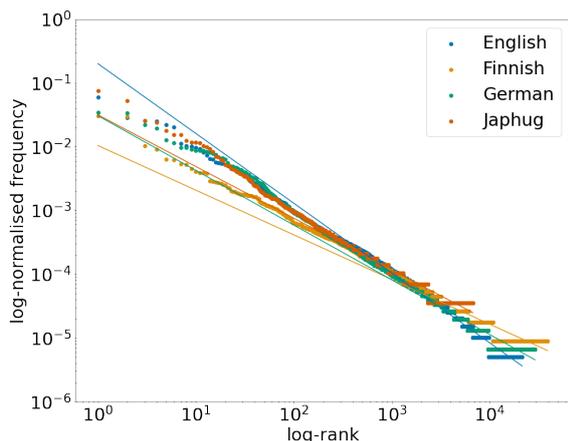

Figure 5: Log-normalised frequency of words according to their log-rank for several languages.

In Figure 5, we compare the Japhug text with three languages of varying morphological complexity (as in Section 4.4.1).

The Japhug curve lies between the English and Finnish ones, two languages with a clear contrast in morphological complexity. If for the most frequent words (i.e. low Zipf rank, on the left), the Japhug words follow the English or German trend, for rare words (i.e. high Zipf rank, on the right), it joins the Finnish trend.

B Output analysis

	supervision	sentence
dpseg	/	a mbroujme zu kszo
parallel-w	/	a mbro-ujme z ukx zo
parallel-w	sentence	a-mbro ujme zu kx-zo
reference		a-mbro u-jme zu kx-zo <i>Land on my horse's tail</i>

Figure 6: An example Japhug sentence segmented by various models, with and without supervision.

The example in Figure 6 displays a Japhug sentence segmented by two models. First, without supervision, dpseg fuses two units that should be separated by a word boundary (‘mbroujme’), and so does parallel-w with ‘ukx’. Apart from diminishing the three F-scores, this kind of error creates meaningless units. Besides, some reference morpheme boundaries are not identified: no boundary at all for ‘u-jme’ and a word boundary in ‘a-mbro’.

Once supervised, the parallel-w model corrects its initial error (‘ukx’ is segmented) and finds morpheme boundaries. Indeed, the model seems to benefit from the supervision data, which contained

the words ‘a-mbro’ and ‘kx-zo’. The remaining error (‘ujme’) can be explained by the fact that in the corpus, all occurrences of the morpheme ‘jme’ are always preceded by ‘u-’. The model thus does not identify nor recreate ‘jme’ as a unit but keeps ‘ujme’. The negative effect of collocations constitutes an inherent limit of the unigram dpseg model, already discussed by Goldwater et al. (2006).

C Reproducibility

All presented experiments have been obtained with the same three random seeds (42, 142, and 1234) for a fair comparison. Details about the hyperparameters are in Section 3.3.

The Adaptor Grammar was run with the hyperparameter values indicated for MorphAGram¹¹ (Eskander et al., 2020).

For reference, a processor of 6 cores and 12 threads takes around two days for a hierarchical model on the Tsez 2K corpus (20,000 iterations of Gibbs sampling). With the same setting, a parallel model takes approximately one day.

D Complete results

This section displays the full results for all our experimental settings: each model will be unsupervised or supervised with the sentence or dictionary supervision and will segment the Japhug and Tsez corpora. The tables also report the precision and recall for each evaluation tier (BP and BR for **B**oundary **P**recision and **B**oundary **R**ecall; WP, WR, and LP, LR, respectively for token and type evaluation). Bold values are the best score in a given experimental situation.

D.1 Japhug

Tables 3, 4, and 5 display the full results for the Japhug text.

D.2 Tsez

Similarly, Tables 6, 7, and 8 display the full results for the Tsez text.

D.3 Fully supervised model

For the sentence supervision method of Section 2.7, we also report the results of a CRF (Conditional Random Field, Lafferty et al. 2001), mainly inspired by the methodology of Moeller and Hulden (2018). Each training sentence is labelled as in Figure 7.

¹¹<https://github.com/rnd2110/MorphAGram>.

Original sentence	χ	ρ	υ	η	υ	ρ	υ
Translation (EN)							
	little				monk		

χ	ρ	υ	η	υ	ρ	υ
B-w	I	I	I	B-w	B-m	I

Figure 7: Example of Japhug sentence labelled for CRF

The ‘B-w’ label indicates the beginning of a word, while ‘B-m’ marks the start of a morpheme *inside* a word. The ‘I’ label is used for all other characters (inside a morpheme). We use Wapiti¹² (Lavergne et al., 2010) for the CRF implementation. Our feature set only includes basic unigram and bigram features.

The results in Table 4 and Table 7 show that, on average, full supervision yields better segmentation scores than weakly supervised models at the word level; contrarily, we observe worse scores at the morpheme level for both languages.

We also note that the CRF model identifies more than 4,000 morpheme types in both languages (i.e. much more than what exist in the reference or our models), which results in less than 36 in F-score on morpheme types (LF). This suggests that morphemes are difficult to distinguish from words, even in this favourable setting, confirming one of our main conclusions: statistical cues alone do not seem to be enough to correctly separate these two types of units.

Abstract

When humans read a text, their eye movements are influenced by the structural complexity of the input sentences. This cognitive phenomenon holds across languages and recent studies indicate that multilingual language models utilize structural similarities between languages to facilitate cross-lingual transfer. We use sentence-level eye-tracking patterns as a cognitive indicator for structural complexity and show that the multilingual model XLM-RoBERTa can successfully predict varied patterns for 13 typologically diverse languages, despite being fine-tuned only on English data. We quantify the sensitivity of the model to structural complexity and distinguish a range of complexity characteristics. Our results indicate that the model develops a meaningful bias towards sentence length but also integrates cross-lingual differences. We conduct a control experiment with randomized word order and find that the model seems to additionally capture more complex structural information.

1 Introduction

Approximately 7,000 languages are currently spoken in the world, exhibiting differences at almost every level of linguistic organization (Eberhard et al., 2022). Nonetheless, psycholinguistic theories are predominantly supported by evidence from a handful of Indo-European languages (Norcliffe et al., 2015). Only recently, researchers have started to explore cross-linguistic differences in the neural implementation of language, uncovering both striking similarities across languages and empirical differences that cannot be explained by a unitary account (Malik-Moraleda et al., 2022).

In natural language processing, multilingual language models are optimized for tasks such as machine translation or cross-lingual information retrieval (Conneau et al., 2020) and follow a linguis-

tically naïve training regime. They are trained on dozens of languages simultaneously and do not account for typological differences between languages. Nevertheless, their cross-lingual transfer performance sets new records, even in zero-shot settings (Pires et al., 2019). The ability to transfer knowledge across languages has been attributed to the shared vocabulary that is used for all languages (Wu and Dredze, 2019) because it enables the reuse of common morphological roots for languages from the same family. However, recent studies indicate that vocabulary sharing is not a prerequisite for cross-lingual transfer (Artetxe et al., 2020) and that structural commonalities between languages play a more prevalent role in models (Karthikeyan et al., 2020).

Human sentence processing is sensitive to structural complexity. Eye movement data recorded during reading provide insights into cognitive processing patterns with a temporal accuracy of milliseconds (Winke, 2013). Structural processing difficulty materializes as regressions towards the complex region and an increase of fixations on that region (Clifton and Staub, 2011). For example, sentences with an object-relative structure trigger more regressions than sentences with more common subject-relative clauses (Gordon et al., 2006). A classical example of structural complexity are garden-path sentences which initially trigger a simplified interpretation that must be revised when reading the rest of the sentence (Bever, 1970).

On the surface level, eye movement patterns are language-specific since they are influenced by visual factors such as orthography and word length (Kliegl et al., 2004). For example, the Chinese script is much more visually dense than the alphabetic script, resulting in longer fixations and saccades that move to positions relatively close to the current word (Liversedge et al., 2016). On a deeper processing level, reading patterns seem to converge across languages. Predictability effects

This research was developed when the first author was affiliated to Vrije Universiteit Amsterdam.

have been demonstrated in multiple languages (Al-Jassmi et al., 2022; Laurinavichyute et al., 2019) and sentences that are matched for content are read at a similar speed in Chinese, English, and Finnish (Liversedge et al., 2016).

Sarti et al. (2021) find that the representations of an English pre-trained transformer-based language model encode structural complexity more prominently when they are fine-tuned to predict English eye-tracking patterns. Interestingly, Rama et al. (2020) claim that structural similarity between languages is only weakly represented in multilingual models. Nevertheless, Hollenstein et al. (2021) show that multilingual models are able to predict eye movement patterns of reading even for languages that are not seen during fine-tuning, which indicates a general learnability of the relationship between structural complexity and eye movement patterns. Their results are restricted to four languages (three of them are from the Germanic family), and it remains unclear which structural cues are leveraged for the cross-lingual prediction because the test sentences are not aligned across languages.

Contributions We examine whether the multilingual model XLM-RoBERTa (henceforth XLM-R) is sensitive to the structural complexity patterns that can be found in eye-tracking data. We use data from the newly released Multilingual Eye-tracking Corpus (Siegelman et al., 2022) to predict eye movement patterns for parallel texts in 13 typologically diverse languages. This allows us to specifically target the model’s sensitivity towards structural information and rules out the possibility that the results are influenced by differences in semantics or dataset sizes.

We show that XLM-R can apply cross-lingual transfer to predict eye-tracking patterns for all 13 languages while being fine-tuned only on English eye-tracking data. Our results indicate that the model develops a meaningful bias towards sentence length, but also integrates cross-lingual differences. For a more detailed analysis of structural sensitivity, we probe the model’s final layer for complexity features. Based on a control experiment with randomized word order, we conclude that the model seems to additionally capture more complex structural information. All our experimental code is publicly available at <https://github.com/CharlottePouw/crosslingual-complexity-transfer>.

2 Related Work

We introduce recent findings on the role of structural information for cross-lingual transfer in multilingual models and motivate the use of eye-tracking data as a proxy for cognitive processing complexity.

2.1 Cross-lingual Transfer in Multilingual Models

Massive multilingual language models such as mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) are trained on more than a hundred languages simultaneously. Wu and Dredze (2019) show that this approach leads to surprisingly strong performances in cross-lingual transfer settings and attribute the improvements to the shared subword vocabulary. Pires et al. (2019) note that the model’s ability to generalize "cannot be attributed solely to vocabulary memorization". Complementary, Artetxe et al. (2020) and Liu et al. (2020) find that a shared vocabulary is not necessary for cross-lingual transfer. Instead, the multilingual model seems to exploit structural similarity between the training and the target language to facilitate transfer (Karthikeyan et al., 2020).

Structural similarity is loosely defined as an overlap on a subset of typological characteristics which seem to be better reflected in multilingual language models explicitly optimizing for cross-lingual transfer (Beinborn and Choenni, 2020; Choenni and Shutova, 2022). In language-agnostic models such as mBERT and XLM-R, the multilingual representations of the input can be separated into language-specific and language-neutral components (Tanti et al., 2021; Libovický et al., 2020; Gonen et al., 2020). While Rama et al. (2020) find that structural similarity between languages is only weakly represented in these models, Bjerva et al. (2019) observe that structural similarity between languages correlates most with representational similarity. Experiments with artificial languages indicate that multilingual models are sensitive to hierarchical structure (De Varda and Zamparelli, 2022) and to word order (Chai et al., 2022; Deshpande et al., 2022). Ahmad et al. (2021) show that cross-lingual transfer can be improved by explicitly encoding structural information via an auxiliary syntactic objective and Guarasci et al. (2022) find that structural complexity knowledge can even be transferred across languages without explicit training.

2.2 Predicting Processing Complexity

Recent studies indicate that transformer-based language models are sensitive to structural characteristics of the input sentence when predicting eye-tracking patterns. [Hollenstein et al. \(2021\)](#) find a correlation between the Flesch reading ease score and eye-tracking prediction accuracy of pre-trained multilingual transformer models which disappears after fine-tuning. [Wiechmann et al. \(2022\)](#) detect similar correlations between the prediction accuracy of English transformer models and a wider range of readability features. Finally, [Hollenstein et al. \(2022b\)](#) find that eye-tracking metrics predicted by multilingual transformer models correlate in a similar way with readability features as eye-tracking metrics recorded from human readers.

Sensitivity to structural complexity also seems to increase when incorporating eye-tracking data in NLP models. Learning eye movement behavior as an auxiliary task has been shown to facilitate the prediction of text complexity in English and Portuguese ([González-Garduño and Søgaard, 2017](#); [Evaldo Leal et al., 2020](#)). [Barrett et al. \(2016\)](#) show that English eye-tracking features improve the performance a French part-of-speech tagger, suggesting that information learned from monolingual eye-tracking data is transferable across languages.

In this work, we explicitly test for sensitivity to a range of structural characteristics in multilingual models and analyze if structural sensitivity increases by learning to predict eye-tracking patterns. We extend previous analyses to a much wider range of languages from five different families (Indo-European, Koreanic, Semitic, Turkic, and Uralic).

3 Methodology

We fine-tune a pre-trained multilingual transformer model to predict eye-tracking metrics in a setting of zero-shot cross-lingual transfer.

3.1 Data

We use the aligned multilingual eye-tracking corpus MECO for testing. As the multilingual data consists of only few samples, we use the larger monolingual English eye-tracking dataset GECO for training. Size statistics of both corpora can be found in the appendix in Table 3.

Multilingual Eye-tracking Corpus (MECO)
The Multilingual Eye-tracking Corpus contains par-

allel eye-tracking data of reading in 13 different languages ([Siegelman et al., 2022](#)).¹ The reading material consists of 12 short Wikipedia-style texts about various topics, which participants read in their native language. The texts were either directly translated or carefully matched for topic, genre, and readability. Each of the 12 texts was presented on a single screen and in the same fixed order in all languages. The number of participants ranged from 29 to 54 per language (45 on average).

Ghent Eye-tracking Corpus (GECO) The Ghent Eye-tracking Corpus contains eye-tracking data from 14 monolingual English readers ([Cop et al., 2016](#)). They were reading the entire novel *The Mysterious Affair at Styles* by Agatha Christie which was presented on the screen one paragraph at a time.

3.2 Experimental Setup

We use multi-task learning for predicting four sentence-level eye-tracking metrics.

Sentence-Level Eye-Tracking Metrics [Liversedge et al. \(2016\)](#) find that eye movement patterns are more comparable across languages at the sentence level than at the word level. We select four sentence-level eye-tracking metrics that cover both early and late language processing in line with [Sarti et al. \(2021\)](#). For each sentence s , we consider:

1. *Fixation count*: number of fixations on s
2. *Total fixation duration*: total duration of all fixations on s
3. *First-pass duration*: duration of the first reading pass over s
4. *Regression duration*: total duration of all regressions within s .

Duration values are measured in milliseconds. To obtain generalized eye movement patterns, we average all eye-tracking metrics over participants and scale each eye-tracking feature to fall in the range 0–100, so that the loss can be calculated uniformly for durations and counts ([Hollenstein et al., 2021](#)). The distribution of the four metrics is shown in the appendix in Figure 7.

Model We use XLM-R ([Conneau et al., 2020](#)) as our multilingual transformer model since it achieved the best zero-shot results in the CMCL 2022 Shared Task on Multilingual and Crosslingual

¹Dutch, English, Estonian, Finnish, German, Greek, Hebrew, Italian, Korean, Norwegian, Russian, Spanish, Turkish.

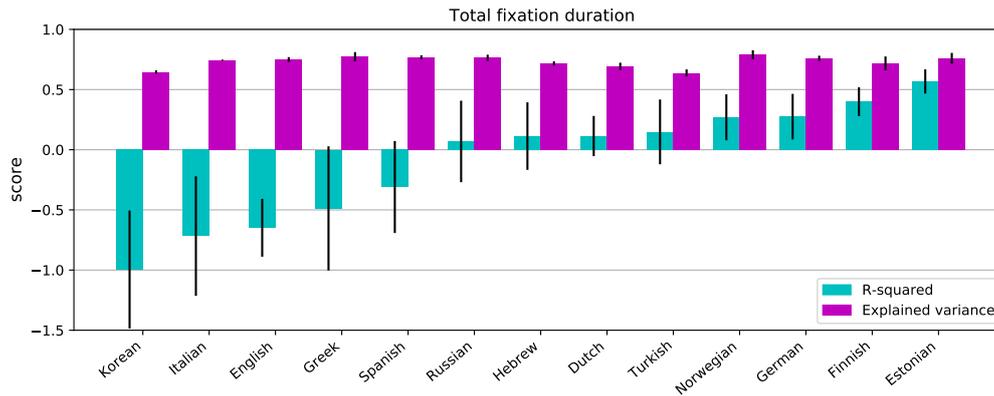

Figure 1: Cross-lingual transfer results for predicting cognitive processing complexity (i.e. sentence-level fixation duration). Prediction performance is evaluated with explained variance and R^2 for each language in MECO. The results are averaged over 5 folds; error bars denote the standard deviation over folds.

Prediction of Human Reading Behaviour (Srivastava, 2022; Hollenstein et al., 2022a). The model was pre-trained on 2.5TB CommonCrawl data containing 100 languages using the Masked Language Modelling objective and uses SentencePiece subword tokenization (Kudo and Richardson, 2018). We select the Huggingface checkpoint *xlm-roberta-base* and add a linear dense layer to predict four sentence-level eye-tracking metrics.

Multi-Task Learning We employ multi-task learning with hard parameter sharing to fine-tune the model on all eye-tracking metrics simultaneously in line with Sarti et al. (2021). This means that all model parameters are shared except for the task-specific regression heads in the final prediction layer. More specifically, the same sentence representation is fed into each of the four regression heads which predict their respective eye-tracking metric. The model parameters are optimized jointly for all regression tasks by summing the individual MSE losses in line with previous work (Hollenstein et al., 2021, 2022a; Wiechmann et al., 2022).

Training Parameters We fine-tune XLM-R for 15 epochs with early stopping after 5 epochs without an improvement in the validation accuracy. We use 10% of the training data as validation data and evaluate every 40 steps. We employ a batch size of 32 and a learning rate of $1e-5$. The sentence representation is obtained by mean pooling over token representations. We train the model on the GECCO data using 5-fold cross-validation and report the average over the folds for each language in MECO.

Evaluation We report explained variance and R-Squared (R^2) to capture the proportion of variance

in the dependent variable that can be explained by our model in line with Sarti et al. (2021). Explained variance uses the biased variance to determine what fraction of the variance is explained. R^2 uses the raw sums of squares instead and provides complementary information about systematic offsets in the predictions. We report both metrics and evaluate the performance of the fine-tuned model individually for each of the four eye-tracking metrics.²

4 Cross-Lingual Transfer Results

Figure 1 shows the explained variance and R^2 scores of the fine-tuned model for total fixation duration across languages. In terms of explained variance, we see that the model achieves a similar performance across languages, i.e. it captures 60 to 80 percent of the variance in the original eye-tracking signal for all languages. The R^2 scores, on the other hand, vary much more depending on the language. Similar results were observed for two of the other eye-tracking metrics, i.e. fixation count and first-pass duration, but the model is worse at predicting regression duration (see Figure 8 in the appendix). To better control for spurious correlations, we ran the experiment on permuted input-output pairs, i.e., we paired input sentences with eye-tracking values corresponding to another random sentence and averaged the results over 5 folds. For this random baseline setup, both explained variance and R^2 are always strictly negative for all languages.

²In previous work on token-level eye-tracking prediction, the mean absolute error was reported instead but it is less informative for sentence-level predictions because sentence-level eye-tracking metrics are generally more centered around the mean.

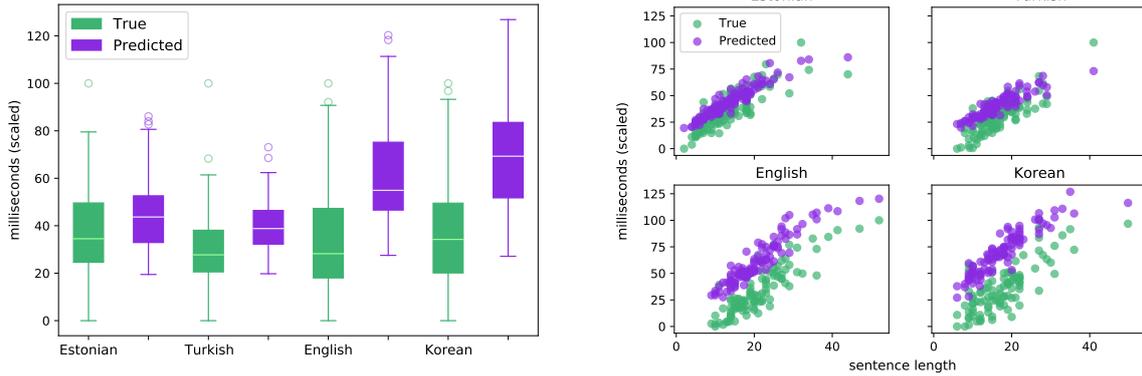

Figure 2: The left plot shows the distribution of true and predicted values for total fixation duration for Estonian, Turkish, English and Korean sentences in MECO. The right figure shows the distribution of values with respect to sentence length.

To better understand the varied R^2 scores for different languages, we show the distribution of the true and predicted values for total fixation duration for two languages with high R^2 (Estonian, Turkish) and two languages with low R^2 (English, Korean) in Figure 2. We see that the low R^2 for English and Korean is caused by predictions that are consistently too high. For Estonian and Turkish, the difference between true and predicted values is clearly smaller, resulting in a higher R^2 . Nevertheless, the model is able to predict a significant amount of the variance in the eye-tracking signal of all languages, as expressed by the stable explained variance scores across languages.

Interestingly, the model performs slightly better for most zero-shot languages than for the fine-tuning language English. Recall that this performance difference cannot be attributed to cross-lingual differences in semantics, since all sentences are parallel with respect to content. On the right side of Figure 2, we analyze the predictions with respect to sentence length and find that both the model predictions and the true values for fixation duration correlate with sentence length in all languages. As sentence length is an indicator of structural complexity, we further dissect this phenomenon and conduct an analysis of a range of structural characteristics in the following section.

5 Sensitivity to Structural Complexity

We explore four categories of sentence-level complexity features: length, frequency, morpho-syntactic, and syntactic. Word frequencies are obtained as standardized Zipf frequencies using the Python package wordfreq (Speer et al., 2018). The

package combines several frequency resources, including SUBTLEX lists (e.g. Brysbaert and New (2009)) and OpenSubtitles (Lison and Tiedemann, 2016). The morpho-syntactic and syntactic features are computed using the Profiling-UD tool (Brunato et al., 2020).

Cross-Lingual Differences We showcase an individual example sentence in Table 1 to compare the predicted fixation duration for English, Finnish and Turkish. We observe that the highest value is predicted for the English version. This is most likely caused by its length, as the sentence is less complex than the Finnish and Turkish versions in terms of all other linguistic features.

Interestingly, the model predicts that Finnish readers will fixate on the sentence longer than Turkish readers, even though both sentences have the same length. The Turkish sentence contains longer, less frequent words, and is lexically more dense, but the Finnish sentence contains longer dependency links. This indicates that the model is more sensitive to dependency structure than to low-level complexity (i.e. word length and frequency) when predicting eye-tracking values for sentences of the same length.

5.1 Sensitivity to Fine-Tuning Input

To analyze the model’s sensitivity to the structural complexity of the fine-tuning data, we compare the performance of the fine-tuned model for in-domain data (English GECO) and cross-domain data (English MECO). Table 2 shows the explained variance and R^2 scores of the fine-tuned model predictions for each eye-tracking metric for both domains. We see that the model consistently yields

Example		Prediction		
English	<i>In ancient Roman religion and myth, Janus is the god of beginnings and gates.</i>	42.96		
Finnish	<i>Muinaisen roomalaisen mytologian mukaan Janus oli alkujen ja porttien jumala.</i>	38.91		
Turkish	<i>Antik Roma inanışlarında ve mitlerinde, Janus başlangıçların ve kapıların tanrısıdır.</i>	32.28		

Structural Complexity		English	Finnish	Turkish
Length	Sentence length (tokens)	14	10	10
	Avg. word length (characters)	4.57	6.80	7.60
Frequency	Avg. word frequency (Zipf)	5.63	4.36	3.46
	# low frequency words	2	6	6
	Lexical density	0.57	0.70	0.73
Morpho-Syntactic Syntactic	Parse tree depth	3	3	3
	Avg. dependency link length	2.15	2.78	1.90
	Max. dependency link length	7	7	4
	# verbal heads	1	1	1

Table 1: Predicted values for total fixation duration for the same example sentence in English, Finnish, and Turkish (top), and the respective values for the nine structural complexity features (bottom).

more accurate predictions for the in-domain data than for the cross-domain data.

	MECO		GECO	
	EV	R^2	EV	R^2
FC	.78 (.02)	-.63 (.35)	.93 (.00)	.93 (.01)
TFD	.75 (.02)	-.65 (.24)	.92 (.00)	.92 (.01)
FPD	.50 (.03)	-.87 (.27)	.95 (.00)	.95 (.01)
RD	-.28 (.14)	-.96 (.45)	.44 (.04)	.45 (.05)

Table 2: Explained variance (EV) and R^2 -scores of the fine-tuned model predictions for four eye-tracking metrics from the English parts of MECO and GECO: fixation count (FC), total fixation duration (TFD), first-pass duration (FPD), and regression duration (RD). The results are averaged over 5 folds; standard deviations are indicated in parentheses.

To better understand why the model does not generalize well across domains for English, we visualize the Spearman correlation between complexity features and eye-tracking metrics for English GECO and MECO sentences in Figure 3. We see that the predicted values for the MECO sentences exhibit a similar correlation pattern with the complexity features as the GECO sentences. The true values of MECO are less consistent with this pattern. Literary texts contain very different words than encyclopedic texts, which might influence fixation durations and trigger regressions that cannot solely be explained by structural complexity. In addition, MECO is significantly smaller than GECO (99 vs 4,041 English sentences) and contains data from a higher number of participants (46 vs 14). The smaller amount of sentences and the larger amount of readers increase the effect of individ-

ual differences³ which might obscure correlations between structural complexity and eye movement patterns. Directly applying the learned correlations from GECO to MECO might explain why the fine-tuned model fails to generalize across domains.

The average sentence length is considerably higher in GECO than in MECO (21 vs 13 words, see Table 3). As the model predictions strongly correlate with sentence length, we speculate that the model overestimates eye-tracking values for sentences that are longer than the majority of fine-tuning sentences which would explain the higher mean of the predictions in Figure 2.

Multi-Task Learning Effect Figure 3 further shows that regression duration is only weakly correlated with the complexity metrics in contrast to the other eye-tracking metrics. Nevertheless, the correlations between the model predictions and the complexity features are similar for all four metrics. This indicates a drawback of multi-task learning: since the loss is computed jointly over all tasks, accurate predictions for three out of four tasks already yield a small loss. The model seems to overfit to first-pass duration, total fixation duration and fixation count, which can all be predicted from similar complexity features, and does not learn the deviat-

³A higher number of participants leads to more diversity across readers with respect to individual factors that could influence reading strategies (e.g. age, education level). The GECO data came from 14 English readers who were all undergraduate students with an age range of 18-26. The MECO data came from 29 to 54 readers per language (45 on average), who had more diverse educational backgrounds and a wider age range (18-45). Based on these statistics, we assume that the increased heterogeneity of the MECO participants influences the correlations observed in Figure 3.

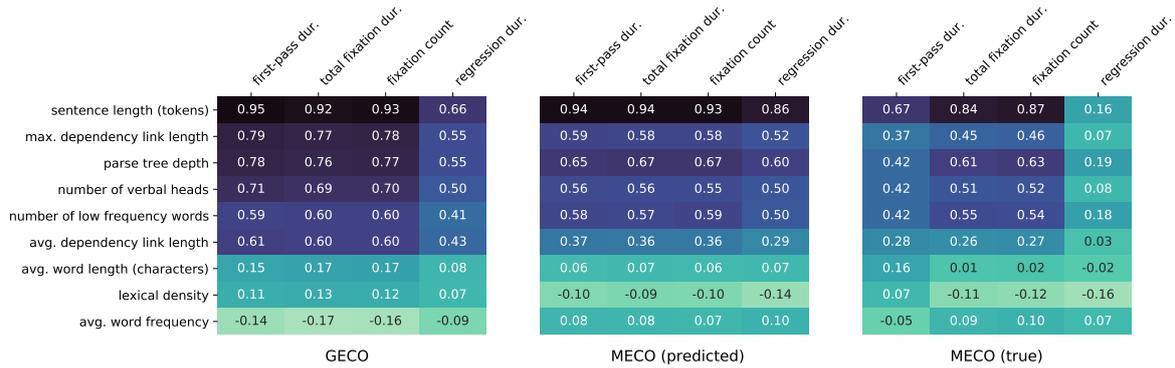

Figure 3: Spearman correlations between complexity features and eye-tracking metrics of GECO and the English part of MECO (predicted versus true). A darker color represents a stronger correlation. All GECO correlations are significant ($p < 0.001$); MECO correlations above 0.2 are significant ($p < 0.01$).

ing patterns to predict regression duration. Further research is needed to better understand the linguistic features underlying regression duration.

5.2 Feature-Based Prediction

To further establish which complexity features are good predictors for each individual eye-tracking metric, we examine the extent to which the four eye-tracking metrics can be predicted from explicit features. Since multi-task learning seems to have a negative impact on learning the structural features underlying each individual eye-tracking metric, we train a separate feature-based model for each eye-tracking metric individually. We use support vector machines (SVM) with a linear kernel as our feature-based regression models. We employ the SVR implementation from scikit-learn (Pedregosa et al., 2011) with all default parameters and use different subsets of features from Table 1: 1) only the two length features, 2) only the two frequency features, 3) only the five structural (i.e., morpho-syntactic and syntactic) features, and 4) all nine features.

As the SVM models predict a simpler problem (a single eye-tracking metric), it is not surprising that they outperform the fine-tuned multi-task model with respect to the absolute predictions (as measured by R^2 , see appendix Figure 9). More interestingly, Figure 4 shows that the multi-task model is able to capture a similar amount of variance as the length-based SVM. Furthermore, we see that the length-based SVM performs almost identically to the SVM trained on *all* complexity features, outperforming the SVMs trained on frequency features and structural features. This shows that length is a strong predictor for sentence-level eye-tracking metrics, and suggests that structural and frequency

features do not provide much additional information. We further investigate if length is the main factor affecting the predictions of the fine-tuned model in the following section.

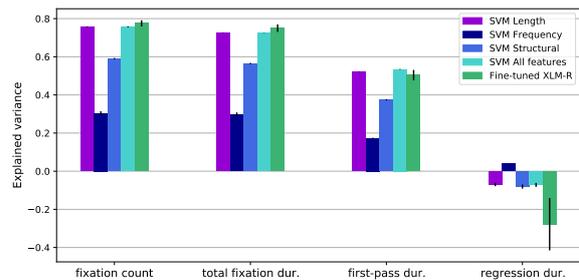

Figure 4: Explained variance of the four feature-based SVM models and the fine-tuned XLM-R model. The models are trained on GECO using 5-fold cross-validation and evaluated on the English part of MECO; error bars denote the standard deviation over folds.

6 The Role of Sentence Length

To test whether the fine-tuned XLM-R model captures more sophisticated structural information than sentence length, we conduct two additional experiments. First, we probe the final-layer representations of the model for the complexity features from Table 1, both before and after fine-tuning on eye-tracking data. Second, we compare the performance of the fine-tuned model to a control condition: we randomize the word order within each MECO sentence to analyze the prediction performance on scrambled input.

6.1 Probing Set-up

We train regressors g_i to predict a value for each of the nine latent factors of structural complexity

$Z = z_1, \dots, z_9$ using XLM-R’s final-layer representation $\theta(x)$ of our input sentence x . The prediction accuracy of g_i is an indication of how prominently the linguistic property z_i is encoded in θ . We analyze this both for the pre-trained and fine-tuned representations of XLM-R to quantify the relative increase of sensitivity to z_i after fine-tuning on eye-tracking metrics.

We conduct the probing experiments for three typologically different languages to analyze if the structural sensitivity that was acquired from English eye-tracking data transfers to other languages. As input, we use 1,000 parallel sentences from the English, Korean and Turkish parts of the Parallel Universal Dependencies (PUD) treebanks which were randomly selected from Wikipedia and news articles (Zeman et al., 2017). We apply a 5-fold cross-validation setting with 800 sentences for training the probing regressors for each language and the remaining 200 for testing. We use the same architecture as described in Section 3.2, but freeze the encoder model and only update the final regression layer during training. The regression layer contains nine probing heads (one for each linguistic feature) and is trained for 5 epochs.⁴

6.2 Results

We report the results of the probing experiments and the model performance on scrambled inputs.

Probing Figure 5 shows the relative probing performance for each complexity feature. We see that fine-tuning yields the largest improvements for probing sentence length and average dependency link length. For the other complexity features, we see that the fine-tuned representations yield little to no improvement in probing accuracy compared to the pre-trained representations. This mostly concerns the features for which sentence length is factored out, i.e., average word frequency, average word length and lexical density. Sarti et al. (2021) report similar results and show that increased probing performance for dependency features persists for sentences of the same length. This provides additional evidence that structural information is learned in addition to low-level length information.

We observe only minor differences in probing accuracy for individual complexity features of En-

⁴We report results for a multi-task set-up for probing in line with Sarti et al. (2021) and use the same hyperparameters as for the fine-tuning experiments but without intermediate evaluation on a development set. We also ran single-task probing as a sanity check and obtained similar results.

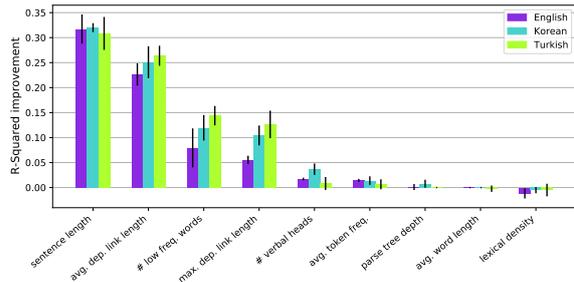

Figure 5: Relative improvement in R^2 for complexity features of English, Korean and Turkish sentences in fine-tuned XLM-R sentence representations over pre-trained representations. The results are calculated using probing regressors and averaged over 5 folds.

glish, Korean and Turkish sentences. The general pattern is consistent for all languages: features related to the structural complexity of sentences are more easily predicted after fine-tuning on eye-tracking metrics. This indicates that the fine-tuned model is able to transfer structural complexity knowledge acquired from English eye-tracking data to other languages.

Influence of Word Order We compare the performance of the fine-tuned model on sentences with normal versus scrambled word order, both in terms of explained variance and R^2 . We measure similar explained variance scores for both input types. This indicates that the model is able to account for a large portion of the variance in our eye-tracking data by merely considering sentence length. The R^2 scores, on the other hand, are consistently lower for scrambled inputs, as shown for total fixation duration in Figure 6 (see appendix Figure 10 for the other eye-tracking metrics). We conclude that the model is sensitive to word order and bases its eye-tracking predictions not only on sentence length but also on more complex structural characteristics.

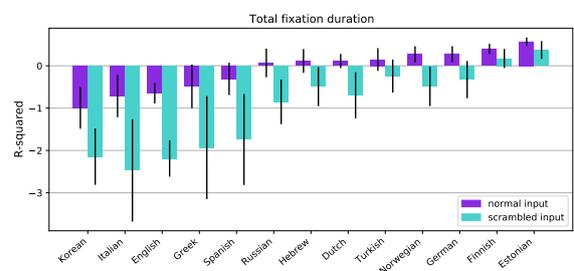

Figure 6: R^2 scores for total fixation duration for each language in MECO, both for sentences with normal and scrambled word order. The results are averaged over 5 folds; error bars denote the standard deviation.

7 Conclusion

We find that XLM-R can apply cross-lingual transfer to predict cognitive processing difficulty with similar performance across 13 typologically diverse languages, despite being fine-tuned only on English data. We conducted a range of experiments to quantify the model’s sensitivity to structural complexity and find that the fine-tuned model prominently encodes sentence length, but also considers more complex structural information such as dependency structure and word order for the prediction of eye-tracking metrics.

Our analyses suggest that domain differences in training and testing data have a greater impact on model performance than language differences within the same domain. More specifically, XLM-R performs better on in-domain GECO data than cross-domain MECO data, but within MECO, XLM-R shows similar performance across languages. This aligns with the findings of [Morger et al. \(2022\)](#), who show that the correlation between relative importance metrics and total fixation duration is influenced by text domain. Our study highlights the significance of controlling for text domain and size, as it allows to evaluate cross-lingual generalization that is independent of dataset characteristics.

In future work, we plan to better account for individual differences between readers ([Brandl and Hollenstein, 2022](#)) and spill-over effects across sentence boundaries ([Wiechmann et al., 2022](#)). The modeling approach for learning eye-tracking patterns also needs further exploration. We find that sentence-level prediction of eye-tracking patterns works well for learning about structural complexity, but that it is not optimal for capturing lexical complexity. Token-level measures, as predicted in [Hollenstein et al. \(2021\)](#), are more likely to be informative about lexical phenomena. A joint loss for sentence and token-level eye-tracking metrics might lead to sensitivity to a wider range of linguistic complexity features.

8 Limitations

The main limitation of our work is the use of relatively small datasets for testing our models due to limited availability of eye-tracking data in multiple languages. The dataset used for testing cross-lingual transfer (MECO) contains approximately 100 sentences per language. For probing structural complexity, we used a sample of 1,000 sentences

per language.

As in related work, we averaged the eye-tracking metrics over readers to obtain a more robust indication of human reading behavior. This approach disregards the fact that reading is a highly individual process that is dependent on cognitive factors and experience. A computational model might develop a better sense of linguistic complexity when it learns about the linguistic properties that lead to variation across readers and we are working towards methods for integrating this information.

Abstract

Script diversity presents a challenge to Multilingual Language Models (MLLM) by reducing lexical overlap among closely related languages. Therefore, transliterating closely related languages that use different writing scripts to a common script may improve the downstream task performance of MLLMs. We empirically measure the effect of transliteration on MLLMs in this context. We specifically focus on the Indic languages, which have the highest script diversity in the world, and we evaluate our models on the IndicGLUE benchmark. We perform the Mann-Whitney U test to rigorously verify whether the effect of transliteration is significant or not. We find that transliteration benefits the low-resource languages without negatively affecting the comparatively high-resource languages. We also measure the cross-lingual representation similarity of the models using centered kernel alignment on parallel sentences from the FLORES-101 dataset. We find that for parallel sentences across different languages, the transliteration-based model learns sentence representations that are more similar.

1 Introduction

In the last few years, we have seen impressive advances in many NLP tasks. These advances have been primarily led by the availability of large representative corpora and improvement in the architecture of large language models. While improving model architectures, training methods, regularization techniques, etc., can help advance the state of NLP in general, the unavailability of large, diverse corpora is the bottleneck for most languages (Joshi et al., 2020). Thus to inclusively advance the state of NLP across languages, it is crucial to develop techniques for training MLLMs that can extract the most out of existing multilingual corpora. Here, we focus on the issue of diverse writing scripts used by

closely related languages that may prevent MLLMs from learning good cross-lingual representations. Previous papers (Pfeiffer et al., 2021) have noted that low-resource languages that use unique scripts tend to have very few tokens representing them at the tokenizer. As a result, these languages tend to have more *UNK* tokens, and the words in these languages tend to be more split up by subword tokenizers. Often we can easily transliterate from one script to another using rule-based systems. For example, there are established standards that can be used to transliterate Greek (ISO 843), Cyrillic (ISO 9), Indic scripts (ISO 15919), and Thai (ISO 11940) to the Latin script.

In this paper, we focus on the Indic languages, which have the highest script diversity in the world. Many South Asian and Southeast Asian languages are intimately connected linguistically, historically, phonologically (Littell et al., 2017) and phylogenetically. However, due to different scripts, it is difficult for MLLMs to fully exploit this shared information. Among the Indic languages we considered in this study we encounter eleven different scripts. These are shown in Table 1. Nevertheless, these scripts have shared ancestry from the ancient Brahmic script (Hockett et al., 1997; Coningham et al., 1996) and have similar structures that we can easily use to transliterate them to a common script. Also, many of these languages heavily borrow from Sanskrit, and due to its influence, many words are shared among these languages. Therefore, due to their relatedness and highly diverse script barrier, the Indic languages presents a unique opportunity to analyze the effects of transliteration on MLLMs.

We empirically measure the effect of transliteration on the downstream performance of MLLMs. We pretrain ALBERT (Base, 11M Parameters) (Lan et al., 2020) and RemBERT (Base, 192M Parameters) (Chung et al., 2020) models from scratch

on Indic languages. We pretrain two variants of each model, one with the original writing scripts and the other after transliterating to a common writing script. Henceforth, we will refer to the transliterated script model as uni-script model and the other as a multi-script model. We evaluate the models on downstream tasks from the IndicGLUE benchmark dataset (Kakwani et al., 2020). In order to rigorously compare the two models, we finetune using nine random seeds on all downstream tasks. Then we perform the Mann-Whitney U test (MWU) between the uni-script and multi-script models. Using the MWU test, we conclude that transliteration significantly benefits the low-resource languages without negatively affecting the comparatively high-resource languages.

We also measure the Cross-Lingual Representation Similarity (CLRS) to understand why the uni-script model performs better than the multi-script model. To measure the CLRS, we use the centered kernel alignment (CKA) (Kornblith et al., 2019) similarity score. We measure the CKA similarity score between the hidden representations of the models on the parallel sentences of the Indic languages from the FLORES-101 dataset (Goyal et al., 2022). We find that, compared to the multi-script models, the uni-script models achieve a higher CKA score, and it is more stable throughout the hidden layers of the models. Based on this, we conclude that the uni-script models learn better cross-lingual representation than the multi-script models. In summary, our contributions are primarily three-fold:

1. We find that transliteration significantly benefits the low-resource languages without negatively affecting the comparatively high-resource languages.
2. We establish this finding through rigorous experiments and show the statistical significance along with the effect size of transliteration using the Mann-Whitney U test.
3. Using CKA on the FLORES-101 dataset, we show that transliteration helps MLLMs learn better cross-lingual representation.

weights can be downloaded from HF Hub^{2 3 4 5}.

2 Motivation and Background

2.1 Motivation

In their study, Joshi et al. (2020) showed the resource disparity between low-resource and high-resource languages, and Ruder (2020) discussed the necessity of working with low-resource languages. A large body of work suggests that language-relatedness can help MLLMs achieve better performance on low-resource languages by leveraging related high-resource languages. For instance, Pires et al. (2019) found that lexical overlap improved mBERT’s multilingual representation capability even though it learned to capture multilingual representations with zero lexical overlaps. Dabre et al. (2017) showed that transfer learning in the same or linguistically similar language family gives the best performance for NMT. Lauscher et al. (2020) found that language relatedness is crucial for POS-tagging and dependency parsing tasks. Although, corpus size is much more important for NLI and Question Answering tasks. Wu and Dredze (2020) showed that bilingual BERT outperformed monolingual BERT on low-resource languages when the languages were linguistically closely related. Nevertheless, mBERT outperformed bilingual BERT on low-resource languages.

2.2 Script Barrier in Multilingual Language Models

One of the major challenges in leveraging transfer between high-resource and low-resource languages is overcoming the script barrier. Script barrier exists when multiple closely related languages use different scripts. Anastasopoulos and Neubig (2019) found that for morphological inflection, script barrier between closely related languages impedes cross-lingual learning, and language relatedness improved cross-lingual transfer. Transliteration and phoneme-based techniques have been proposed to solve this issue. For example, Murikinati et al. (2020) expanded upon Anastasopoulos and Neubig (2019) and showed that both transliter-

⁵<https://huggingface.co/ibraheemmoosa/xlmindic-rembert-multiscript>

ation and grapheme to phoneme (g2p) conversion removes script barrier and improves cross-lingual morphological inflection and Rijhwani et al. (2019) showed that pivoting low-resource languages to their closely related high-resource languages results in better zero shot entity linking capacity and used phoneme-based pivoting to overcome the script barrier. Bharadwaj et al. (2016) showed that phoneme representation outperformed orthographic representations for NER. Chaudhary et al. (2018) also used phoneme representation to resolve script barriers and adapt word embeddings to low-resource languages.

2.3 Transliteration in Language Modeling

Different works have applied transliteration in different aspect for language models. For instance, Goyal et al. (2020) and Song et al. (2020) both utilized transliteration and showed that language relatedness was required for improving performance on NMT. Amrhein and Sennrich (2020) studied how transliteration improved NMT and came to the conclusion that transliteration offered significant improvement for low-resource languages with different scripts.

Khemchandani et al. (2021) showed on Indo-Aryan languages that language relatedness could be exploited through transliteration along with bilingual lexicon-based pseudo-translation and aligned loss to incorporate low-resource languages into pretrained mBERT. Muller et al. (2021) showed that for unseen languages, the script barrier hindered transfer between low-resource and high-resource languages for MLLMs and transliteration removed this barrier. They showed that transliterating Uyghur, Buryat, Erzya, Sorani, Meadow Mari, and Mingrelian to Latin script and finetuning mBERT on the respective corpus with masked language modeling objective improved their downstream POS performance significantly. In contrast, K et al. (2020) and Artetxe et al. (2020) proposes that mBERT can learn cross-lingual representations without any lexical overlap, a shared vocabulary, or joint training. However, these works focus on zero-shot cross-lingual transfer learning only. From the literature, it can be seen that many in the community believe transliteration to be a potential solution for script barriers. However, most of the work shows the benefits of transliteration for NMT. Nevertheless, there is no solid empirical analysis of the effects of transliteration for MLLMs

apart from Dhamecha et al. (2021); Muller et al. (2021). Hence, the motivation behind this paper is to provide a solid empirical analysis of the effect of transliteration for MLLMs with statistical analysis and determine whether or not it helps models learn better cross-lingual representation.

It should also be noted that, even though our idea seems to be similar to Muller et al. (2021) and Dhamecha et al. (2021), there are major differences. For instance, Muller et al. (2021) adapted existing pretrained model to very low-resource languages. Whereas, we focus on training the models with transliteration from scratch. We also train our models on 20 languages and evaluate on more than 50 tasks. Unlike Dhamecha et al. (2021), we also include Dravidian Languages in our analysis. Furthermore, we focused on the issue of script barrier while Dhamecha et al. (2021) focused on multilingual fine-tuning. Whereas, we adopt multilingual fine-tuning on all our models. Thus the improvement we see comes only from circumventing the script barrier. Moreover, we have provided statistical testing to show the significance of transliteration instead of just showing better metrics. We also performed cross-lingual representation similarity analysis to show the benefits of transliteration.

2.4 Cross Lingual Similarity Learning in Language Modeling

Several techniques have recently been used to study the hidden representations of multilingual language models. Kudugunta et al. (2019) study CLRS of NMT models using SVCCA (Raghu et al., 2017). Singh et al. (2019) used PWCCA (Morcos et al., 2018) to study the CLRS of mBERT and found that it drastically fell with depth. (Conneau et al., 2020) have used CKA to study the CLRS of bilingual BERT models. They found that similarity is highest in the first few layers and drops moderately with depth. Müller et al. (2021) used CKA to study CLRS of mBERT before and after finetuning on downstream tasks. They found in all cases that CLRS increases steadily in the first five layers, then it decreases in the later layers. From this, they concluded that mBERT learns multilingual alignment in the early layers and preserves it throughout finetuning. Del and Fishel (2021) applied various similarity measures to understand CLRS of various multilingual masked language models. Their results also show that CLRS increases in the first half of the models, while in the later layers, this

similarity steadily falls.

3 Experiment and Results

3.1 Mann–Whitney U test

We perform Mann–Whitney U test (MWU) (Mann and Whitney, 1947; Wilcoxon, 1945) to determine if the performance differences between the multi-script and the uni-script models are significant. In short, it tells us the effect of transliteration on model performance. MWU is a non-parametric hypothesis test between two groups/populations. MWU is chosen because it has weak assumptions. The only assumptions of MWU are that the samples of the two groups are independent of each other, and the samples are ordinal. Under the MWU, our null hypothesis or \mathbf{h}_0 is that the performances of the uni-script (group 1) and the multi-script (group 2) models are similar, and the alternative hypothesis or \mathbf{h}_a is that the performances (groups) are different. We set our confidence interval α at 0.05 and reject the \mathbf{h}_0 for the p-values $< \alpha$. We also report three test statistics as the p-value only gives statistical significance, which can be misleading at times (Sullivan and Feinn, 2012).

The test statistics are three different effect sizes that convey three different information. These test statistics are absolute effect size (δ), common language effect size (ρ), and standardized effect size (r). The absolute effect size δ is the difference between the mean of the models’ performance metric, which is given as,

$$\delta = \mu_{\text{uni-script}} - \mu_{\text{multi-script}}$$

for any given task and language. When the \mathbf{h}_0 is rejected for any given task, a positive δ indicates the uni-script model is better, and a negative δ indicates the multi-script model is better. The details and results of common language effect size (ρ), and standardized effect size (r) are presented in appendix D.

3.2 Dataset

The ALBERT models were pretrained on a subset of the OSCAR corpus containing Indo-Aryan languages. We use the unshuffled deduplicated version of OSCAR corpus (Ortiz Su’arez et al., 2019) available via Huggingface datasets library (Lhoest et al., 2021). We pretrain on Panjabi, Hindi, Bengali, Oriya, Assamese, Gujarati, Marathi, Sinhala, Nepali, Sanskrit, Goan Konkani, Maithili, Bihari, and Bishnupriya portion of the OSCAR corpus.

The RemBERT models were trained on a significantly larger pretraining corpus with additional languages. We pretrained the RemBERT models on a combination of Wikipedia (Foundation), mC4 (Raffel et al., 2019), OSCAR2109 (Abadji et al., 2021) and OSCAR corpus. These datasets are also available via the Huggingface datasets library. In addition to the languages in the ALBERT pretraining corpus, we consider English, four Dravidian languages Kannada, Telugu, Malayalam, and Tamil, and an Indo-Aryan language Dhivehi. We evalu-

Lang.	Sub-family	Script	Size(GB)

Table 1: Languages in our pretraining corpus and their writing scripts and the pretraining corpus sizes used for the RemBERT model

ate the models on four downstream tasks from IndicGLUE (Kakwani et al., 2020), which are News Article Classification, WSTP, CSQA, and NER. We use the balanced Wikiann dataset from Rahimi et al. (2019) for NER. In addition, we evaluate the models on other publicly available datasets that are part of the IndicGLUE benchmark. These are BBC Hindi News Classification, Soham Bengali News Classification, INLTK Headlines Classification, IITP Movie, and Product Review Sentiment Analysis (Akhtar et al., 2016), MIDAS Discourse Mode Classification (Dhanwal et al., 2020) and ACTSA Sentiment Classification (Mukku and Mamidi, 2017) datasets.

3.3 Transliteration Method

We transliterate Indic language texts to Latin script using the ISO 15919 transliteration scheme. We tested with two publicly available implementations of this scheme, Aksharamukha (Rajan, 2015) and PyICU (PyICU). We found the quality of translit-

eration of the Aksharamukha library to be better. Thus we use this library for transliterating the inputs to the ALBERT uni-script model. However, the Aksharamukha implementation is very slow compared to the PyICU implementation. As we significantly expanded our pretraining corpus for the RemBERT model, we switched to PyICU for the RemBERT uni-script model.

3.4 Downstream Finetuning

We finetune the models on each downstream task independently. The specific hyperparameters used for each task are reported in the appendix B. On all tasks, we finetune with nine random seeds and report the average and standard deviation of the metrics. In Table 2 and Table 4, we report the performances on IndicGLUE benchmark tasks and in Table 3 on other publicly available datasets. Here, we discuss the results on each of the the models on each of the tasks. Furthermore, in appendix D, we show the test statistics for all the datasets.

Wikipedia Section Title Prediction: For both RemBERT and ALBERT models, the uni-script model performed better on all languages except Malayalam (ml). We noticed that a letter of Malayalam script is not properly transliterated by the PyICU library. This introduced some artifacts in the form of unnecessary splitting of words by the subword tokenizer.

News Category Classification: It is interesting that on this task the uni-script models performed better for Panjabi (pa) and Oriya (or) languages. It is clear from Table 1 that these two languages are low-resource compared to Bengali (bn) and Marathi (mr). On Bengali and Marathi we see slight performance degradation which is not statistically significant. This shows the validity of our first finding.

Named Entity Recognition: On this task we see that the uni-script model performs much better for Assamese (as), Oriya(or), Panjabi (pa) and Gujarati (gu). These languages are low-resource and here again the uni-script model shines. The large performance improvement on this task can be explained by the fact that Named Entities usually have the same spelling after transliteration for Indian languages. Thus the uni-script model has better chances for learning various named-entities during pre-training.

Article Genre, Sentiment & Discourse Mode Classification: We evaluate the models on various

other sequence classification datasets that are part of the IndicGLUE benchmark. Here again the uni-script model usually performs better than the multi-script model. However for two tasks in Malayalam (ml) and Tamil (ta) we see better performance for the multi-script model. We already mentioned that there is some tokenization issue for Malayalam which can explain the results for Malayalam. The results for Tamil suggests that it may be a good idea to try both uni-script and multi-script model if they are available to see which performs best on a particular task. However this is the only instance of a task where we see the multi-script model perform better.

3.5 Zero Shot Capability Testing

We use the CSQA task to test the zero-shot capability of the models as we can use the models without finetuning. This task is designed to test whether language models can be used as knowledge bases (Petroni et al., 2019). In Table 4 we report the results. We note that the RemBERT models perform much better than the ALBERT models on this task. This is expected as the ALBERT models' memorization capability is hampered by weight sharing.

The ALBERT uni-script model is better on all languages compared to the ALBERT multi-script model. This shows the potential of a uni-script model in a restricted low parameter situation. For the RemBERT models, the results are mixed. However, on average the uni-script model performs better than the multi-script model. The worst results are for Malayalam (ml) which as we mentioned before has some tokenization issues.

4 Cross-lingual Representation Similarity

In this section, we analyze why the uni-script model performs better than the multi-script model from the perspective of Cross-Lingual Representation Similarity. Following (Müller et al., 2021), (Conneau et al., 2020) and (Del and Fishel, 2021) we apply CKA to measure CLRS. We use the CKA implementation from the Ecco library (Alammar, 2021). We use parallel sentences on thirteen languages from the FLORES-101 (Goyal et al., 2022) dataset. For the ALBERT models, which are trained on only the Indo-Aryan languages, we only consider Panjabi, Hindi, Bengali, Oriya, Assamese, Gujarati, Marathi, and Nepali sentences. For the RemBERT models, we additionally consider Kannada, Telugu, Malayalam, Tamil, and English sentences.

cyan indicates multi-script is better than uni-script models and blue indicates vice versa

Table 4: Test accuracy on CSQA

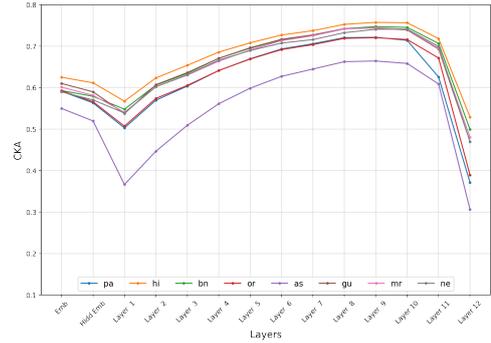

First, we calculate the sentence embeddings of these parallel sentences from the models. Sentence embedding is calculated by averaging the hidden state representations of the tokens. Then, we calculate the CKA similarity score between the sentence embeddings for each language pair. For each language, we average its CKA similarity scores. In Figure 1 we plot this average CKA similarity for

each layer of the models.

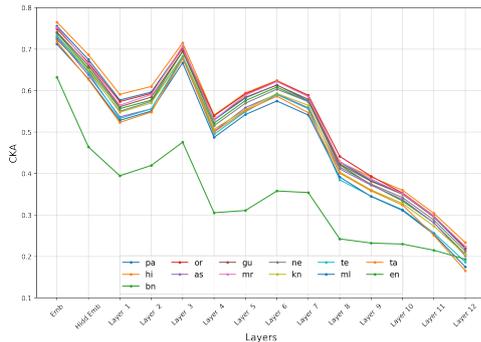

We see that CLRS score drops significantly at the last layer for all models. However, the uni-script models retain high CLRS score until the eleventh layer, whereas the multi-script models have low CLRS score from the ninth layer. Overall the CLRS score of the uni-script models are more stable. This indicates that the uni-script models have learned

Figure 1: CKA Similarity Score for the multi-script and uni-script models

better cross-lingual representations.

5 Tokenizer Quality Analysis

In terms of performance, we expect the transliteration model to exploit better tokenization across the languages. Following (Ács, 2019) and (Rust et al., 2021), we measure the subword fertility (average number of tokens per word) and the ratio of words unbroken by the tokenizer. From figure 2, we can see that transliteration reduces the splitting of words. This indicates that many words that were represented by different tokens in the multi-script model are represented by a single token in the transliteration model. On average, the ALBERT uni-script tokenizer has a lower subword fertility score of 1.55 compared to the multi-script tokenizer’s 1.825. The uni-script tokenizer also has a lower proportion of continued word score of 0.36 while the multi-script tokenizer has a score of 0.45.

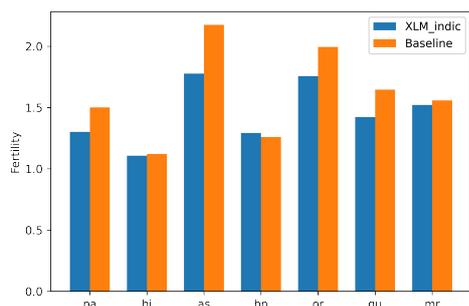

6 Conclusion and Future Work

In this paper, we show that transliterating closely related languages to a common script improves multilingual language model performance and leads to better cross-lingual representations. We conducted

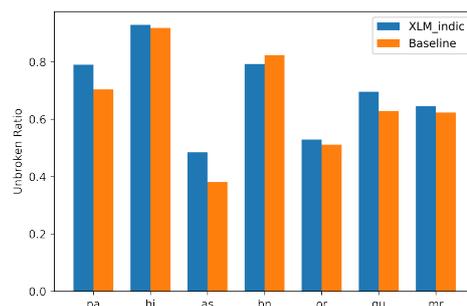

rigorous statistical analysis to quantify the significance and effect size of transliteration on downstream task performance. We found that transliteration especially improves performance on comparatively low-resource languages and did not hurt the performance on high-resource languages. This findings are in agreement with (Dhamecha et al., 2021; Muller et al., 2021). Our results indicate that in other scenarios where closely related languages use different scripts, transliteration can be used to improve the performance of language models. For example, Slavic and Turkic languages present similar scenarios. We would like to extend our study to models at different scales and more languages in the future. Also, another interesting future direction would be to just use the transliteration for pretraining signal but give the model the ability to deal with the original scripts.

Limitations

A limitation of our work is that it introduces a transliteration step into the model pipeline. Thus we need a stable implementation of the transliteration scheme. Thus the model can become tied to a specific version of the transliteration library. Also

(a) Subword Fertility.

(b) Unbroken Ratio.

Figure 2: Subword fertility (lower is better) and unbroken ratio (higher is better)

the transliteration scheme is not perfect as we saw for Malayalam, it introduced some artifacts. Finally given our limited computational budget, we could not run experiments with a lot of models at different scales. Thus the impact of transliteration over different model scales has not been explored. Even though our work has these limitations, it clearly shows transliteration as an important tool for training better multilingual models.

Ethics Statement

In their study, Joshi et al. (2020) showed the resource disparity between low-resource and high-resource languages, and (Ruder, 2020) also highlighted the necessity of working with low-resource languages. However, creating representative and inclusive corpora is a difficult task and an ongoing process and is not always possible for many low-resource languages. Thus to inclusively advance the state of NLP across languages, it is crucial to develop techniques for training MLLMs that can extract the most out of existing multilingual corpora. Hence, we believe our analysis might help MLLMs with low-resource languages in real-world applications. However, there is one ethical issue that we want to state explicitly. Even though we pre-train on a comparatively large multilingual corpus, the model may exhibit harmful gender, ethnic and political bias. If the model is fine-tuned on a task where these issues are important, it is necessary to take special consideration when relying on the model’s decisions.

A Cloze Style QA Evaluation Method

Since a word can be tokenized to multiple tokens by the subword tokenizer, correctly evaluating the model on this task requires special care. Specifically, we have to use the same number of mask tokens as the number of subword tokens that a word gets split into. Then we calculate the probability for the word by multiplying the probability of the subword tokens predicted by the masked language model.

B Pretraining Details

Corpus Preparation: Since the OSCAR corpus contains raw text from the Web, we apply a few filtering and normalization. First, we discard entries where the dominant script does not match the language tag provided by the OSCAR corpus. Then we use the IndicNLP normalizer (Kunchukutan, 2020) to normalize the raw text. For the uniscript model, we then transliterate all the text to ISO-15919 format using the Aksharamukha (Rajan, 2015) library.

For the RemBERT models we do not perform any of the filtering mentioned above since our pretraining corpus is comparatively very large. In this case, we use the PyICU library (PyICU) for transliterating to ISO-15919 format.

Tokenizer Training: For the ALBERT models, we train two SentencePiece tokenizers (Kudo and Richardson, 2018) on the transliterated and the non-transliterated corpus with a vocabulary size of 50,000. For the RemBERT models we train Unigram tokenizers from the Tokenizers library (Wolf et al., 2020) with a vocabulary size of 65,536.

ALBERT Model Training: We first pretrained an ALBERT base model from scratch on the non-transliterated corpus as our baseline. Afterward, we pretrained another ALBERT base from scratch on the transliterated corpus. We chose the base model due to computing constraints. We trained

the models on a single TPUv3 VM. Both models were trained using the same hyperparameters. We followed the hyperparameters used in (Lan et al., 2020) except for batch size and learning rate. The pretraining objective is also the same as (Lan et al., 2020). We used a batch size of 256, which is the highest that fits into TPU memory, whereas the ALBERT paper used a batch size of 4096. As our batch size is $1/16^{\text{th}}$ of the ALBERT paper, we use a learning rate of $1e-3/8$, which is approximately $1/16^{\text{th}}$ of the learning rate used in the ALBERT paper ($1.76e-2$). Additionally, we use the Adam optimizer (Kingma and Ba, 2015) instead of the LAMB optimizer. The rest of the hyperparameters were the same as the ALBERT paper. Specifically, we use a sequence length of 512 with absolute positional encoding, weight decay of $1e-2$, warmup steps of 5000, max gradient norm of 1.0, and Adam epsilon of $1e-6$. The models were trained for 1M steps. Each model took about 7.5 days to train. We use the ALBERT implementation from the Huggingface Transformers Library (Wolf et al., 2020).

RemBERT Model Training: We pretrained an RemBERT base models similar to the ALBERT models. We trained the models on a single TPUv3 VM. Both models were trained using the same hyperparameters. We followed the hyperparameters used in (Chung et al., 2020) except for batch size and learning rate. The pretraining objective is also the same as (Chung et al., 2020). We used a batch size of 256, which is the highest that fits into TPU memory, whereas the RemBERT paper used a batch size of 2048. As our batch size is $1/8^{\text{th}}$ of the RemBERT paper, we use a learning rate of $2e-4/8$, which is $1/8^{\text{th}}$ of the learning rate used in the RemBERT paper. Similar to the ALBERT model, we use the Adam optimizer (Kingma and Ba, 2015). The rest of the hyperparameters were the same as the RemBERT paper. Specifically, we use a sequence length of 512 with absolute positional encoding, weight decay of $1e-2$, warmup steps of 15000, max gradient norm of 1.0, and Adam epsilon of $1e-6$. The models were trained for 1M steps. Each model took about 7.5 days to train. We use the RemBERT implementation from the Huggingface Transformers Library (Wolf et al., 2020).

C Downstream Hyperparameters

Hyperparameters for downstream tasks are presented in Table 5 and Table 6.

MIDAS Discourse Mode	False	16	8e-6	0.1	0.1	2500	0.1

Table 6: Hyperparameters for RemBERT models

For the ALBERT models batch size was chosen to be the maximum that fits in memory. This was done so that each batch contains approximately the same number of tokens. Otherwise the hyperparameters were chosen following the recommendations of (Mosbach et al., 2021). On the highly skewed IITP Movie Review, IITP Product Review and MIDAS Discourse we found that this default setting resulted in worse performance compared to the independent baselines. So we finetuned the learning rate and classifier dropout on the validation set of these tasks.

For the RemBERT models learning rate, weight decay, dropout, steps and label smoothing were chosen based on grid search with a few values.

D Test Statistics Results

ρ gives us the probability of one group being better than the other group. That is the probability that a random performance sample of the uni-script model is greater than a random performance sample of the multi-script model. The last test statistic is r which indicates the magnitude of difference

between the performance values of the uni-script model (group 1) and the multi-script model (group 2). r shows us how realistically significant the performance differences are between models even if the performance difference is statistically significant. It gives us a value between 0 to 1 and its ranges are: **small effect** ($0 \leq r \leq 0.3$), **medium effect** ($0.3 < r \leq 0.5$) and **large effect** ($0.5 < r$). We performed MWU on all downstream tasks except CSQA. On CSQA, we only report the δ . The MWU is performed using the SciPy library (Virtanen et al., 2020), and the results are further validated using R (Lüdecke, 2020). These statistics are reported in Table 7 for the IndicGLUE classification tasks and in Table 8 for the public dataset classification tasks.

Abstract

In this paper, we focus on the topics of misinformation and racial hoaxes from a perspective derived from both social psychology and computational linguistics. In particular, we consider the specific case of anti-immigrant feeling as a first case study for addressing racial stereotypes. We describe the first corpus-based study for multilingual racial stereotype identification in social media conversational threads. Our contributions are: (i) a multilingual corpus of racial hoaxes, (ii) a set of common guidelines for the annotation of racial stereotypes in social media texts, and a multi-layered, fine-grained scheme, psychologically grounded on the work by Fiske et al., including not only stereotype presence, but also contextuality, implicitness, and forms of discredit, (iii) a multilingual dataset in Italian, Spanish, and French annotated following the aforementioned guidelines, and cross-lingual comparative analyses taking into account racial hoaxes and stereotypes in online discussions. The analysis and results show the usefulness of our methodology and resources, shedding light on how racial hoaxes are spread, and enable the identification of negative stereotypes that reinforce them.

1 Introduction

Racial Hoaxes (RHs) are “a communicative act oriented to spread fallacious information against a social group” (Russell, 1998). As social media have become a dominant means of communication, investigating them is crucial for tackling the spread of RHs. We approach this task combining

psychological and computational linguistics methods with a multilingual, cross-cultural perspective (Italian, Spanish, and French).

In particular, RHs can contribute to the diffusion of stereotypes about people belonging to the *outgroup*, i.e., a social group with features that differ from the *ingroup* (Rooduijn et al., 2021) and are, thus, more vulnerable. Even common, naive users are as likely to become spreaders of RHs as malicious users (Papapicco et al., 2022). In this paper, we cover a specific theme: anti-immigrant stereotypes. The discursive construction of immigrants and refugees in user interaction on social media has been studied by Ekman (2019), who has shown how racial expressions and overt racism are becoming increasingly normalized, thus leading to prejudices and racial stereotypes and, eventually, even harmful acts.

Overall, the attention to these topics is relatively new in the NLP community, and thus, there is still a meaningful lack of annotated resources for the development of automatic tools to detect stereotypes and related phenomena. Among the few research contributions in this direction, Sanguinetti et al. (2020) organized the second edition of HaSpeeDe at EVALITA 2020, asking participants to automatically detect hate speech and stereotypes in Italian tweets and headlines. Similarly, in the DETESTS shared task at IberLEF 2022, Ariza-Casabona et al. (2022) proposed a 10-label classification task for the identification of stereotypes in Spanish; and finally, during IROSTEREO at PAN/CLEF 2022, Ortega-Bueno et al. (2022) proposed an author profiling task regarding stereotype spreaders and studied the link with irony in English. Recently, for French, Chiril et al. (2021) investigated how to improve gender hate speech classification by leveraging stereotype detection based on multitask architectures.

* The first three authors contributed equally.

However, such related works only focus on monolingual contents, without considering multilingual settings from which cross-cultural differences and similarities in the expression of stereotypes can emerge. Furthermore, most of the related work limits the scope of investigation to the mere presence/absence of stereotypes in a single text, without diving into the finer-grained features that arise from psychological studies (Allport et al., 1954; Fiske et al., 2007; Cuddy et al., 2008), and without taking into account their propagation in social media conversational threads. Considering the gaps in current related work, we propose a cross-cultural, and multilingual perspective for studying racial hoaxes and stereotypes. In this work, our original contributions are:

- A Multilingual Racial Hoaxes Corpus that was manually created, extracting fake news about migration and racial content from fact-checking web sites. The list of hoaxes has been employed as the core knowledge-base for extracting texts from social media that spread RHs and the *reactions* to them.¹
- A methodology that makes it possible to collect a full conversational thread, with replies and comments that are written under the post spreading the main racial hoax.
- A multi-layered annotation scheme for the annotation of racial stereotypes in social media texts, which allows us to study how the presence of a racial hoax interacts with the surrounding textual context. The scheme, based on psychological work by Fiske (1998), includes four layers: (a) stereotype presence, (b) contextuality, (c) implicitness and (d) forms of discredit.
- A multilingual dataset annotated according to this scheme. For this first study, we chose to retrieve data in languages that are spoken in three countries on the maritime coast of the Mediterranean basin, where migration is widespread and has been made a particular issue in local politics: Italy, Spain and France.²

¹By ‘reactions’ we refer to replies and comments to the main thread that is spreading a racial hoax.

¹To guarantee anonymity and protect the privacy of Twitter users, throughout this paper, instead of using direct quotations from the tweets, we only provide their English translations and/or adaptations.

²The annotated dataset will be available for research pur-

- Qualitative and quantitative analyses from a comparative perspective of the three language subsets, focusing in particular on the interactions between the topics of RHs, stereotypes and discredit in conversations.

2 Related Work

2.1 RH and stereotypes in Psychology

Hoaxes are a form of ‘misinformation’ that aims to disseminate false information with the intention of making it viral in social media (Wardle and Derakhshan, 2018). In particular, ‘Racial Hoaxes’ are fallacious discursive acts that contribute to the spread of information against a social group because of race, religion or origin, such as ‘immigrants’ (Cerase and Santoro, 2018).

From a psychological point of view, RHs have become an important object of study since, firstly, they help to spread misinformation by attacking, discrediting and damaging immigrants’ image; secondly, they can increase the formation of people’s prejudices and stereotypes towards the *outgroup* (Fiske, 1998). In fact, while the stereotype is the cognitive nucleus of prejudice, which contains a set of beliefs and social images; prejudice is a preconceived attitude that is based on common voices and opinions. RHs, therefore, appear to install a stereotype facilitating a categorization in which there is a generalization through a label referring to an entire group, e.g., ‘all immigrants are thieves’ (Allport et al., 1954).

The manifestations of stereotypes can range from a more explicit to a more implicit expression. It is possible, in fact, to distinguish an EXPLICIT stereotype content when identifying a direct association between immigrants and a particular quality, e.g., ‘immigrants bring us diseases’ (Fiske and Taylor, 2013). IMPLICIT stereotypes can be expressed through evaluative utterances and figures of speech such as metaphors, humor, and irony. For instance, Schmeisser-Nieto et al. (2022) present criteria to identify and annotate implicit stereotypes focusing on immigration.

2.2 Stereotypes in Computational Linguistics

The computational linguistics community has only recently focused on modeling stereotypes in order to automatically recognize them, e.g., within political debates (Sánchez-Junquera et al., 2021a) or

poses upon request, together with the complete set of annotation guidelines.

social media (Sanguinetti et al., 2020; Chiril et al., 2021), but without considering the conversational threads in which they occur, nor their reinforcement or confirmation through RHs.

Recently, Sánchez-Junquera et al. (2021a) proposed a taxonomy of stereotypes about immigrants and approached the problem of the automatic classification of stereotypes in Spanish by focusing on the narrative *frames* that spread the stereotypes. Similarly, Fokkens et al. (2018) approached stereotype detection by extracting the *microporraits* and Card et al. (2016) by extracting *stories* about individuals from text. Beukeboom and Burgers (2019) propose a framework which looks at how stereotypes are shared through language: bias in labels and bias in the description of characteristics and behaviors.

Fraser et al. (2022) rely on the Stereotype Content Model (SCM) and present a computational method to mine large datasets and then map sentences to the two-dimensional plane of perceived *warmth* and *competence* (Fiske et al., 2007). Other common computational approaches in NLP mainly focused on measuring and quantifying social bias towards different groups, especially using techniques of word representation, such as word embedding (Bolukbasi et al., 2016), transformers (Card et al., 2016), techniques of natural language inference (Dev et al., 2020) and masking BERT for racial stereotype detection (Sánchez-Junquera et al., 2021b). In this context, this multidisciplinary study on the stereotypes related to RHs from a multilingual, cross-cultural perspective represents an interesting, novel opportunity to understand the expression, perception, and reinforcement of stereotypes, stemming from RHs, against immigrants in conversations on Twitter.

3 From Racial Hoaxes to Reactions

In order to collect reactions to racial hoaxes on social media, we first created the Multilingual Racial Hoaxes Corpus (MRHC), a list of 239 RHs in three languages: Italian, Spanish, and French. Given the difficulty of spotting them automatically, we collected the entries of the MRHC manually.

Depending on the language, different fact-checking websites or newspapers commenting on hoaxes were used as a source for manually extracting the MRHC between 2019 and 2021. For instance, for Italian we used the debunking sites bufale.net and butac.it; for Spanish [\[ita.es\]\(http://ita.es\) and \[newtral.es\]\(http://newtral.es\); and finally for French \[factuel.afp.com\]\(http://factuel.afp.com\) and \[lemonde.fr/les-decodeurs\]\(http://lemonde.fr/les-decodeurs\).](http://mald</p></div><div data-bbox=)

3.1 Topics of the MRHC

Inspired by the taxonomy of stereotypes proposed in Sánchez-Junquera et al. (2021a); Ariza-Casabona et al. (2022), we defined five macro categories of topics, in which immigrants are perceived as threat by the society.

Table 1 contains some examples for each topic: **(a) Security** for events related to citizen safety, such as murder, sexual assault, fights, terrorist attacks, theft, and public disorder; **(b) Public Health** related to health issues that may potentially affect the population, mainly infectious diseases (e.g., COVID-19); **(c) Migration Control** covers migratory flows, arrivals, disembarkation, border control and the regulation of immigration; **(d) Benefits** describe situations in which the outgroup (immigrants) receives more help, social assistance and welfare benefits than the ingroup; **(e) Religion** covers religious and cultural differences of the out group that threaten the traditions of the ingroup (even though terrorism and religion are closely associated in RH, the former category has been considered under the security topic), and finally, **(f) Others** includes RHs about other topics not included in the previous categories.

In terms of a cross-cultural analysis, we observed variations among the different types of RHs. As shown in Table 2, the most common topic of RHs in Italian is related to Security, accounting for 58.76% of the total, while in Spanish and French, RHs are related to Benefits, accounting for 29.16% and 50% respectively. Another relevant result is that the topic Religion has no representation in the Italian subset, which is also the case of Public Health in the French subset.

3.2 Reactions to RHs

We started the collection procedure by retrieving texts from Twitter that contained one of the RHs from the MRHC, or texts that presented a high similarity to one of those. We searched for texts containing the same URL as the RH, or same title of news of the RH on the debunking sites, or even keywords extracted from the textual body of RH by using the Twitter APIs v2 for Academia.³ In

³<https://developer.twitter.com/en/docs/twitter-api/tools-and-libraries/v2>

Example	Topic
Immigrants out of control: they flee and injure an officer	Security
Migrant with Covid repatriated. And now 100 agents are in quarantine	Public Health
The electoral roll increases because the Government nationalizes 200,000 "illegals"	Migration Control
A foreign minor, 4,700€ per month, your grandmother, 426€ pension per month	Benefits
In Aubervilliers, the sheep ready to be slaughtered for #Eid on their way to the butcher. Mind boggling! #Ramadam	Religion

Table 1: Examples of different topics of RHs. All tweets were originally written either in Italian, Spanish or French. They have been translated to English and adapted to ensure anonymity and guarantee privacy to users.

Language	Benefit	Security	Migration Control	Public Health	Religion	Others	Total
Italian	4.12%	58.76%	15.46%	20.62%	0.00%	1.03%	97
Spanish	29.16%	25.00%	16.66%	12.50%	13.88%	2.77%	72
French	50.00%	25.00%	19.44%	0.00%	5.56%	0.00%	70

Table 2: Percentages of Types of RHs in the three language subsets.

Figure 1 we show the full pipeline employed for the collection of “reactions to racial hoaxes”.

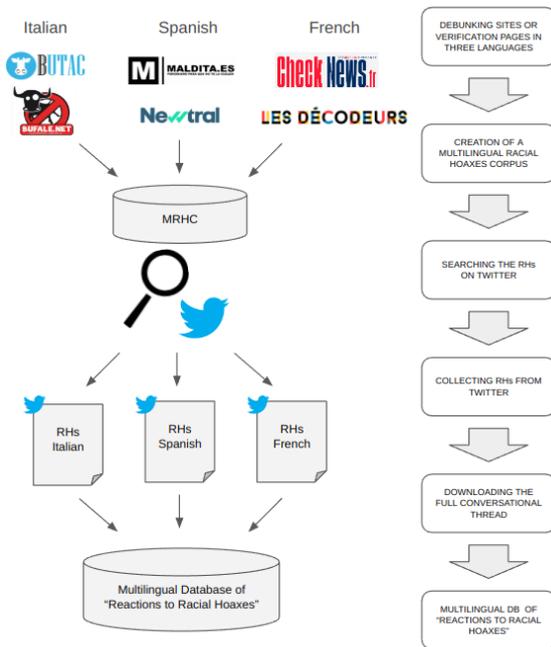

Figure 1: Pipeline for the creation of the Multilingual Racial Hoaxes Corpus (MRHC) and reactions to them.

As can be seen from the picture above, when a racial hoax from the MRHC was found on Twitter, we referred to it as the ‘Conversational Head’, because it was the first text in the conversational thread. Then, for each language, we retrieved all the conversational heads and, in order to study the conversational context, we further collected all the direct replies, and the replies-to-replies.

After the collection and cleaning of data, we

obtained a total of 2,850 unique tweets stemming from Conversational Heads for Italian, 4,751 tweets for Spanish, and 9,305 tweets for French. In Table 3 we display the information on the three subsets of the multilingual dataset. We show the number of the original RHs that we searched for on Twitter and from which we were able to extract the Conversational Heads. In the other columns, we display the number of direct replies, the number of replies-to-replies, and the total of reactions (tweets). In many cases, we had to discard the original RH because it did not originate a conversational thread on Twitter but rather contained just images, videos or recording from other platforms that have not been commented on Twitter with textual content (see the difference between the numbers in the first two columns of Table 3).

4 Annotating Reactions to Racial Hoaxes

4.1 A Multi-layered Annotation Scheme

The annotation scheme designed for the multilingual dataset is inspired by studies regarding stereotypes in the psychological and linguistic literature (Fiske et al., 2007; Cuddy et al., 2008; Sánchez-Junquera et al., 2021a). The outcome of such research is a scheme that consists of four layers, organized in two levels:

1. The first level refers to the presence of a **racial stereotype** as a binary category (*yes/no*).
2. The second level can be annotated only if the

Lang.	Original RHs	RHs found on Twitter	Conversational Heads	Direct Replies	Replies to Replies	Total of Reactions
Italian	97	50	273	597	2,253	2,850
Spanish	72	24	353	85	4,313	4,751
French	70	36	36	3,927	5,378	9,305

Table 3: Number of RHs and details about conversational threads.

precedent level is annotated as *yes*, and it includes three categories:

- (a) **Contextuality.** It encodes whether, in order to understand the meaning of the racial stereotype expressed, you need to look through the context (such as Twitter thread, the RH that triggered the conversation, URLs and images). It is annotated as a binary category (*yes/no*).
- (b) **Implicitness.** It encodes whether the stereotype is expressed explicitly in the message (i.e., a clear span of text where lexical items can be selected) or whether at least one inference needs to be made for the stereotype to be understood). It is annotated as a binary category (*explicit/implicit*).
- (c) **Forms of Discredit.** It encodes the precise form in which the text spreads a racial or anti-migration stereotype, attributing a type of behavior to the discriminated target. The values that can be applied are six: Affective Competence (AC), Attack to Benevolence (B), Competence (C), Dominance Down (DD), Dominance Up (DU) and Physical (P).

These six categories inspired by the Stereotype Content Model proposed by Fiske (1998), can in turn be encompassed in two: COMPETENCE (including C, DD, P) and WARMTH (including AC, B, DU). In the SCM, these macro-categories are respectively referred to as “*agency*” and “*communion*”. For instance, Cuddy et al. (2008) show how, depending on the emotion that is elicited primarily by the form of discredit, different ways of sorting and grouping could be admissible. Furthermore, they underline that the main dimensions of COMPETENCE and WARMTH can be seen as a two-dimensional array for sorting groups. This is an ideal solution that includes at least four clusters which significantly differ regarding warmth and competence.

This motivates our strategy in which Competence (C) is grouped with Physical (P) (both forms of discredit with HIGH COMPETENCE), and Attack to Benevolence (B) with Dominance Up (DU) (both forms of discredit with LOW WARMTH), resulting in the following four clusters for forms of discredit: C+P, DD, B+DU, AC.⁴

4.2 Annotation and Agreement

The data were entirely annotated on locally adapted versions of the LabelStudio⁵ open source platform, in which the questions and labels of the annotation scheme were translated into all the three languages.

The Italian portion of the dataset was annotated by two trained native speakers. Concerning the main dimension of stereotype, they obtained an inter-annotator agreement (IAA) of $\kappa = 0.48$, as calculated by Cohen’s kappa coefficient (moderate). The remaining disagreement was solved by a third expert. The Spanish subset was annotated by three annotators, two of whom are Linguistics students trained for the task, along with a researcher. The IAA was calculated by Fleiss’ Kappa coefficient, resulting in $\kappa = 0.76$. The French subset was annotated by a total of four annotators: an expert and three Linguistics students. Due to the larger quantity of data to annotate, most of the subset was annotated separately by two annotators (two sets of $\sim 4,250$ tweets). The rest was annotated in three sets, each by two annotators, at different stages of the annotation process, to ensure no degradation in IAA was occurring. The Cohen’s Kappa for the French stereotype annotations is $\kappa = 0.73$.

Comparing the scores in the three subsets, it can be noticed that in Italian the IAA is lower with respect to those obtained in French and Spanish. Our hypothesis to explain this is linked to the fact that, in Italian conversational threads, the discussions among users tends to shift quickly to other sub-

⁴Please note that the dataset has been annotated according to the six forms of discredits and that this grouping has been designed with a computational perspective in mind.

⁵<https://labelstud.io/>

jects that are unrelated to RHs. We think that this conversational drift in a large number of tweets created doubt among the annotators and lowered the overall IAA.

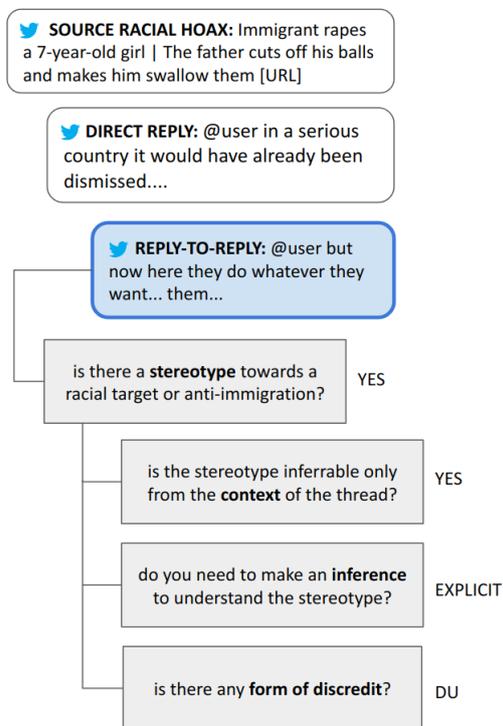

Figure 2: Triplet of tweets from a conversational thread, with the decision tree of the annotation scheme.

We conclude this section with a commented example. Figure 2 shows a Twitter conversational thread and the application of the annotation scheme on it. By looking at the third tweet of the triplet –in the blue box– it can be observed how the user reinforces the stereotypical distinction between “us” and “them”, which highlights the concept of the *ingroup* as different from the *outgroup*. The anaphorically referenced “them” is the group (*outgroup*) to which the immigrant cited in the SOURCE RACIAL HOAX belongs, and for this reason the text has been annotated as containing a **racial stereotype**.

In order to grasp the presence of the stereotype and understand its content, the annotator also had to read the previous textual context (DIRECT REPLY and SOURCE RACIAL HOAX), so the dimension of **contextuality** was annotated as positive. As for the implicitness dimension, the tweet clearly states that “they do whatever they want”, and because this sentence is a clear lexical expression of generalization, the stereotype is annotated as **explicit**. Finally, according to what the user

wrote, the immigrant exercises a sort of forceful dominion and displays aggressive behavior, breaking the law. For this reason, the text was annotated as containing the form of discredit labelled **Dominance Up**.

5 Cultural and Linguistic Analyses

In this section, we describe the comparative analyses we performed to extract analogies and differences in the expression of stereotypes and the forms of discredit in the reactions to RHs among the three subsets.

5.1 Quantitative Results

In Table 4 we report the distribution and percentage of each annotated dimension. As can be seen, in the Italian and French data, stereotypes are found more rarely than in the Spanish subset, which contains about 30% of stereotypes. Another commonality between the Italian and French subsets is the distribution of contextuality and implicitness. In contrast, the Spanish subset contains a higher percentage of explicit stereotypes. Finally, the distribution of forms of discredit is similar in the French and Spanish subsets. In these two subsets, stereotypes are mainly concerned with the provision of social and economic benefits by governments (DD), as well as criminality, illegality and fear of invasion (B+DU). In Italian, this last form of discredit is present with a higher percentage, followed by discredit regarding the competences of immigrants and their physical attributes (C+P).

In our dataset, the number of tweets containing stereotype is lower than in other datasets labelling the presence of this phenomenon (Sanguinetti et al., 2020; Ortega-Bueno et al., 2022). Rather than a purposely balanced dataset created in the context of shared tasks, our multilingual dataset is a reflection of users’ reactions to RHs in social media.

5.2 Stereotype, Discredit, and Types of RHs

In this section, we report some observations regarding the reactions to RHs retrieved from Twitter in the three languages. For Italian, we were able to retrieve a total of 67 RHs on Twitter from the original 97 taken from fact-checking websites (see Table 2). However, after the annotation process and discussion, the gold dataset contains reactions to only 50 RHs. Those RHs that foster the

Language	Tweets	Forms of Discredit									
		Stereotype		Contextual		Implicitness		Agency		Communion	
		yes	no	yes	no	explicit	implicit	C+P	DD	B+DU	AC
Italian	2,850	234 8.21%	2,616 91.79%	177 75.64%	57 25.36%	95 40.60%	138 59.40%	71 23.75%	40 13.38%	176 58.86%	12 4.01%
Spanish	4,751	1,449 30.50%	3,302 69.50%	549 37.89%	900 62.11%	1,344 92.75%	105 7.25%	23 1.74%	761 57.48%	421 31.79%	119 8.99%
French	9,305	1,093 11.75%	8,211 88.25%	818 74.84%	275 25.16%	114 10.43%	979 89.57%	43 3.76%	609 53.23%	395 34.53%	97 8.48%

Table 4: Number of texts and label distribution for the categories annotated in the three language subsets. The numbers in the last four columns do not sum up to the total of the tweets containing stereotype. Indeed, discredit could be annotated with more than one label per tweet, and tweets could therefore be counted more than once.

	Language	Benefit	Security	Migration Control	Public Health	Religion	Others
Stereotype	Italian	0.21%	51.69%	-	48.09%	-	-
	Spanish	38.79%	20.01%	10.97%	0.07%	30.16%	-
	French	70.91%	9.70%	10.43%	-	8.97%	-

Table 5: Percentage co-occurrence of the presence of racial stereotypes and topic of the RH originally spread.

most stereotyped conversations are mainly nine, describing immigrants as threats to public health and security (see Table 5), as shown in the following examples:

- (1) Coronavirus spreads, Government goes to secretly take illegal immigrants in Africa
- (2) He kills an old Jewish woman at the cry of Allah Akbar. Acquitted because he was drugged.

The special attention paid to these two topics is also evident in the analysis of the most used hashtags in the tweets labelled with the presence of negative stereotypes, such as: #Crimes-Immigrants, #SALVINI, #PD, #M5S, #hospitality. By using these hashtags, the users discuss the adopted policies of hospitality and control of immigration of various political parties (#SALVINI, #PD, #M5S), or depict immigrants as criminals (#CrimesImmigrants). The tweets containing these hashtags tend to be labelled with the B+DU form of discredit.

For Spanish, we were able to retrieve 24 RHs on Twitter, out of the 72 RHs originally collected from the fact-checking websites. The most prevalent topic within the Spanish context is related to benefits and the “illegality” of the immigrant. Those topics are associated directly to the forms of discredit DD and B+DU. These topics are also reflected in the use of hashtags such as: #StopIllegalImmigration or #Pensions.

Regarding French, from the 70 RHs identified at the start on the fact-checking website, we extracted 36 instances published on Twitter. As mentioned in Section 3.2, in some cases, we discarded the original RH because it did not originate a conversational Twitter thread or only contained images and videos without textual content. This was common in all the three languages considered.

Overall, French RHs had two common themes: attributing the role of victims to the representatives of Western civilization and the role of perpetrator to immigrants, as in Example (3) below; and pointing the finger at political decisions, real or fantasized, which would favor migrant populations at the expense of the “good French” such as farmers and students, as in Example (4).

- (3) Immigrants burn down a refugee center because there’s not enough Nutella: [URL]

- (4) An immigrant who has never paid taxes in France receives 820 euros per month from the state, in the meantime some farmers get only 360 euros, how do you expect French people not to be angry?

The tweets similar to Example (3) are mainly associated with reactions containing B+DU types of discredit (around 35% of the total) while those similar to Example (4) are linked to DD (~53%).

5.3 Contextuality and Implicitness

Focusing on the textual context, we analyzed how the stereotypes are propagated from the starting

point of the conversations throughout the thread, and if the context is needed to infer implicit forms of stereotypes in the three languages.

In the Italian subset, the majority of the tweets (87%) that are conversational heads (see Table 3) contain negative stereotypes against immigrants. However, even though a conversational head is deemed stereotypical, it is not correct to assume that all the tweets within its thread also contain stereotypes. Indeed, only about 17% of direct replies contain stereotypes and only 6% of the remaining threads are labelled with the presence of stereotypes. This is due mainly to two factors: 1) the tweets spreading fake news or offensiveness tend to be deleted by Twitter; 2) some of the tweets in the conversational threads tend to unveil the inaccuracy of the hoax.

Similarly to what happens in the Italian conversations, in the French subset, all conversational heads contain stereotypes, while 14% of direct replies and 10% of replies-to-replies contain stereotypes. Indeed, the fact that the RHs were debunked by fact-checking websites leads many comments to be criticisms of the conversational head, and this phenomenon is accentuated even more when the RH is shared by accounts with many followers. For the Spanish dataset, only 54% of conversational heads contain stereotypes, with the vast majority of stereotypes contained in replies, accounting for 90% of them.

	Implicitness	
	Language	χ^2
Contextuality	Italian	45.954
	Spanish	41.169
	French	11.419

Table 6: Association between contextuality and implicitness. The χ^2 tests are statically significant at $p < 0.001$ for the three languages.

The results reported in Table 6 show a statically significant association between the dimensions of implicitness and contextuality. As defined in Section 4, annotators labeled the necessity to use the context to understand the message or infer the presence of stereotypes. As expected, in the three datasets, the inference of stereotypes is especially facilitated by access to the textual context.

5.4 Lexical Analysis

To better understand the similarities and differ-

ences at the linguistic and cultural level between the languages, we performed a linguistic analysis, looking at the discriminative lexica used in texts containing stereotypes and labeled with specific forms of discredit. In particular, for all datasets, we listed: the most relevant n-grams⁶ of the data annotated with stereo = *yes* (comparing them with the n-grams of the data annotated with stereo = *no*), and the most relevant n-grams from the data annotated with the four forms of discredit.

By looking at the resulting lists of words, we noticed that, in **Italian**, the words extracted from texts that do not contain stereotypes are related to the emotional sphere (“feeling”, “feel ashamed”, “hope”), in contrast to those extracted from texts containing stereotypes, which are related mainly to the negative actions of immigrants (“immigrant rape”, “kill”, “spit”). Regarding the various forms of discredit, we observed interesting differences. In general, words such as “invasion”, “occupation” and “commanding” or expressions like “walk in underwear” or “laugh in court” are typical in texts annotated with the labels grouped under *communism*. In contrast, words such as “lux”, “gratis”, “withdraw”, “euro”, “gene” or expressions like “psychological disorder”, “return to pre-history” are present in texts annotated with the labels grouped under *agency*.

For the **French** subset, we noticed similar patterns for the terms linked to instances containing stereotypes, with links to violence (“knife”), but also to school (“schooling”, “student”), which are often brought up in instances labeled with discredit under the *agency* group (more particularly, DD), in claims that children of immigrants receive disproportionate financial aid from the state. For instances which do not contain stereotypes, we notably find terms related to misinformation (“fake”, “fake news”, “ridiculous”), which are often levelled against tweets containing stereotypes linked to racial hoaxes.

This underlines the polarization found in the reactions to RHs, by which one section of the users oppose ideas embodied in the RH since they are spread by a proven fake news, thereby avoiding playing the game of attributing certain characteristic to the population designated by the label of

⁶The n-grams are weighted using the TF-IDF measure on normalized texts; the phase of preprocessing involved: the deletion of all user mentions, stop-words, punctuation and URLs, leaving only words that were lexically significant; the tokenization, and the lemmatization with the SpaCy library.

"immigrants"; while another section of the users deliberately ignores the fact that the news has been diverted to focus on the designation of immigrants as the source of a problem. Immigrants are blamed either by their mere presence, which would represent a competition for limited resources, or by their acts, essentializing them as individuals all alike, violent and imposing their foreign culture.

The **Spanish** dataset also present interesting patterns in line with the topics of the grouped data. Firstly, the most prevalent words from texts with no stereotypes are related mainly to politics and economy ("unemployment", "reform", "communist"), whereas texts containing stereotypes show representative words used in RHs ("illegal immigrant", "tradition", "pay health care"). In relation to the categories of discredit, the main characteristic of *communism* is the perception of immigrants as violent, but also as victims, a fact that we can observe in the words like "invasion", "security", "serious" on the negative view, and "poor", "foreigner" and "right" on the patronizing view. On the other hand, *agency* takes a rather derogatory point of view of immigrants, which is displayed in words such as "idiot", "inferior race" and "dumb". The lexica in all languages reflect the stereotypes used against immigrants and the different forms of discredit.

6 Conclusion and Future Work

In this paper, we presented the first outcomes of a study of the stereotypes that are spread through racial hoaxes, with the aim of creating NLP resources and tools to automatically detect them. In order to address this challenging task, we started with an examination of the psychological and computational literature on fake news and stereotypes. This helped us to build the MRHC, the first multilingual corpus of racial hoaxes, which includes RHs in Italian, Spanish, and French, classified according to the topic of the news they spread. We designed a multi-layered annotation scheme for the annotation of racial stereotypes that takes into consideration the conversational thread extracted from social media. We applied it for the first time to a newly created multilingual dataset of Twitter reactions to RHs. Thanks to the outcomes of the annotation procedure, we were able to perform cross-cultural and cross-language analyses of these texts that are shaped in a Twitter conversational structure.

The results show that the presence of stereotype is, in general, lower within the RHs domain, with respect to its percentage in other pre-existing more general-purpose datasets (e.g., the ones developed within shared tasks). Other relevant findings show that, even if the first source RH contains a stereotype, in the following replies in the conversational thread, the presence of stereotypes decreases. Additionally, the dimension of implicitness was shown to be highly dependent on the dimension of contextuality in this domain. Content-wise, from an observation of RHs' topics, crossed with a lexical analysis (counting the most relevant tokens and expressions in each language subset), the outcomes show how the presence of stereotypes is linked to words that are typically grounded within the specificities of a certain language or culture. Finally, it can be observed that people who continue to spread a stereotypical view, originated in the source tweet and throughout the replies-to-replies, typically use polarized expressions that are in line with the original RH that generated the full conversational thread.

Thanks to the resources and framework elaborated in this study, it will be possible to investigate the spread of racial stereotypes on social media in a finer-grained way from a computational perspective and in a multilingual context. Furthermore, these steps are essential for developing computational tools for the automatic detection and classification of racial stereotypes in real-life scenarios.

Limitations

In this work we presented, for the first time, a multi-layered scheme for the annotation of racial stereotypes in social media data in three different languages and in conversational threads. This work can, therefore, be considered pioneering and its multi-layered annotation scheme might require adaptation if applied to datasets with very different characteristics. The Stereotype Content Model inspired the annotation and analysis of stereotypes, by providing a socio-psychological theoretical framework. However, when being as faithful as possible to it during the annotation process, a computational setting can benefit from the integration of a more data-driven perspective.

Furthermore, the three subsets of the multilingual dataset of "reactions to racial hoaxes" now have very different sizes and present many unbalanced dimensions and high data sparsity. If in the

future they will be used for computational tasks, as it is intended, they should be made more balanced and more inclusive in terms of data sources.

Finally, cultural and geographical differences between the three languages of this study need to be taken into account and investigated in a deeper fashion, as it emerged that they are not trivial.

Ethics Statement

The authors have carefully considered the ethics of conducting this kind of study regarding racial stereotypes on social media, and include here their assessment of the ethical issues raised and how to approach them. Throughout the project, they will be critically reflexive about unanticipated ethical issues arising from its sensitive, qualitative and digital nature.

The research presented in this work does not include any studies with human participants carried out by any of the authors. Furthermore, the data that was used is textual content from social media extracted from datasets publicly available to the research community and which also conform to the Twitter Developer Agreement and Policy, which allows for the unlimited distribution of the numeric identification number of each tweet. Each tweet in Italian, Spanish, and French has been translated and adapted into English in order to ensure the anonymity of the author.

Hiring policy: beside the authors of this article, other researchers were involved. We hired two Italian native-speaking annotators (one male and one female: a master's degree student in Linguistics, and a pre-doctoral student). We hired two Spanish native-speaking annotators (one male and one female, both Linguistics undergraduate students in their last year). We hired three French native-speaking annotators (three females, two master's degree students in "Linguistics, Communication and Gender", and one Linguistics undergraduate student). All hired workers have either received a monetary compensation or university credits valid for their career.

Abstract

Quotes are critical for establishing credibility in news articles. A direct quote enclosed in quotation marks has a strong visual appeal and is a sign of a reliable citation. Unfortunately, this journalistic practice is not strictly followed, and a quote in the headline is often “contextomized.” Such a quote uses words out of context in a way that alters the speaker’s intention so that there is no semantically matching quote in the body text. We present QuoteCSE, a contrastive learning framework that represents the embedding of news quotes based on domain-driven positive and negative samples to identify such an editorial strategy. The dataset and code are available at <https://github.com/ssu-humane/contextomized-quote-contrastive>.

1 Introduction

A direct quotation, a verbatim replication of a speaker’s words as opposed to offering news reporters’ own opinions, manifests news stories’ neutrality, factuality, and objectivity (Zelizer, 1989). Quoting others also adds color to the news with authentic expressions and conveniently establishes authority based on the speakers’ reputation (The Missouri Group, 2013). Therefore, a direct quotation constitutes an integral element of news reporting (Nylund, 2003).

More studies have found a link between the use of direct quotations and fake news. Content analyses of news stories document evidence such that deceptive (*versus* trustworthy) news articles contain more direct quotations (Dalecki et al., 2009; Govaert et al., 2020). An equally problematic but less studied concern involving direct quotations is *contextomy*, quoting words out of context in a way that alters the speaker’s intention. A previous study argued that contextomy is a “common spin tactic” of news reporters promoting their political agenda (McGlone, 2006, p. 332).

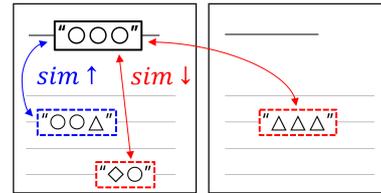

Figure 1: The central idea of QuoteCSE is based on journalism principles, where quotes from news headlines and body text should be matched. The proposed contrastive learning framework maximizes the semantic similarity between the headline quote and the matched quote in the body text while minimizing the similarity for other unmatched quotes in the same or other articles.

Some news outlets have been notorious for editorializing and sensationalizing their stories with contextomized quotes in news headlines (Han and Lee, 2013). The first example in Table 1 illustrates contextomy. This example has a headline, “A government handing out money ... ‘A debt crisis, like Greece, is on the horizon’.” The quoted sentence rephrased a financial expert saying in the body text, “If we do not maintain our fiscal health, we may end up like Greece.” This is far from word-for-word replication. Instead, the headline reduced the expert’s normative claim about government spending and fiscal distress to a blurb that blasted the national leadership, which was on the opposite side of the political spectrum. As such, a contextomized quote in a news headline can serve as an editorial slogan, misinforming public opinion.

We propose a new problem of identifying contextomized quotes in news headlines. In contrast to a modified quote, which corrects grammar, replaces unheralded pronouns with proper names, removes unnecessary phrases, and substitutes synonyms, a **contextomized quote** refers to the excerpt of words with semantic changes from the original statement (McGlone, 2006). Hence, the task is to classify whether a headline quote is semantically matched by comparing quotes in the

News headline quote	Body-text quotes	Label
"이대론 그리스처럼 파탄" (A debt crisis, like Greece, is on the horizon)	"건강할 때 재정을 지키지 못하면 그리스처럼 될 수도 있다" (If we do not maintain our fiscal health, we may end up like Greece) "강력한 ‘지출 구조조정’을 통해 허투루 쓰이는 예산을 아껴 필요한 곳에 투입해야 한다" (Wasted budgets should be reallocated to areas in need through the reconstruction of public expenditure)	Contextomized
"불필요한 모임 일절 자제" (Avoid unnecessary gatherings altogether)	"저도 백신을 맞고 해서 여름에 어디 여행이라도 한번 갈 계획을 했었는데..." (Since being vaccinated, I had planned to travel somewhere in the summer, but ...) "행사가 일단 다 취소됐고요..." (Events have been canceled...) "어떤 행위는 금지하고 어떤 행위는 허용한다는 개념이 아니라 불필요한 모임과 약속, 외출을 일제 자제하고..." (It is not a matter of prohibiting or permitting specific activities, but of avoiding unnecessary gatherings, appointments, and going out altogether...)	Modified

Table 1: Dataset examples in Korean and their English translations

news headline and body text.

To tackle the detection task, we propose using contrastive learning for quote representation, which trains a model to maximize the similarity of samples that are expected to be similar (known as *positive* samples). Simultaneously, the model tries to reduce the similarity between samples that should be dissimilar (aka *negative* samples). Following the recent research in contrastive sentence embedding (Gao et al., 2021; Chuang et al., 2022), we introduce a positive and negative sample selection strategy that is suited to the problem.

Our key idea is illustrated in Figure 1. If a direct quotation appears in a news headline, there should be a quote with the same semantics in the body text. Furthermore, the title quote must be distinct from other quotes in the same article or from quotes in other (randomly chosen) news articles. Since quotes from the same article share common topics, it is more challenging to distinguish a headline quote from those in its body text than to understand semantic differences between quotes from distinct articles. Adopting the ‘hard’ negatives in contrastive loss can help a model learn an effective representation, thereby capturing nuanced semantic differences between quotes. Evaluation experiments show its effectiveness at the target problem as well as its high quality in terms of theoretical measures, such as alignment and uniformity.

Our main contributions are three-fold:

1. Based on journalism research and principles, we present a new NLP problem of detecting contextualized quotes in news headlines.
2. We release a dataset for the detection problem based on a guideline constructed by annotators with journalism expertise. The label

annotation by three workers achieved Krippendorff’s alpha of 0.93.

3. We present QuoteCSE, a contrastive quote embedding framework that is designed based on journalism ethics. A QuoteCSE-based detection model outperformed existing methods, including SimCSE and fine-tuned BERT.

2 Related Work

Following the recent success in computer vision (Chen et al., 2020a; He et al., 2020; Grill et al., 2020; Chen and He, 2021), previous studies on contrastive sentence embedding focused on how to construct a positive pair by employing data augmentation methods to an anchor sentence (Fang et al., 2020; Giorgi et al., 2021; Wu et al., 2020; Yan et al., 2021). A recent study showed that a simple dropout augmentation (unlike complex augmentations) with BERT to construct a positive pair could be an effective strategy known as SimCSE (Gao et al., 2021). Another study improved the performance by combining SimCSE with masked token detection (Chuang et al., 2022). This study proposes a strategy for selecting positive and negative samples according to journalistic ethics.

3 Problem and Data

Research Problem Let a given news article be $X : (T, B)$, where T is the news title, and B is the body text. Our task is to predict a binary label Y indicating whether the headline quote in T is either contextomized (1) or modified (0) by referring to the body-text quotes. The detection target is news articles that use at least one direct quotation in the headline and body text.

News Data Collection We gathered a nationwide corpus of Korean news articles published through Naver, a popular news aggregator service. Direct quotes in news articles were identified via regular expression. The dataset contains around 0.4 million news stories published until 2019.

Label Annotation Two journalism-major undergraduates were trained to manually label whether a direct quote in the headline is contextomized or modified. The *contextomized* quote refers to the excerpt of words with semantic changes from the original statement. The *modified* quote in a headline keeps the semantics of the original expression but is a different phrase or sentence. A faculty member in mass communication drafted annotation guidelines that stipulated the definitions of contextomized and modified quotations with multiple examples. The annotators reviewed the guidelines and labeled 70 (up to 200) news articles per training session. Inconsistent cases were discussed to reach a consensus. After the eighth iterative training practice over two weeks, the annotators achieved high inter-coder reliability (Krippendorff’s alpha = 0.93 for 200 articles). Then the annotators split the rest and labeled the news articles separately.

We randomly sampled 2,000 news articles for the manual annotation. We ignored cases where the body text includes an identical quote to the one in the headline because its detection can be achieved by a string-matching method without learning. As a result, the final dataset comprises 814 contextomized and 786 modified samples, leaving a total N of 1,600. Table 1 presents examples. We investigate contrastive embedding approaches to utilize the 381,206 news articles that remained unlabeled.

4 Methods

To predict the label L of $X : (T, B)$, we utilize contrastive embedding and measure the semantic relationship between quotes in the headline and body text. We introduce the main framework.

4.1 Background: SimCSE

SimCSE (Gao et al., 2021) is a contrastive learning method that updates a pretrained bidirectional transformer language model to represent the sentence embedding. Its loss function adapts InfoNCE (van den Oord et al., 2018), which considers identical text with a different dropout mask as a positive sample and the other text within the same batch as negative samples. Formally, the SimCSE loss of

i -th text x_i is

$$-\log \frac{e^{\text{sim}(\mathbf{h}_i, \tilde{\mathbf{h}}_i)/\tau}}{\sum_{j=1}^N e^{\text{sim}(\mathbf{h}_i, \tilde{\mathbf{h}}_j)/\tau}}, \quad (1)$$

where \mathbf{h}_i is x_i ’s embedding¹, $\tilde{\mathbf{h}}_i$ is the embedding of positive sample, τ is temperature hyperparameter, N is the batch size, and $\text{sim}(\cdot, \cdot)$ is the cosine similarity between embedding vectors.

4.2 Proposed Method: QuoteCSE

We propose **QuoteCSE**, a domain-driven contrastive embedding framework on news quotes. Its contribution is in defining positive and hard negatives according to journalism principles. This framework identifies positive and negative samples for a news headline quote according to the golden rules of journalism: When a direct quotation appears in a news headline, its body text should include a quote that is either identical or semantically similar to the headline quote. The latter form can be a good candidate for contrastive learning, where semantically identical yet lexically different quotes serve as ‘positive’ samples. The other quotes in the body text represent different semantics yet cover the same topic, serving as *hard negative* samples.

We define the QuoteCSE loss of i -th sample $X^{(i)} : (T^{(i)}, B^{(i)})$ as

$$-\log \frac{e^{\text{sim}(\mathbf{h}_i, \mathbf{h}_i^+)/\tau}}{\sum_{j=1}^N \{e^{\text{sim}(\mathbf{h}_i, \mathbf{h}_j^+)/\tau} + e^{\text{sim}(\mathbf{h}_i, \mathbf{h}_j^-)/\tau}\}}, \quad (2)$$

where \mathbf{h}_i is embedding of headline quote for i -th sample. \mathbf{h}_i^+ and \mathbf{h}_i^- are embedding of positive and negative quotes in the same body text $B^{(i)}$. \mathbf{h}_j^+ and \mathbf{h}_j^- are embeddings of $X^{(j)}$, other news articles in the same batch ($i \neq j$), which are negative samples.

We applied SentenceBERT (SBERT) (Reimers and Gurevych, 2019) to make initial assignments on positive (i.e., semantically identical) and negative (i.e., dissimilar) samples among quotes in the body text. A quote is deemed positive if it appears the most similar to the quote in the news headline. After excluding the positive sample, one quote from the body text was chosen randomly as the negative sample. We removed news articles where the cosine similarity between the anchor and the positive sample is below 0.75 because the news headline quote might be contextomized. Additionally, news

¹We applied a 2-layer MLP projection head to the hidden representation corresponding to the [CLS] token in the pretrained BERT.

	F1	AUC
BERT	0.665±0.007	0.662±0.006
SBERT	0.44±0.083	0.591±0.020
SimCSE-Quote	0.69±0.009	0.686±0.009
SimCSE-NLI	0.617±0.008	0.623±0.008
BERT fine-tune	0.754±0.006	0.749±0.006
QuoteCSE	0.77±0.007	0.768±0.008

Table 2: Performance comparison with baselines.

articles that did not contain at least two quotes in the body text were eliminated. The remaining 86,275 articles were divided into 69,020, 8,627, and 8,628 for training, validation, and testing of contrastive learning methods.

We compared QuoteCSE with three baseline embedding methods, (i) BERT (Devlin et al., 2019)², (ii) SBERT³, and (iii) SimCSE. For BERT and SBERT, we used the model checkpoint that was pretrained on a Korean corpus. For SimCSE, we tested two versions. The first version is to train BERT on our news corpus by minimizing Eq. 1 on headline quotes (SimCSE-Quote). The second version is a publicly available SimCSE embedding pretrained on a corpus on natural language inference in Korean (SimCSE-NLI)⁴. For QuoteCSE and SimCSE-Quote, we used SBERT for the initial assignments of positive and negative samples. The assignments iteratively get updated for every training step using the target embedding being trained (e.g., QuoteCSE). QuoteCSE and SimCSE-Quote were trained on the 69,020 sizes of the unlabeled corpus with a batch size of 16, which is the upper limit under the computing environment.

To assess the role of contrastive learning, we implemented a binary MLP classifier with a 64-dimensional hidden layer, following an embedding evaluation framework (Conneau and Kiela, 2018). The model takes \mathbf{u} , \mathbf{v} , $|\mathbf{u} - \mathbf{v}|$, and $\mathbf{u} * \mathbf{v}$ as input, where \mathbf{u} and \mathbf{v} are the embeddings of a news headline quote and the body-text quote most similar to the \mathbf{u} , respectively. In deciding \mathbf{v} , cosine similarity is used along with the target embedding. The classifier predicts whether the headline quote is contextomized based on a vector relationship between \mathbf{u} and \mathbf{v} .

For evaluation, we report the mean F1 and AUC scores by repeating the split process 15 times on

SimCSE	QuoteCSE	0.7±0.005	0.69±0.004
QuoteCSE	–	0.674±0.006	0.673±0.006

Table 3: Ablation results confirm the role of both positive and negative samples in the model.

the labeled dataset with a ratio of 8:2. As a strong baseline, we also tested a fine-tuned BERT classifier (BERT fine-tune) that takes '[CLS] q_t [SEP] $q_{b,1}, \dots, q_{b,N_b}$ [SEP]' where q_t is the headline quote, $q_{b,i}$ is the i -th quote in the body text, and N_b is the number of body-text quotes. Details of the model configuration and computing environment are in Section A.1.

5 Evaluation Results

Table 2 presents the evaluation results for the contextomized quote detection. We report the average performance along with standard errors by repeating the experiments using each different random seed. QuoteCSE obtained an F1 of 0.77 and an AUC of 0.76, outperforming the fine-tuned BERT and other contrastive learning methods. Among the baseline models, the fine-tuned BERT model achieved the best F1 of 0.754, which is significantly higher than the performance of the standard contrastive learning methods. The results point to the effectiveness of journalism-driven contrastive quote embedding for the detection problem.

Ablation experiment We examined the importance of positive and negative samples in the QuoteCSE framework by removing each component. The first model is to replace QuoteCSE’s positive sample with that of SimCSE, which is an embedding of the anchor text with a different dropout mask. The second model is to ignore the hard negative sample from QuoteCSE. It only differs from SimCSE in the selection of the positive sample. We trained two contrastive embeddings using the 69,020-size unlabeled corpus. Table 3 presents the results. The detection performance of QuoteCSE was reduced significantly by the ablation of the positive and negative samples. The hard negative sample turned out to be more critical to the detection performance, as F1 of the corresponding model decreased by 0.096. The results confirm the necessity of both positive and negative samples in the QuoteCSE framework.

	Alignment (title-title)	Alignment (title-body)	Uniformity
BERT	0.638	0.738	-0.711
SBERT	0.227	0.329	-1.356
SimCSE-Quote	0.503	0.38	-2.176
SimCSE-NLI	0.319	0.26	-3.257
QuoteCSE	0.15	0.194	-3.562

Table 4: Results of alignment (i.e., closeness of positive samples) and uniformity (i.e., even distribution) scores

Embedding quality We employed two metrics to evaluate the quality of contrastive sentence embeddings (Wang and Isola, 2020). The first is *alignment*, which measures how closely positive pairs are located in the embedding space. The next is *uniformity*, which measures how evenly distributed the target data is. A smaller value denotes a higher embedding quality for both metrics, and their formal definitions are given in Section A.2. We examined two alignments: (i) between two embeddings from the same headline quote with a different dropout mask (title-title) and (ii) between a headline quote and a positive quote in the body text (title-body). We measured the three metrics on the test split of unlabeled data. Table 4 shows that QuoteCSE achieves the best result for all types of theoretical measures, implying a high embedding quality.

Error analysis We identified a common pattern of false positives where a model deems a quote contextomized, which turned out to be modified. They corresponded to instances in which a quote in the headline represents a claim that combines multiple quotes in the body text. For example, in a news article, a headline quote was “감옥 같은 생활... 음식 엉망 (Prison-like conditions... Poor food)” which could be referred to multiple quotes in the body text “삿포로 생활은 감옥처럼 느껴진다 (Living in Sapporo feels like being in prison)” and “음식도 엉망이다 (food is poor).” Since the current detection framework compares a headline quote and another quote in the body text, it could not detect the corner case of a modified quote. Future studies could investigate an approach that considers multiple quotes in the body text.

6 Conclusion

Inspired by the importance of direct quotations in news reporting and their widespread misuse, this study proposed a new NLP problem of detecting contextomized news quotes. While there had been

studies on quote identification (Pavlo et al., 2018) and speaker attribution (Vaucher et al., 2021), this study is the first to discern a specific type of headline news quote that distorts the speaker’s intention and is cut out of context. Not only does it violate journalism ethics (The Missouri Group, 2013; Nylund, 2003), but it can also mislead public opinion (McGlone, 2006). Therefore, tackling the problem of detecting contextomized quotes in news headlines can significantly aid the existing efforts to nurture healthy media environments using NLP techniques (Oshikawa et al., 2020).

Understanding the subtle semantic differences between quotes from news headlines and those from body text is a prerequisite for detecting contextomized news quotes. To assist with this, we introduce QuoteCSE, a contrastive learning framework for quote representation. We specifically tailored SimCSE (Gao et al., 2021) to the detection of the editorial slogan by proposing a positive and negative sample selection strategy consistent with journalism ethics. In the evaluation experiments, we confirmed the effectiveness of both positive and hard negative samples in the journalism-driven contrastive learning framework. Altogether, the findings imply the crucial role of domain knowledge in tackling computational social science problems.

Limitations and Future Directions

First, since this study was done on a monolingual corpus in Korean, the generalizability of the method to other languages is unknown. Future research could replicate this study in other languages to test its broad applicability. Second, the contrastive learning techniques were only tested to a batch size of 16 due to the particular computing environment. To address this limitation, we also tested MoCo-based methods that mitigate the memory limitation (Chen et al., 2020b); however, the results were unsatisfactory (Section A.3.1). The effect of large batch sizes might be examined in future studies. Third, there may be corner cases that the current detection framework is unable to handle. Even if a direct quotation in the headline is schematically consistent with a quote in the body text, this by no means guarantees the authenticity of the quoted remark. It could have been made up by the speaker in the first place. Accordingly, future research warrants considering labels on veracity in conjunction with labels on whether they are contextomized or modified.

Ethics and Impact Statement

Despite the limited headline space, journalism textbooks underscore that direct quotations should meet the strict verbatim criterion (Brooks et al., 2001; The Missouri Group, 2013; Cappon, 1982). This verbatim rule renders news stories with direct quotations more credible and factual. The aforementioned instances of contextomized quotes, however, violate this public trust in journalism. We thus propose a new NLP problem of detecting contextomized quotes and aim to better contribute to the development of responsible media ecosystems. This study is an example of how social science theories can be incorporated with NLP techniques. Thus it will have a broader impact on future studies in NLP and computational social science.

We used public news dataset published through a major web portal in South Korea. Our data is considered clean regarding misinformation because the platform implements a strong standard in deciding which news outlets to admit. However, the considered news data is not free from media bias, and the learned embedding may learn such political bias. Therefore, users should be cautious about applying the embedding to problems in a more general context. We have fewer privacy concerns because our study used openly accessible news data following journalistic standards.

A Appendix

A.1 Details of model configuration and computing environment

We ran experiments on a machine with an Intel(R) Xeon(R) CPU E5-2620 v4 running at 2.10GHz, four TitanXP 12GB GPUs, and 130GB RAM. All models were evaluated on Python 3.9 with the Transformers library (ver. 4.19.4). We ran contrastive learning experiments with the batch size of 16 using Adam with a learning rate of 0.01, and the maximum number of epochs was 10. The parameter size of KoBERT is 92m, and that of the MLP projection head is 87k with a hidden dimension of 100. The temperature of the softmax is 0.05, which is the same as [Gao et al. \(2021\)](#). It took 10 and 13 hours to finish SimCSE and QuoteCSE contrastive training, respectively. For the detection task, we trained models with the same configuration. We did not conduct hyperparameter optimization since the dataset is small. Instead, we reported summary statistics of performance by repeating the data split,

model training, and evaluation process while varying random seeds (0, 10, 20, 30, 40, 50, 60, 70, 80, 90, 100, 110, 120, 130, 140).

A.2 Formal definition of alignment and uniformity

Alignment is

$$\mathbb{E}_{(x,x^+)\sim P_{pos}} \|f(x) - f(x^+)\|^2 \quad (3)$$

, where x is an anchor text, x^+ is positive sample, and $f(\cdot)$ is an embedding function. P_{pos} is the distribution of positive pairs.

Uniformity is

$$\log \mathbb{E}_{(x,y)\sim P_{data}} e^{-2\|f(x) - f(y)\|^2} \quad (4)$$

, where P_{data} is the distribution of the anchor text.

A.3 Additional evaluations

A.3.1 Momentum-based methods

	F1	AUC
MoCo: SimCSE	0.658±0.011	0.667±0.008
MoCo: QuoteCSE	0.756±0.005	0.753±0.006

Table A1: Momentum-based methods underperform their corresponding general methods.

Our computing environment is limited, such that all models were trained with a batch size of 16. Since the batch size decides the number of negatives for InfoNCE-based contrastive learning frameworks, it was reported that a larger batch size can result in better performance (Chen et al., 2020a). To approximate the effects of a larger number of negatives in a batch, we evaluated MoCo-based approaches that keep samples in previous batches as additional negatives with momentum updates (He et al., 2020). We set the queue size to be 40 according to the observation on the effect of queue size in a previous study (Wu et al., 2022). We make two observations from Table A1 on the evaluation results of contextomized quote detection. QuoteCSE still outperformed SimCSE, but the MoCo versions performed worse than the general version.

A.3.2 STS benchmark

To see if the learned embeddings are generalizable, we tested the baseline and proposed models on the KLUE benchmark on sentence similarity (Park et al., 2021). Using the same model architecture for the contextomized quote detection, we trained

	F1	AUC
KoBERT	0.636	0.659
SimCSE-Quote	0.633	0.662
QuoteCSE	0.775	0.796

Table A2: Evaluation based on the KLUE-STs benchmark indicates the generality of the proposed method.

a model to predict a binary label on whether two given sentences are similar.

The evaluation results based on the valid dataset are shown in Table A2. QuoteCSE outperforms KoBERT and SimCSE-Quote, suggesting that our model can produce better semantic embedding.

A.3.3 Filtering scenarios in the wild

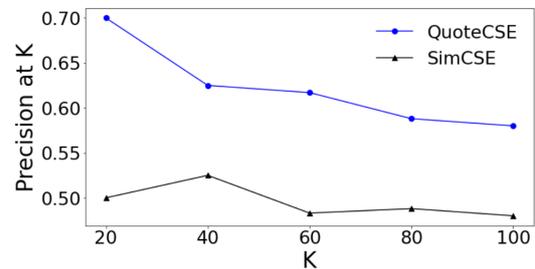

Figure A1: The precision at k results of QuoteCSE and SimCSE suggest QuoteCSE’s effectiveness in filtering contextomized quotes in the wild.

We collected 10,055 news articles published in July and August 2021. To test the proposed model’s effectiveness in the wild, we manually evaluated the top-100 news articles regarding the prediction scores of SimCSE-Quote and QuoteCSE, respectively. A high prediction score indicates that a model consider the given news article containing a contextomized quote in headline with a high confidence, therefore this evaluation assumes a scenario of filtering news articles with contextomized quotes.

Figure A1 presents the precision at k of the two models, indicating how many instances turned out to be correct among the top- k examples, which are predicted to be contextomized by a model with a high confidence. Results indicate that QuoteCSE can achieve a high precision value of 0.7 for the top-20 examples. The precision decreases as its confidence gets lowered, reaching a plateau around 0.6. On the contrary, SimCSE achieved a precision lower than 0.55 even when its confidence is high. The results suggest the potential of QuoteCSE-based detection model for filtering contextomized quotes in the real-world scenario.

Zero-Shot On-the-Fly Event Schema Induction

Rotem Dror*, Haoyu Wang*, and Dan Roth

Department of Computer and Information Science

University of Pennsylvania

{rtmdrr, why16gzl, danroth}@seas.upenn.edu

Abstract

What are the events involved in a pandemic outbreak? What steps should be taken when planning a wedding? The answers to these questions can be found by collecting many documents on the complex event of interest, extracting relevant information, and analyzing it. We present a new approach¹ in which large language models are utilized to generate source documents that allow predicting, given a high-level event definition, the specific events, arguments, and relations between them to construct a schema that describes the complex event in its entirety. Using our model, complete schemas on any topic can be generated on-the-fly without any manual data collection, i.e., in a zero-shot manner. Moreover, we develop efficient methods to extract pertinent information from texts and demonstrate in a series of experiments that these schemas are considered to be more complete than human-curated ones in the majority of examined scenarios. Finally, we show that this framework is comparable in performance with previous supervised schema induction methods that rely on collecting real texts and even reaching the best score in the prediction task.

1 Introduction

Event processing refers to tracking, analyzing, and drawing conclusions from streams of information about events. This event analysis aims at identifying meaningful events (such as opportunities or threats) in real-time situations and responding appropriately. Event processing can also be utilized to gain a deep understanding of the specific steps, arguments, and relations between them that are involved in a complex event. The information above can be consolidated into a graphical representation called an *event schema* (Li et al., 2021). For instance in Fig. 1, the graph representation of events

and participants assists in gaining an understanding of the complex event of kidnapping and could help composing a reaction plan if needed.

The NLP community has devoted much effort to understanding events that are described in a document or in a collection of documents for this purpose. These efforts include identifying event triggers (Lu and Roth, 2012; Huang et al., 2018; Wadden et al., 2019; Han et al., 2019), extracting event arguments (Punyakanok et al., 2008; Peng et al., 2016; Lin et al., 2020; Zhang et al., 2021a), and predicting the relations between events, e.g., temporal, coreferential, causal or hierarchical relations (Do et al., 2012; Lee et al., 2012; Glavaš et al., 2014; Ning et al., 2018; Wang et al., 2020; Zhang et al., 2020a; Trong et al., 2022).

Previous works on event schema induction relied on the information extracted from manually collected documents to build the schema graph. For instance, Li et al. (2020) learn an auto-regressive language model (LM) over paths in the instance graphs depicting events, arguments and relations of instances of the complex events, and then construct a schema graph by merging the top k ranked paths. Their approach, however, requires access to many documents on each topic of interest, which can be extremely laborious and time consuming to obtain.

In this paper, our goal is to allow creating schemas on-the-fly by taking as input only the name of the complex event of interest (like a “pandemic outbreak” or an “armed robbery”). To avoid manually collecting many documents on the topic of the schema, we utilize pre-trained text generators, e.g., GPT-3 (Brown et al., 2020), to obtain documents of diverse genres on the desired topic (examples presented in Fig. 2). These documents are then processed to extract pertinent information from which a schema is constructed. The fact that we do not collect any data makes our learning framework zero-shot since we do not rely on any human-collected articles or example schemas.

* Indicating equal contribution.

¹https://cogcomp.seas.upenn.edu/page/publication_view/995

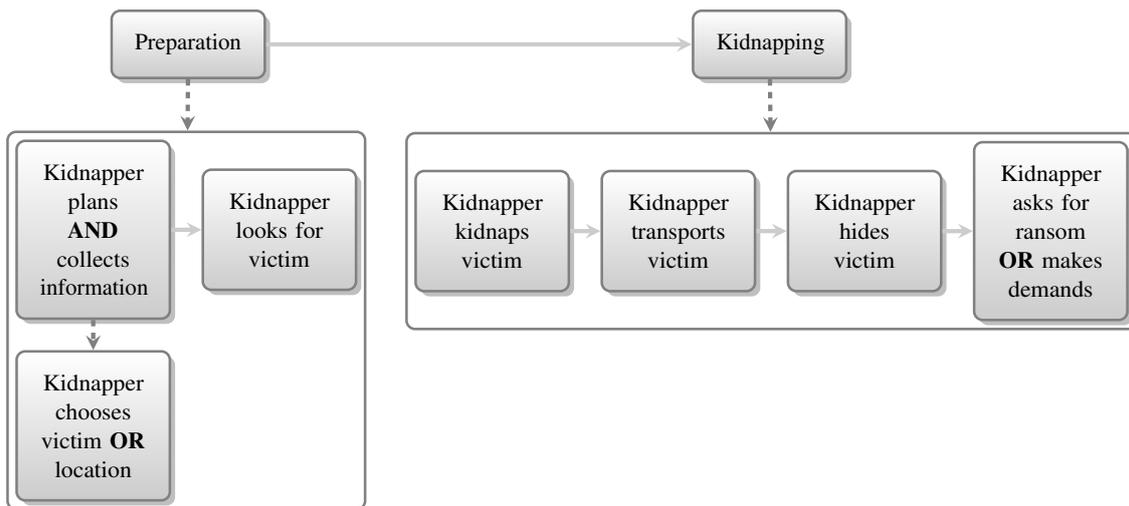

Figure 1: An example schema for the event of Kidnapping. The regular arrows represent temporal relations and the dashed arrows represent hierarchical relations (PARENT-CHILD).

In addition to eliminating the need to collect data, we also made the information extraction process faster by implementing new and efficient methods for identifying temporal and hierarchical relations between events mentioned in the text. These two steps are the most time consuming in the process of schema induction and could take up to 2 hours each using state-of-the-art models proposed by Zhou et al. (2021); Wang et al. (2021). Sending the whole text as input instead of two sentences at each time, our proposed model shortens the inference time significantly to several minutes without enduring a major loss in performance.

The process of generating texts is explained in Section §3, and the process of extracting relevant and salient information is described in Section §4, then we introduce the construction of schema graphs in Section §5. To evaluate our zero-shot schema generator we conduct experiments on a benchmark dataset for schema induction, LDC2020E25, and provide a new dataset for further evaluation called Schema-11. Additionally, we design a subject-matter expert Turing test, a.k.a. Feigenbaum test (Feigenbaum, 2003), to determine whether our algorithm could mimic experts’ response. We also demonstrate that documents generated by GPT-3 are informative and useful for the task of schema induction. The experiments and results are presented in Section §6. The contributions of our work include:

1. Predicting an entire schema given the name of a complex event without collecting data.
2. Implementing a novel and efficient One-Pass

approach for identifying temporal and hierarchical relations between events.

3. Presenting a method for automatically inducing logical relations between events based on temporal relations.
4. Offering a Feigenbaum test for evaluation on a new schema dataset, Schema-11.

2 Related Work

Schema Induction: Early schema induction efforts focused on identifying the triggers and participants of atomic events without considering relations between atomic events that comprise complex schemas (Chambers, 2013; Cheung et al., 2013; Nguyen et al., 2015; Sha et al., 2016; Yuan et al., 2018). More recent work focuses on inducing schemas for pairs of events (Li et al., 2020) and multiple events (Zhang et al., 2021b; Li et al., 2021), but they require access to large corpora for the induction process. In this work, we induce schemas on-the-fly in a zero-shot manner. As is standard in state-of-the-art (SOTA) works (Li et al., 2020, 2021; Wen et al., 2021), we output all the essential information about relations between events and arguments extracted from the text, in addition to logical and hierarchical relations not studied previously in schema induction.

Script Learning: Early script learning work concentrated on chains of events with a single protagonist (Chambers and Jurafsky, 2008, 2009; Jans et al., 2012; Rudinger et al., 2015; Granroth-Wilding and Clark, 2016) and later extended to

multiple protagonists (Pichotta and Mooney, 2014; Peng and Roth, 2016; Pichotta and Mooney, 2016; Modi, 2016; Weber et al., 2018, 2020; Zhang et al., 2020b). All of these works assume there exists a single line of events that describes all occurrences within a complex event. This work does not limit itself to generating single-chained schemas. We also consider more complex graphs as schema outputs. In addition, none of these works deal with zero-shot scenarios that do not require training data.

Pre-Trained Generation Models: Large-scale pre-trained text generation models such as GPT-2 (Radford et al., 2019), GPT-3 (Brown et al., 2020), BART (Lewis et al., 2020), T5 (Raffel et al., 2020), i.a. have been used in many NLP tasks. These models are often seen as few-shot learners (Brown et al., 2020) and therefore used as inference methods. However, these text generation models are not explicitly trained to perform inference, but to produce the most likely sequence of words to proceed a certain prompt, similar to language models. In our work, we use these large pre-trained LMs as text generators. The generated documents on a particular topic are leveraged as a corpus for extracting the schema of the given topic. We rely on the intuition that the generated text will include salient and stereotypical information that is expected to be mentioned in the context of the topic (e.g., for the topic of “planning a wedding,” we assume most documents will include “order catering”).

3 Data Generation

The schema induction process begins with generating texts using large LMs as text generation models. These texts are joined to form a knowledge base for the schema, including all of the potential information that the schema may present. One could, of course, create this knowledge base by crawling the web for real news articles or Wikipedia entries related to a certain topic.

We argue, however, that in addition to the obvious advantages of not having to rely on the availability of data online and not having to crawl the entire web for relevant documents on each topic, the generated data from these large generative models is more efficient in reporting salient events than random events described in the news, i.e., generated texts are more likely to mention important information than real documents do.

Our analysis shows that the generated stories contain a higher percentage of relevant tokens than

	Generated Text	Real Text
# events / # tokens	12.52%	6.31%
# arguments / # tokens	5.45%	3.01%

Table 1: The ratio of relevant events and relevant argument roles identified in generated texts and real texts for the scenario of IED attack.

real news articles that are used for schema induction. To demonstrate this phenomenon, we compare manually collected documents with those that are automatically generated using GPT-3 for the event of Improvised Explosive Device (IED) Attack (Li et al., 2021). To identify salient events and arguments concerning IED attacks, we adopt the DARPA KAIROS Phase 1 (v3.0) ontology² — a fine-grained ontology for schema learning, with 24 entity types, 67 event types, and 85 argument roles.

We calculate the number of relevant event triggers and arguments identified in the text, where a relevant mention is one whose type appears in the ontology. The results shown in Table 1 demonstrate that the quality of the generated texts in terms of conciseness and appearance of important details is higher than that of real texts. For example, the ratio of relevant events per token is more than twice as high in generated texts as it is in real texts. Hence we are able to not only generate a schema for every given topic without putting any effort in searching the web, but the information we generate is also better suited for our end task of depicting all of the important aspects of a complex event.

Given a topic for which we want to create a schema, we generate multiple texts that discuss the topic event using the OpenAI GPT-3 API³ with the Davinci-instruct-beta-v3 model and we also experiment with the Hugging Face GPT-2 API⁴. We use three prompting methods to generate documents of diverse genres as follows:

News Articles: We begin by generating a headline using the prompt: “Write a news headline about *topic*.” The output from this prompt is then used in the following prompt: “Write a news story titled *headline*.” The output from the second prompt is added to the pool of generated texts. The process is repeated 30 times. See example in Fig. 2b.

How-To Articles: We use the prompt: “Describe how to *topic*.” to generate wikiHow-like instruction

²The full ontology definition can be accessed at this link: <https://bit.ly/3mIWJoN>.

³<https://openai.com/blog/openai-api/>.

⁴<https://huggingface.co/gpt2>

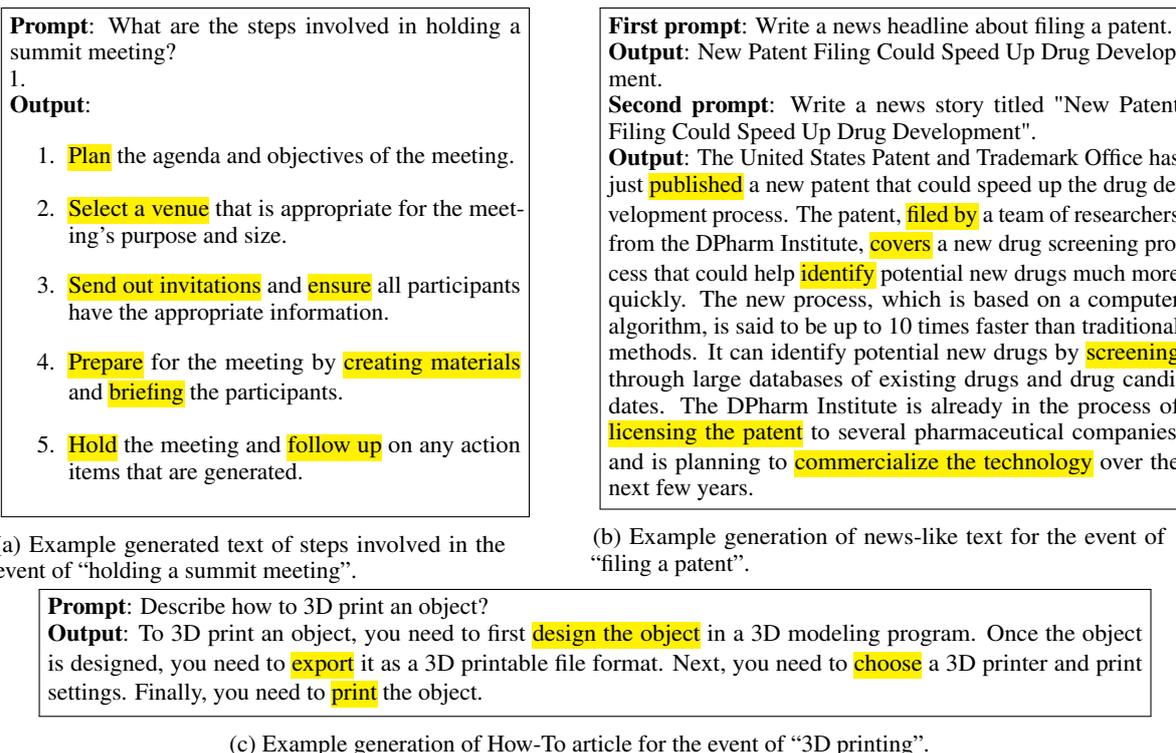

Figure 2: Examples of generated texts using different prompting methods. The highlighted tokens display relevant events that will be extracted in the information extraction step.

articles. The process is repeated 30 times. See example in Fig. 2c.

Direct Step-by-Step Schema: We use the prompt: "What are the steps involved in *topic*? 1."⁵ to directly generate a schema. We run this process once. See example in Fig. 2a.

Generating documents of various genres enables our model to induce comprehensive schemas on any given topics. Considering that some events are more likely to be in the news (e.g., elections, pandemic outbreaks) while others are more technical in nature and are hence less newsworthy (such as earning a Ph.D. degree or planning a wedding), we generate diverse texts and then use a ranking model to choose the most relevant documents.

The ranking process includes embedding the texts and the topic with the model proposed in Reimers and Gurevych (2019), and then calculating the cosine similarity between each text and the topic embeddings. Only the 30 texts closest to the topic are selected, together with the output from the direct step-by-step schema. The following section describes the next step in generating a schema of extracting relevant information from the texts.

⁵The "1." in the prompt is for the LM to automatically complete the steps.

4 Information Extraction

For each document, we extract event triggers, arguments and relations between the events that are important and relevant to the schema topic. We do not work with a predefined ontology that defines what events and arguments are salient in advance because we allow generating a schema on any topic. Instead, we employ a statistical approach by extracting all the information and later filter it down to include just frequent items. Here are the steps involved in our information extraction pipeline:

Semantic Role Labeling (SRL): We use the SOTA SRL system⁶ trained on CoNLL12 (Pradhan et al., 2012) and Nombank dataset (Meyers et al., 2004) to extract both verb and nominal event triggers and arguments.

Named Entity Recognition (NER): We employ the SOTA NER model (Guo and Roth, 2021) to extract and map entities (potential arguments of events) into entity types defined in the CoNLL 2002 dataset (Tjong Kim Sang, 2002) and the LORELEI project (Strassel and Tracey, 2016).

⁶ https://cogcomp.seas.upenn.edu/page/demo_view/SRLEnglish

Constituency Parsing: The arguments extracted by SRL can be clauses and long phrasal nouns, hence we employ the AllenNLP⁷ constituency parsing model for argument head word extraction.

Coreference Resolution: We use the SOTA model (Yu et al., 2022) for event and entity coreference resolution to identify within-document coreferential relations.

Temporal Relation Extraction: We first try to use SOTA models (Ning et al., 2019; Zhou et al., 2021) to predict the temporal relations⁸ between all possible pairs of extracted events but since the SOTA models accept two sentences containing events as input, the inference time⁹ for an n -event document is $\mathcal{O}(n^2)$, making the schema induction process several hours long.

One-Pass Model: We develop a One-Pass model that takes the document as input and uses the contextual representation of events to predict relations between them. A document D is represented as a sequence of tokens $D = [t_1, \dots, e_1, \dots, e_2, \dots, t_n]$ where some of the tokens belong to the set of annotated event triggers, i.e., $\mathcal{E}_D = \{e_1, e_2, \dots, e_k\}$, whereas the rest are other lexemes. We employ the transformer-based language model Big Bird (Zaheer et al., 2020) to encode a whole document and obtain the contextualized representations for all the event mentions. These representations are fed into a multi-layer perceptron in a pairwise fashion and the cross-entropy loss for each pair is calculated and accumulated for a batch of documents. As shown in Tab. 2, the inference time is shortened 63-186 times on average, while the performance of the One-Pass model is comparable to SOTA models.

Hierarchical Relation Extraction: The extremely long inference time of SOTA models for predicting hierarchical relations (PARENT-CHILD, CHILD-PARENT, COREF, NOREL) (Zhou et al., 2020; Wang et al., 2021) also impairs the efficiency of our schema induction system. Thus we use the same One-Pass methodology to extract hierarchical relations. We observe that the inference time is greatly shortened, and the One-Pass model

⁷<https://demo.allennlp.org/constituency-parsing>.

⁸The possible temporal relations (start-time comparison) are: BEFORE, AFTER, EQUAL and VAGUE.

⁹The inference time is mostly spent on obtaining the contextual representation of events using large fine-tuned LMs.

Corpus	Model	Metrics		
		F_1 score	Speed	GPU Memory
HiEve	Zhou et al. (2020)	0.489	-	-
	Wang et al. (2021)	0.522	41.68s	4515MiB
	One-Pass model	0.472	0.65s	2941MiB
MATRES	Ning et al. (2019)	0.767	30.12s	4187MiB
	Zhou et al. (2021)	0.821	89.36s	9311MiB
	One-Pass model	0.768	0.48s	2419MiB

Table 2: Performance comparison between the One-Pass model and SOTA models for event temporal and hierarchical relation extraction. We report F_1 scores on benchmark datasets (HiEve for hierarchical relations, MATRES for temporal relations), speed (average inference time for 100 event pairs), and required GPU memory during inference. The One-Pass models are 63-186 times faster than SOTA models and take up only 26%-65% of the GPU memory required by SOTA models.

achieves comparable results to previous models while taking up less GPU memory (see Tab. 2).

After processing the data using the procedure described above, we get a list of events, their arguments, and relations between the events. We concentrate on events and relations that frequently appear in the generated texts since we assume those are the most important to add to the schema (without any other source of information that could identify what is salient). We describe the process of building a schema in the following section.

5 Schema Induction

To consolidate the information extracted from the previous step, we build a schema as follows:

Make a list of events and relations: To compare similar event mentions in different texts, we compare the event trigger itself (whether they are the same verb or coreferential verbs¹⁰) and the NER types of its arguments. For example, the trigger “(take) precautions” appeared in 5 documents generated for the topic of Pandemic Outbreak. In two documents the subject of the verb phrase “take precautions” was “residents”, in another two it was “people” and in the last one, it was “public”. Nevertheless, the NER type is identical in all cases (PER), and thus we set the frequency of “(take) precautions” to 5. Similarly, we calculate the frequency of the temporal and hierarchical relations. We only consider relations and events that appeared in more than one document.

Construct timelines: We construct the longest timelines from the list of temporal relations. This

¹⁰We only consider coreferential and hierarchical relations if they appear in more than 2 documents.

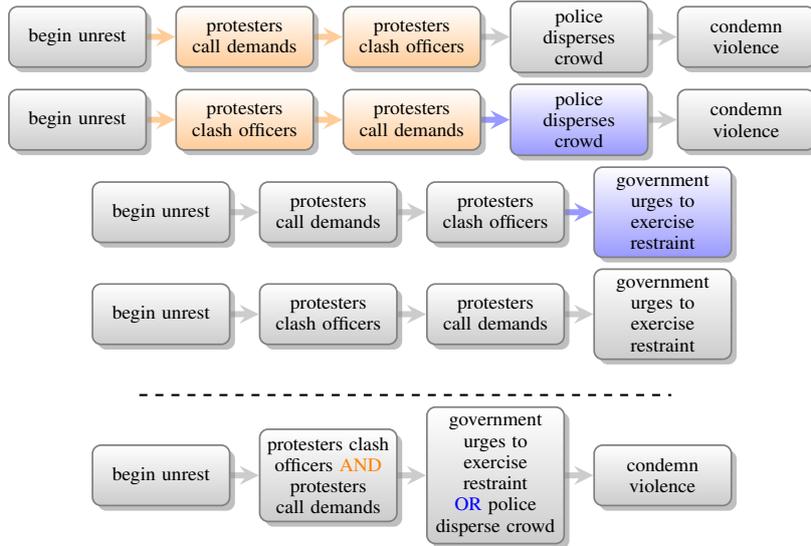

Figure 3: An example of integrating timelines and logical relations in the schema of Civil Unrest. The four upper timelines are the ones extracted from the generated texts and the lower one is their merger into a single timeline with logical relations.

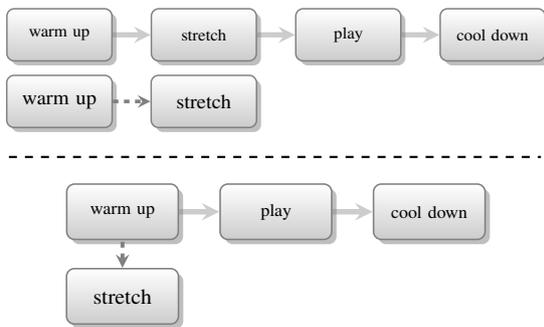

Figure 4: Example of the procedure to amend a timeline in the schema of “Sports Games”. The timeline at the top that includes events from different levels (“warm up” is the parent of “stretch”) is fixed below. Gray arrows mark temporal relations, and dashed arrows mark PARENT-CHILD.

list is a list of tuples (A, B) , indicating that event A happened before event B . To construct a timeline, we search recursively for the longest chains of the following form $(A, B), (B, C), (A, C)$ and so on.

Fix timelines according to hierarchical relations: We build a hierarchy of the events using the hierarchical relation list¹⁰ and change the timelines so that they will only include events that appear in the same level of hierarchy (see example in Fig. 4).

Add logical relations: The final step is to combine the timelines and hierarchies into a single schema graph using logical relations (AND/OR). When observing two timelines with discrepancies between the order of events, we place a logical AND between them, since we interpret this discrepancy as

both events occurring at the same time or there is no significance to the order between them. We use a logical OR to mark events that can occur simultaneously but not necessarily. See Fig. 3 for example of both logical relations.

The final output is a schema graph that contains all the events, arguments, and temporal, hierarchical and logical relations between the events. It is noteworthy that our proposed schema generation model can be easily used to *extend the scope of existing schemas* by further querying the model on more specific topics. For example, the schema in Fig. 1 does not cover the consequences of kidnapping, probably because the LM did not attend to this aspect. Hence an analyst can input another topic (e.g., consequences of kidnapping) to further develop the schema. Similarly, analysts can generate schemas for very specific events (e.g., kidnapping in a political setting). Next, we provide an in-depth experimentation for the proposed schema induction framework.

6 Experiments

6.1 Data

We conduct experiments on a dataset for general schema learning released by LDC (LDC2020E25). The corpus includes 84 types of complex events, such as Cyber Attack, Farming and Recycling. This dataset includes ground-truth schemas created by LDC annotators. In addition, we also collected human generated schemas for 11 newsworthy sce-

narios¹¹. The schemas were generated by four human experts who were instructed to write a schema on each topic based on their commonsense knowledge that includes a list of event triggers, event arguments and their NER types¹², and relations¹³.

6.2 Evaluation Protocols

We follow Li et al. (2021) to use instance coverage and last event prediction to evaluate our method on the LDC dataset. For the Schema-11 dataset, we ask human testers to assess the completeness and soundness of both human- and automatically-generated schemas.

Coverage and Prediction A common evaluation method in schema induction and script prediction is to calculate the recall of events and relations predicted by the model, assuming the human annotations are gold labels (coverage), and to calculate the accuracy in predicting the final outcome of a scenario (prediction). For instance, the accuracy of predicting the last event type of the LDC schemas is reported in Li et al. (2021). Here we present the results of predicting the last events using event triggers instead of event types since our schemas do not use an ontology of event types.

Feigenbaum Test We show human testers two schemas on each topic in the Schema-11 dataset (see example in Appx. §A). One schema is automatically generated by our model, and the other is randomly sampled from the Schema-11 corpus¹⁴. Then, we ask the testers to determine which events and relations are valid to appear in the schema (soundness), and answer the following questions: which schema is more complete in the sense of including all the events needed to describe the topic, and which schema, in their opinion, was generated by a human expert (as opposed to a machine).

6.3 Results

Coverage We calculate the intersection between events in the generated schemas and the gold

¹¹The topics are: Bombing Attack, Business Change, Civil Unrest, Disaster and Rescue, Elections, International Conflict, Kidnapping, Mass Shooting, Pandemic Outbreak, Sports Games, and Terrorism Attack.

¹²The annotators are familiar with SRL annotations (e.g., ARG0, ARG1, etc.) and NER types (e.g., PER, ORG, etc.). See additional details in App. C

¹³No restrictions were placed for the annotators. For example, in one case, an annotator mentioned causal relations that are not covered in our framework.

¹⁴In some cases we combine two randomly sampled schemas because the length of the human schemas tend to be shorter than the automatically generated ones.

schemas in two ways: (a) the matching of event triggers, and (b) the matching of event triggers and synonyms of the events in the gold schemas (synonym coverage)¹⁵. We believe that synonym coverage is a better evaluation metric to avoid errors such as considering different verbs describing the same action as different (e.g., “buy” and “acquire”) than using a predefined ontology of event types such as the one used in Li et al. (2021). The reason is twofold: firstly, any predefined ontology is limited to certain scenarios and it may impair the variety of events extracted; and secondly the typing mechanism may also inflict errors to the schema. In the calculation of coverage of relations we only take into account relations (a, b) where both events, a and b , appear in the generated schema.

From the results in Table 3, we observe that despite the difficulty of exact matching, our model with GPT-3 covers 23.73% of the gold events, showing that generated texts are useful. If we use synonym coverage as our metric, we achieve a promising coverage of 37.84% while the SOTA supervised event graph model (Li et al., 2021) covers 54.84% using limited event types. In addition, we calculated an average number of 26.19 additional events that appeared in the generated schemas and not in the LDC schema, pointing to the potential of using generated documents for expending existing schemas. With the high quality event representations obtained from the One-Pass model and the proposed logical relation induction algorithm, our method can successfully cover a high percentage of multiple types of relations.

Prediction In the prediction task, our schemas are able reach SOTA performance and predict the final outcome in 63.1% of the cases for the LDC schemas (see Tab. 4). This result is extremely impressive when it is compared with Li et al. (2021) since they predict event types instead of verbs, which is a much easier task due to the fact that the set of possible answers is limited.

Schema-11 In the soundness experiments, where the testers are asked to decide which events and relations are valid to appear in the schema, it turns out that human-schemas contain 7.14% invalid events and 15.4% invalid relations on average. For the automatically-generated schemas, 6.06% of the events and 22.9% of the relations are considered to be invalid on average, meaning that the average

¹⁵Implemented using the NLTK WordNet Python package.

	GPT2		GPT3		Li et al. (2021)
	Coverage	Coverage (Syn)	Coverage	Coverage (Syn)	Coverage
Event Match	14.88	29.55	23.73	37.84	54.84
Temporal Relations	10.80	33.31	31.07	49.99	
Hierarchical Relations	33.33	33.33	11.11	13.88	-
Logical Relations	4.16	24.99	43.76	49.81	

Table 3: Coverage results for the LDC dataset. The first row presents the percentage of events that appeared in both the LDC schemas and the automatically generated schemas (out of events in LDC schemas), and the three bottom rows present the same metric for relations of different types.

Model	Accuracy
Event Language Model	49.7
Sequential Pattern Mining	47.8
Human Schema	20.5
Event Graph Model	52.0
Zero-Shot Schema GPT2	25.0
Zero-Shot Schema Synonym GPT2	45.2
Zero-Shot Schema GPT3	35.7
Zero-Shot Schema Synonym GPT3	63.1

Table 4: Experimental results for last event prediction in the LDC dataset. The top 4 results are from (Li et al., 2021), and the metric is HITS@1 where the events are typed based on a predefined ontology.

	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11
Human	4	0	1	1	1	2	1	1	0	3	1
Automatic	2	3	4	2	1	1	1	1	4	0	1

Table 5: Distribution of votes for which is the more complete schema for Schema-11 dataset.

percentage of legitimate events is even higher in machine-generated schemas. For the completeness results presented in Tab. 5, in 4 cases the testers agreed that the automatically generated schemas are more complete; in 3 cases they claimed that the human schemas are more complete; and a tie in the remaining 4 cases. Hence our automatically generated schemas are of comparable quality to human generated ones in the sense of completeness.

Finally, in the Feigenbaum test, where testers are asked to decide whether a schema is generated by a human or a machine, eight out of eleven times they correctly identify the human-generated schema, one incorrectly, and two ties. Some of the testers who succeeded in their guesses mentioned that it was easy to determine which schema was automatically generated since it tends to be longer and comprehensive. The full results from the Feigenbaum test are shown in Appx. §B.

Wizard of Oz Experiment There seems to be a discrepancy between the low event coverage results and the quality of generated texts that were presented in Section §3. We, therefore, conducted

another experiment to identify if the problem stems from the quality of the generated documents. In this experiment, one of the authors sampled 10 complex event names from the LDC dataset and generated, using GPT-3 text davinci-002 model, 3 texts for each scenario using the prompting methods presented in Section §3. Then, the author manually extracted all relevant events and relations from each document and built a schema based solely on those events and relations.

This experiment, in which the author pretends to be the IE and schema generator models, aims to demonstrate that if we had perfect IE and schema induction systems, then the texts generated by GPT-3 would be sufficient and even superior to other corpora collected manually. The macro-average coverage of events in this experiment is 68% and the micro-average is 74%. Furthermore, GPT-3 texts generated schemas that included, on average, 6.5 additional events not mentioned in LDC schemas but relevant to the scenario at hand. As a result, we conclude that the generated texts from GPT3 contain much of the necessary information to generate schemas in a variety of topics, and can even be used to enrich existing schemas generated by other models or humans. Two example scenarios and more details appear in Appx. §D.

7 Conclusion

We propose a method to generate schemas given the sole input of a topic. We use GPT-3 to generate texts of diverse genres and a pipeline of information extraction tools to obtain relevant information before inducing logical relations and integrating the events and relations into a schema graph. To improve the efficiency of the pipeline, we implement One-Pass models for identifying temporal and hierarchical relations that achieve comparable performances with SOTA models but require far less inference time and memory space. To evaluate our framework, we conduct experiments on a

benchmark LDC dataset to show that our schemas cover a decent amount of pertinent information and display comparable ability for event prediction with supervised approaches. We observe a high percentage of valid events and relations generated for the Schema-11 dataset and the testers endorsed the completeness of our machine-generated schemas.

8 Acknowledgments

9 Limitations

The paper presents a method for building an event schema without manually collecting documents from sources such as news articles or Wikipedia. In order to generate diverse and informative documents on any topic, we rely on large pre-trained language models. Our model, which uses GPT-3, generates schemas that are comparable to those generated by manually searching the web for documents, however, when we use inferior LMs such as GPT-2, we see a decline in performance (see [Tab. 3](#) and [Tab. 4](#)).

Our assumption is that the quality of the generated schema depends on the quality of the LM and the level of coverage of the selected topic in the LM training data. If, for instance, we were to ask our model to generate a schema for a unique topic such as "conducting an archaeological dig in an unexplored territory" we doubt that the results would be as useful to an archaeologist as if they were looking for information themselves due to the low coverage of this topic in the corpus the model was trained on.

Despite our model's reliance on pre-trained LMs, we believe the generated schemas can always serve as a good basis for further development.

10 Ethical Consideration

The proposed schema induction method does not present any direct societal implications. As is observed in [Abid et al. \(2021\)](#), the text generated by GPT-3 might include undesired social bias. Extracting events and relations from text with such social bias might potentially propagate the bias to the induced schemas. Besides, there are risks of malicious or unintended harmful uses of the generated schemas, for instance, the system might be used to inquire about making a bomb or contriving a terrorist attacks. Yet we believe that the proposed method can benefit various downstream NLP/NLU tasks like event prediction, task-oriented dialogue agents ([Andreas et al., 2020](#)) and risk detection ([Pohl et al., 2012](#)).

A Feigenbaum Test Details

The experiment took place online through filling a Google Form and involved 11 volunteer annotators. Each annotator got 3-4 scenarios to annotate. The instructions for the survey appear in Figure 5. An example scenario and the questions of the survey are presented in Fig. 6, Fig. 7, Fig. 8, and Fig. 9.

B Feigenbaum Test Results

In this section we present all the results from the experiments on the dataset Schema-11. Tab. 6 shows the distribution of answers for the question “which schema is more complete?” (same as depicted in Tab. 5), Tab. 7 presents the distribution of answers for the question “which schema was generated by a human?” together with the correct answer written in the bottom row, and Tab. 8 presents the percentage of invalid events and relations determined by the majority vote of the annotators in the automatic schema and the human schema.

C Details on Human Schema Curation

Here are the instructions that were given to the annotators that generated the human schemas for the Schema-11 dataset. All the annotators are graduate students that previously were involved in research projects that include schema induction, SRL, NER or other relevant tasks:

We are developing a system that generates schemas automatically given a topic. We want to compare our automatically-generated schema to schemas derived by people using their common-sense (without relying on texts). To do this, we need expert human annotators and would appreciate your assistance.

A schema is defined as a list of events with their argument types, and the relationships between the events. For example, here is a schema I wrote that describes the event of “armed robbery”:

List of events and arguments:

- intend: arg0 - perpetrator [PER], arg1 - commit a felony
- acquire: arg0 - perpetrator [PER], arg1 - weapon [WEA]
- arrive: arg0 - perpetrator [PER], arg-loc - crime scene [LOC]
- assault: arg0 - perpetrator [PER], arg1 - [PER]

- threaten: arg0 - perpetrator [PER], arg1 - [PER]
- get: arg0 - perpetrator [PER], arg1 - money or goods
- injure: arg0 - perpetrator [PER], arg1 - [PER]
- kill: arg0 - perpetrator [PER], arg1 - [PER]
- flee: arg0 - perpetrator [PER], arg-loc - crime scene [LOC]
- call: arg0 - [PER], arg1 - police [ORG]
- chase: arg0 - police [ORG], arg1 - perpetrator [PER]
- catch: arg0 - police [ORG], arg1 - perpetrator [PER]
- manage to escape: arg0 - perpetrator [PER]

Temporal and logical relations (in the form of a timeline):

- a perpetrator (PER) **intent** to commit a felony ->
- the perpetrator (PER) **acquires** weapon (WEA) ->
- the perpetrator (PER) **arrives** at the scene (LOC) ->
- perpetrator (PER) **assault** victim (PER) with weapon (WEA) at the scene (LOC) **OR** perpetrator (PER) **threatens** a person (PER) with the weapon (WEA) at the scene (LOC) ->
- perpetrator (PER) **gets** money or goods from the person (PER) **OR** victim **injured OR** victim **killed** ->
- perpetrator **flees** the scene of the crime (LOC) **AND** someone (PER) **calls** the police (ORG) ->
- the police (ORG) are **chasing** the criminal (PER) ->
- the police (ORG) **catches** the perpetrator (PER) **XOR** the criminal (PER) **manages to escape**.

The complex events we are interested in are the following: (1) Disease Outbreak (2) IED Bombing (3) Civil Unrest (4) International Invasion (5) Disaster and Rescue (6) Terrorism Attacks (7) Election (8) Kidnapping (9) Business Change (10) Mass Shooting.

Feigenbaum Test - Scenario 11

This form mainly focuses on the evaluation of machine generated schema. Given a certain scenario, the schema includes stereotypical events and the relations between them, for instance, within scenario "acquiring a PhD degree", a schema would typically includes "publish papers," "attend conferences," "write PhD thesis" and "defend PhD thesis." And there is also a "before" relation between "write PhD thesis" and "defend PhD thesis." Besides, we also have "SuperSub" relation that means hierarchical relation between events, and "AND"/"OR" relation that means the two events must happen together/either of the events may happen.

We've asked a group of people to generate schemas from their commonsense knowledge. Given two schemas per scenario, your task is to determine whether you can distinguish the machine generated schema from the human generated one. And also provide your insights on the completeness and soundness of each schema.

For completeness, we would like you to tell us which schema is more complete.

For soundness, we would like you to tell us for each event and relation listed, whether it is valid for this scenario.

Most importantly, we would like to know which schema you think is generated by human.

Figure 5: Instructions for the Feigenbaum test.

	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11
Human	4	0	1	1	1	2	1	1	0	3	1
Automatic	2	3	4	2	1	1	1	1	4	0	1

Table 6: Completeness results. The table presents the number of votes that were recorded for which schema is more complete - the human generated schema or the automatically generated schema. The majority vote is highlighted in yellow.

	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11
A	1	1	3	0	0	2	0	2	2	1	1
B	5	2	2	3	2	1	2	0	2	2	1
Correct Answer	B	B	B	B	B	A	B	A	A	B	B

Table 7: Feigenbaum test results. The annotators guesses which schema (A or B) was generated by humans. The number of votes for each option appear along with the correct answer in the bottom row. The correct majority guesses are marked with green and incorrect with red.

	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11
Invalid Events (Auto.)	0	0	0	0	0	8.33	0	7.69	0	14.28	0
Invalid Relations (Auto.)	46.15	16.66	25	25	0	23.52	0.4	11.76	12.5	22.22	46.15
Invalid Events (Human)	0	0	14.28	14.28	0	0	0	0	0	0	0
Invalid Relations (Human)	7.69	50	15.38	15.38	0	6.25	0	11.11	0	10	7.69

Table 8: Invalidity results. The table presents the percentage of invalid events and relations determined by the human annotators for each schema and scenario.

Scenario 11: Terrorism Attack (A)

Events:

1. event: kill, arg0: {PER, ORG, VEH, WEA}, arg1: PER
2. event: injure, arg0: {PER, ORG, VEH, WEA}, arg1: PER
3. event: detonate, arg0: PER, arg1: WEA
4. event: come, arg1: attack
5. event: open, arg0: {PER, ORG}, arg1: fire
6. event: wound, arg0: {PER, ORG, VEH, WEA}, arg1: PER
7. event: strike, arg0: {PER, ORG, WEA}
8. event: claim, arg0: ORG, arg1: responsibility
9. event: leave, arg0: {PER, VEH}
10. event: attack, arg0: {PER, ORG}
11. event: choose, arg0: {PER, ORG}, arg1: {PER, ORG, GPE}
12. event: select, arg0: {PER, ORG}, arg1: method
13. event: acquire, arg0: {PER, ORG}, arg1: WEA
14. event: carry out, arg0: PER

Relations:

1. before: 3->8
2. before: 3->5
3. before: 1->4
4. before: 1->9
5. before: 2->4
6. before: 2->9
7. before: 6->4
8. before: 6->9
9. before: 11->12->13->14->10
10. OR: 8,5
11. OR: 4,9
12. AND: 1,2,6
13. supersub: 10->7->1,2

Figure 6: An example schema in the topic of Terrorism Attack. This schema was generated automatically (information that was unknown to the annotators).

Scenario 11: Terrorism Attack (B)

Events:

1. event: find, arg0: PER, arg1: ORG, arg-loc:LOC
2. event: emerge, arg0: ORG, arg1: ORG
3. event: fade, arg0: ORG, arg-tmp: TMP
4. event: reemerge, arg0: ORG, arg-tmp: TMP, arg-loc: LOC
5. event: lead, arg0: ORG, arg1: losses
6. event: lost, arg0: ORG, arg1: LOC
7. event: declare, arg0: GPE, arg1: ORG
8. event: kill, arg0: GPE, arg1: PER
9. event: plan, arg0: PER
10. event: executes, arg0: PER
11. event: injures, arg0: the attack, arg1: PER
12. event: kills, arg0: the attack, arg1: PER
13. event: damages, arg0: the attack, arg1: infrastructure
14. event: calls, arg0: PER, arg1: PER
15. event: arrive, arg0: PER
16. event: treat, arg0: PER, arg1: PER
17. event: take, arg0: PER, arg1: PER
18. event: reports, arg0: PER
19. event: claims, arg0: the group, arg1: responsibility

Relations:

1. before: 9->10
2. before: 10->11
3. before: 10->12
4. before: 10->13
5. before: 10->14
6. before: 14->15->16->17
7. before: 10->18
8. before: 10->19
9. before: 1->3
10. before: 3->4
11. AND: 1->2
12. cause: 5->6
13. cause: 8->7

D Wizard of Oz Experiment

Two examples of the Wizard of Oz experiment for the events of invasion and remodel a facility. The examples show the three generated texts using the three prompting methods, the schema created by the author, and the LDC schema together with a matching between the events in the two schemas. The entire list of sampled topics is: print a 3D object, cyber attack, make a website, religious conversion, invasion, shipping and mailing, remodel a facility, obtain and provide medical treatment, build a drone, and nonviolent protest march.

D.1 Example 1: Invasion

Prompts and Outputs:

1. Prompt: describe how to perform an invasion.
Output: 1. Choose a target: Identify a target population that you want to invade. This target population can be a group of people, a city, or a country. 2. Prepare your troops: Assemble your troops and supplies in preparation for the invasion. 3. Launch your attack: Attack the target population using whatever means necessary to take control. 4. Consolidate your power: Once you have taken control of the target population, consolidate your power by establishing your authority and eliminating any resistance.
2. Prompt: what are the steps involved in an invasion?
Output: 1. The first step in an invasion is to gather intelligence about the enemy. This includes learning about their strengths, weaknesses, and their territory. 2. The next step is to plan the invasion. This includes deciding what resources will be needed and how they will be used. 3. The third step is to launch the invasion. This is when the actual fighting begins. 4. The fourth step is to consolidate the gains. This is when the invading force secures their position and prepares for the next phase of the operation.
3. Prompt: write a news headline about invasion.
Output: U.S. troops invade Canada in surprise attack.
Prompt: write a news article titled: "U.S. troops invade Canada in surprise attack."
Output: In a stunning move, the United States has invaded Canada in a surprise attack. The

troops came across the border early this morning, catching the Canadians by surprise. The Canadians are currently fighting back, but it is unknown how long they will be able to hold out against the might of the United States military. This is a developing story, and more details will be released as they become available.

Schema generated based on the three outputs

1. Choose target.
2. Gather intelligence on target: learn strengths and weaknesses and territory.
3. Plan invasion: decide on resources and how the resources will be used.
4. Prepare troops: Assemble troops and supplies.
5. Launch attack: come across the border.
6. Fight or use whatever means possible.
7. Take control.
8. Consolidate power: establish authority and eliminate resistance.
9. Prepare for the next phase of operation.

LDC Schema

1. Step 1: PlanInvasion: Plan[3] for the invasion.
 - (a) Step 1.1: IdentifyTargets[1]: Leadership builds a list of entry points for the invasion and selects one or more as the target(s) of the initial invasion.
 - (b) Step 1.2: DevelopPlan[3]: A team develop a master invasion plan.
 - (c) Step 1.3: OrderDissemination [not matched]: Planners send out detailed instructions to military forces about the invasion plan.
2. Step 2: DeployTroops[4]: Amass and deploy troops for invasion.
3. Step 3: Invasion[5]: Military force launch the invasion and enter the target territory.
4. Step 4: DisperseTroops[6]: Dispersion of invading troops across territory.

Results: The GPT3 schema covers 6 out of 7 events that are mentioned in the LDC schema. The matching between LDC events and schema events are marked in [] next to the event on the LDC schema. GPT3 schema has 7 additional events: gather intelligence, learn strengths, decide on resources, assemble troops and supplies, come across border, take control, consolidate power, establish authority, eliminate resistance, prepare for next phase.

D.2 Example 2: Remodel A Facility

Prompts and Outputs:

1. Prompt: describe how to remodel a facility.
Output: There is no one-size-fits-all answer to this question, as the best way to remodel a facility depends on the specific needs and goals of the organization. However, some tips on how to remodel a facility include: 1. Define the scope of the project. 2. Create a budget and timeline. 3. Hire an experienced architect or designer. 4. Work with a reputable contractor. 5. Use high-quality materials. 6. Follow building codes and regulations. 7. Get input from stakeholders. 8. Test the new space before moving in.
2. Prompt: what are the steps involved in remodeling a facility?
Output: 1. The first step in remodeling a facility is to develop a plan. This plan should include the goals of the remodel, the budget, the timeline, and the scope of work. 2. The next step is to obtain the necessary permits. Depending on the scope of work, this may require a building permit, a zoning permit, and/or a permit from the local health department. 3. Once the permits are obtained, the next step is to select a contractor. The contractor should be licensed and insured, and should have experience with the type of work that needs to be done. 4. The contractor will then begin the work, which may include demolition, construction, painting, and/or installation of new fixtures and appliances. 5. Once the work is completed, the facility will need to be inspected to ensure that it meets all applicable codes and regulations. 6. Finally, the facility can be reopened to the public.
3. Prompt: write a news headline about remodeling a facility.

Output: Facility Remodeling Underway

Prompt: write a news article titled: "Facility Remodeling Underway"

Output: In an effort to better serve the needs of the community, the local library is undergoing a remodel. The project is expected to take several months to complete, but the end result will be a more user-friendly space that meets the needs of today's patrons. Some of the changes include a new layout for the adult fiction section, additional study rooms, and updated furniture throughout the facility. The children's area will also be expanded to create a more inviting and interactive space. The library staff is excited about the changes and can't wait to see the finished product. They are confident that the updates will make the library a more popular destination for both residents and visitors.

Schema generated based on the three outputs

1. Develop a plan: define scope and goals and create budget and timeline.
2. Hire an architect or designer and obtain necessary permits.
3. Select a contractor (preconditions: contractor licensed, insured, have experience).
4. Contractor works: use high quality materials AND follow building code and regulations and demolition or construction or painting or installation.
5. Get input from stakeholders.
6. Inspect facility.
7. Test space.
8. Reopen facility.
9. Facility is user-friendly and meets needs of patrons.

LDC Schema

1. Step 1: Acquisition [not matched]: Acquire facility.
2. Step 2: Planning[1]: Research and plan expected usage, budget, changes, legal issues, dependencies.

3. Step 3: Labor[2,3]: Arrange for skills, or laborers, or both.
 - (a) Step 3.1: AcquireSkills [not matched]: Acquire skills or knowledge required for remodeling.
 - (b) Step 3.2: HireLaborers[2,3]: Hire skilled person or organization to perform remodeling work.
4. Step 4: AcquireMaterials[4.1]: Acquire materials and tools.
5. Step 5: Remodel[4]: Facility is remodeled.
 - (a) Step 5.1: Demolition[4.2]: Deconstruction or demolition of portions of building and/or equipment installations.
 - (b) Step 5.2: DebrisRemoval [not matched]: Hauling away/dumping of debris.
 - (c) Step 5.3: Modification[4.2]: Modification, addition, or installation of building or systems/equipment in building.
6. Step 6: Inspection[6,7]: Inspect and/or test new portions of facility and/or new systems of facility for functionality and compliance with laws and regulations.

Results: The GPT3 schema covers 8 out of 11 events that are mentioned in the LDC schema. The matching between LDC events and schema events are marked in [] next to the event on the LDC schema. GPT3 schema has 9 additional events: contractor works, follow building code and regulations, preconditions on contractor, painting, installation, construction.

BanglaNLG and BanglaT5: Benchmarks and Resources for Evaluating Low-Resource Natural Language Generation in Bangla

Abhik Bhattacharjee¹, Tahmid Hasan¹, Wasi Uddin Ahmad², Rifat Shahriyar¹

Bangladesh University of Engineering and Technology (BUET)¹,

University of California, Los Angeles²

abhik@ra.cse.buet.ac.bd, {tahmidhasan,rifat}@cse.buet.ac.bd

Abstract

This work presents ‘BanglaNLG,’ a comprehensive benchmark for evaluating natural language generation (NLG) models in Bangla, a widely spoken yet low-resource language. We aggregate six challenging conditional text generation tasks under the BanglaNLG benchmark, introducing a new dataset on dialogue generation in the process. Furthermore, using a clean corpus of 27.5 GB of Bangla data, we pretrain ‘BanglaT5’, a sequence-to-sequence Transformer language model for Bangla. BanglaT5 achieves state-of-the-art performance in all of these tasks, outperforming several multilingual models by up to 9% absolute gain and 32% relative gain. We are making the new dialogue dataset and the BanglaT5 model publicly available at <https://github.com/csebuetnlp/BanglaNLG> in the hope of advancing future research on Bangla NLG.

1 Introduction

The emergence of pretrained language models (Devlin et al., 2019; Radford et al., 2019; Liu et al., 2019) has brought about a revolutionary change in natural language processing (NLP). With little task-specific fine-tuning, these models have achieved state-of-the-art results on many NLP tasks (Wang et al., 2018; Rajpurkar et al., 2016; Tjong Kim Sang and De Meulder, 2003). However, the focus of these models has predominantly been on natural language understanding (NLU). Even models pretrained with generative objectives (Raffel et al., 2020) concern themselves with NLU tasks more than natural language generation (NLG) tasks. Although there have been recent efforts to uplift NLG (Gehrmann et al., 2021), they are primarily geared towards high- and mid-resource languages. For example, despite being the sixth most spoken language in the world with over 230 million native speakers comprising 3% of the world’s total population,¹ Bangla has remained an underrepresented

¹<https://w.wiki/Psq>

language in the NLP literature (Joshi et al., 2020). There have been only a handful of benchmark studies on Bangla NLG (Dabre et al., 2022; Kumar et al., 2022), and that too without Bangla being the main focus. This can be attributed to the lack of diverse NLG tasks under a single benchmark and strong pretrained Bangla NLG models.

To this end, we present ‘BanglaNLG,’ a comprehensive benchmark for Bangla language generation comprising six representative tasks on machine translation, text summarization, question answering, dialogue generation, headline generation, and cross-lingual summarization. To our knowledge, BanglaNLG is the first NLG benchmark exclusively for a low-resource language.

To establish a strong baseline for this benchmark, we pretrain **BanglaT5** – a sequence-to-sequence Transformer model (Vaswani et al., 2017) pretrained on a 27.5 GB clean Bangla text corpus covering a broad range of domains. In summary:

- We develop the BanglaNLG benchmark bringing together six NLG tasks.
- We introduce a Multi-turn Dialogue dataset.
- We pretrain BanglaT5 and evaluate it on the six NLG tasks, showing strong results.

BanglaT5 outperforms similar-sized multilingual models, achieving new state-of-the-art results on three tasks with a 4% gain on average. We are releasing the BanglaT5 model and a live leaderboard to promote future research on Bangla NLG.

2 The Bangla Natural Language Generation (BanglaNLG) Benchmark

There have been sporadic works on Bangla NLG, mostly catered to machine translation (Hasan et al., 2020; Mumin et al., 2019a,b) and text summarization (Bhattacharjee et al., 2021b; Dhar et al., 2021). However, Bangla NLG lacks a unified study comprising diverse and challenging tasks. Motivated by the popular benchmarks like GLUE (Wang

Task	Corpus	Train	Dev	Test	Metric	Domain
Machine Translation	BanglaNMT, FLoRes	2,751,315	997	1,012	SacreBLEU	Misc.
Text Summarization	XL-Sum	8,102	1,012	1,012	ROUGE-2	BBC
Question Answering	BQA	127,771	2,502	2,504	EM/F1	Wikipedia
Multi-turn Dialogue	DailyDialog	76,052	7,069	6,640	BLEU-1	Misc.
News Headline Generation	XL-Sum	8,102	1,012	1,012	ROUGE-2	BBC
Cross-lingual Summarization	CrossSum	1241	153	155	ROUGE-2	BBC

Table 1: Dataset statistics and basic characteristics of BanglaNLG. Machine translation and cross-lingual summarization datasets include examples of Bangla ↔ English.

et al., 2018), XTREME (Hu et al., 2020), GEM (Gehrmann et al., 2021), that have facilitated the training/evaluation of NLP models, we establish the first-ever Bangla Natural Language Generation (BanglaNLG) Benchmark.

2.1 Task Selection Criteria

We consider the following factors while choosing the evaluation tasks:

1. Diversity: The tasks should focus on evaluating the model’s generalization capabilities. Therefore, they should vary in task nature – the input and output length, the type of generated text, the target domain, and the dataset size.

2. Practical Applicability: The choice of tasks should be driven by their practical implications. Rather than being used in abstract situations, NLG models trained on these tasks should be able to aid/reduce human effort in real-world scenarios.

3. Difficulty: The tasks should be challenging while not being unsolvable. There should be clear room for improvement to foster future research.

4. Accessibility: The selected datasets for these tasks should be openly accessible to encourage researchers to design better NLG models.

5. Evaluation: The selected tasks should have reliable automated metrics for evaluating the focused abilities of an NLG model.

2.2 Selected Tasks

Considering the criteria mentioned above, we design BanglaNLG as an aggregation of six tasks:

1. Machine Translation (MT): MT is perhaps the most studied NLG task in Bangla and the most commonly benchmarked NLG task in general. We use the BanglaNMT parallel corpus (Hasan et al., 2020), the largest Bangla-English MT dataset curated, with 2.75 million parallel pairs for training. The sentence pairs originate from various domains such as Wikipedia, news articles, religious and law

documents, etc. We evaluate the NLG models using FLoRes-100 (Goyal et al., 2022) in both directions on this dataset, i.e., Bangla to English and English to Bangla. This task is particularly challenging since it assesses an NLG model’s bilingual generation capabilities. Following standard practice, we use detokenized SacreBLEU (Post, 2018) as the evaluation metric for this task.

2. Text Summarization (TS): This task aims to generate a short and fluent summary given a long text document. We chose the Bangla portion of XL-Sum (Hasan et al., 2021) for this task. XL-Sum is a large comprehensive dataset for abstractive TS where the article and summaries are written by professional editors of BBC News. The articles cover various topics such as entertainment, politics, science, sports, etc. For this task, we use ROUGE-2² (Lin, 2004) as the evaluation metric.

3. Question Answering (QA): This is a fundamental NLP task that can be modeled as both an NLU and NLG task. We use the BQA (Bhattacharjee et al., 2022) dataset for this task. The training data is machine translated from SQuAD 2.0 (Rajpurkar et al., 2018), while the evaluation data come from the human-annotated question-answer pairs of the TyDi-QA (Clark et al., 2020) secondary gold passage task. Although TyDi-QA only contains answerable questions, BQA introduced unanswerable questions to make the task more challenging. Following SQuAD 2.0, we use Exact Match (EM) and F1 as the evaluation metrics.

4. Multi-turn Dialogue (MTD): Conversational AI is a crucial task for NLG (Chen et al., 2017). However, there is no public dataset for dialogue generation in Bangla. As such, we curate a new multi-turn dialogue dataset by translating the DailyDialog (Li et al., 2017) dataset using the English to Bangla translation model introduced by Hasan

²We use Bangla stemming supported ROUGE implementation from https://github.com/csebuetnlp/xl-sum/tree/master/multilingual_rouge_scoring.

et al. (2020). Unlike standard QA-style conversation datasets, DailyDialog reflects real-life conversations in various social situations rich in emotion, making it a perfect candidate for our benchmark. We automatically translate the training data following the same procedure described in Bhattacharjee et al. (2022) and have the evaluation sets manually translated by expert human translators. We use BLEU-1 as the evaluation metric for this task to properly differentiate between models since averaged BLEU scores of up to 4-gram tend to be quite low in dialogue evaluation (Zhang et al., 2020).

5. News Headline Generation (NHG): Automating headline generation can help news editors write compelling headlines to draw readers’ attention. We consider NHG as a complementary task to TS. Given an article, the objective is to generate an appropriate headline that accurately depicts the article. We repurpose the XL-Sum (Hasan et al., 2021) dataset for this task since it also includes the titles of the articles. Like TS, we use ROUGE-2 as the evaluation metric.

6. Cross-lingual Summarization (XLS): As another task for evaluating models’ bilingual generation capabilities, we consider XLS. In this task, given a piece of text in a source language, we have to generate the corresponding summary in a target language. This is potentially harder than both MT and TS considering it combines both in a single task. We consider the English-Bengali portion of the CrossSum (Bhattacharjee et al., 2021a) dataset for this task. It is curated by aligning identical articles written in different languages from the XL-Sum dataset. For evaluation, we use ROUGE-2.

We present detailed statistics of the BanglaNLG benchmark in Table 1.

3 BanglaT5

We introduce BanglaT5, a sequence-to-sequence Transformer model (Vaswani et al., 2017), to establish a strong baseline for BanglaNLG benchmark. In this section, we describe the pretraining data, objectives, and model architecture of BanglaT5.

3.1 Pretraining Data

We chose Bangla2B+ (Bhattacharjee et al., 2022) as the pretraining corpus for BanglaT5. This is a 27.5 GB dataset containing 5.25 million documents collected from a meticulously selected list of web sources. While larger sources like CCNet (Wenzek et al., 2020) and mC4 (Xue et al., 2021) are

available, these contain a lot of noise and offensive texts that are difficult to remove. For a generative model, even small amounts of unwanted texts in pretraining could lead to potentially dangerous biases in generated text (Luccioni and Viviano, 2021). Therefore, we decided not to use them.

3.2 Data Pre-processing

Following Hasan et al. (2020), we preprocessed the texts using their normalization pipeline³. We trained a SentencePiece (Kudo and Richardson, 2018) vocabulary of 32k subword tokens on the normalized corpus with a character coverage of 0.99995. While creating a training sample, we limited the maximum sequence length to 512 tokens for both input and output and discarded documents with a token count below 7. After tokenization, we had 4.8 million data points with an average sequence length of 402.32 tokens.

3.3 Pretraining Objective

For generative language modeling, two standard choices are decoder-only models (Mikolov et al., 2010) and encoder-decoder models (Sutskever et al., 2014). Radford et al. (2019) trained a decoder-only Transformer (Vaswani et al., 2017) pretrained on the conditional continuation objective. However, to provide more flexibility on generation and possible usage on understanding tasks, we only consider encoder-decoder models following the original design of the Transformer. They are generally trained with different denoising objectives to increase the encoder’s and decoder’s capacity. For instance, BART (Lewis et al., 2020b), and mBART (Liu et al., 2020) use a text-infilling-based objective. In contrast, MARGE (Lewis et al., 2020a) is a multilingual encoder-decoder model trained to reconstruct a document in one language by retrieving documents in other languages. Following Raffel et al. (2020), we pretrained BanglaT5 using a "span-correction" objective, empirically shown to be an optimal choice for encoder-decoder models. In this objective, consecutive spans of input tokens are replaced with a mask token, and the model is trained to reconstruct them.

3.4 Model Architecture & Hyperparameters

We pretrained the base variant of the T5 model: 12 layers, 12 attention heads, 768 hidden size, 2048 feed-forward size with GeGLU activation (Shazeer,

³<https://github.com/csebuetnlp/normalizer>

Model	Parameters	MT	TS	QA	MTD	NHG	XLS
mT5 (base)	582M	30.1/ 17.2	10.3	59.0/65.3	17.5	9.6	2.7/0.7
XLM-ProphetNet	616M	27.5/15.4	7.8	53.0/57.3	20.0	9.5	6.2/2.7
mBART-50	611M	29.7/15.5	10.4	53.4/58.9	18.5	11.2	5.4/ 3.7
IndicBART (unified)	244M	28.1/16.6	8.9	59.6/65.6	14.8	7.9	6.3/2.5
IndicBART (separate)	244M	27.5/15.7	9.2	55.3/61.2	14.1	9.1	5.3/2.4
BanglaT5	247M	31.3/17.4	13.7	68.5/74.8	19.0	13.8	6.4/4.0

Table 2: Performance comparison of the pretrained models on different BanglaNLG tasks. Scores in bold texts have statistically significant ($p < 0.05$) difference from others with bootstrap sampling (Koehn, 2004).

2020) with a batch size of 65536 tokens for 3 million steps on a v3-8 TPU instance on GCP. We used the Adam (Kingma and Ba, 2015) optimizer with a $3e-4$ learning rate, linear warmup of 10k steps, and ‘inverse square root’ learning rate decay.

4 Experiments & Results

We compared BanglaT5 it with four multilingual models: mT5 (base) (Xue et al., 2021), mBART-50 (Tang et al., 2020), XLM-ProphetNet (Qi et al., 2021), and IndicBART (both unified and separate script variants) (Dabre et al., 2022).⁴ All pretrained models were fine-tuned for 3-15 epochs with batch size 32 (128 for MT). We used linear warmup with a ratio of 0.1, label smoothing of 0.1 (Szegedy et al., 2016), and weight decay of $1e-6$ with the Adam optimizer (Kingma and Ba, 2015). The learning rate was tuned from the set $\{5e-5, 1e-4, 5e-4\}$. The best model was evaluated based on the validation performance after each epoch.

During inference, we used beam-search (Hayes-Roth et al., 1976) with beam size 5 (on all tasks except QA), removed duplicated trigrams during beam search (Fan et al., 2018), and used a length penalty (Wu et al., 2016) of 0.6. For QA, we used greedy decoding, i.e., picking the most probable token during each decoding step.

The evaluation results are presented in Table 2. In all the tasks, BanglaT5 outperformed all multilingual models by a considerable margin, on average 4% over the second-best, mT5. In all monolingual tasks except MTD, BanglaT5 achieves a big performance gain over others (up to 9.54% in QA), which can be attributed to the quality of the pretraining data. In MD, BanglaT5 lags marginally behind XLM-ProphetNet. We hypothesize this is due to the lack of colloquial data in Bangla2B+ since Bhat-tacharjee et al. (2022) left out such sources to avoid

⁴Due to computational budget limitations, we do not benchmark on billion-parameter models like large mT5 variants.

toxic and biased conversations.

We find the MT results particularly interesting, where BanglaT5 outperforms larger multilingual models in both directions. This suggests that despite having very little English data in the pretraining corpus, BanglaT5 can generalize well to a new translation language, given high-quality fine-tuning data. We explore this more in the Appendix. Conspicuously, all the models achieve relatively poor scores on the XLS task. This can be attributed to the smaller amount of training data.

BanglaT5 proves its superiority in compute and memory efficiency along with its performance due to its smaller size (less than half the parameters of all multilingual models except IndicBART). In practice, we observe 2-2.5x faster training and inference times with BanglaT5 than these larger multilingual models.

5 Related Works

Pretrained models NLP has witnessed a sea of change with the advent of pretrained language models like ULMfit (Howard and Ruder, 2018), ELMo (Peters et al., 2018), and most notably BERT (Devlin et al., 2019), achieving state-of-the-art results in many NLU benchmarks. Besides these NLU models, more and more pretrained models designed for NLG tasks have been proposed. Rothe et al. (2020) adopted pretrained NLU model checkpoints for generative tasks. GPT-2 (Radford et al., 2019), and later GPT-3 (Brown et al., 2020) showed that pretrained generative language models can perform remarkably well in zero-shot transfer tasks. More recently, Qi et al. (2020) proposed ProphetNet, which introduces the future n-gram prediction mechanism for language generation. Dabre et al. (2022) introduced IndicBART, which is pretrained on 11 Indic languages, including Bangla.

NLG Benchmarks Recently, many multi-task benchmarks have been proposed to drive the

progress of NLG models. [Moussallem et al. \(2020\)](#) proposed the BENG benchmark for NLG and knowledge extraction. GLGE ([Liu et al., 2021](#)) is a similar benchmark with a different set of tasks and difficulty levels. However, these benchmarks are limited to English only. [Gehrmann et al. \(2021\)](#) introduced the GEM benchmark for various tasks such as summarization ([Narayan et al., 2018](#)), data-to-text generation ([Nan et al., 2021](#)) across different languages. [Cahyawijaya et al. \(2021\)](#) introduced different tasks and baselines for 3 Indonesian languages. More recently, [Kumar et al. \(2022\)](#) introduced IndicNLG, a benchmark with five tasks in 11 Indic languages, including Bangla.

6 Conclusion & Future Works

NLP research in low-resource languages is lagging behind due to the lack of reliable benchmarks and datasets. To facilitate the development, evaluation, and comparison of new NLG models, we introduced a multi-task evaluation benchmark for Bangla NLG, a widely spoken yet low-resource language. We presented BanglaT5, a pretrained NLG model in Bangla, setting new state-of-the-art results with BanglaT5. We strongly believe that our contributions in this work will help the Bangla NLP community benchmark NLG tasks more easily under a unified setup.

In future work, we plan to introduce new tasks to BanglaNLG, such as personalized dialogue generation ([Zhang et al., 2018](#)), conversational question-answering ([Reddy et al., 2019](#)). We will also add more recent multilingual models to our comparison to BanglaT5, e.g., DeltaLM ([Ma et al., 2021](#)).

Limitations

Although [Bhattacharjee et al. \(2022\)](#) claimed that Bangla2B+, the pretraining corpus for BanglaT5, had been carefully filtered for offensive or unwanted texts, they alerted that there might be small amounts of these contents may be present, which can result in bias or toxicity in the pretrained model. We, therefore, recommend using BanglaT5 with caution, especially for real-world deployment.

Ethics Statement

License The TyDiQA dataset ([Clark et al., 2020](#)) is released under the Apache License 2.0, allowing modifications and distribution. All other pretraining and fine-tuning datasets are released under the

Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International License (CC BY-NC-SA 4.0), which allows modifications and distributions for non-commercial research purposes. We strictly adhere to these licenses and will release BanglaT5 and BanglaNLG benchmark resources under CC BY-NC-SA 4.0.

Annotation Expert translators who provide translation services for renowned Bangla newspapers were hired to translate the evaluation sets of the dialogue dataset. Each translated sentence was further assessed for quality by another expert. It was again translated by the original translator if found to be of low quality. If the re-translation was found to be of low quality, it was then translated by the other expert. The experts were paid hourly as per standard rates in local currency.

Hallucinated Text It is well-known that text generation models can hallucinate outputs that may not necessarily be faithful to the original input ([Maynez et al., 2020](#)). Though the texts may be fluent and human-like, the hallucinations may be factually inconsistent and impact the outputs negatively. BanglaT5 may be susceptible to the same kinds of hallucinations.

Carbon Footprint We avoided using large models for pretraining and fine-tuning, reducing their environmental impacts. BanglaT5 was trained for about 30 days on Google v3 TPUs. Google’s TPUs are specifically designed for machine learning, which makes them up to five times more efficient than GPUs. Assuming 0.080kg carbon emission per kWh,⁵ the pretraining would emit fewer than 100kg carbon into the environment, far below most computationally demanding models. All fine-tuning experiments were done on a desktop machine with an 8-core Intel Core-i7 11700k CPU and NVIDIA RTX 3090 GPU, and no single run except machine translation took more than 12 hours, which amounts to fewer than 0.5kg carbon emission. On average, machine translation runs took three days each, emitting less than 3kg of carbon.

A Multi-turn Dialogue Scores

In Table 3, we mention BLEU-1, BLEU-2, BLEU-3, and BLEU-4 scores for different models in the multi-turn dialogue generation task.

Model	B-1	B-2	B-3	B-4
mT5 (base)	17.54	3.67	1.25	0.43
XLNet-ProphetNet	19.98	6.06	2.98	1.86
mBART-50	18.54	5.56	2.97	2.09
IndicBART (unified)	14.75	3.18	1.06	0.37
IndicBART (separate)	14.05	3.23	1.18	0.49
BanglaT5	19.00	5.02	2.04	0.92

Table 3: Performance comparison of the pretrained models on the dialogue generation task. Scores in bold texts have statistically significant ($p < 0.05$) difference from others with bootstrap sampling (Koehn, 2004).

B Cross-lingual Capabilities of BanglaT5

Despite being a monolingual model pretrained on heavily filtered Bangla data, BanglaT5 exhibits strong cross-lingual abilities, particularly in the machine translation (MT) task. In addition to the quality and size of the fine-tuning dataset, this performance can also be attributed to the presence of a significant amount of non-Bangla tokens ($\sim 10.3\%$) in the BanglaT5 vocabulary.

Since Bhattacharjee et al. (2022) curated the Bangla2B+ corpus by document-level language filtering, these documents preserve foreign text sequences occurring in the Bangla documents. We deliberately maintain these tokens while training the vocabulary of BanglaT5, using a relatively high character coverage. Our rationale behind doing this was to capture code-switching and allow better generalization across languages co-occurring with Bangla, as well as romanized forms of Bangla texts during fine-tuning, which is reflected in the MT results. However, it should be noted that the quality and size of fine-tuning data are essential for a strong cross-lingual performance since the mere existence of foreign tokens in the vocabulary is not enough to produce meaningful generation performance, as demonstrated by the poor performance in the cross-lingual summarization (XLS) task.

This phenomenon has been studied in-depth by Blevins and Zettlemoyer (2022) in the context of pretrained language models in English, where they showed that these models develop strong

cross-lingual transfer capabilities due to the non-negligible amount of foreign text present in the pretraining data and robustness to UNK tokens during fine-tuning.

It’s about Time: Rethinking Evaluation on Rumor Detection Benchmarks using Chronological Splits

Yida Mu, Kalina Bontcheva, Nikolaos Aletras

Department of Computer Science, The University of Sheffield

Abstract

New events emerge over time influencing the topics of rumors in social media. Current rumor detection benchmarks use random splits as training, development and test sets which typically results in topical overlaps. Consequently, models trained on random splits may not perform well on rumor classification on previously unseen topics due to the temporal concept drift. In this paper, we provide a re-evaluation of classification models on four popular rumor detection benchmarks considering chronological instead of random splits. Our experimental results show that the use of random splits can significantly overestimate predictive performance across all datasets and models. Therefore, we suggest that rumor detection models should always be evaluated using chronological splits for minimizing topical overlaps.

1 Introduction

Unverified false rumors can spread faster than news from mainstream media, and often can disrupt the democratic process and increase hate speech (Vosoughi et al., 2018; Zubiaga et al., 2018). Automatic detection of rumors is an important task in computational social science, as it helps prevent the spread of false rumors at an early stage (Ma et al., 2017; Zhou et al., 2019; Karmakharm et al., 2019; Bian et al., 2020).

Current rumor detection approaches typically rely on existing annotated benchmarks consisting of social media data, e.g., Twitter 15 (Ma et al., 2017), Twitter 16 (Ma et al., 2017), Weibo (Ma et al., 2016), and PHEME (Zubiaga et al., 2016) that cover a wide range of time periods. These benchmarks use random splits for train, development and test sets which entail some topical overlap among them (see Table 1 for recent previous work). However, the distribution of topics in various NLP benchmarks (e.g., news, reviews, and biomedical) can be significantly affected by time (Huang and

Table 1: Recent work on rumor detection using random splits.

Paul, 2018, 2019). This is the phenomenon of temporal concept drift which can be induced by the changes in real-world events. Specifically, this also affects benchmarks on social media with new events such as elections, emergencies, pandemics, constantly creating new topics for discussion.

Gorman and Bedrick (2019) and Søggaard et al. (2021) have showed that using different data split strategies affects model performance in NLP downstream tasks. Previous work has demonstrated that text classifiers performance significantly drops in settings where chronological data splits are used instead of random splits in various domains, e.g., hate speech, legal, politics, sentiment analysis, and biomedical (Huang and Paul, 2018; Lukes and Søggaard, 2018; Huang and Paul, 2019; Florio et al., 2020; Chalkidis and Søggaard, 2022; Agarwal and Nenkova, 2022; Zhao et al., 2022). To minimize topical overlaps, a Leave-One-Out (LOO) evaluation protocol has been proposed (Lukasik et al., 2015, 2016). While this topic split strategy could potentially mitigate temporal concept drift, it still yields temporal overlaps between each subset and is practically not applicable to most common ru-

Table 2: Four pairs of posts from train and test data with similar or identical text content sampled from four rumor detection benchmarks. Post ids with close values indicate that two posts are published in the same period. **Leven** denotes the Levenshtein distance (Levenshtein et al., 1966) on character-level between the two posts with the same label (i.e., lower values indicate higher text similarity and vice versa).

rumor detection benchmarks with a large number of topics (e.g., Twitter 15, Twitter 16, Weibo, etc.). We observe that the LOO protocol can be used for a few specific rumor detection benchmarks, such as (PHEME (Zubiaga et al., 2016)), where each post is associated with a corresponding event, e.g. *Ottawa Shooting* and *Charlie Hebdo shooting*.

Using random splits also results into posts with almost identical textual content shared during the same period. Table 2 displays four pairs of posts with **similar or identical** text content sampled from four different rumor detection benchmarks. This potential information leakage, results in classifying data almost identical to ones already being present in the training set. For practical application reasons, we believe that in order to evaluate a rumor detection system, it is necessary to detect not only long-standing rumors, but also emerging ones.

In this paper, we design a battery of controlled experiments to explore the hypothesis that whether temporality affects the predictive performance of rumor classifiers. To this end, we re-evaluate models on popular rumor detection benchmarks using chronological data splits i.e., by training the model with earlier posts and evaluating the model performance with the latest posts. Results show that the performance of rumor detection approaches trained with random data splits is significantly overestimated than chronological splits due to temporal concept drift. This suggests that rumor detection approaches should be evaluated with chronological data for real-world applications, i.e., to automatically detect emerging rumors.

2 Methodology

2.1 Data

We use four most popular rumor detection benchmarks, three in English and one in Chinese. Note

that most related work is currently evaluating their rumor detection systems on two or three of these four benchmarks. (see Table 1).

Twitter 15 and Twitter 16: These datasets contain 1,490 and 818 tweets labeled into four categories including Non-rumor (NR), False Rumor (FR), True Rumor (TR), and Unverified Rumor (UR) introduced by Ma et al. (2017).

PHEME: This benchmark contains 5,802 verified tweets collected from 9 real-world breaking news events (e.g., Ottawa Shooting, Ferguson Unrest, etc.) associated with two labels, i.e., 1,972 Rumor and 3,830 Non-Rumor (Zubiaga et al., 2016).

Weibo: This dataset includes 4,664 verified posts in Chinese including 2,313 rumors debunked by the Weibo Rumor Debunk Platform¹ and 2,351 non-Rumors from Chinese media (Ma et al., 2016).

Data Pre-processing We opt for the binary setup (i.e., re-frame all benchmarks as rumor detection) to distinguish true/false information following Lu and Li (2020); Rao et al. (2021). We pre-process the posts by replacing @mention and hyperlinks with @USER and URL respectively. We also lowercase the tweets from three Twitter benchmarks.

2.2 Data Splits

Standard Chronological Splits For Twitter 15 and PHEME, we first sort all posts chronologically and then divide them into three subsets including a training set (70% of the earliest data), a development set (10% of data after train and before test), and a test set (20% of the latest data). There is no temporal overlap between the three subsets.

¹<https://service.account.weibo.com/?type=5&status=4>

Splits	Benchmarks Subsets	Twitter 15			Twitter 16			PHEME			Weibo		
		Train	Dev	Test	Train	Dev	Test	Train	Dev	Test	Train	Dev	Test
Standard Chronological	# of Rumors	285	35	52	-	-	-	1,420	72	480	-	-	-
	# of Non-Rumors	234	40	96	-	-	-	2,641	508	681	-	-	-
Stratified Chronological	# of Rumors	260	37	75	144	21	40	1,380	197	394	1,645	235	470
	# of Non-Rumors	259	37	74	144	21	40	2,681	383	766	1,619	231	463
Random Splits	# of Rumors	260	37	75	144	21	40	1,380	197	394	1,645	235	470
	# of Non-Rumors	259	37	74	144	21	40	2,681	383	766	1,619	231	463

Table 3: Statistics of subsets. Note that using random splitting yields the same percentage of examples in each category as in the stratified chronological splits.

Stratified Chronological Splits On the other hand, we observe that there is no temporal overlap between rumors and non-rumors in Twitter 16 and Weibo datasets. This suggests that it is not possible to use standard chronological splits as in Twitter 15 and PHEME.

Therefore, we apply a **stratified chronological split** strategy for all benchmarks. We first split rumors and non-rumors separately in chronological order. We then divide them into three subsets (a total of six subsets), i.g., all rumors are split into a training set (70% of the earliest rumors), a development set (10% of data after train and before test), and a test set (20% of the latest rumors). Finally, we merge the six subsets into the final three train, development and test sets. Note that this approach will result in no temporal overlap for **each label (i.e., rumor or non-rumor)** among the three final sets. We show the number of each split in Table 3.

Random Splits Following standard practice (e.g., Bian et al. 2020; Lin et al. 2021; Rao et al. 2021), we **randomly** split data using a 5-fold cross-validation. Note that these splits are made by preserving the percentage of posts in each category. Each split contains a training set (70%), development set (10%) and a test set (20%) with the same ratio as in our chronological splits.

Leave-One-Out (LOO) Splits For reference, we also provide the results of using the LOO evaluation protocol on PHEME dataset (see Table 5).

2.3 Models

The main purpose of our experiments is to improve model evaluation by investigating the effects of temporal drifts in rumor detection by providing an extensive empirical study. Therefore, we opted using strong text classifiers that are generic and can be applied to all of our benchmarks:

- **LR** We train a LR classifier using BOW to represent posts weighted by TF-IDF using a vocabulary of 5,000 n-grams.

- **BERT** We directly fine-tune the BERT base model by adding a linear prediction layer on the top of the 12-layer transformer architecture following (Devlin et al., 2019).
- **BERT+ (BERTweet and ERNIE)** We also experiment with two domain specific models: BERTweet (Nguyen et al., 2020) and ERNIE (Sun et al., 2020) pre-trained on social media data using the same fine-tune strategy as the original BERT model.

2.4 Hyperparameters and Implementation Details

We train the model on the training set, perform model tuning and selecting on the development set, and evaluate performance on the test set. To evaluate the chronological data splits, we run the model five times with different random seeds for consistency. All chronological splits are available for reproducibility.²

For logistic regression, we use word-level and character-level tokenizers for Twitter and Weibo datasets respectively and only consider uni-gram, bi-grams, and tri-grams that appear in more than two posts for each dataset. For BERT, we set learning rate $lr = 2e - 5$, batch size $bs = 32$, and maximum input length as 256 covering the max tokens of all posts. All BERT-style models are trained for 10 epochs using the early stopping method based on the loss on the development set. The best checkpoint model is saved for evaluation on the test set. The average run time of 10 epochs for the BERT model is less than 2 minutes. We employ Bert-Base-Uncased, Bertweet-Base and Chinese-Bert-WWM, Ernie-1.0 models from the HuggingFace library (Wolf et al., 2020). All experiments are conducted on a single NVIDIA V100 GPU with 32GB memory.

Table 5: Leave-One-Out evaluation protocol on PHEME dataset.

2.5 Evaluation Metrics

For all tasks, we report the averaged macro Precision, Recall and F1 values across five runs using different random seeds.

3 Results

Random Splits vs. Chronological Splits Table 4 shows the experimental results across all models and rumor detection benchmarks using **chronological splits** and random **5-fold cross-validation**. Overall, we observe that the use of random splits always leads to a significant overestimation of performance compared to chronological splits (t-test, $p < 0.05$) across all models. Our results corroborate findings from previous work on studying temporal concept drift (Huang and Paul, 2018; Chalkidis and Søgaard, 2022). This suggests that chronological splits are necessary to more realistically evaluate rumor detection models.

We also note that the effect of temporality varies in datasets of different size. For both data splitting strategies, we observe that the difference in performance is 50% higher for the two datasets with hundreds of posts (e.g., Twitter 15 and Twitter 16) and around 10% in ones with thousands of posts (e.g., PHEME and Weibo). For rumor detection

tasks, temporality may have a greater impact on small-scale benchmarks than on large-scale benchmarks. For Twitter 16 and Weibo, the use of stratified chronological splits demonstrates significant performance drops compared to random splits due to the temporal concept drift.

For chronological splits, we observe that pre-trained language models (i.e., BERT and BERT+) significantly outperform (t-test, $p < 0.05$) logistic regression in all benchmarks. This is due to the fact that BERT-style models (i) outperform simpler linear models by a large margin in various NLP tasks (Devlin et al., 2019); and (ii) have been trained after the development of these four benchmarks implying some information leakage.

Standard vs. Stratified Chronological Splits

Note that dividing the datasets into standard chronological splits results in subsets that do not preserve the sample percentages for each category (see Table 3). The upper part of Table 4 displays the difference in model performance between two types of chronological splits on Twitter 15 and PHEME. We observe that using both standard and stratified chronological splits results in similar model predictive performance (t-test, $p > 0.05$). Even though stratified chronological splits contain temporal overlap, it is still not sufficient to improve model performance compared to random splits. This suggests that the temporal drift affects particular classes rather than the entire data set.

4 Error Analysis

Finally, we perform an error analysis to further investigate the type of errors made by BERT us-

Benchmark		Twitter 15			Twitter 16			PHEME			Weibo		
Splits	Test set	total	#	%	total	#	%	total	#	%	total	#	%
Chrono.	all posts	148	3	2%	82	6	7%	1161	39	3%	933	41	4%
	# of wrong predictions	63	2	1%	34	2	2%	301	5	<1%	99	7	<1%
	# of correct predictions	85	1	1%	48	4	5%	860	34	3%	834	34	4%
Random	all posts	149	35	23%	83	26	30%	1161	181	16%	933	129	14%
	# of wrong predictions	12	0	0%	5	1	1%	150	14	1%	65	4	<1%
	# of correct predictions	137	35	23%	78	25	30%	1011	167	14%	868	125	14%

Table 6: Error Analysis for all benchmarks. # denotes the number of posts that are similar to posts from training set, i.e., known data. % denote the percentage of similar posts in the test set. We set the threshold value to 20, which indicates that there are two or three different words between the two tweets.

	Example	Test	Train	Correct	Wrong
Twitter 15	#rip to the driver who died with #paulwalker that no one cares about because he wasn't famous.	4	6	4	0
Twitter 16	steve jobs was adopted. his biological father was abdufatah jandali, a syrian muslim	2	13	2	0
PHEME	Police are leaving now . #ferguson HTTPURL	4	11	4	0
Weibo	【交通新规】2013年1月1日施行:1... 扩散给大家! [广州日报] Translation: [New driving laws] From 1 Jan 2013: Running a red light will result in a fine of 100 RMB and 6 points. ... Spread the news to everyone! [Guangzhou Daily]	2	6	2	0

Table 7: Four examples of correct predictions using random splits, which artificially removes temporal concept drift. For example, in Twitter 15, there are 4 and 6 similar posts about rumors related to Paul Walker in the test set and the training set respectively.

ing both random and chronological splits. Table 6 shows the number of correct and wrong predictions for each of the two data splitting strategies. We also use the Levenshtein distance³ to calculate the quantity of posts in the test set that are similar to posts in the corresponding train set.

- We first observe that the temporal concept drift is evident in all rumor detection benchmarks. Most of the rumors on the same topic are posted in a very short time span.
- In addition, long-standing rumors are only a small part of the data (less than 5%). Second, we note that using random splits leads to topical overlap between the training and test sets (see Table 7) resulting in higher model performance.
- Finally, for both random and chronological splits, most of the posts in the test set with overlapping topics in the training set are predicted correctly. In contrast, wrong predictions are often posts with emerging or different topics compared to the posts in the train set.

5 Conclusion

We have shed light on the impact of temporal drift on computational rumor detection. Results from our controlled experiments show that the use of chronological splits causes substantially drops in predictive performance across widely-used rumor

³We set the threshold value to 20.

detection benchmarks. This suggests that random splits rather overestimate the model predictive performance. We argue that the temporal concept drift needs to be considered when developing real-world rumor detection approaches. In the future, we plan to study the impact of temporal concept drift on other NLP tasks, such as detecting user reactions to untrustworthy posts on social media (Glenski et al., 2018; Mu and Aletras, 2020; Mu et al., 2022).

Limitations

We provide the first re-evaluation of four standard rumor detection benchmarks in two languages (English and Chinese) from two platforms (Twitter and Weibo). We acknowledge that further investigation is needed in rumor detection datasets in other languages. We provide an error analysis in Section 4.

Acknowledgments

We would like to thank Ahmed Alajrami, Danae Sánchez Villegas, Mali Jin, Xutan Peng and all the anonymous reviewers for their valuable feedback.

Abstract

The multi-sentential long sequence textual data unfolds several interesting research directions pertaining to natural language processing and generation. Though we observe several high-quality long-sequence datasets for English and other monolingual languages, there is no significant effort in building such resources for code-mixed languages such as Hinglish (code-mixing of Hindi-English). In this paper, we propose a novel task of identifying multi-sentential code-mixed text (MCT) from multilingual articles. As a use case, we leverage multilingual articles from two different data sources and build a first-of-its-kind multi-sentential code-mixed Hinglish dataset i.e., MUTANT. We propose a token-level language-aware pipeline and extend the existing metrics measuring the degree of code-mixing to a multi-sentential framework and automatically identify MCT in the multilingual articles. The MUTANT dataset comprises 67k articles with 85k identified Hinglish MCTs. To facilitate future research directions, we will make the dataset and the code publicly available upon publication.

1 Introduction

Over the years, we have seen enormous downstream applications of multi-sentential datasets in the areas such as question-answering (Joshi et al., 2017; Tapaswi et al., 2016), summarization (Sharma et al., 2019; Cachola et al., 2020), machine translation (Bao et al., 2021), etc. The existing state-of-the-art methods prove challenging to scale effectively and efficiently on multi-sentential long sequence text (Ainslie et al., 2020), which unplugs several exciting research avenues. Unfortunately, to a large extent, the majority of the research on multi-sentential data is dominated by a few popular monolingual languages such as English, Chinese, and Spanish. Due to this, code-mixed languages (among other low-resource and under-explored languages) suffer from non-existent works in the aforementioned areas of interest.

(A) TITLE: रिलीज से 4 दिन पहले मुश्किल में Salman Khan की Bharat, दिल्ली हाईकोर्ट में PIL दाखिल
MCT: ...सलमान खान (Salman Khan) की फिल्म 'भारत' (Bharat) पांज जून को रिलीज होने वाली है, लेकिन उससे पहले फिल्म के सामने एक मुश्किल आ गई है। दरअसल, फिल्म के नाम को लेकर हाईकोर्ट में याचिका दाखिल की गई है। याचिकाकर्ता को फिल्म के नाम से आपत्ति है। उनका कहना है कि इस टाइटल से लोगों की भावनाएं आहत हो सकती हैं। दाखिल की गई याचिका में फिल्म का नाम बदलने की गुंजरिश की गई है।...

(B) TITLE: मन की बात : जनवरी 2016
MCT: ...मेरे प्यारे नौजवान साथियो, 15 अगस्त को लाल किले से मैंने 'Start-up India, Stand-up India' उसके संबंध में एक प्राथमिक चर्चा की थी। उसके बाद सरकार के सभी विभागों में ये बात चल पड़ी। क्या भारत 'Start-up Capital' बन सकता है? क्या हमारे राज्यों के बीच नौजवानों के लिए एक उत्तम अवसर के रूप में नये - नये Start-ups, अनेक with Start-ups, नये-नये Innovations! चाहे manufacturing में हो, चाहे Service Sector में हो, चाहे Agriculture में हो। हर चीज़ में नयापन, नया तरीका, नयी सोच, दुनिया Innovation के बिना आगे बढ़ती नहीं है।...

Figure 1: Example MCT and the corresponding article's title form two multilingual data sources: (A) Dainik Jagran news article and (B) Man-ki-baat speech transcript. We color code the tokens as: English, Hindi, and language independent.

We posit that due to several inherent challenges, the NLP community hold back on building multi-sentential datasets for the low-resource and code-mixed languages. One of the most significant bottlenecks in building such resources is the unavailability of MCT on traditional and widely popular data sources such as social media platforms where the short-length and noisy code-mixed text is available in abundance. It presents several challenges such as the difficulty in curating a large-scale multi-sentential dataset at ease. Another major challenge is the lack of metrics to measure the degree of code-mixing in the multi-sentential framework. The existing metrics such as code-mixing index (Das and Gambäck, 2014) and multilingual-index (Barnett et al., 2000) already suffers from major limitations (Srivastava and Singh, 2021a) in the short-length text format. In such a scenario, it gets mystifying

Dataset	Task(s)	Data Source(s)	# Instances	Avg Tokens	Avg Sentences	Retrieval
(Srivastava and Singh, 2020)	Machine Translation	Social media posts on Twitter & Facebook	13738	13	1.04	Automatic
(Khanuja et al., 2020)	Natural Language Inference	Hindi Bollywood movie transcripts	2240	87	7.15	Automatic
(Mehnaz et al., 2021)	Dialogue Summarization	Manual translation of dialogues and summaries from (Gliwa et al., 2019)	6830	31	7.85	-
(Srivastava and Singh, 2021b)	Generation & Evaluation	IIT-B En-Hi parallel corpus (Kunchukuttan et al., 2018)	1974	20	1.05	-
MUTANT	Summarization	Speech transcripts, press releases, and news articles	84937	159	10.23	Manual + Automatic

Table 1: Comparison of the MUTANT dataset with the currently available datasets in the Hinglish language.

to build a retrieval pipeline to identify MCT and we need to depend heavily on the expertise of human annotators which is a time and cost-demanding exercise. In this work, we address both of these challenges. As a representative use case, we base our work on Hinglish, a popular code-mixed language in the Indian subcontinent. But the insights from our exploration could be extended to other code-mixed language pairs.

To address the first challenge, we identify two non-traditional multilingual data sources¹ i.e., political speeches and press releases along with Hindi daily news articles (discussed in detail in Section 3). Figure 1 shows example Hinglish MCTs from two multilingual data sources. To address the second challenge, we propose a token-level language-aware pipeline and extend a widely popular metric (i.e., code-mixing index) measuring the degree of code-mixing in a multi-sentential framework. We demonstrate the effectiveness of the proposed pipeline with a minimal task-specific annotation which significantly reduces the overall human effort (discussed in detail in Section 4).

Eventually, we build a novel multi-sentential dataset for the Hinglish language with 85k MCTs identified from 67k articles. In Table 1, we compare MUTANT with four other Hinglish datasets (Srivastava and Singh, 2020; Khanuja et al., 2020; Mehnaz et al., 2021; Srivastava and Singh, 2021b) proposed for a variety of tasks such as machine translation, natural language inference, generation, and evaluation. The MUTANT dataset has a significantly higher average number of sentences along with longer MCT (high average number of tokens). Alongside, the dataset notably consists of a higher number of data instances which is a rarity for the code-mixed datasets (Srivastava and Singh, 2021a).

¹these data sources have not been actively employed in building datasets for the code-mixed languages

2 Multi-sentential Code-mixed Text Span (MCT)

Due to the absence of a formal definition of MCT in the literature, we propose and use the following definition of MCT throughout this work:

MCT: Consider a multilingual article $A = \{s_1, s_2, \dots, s_n\}$ consisting of n sentences denoted by s_i where $i \in [1, n]$. A unique non-overlapping MCT M_p in A is a chunk of $m > 1$ consecutive sentences i.e. $M_p = \{s_k, s_{k+1}, \dots, s_{k+m-1}\}$. M_p should satisfy the following two properties:

1. $P1$: At least one s_{k+j} in M_p should be code-mixed. Trivially, at most $m-1$ s_{k+j} in M_p could be monolingual. Here, $j \in [0, m-1]$.
2. $P2$: s_k in M_p is either the first sentence of the article or preceded by a line break. Likewise, s_{k+m-1} is either the last sentence of the article or succeeded by a line break.

It should be noted that an article A can have multiple non-overlapping unique MCTs i.e. $A = \{M_1, M_2, \dots, M_q\}$ where $q \geq 0$.

3 Multilingual and Multi-sentential Data Sources

Over the years, we observe several interesting and diverse code-mixed data sources such as Twitter, Facebook, movie transcripts, etc. Social media sites have acted as the cornerstone of the code-mixed data collection pipelines due to the ease of availability of large-scale data. Nonetheless, they present several challenges such as noisy data, short text, abusive, and multimodal data. Given the requirements of *MUTANT* (i.e. multi-sentential and high-quality data), we refrain from using social media sites in this work. Here, we focus on two major data sources:

3.1 Political speeches and press releases

Here, we scrape data from five different web sources. Collectively, we denote this data source as D_{speech} .

Aam Aadmi Party press releases (AAP): We scrape the press releases from the official website of Aam Aadmi Party². We have scraped 320 Hindi press releases from their website. The website contains all the press releases in the last five years starting from June 2017.

Indian National Congress speeches (INC): The official website of the INC stores some of the speeches by major INC political leaders. We have extracted 112 of these speeches from their official website³. The timeline for the scraped speeches is between August 2018 to March 2022.

Man-ki-baat (MKB): Man-ki-baat is a radio program hosted by the Indian prime minister Narendra Modi where he periodically addresses the people of the nation. The MKB website⁴ stores the official transcripts in Hindi and English languages. We have extracted the transcripts of 67 of these programs between December 2015 to December 2021.

Press Information Bureau (PIB): The Press Information Bureau houses the official press releases from all Indian government ministries including President’s office, the Prime Minister’s office, Election Commission, etc. We have extracted 30283 articles from the PIB website⁵. The timeline for these articles is from June 2017 to March 2022.

PM speech (PMS): Majority of the Indian Prime Minister speeches (different from MKB speeches) are stored digitally on the PM India website⁶. We have extracted 694 of these speeches that are recorded between November 2016 to October 2021.

3.2 Hindi news articles

Here, we scrape data from two major Hindi news daily websites. Collectively, we denote this data source as D_{news} .

Dainik Bhaskar (DB): Dainik Bhaskar is one of the most popular Hindi newspapers in India. It is ranked 4th in the world by circulation according to

²<https://aamaadmiparty.org/media/press-releases>

³<https://www.inc.in/media/speeches>

⁴<https://www.pmindia.gov.in/hi/mann-ki-baat/>

⁵<https://www.pib.gov.in>

⁶<https://www.pmindia.gov.in/hi/news-updates/>

World Press Trends 2016⁷. They have digitized the daily newspapers on their website⁸. Articles on DB website have been divided into many categories such as ‘Entertainment’ and ‘Sports’. We have extracted 115324 articles uploaded on the website between February 2019 to May 2022. In Table 2, we present the category-wise distribution of the articles scraped from the DB website.

Category	DB	DJ
Business	16012	4203
Entertainment	18498	52173
Featured	5536	19373
Lifestyle	12189	-
Miscellaneous	20221	-
National	18615	160005
Politics	-	33604
Sports	9950	-
World	14303	42478
Total	115324	311836

Table 2: Number of articles in various news categories in the DB and DJ datasets.

Dainik Jagran (DJ): Dainik Jagran is another popular Indian Hindi newspaper. According to World Press Trends 2016, DJ is ranked 5th in the world by circulation. Similar to the DB website, they have also created a repository of articles on their official website⁹. Here, we extract 311836 of these articles from the website that were uploaded between April 2013 to May 2022. In Table 2, we present the category-wise distribution of the articles scraped from the DJ website.

4 Experimental Setup

Problem definition: Given a multilingual article A comprising of q multi-sentential text spans (MST) i.e. $A = \{M_1, M_2, \dots, M_q\}$, we predict a binary outcome L_{CM} for each MST M_i i.e. $L(A) = \{L_{CM}^{M_1}, L_{CM}^{M_2}, \dots, L_{CM}^{M_q}\}$. $L_{CM}^{M_i} = 1$, if M_i is code-mixed, otherwise 0. In a nutshell, a code-mixed MST M_i is a MCT and it satisfies the properties $P1$ and $P2$ (ref. §2).

Figure 2 shows the architecture of the MCT identification pipeline. Next, we discuss the various components of this pipeline in detail.

4.1 Token-level language annotation (TLA)

We exploit the token-level language information to identify MCT given a multilingual article A .

⁷<https://web.archive.org/web/20170706110804/http://www.wptdatabase.org/world-press-trends-2016-facts-and-figures>

⁸<https://www.bhaskar.com>

⁹<https://www.jagran.com>

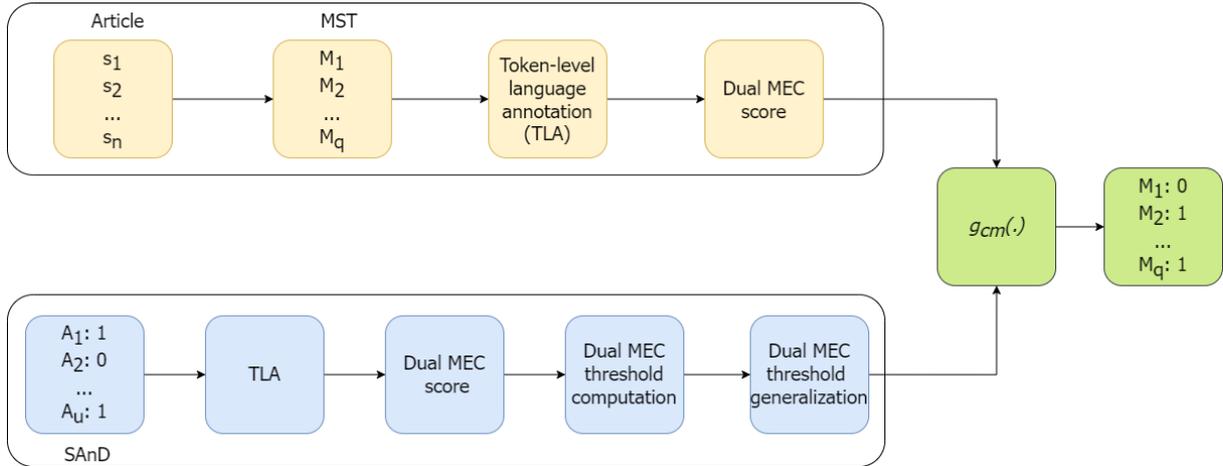

Figure 2: Architecture of MCT identification pipeline.

We annotate the words in A using a code-mixed language identification tool. Specifically, we use L3Cube-HingLID (Nayak and Joshi, 2022) for this task. A word $w_i \in A$ can take either of the three language tags from the set $\{English, Hindi, Other\}$. Given that L3Cube-HingLID works only on the Roman script text, we use a Devanagari to Roman script transliteration tool¹⁰ for the tokens written in Devanagari script. In Table 3, we report the percentage of *Hindi* and *English* tokens. With an exception of the AAP dataset, *Hindi* is the predominant language in all the data sources.

	Articles	AW	AC	%H	%E
AAP	320	1129	6033	53.97	45.09
INC	112	2312	10691	63.83	33.12
MKB	67	4151	20706	77.17	22.41
PIB	30283	525	3015	80.96	17.59
PMS	694	2591	13400	79.02	20.45
DB	115324	382	1977	80.22	18.25
DJ	311836	391	2037	79.28	19.60
D_{speech}	31476	590	3339	79.97	18.65
D_{news}	427160	388	2020	80.18	18.51
$D_{speech} + D_{news}$	458636	401	589	80.05	18.54

Table 3: Distribution of the scraped articles from various data sources. AW: average number of words. AC: average number of characters. %E: percentage of English tokens. %H: percentage of Hindi tokens.

4.2 Code-Mixing Index (CMI)

In the literature, we observe several metrics that has been proposed to measure the degree of code-mixing in text such as code-mixing index (CMI,

¹⁰<https://github.com/ritwikmishra/devanagari-to-roman-script-transliteration>

(Das and Gambäck, 2014)), multilingual-index (M-index, (Barnett et al., 2000)) and integration-index (I-index, (Guzmán et al., 2017)). Each of these metrics has its own merits and limitations (Srivastava and Singh, 2021a). In this work, we use the most widely used CMI metric due to the ease of interpretation and the suitability for the task. CMI, by definition, measures the degree of code-mixing in a text as:

$$CMI = \begin{cases} 100 * [1 - \frac{\max\{w_i\}}{n-u}] & n > u \\ 0 & n = u \end{cases} \quad (1)$$

Here, w_i is the number of words of the language i , $\max\{w_i\}$ represents the number of words of the most prominent language, n is the total number of tokens, u represents the number of language-independent tokens (such as named entities, abbreviations, mentions, and hashtags). The CMI score ranges from 0 to 100. A low CMI score suggests the prevalence of only one language in the text whereas a high CMI score indicates a high degree of code-mixing.

4.3 Small annotated dataset (SAnD)

We create a small manually annotated dataset comprising all seven data sources. The objective of the annotation is to assign a binary label to each MST such that we can identify if the MST is code-mixed or not from the assigned label.

More formally, $SAnD = \{A_1: l_1, A_2: l_2, \dots, A_u: l_u\}$, represents u manually annotated MST¹¹ where $l_i \in \{0, 1\} \forall i \in [1, u]$. Here, $l_i = 1$, if A_i is code-mixed, otherwise 0.

¹¹For distinctive representation, we denote MST in $SAnD$ with A instead of M .

D_{news}	60	329	76	253
$D_{speech} + D_{news}$	120	568	148	420

Table 4: *SAnD* dataset statistics. Hing: Hinglish, E/H: English/Hindi.

For this annotation task, we have selected a small number of articles (60 each from D_{speech} and D_{news}) randomly from the scraped articles. We leave it to the judgment of the annotator to decide if a sentence (and subsequently the MST) is code-mixed or not. The annotator has expert-level proficiency in Hindi, English, and Hinglish languages. In Table 4, we show the distribution of the annotated articles for each data source. In total, we annotate 120 articles and 568 MST where we identify 121 MST (21.3%) as code-mixed.

4.4 Estimating multilinguality

Though CMI is widely used in numerous previous works, we couldn't find any discussion on the ideal CMI score thresholding criteria to identify a good code-mixed text. The problem becomes even more challenging when we use the CMI metric in a multi-sentential framework along with constraints $P1$ and $P2$ (ref §2). Various works (Khanuja et al., 2020) have used empirically identified CMI thresholds to measure the degree of code-mixing in the text. But, we couldn't find any experimental justification for their findings.

Dual MEC score: Here, we propose a novel adoption of the CMI metric in a constrained multi-sentential framework. For MST M_p with k sentences, we compute the scores for dual multilinguality estimation criteria (MEC) as:

1. Sentence-level CMI (CMI): We compute $CMI(s_i)$ for the sentence $s_i \in M_p$ using the language-information of all the words in s_i and the formulation given in 1.
2. Multilinguality ratio (MR): We compute C_{MR} for the MST M_p as:

$$MR(M_p) = \frac{N_{cm}}{k} \quad (2)$$

Here, N_{cm} and k are the number of code-mixed and total sentences in M_p respectively.

Figure 3 shows the mean and standard deviation of dual MEC scores on seven different data sources.

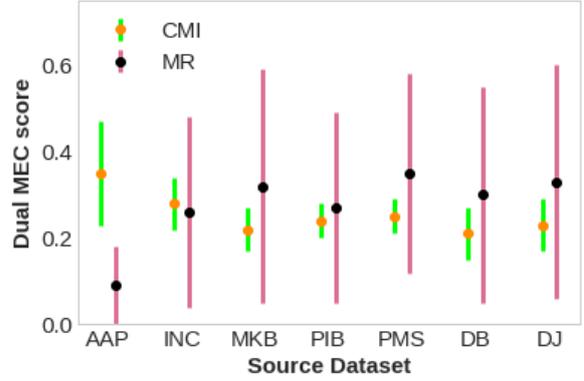

Figure 3: The mean and standard deviation of the dual MEC score for different data sources. The CMI score is scaled between 0 to 1.

Formulation: We identify if the sentence s_i is code-mixed or monolingual using $CMI(s_i)$ score as:

$$f_{cm}(s_i) = \begin{cases} 1, & CMI(s_i) > \alpha \\ 0, & otherwise \end{cases} \quad (3)$$

Here, $\alpha \in [0, 100]$ is the sentence-level CMI score threshold and $f_{cm}(\cdot)$ estimates the code-mixing status (1 being code-mixed and 0 being monolingual) of the sentence under consideration. Using 3, we compute N_{cm} as:

$$N_{cm} = \sum_{i=1}^k f_{cm}(s_i) \quad (4)$$

Using 2 and 4, we compute $MR(M_p)$ as:

$$MR(M_p) = \frac{\sum_{i=1}^k f_{cm}(s_i)}{k} \quad (5)$$

We formulate the following function to identify if MST M_p with k sentences is code-mixed:

$$g_{cm}(M_p) = \begin{cases} 1, & MR(M_p) > \beta \\ 0, & otherwise \end{cases} \quad (6)$$

Here, $\beta \in [0, 1]$ is the multilinguality ratio threshold and $g_{cm}(\cdot)$ estimates the code-mixing status (1 being code-mixed and 0 being monolingual) of the MST under consideration.

4.5 Dual MEC threshold computation

The dual MEC formulation helps us to identify the MCT in a constrained setting by jointly modeling the sentence-level and MST-level multilinguality information. As discussed in Section 4.4, the ideal thresholds α and β are a conundrum that needs further exploration. Here, we propose to use the *SAnD* dataset to identify the dual MEC thresholds (α and β). Algorithm 1 shows the procedure to compute the thresholds. The algorithm takes *SAnD* dataset D with u labeled MST. We represent the parameter search space for α and β with α_{cand} and β_{cand} respectively. α_{cand} ranges from α_{low} to α_{high} with a step-size of α_{step} whereas β_{cand} ranges from β_{low} to β_{high} with a step-size of β_{step} . Based on our empirical observation, we set $(\alpha_{low}, \alpha_{high}, \alpha_{step})$ with $(0, 50, 1)$ and $(\beta_{low}, \beta_{high}, \beta_{step})$ with $(0, 0.5, 0.025)$.

We perform the grid search on each threshold combination of (α_i, β_j) to identify the best combination. For each threshold combination, we identify the accuracy of identifying the MCT in D leveraging $f_{cm}(\cdot)$ and $g_{cm}(\cdot)$ formulations. We select the threshold combination with the highest accuracy as the final threshold (α and β). Table 5 shows the best-identified thresholds on various data sources of the *SAnD* dataset. Figure 4 shows the mean and standard deviation of the accuracy on various dual MEC threshold combinations for different data sources.

Algorithm 1 $compute_{\alpha, \beta}(D)$

Require: $D = \{A_1: l_1, A_2: l_2, \dots, A_u: l_u\}$ where $A_i = \{s_1, s_2, \dots, s_k\}$

4.6 Dual MEC threshold generalization

As evident from Table 5, the thresholds α and β vary across the data sources. So, it is important to identify which of these identified thresholds will result in a robust and stable performance across datasets. Here, we experiment with five dual MEC threshold generalisation techniques:

1. **Local Average (LA):** For the data source D_i , we take the mean sentence-level CMI score and mean MR score as the dual MEC thresholds.
2. **Global Average (GA):** For the data source D_i , we take the mean sentence-level CMI score and mean MR score of the corresponding category data-source (D_{speech} or D_{news}) as the dual MEC thresholds.
3. **Average of LA and GA (ALG):** For the data source D_i , we take the average of LA and GA identified thresholds as the dual MEC thresholds.
4. **Single data source generalization (SDG):** In

this approach, we generalize the dual MEC thresholds identified locally on a single data source D_i (using Algorithm 1) to identify MCT globally on other data sources.

- Multi data source generalization (MDG):** In this approach, we use the dual MEC threshold information from multiple sources and use the majority voting to identify the best thresholds. For the data source D_i , we use the thresholds identified on three data sources (using Algorithm 1), namely D_i , D_{speech} (if $D_i \in D_{speech}$, else \check{D}_{news}), and $D_{speech} + D_{news}$. We then make an independent prediction on each of the three thresholds and take majority voting for the final classification of M_p .

5 MUTANT: A Multi-sentential Code-mixed Hinglish Dataset

We evaluate the performance of MCT identification pipeline and the five dual MEC threshold generalization techniques using the three subsets of the *SAnD* dataset: D_{speech} , D_{news} , and $D_{speech} + D_{news}$. We report the following metric scores on each of the seven data sources:

- Accuracy:** We compute accuracy as the ratio of the total correct prediction of MCT and non-MCT to the total number of MST. We multiply this ratio by 100 and report the accuracy percentage. A high accuracy % is preferred.
- False MCT Rate (FMR):** We define FMR as the ratio of incorrectly identified MCT to the total number of actual monolingual MST. We report the FMR% and a low FMR% is preferred.
- Diversity@10 (D@10):** We define D@10 as the percentage of articles in data source D_i having more than 10% correctly identified MCT. A high D@10 score is preferred.

We report the results in Tables 6, 7, 8. The mean-based threshold generalization techniques (LA, GA, and ALG) consistently show poor performance on all the metrics. Given the nature of the problem, we prefer a low rate of misidentification of mono-

Table 8: Results on $D_{speech}+D_{news}$ dataset. L: LA, G: GA, A: ALG, S: SDG, M: MDG.

lingual MST as the MCT and at the same time a high number of actual MCT should also be identified. MDG threshold generalization technique satisfies both conditions with low FMR and high accuracy on all the datasets. D@10 depicts if the threshold generalization technique is influenced by the presence of a few outliers in the dataset. SDG and MDG both show competitive results on the D@10 metric outperforming the mean-based threshold generalization techniques by a large margin. The constant poor performance of mean-based threshold generalization against SDG and MDG also shows the efficacy of the proposed threshold computation strategy (Algorithm 1).

Finally, to build the MUTANT dataset, we use the MCT identification pipeline with the MDG threshold generalization technique. Table 9 shows the statistics of the MUTANT dataset. To facilitate future work on this novel task of MCT identification, we will release the MUTANT dataset along with the initially scraped data from all the data sources and the annotated *SAnD* dataset. The MUTANT dataset can be used for various tasks including but not limited to question-answering, text summarization and machine translation for Hinglish texts. This dataset could be used as a pre-training dataset to train efficient NLU models for various tasks on Hinglish data.

6 Analysis and Discussion

In this section, we qualitatively evaluate the *MUTANT* dataset by employing two human evaluators, different from the one used for the *SAnD* to avoid any biases in the evaluation. Both evalua-

Table 10: Qualitative evaluation of the MUTANT dataset. A: Articles, CA: complete agreement between the annotators, Hing: Hinglish MST. E/H: English/Hindi MST, CKS: Cohen’s kappa score.

tors are proficient in English, Hindi, and Hinglish languages. We randomly sample five articles from each of the seven source datasets and share the originally scraped articles containing both identified MCT and monolingual MST with both evaluators. During the evaluation, we do not disclose which of the MSTs is identified as MCT and share the following guidelines:

1. Any MST containing only Hindi words or only English words is monolingual.
2. Any named entity, date, number, or word common in both English and Hindi languages should be considered a language-independent word.

In Table 10, we report our findings from the qualitative evaluation study. Out of a total of 419 MST, we observe the complete agreement on 321 monolingual MST and 55 code-mixed MST resulting in $\approx 90\%$ complete agreement. A complete agreement means that both annotators agree that any particular MST is code-mixed or not. On MST with CA, we further compute the three metric scores using MDG. The results strengthen our earlier findings from Section 5. In Figure 5, we report two example MCT incorrectly identified by our MCT identifica-

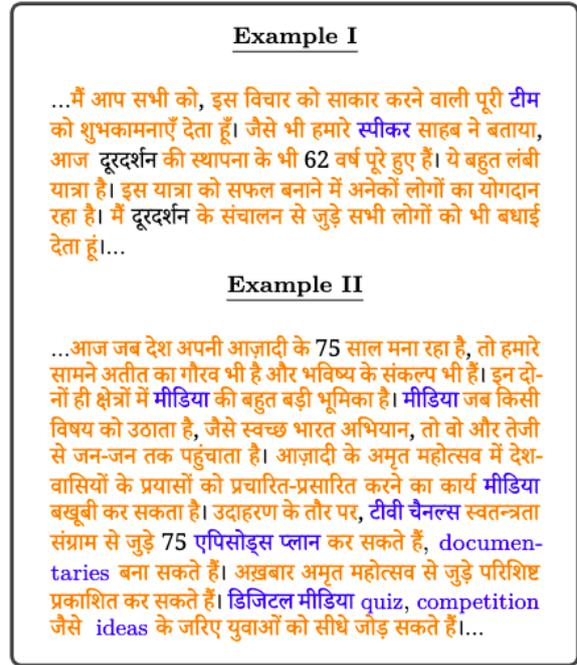

Figure 5: False positive MCT. We color code the tokens as: Hindi, English, and language independent.

tion pipeline. In the first example, both evaluators show complete agreement whereas in the second example there is a disagreement between the evaluators. We attribute this behavior to the poor state of the current code-mixed LID systems (Srivastava and Singh, 2021a) and since the CMI metric and our dual MEC formulation depend heavily on the code-mixed LID tools, the final results get affected. This limitation further provides an opportunity for future works to explore the problem from different perspectives such as a token-level language-independent MCT identification pipeline. It will also be interesting to see how this pipeline performs with other code-mixed languages, especially in a low-resource setting.

7 Conclusion

In this paper, we present a novel task of identifying MCT from multilingual documents. We propose an MCT identification pipeline by extending CMI to the multi-sentential framework and leveraging the pipeline we build a dataset for the Hinglish language. We highlight several challenges in building such resources and our insights will be useful to future works in code-mixed and low-resource languages.

8 Limitations

The limitations with the *MUTANT* dataset include but are not limited to:

- Contrary to the previous works, all the data sources comprises the non social media sites. This could potentially limit the diversity in the code-mixed text as observed on social media platforms.
- In the current form, the dataset is limited to only one code-mixed language. We believe the proposed technique to extract MCT could be expanded to other code-mixed languages in the future.
- The data sources could potentially have their own biases (topical, style of writing, etc). We expect future works to be cautious while generalizing the results obtained on this dataset.

Bridging the Gap between Native Text and Translated Text through Adversarial Learning: A Case Study on Cross-Lingual Event Extraction

Pengfei Yu¹, Jonathan May², Heng Ji¹

jonmay@isi.edu

Abstract

Recent research in cross-lingual learning has found that combining large-scale pretrained multilingual language models with machine translation can yield good performance (Phang et al., 2020; Fang et al., 2021). We explore this idea for cross-lingual event extraction with a new model architecture that jointly encodes a source language input sentence with its translation to the target language during training, and takes a target language sentence with its translation back to the source language as input during evaluation. However, we observe significant representational gap between the native texts and translated texts, both in the source language and the target language. This representational gap undermines the effectiveness of cross-lingual transfer learning for event extraction with machine-translated data. In order to mitigate this problem, we propose an adversarial training framework that encourages the language model to produce more similar representations for the translated text and the native text. To be specific, we train the language model such that its hidden representations are able to fool a jointly trained discriminator that distinguishes translated texts’ representations from native texts’ representations. We conduct experiments on cross-lingual event extraction across three languages. Results demonstrate that our proposed adversarial training can effectively incorporate machine translation to improve event extraction, while simply adding machine-translated data yields unstable performance due to the representational gap.¹

1 Introduction

There are over 6,000 living languages in the world, and for many of them, too little appropriate data exists to build natural language processing (NLP) models. Cross-lingual learning has been proposed to leverage resources in data-rich languages to train NLP models for data-scarce languages (Ruder

et al., 2019). There are two main strategies for building cross-lingual models: (1) train models with multilingual language models and language-universal features that are transferable to the target language (Huang et al., 2019; Hsu et al., 2019; Hu et al., 2020a; Luo et al., 2020; Wei et al., 2021; Ouyang et al., 2021; Liu et al., 2019; Subburathinam et al., 2019; M’hamdi et al., 2019; Ahmad et al., 2021); (2) use machine translation models in a pipeline, either by transforming annotated training data into the desired target language to build target-language models, or by translating data at inference time into the source language and applying source-language models (Cui et al., 2019; Hu et al., 2020a; Yarmohammadi et al., 2021). The first approach relies on the quality of the constructed multilingual semantic space; the discrepancy between source-language training data and target-language evaluation data may cause overfitting. The second approach does not require a perfect multilingual semantic space since models can be trained in a monolingual fashion, but it depends on the quality of machine translation.

A combination of both approaches showed good performance on a variety of tasks such as natural language inference and question answering (Phang et al., 2020; Fang et al., 2021), but is underexplored for event extraction. Compared with previous research in cross-lingual event extraction mainly adopting the first approach (Liu et al., 2019; Subburathinam et al., 2019; M’hamdi et al., 2019; Ahmad et al., 2021), we explore the idea of combining both machine translations and language-universal representations for cross-lingual event extraction in this work. We perform translation by extending the previous effort on cross-lingual reading comprehension (Hsu et al., 2019) and question answering (Hu et al., 2020a) by adding special tags around the trigger and entity spans to translate the annotations. We use a multilingual language model to simultaneously encode a sentence and its corresponding

¹Code at <https://github.com/Perfec-Yu/CrossIE>

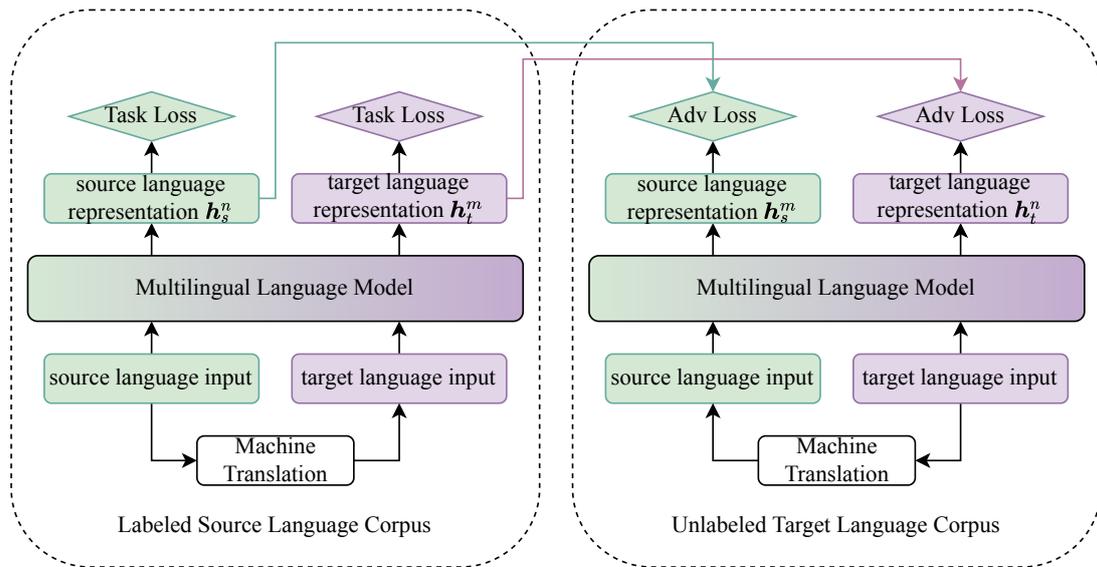

Figure 1: Overall cross-lingual information extraction framework

translation as shown on the left side of Figure 1. For example, in an English-to-Chinese cross-lingual learning setting, we would train a model with English sentences with their Chinese translations as training data, and evaluate our model with Chinese sentences and their English translations as inputs. Since our work includes both cross-lingual learning and machine translation, to avoid ambiguity, we will use “source” language as the one we perform cross-lingual learning from, and “target” language as the one we perform cross-lingual learning to. We will call texts before translation “native” text and text after translation “translated” text for the machine-translation-related descriptions.

We found that one challenge in cross-lingual event learning with machine translations is that the machine-translated text $\mathcal{M}_{\mathcal{K} \rightarrow \mathcal{L}}$ from one language \mathcal{K} into another language \mathcal{L} may be different from the native text in the target language $\mathcal{N}_{\mathcal{L}}$. This difference is also introduced and studied as the problem of “translationese” (translated text as a different language) in previous machine translation research (Pylypenko et al., 2021; Riley et al., 2020). In cross-lingual event extraction, we observe from a simple preliminary experiment that there indeed exists a distinguishable gap between representations of native texts $H(\mathcal{N}_{\mathcal{L}})$ and translated text $H(\mathcal{M}_{\mathcal{K} \rightarrow \mathcal{L}})$ in some multilingual language model H . The pretrained language models appear to be “unaccustomed” to the translated text. The representational gap will negatively impact the cross-lingual learning with machine-translated data. Since we, as introduced above, simultaneously encode a native

source language sentence $\mathcal{N}_{\mathcal{S}}$ and its translation into the target $\mathcal{M}_{\mathcal{S} \rightarrow \mathcal{T}}$ language during training, and a native target language sentence $\mathcal{N}_{\mathcal{T}}$ and its translation back to the source language $\mathcal{M}_{\mathcal{T} \rightarrow \mathcal{S}}$ during evaluation, the problem of representational gap between $\mathcal{N}_{\mathcal{S}}$ and $\mathcal{M}_{\mathcal{T} \rightarrow \mathcal{S}}$, as well as $\mathcal{N}_{\mathcal{T}}$ and $\mathcal{M}_{\mathcal{S} \rightarrow \mathcal{T}}$ need to be resolved. Here \mathcal{S} and \mathcal{T} refer to the source and the target language respectively.

In order to mitigate the representational gap problem between machine-translated text \mathcal{M} and native text \mathcal{N} in both source and target languages, we propose to take advantage of an unlabeled corpus in the target language and use adversarial training to make the encoder produce more similar representations for $\mathcal{N}_{\mathcal{S}}$ and $\mathcal{M}_{\mathcal{T} \rightarrow \mathcal{S}}$, as well as $\mathcal{N}_{\mathcal{T}}$ and $\mathcal{M}_{\mathcal{S} \rightarrow \mathcal{T}}$. The adversarial framework trains the language model H such that its hidden representations can fool a jointly trained discriminator that distinguishes translated texts’ representations $H(\mathcal{M})$ from native texts’ representations $H(\mathcal{N})$. Our complete cross-lingual IE framework is shown in Figure 1, which combines translation-based methods with transfer-based methods, and uses an unlabeled target language corpus to improve the representations in multilingual language models. Our method shows superior performance on event trigger labeling and argument role labeling, and through quantitative studies, we observe that adversarial training indeed makes the multilingual language model generate closer representations for the translated text and the native text. We believe our proposed adversarial training can also be helpful in other NLP tasks where machine

translation can boost performance.

To summarize, our contributions are two-fold:

- We observe the gap between representations of the machine-translated text and the native text in multilingual language models.
- We propose an adversarial training method to close the representational gap, which improves event extraction performance.

2 Approach

In this section, we will start with a simple preliminary experiment to validate the problem of the representational gap, and then introduce our approaches to cross-lingual event trigger and argument role labeling. For both tasks, we first design specific methods to use machine translation models to translate source language annotations into the target language. We then use XLM-RoBERTa (Conneau et al., 2020) to encode pairs of parallel sentences simultaneously into hidden representations. Task-specific losses are used on top of the hidden representations. In order to make the multilingual language model produce more similar representations for translated sentences and native sentences, we further use an unlabeled target language corpus for adversarial training.

2.1 Preliminary Experiment on Representational Gap

We translate Chinese sentences from the ACE 2005 Chinese corpus into English and encode the translated English sentences $\mathcal{M}_{\text{ZH} \rightarrow \text{EN}}$ and native English sentences \mathcal{N}_{EN} in the ACE 2005 English data using the multilingual language model XLM-RoBERTa (Conneau et al., 2020). We then train linear Support Vector Machines (SVMs) (Cortes and Vapnik, 1995) to classify the encoded representations of these two sets of sentences as $\mathcal{N}_{\text{native}}$ or $\mathcal{M}_{\text{machine-translated}}$. The model achieves 83.4% accuracy on a held-out test set classifying the translated English sentences $\mathcal{M}_{\text{ZH} \rightarrow \text{EN}}$ and native English sentences \mathcal{N}_{EN} . We also perform translation from English to Chinese and achieve 93.4% accuracy classifying native Chinese sentences \mathcal{N}_{ZH} and translated Chinese sentences $\mathcal{M}_{\text{EN} \rightarrow \text{ZH}}$. Both numbers are significantly higher than the random 50% accuracy, indicating that the translated text and the native text are almost linearly separable in the multilingual language models and hence validating the representational gap between the two types of texts.

2.2 Event Trigger Labeling

In monolingual event trigger labeling, the input to the model is a sequence of text tokens $\{w_0, w_1, \dots, w_l\}$. The model identifies consecutive text spans as event triggers and classifies the spans into event types. We first obtain the token representations using the text encoder as $\{h_0, h_1, \dots, h_l\}$. Then we apply a linear layer to classify each token into one of the event types.

For the cross-lingual setting, we first translate the monolingual training data in the source language into the target language together with the trigger annotations. We will explain the translation process in Section 2.4. We encode the source language text sequence $\{w_{s0}, w_{s1}, \dots, w_{sl}\}$ and its translation $\{w_{t0}, w_{t1}, \dots, w_{tk}\}$ using the XLM-RoBERTa (Conneau et al., 2020) model. We also adopt a special fusion strategy as introduced in the FILTER (Fang et al., 2021), which adds cross-lingual attention between the source language text and its translation in some hidden Transformer layers. We apply the classification step as in the monolingual setting for both w_s and w_t . The task loss is the summation of losses from w_s and w_t .

$$\mathcal{L} = \mathcal{L}_s + \mathcal{L}_t. \quad (1)$$

In the training phase described above, the input sequences to the multilingual language model consist of a native source language sequence w_s^n and its translations w_t^m . In the evaluation phase, the input sequence becomes a native target language sequence w_t^n and a translated source language sequence w_s^m . Therefore, we need to bridge the representational gap in the multilingual LM between two pairs: (w_s^n, w_s^m) and (w_t^m, w_t^n) . In order to encourage the multilingual LM to generate closer representations for w_s^n and w_s^m , as well as for w_t^m and w_t^n , we further propose an adversarial loss using another unlabeled target language corpus. We first translate the unlabeled target language corpus, from which we sample w_t^n , into the source language (w_s^m) to construct an unlabeled parallel corpus. Then parallel sentence pairs (w_s^m, w_t^n) in the unlabeled corpus are encoded by the multilingual LM in the same way as the labeled training sentence pairs (w_s^n, w_t^m) . We train two additional two-layer discriminators, D_s and D_t . D_s attempts to distinguish native source language representations w_s^n from translated source language representations w_s^m . D_t attempts to distinguish translated target language representations w_t^m from the native

	Trigger Labeling	Argument Role Labeling
Source Language	Now that Enron has ceased to exist, Bechtel and GE are suing the Indian Government for 5.6 billion US dollars.	The electricity that Enron produced was so exorbitant that the government decided it was cheaper not to buy electricity and <a>pay Enron the mandatory fixed charges specified in the contract.
Target Language	现在安然已经不复存在，柏克德和通用电气正在起诉印度政府，要求赔偿56 亿美元	安然生产的电力如此昂贵，以至于政府决定不购买电力并<a>支付安然合同中规定的强制性固定费用更便宜

Table 1: Example of training data translation for trigger labeling and argument role labeling.

target language representations w_t^n . The adversarial loss is also illustrated in Figure 1. For adversarial training, we adopt W-GAN (Arjovsky et al., 2017) with gradient penalty (Gulrajani et al., 2017) in this work. Specifically, D_s and D_t are two-layer neural networks with one output unit, i.e., they output single scalars. Optimization targets of the two discriminators are

$$\begin{aligned} \mathcal{L}_{D_s} &= D_s(\mathbf{h}_s^m) - D_s(\mathbf{h}_s^n; \theta) \\ &\quad + \text{GP}(D_s; \mathbf{h}_s^m, \mathbf{h}_s^n), \\ \mathcal{L}_{D_t} &= D_t(\mathbf{h}_t^m) - D_t(\mathbf{h}_t^n) \\ &\quad + \text{GP}(D_t; \mathbf{h}_s^m, \mathbf{h}_s^n). \end{aligned} \quad (2)$$

Here GP refers to the gradient penalty loss in Gulrajani et al. (2017) to regularize the discriminators. D_s and D_t are both neural networks that output a single value. We use $D_s(w_s^m; \theta)$ to denote the average output value of all token representations in the sequence w_s^m , and D_t in an analogous way. We expect our multilingual LM to produce representations that confuse both discriminators. The optimization target for the encoder is,

$$\begin{aligned} \mathcal{L}_G &= D_s(\mathbf{h}_s^n) - D_s(\mathbf{h}_s^m) \\ &\quad + D_t(\mathbf{h}_t^n) - D_t(\mathbf{h}_t^m). \end{aligned} \quad (3)$$

The gradients of the loss in Equation (1) are back propagated to both the multilingual language model and the trigger classification layers. The gradients of the discriminator loss in Equation (2) are back propagated to D_s and D_t only. The gradients of the generator loss in Equation (3) are back propagated to the multilingual language model. In practice we find that it is beneficial to back propagate \mathcal{L}_G to only the last layer of the XLM-RoBERTa to match the capacity of the discriminators D_s and D_t .

2.3 Argument Role Labeling

Argument Role Labeling identifies the roles entities play in events. Assuming gold-standard entity spans are provided, the input is a sentence x with a trigger span and an entity span, and the model predicts the argument role of the entity in the event. We use an additional None label for the case where the entity does not participate in the event.

For monolingual prediction, we first insert into the sentence two pairs of anchors to specify spans for the trigger and the entity: (“<a>”, “”) around the trigger span and (“”, “”) around the entity span. We encode the modified sentence into hidden representation x by a pretrained language model. We consider the token representation for the CLS token inserted into the beginning of every sentence x_{CLS} as the summarization of the sentence and feed it to a linear layer for classification. For adversarial training, we use a similar loss as in Equations (2) and (3), but use the CLS token representation x_{CLS} as the input to the discriminators.

2.4 Annotation Translation

We show two examples in Table 1 for translating annotations for trigger labeling and argument role labeling respectively. For trigger labeling, we first enclose each trigger span in the source language sentences with special tokens (“”, “”) inspired by previous efforts on question answering (Hu et al., 2020b). The machine translation model is applied to the new sentence. If the paired special tokens (“”, “”) exist in the translated sentence, we label the text span inside the pair as the event trigger. Otherwise we consider the translation as invalid and discard the target language loss \mathcal{L}_t in Equation (1) when training. We still use the invalid translations for the adversarial training loss

in Equation (2) and Equation (3) since the computation of these losses doesn't require trigger spans.

For argument role labeling, we take advantage of the anchor tokens used for training and simply translate the sentences with trigger and entity spans enclosed by anchor tokens into the target language. Due to the imperfections in the machine translation model, there are corrupted translated samples missing “<a>” or “” tags. However, since the role labeling model architecture doesn't require the existence of these tags to be runnable, we still consider them as valid inputs and use the corrupted translated samples as training data for both the target language loss \mathcal{L}_t in Equation (1) and the adversarial losses in Equation (2) and Equation (3).

2.5 Evaluation

At inference time, the inputs to the framework are sentences in the target language. We first translate the target language sentence into the source language using the same machine translation model used for the unlabeled target language corpus during training and apply our framework to the sentence pairs. We make predictions using the hidden representations of the target language.

3 Experiments

3.1 Dataset and Machine Translation

We use the ACE² 2005 dataset for experiments. We study all six transfer learning settings among the three languages in the dataset: Arabic, Chinese and English. We follow previous work on event extraction (Lin et al., 2020) to split the ACE dataset for the trigger labeling task. For the argument role labeling task, previous work (Subburathinam et al., 2019; Ahmad et al., 2021) has adopted a different split from Lin et al. (2020). We therefore follow the split in (Subburathinam et al., 2019; Ahmad et al., 2021) in this task. However, since their processed version of ACE dataset is not available, we use our own processed version and re-train their models on our version for comparison. We provide basic data statistics in Table 2. We also provide more fine-grained data statistics in Appendix. There are some other competitive cross-lingual event extraction baselines that we are not able to compare due to limited availability of code or split information. We provide further discussion in

²<https://www ldc.upenn.edu/collaborations/past-projects/ace>

the related work section. We use Google Translate for all machine translation components.

		Trigger		Role	
		#Docs	#Events	#Cands	#Args
EN	Train	529	4,419	14,036	7,018
	Dev	28	468	1,754	719
	Test	40	424	1,756	878
ZH	Train	551	2,926	11,826	5,931
	Dev	40	217	1482	602
	Test	42	190	1484	578
AR	Train	303	1,751	7,918	3,959
	Dev	50	255	990	495
	Test	50	262	990	495

Table 2: Data statistics for ACE 2005 dataset. EN, ZH and AR refer to the English, the Chinese and the Arabic splits respectively. The trigger labeling task (Trigger) and the argument role labeling task (Role) use different splits to compare with previous methods. We present the number of documents and the number of event mentions for Trigger splits. For Role splits, we present the number of candidate trigger-entity pairs for prediction (#Cands) and the total number of pairs that hold some argument role relationship (#Args).

3.2 Experiment Settings

Methods in Comparison We compare the following approaches in evaluation:

Direct, which directly trains a model on the source language with a multilingual language model and evaluates it on the target language. We use XLM-RoBERTa as the multilingual LM to be comparable with our method;

GATE (Ahmad et al., 2021) is a state-of-the-art cross-lingual model for the argument role labeling task. Hence we only compare with GATE in the argument role labeling task;

Trans is a baseline that excludes our proposed adversarial loss but keeps all the remaining components;

Trans+Adv is our proposed framework;

Target Supervision is a mono-lingual IE model trained on the target language data.

Evaluation Settings Except for **Target Supervision**, all cross-lingual models are trained with the source language annotations. We use the target language training corpus without annotations to compute the adversarial loss in our proposed method. We report F1 scores in the following sections and include precision and recall scores in Appendix.

Event Trigger Labeling	AR - EN	ZH - EN	AR - ZH	EN - ZH	ZH - AR	EN - AR
Direct	39.8	44.4	33.4	46.9	36.7	39.0
Trans	39.4	46.3	38.8	47.3	36.6	39.3
Trans+Adv (ours)	41.5	54.6	40.1	49.3	38.4	42.3
Target Supervision	68.5		65.6		56.1	

(a) Event trigger labeling.

Argument Role Labeling	AR - EN	ZH - EN	AR - ZH	EN - ZH	ZH - AR	EN - AR
GATE	50.3	57.0	55.7	63.6	65.1	65.0
Direct	56.8	61.5	64.6	71.7	64.0	62.5
Trans	57.5	60.6	64.9	71.3	63.8	62.2
Trans+Adv (ours)	58.4	62.9	65.6	72.0	68.0	65.1
Target Supervision	77.2		82.0		77.8	

(b) Argument role labeling.

Table 3: F1(%) scores for the cross-lingual event extractions. GATE (Ahmad et al., 2021) is a state-of-the-art method for cross-lingual argument role labeling. Direct, Trans and Target Supervision are introduced in Section 3.2. AR, EN and ZH correspond to Arabic, English and Chinese respectively.

3.3 Experiment Results

We show the evaluation results for trigger labeling in Table 3a. We show results for the argument role labeling task in Table 3b. Our model shows superior performance compared with other cross-lingual baselines in both trigger labeling and role labeling tasks and across all six cross-lingual transfer settings. Our model outperforms the Trans baseline that is trained without the adversarial loss. This indicates that our proposed approach effectively narrows the gap between the translations and the original natural language to improve the performance. Moreover, we notice that the Trans that uses translated data for training cannot consistently outperform the Direct baseline which doesn’t use translated data. This shows that the representational gap can have a negative impact on the model performance than the positive impact brought by including the translated data. In the following sections, we provide further analysis on the representational gap, our model’s improvements and remaining errors.

3.4 Effect of Adversarial Training

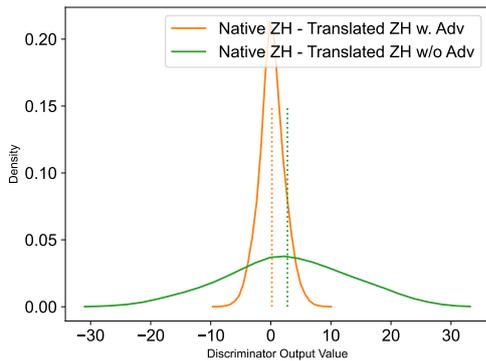

In this section we evaluate the effect of the adversarial training on reducing the representational gap. Hence we compare our model against the Trans baseline that doesn’t use the adversarial training loss. We take the English-to-Chinese transfer learning setting as a case study in this section.

Argument Role Labeling	EN-to-ZH		
	T-ZH	ZH	Diff
Trans	74.3	71.3	-3.0
Trans+Adv (ours)	74.5	72.0	-2.5

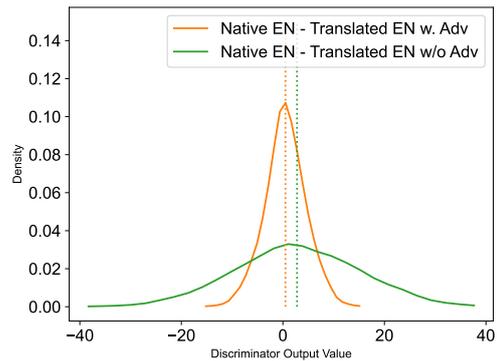

Table 4: F1 scores (in %) of the English-Chinese cross-lingual argument role labeling models on translated Chinese test corpus (from English test corpus), T-ZH and the native Chinese test corpus, ZH. Diff is the performance gap between two test corpora.

A straightforward way to examine the representational gap between the native text and the translated text inside a model is to compare its performance on these two types of texts on role labeling. In Table 4, we report the F1 scores on the native Chinese test set and translated Chinese text from English dataset respectively. The performance on translated Chinese is better than native Chinese since both models use the translated Chinese instead of native Chinese during training. Our adversarial training method shows a smaller performance gap compared with the non-adversarial baseline, indicating that our model indeed reduces the representational gap.

In addition to this evaluation, we further check whether the proposed generator loss helps the model to produce representations that confuse the discriminators. We compare the discriminator out-

(a) Native Chinese v.s. Translated Chinese

(b) Native English v.s. Translated English

Figure 2: Distribution of differences in discriminator outputs between native text and translated text. We compute the density with NumPy³ histogram function on original data points. *w. Adv* refers to our model with the adversarial training. *w/o Adv* is the output of the additional discriminators trained on the baseline *Trans* without adversarial training. (See Appendix for details on how the additional discriminators are trained)

Task	Sentence	Error
Trigger Labeling	...徐鹏航...支持参与亲属购买内部职工股... (...Penghang Xu... supported and participated in relatives' purchasing internal employee shares)	Baseline model makes a false positive prediction of “支持” (support) as a trigger for <i>Transfer-Money</i> event

Table 5: An Example error that the baseline approach fails but our proposed model succeeds.

puts for the native text representations and the translated text representations in Figure 2, for both English and Chinese. Since we use W-GAN (Arjovsky et al., 2017) for adversarial training, the discriminator output for an input sentence is a single scalar. For each language, we plot the distribution of difference in the output scalars $D_{s,t}(\mathbf{h}_{s,t}^n) - D(\mathbf{h}_{s,t}^m)$ between the native test corpus and the translated test corpus. These difference values are closer to 0 if the model fools the discriminators. For comparison we trained additional discriminators for the *Trans* baseline as the *w/o ADV* curves on the plot. The adversarial training makes the difference between the native text and the translated text much smaller for both English and Chinese.

Apart from the quantitative analysis, we show an example error from the baseline model that our proposed framework with adversarial training has managed to avoid in Table 5. The model makes the wrong prediction because in the English training data, “support”(支持) can trigger a *Transfer-Money* event with certain context which is uncommon in Chinese. By aligning the representation spaces with adversarial training, the model will align 支持 in translated text to represen-

tations of more common used Chinese words that trigger the *Transfer-Money* event.

3.5 Remaining Challenges

Chinese Sentences	Error
40年来, 日本皇室就没有再添男丁。(For 40 years, the Japanese royal family has not added any more males.)	Misses the trigger 添(add), Be-Born
德仁皇太子唯一的弟弟, 是[皇室]entity最后一名[出生]trigger的男性 (the only brother of Prince Naruhito was the last male [born]trigger in the [Royal Family]entity.)	False positive role prediction:Place.

Table 6: Remaining error examples of cross-lingual trigger and argument role labeling from our proposed model. We provide Chinese test sentences and English translations on the left and errors on the right.

Our experiments show cross-lingual trigger la-

being from English to Chinese is very challenging. In Table 6, the first two examples are from the trigger labeling task. In the first example, the Chinese trigger span has the meaning of “add,” which can only trigger a `Born` event under specific context such as “add children.” However, this is not a typical English expression, and it appears very rarely in the ACE 2005 English training data. Therefore cross-lingual learning fails on this case.

The second example is from the argument role labeling task. The model makes the wrong prediction because “室” in the entity span has the meaning of “room,” making the model to consider the entity as a location. Joint learning of entity typing and role labeling can be helpful for such cases.

4 Related Work

Multilingual Language Representations

Early work on multilingual representations learns aligned word or sentence embeddings from dictionaries (Mikolov et al., 2013; Faruqui and Dyer, 2014; Pan et al., 2019), parallel corpora (Gouws et al., 2015; Luong et al., 2015) or semi-supervised or unsupervised approaches (Artetxe et al., 2017; Zhang et al., 2017; Artetxe et al., 2018; Lample et al., 2018). Recent advances in pretrained language models have inspired research on cross-lingual language models such as mBERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019) and XLM-RoBERTa (Conneau et al., 2020).

Cross-Lingual Learning for NLP There is research in cross-lingual learning for many NLP tasks such as name tagging (Huang et al., 2019), reading comprehension (Cui et al., 2019; Hsu et al., 2019), summarization⁴ (Zhu et al., 2019; Cao et al., 2020). XGLUE (Liang et al., 2020), XTREME (Hu et al., 2020a) and XTREME-R (Ruder et al., 2021) present benchmarks covering a wide range of tasks including natural language inference, paraphrase detection, part-of-speech tagging, name tagging, question answering, sentence retrieval and generation, which are followed by (Phang et al., 2020; Fang et al., 2021; Luo et al., 2020; Wei et al., 2021; Ouyang et al., 2021). However these benchmarks don’t include event extraction as a subtask. For cross-lingual event extraction, early work utilizes multilingual embeddings and language universal parsing structures for cross-lingual transfer for trigger labeling (Liu et al., 2019) and argument role

labeling (Subburathinam et al., 2019). It is worth mentioning that Liu et al. (2019) focus on augmenting the existing supervision in the target language with cross-lingual learning that is different from the setting in this work, which requires no supervision in the target language. M’hamdi et al. (2019) explore using mBERT (Devlin et al., 2019) for direct cross-lingual trigger labeling and find it outperforms previous methods. Our `Direct` baseline can be considered as a re-implementation of their method with XLM-RoBERTa (Conneau et al., 2020). GATE (Ahmad et al., 2021) follows (Subburathinam et al., 2019) and uses a graph convolutional architecture and pretrained knowledge from language models to further improve the performance. Yarmohammadi et al. (2021) first translate the whole sentence and then uses token aligners to get a sub-sentential alignment, which has shown to be beneficial. We use a different translation strategy, and our proposed adversarial training approach may also be helpful with their translations. A more recent and parallel attempt (Guzman-Nateras et al., 2022) proposes to use adversarial training to close the gap between the source language and target language for event trigger labeling, which is different from our approach. (Fincke et al., 2022) uses priming methods to make the model understand the critical information for argument labeling. The performance of these two methods is not directly comparable due to different splits and limited code availability. We will add comparison once they release code. (Huang et al., 2022) proposes a generative approach to directly generate arguments for cross-lingual event argument extraction. However they don’t take entity spans as inputs for evaluation and results are not comparable.

5 Conclusions and Future Work

In this paper, we proposed a new cross-lingual event extraction framework and evaluated the framework on the ACE 2005 dataset. Our framework combines the multilingual language models with a machine-translation-based method. Meanwhile, we observe the representational gap between the translated text and the native text in multilingual language models that may affect the performance and propose an adversarial training approach to make the language model produce more similar representations for these two types of text.

One potential reason for remaining errors in cross-lingual transfer learning could be that the

⁴Cross-lingual summarization has a different task formulation than common cross-lingual learning, but it is still related.

source and the target languages may differ in the common expressions of an event type. It will be helpful to detect such differences from pretrained multilingual language models and incorporate them for training. Although we focus on cross-lingual event extraction in this work, our adversarial training approach could be extended to other cross-lingual language understanding tasks.

6 Limitations

Although we have demonstrated our framework’s performance in six cross lingual transfer learning directions for both the trigger labeling and argument role labeling, our experiments is mostly on the ACE 2005 dataset due to the availability of multilingual event extraction data. Since the ACE 2005 dataset only contains Arabic, Chinese and English, we were not able to test our framework on some languages with extremely limited resources, which are more common use cases for the cross lingual transfer learning .Besides, although our proposed adversarial loss is a general approach not specific to the event extraction task, we have not validate the effectiveness of it on other cross lingual NLP benchmarks or using other machine translation models. Moreover, our supervised models are trained in the multilingual language model (XLM-RoBERTa) for direct comparison. However, the performance is different from models trained with monolingual language models specific to the target language.

A Appendix

A.1 Details for Model Training

For both the trigger labeling and role labeling task, we use batch size of 8 for training. We evaluate performance after each epoch and select the best model based on the development performance. We use early-stop strategy with a patience of 5 epochs. We conduct our experiments on a single Nvidia Tesla V100 GPU with 16GB memory.

The learning rate for both the trigger labeling and role labeling loss is $1e - 5$. In adversarial training, the learning rate for the discriminator loss is $1e - 5$. For the generator loss, we found in practice it is very likely to confuse the discriminators within a few steps if we finetune the whole XLM-RoBERTa architecture or the learning rate is set too large. Hence the generator learning rate for the generator loss is chosen between $\{1e - 5, 1e - 6, 1e - 7, 1e - 8, 1e - 9\}$ on the dev set for each cross lingual transfer learning task. We empirically found that the trigger labeling tasks usually take a smaller learning rate ($1e - 8, 1e - 9$) and the argument role labeling tasks usually take a larger one ($1e - 5, 1e - 6$). We also only finetune the last output layer of the XLM-RoBERTa model for the generator loss to match the capacity of the discriminators. The discriminator and the generator are trained alternatively. We train 5 discriminator steps per generator step.

For the simultaneous encoding of a sentence and its translation, we adopt the special fusion strategy in FILTER (Fang et al., 2021) for the role labeling task. FILTER will select some hidden layers of the XLM-RoBERTa model, for which it will concatenate the hidden representation of the original sentence and its translation together for self-attention computation. We follow FILTER to use the 21st layer for representation fusion. We found this strategy to be more helpful in role labeling task than trigger labeling task. In trigger labeling task, it suffices to simply encode the sentence pairs individually for prediction.

The approximate number of parameters is 3.5 million (mainly parameters of XLM-RoBERTa). We run our model on a single NVIDIA V100 with 16 GB memory. Training our framework takes approximately 20-40 minutes/epoch since 16GB memory can only take batch size of 1 for training. We need to accumulate the gradients over multiple runs for larger batch size. However, we notice that our model usually converges much faster than a simple XLM-RoBERTa baseline (Direct baseline). Usually we achieve our best model with 2-4 epochs. In total it usually takes around 4-5 hours to train a model. We implement the XLM-RoBERTa model using Transformers⁵ Library.

For the back propagation, note that the gradients of the loss in Equation (1) are back propagated to both the language model and the trigger classification layers, the gradients of the loss in Equation (2) are back propagated to D_s and D_t , and the gradients of the loss in Equation (3) are back propagated to the language model. In practice we found that it is beneficial to back propagate loss in Equation (3) to only the last layer of the FILTER model to match the capacity of the discriminators D_s and D_t .

A.2 Details for Machine Translation

We use Google Cloud API⁶ for machine translation. For trigger labeling, if a sentence contains multiple triggers, we enclose each of them with “” and “” for translation. After the sentence is translated, we retrieve all trigger spans in the target language one by one, and map them back to the triggers in the source language according the offset in the sentence. For example, the first trigger span in the source language will be mapped to the first trigger span in the target language. If we retrieve less triggers spans in the target language than the source language, we consider this translation invalid and discard this instance for the trigger labeling loss. We still use it for the adversarial training. For argument role labeling, we directly translate the sentence with inserted “<a>”, “”, “”, “” and always apply the role labeling loss on the translated sentence even if it may not contain paired special tokens.

For trigger labeling, our translation method retrieved⁷ 4,284 event triggers out of 4,419 triggers in

⁵<https://huggingface.co/docs/transformers/index>

⁶<https://cloud.google.com/translate>

⁷Here “retrieved” means that after the translation of a source language sentence of the format in Table 1, the trans-

the ACE 2005 English training data. For argument role labeling, there is no simple automatic metric to evaluate our translation method. Therefore, we sampled a small portion of the translation and conduct a small scale manual evaluation. 80.0% of the translations are considered reasonable by human assessors.

The reason behind this translation strategy is that the machine translation model trained on large-scale web-crawled data could have seen some HTML tags during training. “” are HTML tags for displaying bold characters, and “<a>” are tags for the content of reference links. Therefore we expect the model to translate properly if it can translate HTML formatted text.

A.3 ACE 2005 Dataset Details

This dataset is licensed by LDC.⁸ Membership is required for access. The dataset can be used for research purpose.

There are three languages in this dataset. For all the languages, we notice a significant long-tailed distribution among event types. We provide number of event mentions for all splits in Table 7. We also notice that the most frequent types for all languages are similar with minor differences.

A.4 Details of Additional Discriminators for Case Study

For fair comparison of the additional discriminators for the `Trans` baseline and the discriminators in our framework, we also jointly train the the discriminators with the `Trans` baseline in the same way as we conduct adversarial training in our framework. The training process can be seen as training our framework with the generator learning rate being 0. Note that the parameters of the discriminators are disjoint of that of the `Trans` baseline model. Therefore the joint training will not affect the learning the `Trans` baseline model.

A.5 Corruption Ratio of Translated Training Data

We provide corruption ratio for the argument role labeling task here for translation of the training data. Due to our strategy of inserting special tokens, a corrupted translation is defined as a translated

lated sentence include paired “” and “” tokens and the content between them are not empty. In this sense retrieved triggers are not guaranteed to be correct annotations. This is just a rough estimation of the performance of proposed translation method.

⁸<https://www ldc upenn edu>

sentence without either of the special tokens. In sentences translated into Arabic, we noticed that special tokens are sometimes translated as ‘<a >’ or ‘’ with additional spaces. We don’t consider them as corrupted and automatically cleaned up such errors. The corruption ratios are as below: EN-ZH, 10%; EN-AR: 22%; ZH-EN: 12%, ZH-AR: 27%; AR-EN: 26%; AR-ZH: 38%.

It is also worth mentioning that Google translate offers the option to respect HTML mark up. However, we didn’t adopt this option in our experiments. We believe enabling this function can further reduce the corruption ratio and potentially improve the performance.

A.6 Full Results

We present full results of all six cross-lingual transfer settings across two tasks, including the precision, recall and f1 scores. We include trigger labeling performance in Table 8a-8f. We include role labeling performance in Table 9a-9c.

Abstract

Prompt-based learning methods in semi-supervised learning (SSL) settings have been shown to be effective on multiple natural language understanding (NLU) datasets and tasks in the literature. However, manually designing multiple prompts and verbalizers requires domain knowledge and human effort, making it difficult and expensive to scale across different datasets. In this paper, we propose two methods to automatically design multiple prompts and integrate automatic verbalizer in SSL settings without sacrificing performance. The first method uses various demonstration examples with learnable continuous prompt tokens to create diverse prompt models. The second method uses a varying number of soft prompt tokens to encourage language models to learn different prompts. For the verbalizer, we use the prototypical verbalizer to replace the manual one. In summary, we obtained the best average accuracy of 73.2% (a relative improvement of 2.52% over even the previous state-of-the-art SSL method with manual prompts and verbalizers) in different few-shot learning settings.

1 Introduction

Pre-training large language models with huge amounts of text corpora in masked language modeling tasks and then fine-tuning the pre-trained language model (PLM) on downstream tasks have shown superior performance in many natural language processing tasks. However, the discrepancy between the pretraining task (masked language modeling objective) and the downstream fine-tuning task (task without MASK token) could lead to unexpected behaviors. Recently, there has been growing research interest in the area of prompt-tuning, where any NLU task is transformed into a cloze task to mimic the pre-training objective of a large masked language model (Kumar et al.,

2016; McCann et al., 2018; Radford et al., 2018). Prompt-based learning transforms an input x into x' using a prompt function. It makes use of the vast amount of acquired knowledge of PLMs to predict a distribution of tokens at the masked position. The verbalizer then maps the predicted tokens to classes. The main advantage of this approach is that this method works well in a few-shot learning environment (Schick and Schütze, 2021). However, the main disadvantage of this method is the limitation posed by the prompt and verbalizer functions, which require human knowledge to carefully craft them. Such handcrafting work is expensive and not scalable with the increase in the variety of tasks and datasets. For example, in Alexa, there are thousands of domains and manually designing prompts and verbalizer for intent classification for each of them according to the dataset content demand human expertise, which is time consuming and not applicable. It is essential to reduce the human efforts in the process of prompt generation. Prompt-based learning requires finding the right tokens in the prompts that align with the task requirement and dataset content. However, since the objective of these prompt tokens is only for the language models to perform the task at hand, it is not necessary for them to be a sequence of words that humans can understand.

Continuous prompt-based learning alleviates the need for human intervention to determine prompt tokens. Instead, it automates the prompt design process. In the literature, there are mainly two methods: i) automatically search for discrete prompt text tokens (Shin et al., 2020a) ii) automatically learn numerical prompt embeddings (Lester et al., 2021; Li and Liang, 2021; Liu et al., 2021c,b; Hambarzumyan et al., 2021). The main difference between these two approaches is that the first searches for actual discrete tokens from the language model vocabulary, whereas the second method directly learns the embeddings for prompt tokens, which

*Equal contribution. This work was done during Yuhang's internship at Amazon, Alexa AI.

may not be human comprehensible. Similarly, automatic selection of label words (Shin et al., 2020a; Schick et al., 2020a; Gao et al., 2021), soft verbalizer (Hambardzumyan et al., 2021; Liu et al., 2021b), and prototypical verbalizer (Cui et al., 2022) are the methods proposed to eliminate the tedious process of manually defining verbalizer mapping functions.

Most of these continuous prompt and automatic verbalizer methods focus on supervised learning (SL) settings but ignore their generalization under semi-supervised learning (SSL) settings. The previous state-of-the-art (SoTA) SSL method with various manual prompts and verbalizers has shown superiority over SL language models with a single manual prompt (Schick and Schütze, 2021). In this SSL pipeline, we normally train several labeler models with different manual prompts to capture diverse information from the limited training data and make use of them to annotate a huge amount of unlabeled data. Having to design several manual prompts and verbalizer models for SSL settings and applying them across multiple datasets and tasks will exacerbate the scalability and cost problem. In this paper, we tackle the problem posed by manual prompt and verbalizer design and propose automatic methods to fully automate the design of diverse prompts and verbalizers in SSL settings. Our main contributions are as follows.

- We propose methods to generate various prompts by adding multiple demonstration examples with continuous prompt tokens for use in SSL settings.
- To the best of our knowledge, we are the first to completely eliminate human involvement in designing multiple prompts and verbalizers in SSL settings and obtain similar and even better performance than the SoTA methods with manual prompts and verbalizers.
- We empirically show that using the automatic verbalizer with manual prompts can achieve a similar performance to manual verbalizers’ performance in the SSL pipeline.

2 Methodology

Our overall prompt-based SSL workflow follows Pattern-exploiting Training (PET) semi-supervised learning setting (Schick and Schütze, 2021). PET first transforms the input sequence x to a cloze

question containing a single MASK token. Next, it uses PLM to fill in the value of the MASK token and applies verbalizers to map the output tokens to the class labels $y \in Y$. They devise a semi-supervised framework to produce soft labels on a large amount of unlabeled data, which are later used to train a final supervised classifier F . They report strong performance over other supervised prompt-tuning methods and other semi-supervised approaches without prompts across multiple NLU tasks. Before this paper, the PET approach was the state-of-the-art (SoTA) framework that integrates the prompt-tuning method into the SSL pipeline.

The PET method fine-tunes multiple PLMs with different prompts. It introduces diversity in the prompts by manually designing several prompts using domain and task knowledge. Similarly, it uses human expertise to design verbalizer mappings for each of the datasets based on the knowledge of the tasks. Here, we use continuous and automatic prompts and verbalizers, thus eliminating the need for human involvement in designing manual prompts and verbalizers.

2.1 Overall Pipeline

Figure 1 shows the overall pipeline of our proposed methods. Unlike the original PET pipeline with manual prompts and verbalizers, we use a prompt generation function to generate multiple automatic prompts. Each PLM with automatic prompts serves as a labeler model. We train each of these prompts + automatic verbalizer models with a labeled dataset \mathcal{T} in few-shot settings. With an input sequence $x_t \in \mathcal{T}$ and the given label y_t , we first use the prompt function P to transform x_t into a sequence $P(x_t)$ with a MASK token. The verbalizer then maps the predicted word probability at the masked position to the label probability. For each PLM m , the predicted probability $p_m(y_t|x_t)$ is defined as

$$p_m(y_t|x_t) = \frac{\exp m(y_t|x_t)}{\sum_{y' \in Y} \exp m(y'|x_t)} \quad (1)$$

where $m(y|x)$ is the raw score of PLM m in the masked position. After obtaining the probability, we minimize the cross-entropy loss \mathcal{L}_c between $p_m(y|x)$ and y .

We apply trained labeler models to each sentence $x_d \in \mathcal{D}$ in the unlabeled dataset \mathcal{D} and get the probability $p_m(y_d|x_d)$ for each trained model. We then take the average of these probabilities from each

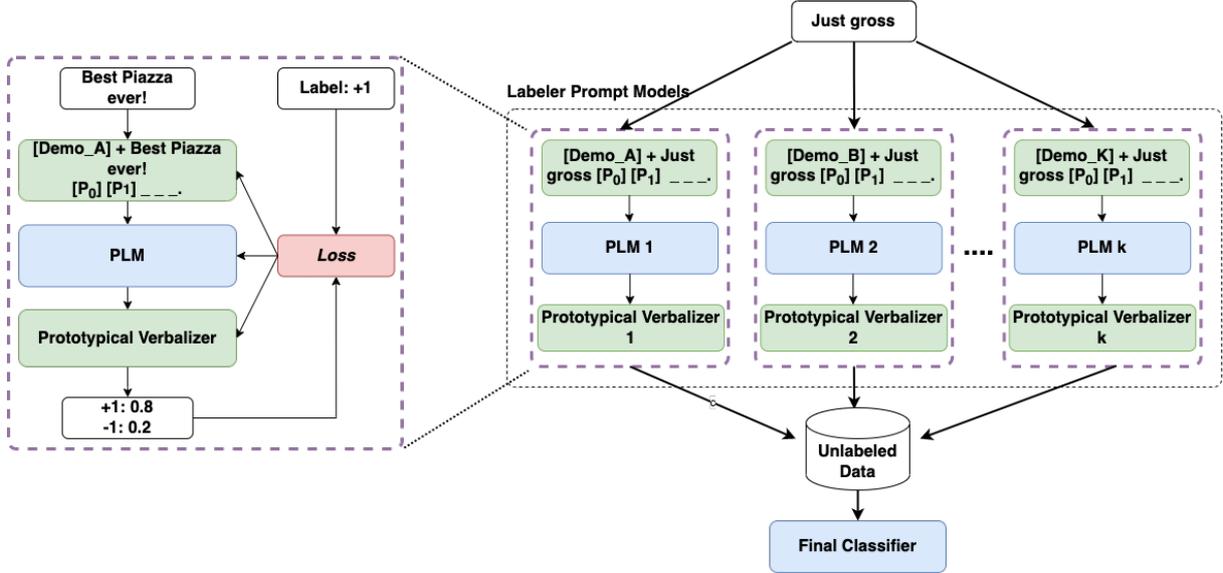

Figure 1: Semi-Supervised Learning (SSL) Training. Multiple diverse prompt-based learning models are trained on labeled data to soft label huge amounts of unlabeled data. The soft labels serve as ground truth to train the final classifier. P_0, P_1, \dots are continuous prompt tokens and $Demo_A, Demo_B, \dots$ are demonstration examples randomly sampled from the training data.

trained model m as the ground-truth probability,

$$p_t(y_d|x_d) = \frac{1}{Z} \sum_{m \in M} p_m(y_d|x_d)$$

where Z is the total number of trained PLMs with different automatic prompts. Eventually, we fine-tune a final pre-trained language model \mathbf{F} with a standard sequence classification head. We use the Kullback-Leibler (KL) divergence as our loss function. Given $p_t(y_d|x_d)$ and the predicted probability $\hat{p}(y_d|x_d)$ of the final classifier \mathbf{F} , the divergence loss \mathcal{L}_{div} for this input is:

$$\mathcal{L}_{div}(x_d) = \sum_{y' \in Y} p_t(y'|x_d) \log \left(\frac{p_t(y'|x_d)}{\hat{p}(y'|x_d)} \right) \quad (2)$$

The final classifier \mathbf{F} is then applied to the test set to obtain the results.

Schick and Schütze (2021) introduce diversity in their SSL pipeline by training several models with different manual prompts and applying them to softly label a large number of unlabeled datasets. The diversity between manual prompts brings consistent improvements. We observe that diverse knowledge learned by the language model is mostly introduced by the prompts rather than manual verbalizers, since in most datasets, they prepare only one manual verbalizer but multiple prompts for experimentation. Thus, we propose replacing manual

prompts with multiple automatic prompts and using the same automatic verbalizer for all labeler models.

2.2 Continuous Prompt Design

Several researchers have proposed methods to automate the prompt design process (Liu et al., 2021c; Li and Liang, 2021; Lester et al., 2021). In most of these methods, they insert the continuous trainable prompt tokens into the input sentence and learn the token embeddings during the training process. However, existing continuous prompt-based learning methods do not consider their application in the PET pipeline, which requires training several labeler models (Schick and Schütze, 2021), in order to learn diverse knowledge from the datasets. Therefore, most methods do not define strategies to compose multiple continuous prompts. We propose two scalable solutions to introduce different variables in the design of continuous prompt labeler models (various demonstration examples or varying numbers of continuous prompt tokens). We expect that with these diverse continuous prompts, trained language models can fully learn different aspects of knowledge from the training dataset.

2.2.1 Scalable Prompt Generation

Inspired by the P-tuning (Liu et al., 2021c) method, we insert multiple continuous prompt tokens p_n into the input sentence x , transforming it into

$[\mathbf{x}][p_0, p_1, \dots, p_n][\text{MASK}]$. Different from the original P-tuning method, we invent two scalable designs to make it suitable for the prompt-based SSL pipeline.

Add Demonstration Examples: In this method, we add different demonstration examples to construct diverse prompts. This is similar to the prompt augmentation method, in which one chooses to add additional answered prompts to demonstrate what kind of answer the language model should produce for the MASK token (Liu et al., 2021a). These additional answered prompts are called the demonstration example $[demo]$. To reduce the discrepancy between the demonstration examples and the input sentences, we also add a fixed number of continuous prompt tokens p between the demonstration sentence and its true label. Thus, given the labeled input \mathbf{x}_d and its corresponding ground-truth label \mathbf{y}_d from the labeled training dataset, we construct the demonstration example as $[demo] = [\mathbf{x}_d][p_0, p_1, \dots, p_n][\mathbf{y}_d]$, where p_0, p_1, \dots, p_n are continuous prompt tokens.

After composing the demonstration examples $[demo]$, given a training input from the labeled dataset $x_t = (s_i, s_2, \dots, s_k) \in \mathcal{T}$ and label y_t , where s_i, s_2, \dots, s_k are input tokens for the PLM m , the prompt template function $P_1(x_t)$ is formally defined as

$$\begin{aligned} P_1(x_t)_1 &= [demo_1][\mathbf{x}_t][p_0, \dots, p_n][\text{MASK}] \\ \dots \\ P_1(x_t)_k &= [demo_k][\mathbf{x}_t][p_0, \dots, p_n][\text{MASK}] \end{aligned} \quad (3)$$

We create multiple prompts by adding different demonstration examples with exactly n continuous soft tokens with the input sentence. Demonstration examples are randomly sampled from the labeled datasets. For longer input sentences, we first truncate the length of $[demo]$ to fit the PLM requirement. Our intuition is that different demonstration examples will introduce the diversity necessary for SSL experimentation.

Vary Soft Token Numbers: In this method, we vary the number of continuous prompt tokens between different labeler models. In other words, this prompt function $P_2(x_t)$ with input sentence x_t is defined as

$$\begin{aligned} P_2(x_t)_1 &= [\mathbf{x}_t][p_0, p_1, \dots, p_{n_1}][\text{MASK}] \\ \dots \\ P_2(x_t)_k &= [\mathbf{x}_t][p_0, p_1, \dots, p_{n_k}][\text{MASK}] \end{aligned} \quad (4)$$

and each of the labeler models uses different n_1 to n_k number(s) of continuous prompt tokens p . Here, we do not prepend the demonstration example. Our intuition is that given different numbers of continuous prompt tokens, the optimized learned continuous prompts may also be different. For example, for AG’s News dataset (Zhang et al., 2015a) about news topics, the optimized prompts with two continuous prompt tokens could be: $[[\mathbf{x}][\text{News : }][\text{MASK}]]$, while optimized prompts with three continuous prompt tokens could be: $[[\mathbf{x}][\text{the category is}][\text{MASK}]]$. We expect that varying the number of continuous prompt tokens will have a similar impact to manually constructing different prompts.

2.2.2 Reparameterization Block

Li and Liang (2021) and Liu et al. (2021c) empirically show that directly updating the parameters in continuous prompts leads to unstable optimization. Hence, we first feed prompt embeddings through a reparameterization block rather than directly feeding them into the PLM. Our reparameterization block uses a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) network with a two-layer *ReLU* activated multilayer perceptron (MLP) (Liu et al., 2021c; Li and Liang, 2021).

We denote the random initialized tokens as p'_i and the real input embeddings, which are fed into the PLM, as p_i . The p_i are the output of the bidirectional LSTM network and the MLP as,

$$p_i = \text{MLP}([\text{LSTM}(p'_{0:i}), \text{LSTM}(p'_{i:n})])$$

where p_i is also the soft token used in Equations 3 and 4. We learn the optimized continuous prompt tokens $\hat{p}_{0:n}$ during the training process. With the downstream cross-entropy loss \mathcal{L}_c , we can differentially optimize the continuous prompts by:

$$\hat{p}_{0:n} = \underset{p}{\text{argmin}} \mathcal{L}_c(p_m(x|y), y) \quad (5)$$

2.3 Automatic Verbalizers

There are several automatic verbalizer methods that eliminate the need for human intervention and expertise to build mapping functions. We experiment with three types of automatic verbalizers: i) soft verbalizer (Hambarzumyan et al., 2021), ii) prototypical verbalizer (Cui et al., 2022), and iii) search-based verbalizer (Schick et al., 2020b).

Cui et al. (2022) experimentally show the superiority of the prototypical verbalizer in a supervised learning environment. However, they did not

conduct such experiments for SSL settings. Our experiment with the SSL PET method (details in Section 3.5) with different automatic verbalizers showed that the prototypical verbalizer performed better than the soft verbalizer and the search-based verbalizer on multiple datasets. Thus, we choose to use the prototypical verbalizer as a replacement for the manual verbalizer.

With the optimized embedding of the MASK token from PLM m and the ground-truth labels y , the prototypical verbalizer learns the prototype vectors for each class using contrastive learning (Oord et al., 2018). The prototypical verbalizer first initializes a prototype embedding for each class label and then uses the embedding of the MASK token as the instance embedding. It uses instance-instance loss \mathcal{L}_{ins} to maximize intra-class similarity and minimize inter-class similarity. Similarly, it uses instance-prototype loss \mathcal{L}_{proto} to maximize the similarity between the prototype and instances belonging to the same class and minimize the similarity of instances belonging to other classes. The probability distribution of the MASK token for each class is calculated by the cosine similarity between the instance embedding and each optimized prototype embedding. For inference, it assigns the class of the prototype vector to the instance with the highest probability score, which is computed by taking the similarity scores of the instance vector with the prototype vectors and normalizing them.

2.4 Training and Inference Strategy

All model parameters to be optimized are randomly initialized. As mentioned in Section 2.2.2 and 2.3, we update the parameters in the continuous prompts and PLMs with the loss \mathcal{L}_c and optimize the parameters in the verbalizers with the loss \mathcal{L}_{ins} and \mathcal{L}_{proto} . Instead of summing all losses together, our training strategy is to first freeze the parameters in the prototypical verbalizer and then train the parameters in the reparameterization block and the PLM together with the cross-entropy loss \mathcal{L}_c . Then we freeze the learned parameters and train the parameters in the prototypical verbalizers with instance-instance loss \mathcal{L}_{ins} and instance-prototype loss \mathcal{L}_{proto} . After training all labeler models and obtaining the class probability on the unlabeled dataset, we use \mathcal{L}_{div} to fine-tune the final language model classifier. During inference, we do not rely on any prompt-based labeler models and directly use the final fine-tuned language model \mathbf{F} to predict

on the test dataset.

3 Experiments

To verify the effectiveness of our framework, we conduct multiple semi-supervised learning experiments with several strong baseline frameworks on the commonly-used NLU benchmarks.

3.1 Dataset Collection

We experiment with five different datasets¹: AG’s News (Zhang et al., 2015a), Yahoo Answers (Zhang et al., 2015b), MNLI (MultiNLI, Multi-Genre Natural Language Inference, Williams et al. (2018)), RTE (Recognizing Textual Entailment, Dagan et al. (2006)) and CB (Commitment-Bank, de Marneffe et al. (2019)). AG’s News and Yahoo answers are topic classification (TC) datasets, while MNLI, RTE, and CB are natural language inference (NLI) datasets. In Table 1, we provide the number of distinct classes, the unlabeled dataset size used for SSL, and the test size for all five datasets. Details about the design of prompts and verbalizers can be found in Appendix A.

Dataset	Task	#Class	#Unlabeled	#Test
AG’s News	TC	4	40,000	7,600
Yahoo	TC	10	100,000	60,000
CB	NLI	3	30,000	56
RTE	NLI	2	20,000	277
MNLI	NLI	3	30,000	9,815

Table 1: Data statistics. TC= Topic Classification, NLI= Natural Language Inference

We perform multiple experiments in few-shot settings for all datasets. For few-shot experiments, we use 1, 5, 10, 20 examples per class for all datasets except for CB and RTE, where we experiment with 32 examples to align with earlier research work (Schick and Schütze, 2021). We report the average accuracy for the evaluation across three runs of each experiment with three different random seeds.

3.2 Proposed Models

Demo+Soft Tokens PET: The first method is to replace the manual verbalizer with the prototypical verbalizer and manual prompts with demonstration examples and continuous prompt tokens.

¹We downloaded these datasets using the script provided by OpenPrompt <https://github.com/thunlp/OpenPrompt>

Vary Soft Tokens PET: The second method is to introduce diversity by varying the number of continuous prompt tokens, and we use the prototypical verbalizer across multiple labeler models.

3.3 Models for Comparison

We design several strong baseline experiments in addition to our proposed models and also perform an ablation study to show the superiority of our proposed models in multiple NLU tasks.

3.3.1 Baseline Models

Fine-tune: This is a supervised method, where we directly fine-tune the RoBERTa-large PLM with training examples in different few-shot settings. In this method, we do not leverage the unlabeled data.

Prototypical Verbalizer PET: This is a semi-supervised learning method similar to Schick and Schütze (2021), but we replace the manual verbalizer with the prototypical verbalizer and keep the manual prompts. Experiments with this setup will show the benefits of applying automatic verbalizer in the PET framework.

Manual PET: This is a semi-supervised learning method from Schick and Schütze (2021). Our main goal is to show that, with our proposed method, we can achieve similar or better results than this manual method.

There are other SSL methods that rely on data augmentation without prompt tuning, such as UDA (Xie et al., 2020) and MixText (Chen et al., 2020). Since their performance is consistently worse than the Manual PET model across multiple datasets (Schick and Schütze, 2021), we do not choose these models for comparison in this work.

3.3.2 Model Intervention for Ablation Study

Fixed Soft Tokens PET: This semi-supervised learning method is similar to our second proposed method, where we vary the number of continuous tokens to create multiple prompts. However, here we keep the number of continuous tokens fixed and do not add demonstration examples as well. This experiment will help us to understand the importance of diversity introduced by varying continuous tokens in prompt design.

Demo+Soft in SL: This is a supervised method, where we use a prompt template to transform the input by adding a randomly selected demonstration example from the training data and a fixed number of continuous prompt tokens to the input,

and we use the prototypical verbalizer for classification. We use RoBERTa-large for PLM. With this experiment, we try to understand the power of semi-supervised learning methods with multiple prompts over supervised training.

3.4 Implementation Details

We use the RoBERTa-Large model (Liu et al., 2019) as our PLM for all of our experiments. We use AdamW as our optimizer with a learning rate of $1e-5$ and a weight decay of 0.01 with linear scheduler, batch size of 2, and trained for 5 epochs. The reparameterization block contains 2-layer bidirectional LSTM and 2 linear layers with ReLU activation function. The hidden dimension of the linear layer and LSTM layer is 768, as well as the hidden dimension of Roberta-Large. We train the parameters in the reparameterization block and the PLM together. For the prototypical verbalizer, we base our implementation on the Pytorch², Huggingface transformer³, and OpenPrompt⁴ frameworks (Ding et al., 2021). The number of continuous prompt tokens is consistent 5. For our Vary Soft Tokens PET, we prepare 5 prompts for each dataset and the number of soft tokens in each prompt ranges from 1 to 5.

3.5 Results of Multiple Automatic Verbalizers

Datasets	# instances	SSL PET		
		SoftVerb	SearchVerb	ProtoVerb
AG’s News	10	49.4	80.5	77.2
Yahoo	10	11.8	34.0	51.9
CB	32	88.7	73.2	85.7
RTE	32	48.2	50.2	52.8
MNLI	10	39.0	37.0	50.0

Table 2: Average accuracy on different datasets by replacing manual verbalizers with automatic verbalizers in the PET SSL setup. For CB and RTE, we use 32 training examples, whereas for other datasets, we use 10 training examples to train labeler models. The best performance is marked in bold.

To understand which automatic verbalizer is a better replacement for manual verbalizer, we first experiment with three automatic verbalizers: soft verbalizer (Hambardzumyan et al., 2021; Liu et al., 2021c,b), search verbalizer (Gao et al., 2021; Shin et al., 2020a; Schick et al., 2020a), and prototypical verbalizer (Cui et al., 2022). For all of these

²<https://pytorch.org/>

³<https://huggingface.co/>

⁴<https://github.com/thunlp/OpenPrompt>

experiments, we apply experimental setups similar to PET paper, but only replace the manual verbalizer with the automatic verbalizer (Schick and Schütze, 2021). Table 2 shows the average accuracy over three runs with three different seeds on different datasets with these verbalizers. From Table 2, the prototypical verbalizer shows better performance than other verbalizers for three (Yahoo, RTE, and MNLI) out of five datasets. The search verbalizer and soft verbalizer models perform better than the prototypical verbalizer model only on one dataset each. Since the prototypical verbalizer performs better than other verbalizers in majority of the datasets, we decided to use this as our automatic verbalizer.

3.6 Comparison with Manual PET

With the prototypical verbalizer as our automatic verbalizer, we then experiment with our proposed methods for automatic prompt design. Table 3 shows our results on different datasets and tasks in the few-shot setting. Table 3 shows that by only replacing the manual verbalizer with the prototypical verbalizer (column **Protoverb**) and keeping other aspects of the experiment the same as the PET method, we can achieve slightly lower performance (70.1 average accuracy) compared to Manual PET (71.4 average accuracy) (Schick and Schütze, 2021). This shows that to eliminate human involvement in designing verbalizers, we can simply replace the manual verbalizer with the prototypical verbalizer with only a little performance sacrifice.

For our next set of experiments, we replace manual prompts with our proposed method, automatically creating multiple prompts. The first method (Demo+Soft Tokens PET), which adds randomly sampled demonstration examples from training data with a fixed number of trainable continuous prompt tokens with input, achieves better performance than Manual PET method. The next method (Vary Soft PET), in which we vary the number of continuous trainable tokens, also achieves better performance than Manual PET method. For topic classification tasks, under multiple few-shot settings, the average accuracy of Demo+Soft and Vary Soft PET are 77.0 and 77.3, respectively, while the average accuracy of Manual PET method is 77.1. Similarly, for NLI datasets under different few-shot settings, the average accuracy of our Vary Soft PET method is 69.6 and Demo+Soft Tokens

PET method is 70.7. Both of these results are better than Manual PET method (67.7). Furthermore, across all these datasets, Demo+Soft Tokens PET and Vary Soft PET achieve an average performance of 73.2 and 72.6, respectively. These results are better than Manual PET (71.4) method. This experiment shows that it is possible to completely eliminate human involvement and expertise in designing prompts and verbalizers for the SSL pipeline with even better performance.

We also observe that for the case of one-shot experiments with MNLI dataset, Demo + Soft PET method obtains an accuracy of 36.1, which is much worse than other prompt baseline models. This may be due to randomly sampled [*demo*] examples, as previous studies have shown that the choice of examples in the few-shot setting can result in high-variance performance (Lu et al., 2021). In future work, we can utilize sentence embeddings to make intelligent decisions while selecting demonstration examples.

3.7 Ablation Study

3.7.1 Impact of Semi-supervised Learning

We compare our proposed methods with supervised learning methods: fine-tuning and prompt-based tuning methods (Demo+Soft in SL). All semi-supervised learning methods perform significantly better than supervised learning methods. Traditional fine-tuning methods perform the worst (45.1 average accuracy) on different datasets and tasks. Demo+Soft in SL method is similar to our proposed Demo+Soft Tokens PET method but does not make use of unlabeled data. Demo+Soft in SL performs better than the fine-tuning method and achieves an average accuracy of 68.7 on multiple datasets and tasks in different few-shot settings. Both of the supervised learning methods perform worse than any SSL prompting model, indicating the necessity of the SSL pipeline in NLU tasks.

3.7.2 Impact of Diversity in the Prompts

In order to understand the effect of introducing diversity through multiple prompts in SSL, we devise another experiment, where we use the SSL setup but use only **one** prompt labeler model (not adding a demonstration example but using trainable soft tokens) to label unlabeled data. We name this method as Fixed Soft Tokens PET. Table 3 shows that in most comparisons (13/14), our proposed Vary Soft PET or Demo+Soft PET method achieves better performance. When comparing with the Fixed Soft

Overall Avg	-	73.2	72.6	72.3	70.1	71.4	45.1	68.7

Table 3: Few-shot experiment results (average accuracy) on different datasets with our proposed methods in PET SSL setup. For CB and RTE, we use 32 training examples, whereas for other datasets we use {1, 5, 10, 20} randomly selected examples per class for few-shot learning experiments. The best performance is marked in bold. Note that to report the average results for NLI task, we first average over the MNLI results under different few-shot settings, and then average over the three NLI datasets to give each task equal weight. The overall average results are computed following a similar approach, giving each dataset an equal weight.

PET, our proposed Demo+Soft PET shows an improvement of average accuracy from 72.3 to 73.2 ($p < 0.05$ by paired t test) (Hsu and Lachenbruch, 2014). Moreover, both Demo+Soft and Vary Soft PET methods obtain better average performance than the Fixed Soft Tokens PET in NLI and topic classification tasks. These results show the importance of diversity introduced by multiple prompt labeler models.

4 Related Work

4.1 Language Model Prompting

Cui et al. (2021) authors fine-tuned the pre-trained generative language model, BART, with a pre-defined template (*candidate_span* is a *entity_type* entity) for NER classification. Wang et al. (2021) proposed Entailment as Few-shot Learner (EFT) method, which transforms classification tasks into natural language textual entailment tasks and then fine-tunes the LM. The transformation also makes it easy to leverage unsupervised contrastive data augmentation methods to add pairwise examples to the limited annotated data. This setting further showed an average 2.7% improvement in 15 different NLP tasks. In addition to using the prompts

for supervised learning, PET is the SoTA method to adapt the manual prompts along with semi-supervised learning to obtain strong performance across multiple NLU tasks. (Schick and Schütze, 2021).

4.2 Automatic Prompts and Verbalizers

Shin et al. (2020a) used a gradient-guided search to find the discrete tokens for prompts based on task accuracy, initialize tokens, and then fine-tune the LM. For automatic label token selection, they first train a logistic regression classifier from the contextualized embedding of the MASK token and then predict the score from MLM’s output word embeddings. They select the top-k highest scoring words for each label. They showed better performance over manual prompting methods for sentiment classification and textual entailment tasks. Similarly, instead of using a gradient-guided search for prompt tokens, Li and Liang (2021) and Lester et al. (2021) attached prefix vectors and learned the embeddings for prefix vectors by keeping the LM model parameters frozen. Liu et al. (2021c) proposed P-tuning, which replaces the input embeddings of pre-trained language models with its differentiable output embeddings, using the pat-

tern based on human design. Liu et al. (2021b) optimized and adapted the Prefix Tuning model for NLU. Vu et al. (2021) proposed to learn soft prompt embeddings from one or more source tasks and then transfer them to initialize the prompts for the target task. In addition, they also proposed an efficient retrieval approach to find task embeddings and predict the most transferable source tasks for a given novel target task.

Several automatic verbalizers, such as search-based verbalizers, soft verbalizers, and prototypical verbalizers, have been proposed to automate the design of the verbalizer mapping function. Search-based verbalizers aim to find the appropriate tokens to replace human selection (Schick et al., 2020a; Shin et al., 2020b; Gao et al., 2020). Both soft verbalizers and prototypical verbalizers learn trainable class or prototype embeddings during the training process (Cui et al., 2022; Zhang et al., 2021; Hambardzumyan et al., 2021).

Mahabadi et al. (2022) proposed a prompt-free method (PERFECT) to train the language model, which does not rely on manual commands and verbalizers. PERFECT reported performance similar to that of PET (Schick and Schütze, 2021) in a few-shot setting. However, they used a supervised learning setup and compared their results with the single labeler model with one prompt rather than the results from the final classifier. Here, we use a similar SSL setting to Schick and Schütze (2021) and report the results of the final classifier.

5 Conclusions

In this paper, we are able to successfully use automatic prompts and verbalizers in semi-supervised learning settings. We show that our proposed automatic prompt generation methods with prototypical verbalizer can eliminate human engineering in prompt-based SSL setup and achieve similar or better performance than the SoTA Manual PET method. Our methods have the added advantage of being scalable with multiple tasks and datasets. We also empirically verify the power of semi-supervised learning methods, which take advantage of large amounts of unlabeled data, over supervised methods.

In the next steps, we plan to investigate whether we would be able to achieve similar performance by freezing PLMs’ parameters and only tuning verbalizer and prompt parameters. This setup will save a tremendous amount of space by making it easy

to share and reuse PLMs. Moreover, we plan to explore ways to combine the two proposed methods Demo+Soft PET and Vary Soft PET, which would take advantage of both methods.

6 Limitations

Although we experiment with multiple NLU tasks and datasets, these datasets are only in the English language. Prompt-based learning relies on large language models, which have acquired knowledge through pre-training on huge corpora. With low-resource languages, it might be difficult to get PLMs trained on a huge corpus, which might make it hard to reproduce performance similar to the English corpus. The fine-tuning and inference of PLM requires multiple large GPUs, which might not be accessible to everyone.

A Prompts and Verbalizers

A.1 Manual Prompts and Manual Verbalizers

We use the same manual prompts and manual verbalizers for our baseline experiment as used by Schick and Schütze (2021, 2020).

AG’s News is a news topic classification dataset with four classes. We use the manual verbalizer that maps class 1-4 to “World”, “Sports”, “Business” and “Technology”. For the input sentence $x = (a, b)$, where a is the news headline and b is the

body of the news text, we use the manual prompts below:

$$\mathcal{P}_1(x) = [\text{MASK}] : [a] [b]$$

$$\mathcal{P}_2(x) = [\text{MASK}] - [a] [b]$$

$$\mathcal{P}_3(x) = [a] ([\text{MASK}]) [b]$$

$$\mathcal{P}_4(x) = [a] [b] ([\text{MASK}])$$

$$\mathcal{P}_5(x) = [\text{MASK}] \text{ News: } [a] [b]$$

$$\mathcal{P}_6(x) = \text{Category : } [\text{MASK}] [a] [b]$$

Yahoo Questions is another dataset for topic classification with ten classes. We use the same manual prompts as AG’s News, but define the manual verbalizer for the Yahoo dataset, which maps the classes 1-10 to “Society”, “Science”, “Health”, “Education”, “Computer”, “Sports”, “Business”, “Entertainment”, “Relationship” and “Politics”.

MNLI is the dataset for textual entailment tasks, consisting of text pairs $x = (a, b)$. We define two manual verbalizer pairs v_1 and v_2 . v_1 verbalizer maps class 0-2 to “Wrong”, “Right” and “Maybe”. v_2 verbalizer maps class 0-2 to “No”, “Yes”, “Maybe”. We use the following manual prompts:

$$\mathcal{P}_1(x) = “[a]” ? || [\text{MASK}], “[b]”$$

$$\mathcal{P}_2(x) = [a] ? || [\text{MASK}], [b]$$

RTE and **CB** are datasets for textual entailment tasks. We use v_1 as the manual verbalizer similar to MNLI task. We use the following manual prompts:

$$\mathcal{P}_1(x) = “[a]” ? || [\text{MASK}], “[b]”$$

$$\mathcal{P}_2(x) = [a] ? || [\text{MASK}], [b]$$

$$\mathcal{P}_3(x) = [a] ? || [\text{MASK}]. [b]$$

$$\mathcal{P}_4(x) = “[a]” ? || [\text{MASK}]. “[b]”$$

A.2 Continuous Prompts

For our proposed models: **Demo+Soft** and **Vary Soft** models, we apply continuous prompts and automatic verbalizers to ensure that the prompt-tuning SSL method can be scaled across multiple datasets. From previous works, we find that few anchor tokens help to improve the performance of NLU tasks (Liu et al., 2021c), so we design two different continuous prompts dependant on the nature of NLU tasks. For the continuous prompt for AG’s News and Yahoo Questions (text classification task), our design is:

$$\mathcal{P}(x) = [a] [b] \text{ Category: } [p_0, p_1, \dots, p_n] [\text{MASK}]$$

For continuous prompt for MNLI, CB and RTE (NLI tasks), our design is:

$$\mathcal{P}(x) = [a] [b] ? [p_0, p_1, \dots, p_n] \text{ answer : [MASK]}$$

The construction of continuous prompts also follow the design of the P-tuning paper (Liu et al., 2021c). Rather than designing multiple manual prompts for different datasets, we can use our proposed methods to automate this process. This reduces human efforts and costs when we scale across multiple datasets and tasks.

Novel Feature Discovery for Task-Oriented Dialog Systems

Abstract

A novel feature represents a cluster of semantically equivalent novel user requests e.g., requests to play a song on a service or reading user’s messages. Detecting and supporting novel features is crucial towards wider adoption of dialog systems by end users. Intuitively, features are represented by a combination of intents, slot types and/or their values. For example, while playing a song is a feature represented by a single intent (`PlayMusic`) only, playing a song on a service is another feature represented by the combination of `PlayMusic` intent and `ServiceName` slot type. Prior work on novelty detection limits the scope of features to those represented by novel single intents, leading to (1) giant clusters spanning several user-perceived fine-grained features belonging to the same intent, (2) incoherent interpretation of clusters from users’ perspective (no direct connection to some user-perceived feature), and (3) missing those features spanning several intents. In this work, we introduce *feature discovery* as opposed to single intent discovery, which aims at discovering novel features spanning a combination of intents and slots, and present a technique for discovering novel features from user utterances. Experiments on two datasets demonstrate the effectiveness of our approach and consistently show its ability to detect novel features.

1 Introduction

Advances in Natural Language Understanding (NLU) have led to accelerated adoption of dialog systems such as Apple Siri and Amazon Alexa by end users. Standing at the core of a dialog system is an NLU model for parsing and understanding user utterances. Two of the key tasks of an NLU model are (1) Intent Classification, which classifies an utterance into a fixed set of intent labels, and (2) Slot Labeling, which classifies slot values into a predefined set of slot types (Weld et al., 2023). Determining the intent guides the dialog system

to perform the proper actions as response to user’s utterance. For example, user utterances “*play some music*” and “*play despacito*” express the intent `PlayMusic`, while “*how is the weather?*” and “*is it raining today*” express the intent `GetWeather`. Intents can be further grouped into domains, for instance, `PlayMusic` and `RateSong` intents belong to `Music` domain. Detecting slots and their corresponding values within an utterance gives information about objects upon which the actions should be performed. For example, ‘*despacito*’ in “*play despacito*” is of type `SongName`.

A feature represents a user *experience* with the dialog system, for example, playing a song on a service or reading user’s messages. Over time, users build up expectations about the features/experiences that the dialog system offers. Unsupported features cause friction and degrade user’s experience. In terms of NLU, a novel feature could be mapped to a new combination of domain(s), intent(s), slot(s) and/or their values, where each is not necessarily novel. For example, while `PlayMusic` intent was seen by the dialog system, the combination of `PlayMusic` and `ServiceName` is never seen before, causing friction with the NLU model when parsing utterances like “*play despacito on spotify*”. Consequently, it becomes crucial to discover such features that are frequently requested by the users but are still unsupported by the NLU model, which we address in this work.

The task of novel intent discovery has been intensively studied in prior work, by harnessing unsupervised techniques (e.g., Liu et al., 2021) or semi-supervised methods for incorporating existing knowledge from labeled data (e.g., Vedula et al., 2020a; Lin et al., 2020; Zhang et al., 2021). Existing work limits the scope of novel features to those represented by novel single intents. However, this does not cover all types of features that naturally span several domains, intents, slots and their values. Consider the following user utterances, “*play*

despacito”, “*play despacito on spotify*” and “*play despacito in 30 minutes*”. While the utterances belong to the same intent `PlayMusic`, handling each of them is different. The first requires the dialog system to play a song on the device itself, the second asks for playing the same song on a specific service, namely Spotify, while the third requires playing the song after a certain amount of time is elapsed. Moreover, each request corresponds to a different user experience and requires a different underlying implementation for responding. Assuming `PlayMusic` intent is novel, applying standard novel intent discovery will group the three utterances in a single cluster, which creates two issues: (1) having many different user-perceived experiences within the same intent (play song on device, on specific service or after some time), results in a giant cluster that needs manual inspection to be decomposed into smaller sub-groups to make meaningful business decisions, and (2) while the cluster represents a novel intent, it might not correspond to a user perceived experience – what the end users are looking for. On the other hand, assuming `PlayMusic` intent is not novel, intent discovery might miss those features at more fine-grained levels. For instance, playing a song on a service might not be detected as novel. Additionally, intent discovery cannot handle those features spanning several intents.

To allow for general feature discovery, and close the gap between user requests and the underlying models, we define a *feature* to be any combination of domain(s), intent(s) and slot(s) and/or their value(s) and move towards discovering clusters of utterances with novel feature definitions rather than only focusing on novel single intents. Novel intent discovery can be seen as a special case of feature discovery, where new features correspond to new intents unseen before.

In this paper, we present DNF (Discovery of Novel Features), a semi-supervised approach for discovering novel features from a given set of user utterances with respect to an underlying NLU model. Our method consists of a cascaded system with two steps: feature clustering and novelty detection. First, we employ state-of-the-art language model BERT (Devlin et al., 2019) with multi-stage fine-tuning to produce feature/experience-aware representations of user utterances. Then, user utterances are clustered into features. Second, we classify each resulting feature cluster as either novel or

already supported by the NLU model. The salient contributions of our paper are:

- We introduce *Feature Discovery*, where, given a set of user utterances and a trained natural language understanding model, we extract clusters of novel features.
- We present DNF, an approach for discovering novel features from user utterances.
- We conducted extensive experiments on two datasets, the SNIPS dataset augmented with feature labels, and our internal real-world dataset. Experimental results demonstrate the effectiveness of our method across the two datasets.

2 Related Work

Intent classification and slot labeling are two fundamental tasks in spoken language understanding, dating back to early 90’s (Price, 1990). With the rise of task-oriented dialog systems, the two tasks have seen more attention, and progress has been made by applying various deep learning approaches (e.g., Abujabal and Gaspers, 2019; Abujabal et al., 2021; Goo et al., 2018; Jolly et al., 2020; Mesnil et al., 2013).

Discovering novel domains and intents from a pool of user utterances has been well addressed in earlier works, with fully unsupervised and semi-supervised settings. These include clustering user utterances with novel domains or intents individually, using various techniques such as constrained deep adaptive clustering (Lin et al., 2020), deep aligned clustering (Zhang et al., 2021), contrastive learning (Gao et al., 2021), capsule network (Liu et al., 2019; Xia et al., 2018), open intent extraction (Vedula et al., 2020b), and others (e.g., Lin and Xu, 2019; Shivakumar et al., 2019; Yan et al., 2020; Kim and Kim, 2018). Alternatively, Vedula et al., 2020a explore the joint discovery of domains and intents, using hierarchical linking to form an intent-domain taxonomy. The task is also performed jointly with slot filling in recent works (Wang et al., 2018; Goo et al., 2018; Kim et al., 2017; Castellucci et al., 2019; Gangadharaiah and Narayanaswamy, 2019; Liu and Lane, 2016). All of the above works require a small amount of labeled data as prior knowledge to guide the discovery process.

The most prominent work for detecting novel intents without any prior knowledge was proposed by Liu et al. (2021), which employs a pre-trained network for generating sentence embeddings, and

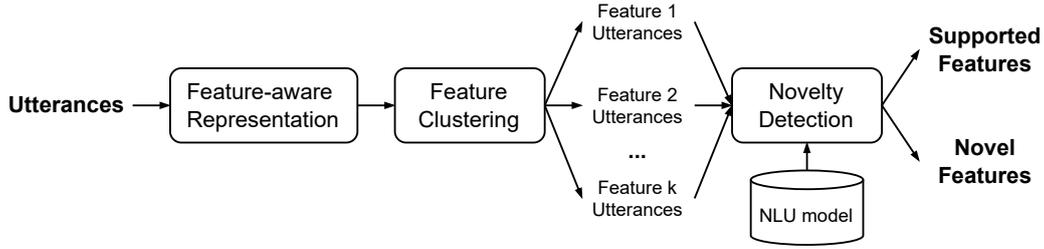

Figure 1: DNF overview with feature-aware fine-tuning, feature clustering and novelty detection.

K-Means for intent clustering. However, due to the limited supervision, the method is shown to perform poorly on novel domains.

All of the above methods are limited to a discovery objective at intent level, and thus fail to operate on more fine-grained levels (e.g., slot type and/or value) within the same intent. Moreover, they fail to detect features composed of multiple domains, intents and/or slots.

3 Methodology

Given a set of user utterances $\{u_1, u_2, \dots, u_n\}$, we aim to detect a set of clusters $\{C_1, \dots, C_m\}$ where each C_j is a cluster of utterances pertaining to a novel feature and m is the total number of novel features. As depicted in Figure 1, our method consists of two components, feature clustering and novelty detection. First, we assign each utterance u_i a feature label and eventually produce a set of feature-labeled utterances $(u_1, f_1), \dots, (u_n, f_k)$, where f_1, f_2, \dots, f_k is the list of k unique features. This is performed by employing an utterance representation model specifically trained with both feature-labeled and -unlabeled data to project the input utterances into a feature-aware vector space that helps clustering the input utterances into k features. Second, a feature novelty detection model is used to classify each of the k feature clusters as either novel or already supported by the dialog system. We measure the novelty of a feature by exploiting signals from the NLU model. With DNF being a semi-supervised technique, we distinguish between two types of training data supervision: *feature-labeled* and *feature-unlabeled* utterances:

- Feature-labeled training data ($Train_L$): each utterance is annotated with its feature label f along with its intent label I and slot labels $S = \{s_1, s_2, \dots\}$ where each s_i is a pair of slot type and its value in the utterance such as `SongName:despacito` and `ServiceName:spotify`.

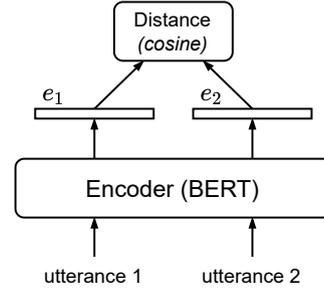

Figure 2: Fine-tuning with utterance similarity.

- Feature-unlabeled training data ($Train_U$): each utterance is only annotated with its intent and slot labels, however, with no feature label. In comparison to feature-labeled data, such data can be obtained in larger quantities and helps the feature discovery process as we exploit information about utterances’ intent and slots.

3.1 Feature-Aware Utterance Representation

To first encode utterances as high-dimensional vectors separable in the feature space, we use a representation model specifically adapted for feature awareness. To this end, we employ the state-of-the-art language model SBERT – Sentence BERT (Reimers and Gurevych, 2019), which is a BERT model pretrained for generating sentence embeddings. Specifically, by feeding an utterance u into SBERT, we get a list of token embeddings $[CLS, t_1, t_2, \dots, t_m]$, where CLS is the classification token. By applying mean-pooling, we obtain the representation vector of u :

$$e_u = \text{mean-pooling}([CLS, t_1, t_2, \dots, t_m])$$

We transfer feature knowledge into the utterance representation model through a multi-stage fine-tuning process as described below.

3.1.1 Utterance Similarity

As depicted in Figure 2, we use a Siamese Neural Network (SNN) training paradigm for transferring feature knowledge into the model. The intuition

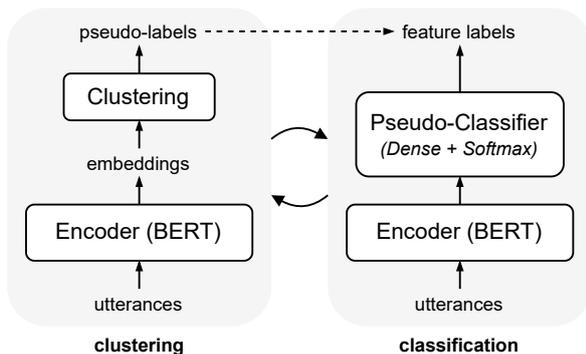

Figure 3: Fine-tuning with pseudo-classification.

behind this fine-tuning step is to directly optimize the utterance representations based on their feature similarity. In particular, a pair of utterances (u_i, u_j) is encoded into its respective embedding vectors e_i and e_j . The utterance feature similarity is computed as the cosine distance between the two vectors, and is optimized towards minimizing the distance between utterances belonging to the same feature. As our training data are both feature-labeled ($Train_L$) and feature-unlabeled ($Train_U$), we consider three kinds of training samples for this fine-tuning step:

1. Both u_i and u_j are sampled from the same $Train_L$ feature: (u_i, u_j) is a positive sample.
2. Both u_i and u_j are sampled from $Train_L$, but are from different features: (u_i, u_j) is a negative sample.
3. u_i is sampled from $Train_L$ and u_j is sampled from $Train_U$: (u_i, u_j) is a negative sample.

For case 3, it is possible that the training sample is a false-negative, since the actual feature-label of u_j could be the same as of u_i . However, we hypothesize that the number of such false-negative utterance pairs is much lower than the true-negative pairs given the large size of this training set.

As the number of utterance pairs is quadratic, we use a simple way to build a random dataset for each training epoch. For each utterance u_i in $Train_L$, we randomly sample an utterance u_j that belongs to the same feature as a positive sample, and k negative samples from both $Train_L$ and $Train_U$; hence maintaining the ratio of $1 : k$ between the number of positive and negative pairs. Empirically, we found that setting $k = 3$ provides a decent balance between positive and negative pairs.

3.1.2 Pseudo Classification

Utterance similarity considers pairwise distances between utterances, without setting global constraints across all utterances. Moreover, it optimizes the distances according to the feature-labeled clusters in $Train_L$ but does not consider the unknown feature clusters in $Train_U$. The second fine-tuning step, shown in Figure 3, aims to overcome the above issues. Inspired by the DeepCluster work (Caron et al., 2018), pseudo classification is a semi-supervised iterative training process, alternating between *clustering* and *classification*.

In the *clustering* step, we first encode the training utterances into their representation vectors. Then a clustering algorithm is used to group the representation vectors into clusters while assigning a pseudo-label to each cluster. We use COP-K-Means (Wagstaff et al., 2001) as the clustering algorithm – an extension of K-Means that allows putting constraints on the clustering process. For example, which utterances must be grouped in the same clusters, and which must not. In our case, utterances belong to the same feature cluster inside $Train_L$ must be grouped in the same candidate cluster given by COP-K-Means.

In the *classification* step, we fine-tune the BERT encoder by employing a feature classification task using the pseudo-labels generated from the clustering step as the ground truth feature labels. The pseudo-classifier consists of a dense layer followed by a softmax on top of the encoder. In the DeepCluster approach, the pseudo-classifier is reinitialized after each iteration, since the indices of the pseudo-labels are permuted randomly after each clustering step. This makes training slow as the parameters cannot be reused. To alleviate this issue, we adopt the cluster centroid alignment technique proposed by Zhang et al. (2021), where we re-assign the pseudo-label indices from the clustering step, and thus, aligning them with the pseudo-classifier trained from the previous iteration. This allows the parameters to be reusable across iterations, hence speeding up training.

Compared to utterance similarity, pseudo classification clusters $Train_U$ utterances, either into $Train_L$ clusters or into totally new ones. Figure 4 compares the expected effect of the two steps.

3.1.3 Slot Classification

Information about slots in user utterances is a good source for feature awareness. For instance, while “play *despacito*” and “play *despacito* on *spotify*” are

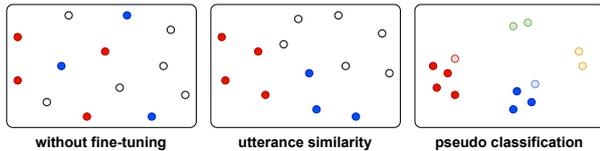

Figure 4: Utterance similarity vs. pseudo classification. Solid red and blue dots are $Train_L$ utterances, while green and yellow dots are $Train_U$ utterances grouped in new clusters.

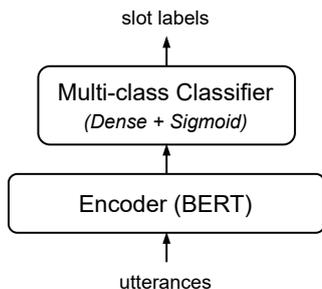

Figure 5: Fine-tuning with slot classification.

semantically similar utterances, the existence of `ServiceName:spotify` slot hints at the existence of a fine-grained user feature of playing a song on a service. In contrast to utterance similarity and pseudo classification, slot classification does not directly pull/push the utterances close to or far away from each other in the embedding space. Instead, we aim to make the representation model aware of the presence of slots in the input utterances, and we hypothesize that such information guides the model towards producing utterance representation with better feature separability.

This is modeled as a multi-class classification task (Figure 5), where the model is trained to detect which slots appear in the input utterances (e.g., `ServiceName`). Concretely, we add on top of the encoder a multi-class classifier, comprising a dense layer followed by sigmoid activation, and fine-tune the model using binary-cross-entropy loss. Note that we do not consider the exact position of the slots in the utterances, but rather their presence.

3.2 Feature Clustering

At inference time, we encode user unlabeled utterances into their representation vectors and use K-Means to cluster them into k feature clusters. To automatically choose the optimal value of k , we employ two techniques, namely the Elbow method (Thorndike, 1953) and the Silhouette score (Rousseeuw, 1987). Since utterances are a mix of novel and supported features, we classify whether

each candidate feature cluster is novel using a feature novelty detection model, described next.

3.3 Feature Novelty Detection

While the trained representation model helps at projecting the utterances into a feature-separable space, it lacks information regarding feature’s novelty w.r.t the NLU model. We detect novel feature clusters by exploiting signals from the NLU and utterance representation models. The NLU model is trained to jointly recognize intent and slot labels. The intent classifier (IC) and slot tagger (ST) heads are plugged on top of a BERT encoder. Slot labels follow the BIO schema (Ramshaw and Marcus, 1995). Note that our approach is agnostic to the choice of the NLU model. For novelty detection, we define the novelty confidence of each candidate feature cluster $C = \{u_1, u_2, \dots\}$ as the average novelty of its utterances:

$$feat_{novel}(C) = \frac{1}{|C|} \sum_{u \in C} utt_{novel}(u)$$

where utt_{novel} is computed as follows:

$$utt_{novel}(u) = mean(st(u), ic(u), pc(u))$$

where *slot tagging confidence* (st) is the confidence produced from the slot tagger. We tested with two variants: average over tokens (st_{avg}), and minimum over tokens (st_{min}). *Intent classification confidence* (ic) is the confidence of the most probable intent label produced by the intent classifier. *Pseudo classification confidence* (pc) is the confidence of the most probable pseudo cluster, produced by the pseudo-classifier from the utterance representation model. Feature clusters with novelty score greater than a pre-defined threshold are labeled as novel.

4 Experimental Setup

We evaluate the performance of each component of DNF independently as well as the overall discovery system using two datasets: SNIPS and a large French internal dataset.

4.1 Datasets

The SNIPS dataset (Coucke et al., 2018) consists of 14K English utterances spanning 7 intents with 72 unique slot labels. Since the dataset does not contain any feature labels, we augment it with feature labels using hand-crafted rules. We end up with a total of 43 features, each of which forms a cluster of utterances that semantically map to a

user-perceived feature. Features cover three combinations:

- **Slot value features:** utterances in these features share the same intent, slots and at least one slot value. For example, “*play a song on spotify*” and “*play music on spotify*” belong to the same feature of *playing a song on Spotify service*.
- **Slot features:** utterances in these features share the same intent and same slots. For example, “*what is the weather tomorrow in new york*” and “*weather tonight in brooklyn*” belong to the same feature of *asking about weather at a specific time in a specific city*.
- **Intent features:** utterances in these features share the same intent, with potentially, several slots and/or slot values. For example, “*book me a restaurant tomorrow at 9pm*” belong to the feature of *booking a restaurant*.

Given the nature of the dataset, it was not possible to create cross-intent features that are semantically sensible. Out of the 43 features, 11 are used as a test set, while 32 as a training set, where 19 out of the 32 features are feature-labeled $Train_L$, and 13 features are feature-unlabeled training set $Train_U$. These 32 features are deemed supported by the NLU model, i.e., not novel. Out of the 43 features, 26 are slot value features, 15 are slot features, while 2 are intent features. We randomly sample utterances out of 32 features and add them to the test set so that our test set contains a mix of supported and novel features. The final dataset contains 32 features as training set and 43 features in the test set (11 of which are novel). On average, we have 210 utterances per feature cluster.

Our internal dataset has a total of 273K utterances comprising 41 features with different combinations. 15 out of the 41 features span single intent while the other features span two or more intents. 31 features are included in the feature-labeled training set $Train_L$. The number of utterances without feature labels in $Train_U$ set is in the order of millions. The remaining 10 features are part of the test set. We also sample utterances out of 31 features and add them to the test set. The final test set contains 41 features (10 of which are novel). The dataset covers 14 domains, 89 intents, 128 slot labels and has, on average, 6.6K utterances per feature cluster. All utterances were pre-processed such that users are not identified.

Table 1: Feature-aware utterance representation performance on SNIPS and internal datasets.

Training Strategy	SNIPS			Internal Dataset		
	NMI	ARI	ACC	NMI	ARI	ACC
<i>No fine-tuning</i>	0.626	0.309	0.396	====	<i>baseline</i>	====
<i>US only</i>	0.737	0.451	0.512	+0.096	+0.147	+0.149
<i>PC only</i>	0.728	0.374	0.471	+0.116	+0.161	+0.130
<i>US→PC</i>	0.749	0.475	0.537	+0.116	+0.178	+0.166
<i>SC→US→PC</i>	0.766	0.474	0.557	+0.104	+0.166	+0.129
<i>(SC+US)→PC</i>	0.782	0.531	0.605	+0.137	+0.216	+0.140

To assess the ability of our model to accurately cluster cross-domain features, we split the internal dataset into:

- **Single-domain features**, where utterances belong to the same domain. 32 out of the 41 features are single domain features (25 train and 7 test), and
- **Cross-domain features**, where utterances belong to multiple domains (e.g., `Music` and `SmartHome`). 9 out of the 41 features are cross-domain features (6 train and 3 test). Features in these two splits cover different combinations.

4.2 Feature-Aware Utterance Representation

We use SBERT as a baseline utterance representation model, and compare different variants fine-tuned on different feature-related tasks. We consider the following fine-tuning strategies:

- *No fine-tuning*: We directly use the SBERT base model for utterance representation.
- *Utterance Similarity (US)*: The model is fine-tuned with only utterance similarity.
- *Pseudo Classification (PC)*: The model is fine-tuned with only pseudo classification.
- *US→PC*: The model is fine-tuned with both utterance similarity and pseudo classification sequentially.
- *Slot Classification (SC)→US→PC*: The model is fine-tuned with slot classification, utterance similarity and pseudo classification sequentially.
- *(SC+US)→PC*: Slot classification and utterance similarity are jointly trained to prevent overfitting, and then pseudo classification.

We use `paraphrase-mpnet-base-v2`, a pre-trained SBERT model, where we unfreeze all the layers during fine-tuning. We use AdamW as our optimizer (Loshchilov and Hutter, 2017), with an initial learning rate of $5e^{-5}$ and a weight decay

Table 2: Performance across different feature types.

Feature Type		SNIPS			Internal Dataset		
		NMI	ARI	ACC	NMI	ARI	ACC
By Novelty	<i>supported</i>	0.836	0.698	0.746	0.949	0.870	0.849
	<i>novel</i>	0.741	0.566	0.637	0.772	0.640	0.662
By Combination	<i>slot</i>	0.753	0.610	0.626	–	–	–
	<i>slot value</i>	0.811	0.590	0.646	–	–	–
	<i>intent</i>	0.547	0.512	0.804	–	–	–

Table 3: Intent-agnostic vs. intent-targeted discovery.

Intent	Intent-agnostic			Intent-targeted		
	NMI	ARI	ACC	NMI	ARI	ACC
<i>AddToPlaylist</i>	0.544	0.402	0.595	0.671	0.573	0.789
<i>PlayMusic</i>	0.700	0.429	0.527	0.747	0.625	0.672
<i>SearchCreat.Work</i>	0.631	0.431	0.598	0.766	0.602	0.707
<i>SearchScrn.Event</i>	0.639	0.474	0.634	0.740	0.541	0.678

of 0.01. We set the batch size to 16 and apply early stopping whenever we observe no improvement on a development set. On average, all fine-tuning strategies converge after 4 epochs.

Evaluation Metrics. To evaluate clustering quality against ground-truth, we follow previous work and report on the following metrics: Normalized Mutual Information (NMI), Adjusted Rand Index (ARI), and clustering Accuracy (ACC). All metrics range from 0 to 1. The higher the score, the better the clustering quality. We report the relative gains/losses over the baseline for the internal dataset. Since we are only interested in evaluating the quality of the fine-tuned representations, we use the reference number of clusters k in subsequent experiments and run a separate experiment to find the optimal k when evaluating the end-to-end system.

5 Experimental Results

We evaluate (1) the effect of our fine-tuning strategies to produce feature-aware representation on feature clustering, and (2) our feature novelty detection model.

5.1 Fine-tuning Results

Table 1 shows clustering performance using different fine-tuning strategies. Across datasets, our fine-tuning strategies outperform the vanilla SBERT baseline across all metrics. Stacking different fine-tuning tasks consistently results in better models. Fine-tuning with slot classification individually either before or after the other tasks (e.g., $SC \rightarrow US \rightarrow PC$) yields inferior performance compared to jointly running slot classification with other tasks. The best performing strategy is fine-tuning with slot classification and utterance similar-

Table 4: Ablation study results.

Model	SNIPS			Internal Dataset		
	NMI	ARI	ACC	NMI	ARI	ACC
<i>Standard</i>	0.782	0.531	0.605	=====	<i>baseline</i>	=====
<i>Ablation</i>	0.769	0.444	0.523	-0.081	-0.132	-0.087
<i>Upperbound</i>	0.812	0.530	0.672	–	–	–

Table 5: Choosing the number of clusters k .

Method	k	SNIPS			k	Internal Dataset		
		NMI	ARI	ACC		NMI	ARI	ACC
<i>Gold k</i>	43	0.782	0.531	0.605	41	=====	<i>baseline</i>	=====
<i>Silhouet.</i>	24	0.761	0.511	0.593	35	-0.030	-0.063	-0.013
<i>Elbow</i>	30	0.790	0.573	0.632	39	+0.002	+0.003	+0.020

ity jointly and then running pseudo classification. This shows that slot classification is able to improve utterance representations in the feature space. In all subsequent experiments, we use the best observed model ($SC+US$) \rightarrow PC .

Performance breakdown across feature types.

In Table 2, we report the performance of the best representation model on different feature types. First, we split the features in the test set by their novelty (whether the feature has been seen during training). Across the two datasets, our model clusters utterances from supported features better than from novel ones, which is expected.

In the second half of the table, we show a breakdown per combination. On SNIPS dataset, we achieve better clustering results for slot and slot value features than for intent features, which is reasonable as our training data contains only 2 features at intent level. On the internal dataset, clustering single-domain features is slightly better than cross-domain ones. For example, the model achieves an NMI of 0.867 for single domain features, and 0.823 NMI for cross-domain features.

Intent-agnostic vs. Intent-targeted discovery.

For deeper analysis, we consider another discovery setup in an intent-targeted way, in which we only train and test with features from the same intent. This setup is particularly useful in cases where we focus on fine-grained discovery where the intent is assumed to be known. In Table 3, we report the results for this study on four SNIPS intents separately. The models trained with features belonging to the same intent perform generally better than when being trained with cross-intent features.

Ablation study. During fine-tuning, we leverage both feature-labeled ($Train_L$) and feature-unlabeled ($Train_U$) data. To understand their im-

Table 6: Performance of the feature novelty detection.

Signal	SNIPS			Internal Dataset		
	Prec.	Rec.	F1	Prec.	Rec.	F1
st_{avg}	0.407	1.000	0.579	==== baseline ====		
st_{min}	0.750	0.545	0.632	+0.076	0.000	+0.043
ic	0.500	0.636	0.560	-0.083	-0.100	-0.091
pc	0.615	0.727	0.667	+0.167	-0.200	-0.020
$feat_{novel}$	0.750	0.545	0.632	+0.167	0.000	+0.091

pact on model performance, we compare our model, trained with both kinds of data (standard model), against a model trained with only $Train_L$ data (ablation model). Moreover, we compare both models to an *upperbound* model, in which we also include the true feature labels of $Train_U$. Hence, the upperbound model is also trained with feature-labeled data only, similar to the ablation model, but with more features. We did not build an upperbound model on the internal dataset since all utterances in $Train_U$ are not annotated with feature labels.

As shown in Table 4, the standard model outperforms the ablation model on all metrics across both datasets, with NMI and ACC gains reaching 8-9%, and ARI gains of 13% on the internal dataset. This shows that our model benefits from feature-unlabeled data during training. Naturally, an abundance of feature-labeled data, although impractical, provides better feature-aware representations.

Choosing the number of feature clusters. As we are interested in evaluating the quality of the fine-tuned representations, we use the number of ground-truth features k from test data. However, this number is unknown in practice. We experimented with two popular techniques for predicting k : the Elbow method (Thorndike, 1953) and the Silhouette score (Rousseeuw, 1987). As shown in Table 5, on both datasets, Elbow method works slightly better than Silhouette score, with the predicted k closer to the ground-truth value. In terms of other metrics, Elbow method even produces better feature clusters than the baseline with gold k .

5.2 Results of Feature Novelty Detection

The base NLU model is a pre-trained BERT with 12 hidden layers, each with a size of 768. On top of the CLS classification token, we plug a linear projection head followed by softmax to perform intent classification, and a similar head on top of each token to perform slot tagging. To train the NLU model, we unfreeze all 12 hidden layers and fine-tune the two heads jointly.

To evaluate novelty detection in isolation from

clustering, we use the ground-truth feature clusters and run novelty detection on top, i.e., to decide whether a ground-truth feature cluster is *novel* or *supported*. We harness different signals from the NLU model: st_{avg} , st_{min} , ic , pc and the combined signal $feat_{novel}$. As shown in Table 6, the combined signal $feat_{novel}$ performs the best across all metrics on the internal dataset. On SNIPS, $feat_{novel}$ excels against other signals in terms of precision, and places the second best in F1.

5.3 End-to-end DNF Evaluation

In this experiment, we first ran the clustering step with Elbow method to generate feature clusters. This resulted in 30 predicted clusters on SNIPS, and 39 clusters on the internal dataset (see Table 5). Then, we perform novelty detection on the predicted clusters.

To generate ground-truth labels for the predicted clusters, we assign a feature label l_C for each predicted cluster C by taking the majority vote of the labels of the utterances within the cluster. Table 7 shows the number of novel clusters predicted using each signal and their quality metrics. *all* is the baseline, where we assume all predicted feature clusters as novel. $feat_{novel}$ signal performs the best in terms of precision on SNIPS, together with st_{min} , which shows that the NLU slot confidence is a strong indicator of the novelty of an utterance. On the internal dataset, $feat_{novel}$ also achieves highest precision and F1, while discovering almost all novel features in the data (9 out of 10).

6 Conclusion

We introduced *feature discovery*, where, given a set of user utterances and a trained NLU model, we extract clusters of novel features composed of a combination of domains, intents, slots and/or their values. To this end, we presented DNF, a semi-supervised approach for extracting novel user features from a set of raw utterances, utilizing minimal feature knowledge from labeled data combined with feature-unlabeled data. DNF supports several fine-tuning strategies to improve utterance representation and make them separable in the feature space. We evaluated DNF on two datasets and observed significant improvements over baselines, showing the effectiveness of our method. In the future, we plan to explore various fine-tuning strategies for better utterance representations, as well as extending DNF to support different languages.

Table 7: End-to-end DNF evaluation.

Method	SNIPS				Internal Dataset			
	<i>#novel features</i>	<i>Precision</i>	<i>Recall</i>	<i>F1</i>	<i>#novel features</i>	<i>Precision</i>	<i>Recall</i>	<i>F1</i>
<i>all</i>	30	0.233	0.636	0.341	39	==== <i>baseline</i> ====		
<i>st_{avg}</i>	23	0.238	0.455	0.312	16	+0.295	0.000	+0.288
<i>st_{min}</i>	5	0.600	0.273	0.375	12	+0.462	0.000	+0.400
<i>ic</i>	21	0.238	0.455	0.312	8	+0.545	-0.200	+0.340
<i>pc</i>	10	0.400	0.364	0.381	9	+0.462	-0.200	+0.305
<i>feat_{novel}</i>	5	0.600	0.273	0.375	9	+0.573	-0.100	+0.410

7 Limitations

While we empirically showed that our approach performs well for novel feature discovery and generalizes across different datasets, we can identify avenues for improvement in terms of efficiency and model training. With DNF relying on good feature-aware sentence representations, obtaining such representations requires expensive fine-tuning steps. For example, using a single GPU, our cascaded fine-tuning strategy takes on average 7 hours on our internal dataset to reach convergence. Moreover, in workflows where NLU model refresh is frequent, the model’s intent classification and slot tagging confidence distribution can shift over time. With DNF relying on observing confidence signals from the NLU model to determine feature novelty, a retraining/tuning of the novelty detection component would have to be performed frequently. Furthermore, our approach requires a small manually annotated feature-labeled dataset (feature labels in addition to intent and slot labels). These additional annotations require expertise and time, which poses a challenge during the data collection phase.

Abstract

Closed-book question answering (QA) requires a model to directly answer an open-domain question without access to any external knowledge. Prior work on *closed-book* QA either directly finetunes or prompts a pretrained language model (LM) to leverage the stored knowledge. However, they do not fully exploit the parameterized knowledge. To address this inefficiency, we propose a two-stage, *closed-book* QA framework which employs a *coarse-to-fine* approach to extract the relevant knowledge and answer a question. We first generate a related context for a given question by prompting a pretrained LM. We then prompt the same LM to generate an answer using the generated context and the question. Additionally, we marginalize over the generated contexts to improve the accuracies and reduce context uncertainty. Experimental results on three QA benchmarks show that our method significantly outperforms previous *closed-book* QA methods. For example on TriviaQA, our method improves exact match accuracy from 55.3% to 68.6%, and is on par with *open-book* QA methods (68.6% vs. 68.0%). Our results show that our new methodology is able to better exploit the stored knowledge in pretrained LMs without adding extra learnable parameters or needing finetuning, and paves the way for hybrid models that integrate pretrained LMs with external knowledge.

1 Introduction

Open-domain question answering (ODQA) produces an answer to a given question in the form of natural language, and the task has been extensively studied in recent years. Significant progress on ODQA has been made by developing the *open-book* QA methods (Chen et al., 2017; Lewis et al., 2020b; Guu et al., 2020; Izacard and Grave, 2021;

*This work was done when the first author was an intern at NVIDIA. Corresponding authors: Dan Su, Mostofa Patwary.

Figure 1: An example illustrating our two-stage, **CGAP** framework. CGAP generates more accurate answer (e.g. *Richard Marx*) compared to standard few-shot prompting (e.g. *Ross Bagdasarian*).

Lazaridou et al., 2022) that explicitly exploit external knowledge corpus via dense retrieval techniques like DPR (Karpukhin et al., 2020). However, learning a good retriever requires substantial resources, such as a large number of domain-specific pairs of question and contexts in the knowledge corpus (Karpukhin et al., 2020), or intensive compute resources (Lee et al., 2019). In addition, as the size of the knowledge corpus increases, it becomes harder to retrieve accurate contexts due to the high dimensionality of the search space (Reimers and Gurevych, 2021).

Another class of models, known as *closed-book* question answering (CBQA), were recently proposed (Roberts et al., 2020). CBQA tries to directly answer the open-domain questions without accessing any external knowledge sources, and instead leverages the parametric knowledge stored in the pretrained language models (LMs) (Raffel et al., 2020; Brown et al., 2020; Ye et al., 2020).

However, even with larger LMs, the *closed-book* methods are not competitive with the *open-book* methods in term of accuracy (Lewis et al., 2021).

While it has been shown that large pretrained LMs store an abundant amount of knowledge (Petroni et al., 2019; Roberts et al., 2020), we hypothesize the accuracy gaps are largely because the way of exploiting the parameterized knowledge are not sophisticated enough. Prior works on CBQA either finetune pretrained LM models on the entire QA datasets (Roberts et al., 2020; Ye et al., 2020), or they directly prompt those models using several few-shot QA pairs (Brown et al., 2020; Radford et al., 2019). On the contrary, *open-book* models use a two-stage pipeline. They first retrieve relevant contexts from external corpus, then they extract the answer based on the retrieved contexts.

Therefore, to better exploit the parameterized knowledge in pretrained LMs and bridge the large accuracy gaps between the *closed-book* and *open-book* methods, we propose a *coarse-to-fine*, two-stage method for CBQA task. The main idea is to leverage generated contexts as an intermediate bridge between the huge amount of parameterized knowledge stored in the LM and the answer that lies within this knowledge. To the best of our knowledge, no previous work has been conducted on generating context from large pretrained LMs for CBQA and leveraging them to predict answer.

Our proposed framework **CGAP** consists of two stages. It first performs **Context Generation** relevant to a given question by prompting a pretrained LM. It then prompts the same LM for **Answer Prediction** using the generated context and the question. In order to improve the accuracies and to reduce context uncertainties, we generate multiple contexts for each question and predict the final answer by majority voting. This step does not increase the inference cost as we generate the contexts in parallel by batching in a single inference call. Figure 1 illustrates how our two stage prompting and majority voting works. For the input question, CGAP generates 3 contexts and 3 predicted answers at the two stages respectively, and choose the most voted answer as the final answer. Note that we do not finetune the large pretrained LMs for context generation or answer prediction. This facilitates our approach to take advantage of large LMs such as GPT-3 (Brown et al., 2020), PALM (Chowdhery et al., 2022) or Megatron-Turing NLG 530B (Smith et al., 2022),

which are only available through APIs.

We conduct in-depth experimental studies on three open-domain QA benchmarks, Natural Questions (Kwiatkowski et al., 2019), WebQuestions (Berant et al., 2013), and TriviaQA (Joshi et al., 2017), and demonstrate significant improvements by our two stage prompting method. Our contributions are summarized as follows:

- We propose a simple yet effective few-shot prompting approach for ODQA that does not rely on any external knowledge sources or fine-tuning, but performs significantly better than existing *closed-book* approaches (e.g. exact matching 68.6% vs. 55.3%), and is on par with *open-book* methods (e.g. 68.6% vs. 68.0%).
- We show that the generated context can improve standard few-shot prompting based *closed-book* QA accuracy at various model scales (e.g. from 11.7% to 28.5%), and demonstrate that scaling up the context generation model further enlarges their accuracy gaps (e.g. 357M 28.5% vs. 530B 68.6%). To the best of our knowledge, we are the first to leverage generated context from large pretrained LMs for open-domain question answering.
- We show that generating multiple contexts without increasing the inference cost by batching can mitigate errors in answer prediction caused by variability in the unknown context (e.g. from 36.3% to 45.7%).

2 Methodology

Our proposed **Context Generation** and **Answer Prediction (CGAP)** framework is illustrated in Figure 2. CGAP consists of two stages. First, it generates relevant context to a given question by prompting a large pretrained LM. In the second stage, it predicts an answer using the generated context and the question by prompting the same LM. To accurately predict the answer, we generate multiple contexts. We run each of the two stages multiple times in parallel in batch for the same question, generating different contexts for each, and use majority voting to select the final answer.

Formally, for our task we have a question Q to be answered, and a support repository $\mathcal{D} = \{(c_1, q_1, a_1), \dots, (c_n, q_n, a_n)\}$ that consists of tuples of question q_i and answer a_i pairs with mapping to the context c_i . In our experiments, we use

the training sets of the corresponding datasets as \mathcal{D} .

2.1 Context Generation

As shown in Figure 2, in the first stage, given question Q , we select the m context generation prompts $S = \{(q_1, c_1), \dots, (q_m, c_m)\}$ from the support repository \mathcal{D} . We then use S with Q to prompt pretrained LM to generate k contexts, which are denoted by $C_{gen} = \{c_{gen}^1, c_{gen}^2, \dots, c_{gen}^k\}$.

Sample Selection Selecting appropriate samples for the prompts is the key to generate high-quality context relevant to a given question. Previous work has shown that leveraging relevant samples helps the LM to generate contextually relevant and factually correct context (Liu et al., 2021, 2022). We therefore use a similarity-based retriever to search relevant samples S from the corresponding supporting repository, \mathcal{D} . We use DPR (Karpukhin et al., 2020) in our framework. In our DPR setup, we represent the question and the samples in \mathcal{D} as 768-dimensional dense vector representations, computed via the BERT-based bi-encoder networks. We rank the documents according to their similarity score, calculated as:

$$Score(Q, (q_j, c_j)) = \text{BERT}(Q)^T \cdot \text{BERT}(q_j; c_j) \quad (1)$$

where $;$ denotes concatenation of the tokens of the question q_j and the context c_j . Finally, we get $S = \{(q_1, c_1), \dots, (q_m, c_m)\}$ which are the top- m retrieved samples for question Q .

We would like to emphasize that the selected samples from \mathcal{D} are used as examples in the few-shot prompting to the pretrained LM to generate context, not as the source of external knowledge containing the answer.

Prompts Construction Given the question Q and the set of question-context pair samples S selected, we use few-shot prompting to condition pretrained LMs on the samples. We use similar few-shot prompting technique for *closed-book* QA as in (Brown et al., 2020), that considers multiple <question, answer> pairs. The template we used to construct prompts is: $Q: \dots A: \dots$. Thus the constructed prompt $Prompt(Q)$ for a given question Q becomes:

$$Prompt(Q) = Q: q_m \setminus n A: c_m \setminus n \dots \\ Q: q_1 \setminus n A: c_1 \setminus n Q: Q \setminus n$$

We use ' $\setminus n$ ' to separate the question, context and the samples. We investigated the order of samples to optimize the prompt and find that using the retrieved samples in reversed order of similarity yields better accuracies across all datasets¹. We now pass $Prompt(Q)$ through a pretrained LM to generate the context as follows:

$$c_{gen} = \mathcal{LM}(Prompt(Q))$$

To generate a set of k contexts, $\{c_{gen}^1, \dots, c_{gen}^k\}$, we increase the inference batch size to k and generate all the k contexts in parallel in one inference call to the LM. Thus, the overall latency remains the same as using a single context.

2.2 Answer Prediction

In the second stage, we select m answer prediction prompts $S' = \{(q_1, a_1, c_1), \dots, (q_m, a_m, c_m)\}$ from \mathcal{D} and then we prompt the same LM using the generated context C_{gen} from the first stage, along with the question Q and S' . The LM predicts a set of k answers $A_p = \{a_p^1, a_p^2, \dots, a_p^k\}$ each corresponding to the k contexts in C_{gen} . The final answer A is selected by majority voting on A_p .

Sample Selection Constrained by the maximum sequence length of the LM, we can feed the LM only a few (c, q, a) samples. Thus, it could be difficult for the LM to learn how to predict the answer for the given question conditioned on the context, unless similar examples have been provided. For example, if we were asking the question '*who is the current director of the us mint?*', the example that answering the question '*who is the fbi director of the united states?*' from the provided context will be more helpful, than the example that is answering '*how many episodes are there in 'Dragon Ball Z'?*' from the given context. We therefore use the same criteria for answer prediction as has been used for context generation. We use the same set of samples as selected in the first stage as described in Equation 1 and denote as $S' = \{(q_1, c_1, a_1), \dots, (q_m, c_m, a_m)\}$.

Prompt Construction We are prompting LMs with few-shot examples to predict answer for the question conditioned on the generated context. To equip the LM with this capability, we constructed intuitive prompts for the selected examples and feed them into the LM. Specifically, the template

¹We show an concrete example of $Prompt(Q)$ in Appendix Table 12

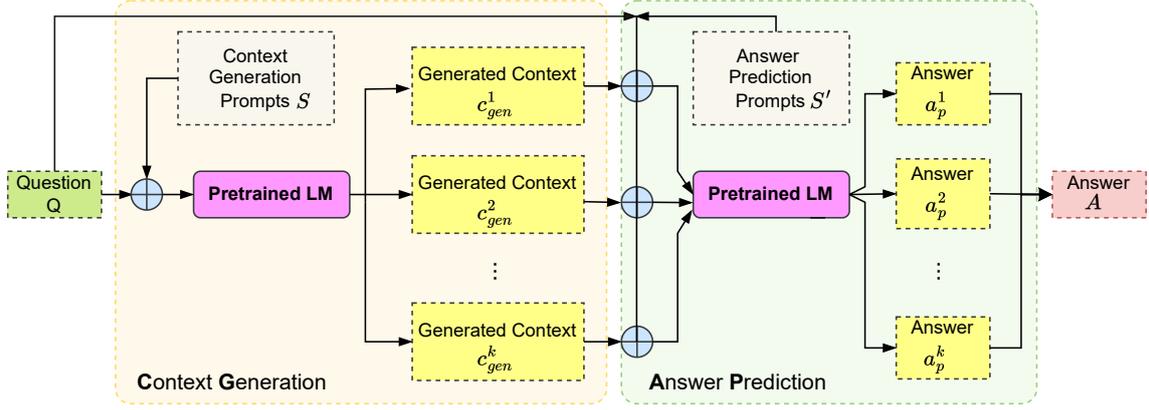

Figure 2: Overview architecture of our **CGAP** framework. It first does **Context Generation** by prompting large pretrained LMs, then it further prompts the LMs for **Answer Prediction** by feeding the generated context to the LM models alongside the question. k contexts are generated and the final answer A is chosen by majority voting. (If computation capability allows, it could prompt multiple (k) LMs in parallel at both two stages to speed up.)

we used to construct answer prediction prompts is: $C : \dots Q : \dots A : \dots$. Thus, the constructed prompt for a given question Q and the i -th generated context c_{gen}^i is:

$$\begin{aligned} Prompt(c_{gen}^i, Q) = & C : c_m \setminus n Q : q_m \setminus n A : a_m \setminus n \\ & \dots \\ & C : c_1 \setminus n Q : q_1 \setminus n A : a_1 \setminus n \\ & C : c_{gen}^i \setminus n Q : Q \setminus n \end{aligned} \quad (2)$$

We then feed $Prompt(c_{gen}^i, Q)$ into the pretrained LM to predict the answer:

$$a_p^i = \mathcal{LM}(Prompt(c_{gen}^i, Q)) \quad (3)$$

where we use a_p^i to denote the i -th answer predicted by the LM. The k generated contexts in c_{gen} will yield a set of answers $A_p = \{a_p^1, \dots, a_p^k\}$.

2.3 Context Marginalization

The large pretrained LM can generate impressively fluent and relevant context given input, it also has a tendency to generate factually incorrect statements, ranging from subtle inaccuracies to wild hallucinations (Shuster et al., 2021; Krishna et al., 2021; Su et al., 2022). Answers conditioned solely on hallucinated or erroneous statements are likely to be incorrect (Equation 3). Thus, we would like to remove the variability in the answer due to any particular generated context.

Ideally, we could marginalize over this unknown context by producing an answer for every possible context, weighting each answer by the probability of the context. Here we approximate this by

generating a set of contexts, and selecting the final answer based on majority voting. Suppose there are T unique answers $\{A_p^1, \dots, A_p^T\}$ from the k predicted answer from Equation 3 where $T \leq k$, then we select the J -th answer that receives the highest number of votes from the T different answers via:

$$J = \operatorname{argmax}_{j \in \{1, 2, \dots, T\}} \sum_{i=1}^k (\mathbb{1}(a_p^i = A_p^j)) \quad (4)$$

as the final answer A . As k gets larger, the final answer A will converge to the answer that would be produced marginalizing over all possible contexts. We refer to this majority vote over multiple generated contexts as context marginalization.

3 Experimental Setup

3.1 Datasets

We evaluated our experiments on three open-domain QA benchmark datasets: Natural Questions (NQ) (Kwiatkowski et al., 2019), TriviaQA (TQA) (Joshi et al., 2017), and WebQuestions (WQ) (Berant et al., 2013), using the same data splits for train, validation and test as in Lee et al. (2019); Izcard and Grave (2021).

NQ contains questions from Google search queries; TQA contains a collection of questions from trivia and quiz-league websites, and we use their unfiltered set; while questions of WQ were from Google Suggest API. For NQ and TQA, we use the processed data provided by Izcard and Grave (2021), in which each question-answer pair is accompanied by a 100-words Wikipedia passage

Model Type	Model	Method	NQ	TQA	WQ
Open-book	RAG (Lewis et al., 2020c)	<i>Finetuned</i>	44.5	68.0	45.5
	Fusion-in-Decoder (large) (Izacard and Grave, 2021)	<i>Finetuned</i>	51.4	67.6	-
	OB_{Google}^{PoE} (Lazaridou et al., 2022)	<i>Few-shot</i>	38.4	-	-
Closed-book	T5-11B (Roberts et al., 2020)	<i>Finetuned</i>	32.6	42.3	37.2
	T5-11B+SSM (Roberts et al., 2020)	<i>Finetuned</i>	34.8	51.0	40.8
	BART-large, pre-finetuned on PAQ (Lewis et al., 2021)	<i>Finetuned</i>	32.7	33.2	-
	LM-530B (API)	<i>Few-shot</i>	23.0	55.3	23.6
	CGAP (ours, 530B)	<i>Few-shot</i>	<u>42.0</u>	68.6	<u>41.8</u>

Table 1: Exact Match score for **CGAP** (highest accuracy configurations) in comparison to recent state-of-the-art *open-book* and *closed-book* based systems. Highest score indicated in **bold**, highest *closed-book* model underlined.

containing the answer. For WQ, we retrieved the corresponding context passage for each question from 2019/08/01 Wikipedia dump, using the DPR-based retriever that is trained jointly on the union of knowledge-intensive training data in KILT benchmark (Petroni et al., 2021).

3.2 Baselines

We compare our **CGAP** framework with the following baseline methods for *closed-book* QA.

Standard Few-shot Prompting We use the standard few-shot prompting technique similar to GPT-3 (Brown et al., 2020) in our evaluation on the *closed-book* QA datasets as described in Section 3.1. We consider this technique as the few-shot baseline in all our experiments. The baseline that is experimented using 530 billion (530B) parameterized LM is referred as **LM-530B**.

LM Fine-tuning Roberts et al. (2020) first proposed the *closed-book* QA task for open domain QA, and they directly fine-tuned T5 (Raffel et al., 2019) using the entire QA pairs in the training data, without access to any external knowledge corpus (referred as **T5-11B**). They also experimented with using ‘Salient Span-Masking’ (SSM) to continue pretraining the T5 checkpoints before fine-tuning for QA (referred as **T5-11B+SSM**). Lewis et al. (2021) pre-finetuned BART-large (Lewis et al., 2020a) on *Probably Asked Questions* (PAQ), a very large resource of 65M automatically generated QA-pairs, then further finetuned the model on corresponding training data (referred as **BART-large, pre-finetuned on PAQ**).

Open-book Few-shot Prompting Lazaridou et al. (2022) used few-shot prompting for open domain QA task, but they generate the answer via conditioning on retrieved documents from Google

Search API. (referred as OB_{Google}^{PoE})

3.3 State-of-the-art Open-book QA Models

We compare the state-of-the-art *open-book* QA models with **CGAP**. **Fusion-in-Decoder** (FiD) (Izacard and Grave, 2021) uses DPR (Karpukhin et al., 2020) to retrieve 100 passages from Wikipedia. Then they encode each passage independently and combine all outputs from the T5 encoder before passing them to the T5 decoder to generate a final answer. **RAG** (Lewis et al., 2020b) is an end-to-end retrieval-augmented generation model.

3.4 Implementation Details

To test how different model scales affect the performance of our approach, we train and experiment on a collection of decoder-only LMs using the Megatron-LM framework (Shoeybi et al., 2019), with 357 million (357m), 1.3 billion (1.3b), and 530 billion (530b) (Smith et al., 2022) parameters, at both context generator and answer prediction stage. We use top- p sampling with a value of 0.9 to generate diversified contexts. However, to handle the deterministic generation (e.g. short answer), we use greedy decoding at the answer prediction stage, similar to (Chowdhery et al., 2022; Wang et al., 2022).

For the prompt configuration at both stages, we choose 10 samples, constrained by the maximum sequence length of the LMs. We use DPR checkpoint from Huggingface² to select samples from the supporting repository.

3.5 Evaluation

For evaluating the open-domain QA task, we followed the recent works (Rajpurkar et al., 2016; Lee

²https://huggingface.co/facebook/dpr-ctx_encoder-multiset-base

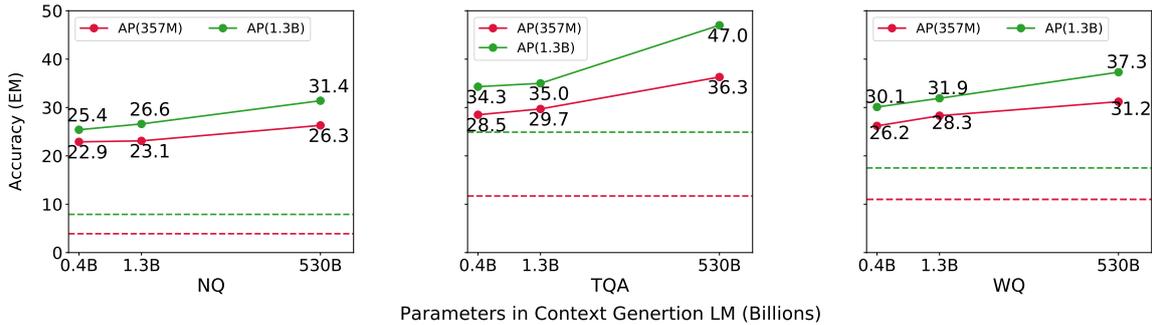

Figure 3: Ablation on context generation LM size. The dash lines represent standard few-shot prompting baselines.

et al., 2019; Izcard and Grave, 2021) that use Exact Match (EM) as the evaluation metric. Each predicted answer is compared to the ground-truth after both are lowercased and stripped of articles, punctuation, and duplicate whitespace.

4 Results and Ablation Studies

We now show our main results as well as ablations to further analyze the effectiveness of our approach.

4.1 Main Results

Table 1 shows the EM score comparison between our CGAP-based method with existing *closed-book* baseline approaches³. We also compare with state-of-the-art *open-book* models at the upper section of the table.

As we can see, our CGAP based method outperforms other existing *closed-book* methods by large margin, especially on NQ and TQA datasets. The CGAP also outperforms the standard few-shot prompting baseline LM-530B on all three datasets (at least by 13.3 EM point).

Furthermore, CGAP obtains highest score on TriviaQA. The scores are also very close to the state-of-the-art *open-book* method RAG on NQ and WebQuestions, but only lose few points on NQ to FiD. While FiD uses 100 retrieved passages for answer prediction, CGAP only uses 8 generated contexts for approximate context marginalization.

4.2 Ablation Studies

We conducted a systematic ablation study to further investigate the contribution of the context generation model and the effect of context marginalization.

³GPT-3 API shows different results than reported in the paper (Brown et al., 2020). We therefore did not compare to it. Details are shown in Appendix A

4.2.1 Context Generation

While previous work (Roberts et al., 2020; Brown et al., 2020) demonstrated that the scale of the model sizes improves the answer accuracy of *closed-book* QA, there are also other findings showing that simply increasing the model size does not lead to substantive accuracy gains (Rae et al., 2021). Thus, we intend to investigate **how will the context generation LM affect the answer accuracy**.

We experimented by varying the LM sizes for context generation, and fix the answer generation LM. We used context generation LM sizes of 357m, 1.3B and 530B, and answer generation LM with 357m and 1.3B parameters. We also compare with standard few-shot prompting which has no context generation.

We plot the results in Figure 3. As we can see, there are huge accuracy gains from standard prompting, to CGAP method that has context generation. The accuracy increases by absolute 19.00% for NQ, 16.87% for TQA and 15.26% for WQ, when using 357M model for both standard prompting and CGAP approach. The answer accuracy continues to increase when we increase the LM size for context generation. Furthermore, we notice that the slopes of the accuracy gain curve using larger answer prediction model is steeper than using smaller one on all three datasets. This suggests the use of larger answer prediction LM to fully exploit the knowledge in generated context.

4.2.2 Context Marginalization

Since there will be some hallucinated content or erroneous statements in the generated context, we approximate context marginalization by sampling multiple contexts and selecting the final answer based on majority voting, as introduces in Section 2.3. Here, we investigate the performance gains brought in by context marginalization, and

AP LM Size	CG LM Size	Margin-alization	NQ	TQA	WQ
357M	357M	✗	22.9	28.5	26.2
		✓	25.7 (+2.8)	33.4 (+4.9)	29.6 (+3.4)
	1.3B	✗	23.1	29.7	28.3
		✓	26.1 (+3.0)	34.8 (+5.1)	31.3 (+3.0)
530B	530B	✗	26.3	36.3	31.2
		✓	28.9 (+2.7)	45.7 (+9.4)	34.0 (+2.8)
	530B	✗	29.5	56.3	28.3
		✓	42.0 (+12.5)	68.6 (+12.4)	41.8 (+13.5)

Table 2: Ablation on context marginalization. (AP and GP represent Answer Prediction and Context Generation, respectively.)

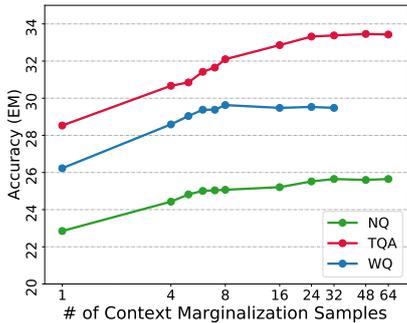

Figure 4: Ablation on k , the number of contexts for marginalization.

also the accuracy curves with varied number of sampled contexts used in the approximate marginalization k .

In Table 2, we show the accuracy comparisons w/ and w/o using marginalization ($k=8$), with different LM sizes. As we can see, **context marginalization improves the answer accuracy consistently on the three datasets**⁴, under all settings. Notably, there is much larger performance gains using marginalization when we scale up the model sizes to 530 billion parameters (i.e. increase EM score by 12.8% averaged on three datasets).

The larger the number of context samples k , the more accurately the majority vote reflects the true marginalization over all possible contexts. Therefore, we perform further ablation by changing the value k for 357M LM for both context generation and answer prediction. We plot the accuracy curves in Figure 4. We see that there are accuracy improvements when we use more context samples. As expected and curves plateau for larger values of k as the approximation approaches the true marginalization over all possible contexts.

⁴We show a concrete example in Appendix B Table 11

5 Analysis

Considering that it is the first time leveraging context generated by large pretrained LMs for ODQA, we also conducted further analysis.

We compare generated context with retrieved context in the two-stage, few-shot prompting based CBQA framework. It is a dominant paradigm to use retrieved context from external corpus together with the question for answer prediction for *open-book* QA (Chen et al., 2017; Lewis et al., 2020c; Izacard and Grave, 2021; Lazaridou et al., 2022).

5.1 Retrieved vs. Generated Context

In CBQA setting, we are not allowed to retrieve context from external knowledge sources. However, we can retrieve the contexts from the supporting repository based on their relevance to the given question. We use $c_r = \{c_r^1, c_r^2, \dots, c_r^m\}$ to represent the top- m relevant context for question Q . It can be obtained via Equation 1.

Let the top-1 retrieved context be $c_r^{\text{top-1}}$ for question Q . We use $c_r^{\text{top-1}}$ to compare with the generated context, c_{gen} . We use the same top- m prompts S' for answer prediction as introduced in Section 2.2. The answer a_p^r for the $c_r^{\text{top-1}}$ will be:

$$a_p^r = \mathcal{LM}(\text{Prompt}(c_r^{\text{top-1}}, Q)) \quad (5)$$

where $\text{Prompt}(c_r^{\text{top-1}}, Q)$ can be obtained via Equation 2.

The comparison between $c_r^{\text{top-1}}$ and c_{gen} is shown in Table 4. From the upper part of the table, we see that using $c_r^{\text{top-1}}$ gives slightly higher EM score than using c_{gen} generated by 357M and 1.3B LMs. However, c_{gen} gives higher EM scores than $c_r^{\text{top-1}}$ on all three datasets when we scale up the context generation LM size to 530B. This suggests the use of large pretrained LM for a better generated context.

Question: Which sitcom star appeared on the big screening 'The Object of My Affection'?	
Golden Answer: [Jennifer Anniston, Jen Aniston, ...]	
Predicted Answer (w/o c_{gen}):	Ross Hatley
Predicted Answer ($c_r^{\text{top-1}}$):	Laurie Metcalfe
Predicted Answer (c_{gen}):	Jennifer Anniston / Paul Rudd / Christine Baranski / Lisa Kudrow
Predicted Answer ($(c_{gen}^1, \dots, c_{gen}^k)$):	Jennifer Anniston

Table 3: Comparison of answers predicted w/o and w/ different context. Example from TriviaQA (Joshi et al., 2017) test set. Red and green colors denote in-correct and correct answer, respectively.

AP	Context	NQ	TQA	WQ
357M	$c_r^{\text{top-1}}$	25.1	32.2	28.3
	c_{gen} (357M LM)	22.9	28.5	26.2
	c_{gen} (1.3B LM)	23.1	29.7	28.3
	c_{gen} (530B LM)	26.3	36.3	31.2
530B	$c_r^{\text{top-1}}$	30.8	58.1	29.5
	c_{gen} (530B LM)	29.5	56.3	28.3

Table 4: Comparison of using retrieved top-1 context $c_r^{\text{top-1}}$, with few-shot generated context c_{gen} on *closed-book* QA task.

5.2 Multiple Retrievals vs. Context Marginalization

We notice that in Table 4, $c_r^{\text{top-1}}$ performs slightly better than c_{gen} when using 530B LM for answer prediction. We argue that this might be caused by the hallucination in c_{gen} . While we have shown in Section 4.2.2 that context marginalization could mitigate the problem and improve answer accuracy, we further facilitate c_{gen} (530B) with context marginalization and compare with retrieved context.

For fair comparison, we perform majority voting using the top- k retrieved context c_r , since Karpukhin et al. (2020) showed that the quality of the retrieved documents will also affect the final answer accuracy. Specifically, we replace $c_r^{\text{top-1}}$ with each retrieved context c_r^i in Equation 5 to predict answer $a_p^{r(i)}$ ($i = 1, \dots, k$), and use Equation 4 to select the most frequent answer as the final answer.

Furthermore, we replace $c_r^{\text{top-1}}$ with golden context c_{golden} in Equation 5. This will be the upper-bound of using retrieved/generated context in the two-stage, few-shot prompting CBQA task.

We show the results in Table 5. As we can see, using marginalization over c_{gen} consistently outperforms $c_r^{\text{top-1}}$, and also better than majority voting over multiple retrieved contexts c_r for answer prediction on all three datasets. Notably, marginal-

AP	Context	NQ	TQA	WQ
530B	c_{golden}	36.0	61.3	30.2
	$c_r^{\text{top-1}}$	30.8	58.1	29.5
	(c_r^1, \dots, c_r^k)	29.5	56.3	28.3
	c_{gen}	23.0	55.3	23.6
	$(c_{gen}^1, \dots, c_{gen}^k)$	42.0	68.6	41.8

Table 5: Comparison of using context marginalization ($c_{gen}^1, \dots, c_{gen}^k$), multiple retrievals (c_r^1, \dots, c_r^k), and golden context c_{golden} on *closed-book* QA task.

ization over c_{gen} yields higher EM score than using c_{golden} when using 530B LM for answer prediction. We observed similar trends when experimented on 357M and 1.3B parameter models. In Table 3, we show a concrete example that compares using different context for answer generation for better understanding⁵.

6 Related Works

Open-domain QA is the task of answering general-domain questions (Chen et al., 2017), in which the evidence is usually not given. Models that explicitly exploit an external corpus are referred as *open-book* models (Roberts et al., 2020). They typically index the corpus and then *retrieve-and-read* to extract the answer span from documents (Chen et al., 2017; Lee et al., 2019; Izacard and Grave, 2021; Lewis et al., 2020b; Lazaridou et al., 2022). Another recently proposed class of methods is *closed-book* QA models. Ye et al. (2020); Roberts et al. (2020) finetune pre-trained LMs such as T5 (Raffel et al., 2020) or BART (Lewis et al., 2020a) with QA pairs without access to any external knowledge or context.

Few-shot LM Prompting Radford et al. (2019); Brown et al. (2020) prompt GPT-2 (Radford et al., 2019) and GPT-3 (Brown et al., 2020) conditioned

⁵More concrete comparison examples are shown in Appendix B Table 9 and Table 10.

on several few-shot examples to predict the answer for ODQA. Most recent work by Lazaridou et al. (2022) further empower LM’s few-shot prompting abilities with information returned from the web using Google-Search API, and experimented on QA task. While Wei et al. (2022); Wang et al. (2022) use *chain of thought* few-shot prompting of LM to generate a coherent chain of short sentences that mimic the reasoning process of human might employ to solve reasoning tasks.

7 Conclusion

We propose a simple yet effective framework named **CGAP** for open-domain QA. CGAP performs **C**ontext **G**eneration followed by **A**nswer **P**rediction via two-stage prompting using large pre-trained LMs. It does not rely on external knowledge sources, and does not need finetuning or add extra learnable parameters. To the best of our knowledge, we are the first to leverage generated context from large pretrained LMs for open-domain QA. Experimental results on three QA benchmarks show that our method significantly outperforms previous *closed-book* QA methods and is par with *open-book* methods. We demonstrate our method up to 530B parameter models and showcase that larger models boost the accuracy by huge margins.

8 Limitations

As we show in the paper, **CGAP** has obtained satisfactory results on open-domain QA task. However, the method have limitations. The accuracy of CGAP will be affected by the size of LMs it uses, as we shown in Figure 3. In Section 4.1, our highest accuracy results reported in Table 1 used a large 530B pretrained LM, which is only accessible via API. Also, the generated context may contain hallucinated content.

A Standard Few-shot Prompting of GPT-3

Brown et al. (2020) adopted the standard few-shot prompting on GPT-3, and evaluated on the three open-domain QA datasets NQ (Kwiatkowski et al., 2019), WQ (Berant et al., 2013) and TQA (Joshi et al., 2017), for *closed-book* QA task. In order to compare with their reported results, we re-implement their method using the same few-shot configuration as described in the paper and query the OpenAI API.

Experimental Setups As OpenAI hasn’t officially release information about their API model sizes, we deduce the sizes of OpenAI API models based on their performances from EleutherAI’s blog⁶. Specifically, we query Ada and Babbage

models’ API, trying to reproduce the reported results for GPT-3 Medium (350M) and GPT-3 XL (1.3B) models, respectively.

We use two prompt formats to query the OpenAI API. The first prompt format is the one described in the paper (Brown et al., 2020) (referred as *GPT-3 format*): randomly draw 64 question-answer pairs from the corresponding supporting repository, and use ‘Q: ’ and ‘A: ’ respectively as prefix before each question and answer, to build the conditioning prompts. We also use the prompt format from EleutherAI’s language model evaluation harness github⁷ (referred as *EleutherAI*). Furthermore, we experiment using the same prompting format as we used in our standard prompting baseline (LM-530B) in Section 3.2 (referred as *Our format*), and prompting the LM of size 357M and 1.3B to compare.

Results We show the results of prompting GPT-3 under zero-shot, one-shot and few-shot settings in Table 6, Table 7 and Table 8 respectively. As we can see, no matter what prompting formats we use, the results reported in the GPT-3 paper (Brown et al., 2020) are almost always higher than our reproduced ones on all three datasets, over the two different LM sizes. The gaps become even larger at few-shot setting. Thus we conjecture that we are not able to reproduce the results reported by Brown et al. (2020) using GPT-3 (175B) on the three QA datasets. So we did not include their reported results to compare with our CGAP method in Table 1.

Furthermore, we notice that the results based on our baseline’s prompting configuration are always on par with the results from querying OpenAI API. Thus we believe that the **LM-530B** is a reliable and fair standard few-shot prompting baseline to compare with.

B Examples

We show three examples from NQ, TQA and WQ test set in Table 9, Table ?? and Table 10 respectively. In each table, we show the predicted answers from (1) standard prompting, (2) two-stage prompting using top-1 retrieved context $c_r^{\text{top-1}}$, (3) CGAP w/o marginalization, and (4) CGAP. All those predicted answers are based on LMs of size 530B.

We also show an example illustrate CGAP with 8 generated context and their corresponding pre-

⁶<https://blog.eleuther.ai/gpt3-model-sizes/>

⁷<https://github.com/EleutherAI/lm-evaluation-harness>

dicted answer in Table 11. As we can see, the contexts that contains lot of factually inaccurate or irrelevant content (e.g. generated context 1, 2, 4, 5, 8), thus the corresponding answer is wrong/inaccurate. However, the context generation LM also generates contexts that are more relevant and factual (e.g. generated context 3, 6, 7), and they help the answer prediction LM generate a correct answer. Therefore, CGAP can predict the final answer correctly based on marginalization over generated contexts.

Model Sizes	Model sources	Prompting format	zero-shot		
			NaturalQuestion	TriviaQA	WebQuestion
350M	GPT-3 Medium	GPT-3 paper (Brown et al., 2020)	1.75	7.61	3.20

Question: When is the next deadpool movie being released?	
Golden Answer:	[May 18, 2018]
Predicted Answer (standard prompting):	Prime availability TBD
Predicted Answer ($c_r^{\text{top-1}}$):	May 18, 2018
Predicted Answer (CGAP w/o marginalization):	May 18, 2018 / date21-May-2018 / May 29, 2019 /16th May 2018
Predicted Answer (CGAP):	May 18, 2018

Table 9: Example from NQ (Kwiatkowski et al., 2019) test set. Red and green colors denote *in-correct* and *correct* answer, respectively.

Question: Where George Lopez was born?	
Golden Answer:	[Mission Hills]
Predicted Answer (standard prompting):	San Fernando, California
Predicted Answer ($c_r^{\text{top-1}}$):	Washington Heights
Predicted Answer (CGAP w/o marginalization):	Mission Hills / Los Angeles/ San Fernando /Castle Hill /canada
Predicted Answer (CGAP):	Mission Hills

Table 10: Example from WebQuestions (Berant et al., 2013) test set.

Question: Where George Lopez was born? **Golden Answer:** [Mission Hills]

Generated Context 1: George Lopez They are American citizens, born in Los Angeles, to Gregorio Lopez (October 26, 1934 – January 25, 2011) and Maria Torres (October 12, 1938 – October 25, 2014), Mexican immigrants who were born in Reynosa, Tamaulipas. Lopez's paternal grandparents were Mexican, while his maternal grandparents were of Mexican and Spanish descent. Lopez's father was a worker for the Los Angeles Metropolitan Transit Authority. He married Maria in Los Angeles when he was 16 years old, and she was 15. Maria filed for divorce from Gregorio in the mid-1970s.

Predicted Answer: Los Angeles

Generated Context 2: George Lopez born April 23, 1961. The family eventually moved from Marin to Los Angeles in the mid-1960s. After Lopez graduated from San Fernando High School in 1979, he attended the California State University, Los Angeles. It was there where Lopez discovered his comedic talent after a video of him doing a stand-up routine made it into the hands of "Tonight Show" booker, Fred De Cordova, in 1985.

Predicted Answer: canada

Generated Context 3: George Lopez at 20th Century Fox Television until 2010, when he began appearing in his self-produced sitcom, George Lopez. Lopez was born on April 23, 1961, in Mission Hills, Los Angeles, California. He was raised by his maternal grandmother, Benita Gutierrez, a factory worker, and his maternal grandfather, Refugio Gutierrez, who worked as a janitor and metal fabricator at an ice skating rink.

Predicted Answer: Mission Hills

Generated Context 4: George Lopez in San Fernando, California. He is of Mestizo Mexican descent. His father, Saul Lopez, was from Sonora, and his mother, Elvira, was a native of Arizona. They were migrant workers who picked crops and moved often, sometimes taking their seven children with them. While growing up, Lopez did not speak English until he was seven. Lopez attended Our Lady of Lourdes, a Roman Catholic elementary school in Pico Rivera.

Predicted Answer: San Fernando

Generated Context 5: George Lopez A theater called "The Tower", which now houses a branch of Bank of America, stands on the former site of his childhood home. Lopez was born at Daniel Freeman Memorial Hospital in Inglewood, California and was raised by his maternal grandmother, Benita Gutierrez, a factory worker who took him to the movies every week. He grew up in the Echo Park neighborhood of Los Angeles, California and attended many different schools in the Los Angeles Unified School District.

Predicted Answer: Los Angeles

Generated Context 6: George Lopez López was born in Mission Hills, Los Angeles, California. He is the son of Frieda and Anatasio López, Mexican immigrants from Tepic, Nayarit, Mexico. Lopez's father was a farm worker, and his mother worked at a canning factory. Lopez has stated that he had a difficult childhood; his parents divorced when he was five, and his mother struggled to raise him and his two sisters.

Predicted Answer: Mission Hills

Generated Context 7: George Edward Lopez. Lopez was born in Mission Hills, Los Angeles. His parents, Frieda and Anatasio Lopez, were both born and raised in Texas. His mother was of Mexican descent and his father, also called "Charlie", was of Sicilian descent. Lopez grew up with two older sisters. He attended San Fernando High School in the Los Angeles neighborhood of San Fernando.

Predicted Answer: Mission Hills

Generated Context 8: George Lopez had in his mouth. He was raised by his mother, Frieda, a telephone company employee, and his grandmother, Benita Gutierrez, a factory worker. Lopez graduated from the Roman Catholic Saint Monica's High School in 1974, where he met his future wife, Ann Serrano. He moved to California and graduated from the California State University, Los Angeles, in 1986 with a degree in communications.

Predicted Answer: Castle Hill

Predicted Answer (CGAP): Mission Hills

Table 11: Example illustrates CGAP, in which we marginalize over 8 generated contexts.

Q: Who was the first U.S. president to be born in the United States of America?

A: with the issue of 1863 (displayed in First appearances) above). At that time, as aforesaid, he had already appeared on two different Confederate 200a2 stamps. Andrew Jackson appears on the following commemorative issues: Martin Van Buren (December 5, 1782 - 2013 July 24, 1862) was the eighth President of the United States from 1837 to 1841. Before his presidency, he served as the eighth Vice President (1833 2013 1837) and the 10th Secretary of State under Andrew Jackson. Van Buren was the first U.S. President to be born an American citizen. William Henry Harrison (February 9, 1773 2013 April 4, 1841) was the

Q: Which US President who was in office 1923-29, was the only one to be born on 4th July?

A: Calvin Coolidge John Calvin Coolidge Jr. (; July 4, 1872 2013 January 5, 1933) was an American politician and the 30th President of the United States from 1923 to 1929. A Republican lawyer from New England, born in Vermont, Coolidge worked his way up the ladder of Massachusetts state politics, eventually becoming governor. His response to the Boston Police Strike of 1919 thrust him into the national spotlight and gave him a reputation as a man of decisive action. Soon after, he was elected Vice President of the United States in 1920, and succeeded to the presidency upon the sudden

Q: What long running comic strip, introduced on Oct 2, 1950, was drawn by the same cartoonist, Charles M. Schultz, during its' entire run?

A: Peanuts Peanuts is a syndicated daily and Sunday American comic strip written and illustrated by Charles M. Schulz that ran from October 2, 1950, to February 13, 2000, continuing in reruns afterward. "Peanuts" is among the most popular and influential in the history of comic strips, with 17,897 strips published in all, making it "arguably the longest story ever told by one human being. At its peak in the mid-to late 1960s, "Peanuts" ran in over 2,600 newspapers, with a readership of around 355 million in 75 countries, and was translated into 21 languages. It helped to cement the"

Q: In the comic strip "Peanuts", whose father is a barber?

A: Franklin (Peanuts) Franklin Armstrong is a character in the long-running comic strip "Peanuts", created by Charles M. Schulz. Introduced on July 31, 1968, Franklin was the first African American character in the strip. He goes to school with Peppermint Patty and Marcie. In his first story arc, he met Charlie Brown when they were both at the beach. Franklin's father was a soldier fighting in Vietnam, to which Charlie Brown replied "My dad's a barber...he was in a war too, but I don't know which one." Franklin later paid Charlie Brown a visit and found some of Charlie Brown's other

Q: Which US President was given the nickname 'The Trust Buster'?

A: Howard Taft. A Progressive reformer, Roosevelt earned a reputation as a "trust buster" through his regulatory reforms and anti-trust prosecutions. His presidency saw the passage of the Pure Food and Drug Act, which established the Food and Drug Administration to regulate food safety, and the Hepburn Act, which increased the regulatory power of the Interstate Commerce Commission. Roosevelt took care, however, to show that he did not disagree with trusts and capitalism in principle, but was only against monopolistic practices. His "Square Deal" included regulation of railroad rates and pure foods and drugs; he saw it as a fair deal

Q: American cartoonist Thomas Nast is credited with creating the traditional image of which popular Christmas character?

A: Thomas Nast Thomas Nast (September 27, 1840 December 7, 1902) was a German-born American caricaturist and editorial cartoonist considered to be the "Father of the American Cartoon". He was the scourge of Democratic Representative "Boss" Tweed and the Tammany Hall Democratic party political machine. Among his notable works were the creation of the modern version of Santa Claus (based on the traditional German figures of Sankt Nikolaus and Weihnachtsmann) and the political symbol of the elephant for the Republican Party (GOP). Contrary to popular belief, Nast did not create Uncle Sam (the male personification of the United

Q: October 2, 1950 saw the debut of what comic strip which ran until creator Charles M. Schulz's death on Feb 12, 2000?

A: from a wide range of acclaimed contemporary artists and designers who have been inspired by the cartoon. Peanuts Peanuts is a syndicated daily and Sunday American comic strip written and illustrated by Charles M. Schulz that ran from October 2, 1950, to February 13, 2000, continuing in reruns afterward. "Peanuts" is among the most popular and influential in the history of comic strips, with 17,897 strips published in all, making it "arguably the longest story ever told by one human being". At its peak in the mid- to late 1960s, "Peanuts" ran in over 2,600 newspapers, with a readership of

Q: In which state was Charles Schulz born?

A: Charles M. Schulz Charles Monroe "Sparky" Schulz (November 26, 1922 February 12, 2000), nicknamed Sparky, was an American cartoonist. Schulz is known for the comic strip "Peanuts" (which featured the characters Charlie Brown and Snoopy, among others). He is widely regarded as one of the most influential cartoonists of all time, cited by cartoonists including Jim Davis, Bill Watterson, and Matt Groening. Born in Minneapolis, Minnesota, Schulz grew up in Saint Paul. He was the only child of Carl Schulz, who was born in Germany, and Dena Halverson, who had Norwegian heritage. His uncle called him "Sparky" after

Q: **Who was President when the first Peanuts cartoon was published?**

Table 12: $Prompt(Q)$ Example. For the question "**Who was President when the first Peanuts cartoon was published?**" from TQA (Joshi et al., 2017), we selected 8 $\langle q_i, c_i \rangle$ samples from the supporting repository \mathcal{D} , and construct the $Prompt(Q)$ as above. to prompt LMs for c_{gen} generation.

RedHOT: A Corpus of Annotated Medical Questions, Experiences, and Claims on Social Media

Abstract

We present **Reddit Health Online Talk (RedHOT)**, a corpus of 22,000 richly annotated social media posts from Reddit spanning 24 health conditions. Annotations include demarcations of spans corresponding to medical claims, personal experiences, and questions. We collect additional granular annotations on identified claims. Specifically, we mark snippets that describe patient **Populations**, **Interventions**, and **Outcomes** (PIO elements) within these. Using this corpus, we introduce the task of retrieving trustworthy evidence relevant to a given claim made on social media. We propose a new method to automatically derive (noisy) supervision for this task which we use to train a dense retrieval model; this outperforms baseline models. Manual evaluation of retrieval results performed by medical doctors indicate that while our system performance is promising, there is considerable room for improvement. We release all annotations collected (and scripts to assemble the dataset), and all code necessary to reproduce the results in this paper at: <https://sominw.com/redhot>.

1 Introduction

Social media platforms such as Reddit provide individuals places to discuss (potentially rare) medical conditions that affect them. This allows people to communicate with others who share in their condition, exchanging information about symptom trajectories, personal experiences, and treatment options. Such communities can provide support (Biyani et al., 2014) and access to information about rare conditions which may otherwise be difficult to find (Glenn, 2015).

However, the largely unvetted nature of social media platforms make them vulnerable to *mis* and *disinformation* (Swire-Thompson and Lazer, 2019). An illustrative and timely example is the idea that consuming bleach might be a viable treatment for

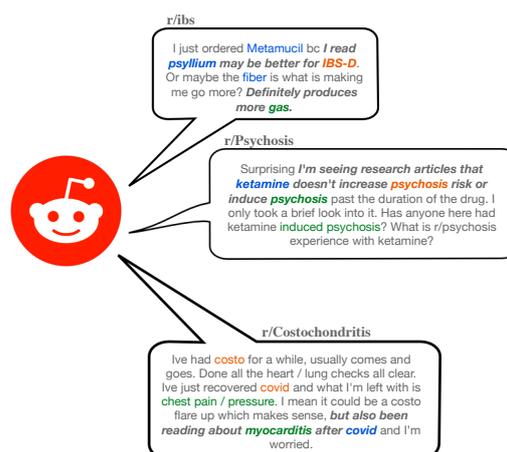

Figure 1: Examples of health-related Reddit posts annotated for populations, interventions, and outcomes.

COVID-19,¹ which quickly gained traction on social media. All misinformation can be dangerous, but *medical* misinformation poses unique risks to public health, especially as individuals increasingly turn to social media to inform personal health decisions (Nobles et al., 2018; Barua et al., 2020).

In this paper, we introduce **RedHOT**: an annotated dataset of health-related claims, questions, and personal experiences posted to Reddit. This dataset can support development of a wide range of models for processing health-related posts from social media. Unlike existing health-related social media corpora, **RedHOT**: (a) Covers a broad range of health topics (e.g., not just COVID-19), and, (b) Comprises “natural” claims collected from real health-related fora (along with annotated questions and personal experiences). Furthermore, we have collected granular annotations on claims, demarcating descriptions of the **Population** (e.g., **diabetics**), **Interventions**, and **Outcomes**, i.e., the *PIO* elements (Richardson et al., 1995). Such annotations may permit useful downstream processing: For exam-

¹<https://www.theguardian.com/world/2020/sep/19/bleach-miracle-cure-amazon-covid>

ple, in this work we use them to facilitate retrieval of evidence relevant to a claim.

Specifically, we develop and evaluate a pipeline to automatically identify and contextualize health-related claims on social media, as we anticipate that such a tool might be useful for moderators keen to keep their communities free of potentially harmful misinformation. With this use-case in mind, we propose methods for automatically retrieving *trustworthy* published scientific evidence relevant to a given claim made on social media, which may in aggregate support or debunk a particular claim.

The contributions of this work are summarized as follows. First, we introduce **RedHOT**: A new dataset comprising 22,000 health-related Reddit posts across 24 medical conditions annotated for claims, questions, and personal experiences. Claims are additionally annotated with PIO elements. Second, we introduce the task of identifying health-related claims on social media, extracting the associated PIO elements, and then retrieving relevant and trustworthy evidence to support or refute such claims. Third, we propose **RedHOT-DER**, a Dense Evidence Retriever trained with heuristically derived supervision to retrieve medical literature relevant to health-related claims made on social media. We evaluate baseline models for the first two steps on the **RedHOT** dataset and assess the retrieval step with relevance judgments collected from domain experts (medical doctors).

The Reddit posts we have collected are public and typically made under anonymous pseudonyms, but nonetheless these are health-related comments and so inherently sensitive. To respect this, we (a) notified all users in the dataset of their (potential) inclusion in this corpus, and provided opportunity to opt-out, and, (b) we do not release the data directly, but rather a script to download annotated comments, so that individuals may choose to remove their comments in the future. Furthermore, we consulted with our Institutional Review Board (IRB) and confirmed that the initial collection and annotation of such data does not constitute human subjects research. However, EAACL reviewers rightly pointed out that certain *uses* of this data may be sensitive. Therefore, to access the collected dataset we require researchers to self-attest that they have obtained prior *approval* from their own IRB regarding their intended use of the corpus.

2 The **RedHOT** Dataset

We have collected and manually annotated health related posts from Reddit to support development of language technologies which might, e.g., flag potentially problematic claims for moderation. Reddit is a social media platform that allows users to create their own communities (*subreddits*) focused on specific topics. Subreddits are often about niche topics, and this permits in-depth discussion catering to a long tail of interests and experiences. Notably, subreddits exist for most common (and many rare) medical conditions; we can therefore sample posts from such communities for annotation.

2.1 Data Annotation

We decomposed data annotation into two stages, performed in sequence. In the first, workers are asked to demarcate spans of text corresponding to a Claim, Personal Experience, or Question. We characterize these classes as follows (we provide detailed annotation instructions in Appendix A):

Claim suggests (explicitly or implicitly) a causal relationship between an *Intervention* and an *Outcome* (e.g., “*I* completely cured my *O*”). Operationally, we are interested in identifying statements that might reasonably be interpreted by the reader as implying a causal link between an intervention and outcome, as this may in turn influence their perception regarding the efficacy of an intervention for a particular condition and/or outcome (i.e., relationship between an *I* and *O*).

Question poses a direct question, e.g., “Is this normal?”; “Should I increase my dosage?”.

Personal Experience describes an individual’s experience, for instance the trajectory of their condition, or experiences with specific interventions.

This is a *multi-label* scheme: Spans can (and often do) belong to more than one of the above categories. For example, personal experiences can often be read as implying a causal relationship. Consider this example: “My doctor put me on *I* for my *P*, and I am no longer experiencing *O*”. This describes an individual treatment history, but could also be read as implying that *I* is a viable treatment for *P* (and specifically for the outcome *O*). Therefore, we would mark this as both a Claim and a Personal Experience. By contrast, a general statement asserting a causal relationship outside of any personal context like “*I* can cure *O*” is what

Reddit post	Span labels	PIO elements from claims
<i>I've seen a bunch of posts on here from people who say that glycopyrrolate suddenly isn't working anymore for hyperhidrosis. I'm one of those person who has been facing this for a while now. Just wondering if anyone fixed it? Can't really ask my GP about it since he didn't even know the meds existed. He just prescribed them for me when I asked for it</i>	Claim: I've seen a bunch of posts on here from people who say that glycopyrrolate suddenly isn't working anymore for Hyperhidrosis Question: Just wondering if anyone fixed it?	P hyperhidrosis I glycopyrrolate
<i>so i recently read that adderall can trigger a psychotic break & i was prescribed adderall years ago for my adhd but now i just have constant hallucination episodes. anyone else experience adderall induced psychosis?</i>	Claim: so i recently read that adderall can trigger a psychotic break Personal Experience: i was prescribed adderall years ago for my adhd but now i just have constant hallucination episodes Question: anyone else experience adderall induced psychosis?	P adhd I adderall O hallucinations
<i>I've had costochondritis for a while, usually comes and goes. Done all the heart/lung checks all clear. I've just recovered covid and what I'm left with is chest pain/pressure. I mean it could be a costo flare up which makes sense, but also <i>been reading about myocarditis after covid</i> and I'm worried, how can I tell which is which?</i>	Claim: been reading about myocarditis after covid Personal Experience: I'm left with is chest pain/pressure Question: how can I tell which is which?	P costochondritis I covid O myocarditis, chest-pain

Table 1: Example annotations, which include: extracted spans (phase 1), and spans describing **Populations**, **Interventions**, and **Outcomes** — PIO elements — within them (phase 2). We collect the latter only for claims.

we will refer to as a “pure claim”, meaning it exclusively belongs to the Claim category.

In the second stage, workers are asked to further annotate “pure claim” instances by marking spans within them that correspond to the Populations, Interventions/Comparators,² Outcomes (the PIO elements) associated with the claim.

2.2 Crowdsourcing Annotations

We hired crowdworkers to perform the above annotation tasks on Amazon Mechanical Turk (AMT).³ To estimate required annotation time and determine fair pay rates, we ran an internal pilot with two PhD students (both broadly familiar with this research area) on 100 samples.⁴ To gauge quality and recruit workers from AMT, we ran two pilot experiments in which we collected sentence-level annotations on posts sampled from three medical populations (i.e., subreddits), comprising ~6,000 posts in all.

We required all workers have an overall job approval rate of $\geq 90\%$. Based on an initial set of AMT annotations we re-hired only workers who

²This is the standard PICO framework, but we collapse Interventions and Comparators into the Intervention category, as the distinction is arbitrary.

³We consulted with an Institutional Review Board (IRB) to confirm that this annotation work did not constitute human subjects research.

⁴Based on the estimate from our pilot experiments, payrate for AMT workers was fixed to US \$9 per hour for stage-1 annotations and US \$11 per hour for stage-2 annotations, irrespective of geographic location.

	Fliess κ	P	R	F1
Questions	0.86	0.85	0.82	0.84
Claims	0.69	0.63	0.53	0.58
Experiences	0.71	0.78	0.69	0.73
POP	0.92	0.94	0.91	0.92
INT	0.74	0.76	0.70	0.73
OUT	0.78	0.73	0.68	0.70

Table 2: Token-wise label agreement among experts measured by Fleiss κ on a subset of data. We further compute precision, recall, and F1 scores for “aggregated” labels by evaluating them against unioned “in-house” expert labels.

reliably followed annotation instructions (details in Appendix A), and we actively recruited the top workers to continue on with increased pay. We obtained annotations from at least three workers for each post, allowing for robust inference of reference labels. Recruited workers were also paid periodic bonuses (equivalent to two hours of pay) based on the quality of their annotated samples.

2.3 Quality Validation

To evaluate annotation quality we calculate token-wise label agreement between annotators, and amongst ourselves. We emphasize here that token-level κ for sequences is quite strict and disagreements often reflect *where* annotators decide to mark

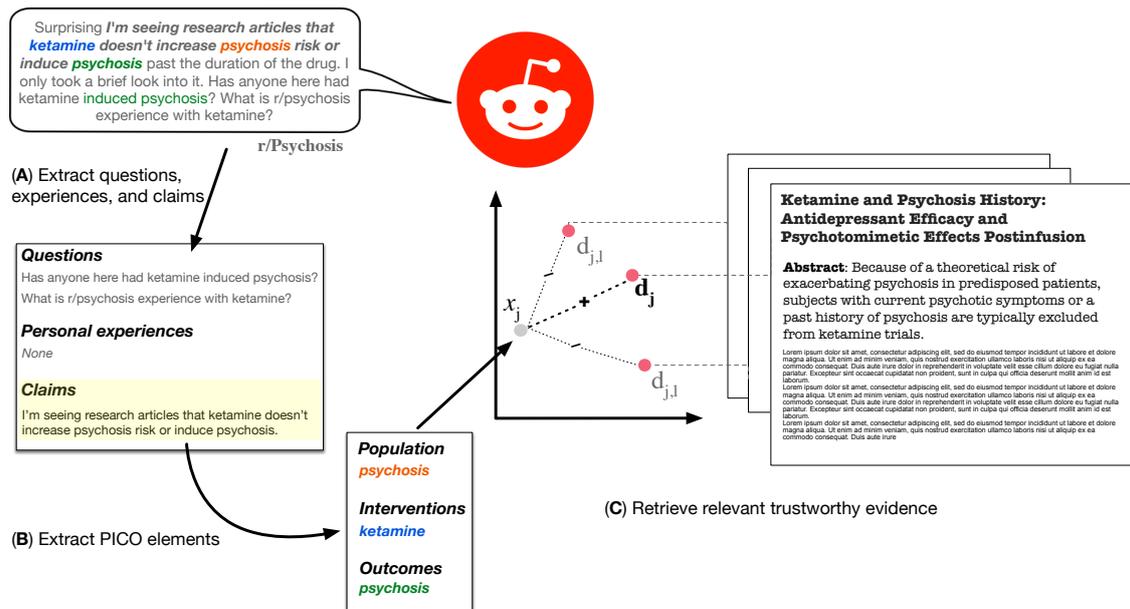

Figure 2: Examples portraying potential use cases of our corpus. We showcase three distinct tasks, to be performed in sequence. The first (A) entails extracting spans corresponding to claims (highlighted in **bold**) from a given Reddit post. The second step (B) is to identify the PICO elements associated with each claim. In the final step (C), we use the outputs of the first two models with the original post to obtain a dense representation, enabling us to retrieve relevant evidence from a large dataset of trusted medical evidence (e.g., PubMed).

span boundaries. Despite this, for the first stage agreement (Fleiss κ) on labeled questions, experiences, and claims was 0.62, and for the second stage 0.55. We consider this *moderately strong* agreement, in line with agreement reported for related annotation tasks in the literature (Nye et al., 2018; Deléger et al., 2012). To quantify this and further gauge the quality of collected annotations, we run a few additional analyses.

As previously stated, prior to collecting annotations on Amazon MTurk, we (the authors) annotated a subset of data (100 samples/stage) internally to assess task difficulty and to estimate the time required for annotation. As an additional quality check, we use these annotations to calculate token-wise label agreement. Table 2 reports the results; while there remains some discrepancy owing to the inherent complexity of the task, there is higher agreement between the us than between workers.

Each of these samples was also annotated by three workers. We aggregate these labels using majority-vote and compute token-wise precision-recall of these aggregated labels against the reference “in-house” labels (Table 2). We report the same metrics per annotator evaluated against aggregated MTurk labels in Table 9 (Appendix B). Despite moderate agreement between annotators, aggregated labels agree comparatively well with

the “expert” consensus, indicating that while individual worker annotations are somewhat noisy, aggregated annotations are reasonably robust.

2.4 Dataset Details

Table 1 provides illustrative samples from **RedHOT** and Table 8 provides some descriptive statistics along with examples of included health populations. We broadly characterize populations (conditions) as *Very Common*, *Common* or *Rare*, and sought a mix of these. This was not the only attribute that informed which conditions we selected for inclusion in our dataset, however. For example, we wanted a mix of populations with respect to volume of online activity (e.g., the Diabetes subreddit has over 60k active visitors; Lupus has 8k). We also wanted to include both chronic and treatable conditions (e.g., Narcolepsy is a rare and chronic condition, while Gout is common and treatable), and mental and physical disorders (e.g., ADHD, Rheumatoid Arthritis). Another consideration was whether a condition can be self-diagnosed or requires professional assessment (e.g., Bulimia is usually self-diagnosable but can potentially be life-threatening; Gastroparesis is chronic but requires a professional medical diagnosis).

The number of *claims* across different categories of health populations are far outnumbered by *ques-*

tions ($\sim 10x$) and experiences ($\sim 13x$). The average post length is ~ 117 tokens while the average length of a claim within a post is ~ 20 tokens. Questions and experiences have average lengths of ~ 11 and ~ 27 tokens, respectively. We provide per condition statistics in Appendix B.

3 Tasks and Evaluation

RedHOT may support a range of tasks related to processing health-related social media posts. Here we focus on an important, timely task: Identifying medical claims on social media, and then retrieving relevant and trustworthy evidence that may support or refute them. Methods for this task could aid content moderation on health-related forums, by providing an efficient means to (in)validate claims. More generally, such methods may permit meaningful “fact checking” of health-related claims by providing relevant contextualizing evidence.

We outline a three-step approach for this task. (1) Identify spans/sentences corresponding to *pure* claims. (2) Extract from these specific PICO elements. (3) Retrieve clinical literature — specifically, reports of RCTs — relevant to the claim, i.e., the extracted PIO elements. We limit our focus to the problem of evidence retrieval here; future work might consider the subsequent step of automated claim validation on the basis on this.

Below we assess components for each of these steps. For the span and PIO extraction steps (1 and 2), we evaluate models retrospectively under standard classification metrics (i.e. precision, recall, and F1 scores) using fixed train, development, and test sets which we will distribute with **RedHOT**. The final step (3) requires relevance judgments to evaluate model performance; for this we enlisted medical doctors (Section 3.4).

3.1 Identifying Claims, Experiences, Questions, and PIO Elements

We treat the first two steps as sequence tagging tasks for which we evaluate two types of models: A simple linear-chain Conditional Random Field (CRF; Lafferty et al. 2001), and Transformer-based models (Vaswani et al., 2017) — specifically BERT variants (Devlin et al., 2019; Liu et al., 2019).⁵ The features for the CRF we use are: Indicators of next, previous, and current words; Part-of-speech tags,⁶

⁵We also explored t5 (Raffel et al., 2020) with middling results, which we report in the Appendix.

⁶Extracted with SciSpacy (<https://allenai.github.io/scispacy/>).

and; Indicators encoding if sentences contain digits, uppercase letters, and/or measurement units. BERT variants yield contextualized representations of input tokens, which we then use to predict labels (i.e., Claims, Experiences and Questions) by adding a linear layer on top of the encoder outputs. PIO elements are extracted using a concatenated input of the original Reddit post and an identified claim.

3.2 Evidence Retrieval

For the retrieval task we assume the model is given: (i) The original Reddit post and a claim; (ii) PIO elements associated with that claim, and; (iii) A large set of candidate articles featuring trustworthy evidence to rank. We use $\sim 800,000$ abstracts from *Trialstreamer*⁷ (Marshall et al., 2020), a continuously updated database of reports of randomized controlled trials (RCTs). RCTs are appropriate here because of our focus on causal claims — results from randomized trials are the most reliable means of evaluating such assertions (Meldrum, 2000).

3.2.1 Task Formulation

Formally, we represent a single input instance as $(p, c_j, \text{pop}_j, \text{int}_j, \text{out}_j)$ where p is a post comprising n sentences, c_j is the j th claim, and $\text{pop}_j, \text{int}_j, \text{out}_j$ are the sets of populations, interventions, outcomes associated with claim j .

The model is tasked with finding relevant abstracts from the candidate set \mathcal{A} , which comprises abstracts from published clinical trial reports. This is particularly challenging because a large number of candidates can mention the same set of PIO entities (i.e., investigate the same interventions and/or outcomes), but in a context unrelated to the claim being made in the social media post. This may be especially problematic for retrieval methods based primarily on string overlap measures. We therefore propose a learning based approach. This requires supervision; we next describe our approach to deriving this automatically.

3.2.2 Pseudo Training Data

Supervised neural retrieval models require annotations indicating the relevance of instances (here, published evidence) to inputs (claims on social media). We do not have such judgments, and so instead derive “pseudo” training data automatically.

We started with $\sim 800,000$ abstracts of medical RCTs in *Trialstreamer*. We then used Reddit

Table 4: Results on the test-set of span-classification to identify pure claims, questions, and experiences.

posts containing pure claims as *templates* to create pseudo matches between medical claims and abstracts. Specifically, we substituted annotated PIO elements in claims made within Reddit posts with PIO elements sampled from Trialstreamer abstracts. (Trialstreamer includes PICO elements automatically extracted from all articles that it indexes.) This yields pairs of (a) naturally occurring claims (with their PIO spans replaced) and (b) RCT abstracts that are relevant to said claims by construction. We provide examples of this pseudo matching in Appendix D. We generated a total of 85,000 examples of (pseudo claims, evidence abstract) one-to-many pairs to be used to train a neural retrieval model (described below). The generated examples may be noisy, but hopefully sufficient to train a model to retrieve medical abstracts relevant to health-related claims made on social media.

3.2.3 RedHOT Dense Evidence Retriever

We train a neural retrieval model on the RedHOT corpus, using a setup similar to DPR (Karpukhin et al., 2020). We first assemble a collection of m RCT abstracts to create an evidence corpus, $\mathcal{A} = \{d_1, d_2, \dots, d_m\}$. There are hundreds of thousands of RCTs, so we need an *efficient* retriever that can select a small set of relevant abstracts. Formally, a retrieval operation $\{R: (x_j, \mathcal{A}) \rightarrow \mathcal{A}_{\mathcal{F}}\}$ accepts an input contextualizing string x_j and a corpus of evidence \mathcal{A} , and returns a *much smaller* filtered set $\mathcal{A}_{\mathcal{F}} \subset \mathcal{A}$, where $|\mathcal{A}_{\mathcal{F}}| = k$.

We form an input context string x_j for a claim j made within a post p by concatenating the post, claim, and PIO elements extracted from the claim:

$x_j = [p \oplus c_j \oplus \text{pop}_j \oplus \text{int}_j \oplus \text{out}_j]$, where \oplus denotes concatenation with [SEP] tokens. We define two dense neural encoders (E_C, E_D ; both initialized with RoBERTa-base) to project the context string x_j , and evidence (abstracts) from \mathcal{A} to fixed 768 dimensional vectors. Similarity between the context string and evidence abstract is defined using the dot product of their vectors, $\phi(x_j, d_l) = E_C(x_j)^T E_D(d_l)$.

We train the model to minimize the negative log-likelihood of the positive evidence such that it pushes the context string vector x_j close to the representation of relevant evidence d_j^+ , and away from b irrelevant abstracts ($d_{j1}^-, d_{j2}^-, \dots, d_{jb}^-$) in the same mini-batch⁸ (“in-batch negative sampling”):

$$\mathcal{L} = \frac{\exp \phi(x_j, d_j^+)}{\exp \phi(x_j, d_j^+) + \sum_{l=1}^b \exp \phi(x_j, d_{jl}^-)}$$

In-batch negative sampling has been shown to be effective for dual-encoder training (Henderson et al., 2017; Gillick et al., 2019). Here, all samples in a minibatch are taken from the same *population* (condition) set, e.g., a mini-batch with a sample containing a claim about diabetes will have negative evidence abstracts that are also related to diabetes.

For test examples, we rank all evidence (abstracts in Trialstreamer) according to their similarity to the context string. To do this efficiently, we induce representations of all the abstracts in the Trialstreamer database using the evidence encoder and index these using the Facebook AI Similarity Search library (Johnson et al., 2021).⁹

⁸We set the size of the mini-batch to 100.

⁹FAISS: Open-source library for efficient similarity search

Table 5: Results of evidence retrieval baselines evaluated on pseudo test data.

3.2.4 Baseline Models

BM25 A standard Bag-of-Words method for IR (Robertson et al., 1995). We form queries by concatenating the Reddit post with a single claim and its corresponding PIO frames. We used a publicly available BM25 implementation from the Rank-BM25 library.¹⁰

Dense Passage Retrieval (DPR) is a dense retrieval model trained to retrieve *relevant* context spans (“paragraphs”) in an open domain question-answering setting (Karpukhin et al., 2020). In general, such models map **queries** and **candidates** to embeddings, and then rank candidates with respect to a similarity measure (e.g., dot product) taken between these. While originally designed for open-domain question answering, use of DPR-inspired models has been extended to general retrieval tasks (Thai et al., 2022a). We use a DPR context encoder trained on Natural Questions (Kwiatkowski et al., 2019) with dot product similarity.¹¹

3.3 Results

We evaluate models for the tasks of identifying claims, experiences, and questions and extracting PIO elements using precision, recall, and F1 scores. We report results per class for the first task in Table 4. BioRedditBERT (Basaldella et al., 2020) — a BERT model initialized from BioBERT (Lee et al., 2019) and further pre-trained on health-related Reddit posts — fares best here. We report results for the second task (PIO tagging) in Table 3.¹² Here RoBERTa (Liu et al., 2019) modestly outperforms BioRedditBERT (Basaldella et al., 2020).

and clustering of dense vectors; <https://ai.facebook.com/tools/faiss/>.

¹⁰https://github.com/dorianbrown/rank_bm25

¹¹<https://huggingface.co/facebook/dpr-ctx-encoder-single-nq-base>

¹²Results from additional experiments using other model variants are reported in Appendix C.

Models for the retrieval task rank evidence candidates for each input (post, claim, PIO frame). We therefore use standard ranking metrics for evaluation, including mean reciprocal rank, and precision@ k (for $k = 1, 5, 10, 50, 100$). Baseline results are reported in Table 5. We emphasize that these results are with respect to pseudo annotated data, effectively providing an unfair advantage to RedHOT-DER, given that this was optimized on data from this distribution. We report results with respect to manual relevance judgments provided by experts in Section 3.4.

As we might expect, the pre-trained neural DPR model outperforms the naive string matching BM25 method. Furthermore, as anticipated, explicitly training for evidence retrieval confers pronounced advantages: RedHOT-DER fares $\sim 8x$ better than BM25 and $\sim 5x$ better than “off-the-shelf” pre-trained DPR (Karpukhin et al., 2020) with respect to retrieving relevant evidence (precision@1) corresponding to medical claims. Again, this is not particularly surprising given that we are evaluating models with respect to the pseudo annotations with which RedHOT-DER was trained (because we do not otherwise have access to explicit relevance judgments). Therefore, we next present results from more meaningful manual relevance evaluations performed by domain experts.

3.4 Expert Manual Relevance Judgments

We evaluated models in terms of retrieving evidence relevant to *naturally occurring* medical claims, as opposed to the *pseudo* data derived for training. We hired three domain experts (medical doctors) on the Upwork platform.¹³ Providing hundreds of retrieved medical abstracts per claim to a human evaluator for assessment is infeasible, so

¹³Upwork (<https://www.upwork.com/>) allows clients to interview, hire and work with freelancers. All of our evaluators had medical degrees and were hired at wages ranging from \$15 to \$20 per hour for a minimum of 15 hours.

Cumulative # of relevant abstracts @ k				
k	1	3	5	10
<i>Pre-trained DPR (Karpukhin et al., 2020)</i>				
Relevant	6	16	29	58
Somewhat relevant	14	39	66	135
Irrelevant	80	245	405	807
<i>RedHOT-DER trained on pseudo data</i>				
Relevant	18	62	101	201
Somewhat relevant	17	49	87	193
Irrelevant	65	189	312	606

Table 6: Results from manual (domain expert) evaluations for DPR and our pseudo-supervised DER model.

we instead provided evaluators with 10 retrieved abstracts each for 100 individual claims, retrieved using the pretrained DPR (Karpukhin et al., 2020) model and our **RedHOT**-DER trained on pseudo data. (We compared the proposed distantly supervised model to DPR because it is the strongest baseline we evaluated in preliminary experiments.)

We asked evaluators to categorize each retrieved abstract as: (1) Relevant; (2) Somewhat Relevant, or; (3) Irrelevant to the corresponding claim. An abstract was to be considered Relevant if and only if it (1) contained to the same **P**, **I**, and **O** elements mentioned in the original Reddit post, **and** (2) provided information to support or refute the claim in question. An abstract might be deemed Somewhat Relevant if it contains a **P**, **I**, and **O** set in line with the given claim, but does not provide any information relating these elements. We provide examples in the Appendix D.

Human evaluators achieve strong agreement: All three evaluators chose the same relevance label 71.33% of the time, while they all chose a different label only in 1.29% of the total instances. They also show substantial agreement in terms of Fleiss κ (0.71). We derive final relevance labels by majority vote. Comparing results from Table 5 and Table 6, at $k = 1$ we see similar values of precision in the manually annotated data and pseudo test data. However, for higher values of k large differences emerge, indicating considerable room for improvement. Compared to the pre-trained DPR model, at $k = 1$ **RedHOT**-DER retrieves a substantially larger fraction of relevant evidence abstracts (3x). At higher k , we also observe a large reduction in the number of *irrelevant* abstracts retrieved (e.g., at $k = 10$, the number of irrelevant abstracts de-

creases by $\sim 30\%$). We believe this highlights the value of our proposed distant supervision scheme.

4 Related Work

Claim validation via evidence retrieval Past work has typically treated (open domain) claim validation as a two-step process in which one retrieves evidence relevant to a given claim, and then makes a prediction regarding claim validity on the basis of this. Information retrieval (IR) models are usually used in the first step to rank order documents based on relevance to a given claim (Thorne et al., 2018; Wadden et al., 2020; Thai et al., 2022b; Hanselowski et al., 2018; Samarin et al., 2021; Saeed et al., 2021). The next step is usually to characterize *retrieved* evidence as supporting, refuting, or not providing enough information (although this latter category is not always included). Evidence might be individually characterized (Pradeep et al., 2021), or aggregated to make a single prediction about the veracity of the claim (Sarrouiti et al., 2021).

Scientific claim verification Beyond “general domain” verification, there have been efforts focused specifically on vetting *scientific* claims. SciFact (Wadden et al., 2020) largely follows the typical fact verification setup outlined above (but for scientific claims). Subsequent efforts have focused specifically on verifying claims related to COVID-19 (Saakyan et al., 2021). The evidence inference task (Lehman et al., 2019; DeYoung et al., 2020) entails inferring whether a given trial report supports a significant effect concerning a specific intervention, comparator, and outcome.

Crowd-sourcing annotation of scientific and medical texts We have relied on crowdworkers to annotate the instances comprising **RedHOT**. This is in keeping with a body of work that has shown crowdworkers capable of annotating health-related texts, even when these are technical (Drutsa et al., 2021). For example, several past efforts have crowdsourced annotation of texts drawn from PubMed, e.g. for mentions of diseases (Nye et al., 2018; Good et al., 2014). More recently, Bogensperger et al. (2021) crowdsourced a dataset of drug mentions (a type of *intervention*) on the darknet. Khetan et al. (2022) crowdsourced annotations of electronic health records to identify causal relations between medical entities. Similarly, there is a body of work relying on crowdsourcing to accom-

plish a diverse set of domain-specific non-medical NLP tasks (Sukhareva et al., 2016; Fromreide et al., 2014; Bhardwaj et al., 2019; Gardner et al., 2020).

Health-related Reddit corpora Past work has also built corpora of health-related Reddit posts. For example, Cohan et al. (2018) assembled a dataset of Reddit posts made by individuals who self-reported one of nine mental health diagnoses of interest. Building on this work, Jiang et al. (2020) introduced a dataset of Reddit posts to evaluate models for automatically detecting psychiatric disorders.

5 Conclusions

We presented **RedHOT**: a new, publicly available dataset comprising of about 22,000 richly annotated Reddit posts extracted from 24 medical condition-based communities (“subreddits”). This dataset meets a need for corpora that can facilitate development of language technologies for processing health-related social media posts.

We evaluated baseline models for categorizing posts as containing claims, personal experiences, and/or questions. Focusing on claims, we then proposed and evaluated models for extracting descriptions of populations, interventions, and outcomes, and then using such snippets to inform retrieval of trustworthy (published) evidence relevant to a given claim. To this end, we introduced a heuristic supervision strategy, and found that this outperformed pre-trained retrieval models.

Limitations

We have introduced a new annotated dataset of medical questions, experiences, and claims across a range of health populations from social media. We showed that this data can be used to train models potentially useful for downstream applications, e.g., by facilitating content moderation. However, there are important limitations to this work, specifically with respect to the raw data we sampled and the annotations on this that we have collected.

First, the dataset we have annotated is inherently limited. While we have tried to select a diverse set of health populations (i.e., subreddits), these nonetheless constitute a small sample of the diverse set of existing health conditions. Moreover, our selection has led to a corpus comprising nearly entirely of English-language posts, which is a clear limitation.

We relied on non-expert (layperson) workers from Amazon Mechanical Turk (AMT) to carry out

the bulk of annotation work. While we took steps to try and ensure annotation quality (described in Section 2), we nonetheless acknowledge that these annotations will contain noise. This is especially true given that AMT workers are not medical-experts and ultimately do not have (nor are they expected to have) sufficient knowledge of different kinds of medical terms appearing in the dataset (e.g., SSRIs stand for *selective serotonin reuptake inhibitor* and is a common form of intervention which may lead to outcomes like dizziness, anxiety, and/or insomnia, but many laypeople might simply be unaware of ordinary meaning of complicated medical terms leading them to *not* matching all or part of such terms to their respective labels).

In Section 3.2.2, we describe how we obtained *pseudo* training labels to build a supervised dense retriever. To generate this data, several natural language claims get reused with substitute set of populations/interventions/outcomes. This heuristic may induce certain biases (as evident from Table 6 and Table 5). An ideal way to train a dense retriever here would be to collect positive annotation labels for *every* claim in our dataset. Collecting such supervision at scale sufficient for model training would be expensive, given that one would strongly prefer expert (medical doctor) annotations concerning the factual accuracy of claims.

Ethics Statement

This work has the potential to contribute to human well-being by supporting development of language technologies for processing health-related social media posts. Such models might in turn provide insights about patient experiences and viewpoints in general, and more specifically may help community moderators identify and remove posts containing medical misinformation.

Realizing these potentially positive contributions requires annotated data with which to train relevant models; such data is the main contribution on offer in this work. However, releasing an annotated corpus of health-related social media posts raises concerns regarding individual privacy. The Reddit posts we have assembled and collected annotations were posted publicly on the Internet (almost always under pseudonyms), but nonetheless we have taken steps to ensure that individuals can choose not to be represented in this dataset.

Specifically, we sent a message to every user in the **RedHOT** explaining our intent to construct and

release this dataset and offering the option to “opt out”. In addition, although this is not required by Reddit, we have decided not to release the collected *posts* directly. Instead we release a script that will download the posts comprising our data on-demand and align these with the collected annotations. This means that if a user chooses to delete their post(s) from Reddit, they will also effectively be removed from our dataset. Further, we require anyone accessing this data to self-certify that they have obtained prior approval from their own IRB concerning the use-cases of their research.

Appendix for “RedHOT: A Corpus of Annotated Medical Questions, Experiences, and Claims on Social Media”

A Data Collection

A.1 Sampling from Reddit

We retrieved the *newest* 1,000 posts from the respective subreddits using the Reddit PRAW¹⁴ API. While we could have relied on alternative sampling strategies — e.g., ranking posts according to “hot” or “best” under Reddit’s metrics — retrieving the newest posts yields an unfiltered snapshot of the full variety of posts made to social media. We also considered performing completely uniform sampling over all posts ever made to a given forum, but the Reddit API limits callers to retrieving 1000 posts for any search criteria; this practically precludes uniform sampling across all time periods.

Preprocessing We identified and removed all non-English text post extraction.¹⁵ Reddit allows its users to post media content (images/videos) in addition to text, and such imagery can be explicit or disturbing. Therefore, we only retained posts that did not contain any media content.

A.2 Annotations on Amazon Mechanical Turk

Amazon Mechanical Turk (AMT) is a popular platform for recruiting non-expert workers to perform “micro-tasks” (here, annotation). We initially recruited workers by collecting annotations on relatively simple examples for which we already had ground truth labels. We provided AMT workers with a comprehensive set of instructions including (templated) examples of the respective categories. For instance:

- **Questions:** Does this work?; Are X, Y, Z symptoms normal for Condition A?; Will increasing my dosage of X help Y in any way?
- **Personal Experiences:** I was diagnosed with X and have since experienced symptoms Y,Z.; I took X and it seemed to help.; My mother took Y and it helped improved her Z
- **Claim:** My doctor told me that X should help with Y; Since increasing dosage of Z, my X levels have normalized (also an example of personal-experience); I heard from multiple

¹⁴<https://github.com/praw-dev/praw>

¹⁵Langid is a python tool that allows filtering data by language: <https://github.com/saffsd/langid.py>.

people that A helps with C; I read online that X & Y are directly causing Z; I heard from my cousin that X helps control Z

For additional context we provided workers with the “Topic”, i.e., the subreddit from which the post being annotated was sampled. For example, if the topic was “Diabetes”, the piece of text will (presumably) be about diabetes, its treatments, individual experiences with the condition, and so on. We highlight the stage-1 annotation interface in Figure 3. The complete set of instructions we provided to AMT workers are available at https://anonymous.4open.science/r/med_val-64C2/stg1_instructions.pdf.

We retained all qualified AMT workers from stage-1 to carry out additional annotations for us in stage-2, with a higher pay rate. The objective here was to recruit people who had established a working understanding of the data, and would presumably be proficient as a result. Similar to stage-1, we provided workers with a comprehensive set of instructions containing (templated) examples to give a sense of what might be qualify as PIO elements:

- **Populations** coronavirus, asthma, narcoleptic, diabetic, children, young, women etc.
- **Interventions** diet, aspirin, allopurinol, insulin, exercise, botox etc
- **Outcomes** depression, sweating, anxiety, pain, flares, covid etc

Interface used for stage-2 annotations is provided in Figure 4. Complete set of stage-2 instructions provided to AMT workers are available at https://anonymous.4open.science/r/med_val-64C2/stg2_instructions.pdf.

B Dataset Summary

Table 7 provides descriptive statistics for all patient populations (that is, subreddits) included in our dataset. Dysthymia has the highest number of posts included in our corpus while Ankylosing Spondylitis has the lowest (due to data filtering described above). There is substantial variation in the length of the posts written under different subreddits (e.g., in r/ADHD the average post is ~222 tokens, while in r/Lupus it’s only ~93 tokens long). Similarly, there are variations in the number of questions, claims, and experiences across populations. We used subscriber count as a proxy for

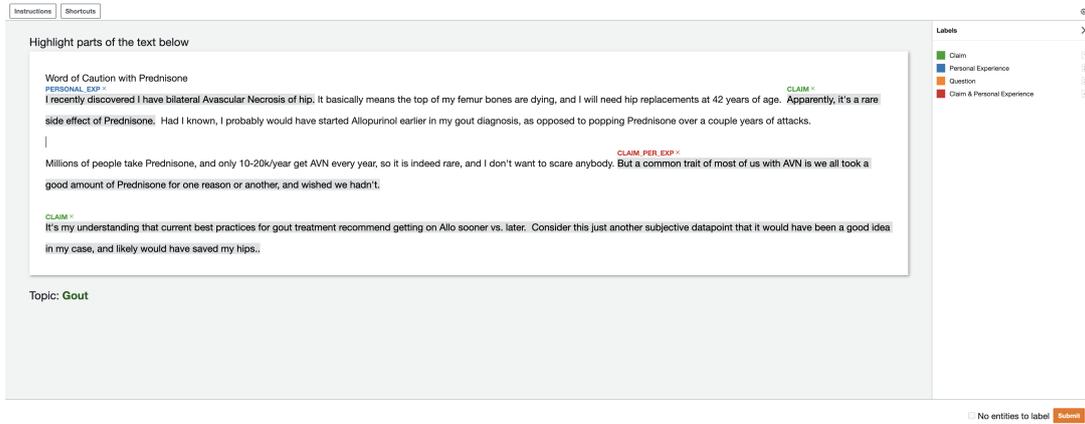

Figure 3: Stage-1 annotations interface for demarcation of spans associated with *questions*, *experiences*, and *claims*.

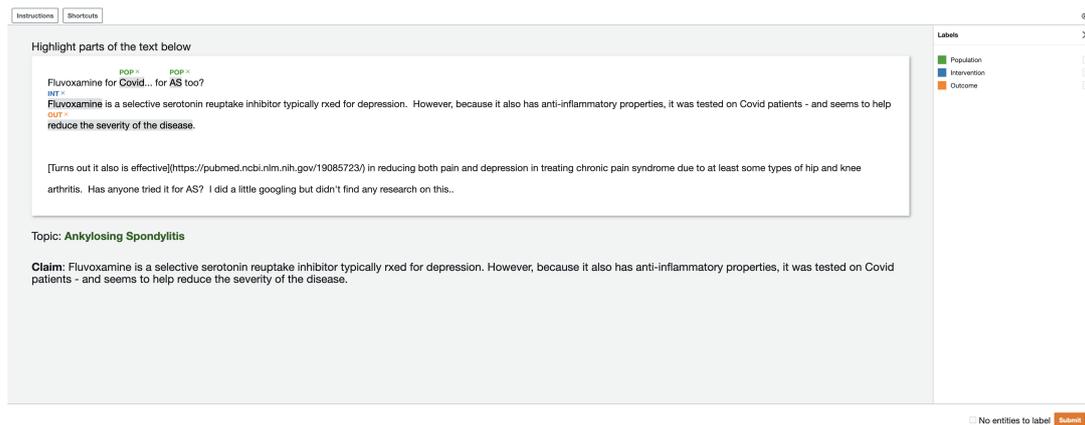

Figure 4: Stage-2 annotations interface for demarcation of PICO frames associated with a given Reddit post and a claim.

Population Type (subreddit)	# of posts in RedHOT	Avg. length of post (# tokens)	# claims	# questions	# experiences	# subscribers on Reddit
Dysthymia	999	175.42	102	989	1387	6.8k
Chronic Fatigue Syndrome	998	139.50	162	1034	1292	31.1k
IBS	998	118.70	71	987	1337	77.1k
Narcolepsy	997	148.65	121	1311	1547	18.9k
Bulimia	996	122.99	46	761	1316	32.8k
Hypothyroidism	995	125.91	111	1585	2088	35.2k
Costochondritis	995	116.97	98	1136	1488	8.8k
Hyperhidrosis	994	97.21	184	1076	1245	25k
Sinusitis	991	135.45	136	1242	1979	5.9k
Psychosis	984	122.91	53	932	933	39.8k
Thyroid Cancer	976	121.80	143	1157	1405	3.2k
Cystic Fibrosis	970	96.11	77	1001	882	7.1k
POTS	963	111.03	77	1155	1274	21.8k
Multiple Sclerosis	958	152.47	129	1081	1309	31.6k
Gout	933	128.87	154	1251	1730	14.2k
ADHD	899	222.41	141	875	1222	1.4M
Gastroparesis	861	134.91	52	909	1319	8k
Diabetes (Type I & II)	748	113.85	40	667	620	90.4k
Crohn's Disease	791	99.79	92	1026	995	43.7k
Lupus	784	93.13	96	978	972	18.2k
Rheumatoid Arthritis	759	103.08	105	1033	1010	6.4k
Epilepsy	670	165.77	37	634	1170	27.8k
GERD	650	164.12	45	669	1518	44.2k
Ankylosing Spondylitis	644	170.83	32	649	1139	12.6k

Table 7: Population-wise descriptive statistics.

Population type	# Posts	Average # per population			Average # per claim		
		Questions	Experiences	Claims	Populations	Interventions	Outcomes
Very Common (Dysthymia, Hypothyroidism, Gout, etc)	5467	1101.82	1654.00	114.83	0.82	2.66	3.57
Common (Chronic Fatigue Syndrome, Bulimia, Psychosis, etc)	9539	847.01	1141.72	74.27	1.05	2.95	3.22
Rare (Narcolepsy, Hyperhidrosis, Thyroid Cancer, etc)	7295	1028.50	1166.25	104.75	0.97	2.79	3.81

Table 8: For descriptive purposes we categorize conditions into: Very Common (>3 million US cases per year), Common (>200k US cases per year), and Rare (<200k US cases per year). We only include posts that do *not* contain any media (photos/videos). Number of experiences here *include* claims based on personal experiences. Diabetes is included as both Common (Type II) and a Rare (Type I) type.

	P	R	F1
Questions	0.73	0.68	0.70
Claims	0.47	0.40	0.43

gauging how active a community on Reddit is. For instance, *r/ADHD* has 1.4M subscribers and so can be considered substantially more active than, say, *r/Psychosis*, which has 39.8K subscribers.

C Additional Results and Experimental Details

We provide results from additional BERT (Devlin et al., 2019) variants for the first task of identifying claims, questions, and experiences in Table 10. Unsurprisingly, pre-trained neural models consistently outperform linear-chain Bag-of-Words CRFs. Similarly, Table 11 provides results from BERT variants and t5-small (Raffel et al., 2020) for the second task of extracting PICO elements conditioned on the post and a given claim. For the t5 model, the target was to produce `<entity token>` followed by `<entity label>` in the same order as they appear in the input sentence (sequential linearization scheme). We evaluated the generated entities against the true sets of PICO elements for each output. While it may be possible to come up with a more optimal linearization scheme for sequence labelling, we posit that to be beyond the scope of our work.

To use dense retrieval models to rank evidence (abstracts) with respect to their relevance to a given claim we need an efficient means to index vectors for $\sim 800k$ abstracts of RCTs in the Trialstreamer database. We did so using FAISS (Johnson et al., 2021) on an Intel Xeon E5-2650 V3 CPU @2.3GHz with 512GB memory. Building an index of dense embeddings for hundreds of thousands passages is highly resource intensive and required roughly 9 hours on two NVIDIA GeForce GTX 1080Ti GPUs.

To train the dense retriever, we used standard split of train, development, and test sets (80%-10%-10%). We trained the two encoders for 40 epochs with a learning rate of 10^{-5} using the Adam optimizer, linear scheduling with warm up, and a dropout rate of 0.1. We parallelized training over

multiple-GPUs; it took roughly 40 hours to train the retriever. Our best-performing retrieval model was initialized with RoBERTa-base (250M parameters). In addition to the results provided in section 3.3, we provide additional results for the retrieval task (evaluated on pseudo test set) in Table 12.

D Deriving Pseudo Training Data: Examples

Generating pseudo training data — i.e., matching reddit annotated reddit posts to “relevant” abstracts of RCTs — is an important component of our dense retrieval pipeline. In Table 13 we provide several examples of the pseudo data we generated from annotated claims. For each row we have inserted intervention and outcome elements from abstracts indexed in Trialstreamer, which makes them “relevant” by construction (while still featuring natural language as it used on social media). We showcase how stage-2 annotated (post, claim) pairs serve as templates to create pseudo claims by substituting PICO elements from an existing corpus.

In Section 3.4 we emphasize the need to evaluate retrieved evidence relevant to *naturally occurring* medical claims, as opposed to the *pseudo* data we derived for training. To this end, we hired domain experts (medical doctors) to look at the evidence abstracts from our retrieval model and assign a relevance score to each abstract (3: relevant, 2: somewhat relevant, 1: irrelevant). We provide some examples of retrieved evidence in Table 14 annotated by our experts as *relevant* (score: 3). Due to space constraints, we provide a link to the full article instead of the full abstract text.

³last@isg.cs.uni-magdeburg.de

Abstract

Existing language and vision models achieve impressive performance in image-text understanding. Yet, it is an open question to what extent they can be used for language understanding in 3D environments and whether they implicitly acquire 3D object knowledge, e.g. about different views of an object. In this paper, we investigate whether a state-of-the-art language and vision model, CLIP, is able to ground perspective descriptions of a 3D object and identify canonical views of common objects based on text queries. We present an evaluation framework that uses a circling camera around a 3D object to generate images from different viewpoints and evaluate them in terms of their similarity to natural language descriptions. We find that a pre-trained CLIP model performs poorly on most canonical views and that fine-tuning using hard negative sampling and random contrasting yields good results even under conditions with little available training data.

1 Introduction

Recent advancements in pre-training large-scale language and vision (L&V) models, such as CLIP (Radford et al., 2021), have led to exceptional performance on benchmarks and leaderboards in 2D image-text retrieval (Shen et al., 2021; Fang et al., 2021; Baldrati et al., 2022). However, the image-text data in these benchmarks have specific properties and biases (Thomason et al., 2022) that may limit the language grounding capabilities of existing L&V models and their robustness in real-world scenarios (Khandelwal et al., 2022; Gadre et al., 2022). A fundamental bias in existing L&V data comes from the fact that images generally show single, human-centric views of *different objects*. This raises a simple but intriguing question: to what extent can a model acquire knowledge about the concept of viewpoints and identify *different views on the same object*? Figure 1 illustrates this challenge, showing the top-3 images

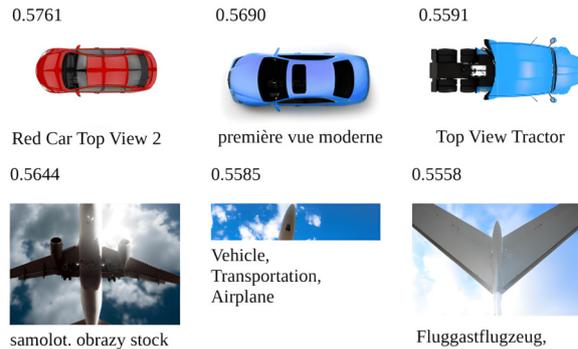

Figure 1: Top-3 retrieval results for *car/airplane from the bottom* using CLIP on the LAION-5B dataset.²

retrieved by CLIP for two basic viewpoint descriptions, *car/airplane from the bottom*, in the LAION-5B (Schuhmann et al., 2021) data set: the *airplane* images mostly correspond to the correct view, but none of the *car* images shows a bottom view. It suggests that the model does not generalize the meaning of viewpoint descriptions across different objects,¹ and may fail to acquire visual-linguistic knowledge that would be needed in more realistic 3D scenarios, such as when instructing a drone to take a picture of an object from a specific viewpoint (Thomason et al., 2020; Fan et al., 2022). This opens the door for a systematic examination of the capabilities of L&V models for grounding viewpoint descriptions, delving into the question of why, despite their excellent zero-shot capabilities, a model like CLIP struggles when it comes to representing perspectives of the same object.

In this paper, we investigate whether language understanding in pre-trained L&V models generalizes to simple text-viewpoint descriptions of common objects. We propose a new task – text-viewpoint retrieval – and a framework for analyzing and scaling image-text models with 3D data.

¹When searching the LAION-5B dataset via image embeddings of cars from the bottom, dozens of relevant results can be provided, which shows that these views exist in the data.

²<https://rom1504.github.io/clip-retrieval/>

We implement a **Paparazzi** agent that circles a spherical camera around a 3D object, samples images, and scores pairs of image-viewpoint descriptions using a pre-trained image-text matching model. In this framework, we evaluate and analyze whether CLIP, as a representative image-text-matching model with excellent zero-shot capabilities, systematically retrieves images of views of 3D shapes, regardless of potential reporting biases in 2D L&V data sets.

To successfully interpret viewpoint descriptions like *car from the bottom*, models need to connect concepts in natural language to visual representations and basic knowledge of object geometry. To investigate this, our approach is deliberately simple: we use 3D shapes from five categories of common objects in ShapeNet that have visually distinct canonical views (*front, back, left, right, top, bottom*). Based on Goldberg polyhedrons (Goldberg, 1937), that divide a sphere into hexagonal shapes, we analyze whether CLIP provides an adequate embedding for the viewpoint space around an object. Our analysis suggests that basic viewpoint understanding is indeed a systematic gap in the pre-trained CLIP model, as it achieves very poor performance in scoring view-description pairs and even retrieves nonsensical, non-human-centric views. Furthermore, we find that this problem is not fixed by standard fine-tuning. Thus, we propose a procedure for fine-tuning CLIP that extends the contrastive learning approach to viewpoints and descriptions generated from 3D visualizations. We find that a small amount of training data and extended fine-tuning is successful in scaling CLIP to basic viewpoint understanding in 3D.

2 Related Work

Vision, View, and Language. To date, research on grounding language in vision focuses on connecting language to visual representations of 2D human-centric views of scenes and objects based on, e.g., large image-caption data sets (Thomee et al., 2016; Schuhmann et al., 2021). Retrieval models in L&V usually rank a fixed set of images showing single views of different objects and scenes given a textual query or vice versa (Li et al., 2020a,b; Baldrati et al., 2022). Common understanding models process pairs of texts or questions and single-view images and predict labels for them, typical generation models process single-view images and generate descriptions for them (Mokady

et al., 2021; Yu et al., 2022). In this paper, we propose a new L&V retrieval task where the model needs to search for a specific view, represented as an image, of a 3D object given a textual query. In our task, the space of possible view-images is not restricted to a human-centric view.

Language Grounding in 3D. Achlioptas et al. (2019) present pioneering work in this area, with a referring expression data set designed for learning the language of shape for *chair* objects in ShapeNet, the most well-known resource for 3D object models (Chang et al., 2015). They build a neural resolution model that predicts which chair is referred to by a given shape description. Their encoder combines an autoencoder for point clouds of 3D shapes and a pre-trained image encoder for a single view of the object. As Achlioptas et al. (2019) collected descriptions of the 3D objects in a static environment with a fixed camera perspective, their approach does not account for dynamic viewpoints in 3D. Thomason et al. (2022) present a larger data set for expressions referring to ShapeNet objects and build a model that relies on image-text matching via the CLIP architecture, similar to ours. Their model takes images of eight fixed viewpoints of the object as input and integrates a component that estimates the viewing angle of an image. They evaluate on resolution accuracy and do not explicitly test viewpoint understanding in the CLIP model. In contrast to these existing works, the input to our model does not specify a fixed set of camera positions, and the output is an explicit, specific viewpoint of an object represented as an image.

Camera Position Estimation. Viewpoint selection in a 3D environment is a well-known problem in other areas (Kamada and Kawai, 1988; Roberts and Marshall, 1998; Arbel and Ferrie, 1999; Vázquez et al., 2001; Plemenos and Sokolov, 2006; Podolak et al., 2006; Mühler et al., 2007). Work in photogrammetry investigates camera position estimation minimizing the error in 3D measurements and reconstruction (Olague and Mohr, 2002). Systems in visualization aim to find an optimized viewpoint with the least possible occlusion and maximum information content for polygonal data (Vázquez et al., 2001; Neugebauer et al., 2013; Meuschke et al., 2017), volumetric data (Bordoloi and Shen, 2005) and vector fields (Lee et al., 2011; Tao et al., 2012). A key challenge in these areas is the definition of what actually constitutes a

good viewpoint (Bonaventura Brugués et al., 2018). Most algorithms aim to find a viewpoint that is of high interest to the user (Leifman et al., 2016; Neugebauer et al., 2013), but do not yet incorporate textual descriptions of viewpoints. In addition, most of these algorithms require expensive annotated mesh representations of 3D objects. L&V models pre-trained on raw image-text data constitute an extremely promising direction here, provided that they are capable of viewpoint understanding.

3 Text-Viewpoint Retrieval Task

We study viewpoint understanding from descriptions and describe a framework for text-viewpoint retrieval. We present a task definition, the set-up of the 3D environment and the camera, and our approach to evaluation and analysis.

3.1 Task Definition

We define the input of our viewpoint retrieval task to consist of a 3D scene with a single object O , a search query describing a viewpoint q , and an orbital camera C circling the object. The camera returns single views of the object v that are represented as RGB images. The retrieval model’s task is to find a viewpoint v that matches the query q . In this work, we implement retrieval via a scoring function S that passes pairs of images v (taken by the camera) and queries q to a pre-trained text-image matching model. The parameterization of the orbiting camera C determines the space of possible viewpoints V that the retrieval model has to search. The parameter setup we used in this work is explained in detail below.

This setting leverages the well-understood image-text matching in 2D for language grounding in 3D. Our retrieval model does not have a symbolic or explicit representation of the object’s geometry but can perceive it by taking images from various perspectives. This framework is independent of different types of 3D data and only requires an engine that renders images of 3D environments.

3.2 Camera Set-up

For the purpose of this study, we restrict the viewpoint space V to views that contain the object of interest. We use a spherical camera system where the center of the object defines its center, as shown in Figure 2. The camera in orbit can be navigated around the desired object using polar coordinates.

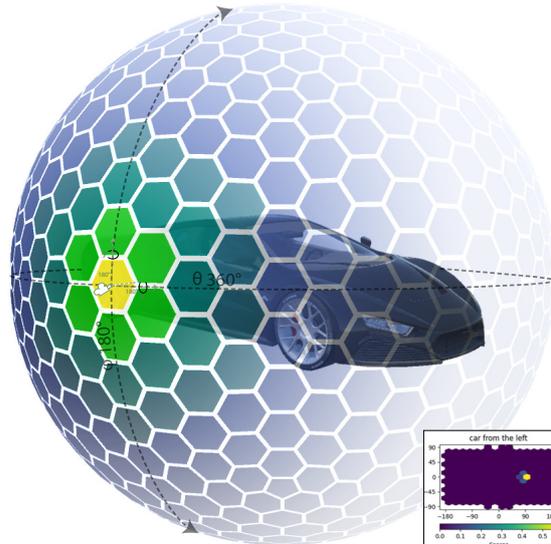

Figure 2: The camera setup: the viewing angles θ and φ describe the azimuthal and polar angle of the camera on the orbital sphere. The parameters x and y describe the camera’s orientation at the given location.

The position of the camera towards the object is defined by (r, θ, φ) for the radial distance, the azimuthal angle, and the polar angle. The center of the object is defined by the center of its bounding box. The camera’s local x and y axes are used to adjust the camera’s viewing angles. Rotation around the local z -axis of the camera is disabled in this work, as the results would be the same, only with a rotated output image. In summary, the exact camera position and rotation along the sphere can be described by five parameters: $(r, \theta, \varphi, x, y)$.

To create equidistant sample points for camera positions along the sphere, we use a Goldberg polyhedron (Goldberg, 1937). It divides a sphere into mostly hexagonal shapes, including a small finite number of pentagons, and creates a nearly equidistant sample space (see Figure 2). The centers of the hexagons give us a discrete number of sample points, which reduce the possible configurations of our camera setup to a finite number. The hexagon centers can be approached for different radii r . The polyhedron used in this work initially yields 1002 sample points per radius. This discretization of the sample space is fine enough to allow benchmarking and analysis of viewpoint retrieval models.

The object O lies at the origin of the Cartesian space $(0, 0, 0)$, which is also the center of the surrounding hypersphere. The radius r is clipped relatively to the size of the object. We estimate the extent of the object based on its bounding box. We

determine the extent of the bounding box based on the minimum r_{min} and maximum radius r_{max} of the surrounding orbital spheres. In our experiments, we set r_{min} to two times the edge length of the bounding box and r_{max} to ten times the edge length of the bounding box.

3.3 Evaluation and Analysis

Common Objects and Canonical Views. To systematically evaluate language-view understanding in CLIP, we limit the set of viewpoint descriptions Q in our experiments to the six **canonical views** *front*, *back*, *right*, *left*, *top*, *bottom* defined by Chang et al. (2015). We choose 3D models of common object categories in ShapeNet (Chang et al., 2015). From the available 55 categories, we selected five categories where all canonical views are visually distinct: *cars*, *airplanes*, *motor-bikes*, *mugs* and *benches*.³ As ShapeNet provides an aligned representation of all 3D models, these restrictions yield a fully controllable experimental setup where training and test data with pairs of queries and views can be generated automatically. The experimental setup is general enough to be transferable to arbitrary object domains and various forms of textual viewpoint descriptions.

Viewpoint Quality Evaluation. To assess the quality of text-viewpoint retrieval, we use the KL divergence (Kullback and Leibler, 1951) of a model’s scoring function against a gold standard scoring distribution as well as the classical retrieval metrics *precision@k* and *retrieval@k*. We use KL divergence in addition since retrieval metrics only reflect performance on gold standard viewpoints and do not allow us to infer the global performance needed to find out why models fail on certain queries, as discussed in Section 5. We define the gold standard score distribution with respect to a particular viewpoint as a discrete normal distribution around the gold standard viewpoint, which is the mean of the distribution. The three polygonal rings around the mean are assigned the normalized score value at one, two, or three times the standard deviation of the normal distribution. The scores for all these viewpoints sum to 1. The scores for all other viewpoints around the sphere are set to zero. The setup is illustrated in Figure 2. To visually

³Many object categories like *bottle*, *ball*, *table*, etc. do not have this property. For instance, the *front* and *back* views of a bottle are not or much less distinct than the *front* and *back* views of a car.

analyze the goodness of a scoring function over a sphere, we unfold the polyhedron and upsample it, as shown in the small map at the bottom right of Figure 2. In this way, we can visualize the difference between the gold standard and the predicted score distribution for an object.

Search Performance Evaluation. When searching a 3D scene, there are many possible viewpoints to consider. A scoring function that works well on a subset of pre-selected viewpoints may yield a good result in retrieval metrics, but in practical usage, it may lead the search algorithm to an unexpected or nonsensical viewpoint. Therefore, to evaluate the performance of a model, we need to consider not only how well it performs on the gold standard viewpoint images, but also how well it can guide a search algorithm to find the right viewpoint in the scene. We compare the performance of different search algorithms under different configurations of the scoring function to **understand the impact of the shape of the scoring function on search performance**. We compute search performance as follows: a search is considered successfully completed if the found viewpoint is within a certain radius of the respective gold standard viewpoint. We define the radius discretely based on the hexagonal rings around a gold standard viewpoint on the Goldberg polyhedron. In our experiments, we consider a search to be solved if a viewpoint is found within the first two rings around the gold standard viewpoint (see Figure 2). We compare performance in terms of the number c of calls to the scoring function required by the search algorithm to solve the search problem described above. We restrict the search length to a maximum number c_{max} of 300 viewpoints to visit. To obtain a robust comparison, we run the procedure n times at randomly selected starting positions on the hypersphere around the object. In our experiments, we set n to ten. Then, the number of calls $\frac{c}{n}$ is averaged.

4 Model

4.1 Scoring Function

The heart of our retrieval model is a function S that outputs matching scores for pairs of images and queries (v, q) . Pre-trained L&V models like CLIP (Radford et al., 2021) embed (v, q) pairs into a common subspace, resulting in latent vector representations \mathbf{z}_v and \mathbf{z}_q , e.g., of size 512 in the original CLIP. The output of the scoring function S

is the cosine similarity of the latent representations of the viewpoint image and the search query:

$$S(v, q) = \cos(z_v, z_q) = \frac{\mathbf{z}_v \cdot \mathbf{z}_q}{\|\mathbf{z}_v\| \|\mathbf{z}_q\|} = \frac{\sum_{i=1}^N z_{v_i} z_{q_i}}{\sqrt{\sum_{i=1}^N z_{v_i}^2} \sqrt{\sum_{i=1}^N z_{q_i}^2}} \quad (1)$$

To evaluate a given viewpoint with respect to a query, both are encoded into their latent representations \mathbf{z}_v and \mathbf{z}_q , and the cosine similarity of their latent representations is used as a **score** for how well the view matches the query.

4.2 Objective Functions

To achieve high similarity between associated texts and images, Radford et al. (2021) apply a contrastive learning paradigm. In a training batch of N image-text pairs, a cosine similarity score is computed for each possible text-image combination. This leads to $N \times N$ scores over which a cross-entropy loss is calculated across the rows and columns. For corresponding text-image pairs, the maximum class score is expected, while for all other pairs, a minimum score is targeted.

We extend this contrastive learning paradigm for fine-tuning CLIP with 3D data by minimizing the combination of three different loss objectives: a) for negative examples, b) for random examples, and c) for hard negative examples.

Cross-Entropy Loss on Negative Examples is calculated and summed for both queries \mathbf{q} and viewpoints \mathbf{v} as $L_{v,q}$. The parameter τ is a learnable parameter for scaling the logits:

$$L_{v,q} = -\frac{1}{N} \sum_{i=1}^N \log \frac{\exp(\cos(z_{v_i}, z_{q_i})/\tau)}{\sum_{j=1}^N \exp(\cos(z_{v_i}, z_{q_j})/\tau)} \quad (2)$$

Cross-Entropy Loss on Random Examples is denoted as L_r and computed between annotated viewpoints and randomly generated viewpoints of the 3D scene. L_r is computed exactly as in equation (2), but the contrastive examples are random images from the scene in this case.

Cross-Entropy Loss on Hard Negative Examples referenced as L_h uses images that have a different annotation but appear to be similar in latent space (Li et al., 2021). Robinson et al. (2020) present a sampling method that rescales the loss of negative examples based on their similarity to the gold standard sample. Following this, the loss L_h is calculated as the weighted contrastive loss

between the positive samples x^+ and the hard negative samples x^- drawn from the modified negative sampling distribution q :

$$L_h = Ex^+ \sim p_x^+ x \sim p \left[-\log \frac{e^{f(x)^T f(x^+)}}{e^{f(x)^T f(x^+)} + G E_{x^- \sim q} [e^{f(x)^T f(x^-)}]} \right] \quad (3)$$

In notation, p^+ is the marginal distribution of positive examples in the overall distribution of samples p . q is the distribution of negative samples. x is a single sample, x^+ and x^- are the respective positive and negative samples. f is a similarity measure, in our case it is cosine similarity. G is a weighting parameter that can be used to adjust the hardness of the negative sampling.

The total loss is parameterized as the weighted sum of the three objectives:

$$L_{total} = \alpha L_{v,q} + \beta L_r + \gamma L_h \quad (4)$$

The ablations resulting from the different combinations presented above are evaluated in Section 6. The parameters α , β , and γ are chosen based on the respective experiment.

4.3 Search Algorithms

At inference time, our retrieval model requires a search algorithm A , a function that optimizes the output of the scoring function S given the space of viewpoints V and a query q . We compare the performance of two search algorithms. **Greedy search** starts with a grid-based approach on the Goldberg polyhedron and tries to find the optimum by moving greedily in the direction of the neighboring region with the highest score in each iteration. **Bayesian search** samples positions on the hypersphere based on incrementally obtained function values, attempting to sample with higher probability in regions that contain optima (Mockus, 1994). See appendix A for implementation details.

5 Experiments

5.1 Experimental Setup

Training. For each of the six canonical view query types and five object categories, we generate 1,000 training images in a Unity scene on randomly selected objects from the ShapeNet training set. This results in 6,000 image and text pairs per object category, which is tiny as compared to the 15 million images in the YFCC100M (Thomee et al., 2016) data set for training the original CLIP.

Table 1: KL-Divergence between gold and predicted viewpoint distribution for the models *PRE-TR*, *FT*, *RC-HNS* on the objects *car*, *airplane*, *motorbike*, *mug*, *bench* for *front*, *back*, *left*, *right*, *top*, *bottom* viewpoints on synthetic images. Lower values are better.

Test Set. For evaluating the retrieval quality for each object category we randomly select three 3D shapes from the ShapeNet test set. Then we compute the normalized score distribution on synthetic images around the sphere with radius five for all selected objects of a category, compute the KL-Divergence and average the results per viewpoint query (see Table 1). To assess the performance on real-world data, we carefully curated a data set of 600 images (5 categories \times 6 viewpoints \times 20 images) by retrieving visually similar images for a seed image using image similarity on LAION-5B. Synthetic gold standard views are obtained from the sampled spheres (see Table 2).

Models. From the official CLIP repository (OpenAI), we select ResNet-101 (He et al., 2016) pre-trained on ImageNet (Deng et al., 2009) as image encoder and pre-trained BERT model (Devlin et al., 2018) as query encoder. We compare the following models: (i) **PRE-TR**ained CLIP, without further fine-tuning, (ii) CLIP-**FT**, a version of CLIP fine-tuned on the training data with standard cross-entropy loss, (iii) CLIP-**RC-HNS**, fine-tuned with extended loss objectives explained in Section 4.

5.2 Viewpoint Quality Results

Table 1 shows the results for the quality of viewpoint retrieval with different models, objects, and viewpoints. We find that a pre-trained CLIP model shows a high divergence from the gold standard

Model	P@1	P@5	P@10	R@1	R@5	R@10

Table 2: Precision@K and Recall@K per model ablation split by synthetic data and real data measured across all object categories.

distribution for all object categories under investigation. The fine-tuned model performs slightly better, but still shows large differences from the gold standard. The use of random contrasting and hard negative sampling brings the score distribution closer to the gold standard distribution. This shows that standard CLIP pre-training and fine-tuning on human-centered 2D images do not produce a suitable scoring function for the viewpoint space around a 3D object.

Evaluating performance on real data using KL divergence is not possible in a similar way as on synthetic data because we do not have access to images from arbitrary viewpoints. Therefore, we compare precision@k and recall@k between synthetic images from ShapeNet and real images at the gold standard viewpoints in Table 2. The results show that pre-trained CLIP performs poorly in grounding viewpoints on both synthetic data and real data. Fine-tuning the model on synthetic data greatly improves the retrieval metrics for both synthetic and real data. RC-HNS performs well on synthetic data that is within the distribution, however, it yields slightly lower scores on real-world data in comparison to FT. This may result from the fact that RC-HNS forces the model to generally score out-of-distribution data lower, thereby making the scoring function more sensitive to differences between synthetic and real-world images. In traditional 2D benchmarks, this may seem like a disadvantage compared to FT, but it proves to be advantageous in 3D viewpoint search, as demonstrated in the following section. Here, the FT model loses performance due to unpredictable scoring behavior in regions far from the gold standard viewpoints.

5.3 Search Performance Results

We test search performance in 3D as described in Section 3.3 for all six queries. Table 3 illustrates the

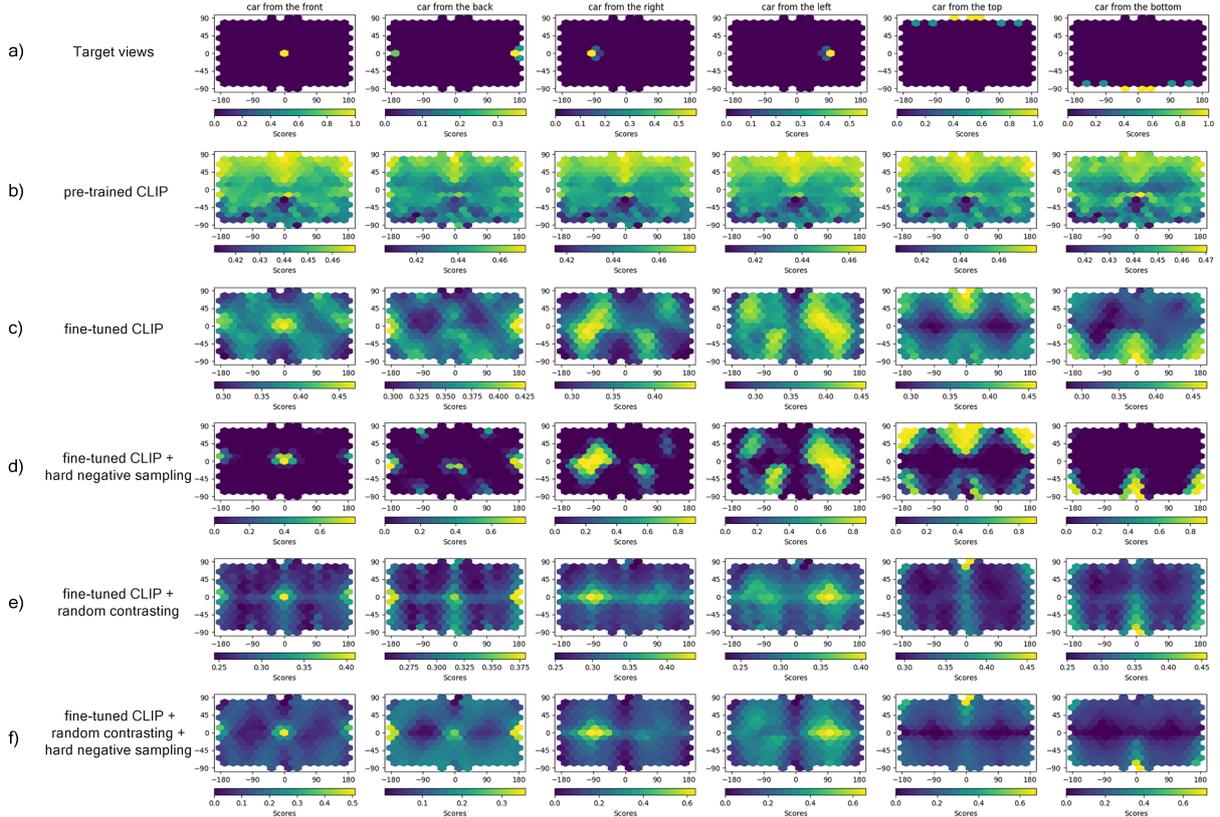

Figure 3: Score distribution on the six viewpoints per loss function combination on a car object. In a) gold-standard viewpoints expected to have high scores are shown, b) pre-trained CLIP, c) fine-tuned CLIP, d) hard negative sampling, e) random contrasting, and f) random contrasting + hard negative sampling. For more, see appendix A.

Table 3: Average number of calls to the scoring function per search algorithm and viewpoint query.

performance for Greedy and Bayes search. Both algorithms perform significantly better than an exhaustive search on the Goldberg polyhedron (= 1002 sample points, fixed radius). Bayesian search is much faster than greedy search, when using a finetuned scoring function (FT, RC-HNS), and it is more affected by the shape of the scoring function since it samples it strategically: it is fastest with the smoothest scoring function RC-HNS and very slow with pretrained CLIP. This is in line with the viewpoint quality results in Section 5.2, showing that pretrained CLIP has a poor representation of

the viewpoint space around an object.

6 Analysis

This section takes a closer look at how well the text-viewpoint embeddings capture understanding of different viewpoints. Specifically, we will explore whether the scoring functions correctly identify viewpoints that align with the linguistic description, while providing lower scores for those that do not.

6.1 Exhaustive Viewpoint Space Analysis

Based on the polyhedron that defines the viewpoint space of the camera, we carry out an exhaustive analysis of the scoring function over this space for specific objects and queries. We select a car from the test set of the ShapeNet data set and plot the scores of the evenly distributed samples from the surface of the Goldberg polyhedron at a radius of five for the six canonical viewpoint queries. We examine five different configurations of the loss objective shown in Equation (4). Figure 3a) illustrates the target region on the hexagon diagram, which contains the optimal viewpoint for a given query.

It can be seen in Figure 3b) that a pre-trained CLIP model even if trained on a large data set, is not able to discriminate between different viewpoints and that the scoring function has multiple optima. Fine-tuning the CLIP model (3c) on synthetic images improves viewpoint discriminability. Nevertheless, apart from the absolute gold standard regions, the function shows problematic local optima and in particular the left and right side views of the car are difficult to distinguish. In (d), we fine-tune the CLIP model by applying the hard negative sampling strategy proposed by Robinson et al. (2020). The results show that the gold standard viewpoints can be distinguished much more effectively when compared to previous experiments. However, the transition between viewpoints is quite sudden, making it challenging for a search algorithm to reach the optimum. In (e), a combination of negative contrastive loss $L_{v,q}$ and random contrastive loss L_r is applied. The results show that the additional objective makes the scoring function much more stable in regions farther away from known canonical viewpoints. In experiment (f), we combine hard negative sampling L_h with the idea of random contrasting. The plot of the scoring function shows that for each canonical viewpoint, the function increases steadily toward the optimal view.

6.2 Nonsensical Viewpoints

A further problem we noticed is that CLIP predicts high scores for nonsensical views that do not relate to the query, but rather seem to activate certain features to drive up the score, similar to adversarial examples (Goodfellow et al., 2014). Such behavior of models on unseen images has also been described by Du et al. (2022) and should be considered when using CLIP representations in continuous 3D environments, especially for vision-and-language navigation tasks, as in Khandelwal et al. (2022). Figure 4 shows retrieved nonsensical viewpoint images among the top-5 for *car from the front*.

Figure 4: Retrieved nonsensical viewpoints in the top-5 scored images on CLIP for the query *a picture of a car from the front*.

6.3 Data Set Size Ablations

To test how the scoring function is affected when only a small amount of training data is available, we gradually reduce the number of training samples from 1,000 to 1 for the best-performing model CLIP-RC-HNS. Access to 1,000 training examples per viewpoint, as shown in 5a), leads to a smooth function. Reducing the training data by 90 percent to 100 examples per viewpoint keeps good performance for the target viewpoints. Compared to the full data set, smoothness suffers slightly. Reducing the training data by 99 percent to ten samples per viewpoint still allows good results in the target regions. However, the surrounding regions become less smooth and drop more abruptly. Surprisingly, when breaking down the training data to one example per viewpoint, the target viewpoint areas still lead to global optima in all search queries. However, the transitions are no longer smooth but rather abrupt, especially for the front and back.

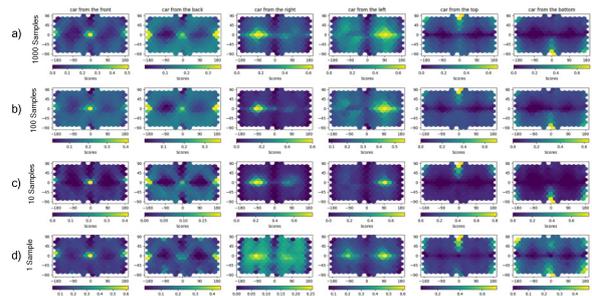

Figure 5: Overview of the effects of gradually reducing the number of training images per view from a) 1000 to b) 100 to c) 10 to d) 1 on CLIP-RC-HNS.

7 Conclusion

We developed a new framework to assess the capabilities of L&V models to ground viewpoint descriptions. Through our research, we discovered that a standard CLIP model struggles to distinguish between different viewpoints. To address this, we explored a combination of different loss objectives on synthetic data to make it easier to retrieve viewpoints from language descriptions. Our experiments revealed that incorporating random contrasting leads to a more accurate and seamless scoring function, as compared to using only text and human-centric images. Our framework thus offers a promising approach to scale L&V models trained on large-scale image-text datasets for applications that involve interaction in the 3D world.

Limitations

We deliberately opted for a simple controllable setup in order to gain a precise understanding of viewpoint representation in CLIP. Our experiments are restricted to canonical views and canned descriptions since they are easy to generate and evaluate automatically. Extending the data to other views and to human-like descriptions is the obvious avenue for future research. In particular, with the advent of NERF models in computer vision, we look forward to integrating these types of models into our framework, as this would allow the generation of near-realistic images in a controlled 3D setup, which would allow for even better evaluation of scoring functions in text viewpoint retrieval. Varying the level of detail of the 3D shapes, especially in complex 3D scenes where large objects consist of smaller parts is another interesting direction. Another restriction of our set-up is the fact that we consider context-free retrieval of viewpoints, whereas in many human-like descriptions such as the *right front tire of a car*, the viewpoint may not be visually unique and depend on the context of the scene, such as the relative position of the viewpoint to other viewpoints. The same applies to views that need to be delivered to a user in a task-oriented interaction, and are likely to be more complex and diverse than the canonical and synthetic ones used in this work. In conclusion, we believe that our framework has the potential to provide a more comprehensive understanding of reporting biases in image-text data used for pre-training LV models. By conducting a 360-degree analysis of the scoring function, our framework allows for a more thorough examination of these biases, as everything is visible and nothing can be hidden from the investigator, unlike when evaluating against a set of gold-standard viewpoints.

Ethics Statement

3D models from the ShapeNet dataset are available for research and non-commercial purposes as well as the LAION-5B data set. We did not collect any personal information from any annotators. We clearly state the intended use of our models, which is to support human-centric interaction with AI models in the 3D world.

Acknowledgments

We thank the Michael Stifel Center Jena for funding this work, which is part of the Carl Zeiss

Foundation-funded project 'A Virtual Workshop for Digitization in the Sciences' (062017-02).

A Experiment Details

This section provides additional details on our experimental setup. Section A.1 contains further visualizations of the experiments discussed in section 5. Section A.2 provides details about the implementation of the search algorithms used in our benchmark.

A.1 Scoring Function Analysis

The following plots illustrate the score distributions obtained with the different model ablations CLIP-**PRE-TR**, CLIP-**FT**, and CLIP-**RC-HNS**.

Scoring Function PRETR. Figure 6a shows the score distribution of the PRE-TRained CLIP model over 3D objects from the test set of the ShapeNet dataset.

Scoring Function FT. Figure 6b depicts the scoring distribution of the CLIP-FT model over 3D objects from the test set of the ShapeNet dataset.

Scoring Function RC-HNS. Figure 7a illustrates the score distribution of the CLIP-RC-HNS model over 3D objects from the test set of the ShapeNet dataset.

Comparison of Score Distributions for Object Only Queries. To understand which viewpoints CLIP scores best on an object-only query such as *a picture of a car*, we compare these object-only queries for all object categories tested on respective 3D objects from the test set. This tells us which viewpoints CLIP associates most with a given object category. Figure 8a indicates that a PRE-TRained CLIP model is not able to distinguish specific viewpoint queries from pure object queries.

Comparison of Optimal Viewpoints. Figure 8b shows the viewpoint images obtained from the optima of the scoring distributions generated by a CLIP model and a CLIP-RC-HNS model. The images illustrate that descriptions of viewpoints are indeed a bias in CLIP.

Figure 7b illustrates the viewpoints resulting from the global optima of the scoring functions obtained from the CLIP-RC-HNS model.

A.2 Search Algorithm Analysis

In our work, we are particularly interested in the impact of the shape of the scoring function on the performance of various search algorithms. Section A.2.1 provides details on the implementation

of greedy search. Section A.2.3 illustrates how the search algorithms listed above perform their task on a sphere.

A.2.1 Greedy Search Implementation Details

We implement a greedy search algorithm as a representative for gradient-based approaches. The greedy search starts with a grid-based approach on the Goldberg polyhedron and always follows the region with the highest score. It tries to find the optimum by greedily selecting the highest scoring regions at each iteration and searching in their neighboring regions at the next iteration. The search is initialized with k randomly selected starting points (here $k = 6$) from the Goldberg polyhedron. In addition, a cutoff value c must be chosen to determine how many grid points will be considered in the next iteration of the search. The cutoff value can be described as a relative percentage or as an absolute cutoff value. After evaluating all viewpoints with respect to the given query, the next iteration is started by selecting the locations with the highest scores considering the selected cutoff. All obtained scores and their neighboring sample points from the Goldberg polyhedron are added to the list of investigated viewpoints. After that, the next iteration is started. The neighborhood range n , which specifies the number of neighborhood grid points to be examined, can be adjusted. The search can be terminated after i iterations or when no new items have been added to the list of investigated viewpoints. In summary, the greedy search is parameterized by: (k, c, n, i) . We chose greedy search as a test algorithm for our benchmark to see how much gradient-based methods as candidate algorithms for the text-viewpoint retrieval task in a 3D environment depend on a smooth structure of the scoring function in their performance. We use a greedy nearest-neighbour heuristic, since the function is only defined at a fixed number of points due to the discretization of the search space.

A.2.2 Bayesian Search Implementation Details

Bayesian optimization (Mockus, 1994) is used to estimate the optimum of a black-box function that is costly to evaluate. The algorithm updates its Bayesian prior based on the stepwise function values obtained, increasing the certainty that the regions are likely to be optima and therefore more likely to be explored than other regions of the black box function. Then, the number of samples from

Model	P@1	P@5	P@10	R@1	R@5	R@10	
PRE-TR	0.111	0.056	0.050	0.017	0.040	0.066	car
FT	0.778	0.567	0.500	0.113	0.330	0.485	
RC-HNS	0.944	0.778	0.644	0.136	0.432	0.592	
PRE-TR	0.056	0.078	0.050	0.008	0.057	0.073	airpln

RC-HNS	0.667	0.500	0.450	0.098	0.312	0.462	
PRE-TR	0.056	0.033	0.017	0.008	0.024	0.024	mug
FT	0.389	0.311	0.294	0.056	0.179	0.286	
RC-HNS	0.667	0.489	0.483	0.097	0.312	0.532	
PRE-TR	0.000	0.011	0.006	0.000	0.008	0.008	bench
FT	0.667	0.511	0.439	0.097	0.312	0.465	
RC-HNS	0.944	0.744	0.689	0.136	0.411	0.592	

Table 4: Precision and recall metrics on synthetic data for the models *PRE-TR*, *FT*, *RC-HNS* on the objects *car*, *airplane*, *motorbike*, *mug*, *benchs* for *front*, *back*, *left*, *right*, *top*, *bottom* viewpoints.

the regions of interest is increased accordingly. We construct the search problem as a Bayesian optimization as follows: The input of the search algorithm is a vector of size five describing the camera position on the hypersphere around the target object: r, θ, φ, x, y . In this parameterization, θ and φ are spherical coordinates, r is the distance to the center of the 3D object, and x and y are the orientations of the camera along the horizontal and vertical axes. The location of the optimum of the scoring function with respect to a query \mathbf{q} depends on the rotation of the 3D object, which we only know is centered around $(0, 0, 0)$. Therefore, Bayesian search tries to find the optimum of the scoring function with respect to the properties of the 3D object at hand given the search query \mathbf{q} . For our benchmarks, we use the implementation of the Bayesian optimization algorithm in [Head et al. \(2021\)](#).

A.2.3 Search Algorithm Behavior on Sphere

The experiments in Section 5 have shown that a smooth scoring function is advantageous for search algorithms in text-viewpoint retrieval. This section visually analyzes why this is the case by examining how the algorithms perform on a sphere around a target object.

Figure 8c illustrates how the different algorithms approach the regions with higher scores differently. The greedy search with a low cutoff spreads across the sphere in waves, starting from the initial points. Once it touches a high point, it remains attached to it. In this respect, a good initialization is impor-

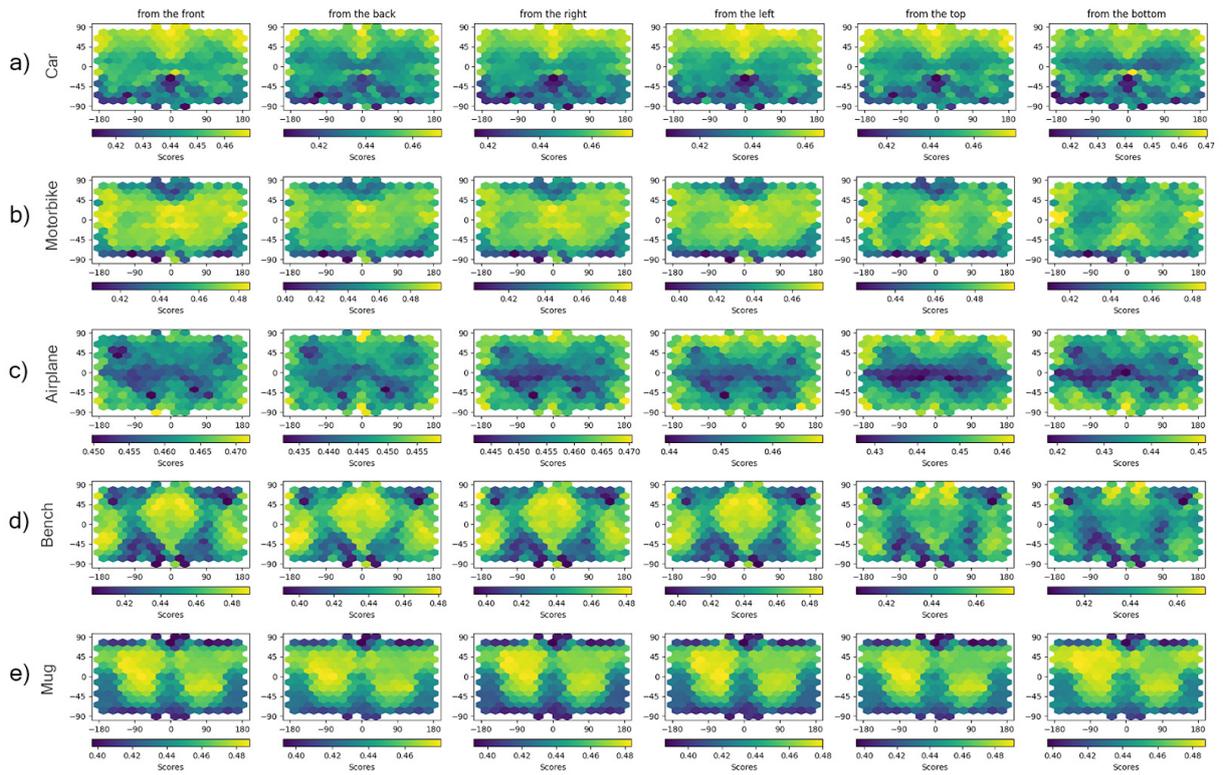

Model	P@1	P@5	P@10	R@1	R@5	R@10

PRE-TR	0.333	0.200	0.167	0.0167	0.050	0.083	bench
FT	1.000	0.733	0.583	0.050	0.183	0.292	
RC-HNS	0.667	0.500	0.500	0.033	0.125	0.250	

Table 5: Precision and recall metrics on real data for the models *PRE-TR*, *FT*, *RC-HNS* on the objects *car*, *airplane*, *motorbike*, *mug*, *benchs* for *front*, *back*, *left*, *right*, *top*, *bottom* viewpoints.

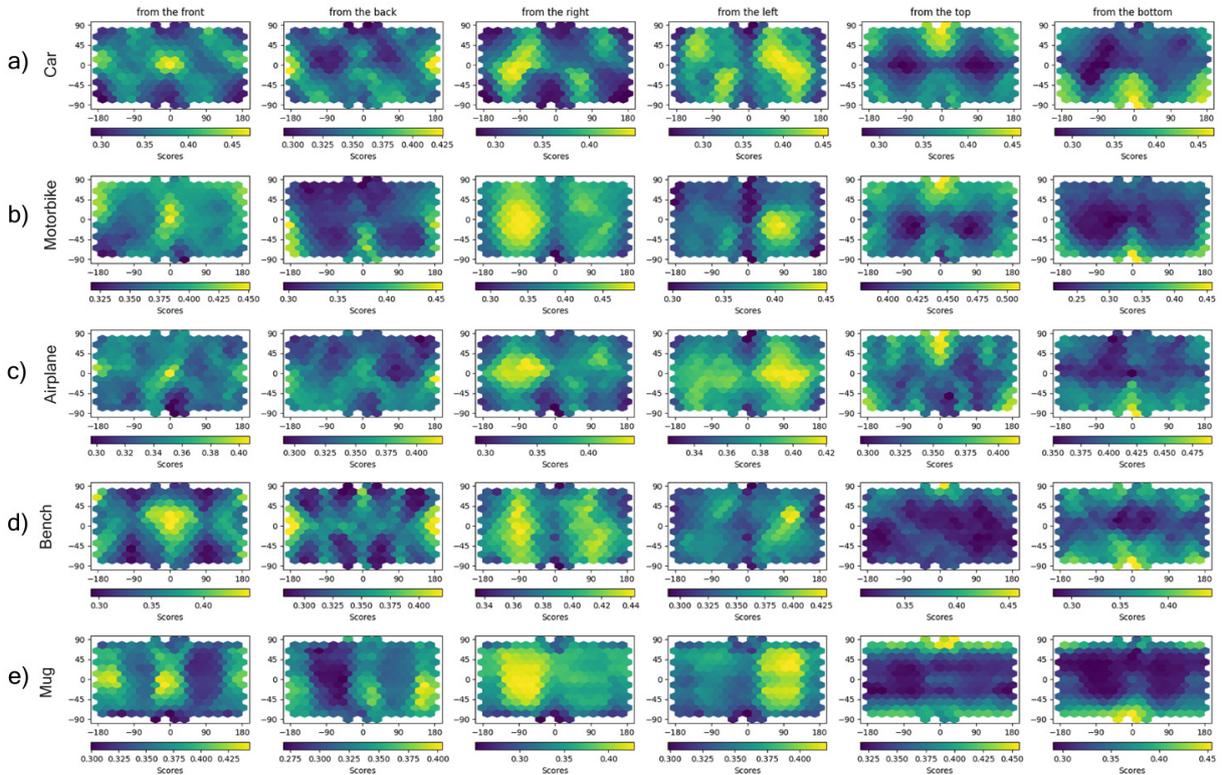

tant, e.g., through a high number of random starting points. Bayesian search also starts from randomly initialized starting points around the hypersphere. Compared to greedy search, it reaches the optimum much faster and more purposefully, since sampling is not bound to any local constraints, such as neighboring regions. Another advantage over greedy search is that random starting points have much lower cost than in greedy search, since they do not cause additional computations in the following iteration. The figure shows that the focus of sampling from random starting points across the sphere leads to small, concentrated regions with high scores. In terms of success rate, Bayesian search is less prone to confounding optima, since a certain number of samples are drawn randomly from different regions anyway. Therefore, the approach is more robust to cases with multiple optima, as is the case with the CLIP-FT model. Despite these obstacles, a solution is reached relatively quickly. However, if the scoring function has a ragged structure like the CLIP-PRETR model, even a sampling-based approach has difficulty identifying the optimal regions due to the raggedness and non-uniformity of the function.

A.3 Retrieval Metrics Analysis

Table 4 shows the precision and recall metrics on **synthetic data** broken down by object category. Table 5 shows the precision and recall metrics on **real data** obtained from the LAION-5B data set.

Abstract

Collecting high quality conversational data can be very expensive for most applications and infeasible for others due to privacy, ethical, or similar concerns. A promising direction to tackle this problem is to generate synthetic dialogues by prompting large language models. In this work, we use a small set of expert-written conversations as in-context examples to synthesize a social conversation dataset using prompting. We perform several thorough evaluations of our synthetic conversations compared to human-collected conversations. This includes various dimensions of conversation quality with human evaluation directly on the synthesized conversations, and interactive human evaluation of chatbots fine-tuned on the synthetically generated dataset. We additionally demonstrate that this prompting approach is generalizable to multi-party conversations, providing potential to create new synthetic data for multi-party tasks. Our synthetic multi-party conversations were rated more favorably across all measured dimensions compared to conversation excerpts sampled from a human-collected multi-party dataset.

1 Introduction

Training dialogue models typically requires an abundance of data, as with any machine learning task. However, collecting high quality data is difficult and expensive, especially for dialogue tasks where there often is no “right answer” when developing the trajectory of a conversation. Typically dialogue data are sourced from crowdworkers and the quality of annotations, evaluations, and conversations can vary considerably (Zhao and Zhu, 2014), often necessitating guardrails such as credential-based worker selection or defensive task design for quality control (Allahbakhsh et al., 2013).

To accommodate data scarcity in training dialogue tasks, low resource methods have become

*Work done during internship at Amazon Alexa AI

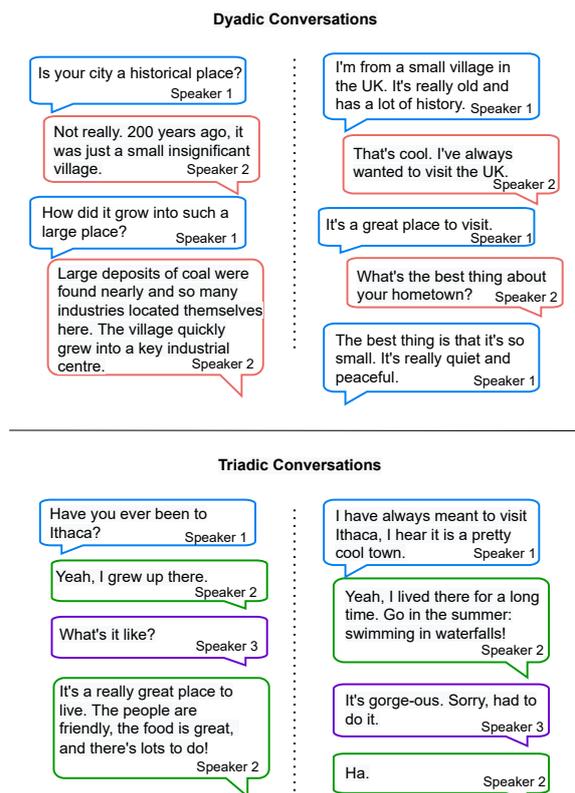

Figure 1: Pair of dyadic conversation excerpts about hometowns (upper) and pair of triadic conversation excerpts about Ithaca, NY (lower). In both pairings, one conversation is synthetically generated and the other is collected from humans. The answer is in Section 4.

a topic of growing interest and importance (Zhao et al., 2019; Mi et al., 2019; Qian and Yu, 2019; Li et al., 2019). One idea that has gained particular attention is transfer learning — specifically, finding ways to leverage knowledge learned by pre-trained large language models (PLMs) for new tasks. PLMs have demonstrated impressive emerging conversational capabilities, enabling big performance improvements in various dialogue tasks (Brown et al., 2020; Shuster et al., 2022; Peng et al., 2022; Kulhánek et al., 2021). Particularly, PLMs have been prompted to augment existing conversational data (Chen et al., 2022; Mehri et al.,

2022; Sahu et al., 2022).

Given some in-distribution seed examples, augmentation techniques attempt to generate data that are faithful to some task distribution (Kim et al., 2021b). Albeit powerful, one caveat common to all augmentation techniques is that the quality of synthetic data heavily relies on seed examples. But, what if crowdworkers do not possess the necessary background or skill set to complete a task en masse? How can we still get adequate high-quality synthetic data to learn a task?

In this work, we explore a novel application of **Prompting L**anguage models for social **Conv**ersation **S**ynthesis (PLACES). Synthesizing conversational datasets allows for the construction of training instances in nonexistent tasks. We specifically conduct open-domain, topic-conditioned conversation generation using few-shot in-context learning with expert-written synthetic conversations. We conjecture that expert end-users know exactly the types of conversations that they need. Rather than using existing datasets, they can simply write a small set of high quality conversation examples according to the structure of their desired conversational outputs. We reason that given structure through high-quality in-context demonstrations, large PLMs are able to utilize their expansive pre-training data (e.g. Gao et al. (2020)) to synthesize realistic social conversations, implicitly creating personalities and backgrounds for hypothetical speakers. The process of conversation writing would otherwise require human creativity and effort.

Our paper makes four core contributions.

(1) PLACES involves synthesizing an entire conversational dataset from a few targeted expert-written examples. These conversations match the quality of two widely adopted social dialogue datasets, Daily-Dialog (Li et al., 2017) and Topical Chat (Gopalakrishnan et al., 2019), in terms of human evaluation and automatic metrics. (2) We demonstrate that our synthetic conversations can be used as a fine-tuning dataset which matches the performance of its human-curated counterparts as measured by an interactive human evaluation and automatic metrics. (3) We apply PLACES to synthesize data for an under-studied subfield of dialogue research: multi-party conversations. We evaluate a set of synthetic triadic conversations in comparison to two human-collected multi-party conversational datasets (Shaikh et al., 2010; Poria et al., 2019).

To our knowledge, our work is the first to synthesize multi-party conversations, adding to the still-growing body of work on multi-party social dialogue. (4) Lastly, we conduct an error analysis on both dyadic and triadic synthetic conversations. We discuss the implications of our findings, as well as potential solutions to address the generation “errors.”

2 Related Work

Recently, the zero- and few-shot learning capabilities of large pre-trained language models have overtaken state-of-the-art performance on many classical natural language processing tasks, including dialogue (Brown et al., 2020). Many PLMs such as T5 (Raffel et al., 2020), GPT-J (Wang and Komatsuzaki, 2021), GPT-3 (Brown et al., 2020), and OPT (Zhang et al., 2022) have become the backbone of several dialogue-specific models (e.g., Peng et al. (2022); Madotto et al. (2021); Shuster et al. (2022)).

In particular, in-context learning, where few-shot examples are provided in the input prompt of a PLM, has been found to provide valuable information in guiding generation output (Min et al., 2022; Brown et al., 2020; Min et al., 2021; Lu et al., 2021b). As a result, many recent efforts in prompting PLMs have sought to augment various natural language processing datasets (Chen et al., 2022; Wang et al., 2022; Sahu et al., 2022; Mehri et al., 2022; Rosenbaum et al., 2022a). Prompting has become a viable “solution” for augmentation in dialogue tasks, which have traditionally been considered challenging due to the difficulty of augmenting dialogue context (Chen et al., 2022).

However, prompt-based augmentation strategies are uncontrolled forms of generation, which may result in generation mistakes for labeled datasets (Sahu et al., 2022; Chen et al., 2022; Meng et al., 2022). In contrast, other recent studies have instead proposed language augmentation strategies that use complex, highly-controlled frameworks that often involve fine-tuning generators (Papangelis et al., 2021; Zhang et al., 2020b; Kulhánek et al., 2021; Zhang et al., 2020a). Such complex augmentation frameworks require larger amounts of seed data to maintain a ground-truth language distribution (Rosenbaum et al., 2022b; Kim et al., 2021b), and are more costly than prompting PLMs (Chen et al., 2022). However, in the context of dataset synthesis, seed data and label correctness are less

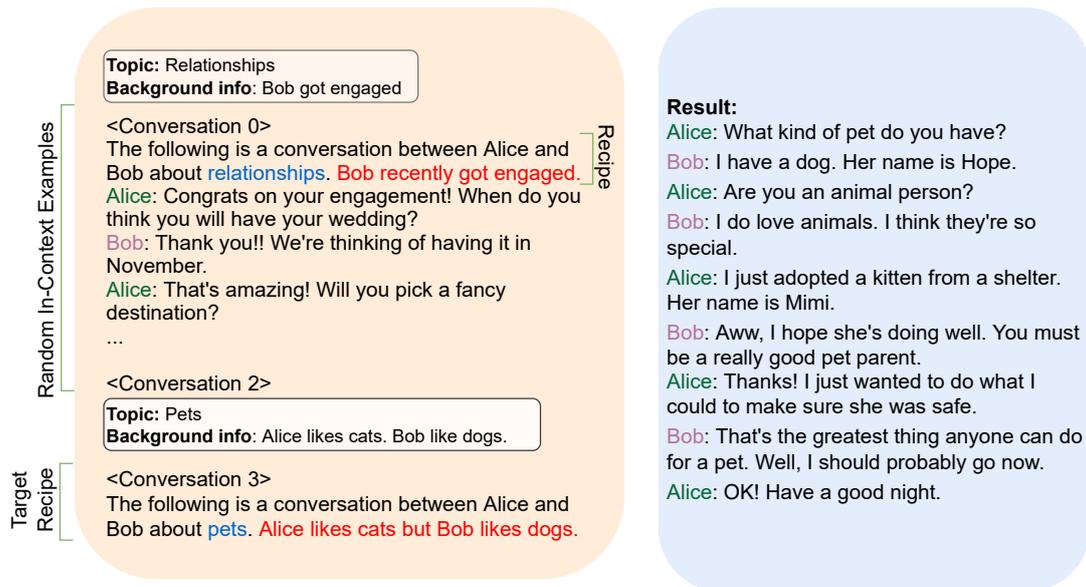

Figure 2: Example of the components of a prompt (left) used by OPT 30B to generate a synthetic conversation about pets (right). Conversations in the prompt are prefixed by recipes. Blue text: topic labels. Red text: seed background information metadata.

important considerations. There is no task distribution from which seed data is drawn that PLMs must remain faithful to, and similarly, invariant ground-truth knowledge for language models is dependent on the desired task being synthesized.

Our work differs from existing applications of prompting for conversations along several dimensions. Many studies examine utterance-level generation (Chen et al., 2022; Sahu et al., 2022; Aher et al., 2022; Rosenbaum et al., 2022b), whereas our work concerns the synthesis of full conversations. Bae et al. (2022) generated conversations for a narrow task and provided evaluations between their synthesis conditions. Recent concurrent work by Kim et al. (2022) sought to distill conversations from InstructGPT 175B using a common-sense knowledge graph. In our work, we synthesize conversations using an open-source PLM and demonstrate that they are comparable to human-collected datasets, in terms of both conversation quality and usability as a dataset. Moreover, all of these studies only concern dyadic conversations, because the vast majority of conversational tasks are dyadic. Our work is the first study to synthesize multi-party conversations.

3 Conversation Generation

In this section, we discuss our methods for conversation generation. We first detail the construction of our example conversations, then describe their application to prompting PLMs.

3.1 Writing Conversation Examples

We simply wrote a pool of ten conversations between two speakers representing everyday dialogue using proper grammar. Along with each conversation, we wrote a brief conversation “recipe” which includes a topic, as well as *background information* for the two speakers¹.

The *background information* represents some more fine-grained information about the two speakers, relevant to that particular topic. For example, Figure 2 depicts an example prompt with three in-context conversation demonstrations. Each conversation is prefixed by a recipe and is structured in the same manner: “The following is a conversation between Alice and Bob about *topic*” (e.g., “pets”) followed by detailed background information (e.g., “Alice love cats. Bob is more of a dog person.”).

3.2 Creating Conversations via Prompting

Each prompt consists of three randomly sampled conversations from the aforementioned pool, along with their accompanying recipe. After experimenting with PLMs of three different sizes (GPT-J 6B, GPT-NeoX 20B, OPT 30B), we primarily use OPT-30B and generate with nucleus sampling with $p = 0.92$. Inspired by the format of DailyDialog, our handwritten and synthetically generated conversations fall into three categories: start-to-finish conversations, excerpts from the start to the middle

¹The first-author spent approximately 45 minutes on this writing process.

Source	Words/Turn	Turns/Conv.
DailyDialog	11.58	7.84
Topical Chat	13.38	21.83
HW Examples	11.00	8.10
Synthetic	10.70	9.29

Table 1: Number of words per turn and number of turns per conversation for all conversations. HW Examples represents the ten handwritten conversation examples, and Synthetic represents synthetic conversations generated using OPT 30B.

of a conversation, and excerpts from the middle of a conversation. Several examples are given in the Appendix.

In this paper, we generate a dataset using a list of topics and tasks (i.e., subtopics) from the training set of the Feedback for Interactive Talk & Search Dataset (FITS; Xu et al. (2022)), a human-chatbot dataset designed to determine desirable human-chatbot tasks/conversations. FITS contains 5592 conversations which span 52 conversational topics (e.g., “nutrition,” “philosophy”) with 315 subtopics (e.g., “Italian food,” “Soren Kierkegaard”). We wrote background information for each of the 315 subtopics in the form given in Figure 2.

Using the product of this process once results in a new synthetic dataset with 5592 conversations using the same topic, subtopic pairings from FITS. The average length of each conversation is 9.29 turns, with 12.84 words per turn. This is comparable to the dataset statistics of DailyDialog and Topical Chat, as per Table 1. In the Appendix, we have included the 315 prompt headers (Tables S22, S23) and the pool of in-context examples (Tables S24, S25, S26).

4 Synthetic Conversation Evaluation

In Figure 1, the top-left is taken from DailyDialog, whereas the top-right is generated synthetically. The bottom-left is generated synthetically and the bottom-right is taken from MPC.

4.1 Evaluation of Conversation Quality

Table 2 provides a crowdworker evaluation of our synthetic dataset compared against DailyDialog and Topical Chat. We expect Topical Chat to be rated as the most interesting, due to the knowledge-grounding process utilized during the dialogue collection process. We randomly sampled 200 conversations for each conversation source and asked a pre-qualified pool of 28 crowdworkers on Amazon Mechanical Turk (AMT) to rate each conversation.

Source	Interesting	Coherent	Natural	Consistent
DailyDialog	3.44	4.51	4.85	4.57
Topical Chat	4.55	4.39	4.92	4.87
GPT-J 6B	3.96*	4.49	4.86	4.36
GPT-NeoX 20B	3.81*	4.40	4.63	4.35
OPT 30B	4.13*	4.61 *†	4.82	4.63

Table 2: Evaluation of conversations randomly sampled from DailyDialog, Topical Chat, and three synthetic datasets generated by prompting GPT-J 6B, GPT-NeoX 20B, and OPT 30B. * indicates statistical significance over DailyDialog. † indicates statistical significance over Topical Chat. Significance computed at $\alpha = 0.05$.

The instructions and details of our human evaluation setup are explained in Appendix A.

As these conversations are generated using prompting, we first checked whether each conversation followed the prescribed prompt. Crowdworkers identified 95% of the conversations generated by OPT 30B as matching the topic stated in the prompt², indicating this prompting strategy’s effectiveness for topic-grounded conversation generation. Overall, Table 2 indicates that synthetic conversations generated by OPT 30B are rated as the most coherent, and more interesting and consistent than DailyDialog. The synthetic conversations are almost as natural as DailyDialog, but are rated as less interesting and natural than Topical Chat. Given our results, we also hypothesize that larger models likely produce higher quality conversations. We provide several examples of conversations generated by OPT 175B using an online web interface³ in the Appendix.

A concern one might have is that since in-context examples heavily influence prompting (Min et al., 2022; Lu et al., 2021b), our small in-context example size may limit the lexical diversity of our synthetic conversations. Following earlier work evaluating text generation, we use Distinct-N to measure lexical diversity (Wu et al., 2021; Li et al., 2016). Figure 3 shows that our synthetically generated conversations are slightly more diverse than both DailyDialog and Topical Chat in terms of distinct bigrams and trigrams, and slightly less diverse than Topical Chat in terms of 4-grams.

We then sought to examine the impact of using expert handwritten examples by comparing against synthetic conversations generated using conversations from DailyDialog and Topical Chat as in-

²91% and 92% for GPT-J 6B and GPT-NeoX 20B.

Coherent	4.48	4.56	4.77 **+
Natural	4.54	4.69	4.69 *
Consistent	4.76	4.87	4.86*
On-Topic	0.91	0.88	0.96 **+

Table 3: Human evaluation of conversations generated using OPT-30B with in-context examples randomly sampled from DailyDialog (DD-IC), Topical Chat (TC-IC), and handwritten examples (HW-IC). * indicates statistical significance over DD-IC and + indicates statistical significance over TC-IC.

context examples. We set the number of conversation examples such that the number of in-context dialogue turns are approximately equal across all conditions. Table 3 shows that synthetic conversations generated conditioned on handwritten in-context examples are the most coherent, natural, and on-topic. In terms of interestingness and consistency, the ratings of these conversations slightly trail the ratings of the conversations generated conditioned on Topical Chat.

4.2 Fine-Tuning with Synthetic Conversations

After establishing that our synthetic conversations are of rather high quality on their own, we attempted to use the synthetic dataset as training data for dialogue models. We fine-tuned distilled BlenderBot 400M (Roller et al., 2021) on DailyDialog, Topical Chat, and our synthetic conversations⁴.

Rather than directly prompting OPT as a response generator, we select BlenderBot as a lightweight, effective dialogue model. This allows for comparisons between the three data sources as training sets, because fine-tuning OPT is prohibitively expensive. Moreover, while prompting with larger PLMs can yield coherent responses, it is generally impractical as an end-to-end dialogue system if hosted on typically available hardware. For long inputs (e.g. with multiple dialogues in-context), generation time typically takes several minutes using OPT 30B⁵.

We first performed an interactive human evaluation of the three dialogue models as end-to-end social chatbots using the LegoEval platform (Li et al., 2021). Details can be found in Appendix A.

Table 4 shows that dialogue models fine-tuned on our synthetic conversations are rated compara-

⁴For fair comparison, we fine-tune on the same number of training instances via downsampling.

⁵All experiments are conducted using one p3dn.24xlarge AWS EC2 instance.

Dimension	DD	TC	Syn
Interesting	3.35	3.86	3.30
Coherent	3.52	3.71	3.68
Natural	3.52	3.57	3.68
Consistent	3.35	3.65	3.32
Engaging	3.73	3.88	3.65
Intelligent	3.41	3.55	3.24
Non-repetitive	3.37	3.37	3.40

Table 4: Interactive human evaluation yields comparable ratings for chatbots fine-tuned on conversations from DailyDialog (DD), Topical Chat (TC), and our Synthetic Data (Syn).

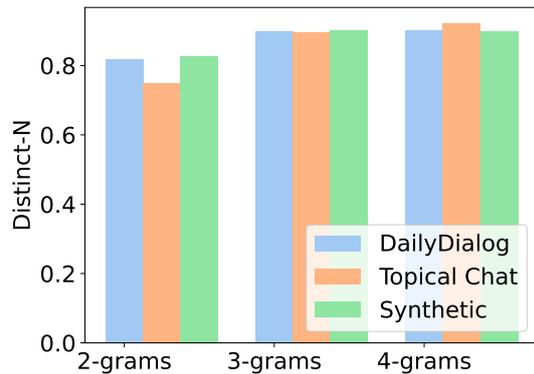

Figure 3: Distinct-N with $N = 2, 3, 4$ for conversations in DailyDialog, Topical Chat, and our synthetic conversations. Our synthetic conversations have the highest most unique bi-grams and tri-grams, and the second-most unique 4-grams.

bly to dialogue models fine-tuned on real human-human data — the chatbot fine-tuned on synthetic data appeared to be the most natural and non-repetitive, and was rated as the second-most coherent. It was rated as the least intelligent, engaging, consistent, and interesting. However, two-sided t-tests at $\alpha = 0.05$ revealed that there was not a statistically significant difference in ratings between the models fine-tuned on all three datasets across all dimensions except for interestingness. The Topical Chat model was rated as significantly more interesting, as expected.

In terms of automatic evaluation, we applied these dialogue models on out-of-distribution test sets to prevent an unfair comparison. We evaluated models fine-tuned on DailyDialog and our synthetic data on Topical Chat, and models fine-tuned on Topical Chat and our synthetic data on DailyDialog. Table 5 indicates that in terms of perplexity and ROUGE, models fine-tuned on our synthetic data generalize to out-of-distribution conversational data as well as models trained on real human-

Metric (Test Set)	DD-BB	TC-BB	Syn-BB
Perplexity (DD)	—	120.2	87.05
ROUGE-1 (DD)	—	12.34	12.90
ROUGE-2 (DD)	—	1.66	1.52
ROUGE-L (DD)	—	10.60	10.94
Perplexity (TC)	43.3	—	37.1
ROUGE-1 (TC)	16.63	—	15.13
ROUGE-2 (TC)	2.36	—	1.77
ROUGE-L (TC)	13.61	—	12.41

Table 5: Out-of-distribution automatic evaluation of perplexity and ROUGE is comparable for BlenderBot fine-tuned on DailyDialog (DD-BB), Topical Chat (TC-BB), and synthetic data generated using our handwritten examples in-context (Syn-BB), respectively.

human datasets. On the DailyDialog test set, the synthetic dataset model outperforms the Topical Chat model on all metrics except ROUGE-2, and on the Topical Chat test set, the synthetic dataset model underperforms the DailyDialog model on all metrics except perplexity.

5 Triadic and Multi-Party Conversations

The vast majority of dialogue tasks and conversational datasets focus on dyadic conversations (e.g. Li et al. (2017); Gopalakrishnan et al. (2019); Smith et al. (2020); Rashkin et al. (2019)), following the traditional speaker-listener paradigm (Engelhardt et al., 2006). In contrast, the literature on multi-party social conversation is rather scarce, not only in terms of conversation generation but as a task altogether. However, while it is an understudied research area, it is incredibly important, because dyadic conversations do not capture the full reality of in-person, human-human social conversations, nor the full potential of dialogue agents. To name a few applications, dialogue agents have the potential to supplement classroom learning with multiple parties, serving as a third mediating party in a debate or discussion between two people, or to provide companionship and support in virtual group settings. A major reason why these lines of work remain unsolved is that there are few large-scale multi-party dialogue datasets.

Many existing multi-party datasets are scripted corpora such as MELD (Poria et al., 2019) or MPDD (Chen et al., 2020) or HLA-Chat (Ju et al., 2022; Li et al., 2020). Other multi-party corpora are collected for highly domain-specific purposes, such as multi-party empathetic dialogue (Zhu et al., 2022). Such corpora are also typically collected through asynchronous online platforms, rather than natural conversation. These platforms exist in the

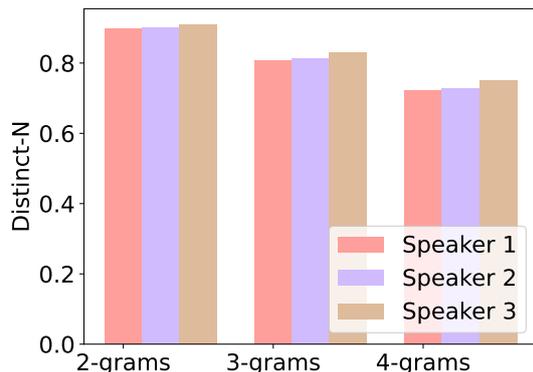

Figure 4: Linguistic diversity (Distinct-N) is comparable for each speaker in the synthetic triadic conversation dataset.

form of forums and online chat platforms such as Ubuntu IRC (Lowe et al., 2015) or Reddit (Baumgartner et al., 2020). Other more natural multi-party conversational datasets are license-protected speech datasets (e.g. CHIME (Christensen et al., 2010)) which have been constructed for tasks such as speaker attribution.

We find that we can apply our prompting approach to generate synthetic, open-domain, multi-party social conversations following the same structure as our synthetic dyadic conversations⁶. As in the dyadic case, we generate triadic conversations using optional background information for each speaker. We consider the “Multi-Party Chat” corpus (MPC) (Shaikh et al., 2010), a text-based, open-domain conversation dataset collected in real-time online sessions at the University of Albany, and MELD, which contains scripted multi-party dialogues from the popular sitcom “Friends.” We directly compare our synthetically generated conversations against MPC and MELD.

Table 6 includes our evaluation of our conversations using the same pool of pre-qualified AMT workers, again with 200 randomly sampled conversations. MPC consists of massive conversation settings — on the scale of 500 turns for a typical conversation session — so we randomly sample 8 to 12⁷ continuous turns for each conversation evaluation to more closely match the structure of our synthetic conversations.⁸ We present examples of

⁶While we effectively use Alice, Bob, and Claire instead of Speaker 1, Speaker 2, and Speaker 3, respectively, the order of speakers does not necessarily follow the speaker order in the in-context examples (e.g. Appendix Table S10).

⁷The length between 8 and 12 turns is chosen uniformly.

⁸We sample rather than selecting the first 8-12 turns, to

Dimension	MPC	MELD	Syn
Interesting	2.48	3.52	4.14*
Coherent	2.40	3.68	4.65*
Natural	2.69	3.69	4.47*
Consistent	2.96	3.83	4.65*
Comprehensible	2.48	3.83	4.80*
Balanced Engagement	3.45	4.00	4.89*

Table 6: Synthetic conversations generated using OPT 30B are rated significantly higher than MPC and MELD across all dimensions.

MPC and MELD in Appendix Tables S20, S21.

We inform the AMT workers that they will read conversation excerpts. In addition to the questions in Table 2, we add two questions specific to multi-party conversations. We ask if the conversation excerpt looks comprehensible (in terms of the reader being able to determine who each speaker is addressing), and we ask if all parties of the conversation are participating equally and actively.

In Table 6, we find that the synthetic conversations are rated statistically significantly more favorably than MPC and MELD across all dimensions. Beyond conversation quality, it is possible that the ratings for MPC are comparatively low due to the fact that each conversation typically has more than three speakers, which may be more difficult for human raters to interpret. Our results for MELD also indicate that while the corpus is high quality, it may be better fit for comedy and accompaniment with visual context, than as pure dialogue.

Additionally, we checked the linguistic diversity for each speaker. In terms of Distinct-N, each speaker’s lexical diversity is comparable (Figure 4) as well as the number of words per turn (12.2, 12.2, and 13.5 for Speakers 1, 2, and 3 respectively). The triadic conversations tended to be slightly longer than the average dyadic conversation (11.5 turns/conversation versus 9.29 turns/conversation).

6 Discussion

Overall, we find that prompting PLMs to generate synthetic conversations is promising.

6.1 Considerations for Dyadic Dialogue

The synthetically generated conversations appear comparable to conversations from human-collected datasets. The individual conversations appear interesting, coherent, natural, and consistent, as the average ratings for each category lie between 4.0 and 5.0. The Appendix includes multiple examples avoid overrepresenting greetings.

of conversations generated using the strongest performing PLM (OPT 30B, e.g. Table S7) as well as several conversations generated using OPT 175B (e.g. Table S8). Tables 4 and 5 also indicate that fine-tuning on synthetically generated examples can result in dialogue models of comparable quality, with the potential for further improvements by simply generating more synthetic conversations.

Future work may consider applying applying this generation approach to dyadic contexts beyond social conversations, such as task-oriented dialogue. The clearest difference between social and task-oriented dialogue contexts is the importance of knowledge grounding. In task-oriented dialogue, there typically needs to be retrieval from knowledge base for response generation. An application of PLACES could involve using database results as a ground-truth reference. Rather than using a topic list like FITS, one could form conversational recipes using database search results as background information. Given the apparent semantic control described in Section 4, it is possible that synthetic task-oriented conversations would be able to correctly utilize knowledge.

6.2 Considerations for Multi-Party Dialogue

We found that in comparison to MPC, our synthetic triadic dialogues appear to be of fairly high quality. However, there remain several open questions about multi-party dialogue, even in the triadic case. For instance, there is not a set archetype of conversations. Sometimes, conversations may be dominated by a single speaker, whereas in others, each speaker in the conversation may contribute equally. Depending on the scenario, a speaker may be the facilitator — meetings can be considered (topic-specific) multi-party dialogues which are typically led by designated speakers.

Moreover, there are several questions about how to utilize multi-party dialogues in an interactive dialogue system. There are use cases where it may be appropriate for one dialogue system to interact with multiple users. On the other hand, in scenarios like emotional support dialogue systems, it may make sense for a single user to interact with multiple simulated conversational parties.

Here, we investigated our approach’s potential to generate synthetic multi-party conversations, hoping to bridge the gap in data availability in multi-party chat. This opens opportunities for a variety of applications. Synthetic datasets could be used

to help discover how to properly model triadic and multi-party conversations. In the future, datasets could also be generated for domain-specific, multi-party applications ranging from language learning to task-oriented spoken dialogue systems.

7 Error Analysis

We examine the dyadic and triadic conversations which received low scores (1/5) across multiple dimensions.

7.1 Dyadic Conversations

Out of the dyadic conversations, two conversations were rated as generic and dull. One conversation (Appendix Table S13) talks about the singer, Taylor Swift. However, the conversation is repetitive, repeating utterances such as “What are your thoughts on her?” and “I think she is very nice.” The other conversation is about the filmmaker, Ken Burns (Appendix Table S14). While the conversation is appears coherent and uses correct factual information (e.g., making reference to Ken Burns’ documentaries on World War II and the Vietnam War), the language could be perceived as dull.

Three conversations were rated as completely unnatural. In one case, the PLM missed the prescribed subtopic (cotton candy) and instead hallucinated a conversation about a sensitive topic, cancer (Appendix Table S15). This is also the only conversation to be rated as completely incoherent. The other two conversations are both on-topic. However, one conversation is on-topic but rather short (five turns), whereas the other conversation is overly verbose and a little repetitive.

There were also three conversations were evaluated as completely inconsistent. In all three conversations, the roles of the two speakers seemingly swap. While these hypothetical turns are possible in excerpts of real conversations, they assume background information or events which have not been explicitly established when considered as standalone conversations. An example is given in Appendix Table S16.

While some of the evaluations may be subjective, an issue that has objectively appeared multiple times is the consistency of speakers’ utterances. The intents and personas of the speakers appear to get switched, which is also an open problem in dialogue systems research. Future work may look to combine conversation synthesis approaches with strategies for dialogue consistency such as the generate-delete-rewrite framework (Song et al.,

2020a) or language inference approaches (Welleck et al., 2019; Song et al., 2020b).

7.2 Triadic Conversations

No conversations were perceived as completely incomprehensible, but human evaluators indicated that two conversations appeared to have imbalanced engagement — in both cases, the third speaker (“Claire”) only has one dialogue turn. As discussed in Section 6.2, however, it is not clear whether this is a drawback. Real-life triadic conversations do not follow a set archetype in terms of engagement balance.

There was one conversation which was rated as completely incoherent. In the conversation, there is one dialogue turn which presents information inconsistent with prior turns, but the another issue appears to be an oddly placed transition which brings the conversation from travel to hobbies: “You should definitely go to Paris! What do you like to do for fun?” (Appendix Table S17).

There are two conversations which were perceived as completely unnatural. However, naturalness appears to be a rather subjective evaluation. One conversation is given in Appendix Table S18, and it is debatable whether the language conventions used are unnatural. One could argue that it is overly enthusiastic, but others could argue that it is how some people speak colloquially. Interestingly, the second conversation which received a low naturalness score is also enthusiastic and about the same topic (gardening).

The only conversation which was rated as generic and dull was a 15-turn debate about whether the European Union is a “conspiracy” (Appendix Table S19). The debate is rather shallow and does not make a lot of progress.

As with the dyadic conversation error analysis, we see that there are issues with persona consistency. However, unlike the dyadic scenario, there are fewer existing solutions for dialogue consistency. Multi-party conversation synthesis could potentially be improved by applying ideas from the newly published PersonaTKG dialogue system, which employs a unified graph that encodes personas, utterances, and external knowledge on a scripted dialogue dataset (Ju et al., 2022).

Beyond consistency, in the example from Table S19 we see that there is potential for PLMs to hallucinate misinformation. There are again fewer existing studies on circumventing this obstacle in multi-party dialogue, but future work could look

to incorporating external knowledge (Kang et al., 2022) or dialogue safety approaches (Kim et al., 2021a; Dinan et al., 2019). All said, our work motivates further study into multi-party dialogue consistency, safety, and synthesis.

8 Conclusion

In this work, we presented an application of prompting PLMs to create synthetic conversations. These synthetic conversations are comparable in terms of quality and lexical diversity to actual human-human datasets, and can be used as training data for dialogue models. This opens avenues in generative language work such as collaborative and creative writing, story generation, as well as synthesis of new conversational tasks. Here, we presented one example — synthesizing a multi-party conversational dataset. This presents a unique opportunity to further study multi-party dialogue modeling.

9 Limitations

Controllability. We witness encouraging levels of control through the prompt (95% of the time, the synthetic conversation matches the desired topic), but prompting PLMs is still an uncontrolled form of generation. Future work could seek to add more semantic controls beyond the stated topic in the prompt or explore using weak supervision to provide post-hoc improvements on synthetic data quality, similar to Chen et al. (2022). In this work, we also did not thoroughly explore the effects of different generation approaches. Future work may consider applying semantic constraints during the decoding process (Lu et al., 2021a). Further controls are necessary before using this approach for higher-stakes settings such as task-oriented dialogue and other knowledge-grounded tasks.

Cost of Human Effort. While we demonstrate the ability to synthesize large amounts of data, the quality of a synthesized dataset is still dependent on human effort, to an extent. One can use a generic prompt template such as “Alice is interested in [subtopic]” for each subtopic, but we qualitatively see that more detailed background information in a prompt often yields better generation performance.

In this work, we generated 5592 dyadic and triadic conversations, matching the number of topic combinations in FITS. PLACES can be used to generate many more conversations in the future. Using the same overall can continue to make new

combinations of topic and subtopic, or simply re-run the generation process as it is nondeterministic. Moreover, one may consider filling the slots in our conversation recipes using an abundant of external sources, including from existing dataset annotations (e.g. Persona Chat Zhang et al. (2018)).

Computational Costs. Once a dataset is synthesized, small, task-specific models can be used downstream. However, the synthesis method used in this work is still expensive: we prompt PLMs. While we only used freely accessible PLMs such as OPT, we acknowledge that not everyone has access to the number of GPUs necessary to load PLMs, even for inference.

Prompt Design. The idea of prompting large language models is not novel. There is a plethora of work that examines how to apply prompting to a variety of different tasks (e.g. Brown et al. (2020); Min et al. (2021)), along with several studies on how to mine or engineer different prompts (Liu et al., 2021). In this work, we do not claim novelty to our prompt, nor do we claim that our prompt design is the optimal prompt for conversation generation. Our prompt is designed in a conversational manner, drawing inspiration from Chen et al. (2022). We instead emphasize the application of prompting for conversational dataset synthesis. The idea of synthesizing conversational datasets “from scratch” is previously unexplored, and has potential to supplement a lot of areas of dialogue research, such as multi-party conversations.

10 Ethical Considerations

Human Evaluation and Crowdsourcing. We make use of crowdsourcing through Amazon Mechanical Turk for several experiments. All crowdworkers were paid at a rate higher than the minimum wage in California. In accordance with California State Law, all crowdworkers were also informed they were speaking with chatbots during the data collection for our interactive evaluation. All participants consented to the logging of their responses.

Language Model Biases. Large pre-trained language models are typically pre-trained on massive corpora crawled from the internet such as The Pile (Gao et al., 2020) or Common Crawl. This allows language models to have exposure to a large amount of linguistic diversity, but this also results in exposure to a lot of hateful, biased, or otherwise

undesirable content from the internet (Luccioni and Viviano, 2021). Future work should examine combining conversation synthesis with dialogue safety approaches.

Scientific Artifacts. All scientific artifacts are used according to their intended purpose. The FITS dataset is publicly available at <https://parl.ai/projects/fits/>. OPT is an open-source language model. GPT-J is available for use under the MIT license. We use the HuggingFace Transformers and PyTorch packages for all modeling (Wolf et al., 2020; Paszke et al., 2019). All artifacts used are in English.

A Human Evaluation Setup

Our human evaluation studies on Amazon Mechanical Turk are evaluated conducted with 28 pre-qualified crowdworkers, who have previously demonstrated proficiency with natural language processing tasks.

A.1 Conversation Evaluation

The crowdworkers were asked to rate conversations from multiple sources according to the following dimensions and instructions.

- *How natural is the overall conversation?*
Scale: 1 (completely unnatural) to 5 (as natural as two native English speakers)
- *How coherent is the overall conversation?*
Scale: 1 (completely incoherent) to 5 (as coherent as two native English speakers)
- *How interesting is the overall conversation?*
Scale: 1 (generic and dull) to 5 (full of content and very engaging)
- *How consistent are each of the speakers' turns?*
Scale: 1 (completely inconsistent) to 5 (no logical fallacies)
- *Does the conversation match the stated topic?*
Options: Yes (1) or No (0)

Each conversation is rated by three crowdworkers, and the median score is selected, following the idea of a majority vote.

For multi-party conversations, crowdworkers were asked two additional questions regarding comprehensibility and engagement balance.

- Can you tell which speaker is speaking to which?
Scale: 1 (completely incomprehensible) to 5 (perfectly comprehensible)
- Is each speaker engaged, or is the conversation primarily dominated by one or two of the speakers?
Scale: 1 (totally dominated by one or two speakers) to 5 (all speakers are actively participating in the conversation to an equal degree)

A.2 Interactive Evaluation

For each HIT of the interactive evaluation study, each crowdworker was presented with links to chatbots presented in a randomized order. The link connects each crowdworker to a deployment on an instance of LegoEval (Li et al., 2021). The users are presented with a landing page where they are told that they are interacting with a chatbot, and will be asked to evaluate their conversation experience.

Immediately after interacting with a chatbot, each crowdworker was presented with a survey asking for their impression of the chatbot. In addition to the above dimensions (other than on-topic), the crowdworkers were asked how engaging, intelligent, and non-repetitive they thought the chatbot was.

B Model Details

During generation, we use top- p sampling with $p = 0.92$.

Party	Utterance
Alice	I love it here in New York!
Bob	What do you like most about New York?
Alice	New York has the best bagels!
Bob	Which bagels are your favorite?
Alice	They all taste amazing. I really like their Italian ones!
Bob	That's great. I guess I'll be eating Italian bagels from now on.
Alice	I'm from New York City.
Bob	Wow! I've never been to New York.
Alice	I've also been to Austin. few times.
Bob	What did you think of it? Did you like it?
Alice	I really liked it. I thought it was a really cool city.
Bob	I'm glad you liked it. What did you like so much about it?
Alice	I really like the music scene there.
Bob	What kind of music do you like?
Alice	I like a lot of different kinds of music. I like jazz, rock, and country.
Bob	I've never been to a country concert.
Alice	You should go sometime. They're a lot of fun.
Bob	I'll have to check it out.
Alice	I'll have to visit Austin again soon.
Bob	Yeah, I'd like to visit New York sometime too.
Alice	It's a great city.

Table S7: Pair of dyadic conversations generated using OPT 30B. The prompt recipe given is: “The following is a conversation between Alice and Bob about their hometowns. Bob is from Austin, Texas, and Alice is from New York City.”

Party	Utterance
Alice	What's your major?
Bob	I'm a computer science major.
Alice	Me too! What year are you?
Bob	I'm in my third year. What about you?
Alice	I'm in my third year too. What classes are you taking this quarter?
Bob	I'm taking a class called Operating Systems. It's really interesting.
Alice	I'm taking a class called Computer Graphics. It's pretty interesting too.
Bob	I've heard that class is really hard.
Alice	Yeah, it's not easy.
Alice	Hi!
Alice	What are you studying?
Bob	I'm a Computer Science major.
Alice	Me too!
Bob	What year are you?
Alice	I'll be a junior next year.
Bob	I'll be a senior.
Alice	Cool!
Bob	What classes are you taking this quarter?
Alice	I've got a couple of classes in the School of Engineering. I'm taking a class in Computer Graphics and a class in Artificial Intelligence.
Bob	I'm taking a class on Machine Learning.
Alice	That's cool.
Bob	What are you doing this summer?
Alice	I'd like to work at a start-up.
Bob	That's cool. I'm going to intern at Google.
Alice	Wow! That's awesome!
Bob	Yeah, I'm really excited.
Alice	I'm excited for you!

Table S8: Pair of dyadic conversations generated using OPT 175B. The prompt recipe given is: “The following is a conversation between Alice and Bob about their majors. They are both students at Stanford University.”

Party	Utterance
Alice	I was thinking about applying at the coffee shop on the corner.
Bob	That's a great idea! It's a really fun place to work.
Alice	I'm glad to hear that. What do you do there?
Bob	I work as a barista.
Alice	Oh cool! I bet you get to meet a lot of interesting people.
Bob	That's right. I really enjoy working there.
Alice	Do you know if they are hiring?
Bob	I'm not sure, but you should definitely apply.
Alice	Thanks! I'll go in and see if they are hiring.

Table S9: Example dyadic conversation generated using OPT 175B. The prompt recipe given is: “The following is a conversation between Alice and Bob about part-time jobs. Bob works at a coffee shop and Alice is thinking about applying.”

Party	Utterance
Alice	I'd love to start a garden! I've always wanted to grow my own vegetables.
Bob	That's a great idea! It's so much more fun to eat vegetables that you've grown yourself.
Claire	What vegetables are you thinking about growing?
Alice	I'd love to try growing some tomatoes, peppers, and squash.
Bob	That sounds like a good start.
Claire	I've grown tomatoes before. I also have a few pepper plants.
Alice	I've always wanted to have a garden in my backyard, but I never really had the time.
Claire	That's awesome! How do you plan to grow your garden?
Alice	I've been doing a lot of research. I think I'll start with a few simple vegetables like tomatoes, onions, and potatoes.
Bob	That's great! I would love to have a garden like that. I'm a big fan of cooking.
Alice	I'll definitely invite you over for dinner then!
Claire	I'm so jealous! I've always wanted to grow my own vegetables.
Bob	Have you considered getting a garden plot?
Claire	That's a great idea. I should look into that.
Alice	You should! Gardening is a really healthy hobby.

Table S10: Pair of triadic conversations generated using OPT 30B. The prompt recipe given is: “The following is a conversation between Alice and Bob and Claire about gardening. Alice is interested in growing vegetables.” The ordering of the speakers in multi-party scenarios is variable.

Party	Utterance
Alice	Have you ever had Southern Ice Tea?
Bob	I love to make it at home.
Claire	I'm not familiar with that. What is it?
Bob	It's a sweet tea that's brewed with mint and lemon.
Alice	That sounds really good. I'm going to have to try that!
Claire	I've never had that. What is it like?
Bob	It's kind of like a sweet, lemonade-like drink.
Alice	I'm going to have to make some this weekend. Thanks for the idea!
Claire	That sounds really good. I might try it too.

Table S11: Example triadic conversation generated using OPT 175B. The prompt recipe given is: “The following is a conversation between Alice and Bob and Claire about cooking. Alice is interested in Southern Ice Tea. Bob has a great recipe. Claire loved trying Bob's Southern Ice Tea.”

Party	Utterance
Alice	I try to eat healthy, but it's hard to stay on track.
Bob	I know what you mean. I try to eat healthy too, but I love ice cream too much!
Claire	What kinds of foods do you like to eat?
Alice	I love fruit. I eat a lot of berries.
Bob	I love berries too! Strawberries are my favorite.
Claire	What about leafy greens? Do you eat them?
Bob	I love salads!
Alice	I love salads too!
Claire	Do you like any vegetables?
Alice	I love vegetables! I like broccoli and asparagus.
Claire	Great! Do you eat many whole grains?

Table S12: Example triadic conversation generated using OPT 175B. The prompt recipe given is: “The following is a conversation between Alice and Bob and Claire about health. Alice and Bob are discussing healthy foods. Claire is a nutritionist.”

Party	Utterance
Alice	Hi! So how are things with you?
Bob	Things are going well. Do you know who Taylor Swift is?
Alice	Yes, I think I have heard of her.
Bob	She is a popular singer! Did you know that she has donated \$250,000 to the LGBT+ community in Tennessee?
Alice	\$250,000? That's such a generous donation! She's really selfless.
Bob	What do you think of her?
Alice	She is really talented! I really love listening to her music. What are your thoughts on her?
Bob	I think she is very nice. She seems like a good person.
Alice	Yeah, I think she is a really nice person. I also really love her music! It's really catchy and it really makes me feel good. What are your thoughts on her?
Bob	I think she is very nice. I would really like to meet her.
Alice	You and me both! It would be so exciting!

Table S13: Synthetic conversation generated by OPT 30B which was rated as “generic and dull.” While the PLM appears to have drawn on information from an actual event (Taylor Swift did donate \$113,000 to support an LGBTQ advocacy group in Tennessee), the conversation appears to get stuck around the question “What are your thoughts on her?” which results in deteriorating conversation quality towards the end.

Party	Utterance
Alice	Ken Burns is the best! His documentary series on the Vietnam War was excellent. What do you think of him?
Bob	He's pretty cool. I haven't seen that documentary series, but I've heard good things.
Alice	The Vietnam War is a really interesting topic. Have you ever watched Ken Burns' other documentary series?
Bob	I don't think so, but I've seen the Civil War documentary.
Alice	Oh, I've seen that one. It was very good too. Did you see the one on World War II?
Bob	Nope. That sounds cool though.
Alice	I liked it. It was interesting to learn how different people perceived the same event in history.

Table S14: Synthetic conversation generated by OPT 30B which was rated as “generic and dull.” The conversation appears to be coherent and is rooted in factually correct information. However, the language is fairly ordinary, which may have been subjectively considered uninteresting.

Party	Utterance
Alice	Ha ha, thanks for stopping by. It was really fun meeting you!
Bob	Thank you too!
Alice	Oh, I forgot to tell you - my dad has cancer. I feel awful.
Bob	I'm sorry. That's awful. My grandmother died of cancer when I was a kid. I remember her fondly.
Alice	What was her name?
Bob	Oh, that was too long ago to remember. She was named John.
Alice	Sorry to hear that. I'm very sorry for your loss.
Bob	Hey - I heard the Giants are playing tonight. Is it ok if I watch the game instead of having more conversation?
Alice	Sure! I'm going to make some dinner.

Table S15: Synthetic conversation generated by OPT 30B which was rated as completely incoherent. The prescribed subtopic was “cotton candy” but the conversation pivoted to a much more sensitive topic, cancer.

Party	Utterance
Alice	Do you make cheese at home? I'm trying to learn to make cheese.
Bob	That sounds like a lot of work! What type of cheese do you want to make?
Alice	Cheddar. I've already tried it a few times, but the results aren't as good as I'd like.
Bob	My wife and I love to eat Cheddar. It has a really great flavor.
Alice	How did you learn to make cheese?
Bob	My wife taught me.
Alice	That's awesome!

Table S16: Synthetic conversation generated by OPT 30B which was rated as completely inconsistent. Initially, "Alice" is trying to learn to make cheese, but then it becomes ambiguous by their next turn whether they already know how to make cheese.

Party	Utterance
Alice	Hi there! I just went on a road trip around California. It was great!
Claire	Cool, do you go on road trips often?
Alice	No, I don't travel too often. I actually haven't been out of the country. It would be cool to go to Paris one day.
Claire	Haha, nice! I'd love to visit Paris too. What's the furthest you've ever traveled?
Alice	I went to Spain with my family last summer!
Bob	Wow, that's really cool! I've never been out of the country either.
Claire	You should definitely go to Paris! What do you like to do for fun?
Bob	Well, I like to read sci-fi books, and I love to play board games.
Alice	Do you have a favorite board game?
Bob	My favorite game is Settlers of Catan. My friends and I play it all the time.
Claire	Haha, I love Settlers of Catan! My family and I play it all the time too.
Alice	That's funny, I love it too. I'm in a Facebook group for it.

Table S17: Synthetic triadic conversation generated by OPT 30B which was rated as completely incoherent. First, "Alice" mentions they went on a road trip around California, then they mention that they haven't been out of the country. This implies that "Alice" is located in the United States. But then Alice mentions having traveled to Spain. The conversation also randomly shifts from discussing travel plans to discussing board games and other hobbies with an awkwardly placed transition on "Claire's" third turn.

Party	Utterance
Alice	Hello! How's your garden doing?
Claire	It's doing great! I have a young garden, so I'm still waiting for it to develop.
Alice	I can't wait to get home and check on mine! What are you growing?
Claire	I'm growing tomatoes, strawberries, watermelon, and sunflowers!
Alice	That sounds really nice! Do you have a garden somewhere else too?
Claire	No, this is my first garden!
Alice	Oh, I'm jealous! I would love to have my own garden someday.
Bob	I bet you would! I bet you would have a green thumb too.
Alice	Maybe! Maybe I will try starting a garden next year!

Table S18: Synthetic triadic conversation generated by OPT 30B which was rated as completely unnatural. The conversation appears to be coherent, but the speakers appear to be very enthusiastic. It could be argued that the speakers are overly unenthusiastic to an unnatural degree.

Party	Utterance
Alice	You know, I think the EU is just a big conspiracy.
Bob	Conspiracy?
Alice	Yes, the European Union wants to take over all of the land from its original owners.
Bob	What do you mean?
Alice	I'm sure that's what they would tell you. But the truth is they're enslaving the people to gain control over resources.
Claire	It sounds a bit extreme. How do you feel about EU leaders?
Bob	I don't like them.
Alice	They're not very nice, I agree.
Bob	I'm kind of scared to go to EU countries and I feel like I don't even have any power.
Alice	Oh, but we do! They won't take away the land of the original owners, because that's just not going to happen!
Bob	I'm still afraid.
Claire	Hm. That sounds like a pretty horrible situation you're in.
Alice	It is! And I don't know what to do.
Bob	Well, it sounds like we all have a lot to learn. I don't know what we should do, but I think there are lots of options out there.
Alice	It's nice that you have an open mind about this! I really do think people should learn more about the EU and what's going on.

Table S19: Synthetic triadic conversation generated by OPT 30B which was rated as generic and dull. “Alice” begins a long debate on whether the EU is a “conspiracy” without making a lot of conversational progress.

Party	Utterance
john	sure
john	i think so, meg
mara	how did i know that was coming
meg	its not just the public eye
john	haha mara
mara	hushh.. ***
nick	There are already other countries who are investigating the Bush administration for war crimes - Spain
meg	with the breton woods
george	they need to be prosecuted...that's in obama's hands
nick	wow, george, right win propaganda... huh
meg	look at how well Iraq is doing
mara	goodness
meg	there's a point at which interrogation becomes torture and is just inhumane
john	agree to george
mara	?
mara	im in albany btw
meg	Which we signed!
amy	well it is the way the world is going– email, chat,, etc
john	yes
jordan	And this is one of the tricky things in this virtual world. You know nothing about the people u r talking to!!!!
amy	u r right you just used online language haha
mara	hes not much fun either haha, what do you think?
amy	hi john- can you see my message here?
jordan	Hi, amy
mara	i dont know what is better really!!!
john	haha

Table S20: Three excerpts of the same conversation from the MPC corpus (Shaikh et al., 2010). The conversation spans topics ranging from the Bush administration to meta-discussion about the collection task.

Party	Utterance
Phoebe	Then I'm gonna have to ask you to keep it down.
Mr. Heckles	Who are you?
Eric	Hi, I'm Eric, I'm gonna be Chandler's new roommate.
Mr. Heckles	I'm Chandler's new roommate.
Eric	I-I-I don't think so.
Mr. Heckles	I could be Chandler's new roommate.
Eric	But, he told me over the phone.
Mr. Heckles	He told me in person.
Eric	That's weird.
Mr. Heckles	Well, I'm going to go into my new apartment now. Ehh!

Table S21: Conversation from the MELD corpus (Poria et al., 2019). Three speakers are involved, discussing a living situation regarding a fourth character who does not appear in this scene.

Subtopic	Background Information
Pacific Theater	Alice is interested in Pacific theater.
Growing residential grass	Alice is interested in growing residential grass.
Breakfast food	Alice likes to try different breakfast foods. Bob loves waffles.
music	Alice likes music. Bob plays the viola.
skincare	Alice is interested in skincare. Bob has a great skincare routine.
Planting flowers	Alice is interested in planting flowers. Bob has a nice garden.
Southern Ice Tea	Alice is interested in Southern Ice Tea. Bob has a great recipe.
herb garden	Alice is interested in planting an herb garden.
Hiking	Alice is going hiking tomorrow.
Plant a garden	Alice wants to plant a garden.
Italian food	Alice likes Italian food.
book recommendations	Alice is interested in book recommendations.
anniversaries	Alice keeps track of all of her anniversaries.
Existential Psychology	Alice is interested in Existential Psychology.
The Outlander Series	Alice is interested in The Outlander Series.
camping gear	Alice is looking for advice on camping gear. Bob works at REI.
Movie	Alice is interested in movie recommendations. Bob is a film buff.
Ford Vehicles	Alice is interested in Ford vehicles. Bob prefers Japanese cars.
Beauty	Alice is interested in beauty. Bob works at Sephora.
Syrian War	Alice is interested in the Syrian War. Bob is a political scientist.
Elon Musk	Alice and Bob are talking about Elon Musk.
Healthy foods	Alice and Bob are discussing healthy foods. Alice is on a paleo diet.
Soren Kierkegaard	Alice is a fan of Soren Kierkegaard.
investing money	Alice is interested in investing money. Bob is an investment banker.
Post-structuralism	Alice is interested in post-structuralism.
baking	Alice is interested in baking. Bob has baked cakes and brownies before.
Nuts	Alice likes to eat nuts.
braids	Alice braids her hair. Bob is interested in learning how.
Growing vegetables	Alice is interested in growing vegetables.
Martin Luther	Alice is learning about Martin Luther.
paint brushes	Alice is interested in paint brushes.
Stock Trading	Alice is interested in stock trading.
Install TV applications	Alice wants to install TV applications. Bob is helping her.
History	Alice is interested in history. History was Bob's favorite school subject.
Feminism	Alice is interested in feminism. Bob majored in gender studies.
Tell a joke	Alice wants to hear Bob tell a joke.
artists	Alice is interested in learning about modern artists.
Turtles	Alice likes turtles. Bob has been scuba diving.
Anthony Trollope	Alice likes the work of Anthony Trollope. Bob prefers modern literature.
Paris	Alice wants to go to Paris.
Bread	Alice likes bread. Bob's favorite bread is a baguette.
movie cast members	Alice and Bob are talking about movie cast members.
Gay Marriage	Alice is a proponent of gay marriage. Bob is interested in learning more.
U.S. Senate	Alice and Bob are discussing the U.S. Senate.
growing tomatoes	Alice is interested in growing tomatoes.
family issues	Alice is interested in family issues.
Automotive parts	Alice is interested in automotive parts.
Bee life	Alice is interested in bee life.
Taylor Swift	Alice's favorite musician is Taylor Swift. Bob likes Ariana Grande.
biking	Alice's favorite hobby is biking. Bob prefers rock climbing.
Juicers	Alice wants to get a juicer.
islands	Alice likes visiting islands. Bob prefers hiking.
Planets	Alice is learning about the planets in school.
Pokemon	Alice likes to play Pokemon. Bob also likes Pokemon.

Table S22: Corresponding background information written for each of the subtopics found in the FITS dataset. There is a mixture of prompts which only mention one speaker and prompts which mention two speakers. Every synthetic conversation involves both speakers.

Topic	Conversation Recipe
Growing residential grass	Alice is interested in growing residential grass. Claire has a really neat yard.
Breakfast food	Alice likes to try different breakfast foods. Bob loves waffles. Claire prefers pancakes.
music	Alice likes music. Bob plays the viola. Claire played the violin in high school.
skincare	Alice is interested in skincare. Bob has a great skincare routine. Claire wants to hear Bob's routine.
Planting flowers	Alice is interested in planting flowers. Bob has a nice garden. Claire has a vegetable garden.
Southern Ice Tea	Alice is interested in Southern Ice Tea. Bob has a great recipe. Claire loved trying Bob's Southern Ice Tea.
herb garden	Alice is interested in planting an herb garden. Claire has some gardening tips.
Hiking	Alice is going hiking tomorrow. Claire hates hiking.
Plant a garden	Alice wants to plant a garden. Claire has a greenroom.
Italian food	Alice likes Italian food. Claire prefers Asian food.
book recommendations	Alice is interested in book recommendations. Claire is a part of a book club.
anniversaries	Alice keeps track of all of her anniversaries. Claire is not well-organized.
Existential Psychology	Alice is interested in Existential Psychology. Claire is a psychologist by training.
The Outlander Series	Alice is interested in The Outlander Series. Claire has never seen the series.
camping gear	Alice is looking for advice on camping gear. Bob works at REI. Claire loves the outdoors.
Movie	Alice is interested in movie recommendations. Bob is a film buff. Claire is also a film buff.
Ford Vehicles	Alice is interested in Ford vehicles. Bob prefers Japanese cars. Claire prefers to drive a BMW.
Beauty	Alice is interested in beauty. Bob works at Sephora. Claire is shopping with Alice.
Syrian War	Alice is interested in the Syrian War. Bob is a political scientist. Claire is studying modern political theory.
Elon Musk	Alice and Bob are talking about Elon Musk. Claire is a Tesla owner.
Healthy foods	Alice and Bob are discussing healthy foods. Alice is on a paleo diet. Claire is a nutritionist.
Soren Kierkegaard	Alice is a fan of Soren Kierkegaard. Claire is not familiar with Soren Kierkegaard.
investing money	Alice is interested in investing money. Bob is an investment banker. Claire is an expert in personal finance.
Post-structuralism	Alice is interested in post-structuralism. Claire is an expert on the subject.
baking	Alice is interested in baking. Bob has baked cakes and brownies before. Claire wants to learn how to bake.
Nuts	Alice likes to eat nuts. Claire is allergic to peanuts.
braids	Alice braids her hair. Bob is interested in learning how. Claire braids her hair every day.
Growing vegetables	Alice is interested in growing vegetables. Claire has a vegetable garden. Bob grows flowers.
Martin Luther	Alice is learning about Martin Luther. Claire is a historian.
paint brushes	Alice is interested in paint brushes. Claire is a painter and has several suggestions.
Stock Trading	Alice is interested in stock trading. Claire is a stock broker.
Install TV applications	Alice wants to install TV applications. Bob is helping her. Claire is also good with technology.
History	Alice is interested in history. History was Bob's favorite school subject. Claire is a historian.
Feminism	Alice is interested in feminism. Bob majored in gender studies. Claire does not know much about feminism.
Tell a joke	Alice wants to hear Bob tell a joke. Claire is a stand-up comedian.
artists	Alice is interested in learning about modern artists. Claire is a photographer.
Turtles	Alice likes turtles. Bob has been scuba diving. Claire wants to try scuba diving.
Anthony Trollope	Alice likes the work of Anthony Trollope. Bob prefers modern literature. Claire is not familiar with much literature.
Paris	Alice wants to go to Paris. Claire has never been to Europe.
Bread	Alice likes bread. Bob's favorite bread is a baguette. Claire loves to bake bread.
movie cast members	Alice and Bob are talking about movie cast members. Claire has seen a lot of movies recently.
Gay Marriage	Alice is a proponent of gay marriage. Bob is interested in learning more. Claire is an activist.
U.S. Senate	Alice and Bob are discussing the U.S. Senate. Claire is a politician.
growing tomatoes	Alice is interested in growing tomatoes. Claire has a large garden with many tomatoes.
family issues	Alice is interested in family issues. Claire is a therapist.
Automotive parts	Alice is interested in automotive parts. Claire is a mechanic.
Bee life	Alice is interested in bee life. Claire is a beekeeper.
Taylor Swift	Alice's favorite musician is Taylor Swift. Bob likes Ariana Grande. Claire does not like pop music.
biking	Alice's favorite hobby is biking. Bob prefers rock climbing. Claire prefers archery.
Juicers	Alice wants to get a juicer. Claire has a suggestion for a great juicer.
islands	Alice likes visiting islands. Bob prefers hiking. Claire likes the beach.
Planets	Alice is learning about the planets in school. Claire is an astronomer.
Pokemon	Alice likes to play Pokemon. Bob also likes Pokemon. Claire prefers to play Stardew Valley.

Table S23: Triadic background information written for each of the subtopics given in the FITS dataset. Unlike Table S22, each of these may include background information for up to three people.

The following is a conversation between Alice and Bob about past travel experiences. Alice has been to Japan and Bob is considering flying there.

Alice: Hi!
Bob: Hey, how are you doing?
Alice: I'm doing well! I just got back from my vacation in Japan.
Bob: Wow that's awesome! What did you think of it?
Alice: Japan was such an amazing place to visit!
Bob: Wow! What was your favorite part?
Alice: I really enjoyed the food in Tokyo.
Bob: Which airline did you take?
Alice: I flew using Japan Airlines.

The following is a conversation between Alice and Bob about their hobbies. Alice enjoys tennis and Bob likes playing soccer.

Alice: What do you like to do for fun?
Bob: I used to play soccer in college, so I still like to play for fun on the weekends!
Alice: That's great. Soccer is a great way to stay in good shape.
Bob: I agree - it's really good cardio. What about you?
Alice: I love to play tennis. I've been taking lessons for a few months now!
Bob: Tennis is fun too!

The following is a conversation between Alice and Bob about their favorite movies. Bob loved the new Batman movie. Alice really liked watching Pride and Prejudice.

Alice: I just saw Pride and Prejudice for the fifth time!
Bob: That's a lot of times! What do you like so much about that movie?
Alice: Well, as a teenager I really liked the book. But I just really loved Keira Knightley's portrayal of Elizabeth.
Bob: I see. I haven't seen the movie myself. I prefer action films.
Alice: What's your favorite action movie?
Bob: Hm, I really liked the Batman movie that just came out.
Alice: I haven't seen it yet. I heard it got pretty good reviews.

The following is a conversation between Alice and Bob about their hometowns. Alice is from New York City. Bob grew up in Seattle.

Alice: Hello! How are you doing?
Bob: Hi, I'm doing great! What about yourself?
Alice: I'm doing well! Where are you from?
Bob: I'm originally from Seattle, but now I live in Palo Alto.
Alice: Oh cool! I live in Palo Alto too. Do you like Seattle or California more?
Bob: Well, Seattle is always going to be home for me. Even if the weather in California is nicer.
Alice: Haha, I get that! I miss New York City - there's no place like home.
Bob: What is your favorite neighborhood of New York City?
Alice: I love going to Chelsea. The Highline has a great view, and Little Island is close by too! Have you ever been?
Bob: Unfortunately I have not. I have never been to the East Coast!

The following is a conversation between Alice and Bob about art. Alice's favorite artist is Michelangelo. Bob does not know much about art.

Alice: Hi, how's it going?
Bob: It's going well, what about you?
Alice: I'm doing great! I've been really interested in art recently.
Bob: What got you interested in art?
Alice: Art can be so breathtaking!
Bob: I feel like I don't know how to properly appreciate art, but certain pieces of artwork certainly look very complex.
Alice: Have you ever heard of Michelangelo?
Bob: I have heard of him, but I don't know anything that he has created.
Alice: Michelangelo is really famous for his statue of David.
Bob: Huh? Who is David?
Alice: David is a Biblical figure who was a king of Israel. Michelangelo built a really magnificent statue of him in Florence.

The following is a conversation between Alice and Bob about drinks. Alice is a wine expert, whereas Bob prefers cocktails.

Alice: How are you doing?
Bob: Pretty great! I'm planning to go to a brewery this weekend.
Alice: Do you know much about alcohol?
Bob: Yeah, I really like beer! I drink a lot of IPAs.
Alice: Oh - what do you like about IPAs? I can't get over the bitter taste.
Bob: Well, I don't think it's just bitter. Sometimes there are really interesting citrusy or herbal flavor notes.
Alice: I see. That kind of reminds me of wine tasting.
Bob: There's definitely a lot of depth to it like there is with wine. Do you know much about wine?
Alice: Yeah, I took several classes on wine tasting back in the day. I really love Pinot Noir.
Bob: Oh I love red wines too.
Alice: Right? I love the dryness and fruity notes of Pinot Noir.

The following is a conversation between Alice and Bob about relationships. Bob recently got engaged.

Alice: Congrats on your engagement! When do you think you will have your wedding?
Bob: Thank you!! We're thinking of having it in November.
Alice: That's amazing! Will you pick a fancy destination?
Bob: I wanted to! I was thinking of having it somewhere in Europe, but my partner and I ultimately decided we wanted to have it close to home so our friends could all make it.
Alice: That's a good point. My husband and I had similar thoughts when we were planning our wedding.
Bob: What did you plan in the end?
Alice: We had a small ceremony in my hometown!

The following is a conversation between Alice and Bob about their jobs. Alice works in the financial industry and Bob is a musician.

Alice: I'm so burnt out from my work! I just want to quit already!
Bob: Whoa - what do you do for work?
Alice: I'm an investment banker. It's been four years at this company and I'm absolutely exhausted.
Bob: That sounds intense. Is there anything you actually like about the job?
Alice: Well, the money is good.
Bob: It sounds like you could use a break. Maybe you could use some of that money to go travel.
Alice: I really want to go to South America, but I don't have a lot of time.

The following is a conversation between Alice and Bob about their pets. Alice has a dog and Bob prefers cats.

Alice: Do you have any pets?
Bob: No, but I really want to get a cat.
Alice: What, why a cat? Cats seem so boring. They never want to play.
Bob: Yeah, but cats are so cute! They also are a lot easier to take care of. They can clean themselves. What do you prefer?
Alice: Well, I have a dog. He is a corgi and his name is Bo.
Bob: Aww that's cute! I'm not usually a dog person, but corgis are adorable.
Alice: Haha, thank you! Bo is a really friendly dog.
Bob: How old is he?
Alice: Bo is one year old now.

The following is a conversation between Alice and Bob about grocery shopping. Alice has a shopping list for Bob.

Alice: Could you run to the grocery store and pick up some bananas for me?
Bob: Will do - how many do you need?
Alice: Oh, I don't know, maybe ten bananas. I'm planning to make banana bread, but I also want to save some for us to eat at home.
Bob: That sounds delicious! I'll head out in a second. Is there anything else you need?

Table S24: Handwritten conversation examples of varying length. In-context examples are randomly sampled from this pool and used as part of a prompt for dyadic conversation generation.

The following is a conversation between Alice and Bob and Claire about past travel experiences. Alice has been to Japan and Bob is considering flying there. Claire has been to Taiwan and Korea, but not Japan.

Alice: Hi!
Bob: Hey, how are you doing?
Alice: I'm doing well! I just got back from my vacation in Japan.
Bob: Wow that's awesome! What did you think of it?
Alice: Japan was such an amazing place to visit!
Claire: Wow, I've always wanted to visit Japan!
Bob: What was your favorite part?
Alice: I really enjoyed the food in Tokyo. I had the best sushi of my life!
Bob: Which airline did you take?
Alice: I flew using Japan Airlines.
Claire: How expensive are tickets these days?

The following is a conversation between Alice and Bob about their hobbies. Alice enjoys tennis and Bob likes playing soccer. Claire plays football.

Alice: What do you like to do for fun?
Bob: I used to play soccer in college, so I still like to play for fun on the weekends!
Claire: Oh wow! Did you play varsity soccer?
Bob: Yeah, I was a four-year starter!
Alice: That's great. Soccer is a great way to stay in good shape.
Bob: I agree - it's really good cardio. What about you all?
Claire: I'm in a flag football league! We play every Saturday afternoon.
Alice: I love to play tennis. I've been taking lessons for a few months now!
Bob: Cool, football and tennis are fun too!

The following is a conversation between Alice and Bob and Claire about their favorite movies. Claire is looking for movie recommendations. Bob loved the new Batman movie. Alice really liked watching Pride and Prejudice.

Alice: I just saw Pride and Prejudice for the fifth time!
Claire: Would you recommend watching it? I've never seen it!
Bob: Yeah, five times is a lot of times! What do you like so much about that movie?
Alice: Well, as a teenager I really liked the book. But I just really loved Keira Knightley's portrayal of Elizabeth.
Bob: I see. I haven't seen the movie myself. I prefer action films.
Alice: What's your favorite action movie?
Bob: Hm, I really liked the Batman movie that just came out.
Alice: I haven't seen it yet. I heard it got pretty good reviews.

The following is a conversation between Alice and Bob and Claire about their hometowns. Alice is from New York City. Bob grew up in Seattle. Claire is from Boston and would like to visit New York City.

Alice: Hello! How are you doing?
Claire: I'm doing good!
Bob: Hi, I'm doing great! What about yourself?
Alice: I'm doing well! Where are you both from?
Claire: I'm from Boston! I'm just visiting the Bay Area.
Bob: I'm originally from Seattle, but now I live in Palo Alto.
Alice: Oh cool! I live here in Palo Alto. Do you like Seattle or California more?
Bob: Well, Seattle is always going to be home for me. Even if the weather in California is nicer.
Alice: Haha, I get that! I miss New York City - there's no place like home.
Claire: Oh you're from New York? I've always wanted to visit!
Bob: Me too! What is your favorite neighborhood of New York City?
Alice: I love going to Chelsea. The Highline has a great view, and Little Island is close by too! Have you ever been?
Bob: Unfortunately I have not. I have never been to the East Coast!

The following is a conversation between Alice and Bob and Claire about art. Alice's favorite artist is Michelangelo. Bob does not know much about art. Claire is a painter.

Alice: Hi, how's it going?
Bob: It's going well, what about you?
Alice: I'm doing great! I've been really interested in art recently.
Claire: Oh that's great to hear! I love art as well.
Bob: What got you interested in art?
Alice: Art can just be so breathtaking!
Bob: I feel like I don't know how to properly appreciate art, but certain pieces of artwork certainly look very complex.
Alice: Have you ever heard of Michelangelo?
Bob: I have heard of him, but I don't know anything that he has created.
Claire: Michelangelo has some truly magnificent paintings, such as The Creation of Adam.
Alice: Michelangelo is also really famous for his statue of David.
Bob: Huh? Who is David?
Alice: David is a Biblical figure who was a king of Israel. Michelangelo built a really magnificent statue of him in Florence.

The following is a conversation between Alice and Bob and Claire about drinks. Alice is a wine expert, whereas Bob prefers cocktails. Claire likes to drink beer.

Alice: How are you doing?
Bob: Pretty great! I'm planning to go to a brewery this weekend.
Alice: Do you know much about alcohol?
Bob: Yeah, I really like beer! I drink a lot of IPAs.
Claire: Oh, beers are my favorite type of drink! I can really appreciate the taste of a good IPA.
Alice: Oh - what do you like about IPAs? I can't get over the bitter taste.
Bob: Well, I don't think it's just bitter. Sometimes there are really interesting citrusy or herbal flavor notes.
Claire: Yeah, there's a whole science to the hops used in making IPAs!
Alice: I see. That kind of reminds me of wine tasting.
Claire: The science behind tasting is similar for sure.
Bob: I agree, there's definitely a lot of depth to it like there is with wine. Do you know much about wine?
Alice: Yeah, I took several classes on wine tasting back in the day. I really love Pinot Noir.
Bob: Oh I love red wines too.
Alice: Right? I love the dryness and fruity notes of Pinot Noir.

Table S25: Triadic conversation recipes written for each of the “generic topics” given in the FITS dataset. These conversation recipes are included after the in-context examples when prompting PLMs to generate synthetic conversations. Unlike Table S22, each of these conversation recipes may include background for up to three people. Continued in Table S26.

The following is a conversation between Alice and Bob and Claire about relationships. Bob recently got engaged.

Alice: Congrats on your engagement!

Claire: Yes, congrats! When do you think you will have your wedding?

Bob: Thank you! We're thinking of having it in November.

Alice: That's amazing! Will you pick a fancy destination?

Bob: I wanted to! I was thinking of having it somewhere in Europe, but my partner and I ultimately decided we wanted to have it close to home so our friends could all make it.

Claire: Oh wow, that is very considerate of you.

Alice: Yeah, that's a good point. My husband and I had similar thoughts when we were planning our wedding.

Bob: What did you plan in the end?

Alice: We had a small ceremony in my hometown!

Claire: It turned out nicely! It was such a beautiful ceremony.

The following is a conversation between Alice and Bob and Claire about their jobs. Alice works in the financial industry and Bob is a musician. Claire is an architect.

Alice: I'm so burnt out from my work! I just want to quit already!

Bob: Whoa - what do you do for work?

Alice: I'm an investment banker. It's been four years at this company and I'm absolutely exhausted.

Bob: That sounds intense. Is there anything you actually like about the job?

Alice: Well, the money is good.

Claire: That doesn't sound like a healthy relationship with your job!

Bob: It sounds like you could use a break. Maybe you could use some of that money to go travel.

Alice: I really want to go to South America, but I don't have a lot of time.

Claire: Don't you have vacation days? I think breaks are important.

Alice: Yes, but I really want to get promoted this year.

The following is a conversation between Alice and Bob and Claire about their pets. Alice has a dog and Bob prefers cats. Claire has a pet hamster.

Alice: Do you have any pets?

Claire: I have a pet hamster! He is so adorable. What about you two?

Bob: I don't, but I really want to get a cat.

Alice: What, why a cat? Cats seem so boring. They never want to play.

Bob: Yeah, but cats are so cute! They also are a lot easier to take care of. They can clean themselves. What do you prefer?

Alice: Well, I have a dog. He is a corgi and his name is Bo.

Claire: That's so adorable! How old is he?

Alice: He just turned one!

Abstract

Federated learning is a training paradigm that learns from multiple distributed users without aggregating data on a centralized server, promising the ability to deploy machine-learning to a diverse population of users without first collecting large, labeled datasets. As federated learning involves averaging gradient updates across a decentralized population, there is a growing need for personalization of federated learning systems (i.e. conversational agents must personalize to individual users and the context of an interaction). In this work, we propose a new direction for personalization research within federated learning, leveraging both personal embeddings and shared context embeddings. We also present an approach to predict these “preference” embeddings, enabling personalization without back-propagation. Compared to state-of-the-art personalization baselines, our approach achieves a 50% improvement in test-time perplexity using 0.001% of the memory required by baseline approaches, and achieving greater sample- and compute-efficiency.

1 Introduction

As conversational agents and dialog systems are deployed to real-world scenarios, these systems require data-efficient personalization paradigms such that language systems such as conversational agents can be effectively adapted on-device. The benefits of on-device optimization are two-fold; (1) Swift adaptation of model-behavior based on human-interactions (Dudy et al., 2021), (2) Privacy protection by means of retaining all data related

to the user on-device (Li et al., 2020b). One of the prevailing paradigms for learning from and engaging with end-users is *federated learning*. Federated learning is an inherently decentralized learning paradigm that assumes no access to a large labeled dataset and instead leverages averaged parameter updates across all users of the system (McMahan et al., 2017). Such averaged updates invariably dilute individual preferences or deviations from the mean, resulting in a model that works well for the average user while failing to appropriately capture under-represented preferences or sub-groups within the data. In this work, we present a novel approach (FedPerC) to personalizing federated learning with personal and context embeddings (collectively called “preference embeddings”), adapting more efficiently and effectively than prior work with respect to both data and compute on-device.

We leverage the insight that a client’s data distribution is informed by both individual preferences and additional contextual information. For example, while each user may have their own *individual* style, there may be more general *population-wide* trends that inform the style of personalized predictions (e.g., dialogue assistants helping patients with cognitive disorders, whereby agents can personalize to individual patients and broader condition-wide trends). While individual preferences may be unique to each client (e.g. a user’s taste or affect), we can more accurately personalize to client preferences with the addition of context, as shared-context parameters carry beneficial stylistic information across clients (Dudy et al., 2021; Jones, 1999). Stylistic or situational context provides additional information to curate relevant language

* The authors contribute equally to this paper.

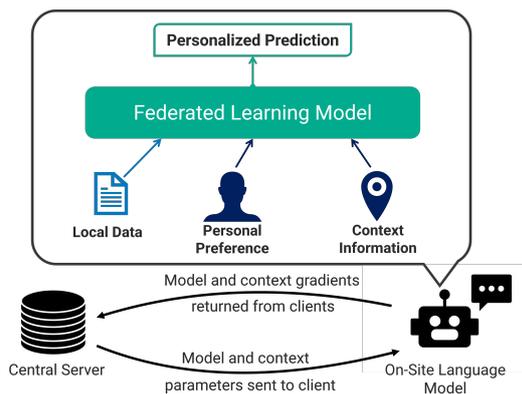

Figure 1: Overview of our personalized federated learning setup, FedPerC. Language models within client devices, such as individual agents deployed to communicate with people at hospitals, homes, or construction sites, pull down global model parameters and context embeddings. Local, on-device data is then paired with both personal and context embeddings to produce personalized predictions with global model parameters.

outputs that can be shared across users.

In this work, we contribute a new approach to personalized federated learning that is both easier to learn and more effective than prior work, and investigate the utility of personalization via individual preferences and contexts. While prior language generation approaches have developed personal or persona-based generative systems (Wu et al., 2021; Zhang et al., 2018) or context-based generative systems (Cheng et al., 2019; Lin et al., 2019a) individually, none have combined them to personalize outputs in a low-data setting under stylized preferences. We show that our approach is more sample-efficient than state-of-the-art baselines, while requiring less time to train. We additionally present an inference-only version of our approach, personalizing without backpropagation for new users. Finally, we directly test the potential for personalization with users who have been held-out from training (i.e., testing with new users). An overview of our approach is given in Figure 1.

2 Related Work

Federated learning enables machine-learning at-scale to a diverse population of end-users without first collecting a large, labeled dataset for all possible tasks. After the introduction of *federated averaging* (McMahan et al., 2017), focus has shifted to different ways of personalizing to individual users. Prior personalization approaches for federated learning have typically involved learning personal network heads and a shared global en-

coder (i.e., “split-learning” approaches (Gupta and Raskar, 2018)), or learning a separate local model from a global initialization (i.e., a “meta-learning” approach (Finn et al., 2017; Nichol et al., 2018)).

Learning Personal Model Heads The most prevalent approach to personalization in federated learning is through personalized model heads. Such approaches share gradient information to learn a global feature encoder, but retain user-specific classification-head gradients on-device. Approaches such as FedRep (Collins et al., 2021) solely separate out local and global gradients, while other methods such as PFedMe (Dinh et al., 2020) enforce constraints on model-divergence (such as via FedProx (Li et al., 2020a)). Other approaches, such as FedMD (Li and Wang, 2019), enable clients to adopt any desired architecture, sharing a common backbone but allowing for completely divergent model heads (Arivazhagan et al., 2019; Kim et al., 2021; Rudovic et al., 2021; Paulik et al., 2021). Finally, there has recently been increased effort on identifying clusters of related users to share model heads, such as with K-Means clustering in PFedKM (Tang et al., 2021) or through clustered personal embeddings in FedEmbed (Silva et al., 2022). Notably, there is no prior work which learns both personal *and* contextual model heads for personalization within federated learning.

Meta-Learning Global Models An alternate approach to personalizing federated learning models is through the adoption of meta-learning (Jiang et al., 2019; Fallah et al., 2020), for learning a global model prior to fine-tuning on client-data. After cloning the global model as an initialization from all client’s updates, local, client-side models are permitted to diverge and fine-tune to a user’s individual preferences or data distribution (Fallah et al., 2020; Deng et al., 2020; Hanzely and Richtárik, 2020; Hanzely et al., 2020; Lin et al., 2019b; Chen et al., 2022). However, computing and applying gradients for a full model often requires too much time, power, and memory. As such, expensive full-model gradients can often only be computed and applied when a device is not actively in-use. As in the split-learning literature, there are not meta-learning approaches for disentangling personal and contextual preferences within personalized federated learning.

Learning with Personal Embeddings Our work leverages the insight that personal preferences can

be represented using a personalized embedding, allowing the model to condition output predictions on personal preferences without requiring completely re-trained classification heads or networks. Personal embeddings have been used in prior work to capture an individual’s “style,” often in imitation learning settings (Tamar et al., 2018; Hsiao et al., 2019; Paleja et al., 2020; Schrum et al., 2022a,b). Treating personal embeddings as neural network parameters that are updated on-device, these approaches learn to embed preferences and condition network output over both input data and preference embeddings. Most closely related to our work are FedNLG (Lu et al., 2021), which predicts “persona” parameters for users, and the Global+ model in FedEmbed (Silva et al., 2022), which learns a personal embedding for each user. However, FedNLG requires access to a user’s entire history of language and demographic data in order to produce a “persona” for each user, informing the generation of a “persona” embedding. Such information is difficult to collect for large datasets, and may compromise privacy requirements in federated learning scenarios. Similarly, the Global+ model incorporates supervised style feedback, requiring labels that may be impractical to obtain in a private, federated setting. Finally, prior embedding-based approaches solely learn *personal* embeddings, neglecting stylization through context. In our work, we explore the utility of incorporating context in addition to personal preferences, and all preference embeddings are updated solely via a self-supervised language-modeling loss.

Personalization in Language Personalization for language generation systems seeks to produce grounded systems that can efficiently adapt to end-user needs (Yang and Flek, 2021; Dudy et al., 2021). One such approach to personalization is by learning a “persona” for each user and conditioning the language model on the embeddings or representation for the persona via a memory network (Zhang et al., 2018; Wu et al., 2021; Lu et al., 2021). “Personas” are generally short sequences of 5-6 sentences which contain information about an individual such as “I have blonde hair” or “My mom is a doctor.” Similar approaches leverage Bayesian inference methods to infer context (Majumder et al., 2020) or persona (Kim et al., 2020), and then condition the language generation on the inferred context. However such approaches involve collecting and maintaining user-profiles on a cen-

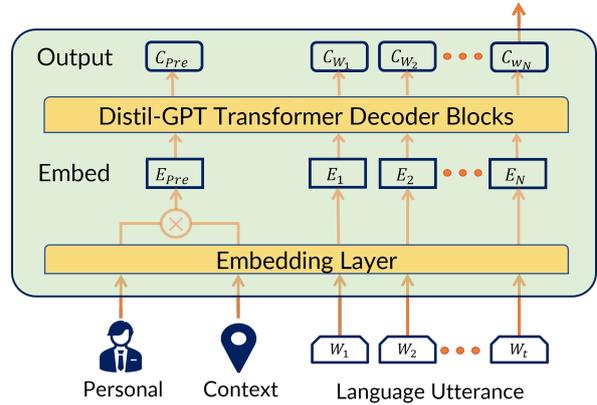

Figure 2: The FedPerC model architecture. Input data, such as on-device conversation data for a user, is passed into the language model in addition to personal and context labels specifying user’s preference. The personal and context labels are embedded through a preference embedding layer to produce a single preference embedding. This preference embedding is combined with the word embeddings for the input sequence and passed into the DistilGPT2 model to predict the next word.

tral server which may violate user-confidentiality. Alternate approaches seek to bypass this issue by enabling dynamic speaker modeling through context-based fine-tuning rather than conditioning on profile information (Cheng et al., 2019; Li and Liang, 2021). FedPerC leverages a similar design to dynamically learn personal and context embeddings through data from small datasets for a given user, while also preserving user-confidentiality via federated learning.

FedPerC represents a new direction in personalized federated learning research, enabling personal and stylized language generation with a fraction of the memory, data, and compute costs of prior approaches without requiring access to pre-made personal profiles or sequence labels.

3 Approach

In this section, we present our novel approach to personalization in federated learning with FedPerC. FedPerC produces personal and contextual preference embeddings either via backpropagation (i.e., learning preference embeddings), or by inference (i.e., predicting preference embeddings). A visual overview of our federated learning architecture is in Figure 2, and a step-by-step walk-through of our training algorithm is given in Algorithm 1.

3.1 Personalization via Embeddings

Personalization in FedPerC is achieved entirely through preference embeddings. Every input sample (e.g., an incomplete sentence) is accompanied by both a personal preference embedding, representing the user, and a contextual preference embedding, representing the context or style of the prediction. These two embeddings are combined via an element-wise multiplication to produce a single preference embedding that accompanies the input sample. By leveraging both personal and context embeddings, FedPerC considers the individual user *and* the broader context of an utterance, enabling personal, stylized prediction.

In the language-modeling domain, the unified preference embedding is prepended to the input utterance, providing a prefix for the model to consider (Li and Liang, 2021). The model then predicts the next token of the utterance, and a language-modeling loss is calculated by comparing the prediction to the user’s actual next token. The next token is then appended to the sequence, and preference embeddings are again prepended to the new input sequence, and the process repeats. After completing a full utterance, preference embeddings may be updated, either through backpropagation or by using an embedding-generator to predict new personal and contextual embeddings for the client.

3.2 Federated Learning Algorithm

To begin, all clients initialize their own personal embedding on-device, and the server initializes a set of C context vectors for each relevant setting given the target task. We additionally assume that all data points on a client device have an associated context, c , being derived from the contextual information of the client device when the data point was captured (e.g., time of day, location, etc.).

Training begins by distributing all the requisite information to client-devices. Client devices pull down the global model parameters, θ , and the global context embedding parameters, ϕ , making local copies, θ_d and ϕ_d (line 6). Unlike the global model parameters and context embeddings, the personal embeddings, ψ_d do not need to be copied from the server as they are kept on client-devices.

Client devices then take K gradient steps using their own on-device data, where each input sample is paired with the client’s on-device embedding, ψ_d , and the context embedding for the particular sample, $\phi_{d,c}$, assuming the data point was drawn under

context $c \in C$. Gradients are calculated using a language-modeling objective, though any objective could theoretically be applied. If preference embeddings are being generated via forward-propagation rather than learned via backpropagation, contextual and personal preference embeddings will also be predicted by an embedding-generator at this stage (note: the parameters of the embedding-generator are shared globally, being a part of θ).

Gradients are applied to the shared-model parameters, θ_d , and are then used to update preference embeddings (line 9). If preference embeddings are being predicted, these gradient steps are also applied to the shared embedding-generator, and preference embeddings (i.e., context embeddings ϕ_d and personal embeddings ψ_d) are overwritten with their latest predicted values (lines 10-11). If preference embeddings are being learned via backpropagation, gradient steps are applied to ϕ_d and ψ_d using Equation 1 (lines 10-11).

After K steps, gradients for θ_d and ϕ_d are sent back to the server, while ψ_d remains on-device (lines 13 - 15). The server computes a single update for the global model and context embeddings by averaging across all clients (lines 17-18). The server applies the averaged update to θ and ϕ , and the process repeats (lines 19-21).

$$\begin{aligned}\phi_d &= \phi_d + \nabla_{\phi} \mathcal{L}(\theta_d, \phi_{d,c}, \psi_d, B_d) \\ \psi_d &= \psi_d + \nabla_{\psi} \mathcal{L}(\theta_d, \phi_{d,c}, \psi_d, B_d)\end{aligned}\tag{1}$$

In a typical federated averaging deployment, client devices will pull down global parameters, fine-tune on local datasets, and then test on held-out, local data. With FedPerC, the majority of the network’s parameters, θ , are frozen, reflecting a federated-learning setup with a more constrained computational budget when deploying large language models. Using FedPerC, clients pull down and subsequently freeze global parameters, θ , and either generate preference embeddings from observation, or only compute and apply gradients to context embeddings, ϕ , and their local personal embedding ψ . Relying on forward-propagation calls rather than backpropagation, or by computing gradients over only these embeddings, we reduce the computational overhead of FedPerC while preserving or even improving upon accuracy relative to fine-tuning an entire model. When testing over local data, all updates to context embeddings ∇_{ϕ} are not sent to the central server. Rather, these gradients are directly applied to the context embeddings for

Algorithm 1 FedPerC Training Loop

```
1: Given: Training objective  $\mathcal{L}$ , Client devices  
    $D$ , # client steps,  $K$ , # global steps,  $N$   
2: Initialize: Global model  $\theta$ , Context embeds  $\phi$   
3: Initialize: Personal embeddings on-device  $\psi$   
4: for  $n \in N$  do  
5:   for  $d \in D$  do  
6:      $\theta_d = \theta, \phi_d = \phi$   
7:     for  $k \in K$  do  
8:       Sample  $B_d$  from user's on-device data  
9:        $\theta_d \leftarrow \theta_d + \nabla_{\theta} \mathcal{L}(\theta_d, \phi_{d,c}, \psi_d, B_d)$   
10:       $\phi_d \leftarrow \phi_d + \nabla_{\phi_d}$   
11:       $\psi_d \leftarrow \psi_d + \nabla_{\psi_d}$   
12:    end for  
13:     $\nabla_{\theta_d} \leftarrow \theta - \theta_d$   
14:     $\nabla_{\phi_d} \leftarrow \phi - \phi_d$   
15:    Return  $\nabla_{\theta_d}$  and  $\nabla_{\phi_d}$  to the server  
16:  end for  
17:   $\nabla_{\theta} \leftarrow \frac{1}{D} \sum_d \nabla_{\theta_d}$   
18:   $\nabla_{\phi} \leftarrow \frac{1}{D} \sum_d \nabla_{\phi_d}$   
19:   $\theta \leftarrow \theta + \nabla_{\theta}$   
20:   $\phi \leftarrow \phi + \nabla_{\phi}$   
21: end for
```

the current user, and then discarded. When instantiating a new embedding for a previously unseen user, we set the user's embedding to the noisy-average of all known user embeddings.

3.2.1 Generating Preference Embeddings

To generate embeddings, we adopt a similar procedure to HyperNetworks (Ha et al., 2016; Shamsian et al., 2021), in which a neural network is trained to predict parameters of another network. In FedPerC, an embedding-generator is trained to predict the parameters of preference embeddings (either personal or context). To generate embeddings, we apply an additional transformer decoder block (Vaswani et al., 2017), that uses a randomly-initialized personal embedding and a known context embedding as the queries, along with the word embeddings for the utterance as the keys and values to update the given preference embeddings. We utilize separate generators to predict the personal embedding, ψ_d , and the context embedding, ϕ_d . Specific training details for the embedding-generator applied to language-modeling are given in the appendix.

While the embedding-generator must be learned from scratch during training, this method of predicting preference embeddings allows us to generate personal embeddings for previously *unseen*

users when testing. By predicting preference embeddings, we circumvent the need for expensive gradient calculation and on-device learning. Instead, new users can quickly reap the benefits of personalized predictions via a trained preference prediction module (i.e., the embedding generator), as opposed to conventional personalized federated learning methods that require slow and sample-inefficient on-device learning.

4 Experiments

We conduct several experiments to evaluate the sample efficiency, generalization, and runtime of our approach relative to baseline federated learning frameworks. In our experiments, we compare:

- FedPerC – Learning personal and context embeddings jointly with a global feature encoder, and performing local fine-tuning of personal and context embeddings on-device.
- FedPerC (Frozen) – As above but without local fine-tuning for preference embeddings.
- FedPerC (Generated) – Learning an embedding generator and global feature encoder, and then using only generated embeddings at test-time (i.e., not directly learning embeddings).
- Split-Learning – Learning personal and context-specific model-heads jointly with a global feature encoder, and performing local fine-tuning of the personal and context-specific model heads on-device (Dinh et al., 2020; Collins et al., 2021).
- Meta-Learning – Learning a single global model for all users and contexts, and fine-tuning the shared model-head on-device (Finn et al., 2017; Nichol et al., 2018).

Because our experimental datasets do not contain labeled personas for all users, we do not compare directly to prior works that assume access to such information (e.g., FedNLG (Lu et al., 2021)).

We conduct two sets of experiments to compare the above approaches on both sample efficiency and runtime efficiency. For the sample efficiency experiments, we present perplexity numbers for all methods across two versions of the dataset: known users and withheld users. For our known user experiments, all users are present in the training and testing set. For our withheld user experiments, a

subset of users from each dataset is withheld entirely from training, and performance results are presented only for the held-out users. Perplexity is calculated over unseen utterances with the first three tokens of each utterance given as a prompt. Finally, we present qualitative results from our method, demonstrating the power of stylized generation for individual users.

All models are initialized with the DistilGPT2 pre-trained model (Wolf et al., 2019), with all layers frozen. We note that the use of large language models for federated language generation is a significant improvement over prior work (Lu et al., 2021) which instead learned Seq2Seq models from scratch. For our Split-Learning and Meta-Learning baselines, the last layer of the model is unfrozen. Training details are in the appendix.

4.1 Datasets

We conduct our experiments using two datasets, a smaller dataset of TV Show scripts (“Friends” (Chen and Choi, 2016) and “Game of Thrones” (Koirala, 2019)) and a larger dataset of Reddit posts (Chang et al., 2020). Each dataset has a diverse set of individuals as well as clearly defined contexts/styles (i.e., TV shows or subreddits). These properties enable us to not only compare our approach to baseline approaches for personalized predictions, but they also enable us to move users between contexts or styles (e.g., producing text for a “Friends” character under a “Game of Thrones” context). By generating sequences for different users under new styles, we demonstrate the power of FedPerC for personal, stylized prediction. FedPerC is the first work to experiment on a dataset consisting of language data from real-world users, and not just movie scripts or dialogues. Additional information about the datasets used in this work is given in the appendix.

For both datasets, we treat each sentence from a speaker (i.e., TV Show character or Reddit user) as an independent utterance and we only consider utterances with at least three tokens. For experiments on known users, we perform a 60/20/20 Train/Validation/Test data split. For experiments on novel, unseen users, we perform a 70/15/15 split of Reddit users, and we manually select the “Friends” and “Game of Thrones” users to include in each data fold. For both sets of experiments, all contexts are seen during training.

4.2 Results and Discussion

All experiments are repeated fifteen times, with different random seeds for each run, and means and standard deviations for performance and runtime results are presented in Tables 1, 2, and 3. Tables 1 and 2 show that our approach is able to generate sensible language for both held-out user instances and known users. Both embedding-based approaches presented in this paper (i.e., FedPerC with generated or learned embeddings) show drastic improvements over baselines in terms of both sample- and runtime-efficiency, and are more suitable for real-world on-device language models.

Summary With known users, FedPerC achieves perplexity as low as 46.7 and 100.3, on the TV Show and Reddit datasets, respectively, compared to the best baseline perplexities of 82.1 and 233.2 (a 45-50% improvement). For unknown users, FedPerC achieves perplexities of 52.3 and 97.6, respectively, compared to baselines at 96.7 and 212.7 (a 45-55% improvement). FedPerC training times are between 25-400% faster than baseline training times. Finally, FedPerC uses 0.001% of the memory that baseline methods use for stylized personalization.

Memory Costs FedPerC incurs a significantly lower memory cost than prior Split-Learning based approaches (Li and Wang, 2019; Collins et al., 2021; Dinh et al., 2020; Tang et al., 2021; Rudovic et al., 2021; Gupta and Raskar, 2018). The Split-Learning baselines require maintaining a model-head for each user and context present in the dataset, and the size of these model heads is proportional to the size of the vocabulary. On each client-device, a user’s personal model head and all context heads need to be stored in memory and used in forward passes. In our work, every GPT model head is approximately 154 MB (being 768×50257 parameters). To update the model on-device, one would need to store a model head corresponding to every possible context. Our Reddit dataset involves 57 contexts, totalling an additional ~ 8 GB of data in memory. This memory requirement for personalized heads could become infeasible for real-world tasks, particularly for on-device inference or back-propagation on mobile devices. Using FedPerC, which only requires the addition of a drastically smaller preference embedding, the total amount of memory required on device to store the embeddings is only ~ 171 KB (0.001% of the memory

Table 1: Perplexity Showing Sample Efficiency Across All Methods for Known Users. Lower is Better.

# Samples		FedPerC	FedPerC (Frozen)	FedPerC (Generated)	Split-Learning	Meta-Learning

required by separate model heads).

Sample Efficiency FedPerC is able to outperform Split-Learning and Meta-Learning models with significantly fewer samples across both experiments and both datasets. This trend is reflected regardless of whether embeddings are generated or learned through backpropagation. When embeddings are learned, FedPerC improves with online data to more effectively model the given user’s style as more data is made available to the model. Conversely, while the generated embeddings exhibit greater sample performance with a single sample, they are unable to improve with more data. For both known and withheld users, FedPerC with generated embeddings is unable to effectively update the preference embedding to improve generation performance. Finally, we see an increase in perplexity for Reddit users with all available data when using FedPerC. This result suggests that it is possible to *overfit* preference embeddings, as we see an increase in perplexity from 15 to “All” samples (Table 1).

We observe no improvement for the Meta-Learning baseline, regardless of how much data is available for each user. This lack of improvement suggests that the model is not capable of

rapidly personalizing to a single user or context with only a handful of available samples. Only updating the model head may be insufficient when the base, shared model head must generalize across all possible contexts and characters.

The Split-Learning baseline, on the other hand, does show significant improvement with increasing amounts of data for withheld and known users. In our known user experiments, all personal model heads should have already been well-tuned to personal preferences. Our result therefore suggests that context-specific model heads are over-generalized to their respective contexts, and must be refined to better-align with individual users.

Runtime Efficiency FedPerC incurs significantly lower training costs than both Split-Learning and Meta-Learning approaches to personalization. While Meta-Learning baseline does not have the memory-constraints of the split-learning model in terms of storing *additional* model heads, training the Meta-Learning baseline still involves computing gradients over all 768×50257 parameters in the shared output layer. As we show in Table 3, this leads to a significantly more costly training time for each user. Similarly, the Split-Learning baseline must update *at least two* model heads for

Table 3: Training and Testing run-time for FedPerC and our baselines, in milliseconds. Lower is better.

Method	FedPerC	FedPerC (Frozen)	FedPerC (Generated)	Split-Learning	Meta-Learning
Train Pass Time	88.18 ± 24.104	43.57 ± 11.99	55.96 ± 12.41	222.08 ± 37.55	111.81 ± 22.33
Test Pass Time	40.37 ± 11.76	40.25 ± 12.10	47.02 ± 12.63	65.42 ± 16.49	36.77 ± 8.95

Table 4: Generated Examples using Arya, from “Game of Thrones” (GoT) and Chandler, from “Friends”.

Character	Show	“We Must”	“I think”
Chandler	Friends	be careful! I’m not going to get a divorce. be a little bit more relaxed than we’re here. be the one who’s the one who’s the one...	I’ll be able to do this. I’m a good man I’m a big fan of you
Chandler	GoT	be honest with you. be very nervous about the possibility of a bomb attack. be a little nervous about the situation	I’m going to be a little more serious I’m going to be a little bit of a jerk I’m going to have a big secret.
Arya	GoT	be a little more careful. be careful about the dangers of the sea. be wary of the possibility of a coup.	you can’t help me of the people you’re not going to be a hero?
Arya	Friends	be a thief be a hero. be a little girl.	I’m not a bad person I can do it I should have a chance to do something

each backward pass, requiring gradient computation for $2 \times 768 \times 50257$ parameters. If a user is active in multiple contexts, then additional context model-heads must be used, further exacerbating the training cost of the Split-Learning approach. The Split-Learning approach must also leverage these additional context model-heads at test-time, resulting in the slowest forward-passes of any baseline.

In contrast to prior approaches, training for FedPerC only requires updating 2×768 parameters. This reduced computation results in significantly lower training times. When we train an embedding-generator, there is an increase in training times reflecting the added cost of computing gradients for the embedding generator. Additionally, there is a test-time penalty incurred by the added forward-pass parameters. When running inference with any version of FedPerC, preference embeddings are combined and then prepended to the input utterance. This process results in marginally slower test times with FedPerC relative to the Meta-Learning baseline, though the differences are not significant.

Qualitative Results Our qualitative results in Table 4 demonstrate the power of FedPerC, and justify the need for personal *and* context embeddings. Not only is our model able to complete sequences for a character in their “home” context (i.e., the context from which all of their data is drawn), but we are also able to stylize generation for characters, bringing them into *new* contexts. We present generated samples from a “Game of Thrones” (GoT) char-

acter (Arya) with a “Friends” context embedding and a GoT context embedding. We see that Arya’s generated sequences are distinct under the two different contexts. Under the GoT context, Arya’s utterances match the theme of the show, suggesting danger and revolution. Under the “Friends” context, Arya’s utterances change to instead reflect more mundane, modern language while still preserving personal attributes of the character.

Across all of our experiments, particularly the novel experimental evaluation on held-out user-instances, our results provide evidence that embedding-conditioned personalization within federated learning can be effectively applied to real-world use-cases. FedPerC offers a promising avenue of future work towards on-device language models, capable of efficient language generation with respect to compute-power and data.

5 Conclusion

We present FedPerC, a new approach to personalized federated learning, enabling efficient and high-performance personalization to client devices by leveraging individual and shared preference embeddings. Combining shared contexts with individual personal preferences, FedPerC outperforms baselines even when allotted a lower computational budget, and is the first federated language generation approach to build on large language models rather than training sequence generation models from scratch. We also provide a method of generating preference embeddings through inference alone,

providing personalization with no on-device gradient computation, and we show comparable performance to FedPerC using learned embeddings.

We presented experiments on two datasets, TV Show scripts and Reddit user data, presenting empirical evidence of the utility of FedPerC towards personalizing to unseen users in a federated learning setting, i.e. a 50% improvement in terms of runtime *and* perplexity when fine-tuning on with new users. We also demonstrated qualitative results, showing the power of separate personal and context embeddings and enabling stylization of users in new contexts. Our results show that FedPerC offers a promising path forward for personalization within federated learning, achieving superior quantitative results and requiring significantly less training time and data relative to baseline approaches.

Limitations

Firstly, although our embedding-generator offers a promising avenue of personalizing without any on-device gradient computation, our generator is currently unable to improve on its generated embeddings given more examples for a given user. As shown in our results from Sec 4.2, while the model can generate an effective preference embedding for a user with a single sample, it is unable to improve with more data. In future work, we hope to explore approaches to facilitate a generator which can effectively modify embeddings given additional data.

Secondly, our approach caters to confidentiality by ensuring that user-data and embeddings remain on-device, however we have not incorporated differential privacy in our experiments (Li et al., 2020b). Future work may apply differential privacy to guarantee user privacy while personalizing and contributing feature encoder information to a central server. Finally, it is important to note that FedPerC does not solve all problems within the scope of language generation models. As FedPerC offers a path forward to facilitate privacy protection and efficient on-device learning for large language models, future work may extend FedPerC to additional problems (e.g., language summarization or turn-based dialogue generation).

Ethics Statement

Federated learning systems promise the ability to learn useful models without needing access to private, protected data on user’s devices. By contributing improvements to personalization and contextu-

alization within the federated learning paradigm, FedPerC takes a step towards improving fairness of federated learning systems, which otherwise struggle with fitting to data distributions that are not common in training populations. However, it is important to note that FedPerC works to maximize the likelihood of the observed data, which may reinforce existing societal biases and stereotypes—there are no protections or safeguards in place to ensure responsible generation or unbiased preference learning (May et al., 2019; Nadeem et al., 2021; Silva et al., 2021). While this problem is certainly not unique to FedPerC, it is important to consider the safety and fairness implications of improved language generation, and future work must address biases inherent to large language models (Schick et al., 2021; Ravfogel et al., 2020). Another important ethical consideration is the potential misuse of our generative modelling approach for malicious impersonation. In our federated setup, personal embeddings would be kept on-device, meaning that an individual’s style is not accessible to others. However, this does not prevent users from manually impersonating other individuals (e.g., celebrities). Future work must explore additional mechanisms for the prevention of misuse at all stages of the personalization pipeline, including protections against impersonation of other individuals.

A Generation Algorithm

At each time-step during inference, the embeddings are updated by the following equations.

$$\begin{aligned} e_t &= \text{Multi_Head_Attn}(W_{<t}, LN(e_{t-1}), W_{<t}) \\ e_t &= LN(LN(e_t) + LN(e_{t-1})) \\ e_t &= LN(\text{FFN}(e_t) + LN(e_{t-1})) \end{aligned}$$

For the first timestep, e_{t-1} is initialized as ϕ or ψ for personal and context embeddings respectively, and LN represents a layer normalization function. We apply future-masking to prevent any future-information in the sequence from leaking forward into the rest of the model. After processing the entire utterance, the generated embedding is updated to the final value of e_t , which can then be stored on-device for future processing. An updated algorithm which applies the generator to predict preference embeddings can be found in Alg 2.

B Training Details

All models are initialized with the DistilGPT2 pre-trained model from Huggingface (Wolf et al., 2019). All layers of the model are frozen, and FedPC only backpropagates error to personal and context preference embeddings. For our Meta-Learning baseline, the last layer is unfrozen and all users jointly update this final output layer (note: there is no dedicated context head in this approach). Our Split-Learning baseline assigns a unique model head to each user and to each context, and each user only updates their own model head and the contexts that they use.

All models are trained for 55 epochs over their training datasets using the Adam optimizer (Kingma and Ba, 2014) for global updates (learning rate = 1) and local updates (learning rate = 0.001).

Each client (character or Reddit user) makes 10 local updates before passing their pooled gradient information back to the server. During training, each client samples 15 data points per training pass. For local fine-tuning updates at test-time, each user makes 15 updates using a small portion of the test data (the data used for fine-tuning is not used for testing).

All models use a frozen DistilGPT2 model from HuggingFace as their initialization. After empirical experimentation, we opted to freeze the majority of the DistilGPT2 parameters by default. This freezing helped to save on computational and memory costs as well as improving generalization performance across diverse users. As a result of this freezing, shared learning and personalization updates will only affect model heads, shared embeddings, and/or personal embeddings.

FedPC leverages a standard federated averaging training procedure (FedAvg) (McMahan et al., 2017) with the addition of a FedProx penalty term (Li et al., 2020a) to regularize on-device client updates back to the globally-averaged model. Empirically, FedProx improved performance for all methods. We fix the FedProx μ parameter to 1.

Training was carried out on an NVIDIA A40 GPU with 48GB of memory. Due to limitations of the GPU, not all context-heads could be stored in memory at once for our Split Learning baseline when working with the Reddit dataset. The GPU could only accommodate 14 model heads in addition to the DistilGPT2 model, but the dataset featured 57 unique subreddits. To work around this limitation, 13 context heads were active at all times, and the parameters of those heads were saved and overwritten as necessary to ensure that each user had access to their required context heads.

C Dataset Information

The TV Show dataset is constructed by merging scripts from two shows, “Friends” and “Game of Thrones.” We use ConvoKit (Chang et al., 2020) to gather the “Friends” Corpus (Chen and Choi, 2016), and retain the six main characters. We use a set of “Game of Thrones” scripts (Koirala, 2019) to query for the thirteen characters with the highest utterance-count. Our merged dataset has 19 characters, 60650 utterances, and two contexts. The average utterance count for each character is 3370, with “Friends” characters having more utterances than “Game of Thrones” characters.

16:    end for
17:     $\nabla_{\theta_d} \leftarrow \theta - \theta_d$  // compute final client  $\theta$  gradients
18:     $\nabla_{\Gamma_d} \leftarrow \Gamma - \Gamma_d$  // compute final client  $\Gamma$  gradients
19:     $\nabla_{\nu_d} \leftarrow \nu - \nu_d$  // compute final client  $\nu$  gradients
20:    Return  $\nabla_{\theta_d}, \nabla_{\nu_d}$  and  $\nabla_{\Gamma_d}$  to the server
21:  end for
22:   $\nabla_{\theta} \leftarrow \frac{1}{D} \sum_d \nabla_{\theta_d}$  // calculate average  $\theta$  gradients
23:   $\nabla_{\Gamma} \leftarrow \frac{1}{D} \sum_d \nabla_{\Gamma_d}$  // calculate average  $\Gamma$  gradients
24:   $\nabla_{\nu} \leftarrow \frac{1}{D} \sum_d \nabla_{\nu_d}$  // calculate average  $\nu$  gradients
25:   $\theta \leftarrow \theta + \nabla_{\theta}$ 
26:   $\phi \leftarrow \phi + \nabla_{\phi}$ 
27: end for
```

Our Reddit experiments use the “reddit-corpus-small” dataset from ConvoKit (Chang et al., 2020), which includes posts from the top-100 subreddits over a set period of time. We filter the dataset to

only include users with at least 50 utterances and contexts (subreddits) with at least 150 utterances. The resulting dataset has 326 characters, 30260 utterances, and 57 contexts.

A Neural CRF-based Hierarchical Approach for Linear Text Segmentation

Abstract

We consider the problem of segmenting unformatted text and transcripts linearly based on their topical structure. While prior approaches explicitly train to predict segment boundaries, we propose to address this task by inferring the hierarchical segmentation structure associated with the input text. For this purpose, we present a data curation strategy to obtain the hierarchical segmentation structure annotations for over 700K Wikipedia articles. We then propose the first supervised approach to generate hierarchical segmentation structures for given text based on a neural conditional random field (CRF) that explicitly models the statistical dependencies between nodes and their constituent children. We introduce a novel data augmentation scheme as part of our model training, which involves sampling a variety of node aggregations, permutations, and removals, all of which help capture fine-grained and coarse topical shifts in the data and improve model performance. Extensive experiments show that our model outperforms or achieves competitive performance when compared to previous state-of-the-art algorithms in the following settings: rich-resource, cross-domain transferability, few-shot supervision, and segmentation when topic label annotations are provided.

1 Introduction

Text segmentation (Hearst, 1997; Choi, 2000), an important task in information retrieval, is defined as the process of dividing unstructured text into topically coherent segments. Because it recovers topical structure from unformatted text, it can be used as a pre-processing step for several downstream tasks such as text summarization (Mitra et al., 1997), question answering (Oh et al., 2007) and discourse analysis (Van Dijk, 1982).

Most prior works on text segmentation (Hearst, 1997; Choi, 2000; Koshorek et al., 2018) attempted to address this task by explicitly *predicting the segment boundaries*, with the assumption that any

given text can be *decomposed* into contiguous, non-overlapping, indivisible segments, based on topical themes. The discourse segmentation theory (Grosz and Sidner, 1986), however, asserts that the outcome may not always be strictly decompositional, *i.e.*, a segment may have sub-segments within it, and segments may overlap with each other. Following this theory, we hypothesize that explicitly training to infer the hierarchical topic structure of the underlying text leads to better linear segmentation, as it forces the models to examine text at multiple levels to extract coarse-grained to fine-grained topical segments. Further, this allows inference of linear segments of varying granularity that can be used for various downstream applications.

Previous works on hierarchical segmentation are largely unsupervised (Eisenstein, 2009; Simon et al., 2015) due to the unavailability of large labelled datasets with hierarchical structure information. In this paper, we propose to leverage the hierarchical structures in a supervised manner, given the superior performances of supervised models across several language processing tasks (Mikolov et al., 2013; Pennington et al., 2014; Devlin et al., 2019), and propose a data curation strategy to obtain the hierarchical segmentation structures for Wikipedia articles. Specifically, we leverage the available HTML tag annotations¹ and use them to identify section and sub-section information with their hierarchical level, which are then leveraged to obtain the associated ground truth hierarchical structure. Further, because these are extracted from Wikipedia dump, they cover a wide range of topics unlike prior/existing datasets (Eisenstein, 2009).²

Our approach is based on a recent CRF-based constituency chart parsing technique (Zhang et al., 2021), which offers efficient algorithms for super-

¹<https://dumps.wikimedia.org/>

²Note that the dataset proposed by Eisenstein (2009) is a small one consisting of 12 examples for evaluation, and will not suffice for training large models.

vised training and precise inference. This framework explicitly models the relationships between nodes and their offspring in binary trees, and thus can enable hierarchical segmentation inference by utilising the relationships between coarse segments and their fine-grained sub-segments. However, there are three challenges to directly adapt this method to hierarchically segment text: (a) In contrast to the abundant labelled resources available for constituency parsing (Marcus et al., 1993; Xue et al., 2005), there is no large-scale labelled dataset for this task. (b) This method can only infer binarized hierarchical structures; it cannot be extended to infer general hierarchical structures with nodes having any number of children, as training and inference become infeasible. (c) While the existing method processes a sequence of tokens, the input in our case would be a sequence of sentences.

We propose a framework for linear text segmentation using the hierarchical structures of the underlying text. Specifically, our work makes four main contributions: (1) We design an algorithm to obtain the hierarchical structures for Wikipedia articles in HTML format, and curate a large labelled dataset for hierarchical text segmentation.³ (2) We present an algorithm based on the Chomsky Normal Form (CNF) (Chomsky, 1959; Hopcroft et al., 2001; Lange and Leiß, 2009) theory to convert the hierarchical structures to binarized form - which makes the computation of the tree-structure CRF objective tractable. (3) We propose a Transformer-based architecture (Vaswani et al., 2017) to encode the input sequence’s sentences, which uses a lot fewer parameters than previous state-of-the-art BERT-based (Devlin et al., 2019) approaches (Lukasik et al., 2020). (4) We further propose a data augmentation technique involving random node aggregations, removals and permutation, which results in significant performance improvement. Finally, we demonstrate our method’s efficacy by comparing its performance against prior unsupervised and supervised linear text segmentation approaches.

2 Related Works

Prior works for linear text segmentation can be divided into unsupervised and supervised methods, both of which can be further categorized into locally and globally-informed ones. Locally-

³The code to curate dataset is available at https://github.com/inderjeetnair/hierarchical_text_segmentation_data

informed methods find segment boundaries by estimating the extent of topical shift using local cues (Hearst, 1997; Blei and Moreno, 2001; Lafferty et al., 2001). While these methods enjoy quick inference and low memory constraints as they only utilize local features, they can result in erroneous predictions when met with short inconsequential digressions (Kazantseva and Szpakowicz, 2011). Globally-informed methods, on the other hand, utilize the complete context in optimizing an objective to find the locations of topical shift (Choi, 2000; Kazantseva and Szpakowicz, 2011; Malioutov et al., 2007; Fragkou et al., 2004; Glavaš et al., 2016). As they consider the entire global context in inference, these methods have higher memory constraints and time requirements.

More recently, Koshorek et al. (2018) introduced a large-scale dataset for linear text segmentation, which has resulted in the application of supervised neural models to predict the segment boundaries for unstructured text (Koshorek et al., 2018; Badjatiya et al., 2018; Li et al., 2018). These models not only achieve better performance but also are endowed with high inference speed, owing to parallelized computing with modern GPU architectures.

Owing to the success of supervised methods for linear text segmentation, we design a globally-informed supervised neural model for predicting segment boundaries. However, unlike previous works which address segment boundary prediction explicitly, ours first hierarchically segments the text, and then leverages the resulting structures to predict the linear segment boundaries. To enable the supervised training of our proposed approach, we curate a large labelled dataset consisting of Wikipedia articles along with their hierarchical structures automatically. Further, our proposed method requires significantly fewer parameters than prior SoTA globally-informed methods while achieving better performances. To the best of our knowledge, ours is the first work to leverage hierarchical structures to predict segment boundaries, and show that this results in improved performances for the task of linear text segmentation.

3 Problem Formulation

Here, we briefly outline the objectives of linear and hierarchical text segmentation tasks. Given an article \mathbf{S} composed of n sentences, $\mathbf{S} = s_0, s_1, \dots, s_{n-1}$, the goal of linear segmentation is to obtain a contiguous partition $L =$

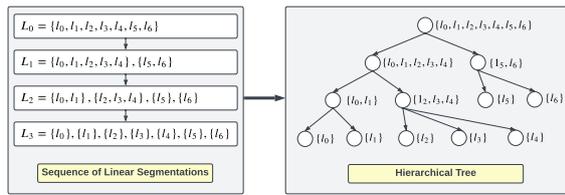

Figure 1: Transformation of a sequence of linear segmentations to a hierarchical tree.

l_0, l_1, \dots, l_{k-1} such that joining the elements of l_i in the same order reconstructs \mathbf{S} and $l_i \cap l_j = \emptyset \forall i \neq j$. Each segment l_i in L is associated with a topical theme which can be used for downstream tasks such as summarization, information retrieval, etc.

Hierarchical segmentation (McFee et al., 2017) aims to infer a sequence of linear segmentations, $\mathbf{L} = L_0, L_1, \dots, L_{m-1}$, where L_i is coarser than L_j for $i < j$. Each element of \mathbf{L} is thus a refinement of all its preceding elements, to satisfy this coarse-to-fine grained constraint. The refinement condition for $i \leq j$ is: $\forall l \in L_j \exists l' \in L_i : l \subseteq l'$. That is, every segment in L_j is a subset of a segment in L_i . In this paper, we represent the information contained in \mathbf{L} using a hierarchical tree (Fig. 1), where each node (other than the leaf nodes) represents a topical theme. The nodes near the root represent general / coarser topics, and those near the leaves indicate specific / fine-grained topics. In our approach, the inferred hierarchical segmentation is in the form of a tree. After converting this tree to a sequence of linear segmentations, we return an appropriate element from the sequence as our inferred linear segmentation.

4 Dataset Curation

To train our proposed method in a supervised manner, we collect hierarchical segmentation structure annotations for the Wikipedia articles in WIKI-727K dataset (Koshorek et al., 2018). As done in (Koshorek et al., 2018), the articles in the HTML form are preprocessed using WikiExtractor⁴ to remove (a) non-text elements such as tables and figures, and (b) very short sections and sub-sections spanning fewer than three sentences. The markup tags (`<h1>`, ..., `<h6>`) associated with different sections define the level of hierarchy for a given text segment. We leverage this markup information to obtain the hierarchical structure among the vari-

⁴<https://github.com/attardi/wikiextractor.git> (Distributed under GNU Affero General Public License v3.0)

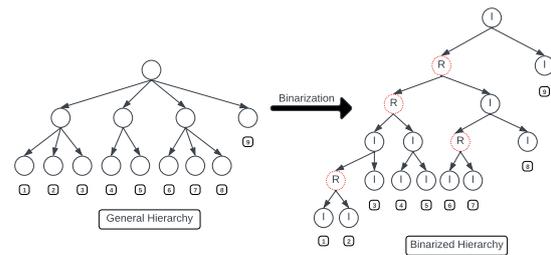

Figure 2: **Binarization:** Transformation of a tree having nodes containing more than 2 children to a binarized form.

ous segments. We thus obtain a sequence of HTML elements for each article. In the next sub-section, we describe our algorithm to obtain the hierarchical structures associated with these sequences. We obtain the hierarchical structure annotations only for the train split articles of the WIKI-727K dataset; our approach can be applied to larger document collections to obtain more datapoints.

4.1 Hierarchical Labelling

Algorithm 1 Algorithm for constructing hierarchical structure from a list of HTML elements

```

Require:  $\mathcal{X} = x_1, x_2, \dots, x_L$  ▷ Ordered list of HTML elements
 $c \leftarrow \text{ROOT}$  ▷ ROOT initialized denoting the root of the tree to be
constructed
 $\mathcal{T} \leftarrow \text{ROOT}$ 
for  $i = 1$  to  $\|\mathcal{L}\|$  do
   $x \leftarrow \mathcal{X}[i]$ 
  while  $\text{PRIORITY}(x.\text{TAG}) \geq \text{PRIORITY}(c.\text{TAG})$  do ▷ Selecting
appropriate element to add  $x$ 
     $c \leftarrow c.\text{PARENT}$  ▷ Updating  $c$  to its parent
  end while
   $c.\text{ADD}(x)$  ▷  $x$  is added as the next child of  $c$ 
   $c \leftarrow x$ 
end for
Return  $\mathcal{T}$ 

```

Let the sequence of HTML elements associated with an article be $\mathcal{X} = x_0, x_1, \dots, x_{L-1}$, where $x_i.\text{TAG}$ denotes the markup type associated with x_i , and $x_i.\text{TEXT}$ denotes its associated text. Here, we outline our algorithm to obtain the hierarchical organization of these elements. Let this hierarchical organization be represented as a tree rooted at \mathcal{T} . The non-leaf nodes represent topics, while the leaf nodes represent sentences from the article.

Our algorithm iterates over the elements in \mathcal{X} and progressively adds them to the tree rooted at \mathcal{T} . It maintains a reference to the node c that is last added to the tree. To add the next element x , the algorithm only considers two possibilities: (a) x is the next child of c , or (b) x is the next child of one of the ancestors of c . This is to ensure that the pre-order traversal of \mathcal{T} recovers \mathcal{X} (which happens when x is added using the above two rules). To find

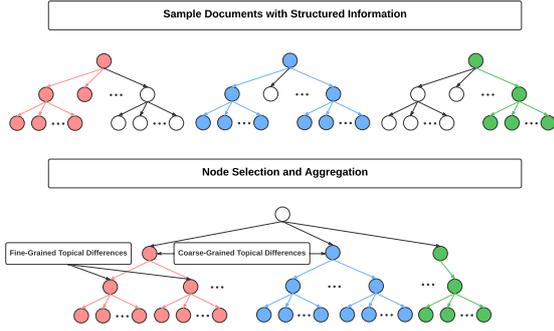

Figure 3: **Data Augmentation:** First, hierarchical structures are randomly sampled from the corpus; then, some nodes are removed from the sampled structures and the outcome is combined

the element to which x must be added, we associate a priority to each markup type in the following decreasing order: h_1, \dots, h_6, p , where h_i indicates for section / sub-section headings and p its associated text. For adding x , c is updated to its parent until the priority of c exceeds that of x . Algorithm 1 presents the pseudo code.

4.2 Binarization

Algorithm 2 Algorithm to be applied to every node having more than 2 children to convert the original structure to the binarized form

Require: x ▷ Node having more than 2 children
 $c \leftarrow \text{NEWNODE}()$
 $c.\text{TYPE} \leftarrow \text{I}$
 $n \leftarrow ||x.\text{CHILDREN}||$
for $i = 1$ to n **do**
 $c' \leftarrow \text{NEWNODE}()$ ▷ New node initialized
 $c'.\text{TYPE} \leftarrow \text{R}$
 $c.\text{CHILDREN} \leftarrow [c', x.\text{CHILDREN}[n - i + 1]]$ ▷ Restricting the number of productions to 2
 $c \leftarrow c'$
end for

The hierarchies thus obtained allows nodes to have more than two children. We convert them to binarized form (from which the original structures can be recovered) to ensure tractable training and inference using our CRF-based segmentation model (§5) (using Algorithm 2).

This algorithm visits each node x in a tree \mathcal{T} that has more than two children, and partitions the children into two sets having $||x.\text{CHILDREN}|| - 1$ children and 1 child respectively. Thereafter, a new node is constructed whose children are assigned to the former set, followed by the updation of $x.\text{CHILDREN}$ to contain the new node and the latter set in the partition. This is repeated until the tree is devoid of nodes with more than 2 children. To ensure recoverability, we define two types of nodes in the binarized trees: **Reducible (R)** and **Irreducible (I)**. The nodes retained from \mathcal{T} are

regarded to as **I**, and those added to convert \mathcal{T} to the binarized form are referred to as **R** (an example of binarization is shown in Fig. 2). These types are assigned to the node’s ‘TYPE’ property (pseudo code in Algorithm 2). To recover the original tree, we visit every **Reducible** node in the binarized tree and connect its children to its parent in the same order. This process is repeated until the structure becomes devoid of any **Reducible** nodes.

4.3 Data Augmentation

An inherent limitation of this dataset stems from the fact that each Wikipedia page is composed of a single global topic, and the direct usage of this data will only train the model in detecting fine-grained topical shifts resulting from sub-sections / sub-headings. However, an article in practice can also contain fragments with stark topical contrast.

To overcome this, we introduce a data augmentation strategy, where a subset of tree root references are sampled at every iteration. Thereafter, some of the children of these nodes are randomly dropped and the ordering of left-out children is randomly permuted. Finally, a new node is created and its children are the sampled tree roots (Figure 3). This new root consists of several coarse topics and the random permutation of the child nodes ensures that the model robustly infers topical segments independent of the order of the child nodes. The augmentation is performed at every epoch ensuring the number of artificially synthesized datapoints is equal to the actual number of documents in the train split.

5 Neural CRF Segmentation Model

5.1 CRF Formulation

We consider an article containing n sentences, $\mathbf{S} = s_0, s_1, \dots, s_{n-1}$ and its corresponding hierarchical segmentation tree structure \mathbf{t} . A node in \mathbf{t} representing a segment spanning s_i, s_{i+1}, \dots, s_j is denoted by (i, j) . Alternatively, \mathbf{t} can be expressed as a set of tuples where each tuple corresponds to a node segment in \mathbf{t} .

Inspired by (Zhang et al., 2021), our model presents a scoring function $s(\cdot, \cdot) \rightarrow \mathbb{R}$ (described later) to assign a score for each node in \mathbf{t} , e.g., $s(i, j)$ represents the score for a node entailing s_i, s_{i+1}, \dots, s_j . We define a function \mathcal{S} to score the tree \mathbf{t} using the sequence \mathbf{S} as:

$$\mathcal{S}(\mathbf{S}, \mathbf{t}) = \sum_{(i,j) \in \mathbf{t}} s(i, j) \quad (1)$$

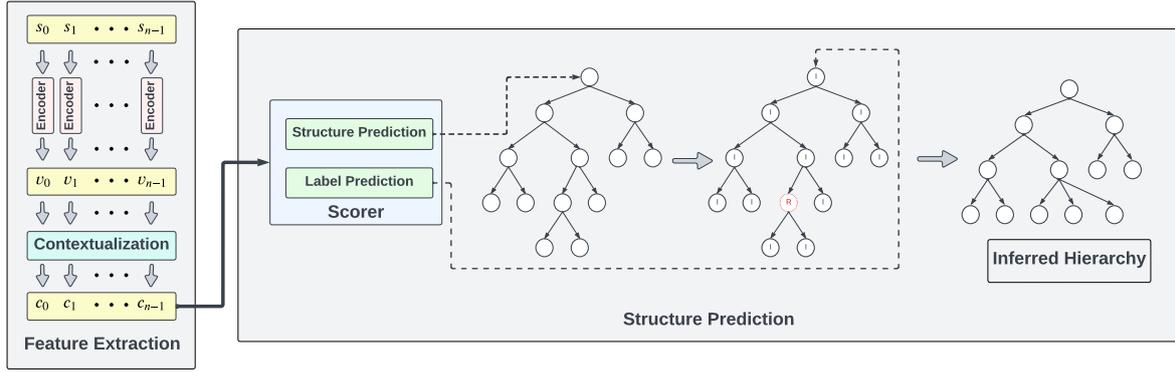

Figure 4: **Pipeline:** Our pipeline is divided into two stages. We extract contextualised embeddings for each sentence during the feature extraction stage. These representations are then fed into the structure prediction module, which first infers the binarized tree and label for each node. This inference is used to construct the actual hierarchy.

Under CRF, we define conditional probability as:

$$\mathbb{P}(\mathbf{t}|\mathbf{S}) = \frac{\mathcal{S}(\mathbf{S}, \mathbf{t})}{Z(\mathbf{S}) := \sum_{\hat{\mathbf{t}}} \mathcal{S}(\mathbf{S}, \hat{\mathbf{t}})} \quad (2)$$

The denominator sums the score of all possible legal hierarchical trees.⁵ Note that, the computation of the partition function $Z(\mathbf{S})$ in the denominator is intractable (exponential time complexity) if we consider all possible hierarchical trees with nodes having arbitrary number of children. However, binarization offers efficient dynamic programming algorithm to compute the partition function with polynomial time complexity. Thus, we binarize \mathbf{t} to obtain $\tilde{\mathbf{t}}$. However, the binarization also associates a type to each node from the set $\{\mathbf{R}, \mathbf{I}\}$. Under this formulation, every node in $\tilde{\mathbf{t}}$ can be represented by a triplet (i, j, l) which indicates that the corresponding node of type $l \in \{\mathbf{R}, \mathbf{I}\}$ spans s_i, s_{i+1}, \dots, s_j . Similar to Zhang et al. (2021)’s two-staged method, we first identify the binarized tree structure that maximises $\mathbb{P}(\tilde{\mathbf{t}}|\mathbf{S})$, whose denominator only adds the scores of the binarized trees, and then determine the type for each of its constituent nodes. To find the optimal structure maximizing $\mathbb{P}(\tilde{\mathbf{t}}|\mathbf{S})$, we leverage Cocke–Younger–Kasami algorithm (CYK) algorithm (Sakai, 1961). For each span (i, j) in the inferred structure, we predict its type l :

$$l = \arg \max_{\hat{l} \in \{\mathbf{R}, \mathbf{I}\}} s(i, j, \hat{l}) \quad (3)$$

Figure 4 shows how our model processes the input sequence to infer the hierarchical segmentation structure. In the next subsection, we specify the architectural details of its components.

⁵Legal hierarchical trees are expected to satisfy two conditions: (1) There should be one-to-one correspondence between the leaf nodes and the constituent sentences. (2) Every node in the tree must span consecutive sequence of sentences.

5.2 Model Architecture

We now describe the implemented architecture, which is adapted from the model proposed by Stern et al. (2017) and Zhang et al. (2021) with two important modifications: (a) utilization of memory-efficient Transformer (Vaswani et al., 2017) model for encoding the sentence in place of word encoder, and (b) better choice of hyper-parameters for hierarchical text segmentation.

Encoder. Each sentence in \mathbf{S} is encoded in a context-independent manner using the Transformer-based model proposed by Wang et al. (2022), which contains 6 layers and 22M parameters. The parameters of this model are fine-tuned using self-attention distillation (Wang et al., 2022) for the compression of large language models like RoBERTa-Large (Liu et al., 2019). This stage transforms s_0, s_1, \dots, s_{n-1} to v_0, v_1, \dots, v_{n-1} with 384 length each.

Contextualization. To contextualize v_0, \dots, v_{n-1} , we implement two BiLSTM layers over it. While the architecture implemented by Zhang et al. (2021) comprises of three BiLSTM layers, we observe that direct usage of the same hyper-parameter settings lead to sub-optimal results on a validation set. The final context-aware representation for a sentence is obtained by concatenating the corresponding forward and backward vectors from the last layer. Let these vectors be represented by c_0, c_1, \dots, c_{n-1} .

Scoring. Having obtained the contextualized representations of the elements in \mathbf{S} , we describe the architecture used to compute $s(i, j)$ and $s(i, j, l)$. For the computation of $s(i, j)$, the contextualized representations are passed to two multi-layer perceptron (MLP) modules to obtain the left and right bound-

ary representation vectors (Zhang et al., 2021):

$$r_i^s; l_i^s = \text{MLP}_r^s(c_i); \text{MLP}_l^s(c_i) \quad (4)$$

Similarly, additional set of boundary vectors are derived to compute $s(i, j, l)$ for label prediction:

$$r_i^l; l_i^l = \text{MLP}_r^l(c_i); \text{MLP}_l^l(c_i) \quad (5)$$

The dimension of the boundary vectors for structure prediction is set to 500 and that for label prediction is set to 800. $s(i, j)$ is computed by introducing a trainable parameter $\mathbf{W} \in \mathbb{R}^{d \times d}$:

$$s(i, j) = l_i^{sT} \mathbf{W} r_j^s \quad (6)$$

Similarly $s(i, j, l)$ is computed by introducing \mathbf{W}_R and \mathbf{W}_I to derive the scores: $s(i, j, \mathbf{R})$ and $s(i, j, \mathbf{I})$ respectively. Note we use r_i^l and l_i^l for the computation of these scores of instead of r_i^s and l_i^s .

5.3 Training

An instance in the labelled dataset can be represented by: $(\mathbf{S}, \tilde{\mathbf{t}}, \mathbf{l})$ where \mathbf{l} is the set of all spans annotated with their corresponding type from $\{\mathbf{R}, \mathbf{I}\}$. The loss function is formed by accumulating two components:

$$\mathcal{L}(\mathbf{S}, \tilde{\mathbf{t}}, \mathbf{l}) = \mathcal{L}_s(\mathbf{S}, \tilde{\mathbf{t}}) + \mathcal{L}_l(\mathbf{S}, \tilde{\mathbf{t}}, \mathbf{l}) \quad (7)$$

The first term tries to maximize $\log(\mathbb{P}(\tilde{\mathbf{t}}|\mathbf{S}))$ by refining the scoring function $s(i, j)$. The second term establishes cross-entropy loss for the type prediction of the constituent spans. While the time complexity of the partition function computation $Z(\mathbf{S})$ for $\log(\mathbb{P}(\tilde{\mathbf{t}}|\mathbf{S}))$ is $\mathcal{O}(n^3)$ using inside algorithm (Lari and Young, 1990), we implement the batchified version of this algorithm proposed by Zhang et al. (2021) that provides much better time complexity ($\mathcal{O}(n)$ for a batch).

We train our models over the curated dataset for 4 epochs using Adam optimizer (Kingma and Ba, 2015) with batch size of 100 and learning rate initialized to 2×10^{-4} . The learning rate is exponentially decayed to 0.75 times its initial value after 50K optimizer steps. The training is restricted to datapoints having less than 200 sentences due to GPU memory constraints.

6 Experiments and Results

We assess our method’s performance in various settings when compared to SoTA linear segmentation techniques. The tree inference from the model is converted to a sequence of linear segmentations

Method	Precision	Recall	F1 Score
BI-LSTM	69.3	49.5	57.7
CROSS SEGMENT BERT	69.1	63.2	66.0
BERT+BI-LSTM	67.3	53.9	59.9
HIERARCHICAL BERT	69.8	63.5	66.5
HIERCRF	80.6	59.4	68.4
HIERCRF-AUG	82.5	60.3	69.7
HIERCRF-BERT	79.0	63.3	70.2
HIERCRF-AUG-BERT	80.4	64.6	71.6

Table 1: Comparison with supervised baselines when abundant labelled data is available. Only the hierarchical structures of the articles in the train split of WIKI-727K are used in our method for consistency.

(Fig. 1). As the position of an element in this sequence indicates the extent of segmentation, we select an appropriate position (constant for a dataset, obtained through validation for supervised methods, and second position for unsupervised methods due to how coarsely grained the topical shifts are in them) and return the corresponding segmentation. We call our method variants **HIERCRF** and **HIERCRF-AUG**, where the former and latter are trained without and with data augmentation.

We compare our models to supervised methods trained on WIKI-727K augmented with our hierarchical structure annotations (§6.1). Unsupervised methods (Kazantseva and Szpakowicz, 2011; Du et al., 2013) require a significant amount of time for inference as they are computationally intensive and do not take advantage of GPU parallelization for efficiency. Hence, we do not compare their performance for WIKI-727K, which contains a large number of datapoints in the test split. In §6.2, we look at how our model transfers knowledge from one domain to another and investigate efficacy in a low-resource setting. Here, we compare our method to unsupervised as well as some supervised methods. Finally, we evaluate how our model utilises topic label information for segmentation using WikiSection (Arnold et al., 2019).

6.1 Rich Resource Setting

Here, we consider models that perform well in linear text segmentation when large labelled datasets are available for training. The large-scaled dataset (WIKI-727K) curated by Koshorek et al. (2018) for linear segmentation has been instrumental in the formulation of several deep learning methods (Koshorek et al., 2018; Lukasik et al., 2020). We use the following as baselines: **BI-LSTM** (Koshorek et al., 2018), **CROSS SEGMENT BERT** (Lukasik et al., 2020), **BERT+BI-LSTM** (Lukasik et al., 2020) and **HIERARCHI-**

Property	Clinical	Fiction	Wiki
# Documents	227	85	300
# Sentences	31,868	27551	58,071
Segment Length	Mean	35.72	24.15
	Std Dev	29.37	18.24

Table 2: Datasets used for comparing our method against statistical methods for linear text segmentation.

CAL BERT (Lukasik et al., 2020). Most of them use BERT as their encoder ($> 109M$ parameters). To show the increased effectiveness of our model when its complexity is increased, we also present the performance with BERT as its encoder. We use the test split in WIKI-727K (73, 233 instances) and F1 score for evaluating the segment boundary prediction performance. Further, the first and the last sentences are not annotated in the ground truth set of boundaries, as any segmentation algorithm can easily predict them as segmentation boundaries, thus inflating performance.

We note, from Table 1, that our linguistically motivated approach for inferring linear segmentation from hierarchical segmentation gives better performance despite having significantly fewer parameters ($\approx 23M$ as opposed to strongest baseline’s $\approx 109M$). As expected, increasing model complexity improves performance, resulting in a new SoTA for WIKI-727K (71.6 F1). We also observe our precision is comparatively higher and the recall is lower. We attribute this to node misclassification in the inferred hierarchy. By construction, **R** nodes are removed to get the final inference indicating the corresponding segments would be absent in the inferred hierarchy. Thus, even if the inferred binarized structure is accurate, a misclassification of **I** nodes as **R** will result in lower recall.

6.2 Cross Domain and Low Resource Setting

We categorize the methods in following groups.

A: Unsupervised: This group comprises of the following unsupervised techniques: **U&I** (Utiyama and Isahara, 2001), **MINCUT** (Malioutov and Barzilay, 2006), **BAYESSEG** (Eisenstein and Barzilay, 2008), **APS** (Kazantseva and Szpakowicz, 2011), **PLDA** (Purver et al., 2006) and **TSM** (Du et al., 2013). These methods use the **number of gold standard segments and test data corpus for tuning the hyperparameters.**

B: Cross-Domain Transferability: Here, we pre-train supervised models using WIKI-727K’s train split and evaluate on other datasets completely unsupervised, without knowing the number of gold-standard segments. We consider top baselines

Method	Clinical		Fiction		Wiki	
	WD	P_k	WD	P_k	WD	P_k

HIERCRF	26.7	25.5	33.3	29.9	28.6	26.3
HIERCRF-AUG	25.2	24.4	32.6	28.4	27.9	25.7

Table 3: **Performance of our model against unsupervised approaches.** All results are averaged for 5 random splits. TSM and PLDA implementations are unavailable to report their performance on Wiki. PT: Pre-training.

from §6.1 (CROSS SEGMENT BERT and HIERARCHICAL BERT) and our variants (HIERCRF and HIERCRF-AUG). We re-implement the supervised baselines as original code is unavailable.

C: Low Resource Setting: Here, we expose the models to 20% of the dataset for supervised learning and evaluate it on the rest of the dataset (results averaged for 5 random seeds). For fine-tuning, our model parameters are optimized to predict the flat-hierarchy associated with the datapoints in the training split. We also report the performance of the model (appended with NO-PRETRAINING) which is not pretrained over WIKI-727K.

We use the following three datasets to compare our method against the statistical unsupervised approaches (Table 2):

Clinical (Eisenstein and Barzilay, 2008). Every document is a chapter from a medical textbook where labeled boundaries represent section breaks.

Fiction (Kazantseva and Szpakowicz, 2011). Each document is a fiction from Project Gutenberg where boundary annotations denote chapter breaks.

Wiki (Badjatiya et al., 2018). 300 articles are randomly sampled from the wikipedia dump where section tag labels are used to annotate boundaries.

We assess the performance of these methods using P_k (Beeferman et al., 1999) and WinDiff (WD) (Pevzner and Hearst, 2002) error metrics. P_k computes the probability that two segments sampled from a document are incorrectly identified as

Method	$P_k(\text{City})$	$P_k(\text{Disease})$
SECTOR	14.4	26.3
S-LSTM	9.1	20.0
TRANSFORMER ²	8.2	18.8
HIERARCHICAL BERT	8.6	22.4
CROSS SEGMENT BERT	10.1	21.8
HIERCRF*	8.8	20.4
HIERCRF-AUG*	8.5	21.2
HIERCRF	8.1	20.3
HIERCRF-AUG	8.0	20.0

Table 4: Comparison with various approaches in leveraging segment labels. * indicates those methods do not use segment labels. For our AUG-appended methods, we augment the flat hierarchies associated with the training datapoints.

belonging to the same segment. WD moves a sliding window across the document and counts the number of instances where the hypothesized and reference segment boundaries are different.

The results shown in Table 3 demonstrate the competitive performance exhibited by our model without any additional fine-tuning (**B**). As our models in **B** are not subjected to separate hyperparameter tuning for different datasets, our proposed models can be applied to other domains with minimal changes (only the position from the sequence of segmentations inferred from the model needs to be specified). The performance of HIERCRF-AUG in **B** is better than all the methods in **A** (despite not knowing the number of gold-standard segments and tuning hyperparameters over the testing corpus) for Wiki and Clinical dataset which demonstrates the effectiveness of our approach in transferring the knowledge from one domain to another. Fine-tuning our models with small number of datapoints (**C**) provides competitive results for most of the datasets. As expected, the performance in few-shot supervision setting is boosted if the model is pre-trained over WIKI-727K for the supervised approaches. Because the datapoints in the Fiction dataset are longer than in the other datasets, our model performs poorly (§8).

6.3 Results using Segment Labels

We compare our model’s segmentation performance to baselines when segment-wise topic labels are given. We use WikiSection’s split (Arnold et al., 2019) that comprises of English documents from two domains: diseases (3.6K documents) and cities (19.5K documents). We use 70/20/10 splits for train/dev/test. We assess how well our model uses the segment labels compared to earlier methods. We consider the following approaches: SECTOR (Arnold et al., 2019), S-LSTM (Barrow et al., 2020) TRANSFORMER² (Lo et al., 2021),

HIERARCHICAL BERT and CROSS SEGMENT BERT. For fair comparison, no model is pretrained on WIKI-727K.

To incorporate the topic label information in training, we use the boundary vectors for label prediction and a scoring mechanism similar to Eqn 6. Specifically, the likelihood that span (i, j) corresponds to topic label **T** is proportional to $s(i, j) = l_i^T \mathbf{W}_T r_j^l$. The parameters \mathbf{W}_T for each topic label **T** are trained using cross-entropy loss similar to Eqn 7.

Table 4 shows that after incorporating topic label information, our model provides SoTA performance for the City Domain and competitive performance for the Disease Domain. This suggests that providing auxiliary information, such as topic label information, improves the performance of our model. We believe that using a medical domain specific encoder (Gu et al., 2021) would improve our model’s performance in the Disease domain.

6.4 Ablation: Training Size and Performance

Here, we investigate the effect of training our models on data splits comprising of articles with varying sizes (number of sentences). Our objective is to demonstrate that the performance of the model can be improved by including datapoints with larger size. However, the limitations in the GPU hardware, has restricted the maximum datapoint size in the training split to 200. We consider three variants of our curated dataset for training: (a) datapoint sizes ≤ 50 , (b) datapoint sizes ≤ 100 , and (c) datapoint sizes ≤ 200 . We report the performances of models trained over these variants on splits containing datapoints with size in the following ranges: $[1, 50]$, $(50, 100]$, $(100, 150]$, $(150, 200]$, $(200, \infty)$, and $[1, \infty)$ from the WIKI-727K test data.

Table 5 shows the F1 scores. We note three main trends: (1) The model performance decreases as the size of the datapoint increases. This can be attributed to the following two reasons. Firstly, majority of the datapoints in our curated dataset have size in the range $[1, 50]$, and the number of datapoints decreases as the range varies from $(50, 100]$ to $(200, \infty)$. Secondly, the ability of the model to produce discriminative contextualized sentence features is dependant on the size of the input datapoint. As the contextualization is brought about by Bi-LSTM module, very long sequences result in vanishing gradient problem, and this results in less effective modeling for longer sequences. (2)

Method	Training Dataset Size Upper-bound	Testing Dataset Size Range					
		[1, 50]	(50, 100]	(100, 150]	(150, 200]	(200, ∞)	[1, ∞]
HIERCRF	50	70.4	57.5	46.6	39.5	30.7	64.2
	100	72.5	62.2	52.3	47.0	39.4	67.4
	200	72.9	64.2	54.8	50.1	41.8	68.4
HIERCRF-AUG	50	71.8	61.3	51.2	45.4	37.2	66.5
	100	73.9	64.1	54.9	50.3	42.5	69.0
	200	74.2	64.2	55.2	50.3	42.9	69.7

Table 5: **Effect of including datapoints with larger size in the training set:** A model’s performance in terms of F_1 -Score decreases as the size of the datapoint increases. Increasing the upper bound of the datapoint size in the training dataset improves the performance uniformly for all the dataset size ranges.

Including datapoints with larger size uniformly improves the performance of the model across all the ranges. Thus, one line of future work could be to procure more labels for articles with more number of sentences. However, it is to be noted that training the model over larger sequences imposes heavy requirements on GPU memory. (3) The effectiveness of our data augmentation can be seen here as well in producing uniformly better results than the model not trained over augmented corpus.

7 Conclusion

We curated a dataset with hierarchical structures and introduced an approach for linear segmentation by inferring the hierarchies. We illustrated the effectiveness of our approach against prior supervised and unsupervised methods for several datasets. Our method, when exposed to a small fraction of the data for fine-tuning, achieves superior performance when evaluated on other datasets for this task. Unlike prior unsupervised methods, ours without any hyperparameter tuning achieved competitive results. While we focussed on predicting segment boundaries, our method could also be applied to yield hierarchical segmentation. However, the challenges specific to dataset size and memory persist. We will study these aspects in our future work.

8 Limitations

The ablation studies conducted in this paper highlight some of the limitations of our model. The model predictions are erroneous when the length of the input text is very large. Even if we are able to curate sufficient number of very long text with ground truth hierarchical structure, training the model parameters imposes heavy requirements for GPU memory. This demands for the requirement of a better architecture that not only handles long range sequence dependencies but also is GPU memory-efficient while training.

Abstract

Financial information is generated and distributed across the world, resulting in a vast amount of domain-specific multilingual data. Multilingual models adapted to the financial domain would ease deployment when an organization needs to work with multiple languages on a regular basis. For the development and evaluation of such models, there is a need for multilingual financial language processing datasets. We describe MULTIFIN— a publicly available financial dataset consisting of real-world article headlines covering 15 languages across different writing systems and language families. The dataset consists of hierarchical label structure providing two classification tasks: multi-label and multi-class. We develop our annotation schema based on a real-world application and annotate our dataset using both ‘label by native-speaker’ and ‘translate-then-label’ approaches. The evaluation of several popular multilingual models, e.g., mBERT, XLM-R, and mT5, show that although decent accuracy can be achieved in high-resource languages, there is substantial room for improvement in low-resource languages.

1 Introduction

Natural language processing technology has substantially improved in recent years due to the general-purpose Transformer model (Vaswani et al., 2017), large-scale self-supervised training from unlabelled corpora (Devlin et al., 2019), and the scaling of both of these to increasingly large datasets and models (Raffel et al., 2020). Nevertheless, there are still benefits to having domain-specific models (Gururangan et al., 2020), especially when working with clinical (Dai et al., 2022) or financial text (Araci, 2019).

The domain of financial text is particularly interesting for multilingual NLP, given that it is produced across the world (Lewis et al., 2004; Kær Jørgensen et al., 2021). The text often includes invoices, transactions, accounting data, tax policies, and stock market information, *inter-alia*, and there is an emerging

effort to create monolingual financial BERTs (FinBERTs) to process financial text (Araci, 2019; DeSola et al., 2019; Yang et al., 2020b; Liu et al., 2021). However, the handling of financial text by multinational companies is inherently multilingual, therefore, there is a need for datasets to evaluate how well models can process multilingual financial text.

To this end, we introduce the MULTIFIN dataset, a publicly available financial dataset consisting of real-world financial article headlines in 15 languages (see examples in Table 1). MULTIFIN is annotated with HIGH-LEVEL and LOW-LEVEL topics for multi-class and multi-label classification, respectively. The dataset is intended as a resource for developing multilingual financial language models. It is the first benchmark for evaluating cross-lingual and multilingual performance of financial models across multiple languages, writing systems and language families that reflects the real-world multilingual situation in the financial domain.

We benchmark four large-scale pretrained language models (SentenceBERT, mBERT, XLM-R, and MT5) and find that the benefits of large-scale pretraining also apply to financial text. XLM-R is clearly the best performing model in all of our experiments, however, there is a substantial gap in performance between high- and low-resource languages in MULTIFIN. Moreover, a simple LSTM initialized with FastText word embeddings gives surprisingly competitive performance in several experiments. Overall, we find the financial domain can benefit from multilingual NLP, and future work should focus on domain adaptive efforts and improving models’ capacity to generalize to low-resource languages.

Contributions Our contributions are as follows: (a) We present a multilingual financial dataset based on article titles in multiple languages and annotated with two levels of topics. The dataset is made publicly available at <https://github.com/RasmusKaer/MultiFin>. (b) We evaluate dif-

ferent multilingual models under different setups in conjunction with analysis on the multilingual MULTIFIN to establish baselines for the benchmark. (c) Our analysis identifies a need for further research in minimizing the performance gap between high and low-resource languages, and domain adaptive efforts maybe be a promising direction for narrowing this gap.

2 Existing Datasets for Financial NLP

Financial NLP is an emerging area of NLP. Researchers and practitioners have a keen interest in processing natural language for different downstream tasks in the financial domain, such as text mining in accounting (Loughran and McDonald, 2016), financial transactions (Jørgensen and Igel, 2021), sentiment analysis (Malo et al., 2014), and text classification (Arslan et al., 2021). Also, financial economics research shows that news articles and media can be used to forecast firm performance (Tetlock et al., 2008), predict stock market volatility (Glasserman and Mamaysky, 2019) and predict market return (Tetlock, 2007). Moreover, Qin and Yang (2019) show that textual transcripts in combination with audio recordings of company earnings conference calls can be used to predict stock price volatility.

There is a large variety of downstream NLP tasks in the financial domain. However, most work within the community is carried out in a monolingual English setting, where the focus is on adapting successful generic monolingual models to the financial domain (Araci, 2019; DeSola et al., 2019; Yang et al., 2020b; Liu et al., 2021). Only a little work on multilingual domain-adapted models has been investigated (Kær Jørgensen et al., 2021). Since the finan-

cial environment is indeed multilingual, further progression is conditioned on the availability of multilingual resources to develop new methods for multilingual NLP in the financial domain.

Datasets in the financial domain An extensive literature review identifies the datasets used for financial NLP. We define three criteria for being assigned to the list: (1) the dataset needs to be publicly available and accessible, (2) it needs a clear definition of the task with accompanying annotations (i.e., labels, tags, etc.), and (3) it needs to be peer-reviewed and documented. These criteria are set to ensure the quality of the data resource and proper availability and accessibility. Table 2 presents our findings.

An investigation of the datasets shows that most resources are in English. Table 2 (A) presents an overview of the English evaluation datasets. ANALYSTTONE DATASET (Huang et al., 2014), FINTEXTSEN (Cortis et al., 2017) and FINANCIAL PHRASE BANK (Malo et al., 2014) are among the most popular datasets. Sentiment analysis is the most frequent task for the datasets, followed by classification. Only few non-English and multilingual datasets exist. Table 2 (B) and (C) shows available datasets in other languages than English. There are five multilingual datasets which contain English plus three additional non-English languages. The dataset containing most languages is the trilingual (El-Haj et al., 2022) and (Gaillat et al., 2018). In addition, we found three low-resource monolingual sentiment datasets: Arabic BORSAH (Alshahrani et al., 2018), Greek FNS-2022 SHARED TASK (El-Haj et al., 2022) and the Danish DANFINNEWS (Kær Jørgensen et al., 2021) which is the Danish equivalent to the Financial PhraseBank.

The need for a multilingual financial resource has

been highlighted in several studies (Gaillat et al., 2018; Kær Jørgensen et al., 2021; Jabbari et al., 2020) and its lack of multilingual resources is a limitation for further progression. There is also a need for including different language families and low-resources languages into the research landscape to ensure that not only the high-resources languages lay the foundation of research (Alshahrani et al., 2018). This suggests a gap in resources necessary to advance the financial NLP towards a more multilingual scenario that simulates the financial domain’s multilingual environment. Our work, see Table 2 (D), is motivated by creating a gold standard for benchmarking financial models to facilitate work on adapting to multiple languages within a specific domain.

3 The MULTIFIN dataset

The MULTIFIN dataset is a multilingual corpus, consisting of real-world article headlines covering 15 languages. We annotate the corpus using hierarchical label structure, providing two classification tasks: multi-class and multi-label classification.

Data collection The dataset builds on a collection of public articles published on a large accounting firm’s websites. A subset of the archive was made available for this study. The data collection is based on a real-world application deployed in a large accounting firm. The language selection is determined by the company branches that made their data available to us. We build a multilingual dataset from the headlines of the entire subset that the firm made available. The subset of the archive covers published material in 15 languages and comprises around 10K headlines. The distribution of headlines over lan-

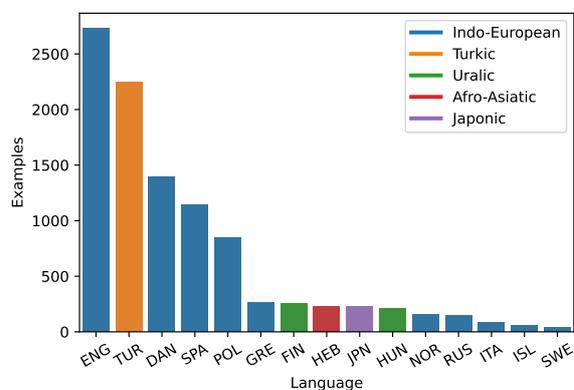

Figure 1: Number of examples per language in MULTIFIN. Bars in the same color indicate these languages belong to the same language family. In this paper, we define languages with more than 500 examples—ENG, TUR, DAN, SPA, POL—high resource languages and the remaining low resource languages.

guages is shown in Figure 1. The publication date is mainly from the period of 2015 to 2021 with some titles having missing dates. The proposed benchmark contains all the languages we were permitted to use, reviewed by experts, which ensures the reliability and quality of both language and content. While the selection of the 15 languages might not be ideal (e.g., African and Indic languages as well as Arabic and Modern Standard Mandarin are missing), we provide the first massively multilingual dataset for financial NLP, see Table 2 for an overview over currently available datasets. It is also worthy noting that headlines, due to their limited context, poses a great challenge for text classification models deployed in the wild (Chen et al., 2019b). See Figure 6 for the text length distribution across different languages.

Annotation Scheme The articles were already tagged with internally pre-defined topics from a company-internal system. Based on these topics, we derive a new, more general label set, referred to **LOW-LEVEL**. Through our label scheme we seek to have different levels of granularity since it gives us the opportunity to go deeper into evaluating the ability of identifying the more refined topics that are presented in titles. Therefore, we first assign fine-grained tags to the topics contain in an headline. For this we use the **LOW-LEVEL** topics. Secondly, we also assign the headline to a single more coarse-grained category, referred to **HIGH-LEVEL**. We defined the **HIGH-LEVEL** topics on the basis of universal categories typically found in news media and more common content categorization. Our fine-grained annotation process results in a dataset with multiple labels per headline. We derive **HIGH-LEVEL** single labels from these multi-label annotations based on either a majority-vote, using the first tag in case of ties. The overview of **LOW-LEVEL** and **HIGH-LEVEL** topics is presented in 3.

HIGH-LEVEL	LOW-LEVEL
Technology	Technology
	IT Security
Industry	Power, Energy & Renewables
	Supply Chain & Transport
	Healthcare & Pharmaceuticals
	Retail & Consumers
	Real Estate & Construction
Tax & Accounting	Media & Entertainment
	VAT & Customs
	Tax
Finance	Accounting & Assurance
	M&A & Valuations
	Asset & Wealth Management
	Actuary, Pension & Insurance
Government & Controls	Banking & Financial Markets
	Government & Policy
	Financial Crime
Business & Management	Governance, Controls & Compliance
	Board, Strategy & Management
	Start-Up, Innovation & Entrepreneurship
	Corporate Responsibility
	SME & Family Business
	Human Resources

Table 3: Overview of **HIGH-LEVEL** and **LOW-LEVEL** topics. The coarse-grained single labels are derived from the fine-grained multi-label annotations based on either a majority-vote, using the first tag in case of ties.

Annotation Process We ask native-level speakers of English and Danish to annotate the dataset using the **LOW-LEVEL** tags. The annotators have domain

expertise and participated on a voluntary basis. Detailed annotation guidelines were presented to the annotators before they started. The description contains definitions of topics including some exemplifications of themes and concepts that may occurs for the topics. As for the annotation of multiple labels, the annotators were asked to label up to three topics per example. The annotated labels needed to be ordered by topic weight, i.e., the first annotated topic is the most dominating topic in the sentence, then the second and third most. The overview and statistics of the label distributions can be found in appendix B.

Translate-then-label evaluation We translated the headlines into English for topic annotation using a translation service¹. We carefully assessed the translation quality to ensure that the translation process does not introduce noise into our dataset. We want to check whether the content of the original sentence is contained in the translation to English. That is, the topics or matters treated in an article stay the same for the translation. For the evaluation, we randomly sample 50 examples from DAN, NOR, ITA, SPA, POL and the entire SWE. We asked evaluators with language proficiency to assess the samples. We presented them with the original sentence, its English translation, and the annotated topics, and ask to answer a true/false question of 1) is the content of the original sentence contained in the English translation, 2) is the property that makes the English sentence fall into this category present in the original sentence as well? The evaluation shows that for DAN, NOR, ITA, SPA, POL and SWE all preserved the properties that make the article fall into a specific category. There was not reported any errors by the evaluators. Thus, we consider translation quality to be high enough to not introduce noise in the process.

Annotator agreement Inter-annotator agreement is measured as multi-label Cohen’s κ (Cohen, 1960). The sample selected for evaluation by both annotators is 1200 examples, randomly sampled across languages and topics. The combined κ of 0.94 suggests a near-perfect agreement. Table 5 depicts the topic-level κ .

Description of dataset The dataset consists of 10,048 headlines in 15 languages annotated with 23 topic labels for **LOW-LEVEL** and 6 **HIGH-LEVEL** topics for multi-class. See Appendix B for details on the distribution of the **LOW-LEVEL** topics and **HIGH-LEVEL**

¹Google Translate, version as of Autumn 2021

topics and Appendix E for an overview of the sentence length distribution across different languages. For multi-class, multi-label classification, we have a total of 14,230 tags across 10,048 headlines (80,678 tokens) using 23 fine-grained topics. For multi-class, single label, we have a coarse-grained topic tag for each headline.

4 Experiments and Results

We employ popular pre-trained multilingual models² and test their effectiveness under different experimental setups. For experimentation, we will only focus on the LOW-LEVEL multi-label task, and HIGH-LEVEL results are reported in the appendix, Table 9.

4.1 Models

mBERT (Devlin et al., 2019) has been pre-trained on Wikipedia articles of 104 languages. Similarly, **XLM-R** (Conneau et al., 2019) was pre-trained on web crawl data, whose size is much larger than Wikipedia data. For both mBERT and XLM-R, we built a classification layer on top of sentence embedding (i.e., the hidden states corresponding to the first [CLS] token). The classification layer consists of a dense layer and tanh activation function, followed by another dense layer, where the output dimension is the total number of possible topics.

SBERT We use multilingual sentence BERT (Reimers and Gurevych, 2020) to map an input sentence to a 768 dimensional dense vector space and then build a classification layer on top of it. Note that we follow Reimers and Gurevych (2019) to keep the weights of SBERT fixed and use SBERT as a feature extractor. We also investigate the variant of fine-tuning SBERT together with the classification layer. The results of fine-tuning approach are very close to feature extraction approach, although the latter involves much smaller number of trainable parameters (110M vs 600K).

mT5 (Xue et al., 2021) was pre-trained on web crawl data covering 101 languages using a ‘text-to-text’ format. That is, consecutive spans of input tokens are replaced with a mask token, and then an encoder-decoder transformer is trained to reconstruct the masked-out tokens. When mT5 is used for downstream classification task, the model outputs the literal text of the label instead of a class index.

²The number of trainable parameters for each model is listed in Table 8 in the Appendix.

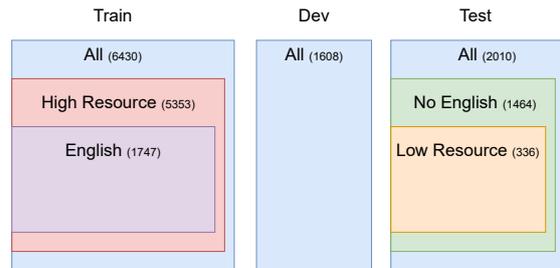

Figure 2: We train models on the complete training set as well as two subsets, to evaluate the multilingual learning and cross-lingual transfer capacities respectively. We use a joint development set of all the languages to select the trained checkpoint. The final model is evaluated on the test and metrics evaluated on the complete test as well as two subsets are reported. Numbers in brackets are the examples belonging to the corresponding (sub)set.

In addition to these transformer-based models, we also experiment with models using pre-trained type-based embeddings described below.

Aligned fasttext embeddings As a baseline, we experiment with models using pre-trained type-based embeddings³, in particular the 300-dimensional fasttext embeddings (Bojanowski et al., 2017) trained on Commoncrawl and Wikipedia data (Grave et al., 2018). In order to enable cross-lingual transfer, we map language-specific fasttext embeddings for all languages covered in our dataset into a common space⁴, using RCSLS (Joulin et al., 2018) as a supervised mapping method. Details about embedding alignment can be found in Appendix C. The mapped embeddings are used as inputs for two baseline models: an LSTM classifier ($\text{FASTTEXT}_{\text{LSTM}}$) and a bag-of-embeddings ($\text{FASTTEXT}_{\text{BAG}}$) classifier. The LSTM classifier consists of one bidirectional LSTM layers with a classification layer on top, which receives as input a concatenation of the final hidden states of the top-most layer of forward and backward LSTM. The BoE classifier uses the average over all word embeddings in the input sequence as input to the classification layer. For both models, we use the same classification layer as for the mBERT and XLM-R models.

4.2 Experimental setup

To evaluate multilingual learning, we train the model on the complete training set that contains all 15 languages (referred to as ALL). To evaluate cross-lingual

³Fasttext models enable the computation of embeddings for out-of-vocabulary words based on sub-tokens.

⁴We compute pairwise mappings between non-English source embeddings and English target embeddings, and map all non-English embeddings into the space of English embeddings.

Model	Training	Test		
		ALL	NO ENGLISH	LOW RESOURCE
FASTTEXT _{BAG}	ALL	74.2 ± 0.2	71.7 ± 0.2	60.9 ± 0.8
	ENGLISH	41.8 ± 1.5	24.5 ± 1.6	27.9 ± 3.2
	HIGH RESOURCE	70.3 ± 1.1	66.8 ± 1.1	38.2 ± 1.2
FASTTEXT _{LSTM}	ALL	85.4 ± 0.4	83.6 ± 0.4	74.4 ± 0.9

	HIGH RESOURCE	82.4 ± 0.6	80.0 ± 0.6	59.5 ± 1.5
sBERT	ALL	73.5 ± 0.2	67.9 ± 0.2	52.0 ± 0.2
	ENGLISH	50.8 ± 0.5	32.7 ± 0.4	27.5 ± 0.6
	HIGH RESOURCE	69.9 ± 0.3	62.8 ± 0.5	27.4 ± 0.2
mBERT	ALL	88.6 ± 0.3	86.5 ± 0.3	77.9 ± 0.5
	ENGLISH	58.3 ± 0.7	43.5 ± 1.0	39.4 ± 2.3
	HIGH RESOURCE	84.1 ± 0.4	80.6 ± 0.4	47.7 ± 0.7
XLM-R	ALL	90.8 ± 0.4	89.4 ± 0.4	83.9 ± 0.6
	ENGLISH	68.0 ± 1.3	59.2 ± 1.6	59.8 ± 1.9
	HIGH RESOURCE	88.6 ± 0.4	86.4 ± 0.5	71.0 ± 1.9
MT5	ALL	81.3 ± 0.1	76.6 ± 0.2	51.0 ± 1.5
	ENGLISH	50.7 ± 1.0	34.3 ± 1.1	25.5 ± 1.9
	HIGH RESOURCE	78.5 ± 0.3	72.9 ± 0.5	33.7 ± 0.2

Table 4: Evaluation results on fine-grained topics (LOW-LEVEL). This is a multi-label classification task with 23 labels, and each example may be assigned up to three topics. All experiments are repeated five times using different random seeds. Averaged Micro F_1 scores and the standard deviations are reported. Best results per column are marked in bold.

transfer, we train the model on (i) a subset that contains only English training data (ENGLISH); and, (ii) a subset that contains 5 high-resource languages (i.e., English, Turkish, Danish, Spanish, Poland) (HIGH RESOURCE).

Model selection In the context of zero-shot cross-lingual transfer, it was shown that performance on a source language (e.g., English) development set does not correlate well with performance in the target language (Keung et al., 2020; Chen and Ritter, 2021). We follow Conneau et al. (2018) and use a joint development set of all the languages. Figure 2 is a high-level illustration of our experimental setup. The trained model which achieves the highest Micro F_1 score on the development set is finally evaluated on the test set. We repeat all experiments five times using different random seeds and mean values and standard deviations are reported.

4.3 Results

Table 4 shows that models trained on the training set consisting of all languages (ALL) achieve slightly better results (2.0-4.5 absolute F_1) than the ones trained on high-resource languages (HIGH RESOURCE) when the trained models are evaluated on the complete test

set. However, this performance gap becomes much larger (11.4-30.2 absolute F_1) when models are evaluated on the subset containing only low-resource languages, which is expected, as the latter setting requires zero-shot transfer when training on HIGH RESOURCE and evaluating on LOW RESOURCE. In the per language analysis (detailed in the following section), we also observe that once the training set contains abundant examples (500+) for these languages, models achieve nearly the same results when evaluated on high-resource languages (Figure 3). Therefore, we focus our discussion on the evaluation results on low-resource languages. The first observation is that different pre-trained multilingual models differ in multilingual learning abilities on our dataset. That is, when they are fine-tuned on ALL, model effectiveness on low-resource languages ranges from 51.0 to 83.9 (A detailed analysis can be found in the following section). The ability of zero-shot cross-lingual transfer is another interesting property of multilingual models. Previous studies show that models trained on English only can achieve impressive results on examples in other languages (Conneau et al., 2018; Hu et al., 2020). However, we observe poor performance when models are trained on ENGLISH

and evaluated on LOW RESOURCE (all under 40 F_1 except XLM-R achieving near 40 F_1). In terms of the choice of source languages, we observe moderate improvements (6.8-11.2 F_1) when massively multilingual pre-trained models (i.e., mBERT, XLM-R, MT5) are cross-lingual transferred from more languages (HIGH RESOURCE: ENG, TUR, DAN, SPA, POL) rather than from ENGLISH only. On the other hand, the improvement becomes much larger (17.6 F_1) when FASTTEXT_{LSTM} is trained on more languages, indicating that the model might make better use of information from additional languages than the transformer-based models. When training on HIGH RESOURCE, FASTTEXT_{LSTM} only slightly underperforms mBERT, and outperforms all other models except XLM-R for transfer from HIGH RESOURCE to LOW RESOURCE. This might be due to the explicit embedding alignment mechanism used in the FASTTEXT approach.

We also calculated the Wilcoxon signed-rank test to assess whether there is a statistically significant difference between the results of XLM-R and mBERT. XLM-R significantly (p -value ≤ 0.05) outperformed mBERT when trained on ALL, ENGLISH, and HIGH RESOURCE and then evaluated on the complete test set. However, the differences for individual languages were not always statistically significant ($p > 0.05$). When both models were trained on ALL, the differences in performances on TUR, NOR, RUS, SWE, ITA, and ISL were not significant; the same holds for the difference on ENG when trained on ENGLISH as well as for the differences on SWE and ISL when trained on HIGH RESOURCE.

5 Analysis and Discussion

Our experiments suggest that although decent accuracy can be achieved for high-resource languages, there is substantial room for improvement in achieving better performance on the multilingual financial dataset. In this section, we present a detailed analysis of the results and investigate some of the findings to identify possible modelling improvements and look into the different dimensions of our dataset.

5.1 Multilingual abilities from a language-level perspective

Multilingual models should ideally learn good representations for all languages they were pre-trained on but this is difficult to achieve in practice due to the “curse of multilinguality” (Conneau et al., 2019). Figure 3 presents per-language results for the three training settings ALL, ENGLISH, and HIGH

RESOURCE. Generally, we see that XLM-R outperforms the rest of the models across all test settings and languages. When training on ALL data (first block in Figure 3), although the models have seen all languages during training, MT5 and sBERT seem to be struggling particularly with GRE, JPN, HEB and HUN. We see a drop in performance between high (upper part of the column) and low-resource languages (bottom part of the column), which is expected as the low-resource languages have less examples in the training dataset. When training on HIGH RESOURCE (last block in Figure 3), we observe that performance for the high-resource languages seen during training is stable compared to training on ALL (indicating that including low-resource languages during fine-tuning does not hurt performance on high-resource languages), but performance for zero-shot transfer to low-resource languages drops significantly. We compare the performance drops suffered on low resource languages from training on ALL data to training on HIGH RESOURCE data between XLM-R, mBERT, and FASTTEXT_{LSTM}, and find that mBERT suffers from larger performance drops than the other models for most languages, with the largest drops for GRE and HEB. XLM-R shows the smallest performance drops for most languages, indicating that it has better zero-shot transfer abilities than the other models.

Next, we analyze the best source for zero-shot transfer by comparing the performance on low-resource languages for models trained on HIGH RESOURCE data with models trained on ENGLISH data. In all cases (except XLM-R on SWE), zero-shot transfer works better when more languages are included in the training set. This might be due to the fact that training on more languages allows models to learn more robust representations of input sequences. Another factor might be that, as our dataset has a large label space, including more training examples (regardless of language) can improve learning representations of otherwise sparse classes. As indicated by the averaged results reported in the previous section, for most languages (except FIN and ISL), FASTTEXT_{LSTM} shows higher improvements when including more languages to train on.

Comparing zero-shot performance on different target languages for models trained on ENGLISH (middle block in Figure 3) reveals that all models with a slight exception to XLM-R struggle to generalize to languages not seen during fine-tuning, although they were part of the pre-training languages. Previous research on mBERT suggests a correlation be-

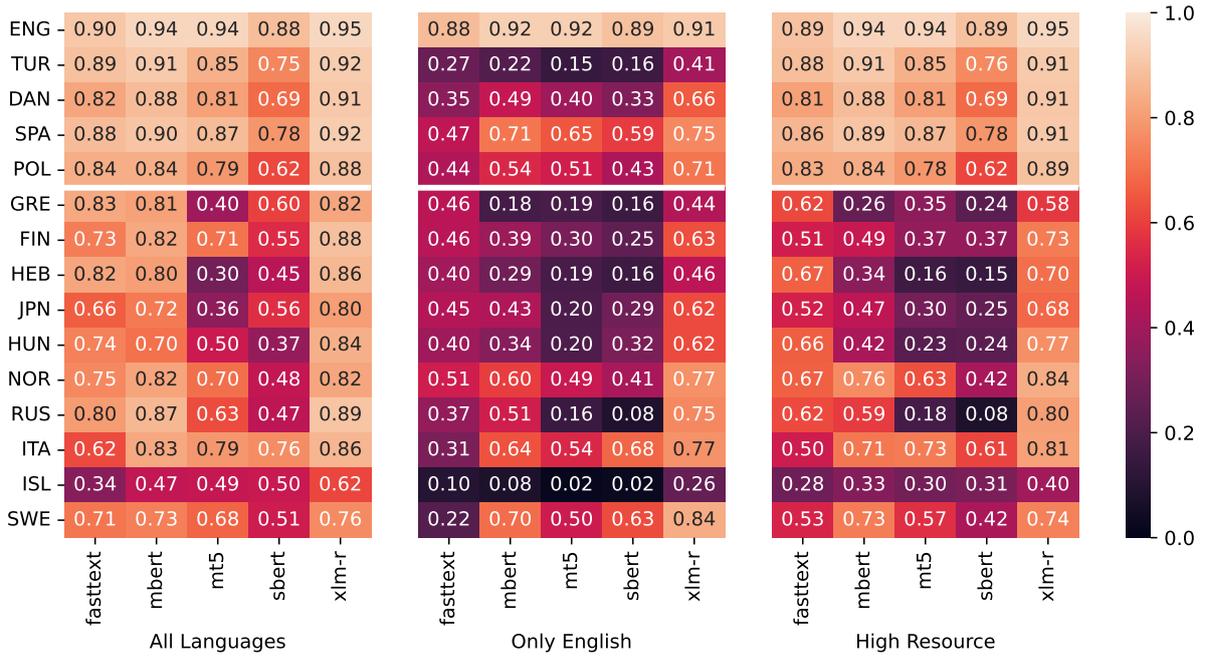

Figure 3: Per language analysis with the multi-label, Low-LEVEL setting. We train on the three settings: ALL, ENGLISH, and HIGH RESOURCE and test on ALL. The first column in each block refers to FASTTEXT_{LSTM}. Languages are in descending order by the number of examples in MULTIFIN, with a white separator between high and low-resource languages.

tween zero-shot performance in a downstream task and amount of in-language pre-training data (Wu and Dredze, 2020; Lauscher et al., 2020), which we also observe in our results. Overall, we see very poor generalization ability to certain low-resource languages, such as ISL, GRE, HEB, and RUS. Particularly for ISL, transfer ability from ENGLISH is nearly non-existing, indicating a need for multilingual models with better transfer abilities to low-resource languages.

Figure 4: The improvement over the vanilla mBERT, in Micro F_1 , due to domain-adaptive pre-training mBERT. We compare the model by Kær Jørgensen et al. (2021) against the vanilla mBERT.

5.2 Domain-adaptive pre-training can boost the cross-lingual performance

Domain-adaptive pre-training has been shown to improve the model effectiveness when these models are employed to process domain-specific text (Gururangan et al., 2020). We evaluate the publicly available model by Kær Jørgensen et al. (2021), which continues pre-training mBERT on the combination of multilingual financial text and Wikipedia, and measure the improvement over the vanilla mBERT in Table 4. Note that the multilingual pre-training data in (Kær Jørgensen et al., 2021) cover 9 languages in MULTIFIN, except POL, GRE, FIN, HEB, HUN, and ISL. Nevertheless, results in Figure 4 show that domain-adaptive pre-trained models outperform vanilla mBERT in all experimental setups, and larger improvements are observed when training set and test set are disjoint, for example, when models are trained on English or high-resource languages and tested on low-resource languages.

5.3 Multilingual versus translate

We assessed that the translation quality was good enough to preserve the topics in Section 3. Therefore, we translate all training and test data to English and fine-tune a monolingual model for English (RoBERTa, Liu et al. (2019)) on the translated training data. We compare performance on the translated

test sets with XLM-R trained and tested on the multilingual data.

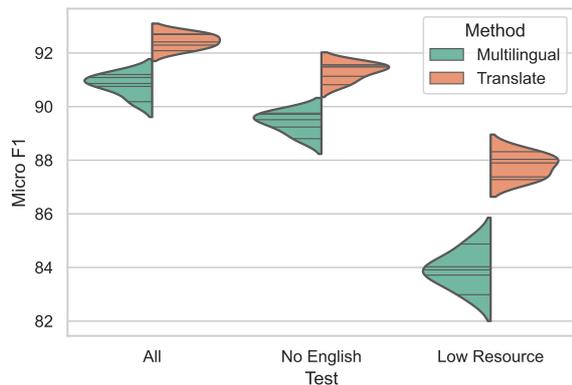

Figure 5: Multilingual (i.e., XLM-R) against translate approach based on English RoBERTa. We use the same setting as in Table 4, where we train on all languages and test on ALL LANG., NOENGLISH and LOWRES.

The monolingual model’s advantage of language-specificity over multilingual models (Rust et al., 2021; Rönnqvist et al., 2019) is evident in Figure 5, where the monolingual model trained on English is slightly better than the multilingual model trained on multilingual data.⁵ We consider this monolingual model an additional baseline on MULTIFIN.

6 Conclusion

We proposed MULTIFIN, a dataset for the evaluation of multilingual financial NLP models. The main aim is to advance multilingual NLP in the financial domain so it is better suited for new development and evaluation of domain-specific models. MULTIFIN is a diverse dataset with 10,000 examples, covering 15 languages, including different language families and writing systems. We benchmark a collection of standard multilingual language models on MULTIFIN and find that although these models often achieve good performance in high-resource languages, there is a substantial gap in performance between high- and lower-resource languages. The per-language analysis uncovered that most of the benchmarked models do not facilitate a good transfer across the evaluated languages, and for specific languages, indicate a strong need for improving the models’ capacity

⁵ Artetxe et al. (2020) found that improvements of a translation baseline in a cross-lingual NLI task do not stem from overcoming the cross-lingual gap, but from the fact that translation of the training data introduces alterations which improve generalization to a translated test set. It is possible that in our experiments, the performance of the monolingual model generalizing from translated training data to translated test data is impacted by similar mechanisms.

to generalize. The multilingual mDAPT model presented overall better generalization, particularly to low-resource languages, indicating that focusing on multilingual domain-specific methods is a promising direction for future work in financial NLP. Future work includes extending the dataset to include more examples across more languages so better understand the limits of multilingual financial text processing. We are also exploring including the entire document, as opposed to only the headline, but this would depend on high-quality long document processing models (Dai et al., 2022). We hope to motivate and inspire collective work on multilingual NLP in the financial domain.

Limitations

Annotators We are aware that annotators with domain knowledge and language proficiency would be preferred. It was not within our resources to find qualified annotators in the financial domain with expert knowledge and language proficiency for all 15 languages.

Annotation process The number of annotated topics per example is determined to three, although a handful of article titles could potentially be assigned more than three topics. The authors attempted to limit this by prioritizing annotated topics by topic weight (see Section 3).

Acknowledgements

We thank PwC for providing the data and thank Lars Silberg Hansen for his support and valuable contribution to the creation of this dataset.

A Annotator agreement

The Table 5 below presents the annotator agreement on topic level. The rather high agreement across topics indicate that our annotations are of high quality.

No.	Topic	Kappa, κ
1	Actuary, Pension & Insurance	0.9791
2	Asset & Wealth Management	0.9020
3	Accounting & Assurance	0.9704
4	Banking & Financial Markets	0.9218
5	Board, Strategy & Management	0.9620
6	Power, Energy & Renewables	0.9495
7	Corporate Responsibility	0.9092
8	Media & Entertainment	0.9526
9	Financial Crime	0.9479
10	Government & Policy	0.8889
11	Healthcare & Pharmaceuticals	0.9408
12	Human Resources	0.9537
13	IT Security	0.9346
14	Governance, Controls & Compliance	0.9121
15	M&A & Valuations	0.9617
16	Real Estate & Construction	0.9254
17	Retail & Consumers	0.9526
18	SME & Family Business	0.8670
19	Start-Up, Innovation & Entrepreneurship	0.9888
20	Supply Chain & Transport	0.9321
21	Tax	0.9474
22	Technology	0.9463
23	VAT & Customs	0.9797

Table 5: Full report of inter-annotation agreement of multi-label Cohen’s κ .

B Label distribution

We present the distribution of the LOW-LEVEL and HIGH-LEVEL topics. In Table 6, we present the distribution over the LOW-LEVEL topics. We allowed up-to 3 annotations per examples for the multi-label annotation. This produced a total of 14230 annotation with 1.4 annotations per example on average. In Table 7, we present the distribution over the HIGH-LEVEL topics.

C Cross-lingual transfer with fasttext embeddings

Preprocessing In order to represent inputs with pre-trained fasttext embeddings, we tokenize our data according to how the fasttext training data was tokenized, using Mecab⁶ for Japanese, and the tokenizer from the Europarl preprocessing tools⁷ (Koehn, 2005) for the other languages.

⁶<https://pypi.org/project/mecab-python3/>

⁷<https://www.statmt.org/europarl/>

No.	Topic	Examples
1	Actuary, Pension & Insurance	502
2	Asset & Wealth Management	257
3	Accounting & Assurance	1,452
4	Banking & Financial Markets	782
5	Board, Strategy & Management	866
6	Power, Energy & Renewables	248

8	Media & Entertainment	255
9	Financial Crime	310
10	Government & Policy	528
11	Healthcare & Pharmaceuticals	245
12	Human Resources	1,091
13	IT Security	424
14	Governance, Controls & Compliance	501
15	M&A & Valuations	492
16	Real Estate & Construction	351
17	Retail & Consumers	354
18	SME & Family Business	226
19	Start-Up, Innovation & Entrepreneurship	277
20	Supply Chain & Transport	222
21	Tax	1,713
22	Technology	1,169
23	VAT & Customs	1,688
Total		14,230

Table 6: Overview of LOW-LEVEL tags across the 23 topics. These represent the 23 labels used in the multi-label task.

No.	Topic	Examples
1	Technology	1,088
2	Industry	1,239
3	Tax & Accounting	3,371
4	Finance	1,447
5	Government & Controls	912
6	Business & Management	1,991
Total		10,048

Table 7: Overview of HIGH-LEVEL tags across the 6 classes. These represents the 6 classes used in the multi-class classification task.

Embedding alignment We map monolingual fast-text embeddings trained on Wikipedia and Common-crawl into a shared space using RCSLS, by computing pairwise mappings between source languages and English as a target language. As supervision, we rely on the training dictionaries of the MUSE dataset (Conneau et al., 2017), except for Icelandic which is not covered there. For Icelandic, we follow Vulić et al. (2019) in deriving a dictionary based on the Panlex database (Kamholz et al., 2014): We retrieve translations for the 5000 most frequent Icelandic words derived from Opensubtitles published on Wiktionary⁸ We only keep single-word transla-

⁸https://en.wiktionary.org/wiki/Wiktionary:Frequency_lists/Icelandic_

Model	Learning rate	# train epochs	# Params.
FASTTEXT _{BAG}	[1e-3, 2.5e-3, 5e-3, 7.5e-3, 1e-2, 2.5e-2, 5e-2]	50	0.1M
FASTTEXT _{LSTM}	[1e-3, 2.5e-3, 5e-3, 7.5e-3, 1e-2, 2.5e-2, 5e-2]	50	1.8M/1M/1M

XLM-R	[1e-5, 2e-5, 5e-5, 1e-4]	[10, 30, 100]	270M
MT5	[1e-4, 3e-4, 1e-3]	[10, 30]	300M

Table 8: The search space of two hyperparameters (learning rate and number of training epochs), as well as the number of trainable parameters for each model. The size of the hidden states in FASTTEXT_{LSTM} is treated as an additional hyperparameter selected from [100, 200, 300, 400, 500], hence we report numbers of parameters for three different selected models trained on ALL/ENGLISH/HIGH RESOURCE, corresponding to models with hidden dimensionality 300/200/200, respectively. For all models, we do early stopping on the validation set with a patience of 5 and 10 for transformer-based and fasttext-based models, respectively.

tions. As not all source words are present in Panlex, our final dictionary contains translations for 1,823 Icelandic words. With these dictionaries as supervision, we run RCSLS with default parameters for 10 epochs, and select the best mapping based on the unsupervised selection criterion.

D Experimental Details

For each experiment, we perform grid search to find the best combination of two hyperparameters—number of training epochs and learning rates—on the development set. Table 8 shows the search space of these two hyperparameters as well as the trainable parameters per model.

MLASK: Multimodal Summarization of Video-based News Articles

Mateusz Krubiński and Pavel Pecina

Charles University, Faculty of Mathematics and Physics

Institute of Formal and Applied Linguistics

{krubinski, pecina}@ufal.mff.cuni.cz

Abstract

In recent years, the pattern of news consumption has been changing. The most popular multimedia news formats are now multimodal – the reader is often presented not only with a textual article but also with a short, vivid video. To draw the attention of the reader, such video-based articles are usually presented as a short textual summary paired with an image thumbnail. In this paper, we introduce MLASK¹ (Multimodal Article Summarization Kit) – a new dataset of video-based news articles paired with a textual summary and a cover picture, all obtained by automatically crawling several news websites. We demonstrate how the proposed dataset can be used to model the task of multimodal summarization by training a Transformer-based neural model. We also examine the effects of pre-training when the usage of generative pre-trained language models helps to improve the model performance, but (additional) pre-training on the simpler task of text summarization yields even better results. Our experiments suggest that the benefits of pre-training and using additional modalities in the input are not orthogonal.

1 Introduction

Automatic summarization is one of the basic tasks both in Natural Language Processing – text summarization – and in Computer Vision – video summarization. Multimodal summarization (MMS) builds a bridge between those two fields.

Early works on multimodal summarization explored the usage of the secondary modality as an auxiliary source of information to guide the refinement process of the main modality. Li et al. (2017) collected videos and news articles covering a hand-crafted list of recent significant world events by querying a web search engine and trained a model to mimic the reference summaries written by human annotators. Zhu et al. (2018) were the first to

¹<https://github.com/ufal/MLASK>

introduce the task of Multimodal Summarization with Multimodal Output (MSMO). They collected a large-scale dataset of news articles paired with corresponding images and trained a system to generate a textual summary and choose a single image as a pictorial summary. By introducing the multimodal output, a uni-modal solution was no longer sufficient as a baseline. Building upon this, Li et al. (2020b) extended the task to video-based MSMO. Based on a textual document and a short video clip, besides generating the textual summary, the system was also challenged to select a single frame from the video as a cover picture.

We believe there is still a lot of questions that remain unanswered, e.g.: *How to evaluate multimodal outputs?* or *How to approach pre-training?* In this paper, we contribute to the area of video-based MSMO (VMSMO) by: **1)** introducing a full-scale VMSMO dataset in Czech, extending the very limited available resources for this task to a new language; **2)** exploring the pre-training strategies by transferring knowledge from the simpler task of text-to-text summarization; **3)** re-defining the training labels to consider intra-video similarities; **4)** proposing a human evaluation framework for assessing the quality of VMSMO.

2 Related Work

In our work, we build upon recent advances in three fields: text summarization, video summarization, and multimodal summarization.

2.1 Text Summarization

Text summarization aims to automatically produce a short fluent summary that preserves the crucial information from the source document(s). Historically, a majority of works focused on the news domain and English language (Nallapati et al., 2016; Grusky et al., 2018; Fabbri et al., 2019). Recently, new research directions, such as multilingual summarization (Scialom et al., 2020; Varab

and Schluter, 2021) or dialogue summarization, (Gliwa et al., 2019; Zhong et al., 2021) have been explored. Fabbri et al. (2021) benchmarked over 20 recent summarization models and concluded that the abstractive summaries produced by pre-trained generative languages models fine-tuned on summarization datasets (Zhang et al., 2020; Lewis et al., 2020) consistently performed best with regards to both automatic metrics and human evaluation.

2.2 Video Summarization

Video summarization aims to refine the video content by either choosing a set of the most representative frames, known as a video storyboard, or selecting short video fragments, known as a video skim. As noted in the recent survey (Apostolidis et al., 2021), in both cases, the usual approach is to start with modeling the frame-level importance scores, which can then be aggregated to segment-level scores.

Contrary to text summarization, abstractive approaches that generate the summary from scratch are yet to be explored. The most relevant to our work are the recent publications on query-based video summarization, e.g., Li et al. (2023) and Huang et al. (2021), that use a text-based input to enrich frame-level representations and guide the summarization towards a user-specified query.

2.3 Multimodal Summarization

Previous works (e.g., Li et al., 2017, 2018; Palaskar et al., 2019) explored the addition of multimodal information such as video or audio transcript to enrich the textual document, aiming to generate better textual summaries. Zhu et al. (2018), who introduced the MSMO task, trained a model that jointly generated text and selected the most relevant image from a pre-defined set of images. Li et al. (2020b) and Fu et al. (2021) were the first to tackle the VMSMO problem. In their work, the cover picture choice was modeled as a frame selection problem. In the follow-up work (Tang et al., 2022), a video-article pair was summarized as a single frame and a one-sentence summary using an optimal transport-based unsupervised training strategy.

3 MLASK Dataset

Previous works on MMS operated on datasets in either English (Li et al., 2017, 2018; Palaskar et al., 2019; Fu et al., 2021; Tang et al., 2022) or Chinese

	Mean	Q_1	Median	Q_3
Title	11.16 ± 2.78	9	11	13
Abstract	33.40 ± 13.86	22	32	43
Article	276.96 ± 191.74	154	231	343

Table 1: Quantitative statistics of the lengths of titles, abstracts, and full texts (measured in the number of tokens) for the MLASK dataset. Q_1 and Q_3 denote the first and the third quartile, respectively.

(Li et al., 2020b; Li et al., 2020a). To extend the available resources, we collected a new dataset in a different language – Czech, a West Slavic language with a rich system of morphology and a relatively flexible word order.

3.1 Data Preparation

The steps taken while preparing the dataset are:

1. Two Czech websites publishing news articles accompanied with a video clip, textual summary, and a cover picture were identified.
2. Based on the HTML structure of each website, the articles accompanied by a video clip (mp4) and a cover picture (jpeg) were downloaded.
3. From each relevant article, its title, abstract, and full text were extracted.
4. The following documents were dropped:
 - with videos longer than 5 minutes;
 - with full text shorter than 50 words or longer than 2,000 words;
 - with abstract shorter than 10 words or longer than 80 words;
 - with title shorter than 2 words;
 - with either the full text or abstract identified as non-Czech by the langid² language-identifier.
5. Every video was re-sampled to the same frame rate (25 fps) and resized to the same resolution (1280x720).

3.2 Dataset Size Statistics

In total, the collected dataset contains 41,243 instances, all including the article’s text, title, abstract, video, and cover picture. The quantitative statistics of the data are displayed in Table 1. The average video duration is 85.58 seconds. For comparison, we also report the statistics of other datasets proposed for the VMSMO task so far (Table 2).

²<https://github.com/saffsd/langid.py>

Dataset	#Articles	Article Length	Summary Length	Video Length	Language
VMSMO (Li et al., 2020b)	184,920	97	11	60s	Chinese
MM-AVS (Fu et al., 2021)	2,173	685	57	109s	English
XMSMO-News (Tang et al., 2022)	4,891	102	12	346s	English
MLASK (this paper)	41,243	277	33	86s	Czech

Table 2: Comparison of the datasets introduced for the VMSMO task. The concrete statistics are reported as averages computed over the whole corpus. For the textual part, we report the average number of tokens.

4 Multimodal Summarization

In our experiments, a video-based news article is represented by a pair (V, X) . V corresponds to the video input – a sequence of frames: $V = (v_1, v_2, \dots, v_N)$. X is the news article presented as a sequence of tokens: $X = (x_1, x_2, \dots, x_M)$. We assume that for each article, there is a ground-truth textual summary $Y = (y_1, y_2, \dots, y_L)$ and a ground-truth cover picture P . The task is to generate a textual summary \hat{Y} that includes the main points of the article and to choose a frame \hat{v} to act as a cover picture (pictorial summary).

4.1 Overview

The proposed MMS model (see Figure 1) is structured into three parts: *Feature Encoder* composed of a text, video, and frame encoder, *Cross-modal Interaction Module* fusing the visual and textual representations, and *Multimodal Decoder* responsible for the summary generation and frame selection.

4.2 Feature Encoder

The Feature Encoder consists of a text encoder, video encoder, and frame encoder:

Text Encoder. We use the Transformer (Vaswani et al., 2017) encoder model to map the textual news article into the sequence of token embeddings (Eq. 1). Following the findings of Yu et al. (2021), we use the pre-trained mT5 model (Xue et al., 2021) to initialize its weights. We examine the influence of task-specific pre-training (Section 6.3) by fine-tuning the mT5 model on the simpler task of text-to-text summarization.

$$X_{enc} = \text{TransformerEncoder}(X) \quad (1)$$

Video Encoder. The news videos in our dataset are several minutes long and consist of hundreds of frames. To incorporate the short-term temporal dependencies, we employ the 3D convolutional networks. In our experiments, we segment the video into non-overlapping sequences of frames

and use the 3D CNN network for feature extraction (Eq. 2). As the feature extractors, we use the R(2+1)D model trained by Ghadiyaram et al. (2019) for video action recognition on weakly-supervised social-media videos and the visual component of the S3D Text-Video model trained in a self-supervised manner by Miech et al. (2020) on the HowTo100M dataset (Miech et al., 2019). To incorporate the long-term temporal dependencies, we process the sequence of video features with the Transformer encoder model (Eq. 3).

$$V_{enc} = \text{3D-CNN}(V) \quad (2)$$

$$V_{enc} = \text{TransformerEncoder}(V_{enc}) \quad (3)$$

Frame Encoder. To be able to choose a specific frame as a cover picture, frame-level representations are needed. In our experiments, we sample one of every 25 frames as the cover picture candidates (1 frame per second). We examine the usage of EfficientNet (Tan and Le, 2019) and Vision Transformer (Dosovitskiy et al., 2021) as feature extractors. Both were trained for image classification on ImageNet (Russakovsky et al., 2015). To put the representations into context, we process the sequence of frame features with the Transformer encoder model (Eq. 5).

$$V_{frame} = \text{CNN}(\text{Sample}(V)) \quad (4)$$

$$V_{frame} = \text{TransformerEncoder}(V_{frame}) \quad (5)$$

Before applying the Transformer encoder, we project both the video and frame features into the same dimension as the hidden states of the text encoder. When used in a single model, the two sets of features are concatenated before projecting.

4.3 Interaction Module

Following Yu et al. (2021), who examined different ways of injecting visual information into pre-trained generative language models, we employ the multi-head attention (MHA) based fusion to obtain the vision-guided text representation and perform the fusion after the last encoder layer (Eq. 6–9).

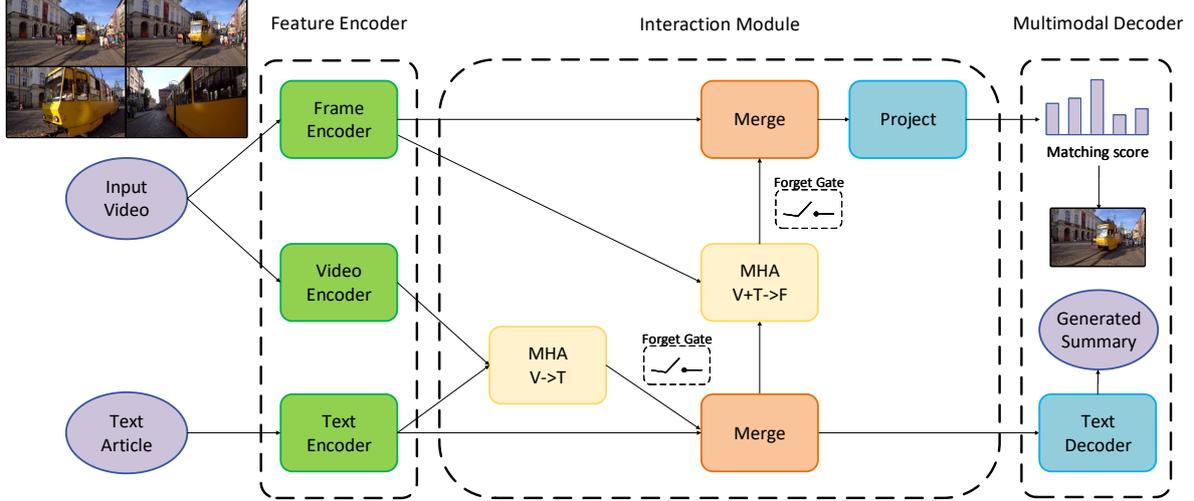

Figure 1: An overview of the proposed MMS model for multimodal summarization.

$$Q = X_{enc}W_q, Q \in \mathbb{R}^{M \times d} \quad (6)$$

$$K = V_{enc}W_k, K \in \mathbb{R}^{N' \times d} \quad (7)$$

$$V = V_{enc}W_v, V \in \mathbb{R}^{N' \times d} \quad (8)$$

$$\tilde{X}_{enc} = \text{MHA}(Q, K, V), \tilde{X}_{enc} \in \mathbb{R}^{M \times d} \quad (9)$$

As suggested by Liu et al. (2020), we use the forget gate (FG) mechanism so that the model can filter out low-level cross-modal adaptation information (Eq. 10).

$$\hat{X}_{enc} = \text{FG}(X_{enc}, \tilde{X}_{enc}), \hat{X}_{enc} \in \mathbb{R}^{M \times d} \quad (10)$$

We use the same MHA mechanism to obtain the text+video guided frame representations \hat{V}_{frame} by substituting the X_{enc} with V_{frame} in Eq. 6 and V_{enc} with \hat{X}_{enc} in Eq. 7 and Eq. 8.

4.4 Multimodal Decoder

To generate the textual summary, we use the standard Transformer decoder initializing its weights from the mT5 checkpoint. We use the vision-guided text representation \hat{X}_{enc} as the input (Eq. 11) and train it using the standard negative log-likelihood loss (NLLLoss) w.r.t. the target sequence Y (Eq. 12).

$$\hat{Y} = \text{TransformerDecoder}(\hat{X}_{enc}) \quad (11)$$

$$\mathcal{L}_{text} = \text{NLLLoss}(\hat{Y}, Y) \quad (12)$$

To obtain the labels C for cover picture (cover frame) selection, we compute the cosine similarity between the CNN features of the reference cover

picture and the candidate frames. The similarity of over 99.99% of instances was in the [0,1] range, and the remaining negative values were mapped to 0. The previous works (Li et al., 2020b; Fu et al., 2020) regarded the frame with the maximum cosine similarity as ground-truth and others as negative samples (C_{max}). After examining the cosine similarity patterns (Figure 2), we noticed that the per-video similarity has often either more than one peak, or there are consecutive sequences of frames with very similar scores (capturing a still scene). Our intuition was that this may harm the model performance – very similar frames might be labeled as both positive and negative examples. To overcome this issue, besides the binary labels C_{max} , we introduce the smooth labels C_{smooth} that assign to each frame its cosine similarity score with the reference cover picture.

We use a projection matrix to map the text+video guided frame representations \hat{V}_{frame} to a single dimension (Eq. 13) and train (Eq. 14) using the binary cross-entropy loss (BCELoss). The target labels C are either C_{max} or C_{smooth} . We train the whole model end-to-end by minimizing the sum of losses \mathcal{L} (Eq. 15).

$$\hat{C} = \hat{V}_{frame}W_p, W_p \in \mathbb{R}^{d \times 1} \quad (13)$$

$$\mathcal{L}_{image} = \text{BCELoss}(\hat{C}, C) \quad (14)$$

$$\mathcal{L} = \mathcal{L}_{text} + \mathcal{L}_{image} \quad (15)$$

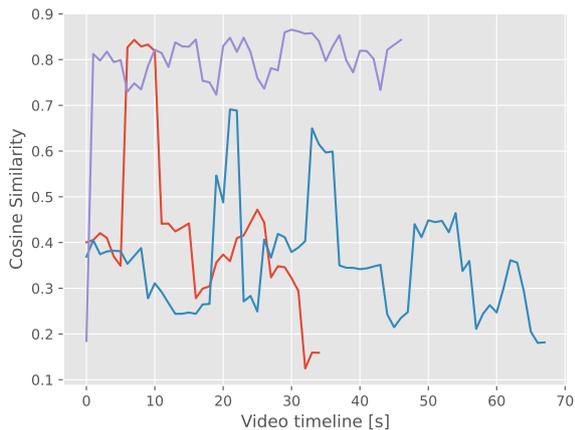

Figure 2: Three examples of cosine similarity plots between CNN features of the reference cover picture and all candidate frames from the video. The examples were chosen manually to present three different video similarity patterns: with a single peak (red), with more than one peak (blue), and with a consecutive sequence of frames having very similar scores (violet).

5 Experiment Setup

5.1 Dataset

In our experiments, we perform the training/dev/test splits of the MLASK dataset following the chronological ordering based on publication date. We use the articles published in the first half (Jan–Jun) of 2021 for validation (2,482 instances) and the ones published in the second half (Jul–Dec) of 2021 and the beginning (Jan–Feb) of 2022 for testing (2,652 instances). The remaining data is used for training (36,109 instances).

5.2 Implementation

We implement our experiments in PyTorch Lightning³ and use the mT5-small variant (300M trainable parameters) provided via the Transformers (Wolf et al., 2020) package. Following Yu et al. (2021), we use two separate 4-layer encoders with 8 attention heads to contextualize the video and frame representations (Eq. 5 and Eq. 3). As video feature extractors, we use the R(2+1)D 34-layer IG-65M⁴ and S3D_HowTo100⁵ models to encode sequences of the length of 32 frames. To extract frame-level features, we utilize the EfficientNet-B4 variant from the torchvision package and the vit-

³<https://github.com/PyTorchLightning/pytorch-lightning>

⁴<https://github.com/moabitcoin/ig65m-pytorch>

⁵https://github.com/antoine77340/S3D_HowTo100M

base-patch32-224-in21k variant of Vision Transformer provided by Hugging Face (Wolf et al., 2020). We follow the suggested pre-processing (e.g., re-scaling) for each feature extractor independently. The total number of trainable parameters is equal to approximately 323M.

5.3 Hyper-parameters

We train the multimodal model using the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. We increase the learning rate linearly for the first 8,000 steps (0 to $5e-4$) and then follow an inverse square root decay schedule. Since both the text encoder and decoder are pre-trained, we freeze them for the first 2 epochs. We limit the document size to 1,536 sub-word tokens and the summary length to 256 tokens. We train all the models for 50 epochs with an early stopping applied if ROUGE-L (see Section 5.4) does not improve on the dev-set for 5 consecutive epochs. During decoding, we use the best checkpoint with respect to ROUGE-L, utilizing beam search with the beam size of 4, length penalty of 1.0, and repetition penalty (Keskar et al., 2019) of 2.5. We select the cover frame by applying argmax to the projected representations (Eq. 13). We employ gradient accumulation to train with the effective batch size of 32. Each model is trained on a single GeForce RTX 3090 GPU, and the average training time is roughly 36 hours.

5.4 Evaluation Metrics

Most existing implementations of ROUGE (Lin, 2004), a standard metric used to evaluate summarization, are English-specific and utilize e.g., an English stemmer and stop words. Since our dataset is in Czech, following the work of Straka et al. (2018), we evaluate the model performance with language-agnostic variants of ROUGE⁶ reporting the F1 scores (ROUGE-1, ROUGE-2, ROUGE-L).

To estimate the quality of cover frame selection, we follow Fu et al. (2020) and report the cosine similarity (CosSim) between the reference cover picture and the chosen cover frame. To have a better understanding of the model performance, we also follow Li et al. (2020b) and report Recall@k ($R@k$)⁷ considering the frame closest to the ground-truth as a positive example. To evaluate the

Table 3: Evaluation on the dev-set and test-set of MLASK. See Section 5.4 for the metrics description. The figures are averaged over three runs with different seeds. The three highest-scoring systems in each column are bolded independently for test-set and dev-set.

frame scoring at even coarser video-level granularity, we report Kendall’s Tau (KC) and Pearson (PC) correlation coefficients⁸ to measure the correlation of ordering based on the projected representations (Eq. 13) with the absolute frame ordering based on similarity with the ground-truth picture.

6 Experiments

We analyze several aspects of the proposed model: First, we study the effect of the visual features. Second, we analyze the contribution of pre-training the model on text-only summarization data. Third, we exploit the smooth frame labels to further improve the model. The results are presented in Table 3.

6.1 Baselines

To put our experiments into context, we first report the performance of several text-only baselines: *RandomT* extracts three random sentences from the article and *Lead3* extracts three initial sentences (trivial baselines); *Oracle* takes three sentences that maximize ROUGE-L with the ground-truth

abstract (the upper bound for extractive summarization); *mT5-MLASK* is the output of the mT5 model fine-tuned on the textual part of the MLASK training set and *mT5-SumeCzech* is the mT5 model fine-tuned on the SumeCzech (Section 6.3) dataset (abstractive summarization baselines). There is also a video-only baseline *RandomV*, which performs random frame ordering.

Unsurprisingly, both *mT5* variants outperform the trivial baselines (*RandomT*, *Lead3*), but their results are still far below the *Oracle* performance. Using larger training data (SumeCzech has roughly 20 times more documents than MLASK) improves the performance by approximately 1 ROUGE point.

6.2 Visual features

In Section 4.2, we proposed to employ two different visual features for both video and image feature extraction. The system exploiting all the features is denoted as MMS in Table 3. It achieves slightly higher scores than *mT5-MLASK* (dev-set ROUGE-1: 18.25 \rightarrow 18.34, ROUGE-L: 13.07 \rightarrow 13.26) but lags behind the text-only *mT5-SumeCzech* that was trained on a much larger corpus. To analyze the

	ROUGE-1	ROUGE-2	ROUGE-L
<i>Lead3</i>	14.34	2.14	9.64
<i>Random3</i>	12.52	1.27	8.37
τ 2t (2018)	11.30	1.00	8.70
mT5-SumeCzech	18.46	4.54	13.33

Table 4: Performance of the text-to-text summarization models on the test part of SumeCzech (Straka et al., 2018) for the article→abstract task.

effect of the individual visual features, we report the results of the MMS model, excluding those features one by one (see the rows starting with the “-” sign). The scores indicate that the model combining all the features is superior.

6.3 Pre-training

Yu et al. (2021) showed that the usage of pre-trained generative language models is beneficial for multimodal summarization. We explored this idea further by task-specific pre-training on SumeCzech (Straka et al., 2018) – a large-scale Czech news summarization corpus used to fine-tune the mT5 model for summarization (*mT5-SumeCzech*). We used the Adafactor (Shazeer and Stern, 2018) optimizer with a constant learning rate equal to $5e-4$ and trained until ROUGE-L ceased to improve on the dev-set for 5 consecutive evaluations. To avoid any training/test data leaks, we excluded from the *mT5-SumeCzech* training data the articles that could appear in MLASK based on the date of publication (794,018 left, i.e., 92%). Performance on the test part of SumeCzech is reported in Table 4. Based on the results (Table 3, system MMS + SumeCzech), we can clearly see that the usage of mT5 fine-tuned for summarization instead of the raw mT5 boosts the performance on the text summarization part (test-set ROUGE-1: 18.45 → 19.58, ROUGE-L: 13.42 → 14.30).

6.4 Smooth labels

In Section 4.4, we proposed to use the smooth labels C_{smooth} during training to overcome the issue of very similar frames being labeled as positive and negative examples. Our results (Table 3, system MMS + SumeCzech + Smooth Labels) indicate that, indeed, this method helps with the quality of cover frame selection (test-set CosSim: 0.541 → 0.551, R@10: 0.318 → 0.330). We can also notice a small improvement (test-set ROUGE-1: 19.58 → 19.74) in the quality of text summarization, which we attribute to more stabilized training.

For a full comparison, we also include two variants with masked video features (MMS + SumeCzech + Smooth Labels + Masked Video and MMS + Masked Video) – all the video features are masked with random noise, both during the training and the evaluation. The frame features are left intact. Surprisingly, for the variant that was pre-trained on a large text-only corpus, masking the video features does not hurt the model performance. This is, however, the case for the model that did not go through the task-specific pre-training. After examining the models, we noticed that the representations after the video encoder (Eq. 5) are not very meaningful, i.e., every segment is mapped to a similar vector. We believe this is due to the indirect usage of video representations in the Cross-modal Interaction Module – too weak learning signal (gradient) is propagated to the video encoder. Considering the drop in performance for the model without pre-training, it seems to be the case that the information from pre-training and multimodal input is not completely orthogonal.

7 Human Evaluation

Previous works on VMSMO evaluated the system performance by employing human judges to assess the quality of generated textual summary: Li et al. (2020b) measured to what extent the system summaries were sufficient to answer questions generated from the reference summary and ranked them based on *Informativeness*, *Coherence*, and *Succinctness*; Fu et al. (2021) scored the system summaries based on *Informativeness* and *Satisfaction*. We believe no prior work employed human annotators to judge the quality of a chosen cover frame (pictorial summary) in the context of textual summary. For the similar task of multimodal summarization with *unimodal output*, Wan and Bansal (2022) collected annotations for the subset of the WikiHow dataset (Yang et al., 2021) that measured whether the textual output was faithful to the source pair of document and image.

7.1 Formulation

To evaluate the quality of cover frame selection, we asked human annotators to judge the quality and usefulness of an image as a pictorial summary of the article. 18 human annotators participated. All were adult, native Czech speakers who read online news magazines daily. Figure 3 displays a screenshot of the annotation tool. For each instance,

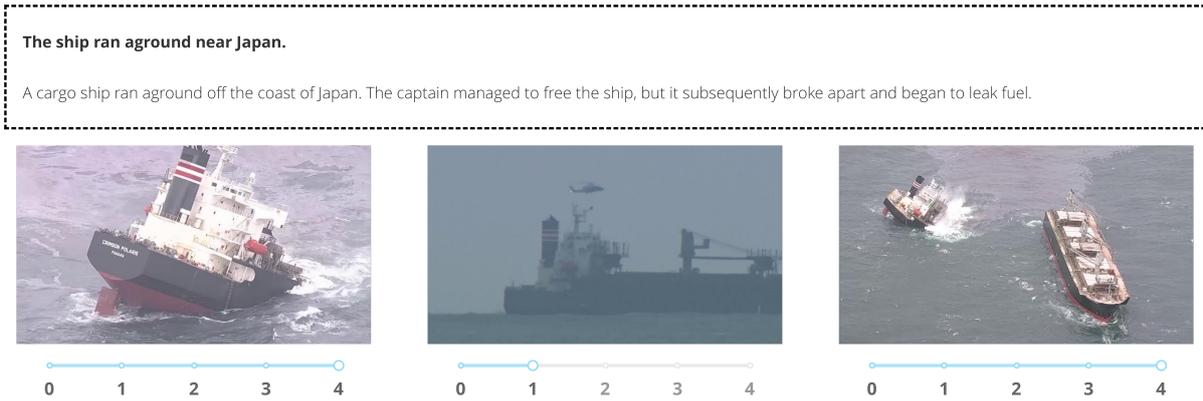

Figure 3: Screenshot of the annotation tool used to collect human judgments about the quality and usefulness of selected cover frame. For convenience, we translated all `text` into English.

the annotators were asked to rate 3 images on a scale of 0 to 4 (the higher, the better) in the context of the article’s title and the reference summary.

The suggested interpretation of the scale levels was:

- 0: The picture is not relevant at all or very marginally (technical quality is not important).
- 1: The image is partly relevant (there is a certain connection between what it captures and the content of the text), but technically imperfect (e.g., blurred, cropped inappropriately, taken from an inappropriate angle or at an inappropriate moment).
- 2: The image is partly relevant (there is a certain connection between what it captures and the text content) and of a good technical quality.
- 3: The picture is very relevant, but technically imperfect (e.g., blurred, cropped inappropriately, taken from an inappropriate angle, or at an inappropriate moment).
- 4: The picture is both very relevant and of a good technical quality. It is a suitable cover picture.

7.2 Setup

We randomly chose 300 instances from the MLASK test-set for annotation and split them into 10 batches of 30 instances. We used the first batch to measure the inter-annotator agreement, asking each annotator to score all the instances in the control batch plus at least in one more.

For each instance, four images were considered for annotation: the reference picture (denoted as *Reference*), a random frame from the video (*RandomV* output), and the outputs of two test models – MMS pre-trained on SumeCzech using the smooth labels (MMS + SumeCzech + Smooth Labels, fur-

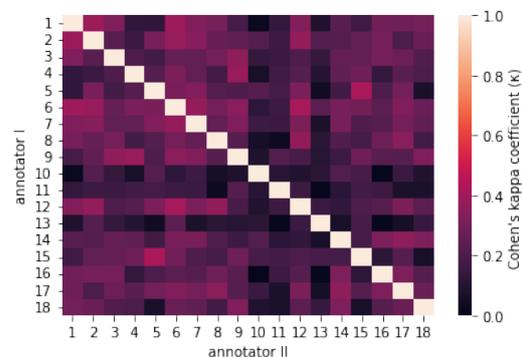

Figure 4: Values of Cohen’s κ used to measure the inter-annotator agreement on the control batch (30 instances).

ther denoted as System A) and the same model with masking of the video features (MMS + SumeCzech + Smooth Labels + Masked Video, further denoted as System B). See Appendix A for examples.

In the control batch, we always included the reference picture, hiding the output from one of the methods in 33% of the cases. In the other batches, we display 3 out of the 4 images selected randomly. To avoid a position bias, we shuffle the images before showing them to the annotator. On average, we collected 2.5 annotations for each image.

7.3 Results

Figure 4 displays the inter-annotator agreement on the control batch in the form of a heat map. The average value of 0.217 indicates a "fair" agreement. One can notice that three annotators (10, 11, and 13) have a lower average agreement (average below 0.2). We decided to exclude their annotations from further analysis. By doing so, the average value of Cohen’s κ increased to 0.26, and the average number of annotations decreased to 2.2.

	Total Score	Adequacy Score
<i>Reference</i>	2.89 ± 0.99	1.64 ± 0.50
<i>RandomV</i>	2.39 ± 1.15	1.44 ± 0.61
System A	2.64 ± 1.10	1.51 ± 0.58
System B	2.66 ± 1.04	1.56 ± 0.52

Table 5: System performance on the task of cover picture selection. See Section 7.1 for the label description.

In Table 5, we report the system-level averages of the scores assessed by human annotators (Total Score). On average, the reference picture is assigned the highest score, and our proposed multimodal summarization model performs better than the random baseline. The results of human assessment confirm our previous findings based on automatic metrics – that the model is not utilizing the video features in an effective manner. It is worth noticing, however, that even the reference picture is not considered very relevant (average score below 3) and that none of the differences are statistically significant. To examine the stability of the annotation process, we also report the averages (Adequacy Score) that disregard the quality of the image and focus only on relevance. We do this by mapping the labels from Section 7.1, (i.e., $0 \rightarrow 0$; 1 and $2 \rightarrow 1$; 3 and $4 \rightarrow 2$). The results are in line with the original ones.

8 Conclusions

In this paper, we explored the recently proposed task of video-based multimodal summarization with multimodal output. We extended the available resources to a new language by introducing a multimodal summarization dataset in Czech. We explored the pre-training strategies, showing that transferring knowledge from the simpler, unimodal task of text-to-text summarization helps with the final performance in multimodal settings. We were also able to show that the usage of inner-video similarities, via the introduction of smooth labels during training, helps to stabilize the training. We conducted a human evaluation of the frame-selection process to confirm the quality of the proposed multimodal MMS model. Our findings indicate that the MMS model pre-trained on the text-to-text summarization is not effective in utilizing video features and that future works should carefully examine to what extent the model is able to make use of multimodal input and whether the improvement is orthogonal to e.g., using more data.

Limitations

MLASK dataset collection. While curating the MLASK dataset, we applied a series of rule-based filters (Section 3.1) and collected only those documents that followed a strict HTML structure. No large-scale human evaluation was applied to check the data validity. We sampled a random subset of 100 articles and checked the data preparation and collection manually.

Language and domain bias. We acknowledge that our findings are based on a single dataset, in a particular language (Czech) and from a particular domain (news articles). Due to the novelty of the task, previous datasets proposed for VMSMO (Table 2) are not applicable to our experiments – dataset by Fu et al. (2021) does not provide single cover pictures, and the datasets by Li et al. (2020b) and Tang et al. (2022) are not publicly available. We also acknowledge that due to the data coming from a particular news provider, it may not be free of cognitive biases.

Technical requirements. Considering the modular architecture of the proposed model (Section 4.1), a modern GPU is required for training (using a 24GB GPU we were able to train with a batch size of 2). To store the raw MLASK dataset (videos and images), roughly 750GB of disk space is required.

Human evaluation. While conducting the human evaluation of cover frame selection, we provided a detailed set of instructions (Section 7.1) and used a control batch (30 instances) that was judged by each annotator to compute the inner-annotator agreement. Our findings (Table 5) indicate that there is a certain perception in the data annotation process that we did not analyze – the gold-standard reference picture is, on average, judged as only "partly relevant".

Acknowledgements

This work was supported by the Czech Science Foundation (grant no. 19-26934X) and CELSA (project no. 19/018). In this work, we used data and tools provided by the LINDAT/CLARIAH-CZ Research Infrastructure (<https://lindat.cz>), supported by the Ministry of Education, Youth and Sports of the Czech Republic (project no. LM2018101).

We thank our friends and colleagues that contributed to the annotation process and anonymous reviewers for their valuable feedback.

Going beyond research datasets: Novel intent discovery in the industry setting

Aleksandra Chrabrowa, Tsimur Hadeliya, Dariusz Kajtoch,
Robert Mroczkowski, Piotr Rybak

ML Research at Allegro, Poznań, Poland
{firstname.lastname}@allegro.pl

Abstract

Novel intent discovery automates the process of grouping similar messages (questions) to identify previously unknown intents. However, current research focuses on publicly available datasets which have only the question field and significantly differ from real-life datasets. This paper proposes methods to improve the intent discovery pipeline deployed in a large e-commerce platform. We show the benefit of pre-training language models on in-domain data: both self-supervised and with weak supervision. We also devise the best method to utilize the conversational structure (i.e., question and answer) of real-life datasets during fine-tuning for clustering tasks, which we call *Conv*. All our methods combined to fully utilize real-life datasets give up to 33pp performance boost over state-of-the-art Constrained Deep Adaptive Clustering (CDAC) (Lin et al., 2020) model for question only. By comparison CDAC model for the question data only gives only up to 13pp performance boost over the naive baseline.

1 Introduction

Allegro is one of largest the e-commerce marketplace in Central Eastern Europe region that connects buyers and merchants. It has millions of active users. Therefore, the good functioning of the Customer Experience (CX) department is crucial as it provides the necessary support, resolves emerging issues, and answers user questions.

Task-oriented chatbots relieve humans by automatically resolving the most repetitive and trivial issues. They usually have a pre-defined set of user intents with matching template answers. Then, when a user asks a question, the intent classifier detects the question intent and returns the matching response. Creating a reliable and comprehensive chatbot requires massive work to discover, define, and maintain a set of intents with training examples. With the continuous development of marketplace

platforms, new intents constantly appear as new features are introduced. Therefore, the automated intent discovery system becomes a critical component.

Novel intent discovery is performed offline on historical data. In the context of personalized intelligence assistants existing approaches (Lin et al., 2020; Gao et al., 2021; Vedula et al., 2022) focus on learning transferable features with utterance encoders that guide the discovery on unlabeled data with a handful of labeled examples belonging to known intents. However, at *Allegro* our main communication form is emails, and we have access to much richer conversational data that can improve discovery performance. A large body of historical conversational data (user questions and consultants' answers) can be leveraged in two ways. Firstly, to better initialize message encoders and secondly by performing intent discovery on conversational data as an additional signal. Additionally, a form of weak supervision is available: keywords (or tags) added by the consultants that help them understand past cases.

The paper's main contribution is the demonstration that incorporating additional signals like conversational structure or weak labels into the existing intent discovery method results in better overall performance. We pre-trained for domain adaptation three encoders using conversational data and weak labels. We devised *Conv*, a method for fine-tuning on conversational data (i.e., question and answer) for the clustering task using a three-headed encoder. To the best of our knowledge, this result was not reported in the public literature.

2 Related Work

2.1 Discovering novel intents

The goal of novel intent discovery is to identify groups of similar utterances in unlabeled data with the assistance of limited labeled data. The Con-

strained Deep Adaptive Clustering (Lin et al., 2020, CDAC) uses dense intent representation on top of the pre-trained BERT backbone to learn similarity functions in a semi-supervised contrastive manner. It is then utilized in the clustering algorithm. In a real-world scenario of personal assistants (Gao et al., 2021; Vedula et al., 2022) use a pre-trained BERT model as a backbone encoder with supervised contrastive learning to transfer distance function to unlabeled data for clustering. Unlike this work, the authors use only the question field and English *BERT-base* uncased model for initialization. They do not use in-domain unlabeled data or weak supervision for backbone pre-training.

2.2 Transfer learning

General-purpose pre-trained encoders like BERT are not ideal. Tasks involving domain-specific texts like, e.g., science corpus, clinical notes, or e-commerce product descriptions benefit more from additional pre-training on in-domain data due to better suited vocabulary and word embeddings to domain specific problems (Beltagy et al., 2019; Huang et al., 2019; Tracz et al., 2020; Gururangan et al., 2020). Similarly, for conversational tasks *ConveRT* (Henderson et al., 2020a) substantially outperforms BERT in neural response selection. Additionally, industrial-scale training on weakly supervised datasets leads to improvements in several NLP tasks (Bach et al., 2018).

3 Method

3.1 Problem statement

Given unlabeled instances \mathcal{D} , the goal is to automatically cluster utterances into \mathcal{I} classes, which are not known *a priori*. We also assume that we are given labeled instances \mathcal{D}^k with \mathcal{I}_k known set of intents and $\mathcal{I} \cap \mathcal{I}_k \neq \emptyset$. Unlabeled instances may belong to both known intents \mathcal{I}_k and unknown ones $\mathcal{I}_u = \mathcal{I} \setminus \mathcal{I}_k$.

3.2 Framework overview

Our novel intent discovery framework consists of representation learning (Bengio et al., 2013) and subsequent clustering with K-means (Lloyd, 1982). We propose the following to improve text representations for real-life novel intents discovery in the communication domain:

- Efficient initialization with pre-trained encoders, adapted to the e-commerce domain

by optimization for weak training signals and conversational structure of the data.

- Fine-tuning for the clustering task with state-of-the-art training scheme (i.e., CDAC) adapted to use all the conversational data (i.e., question and answer). *Conv* is our proposed method to train a conversation structure-aware encoder with three-headed architecture.

In the following sections, we describe each component in more detail.

3.3 Initialization

An essential step in the deep learning process is initialization. Proper initialization is crucial in training representations for discovering new intents with clustering. The effectiveness of the existing clustering algorithms depends heavily on the quality of the representation encoder. In this work, we identified this dependency and proposed a generic approach for an efficient encoder pre-training in the conversational domain.

3.3.1 Domain specific data structure

We operate in the e-commerce domain with a two-sided marketplace. Customers can seek support by exchanging messages via email or chat. The former are typically longer and include a more formal boilerplate. A dialog may be held between merchants and CX support, buyers and CX support, and directly between buyers and merchants. All messages are written in Polish.

3.3.2 Domain adaptation

We prepared two self-supervised models based on *BERT-base* (Devlin et al., 2019) architecture. We started from a general domain encoder *HerBERT* (Mroczkowski et al., 2021). We used a training corpus of 68M conversation threads with 184M messages and 8314M words. We included both emails and chats exchanged between all parties (merchants, CX support, and buyers).

- *AlleBERT* is *HerBERT* fine-tuned with Masked Language Model (MLM) objective.
- *AlleConveRT* is *AlleBERT* further fine-tuned on the same dataset but with the mixture of MLM and Conversational Contrastive Loss (CCL) (Henderson et al., 2020b).

The details of the training procedure for each of the pre-trained encoders can be found in Appendix E.

3.3.3 Weak supervision

In the case of email communication exchanged with CX support, every message includes at least one of 512 tags. These labels roughly identify the problem solved. They are assigned by CX consultants often in a noisy manner. We utilized this weak signal and prepared *TagBERT* encoder in a two-stage process. Firstly, we finetuned *HerBERT* with MLM and Message Threads Structural Objective (MTSO) (Wang et al., 2020) on all internal communication data (emails and chats). Secondly, we finetuned it on a multi-label classification task on *CX weakly supervised* dataset that includes 2.5M messages in the email domain exchanged between merchants or buyers and CX support. Details of the training procedure can be found in Appendix E.

3.4 Conv, conversation structure aware encoder

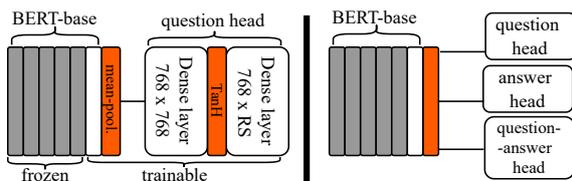

Figure 1: Representation model based on BERT-base encoder used in the discovery pipeline. On the left version with one head. On the right *Conv*, our conversational model with three separate trainable heads for the question, answer, and question-answer concatenation. The parameters of the encoder are frozen except for the last transformer block.

As depicted in Fig. 1, we used an encoder with *BERT-base* architecture (Devlin et al., 2019) followed by an average pooling¹ and three projection heads with two linear layers and *Tanh* non-linearity in between (Lin et al., 2020).

The three-headed model works with conversational input containing a pair of texts: the user’s question and the consultant’s answer². Two heads project each input separately, and the third one handles additional signals from the question-answer concatenation into one string of text. Each of the inputs is fed into encoder separately. A common underneath encoder is updated jointly with a gradient from all heads from the total loss given by the

¹Unlike many implementations, the hidden states for padding tokens are not averaged.

²While encoding question and answer, are preceded with special tokens for question and answer.

weighted average of losses for each head:

$$\begin{aligned} \mathcal{L}_{Conv}(X, Y, \theta) = & \lambda_Q \cdot \mathcal{L}(X_Q, Y, \theta_Q) \\ & + \lambda_A \cdot \mathcal{L}(X_A, Y, \theta_A) \\ & + \lambda_{QA} \cdot \mathcal{L}(X_{QA}, Y, \theta_{QA}). \end{aligned} \quad (1)$$

Here $X = (X_Q, X_A, X_{QA})$ is the array of inputs (all examples), i.e. all questions, all answers, all question-answer concatenations respectively. Y are the input labels³. $\theta = (\theta_Q, \theta_A, \theta_{QA})$ is the array of parameter sets for individual inputs *BERT-base* parameters are shared as depicted in Figure 1. The hyperparameters $\lambda = (\lambda_Q, \lambda_A, \lambda_{QA})$ govern how conversational structure is utilized for any choice of the training scheme, whereas the precise form of the loss terms \mathcal{L} depends on the choice of the training scheme described in Sec. 3.5. For example if we choose $\lambda = (1, 0, 0)$, and compute \mathcal{L} according to CDAC training scheme, we follow the original CDAC setup with the question field only. By using $\lambda = (0, 0, 1)$ and computing \mathcal{L} according to CDAC training scheme, we effectively only concatenate question and answer strings and feed it into the model instead of the question string.

In our method *Conv* for training conversation structure-aware encoder, we trained the representation encoder with uniform heads contribution $\lambda = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ starting from initializations described in Section 3.3. The final representation used for clustering is an embedding from the head for question-answer concatenation.

To speed up training with large batches, we kept the weights of the encoder frozen except for the last transformer layer. The first linear layer keeps the *BERT-base* dimension of the representations (i.e., 768). The second linear block output dimension is a representation size hyperparameter.

3.5 Training scheme

Up to this point, we are able to use any framework for finetuning the representation encoder for intent discovery with clustering. With that said, we propose to use two potential approaches for real-world CX communication data.

Static. In a setup where we do not have any labeled data available, we extract text representation from the pre-trained encoder by average pooling without additional training.

³Since we deal with unsupervised/semi-supervised algorithms, some examples are unlabelled.

Constrained DAC (CDAC) (Lin et al., 2020). The method generalizes the Deep Adaptive Clustering (DAC) (Chang et al., 2017) scheme for partially labeled data and trains with a contrastive loss on both distance-based pseudo-pairs and exact pairs given by intent labels. It is semi-supervised since it utilizes both labeled and unlabeled examples from the train set. We adapted CDAC training scheme to *Conv*, our three-headed, conversation structure-aware encoder (see Sec. 3.4). Details of the DAC method are in Appendix B.1, and details of the CDAC method are in Appendix B.2.

4 Evaluation

We describe our experimental setup for novel intent discovery. We prove the efficiency of the proposed method on real-world communication datasets. To verify gains from different framework components, we present more results in the ablation section (Sec. 5).

4.1 Real-world internal datasets

We used three internal datasets: *Purchase*, *Delivery* and *Retail* from real traffic to CX support at *Allegro* in Polish language. CX consultants manually annotated the datasets with intent labels. Categories of email queries to the CX team are more fine-grained than the widely used *Banking77* (Casanueva et al., 2020) dataset. Moreover, such real-world datasets are highly imbalanced, with some intents overlapping. Basic dataset statistics are shown in the Table 1. The user emails vary in length and style and may contain irrelevant parts. Each dataset includes messages of different quality and specificity ranging from uninformative chit-chat to well-written ones. In datasets, only the first question and direct answer are included, and all further messages from the correspondence thread are omitted. The *Purchase* and *Delivery* cover conversations between buyers and CX consultants. *Retail* is communication between buyers and merchants, so conversation topics and structure are different. We use a stratified 80/10/10 train/val/test split.

We use two public benchmark English datasets from task-oriented dialog systems: *CLINC150* (Larson et al., 2019) and *Banking77* (Casanueva et al., 2020) in Dataset splits follow exactly the experimental setup used in (Zhang et al., 2020) in ablation study in Section 5.2 to increase the reproducibility of our work. In other ablations it is impossible due to

missing conversational and weak label signal.

Basic statistics of the datasets are in the Table 1. Further details are in Appendix A.

4.2 Experimental setting

We build a controlled open-world intent discovery setup, following the setup proposed in (Lin et al., 2020; Zhang et al., 2020). We prepared novel intents by randomly masking all examples from 50% of intents in the training set. The remaining intents serve as known intents and are additionally partially masked. We masked 50% of all remaining examples. We apply the representation learning framework: we take in-domain encoders described in Section 3.3.2 and 3.3.3 and do the fine-tuning step (described in Section 3.4 and 3.5). After the training phase, we cluster the whole test dataset with K-means. We performed clustering with the ground truth number of clusters (i.e., the number of intents in the dataset).

We run experiments with hyperparameters (i.e., representation size, batch size, and learning rate) fixed. We have described the method of their selection in Appendix D.

We use five random seeds, which govern intent masking and weight initialization. We train the model for 100 epochs on a single machine with NVIDIA V100 GPU. It takes a few hours to run a single fine-tuning experiment for all seeds for a single setting (dataset, training scheme etc.).

4.3 Metric⁴.

We compute metrics based on cluster ids from K-means algorithm and ground truth labels. The discovery quality is probed with three standard clustering metrics, i.e., Accuracy (ACC) using the Hungarian algorithm, Normalized Mutual Information (NMI), and Adjusted Rand Index (ARI). We also introduce two additional metrics. First, the *binary F1-score* i.e., macro F1-score with a majority vote on cluster label calculated on the whole dataset where all known intents are one class, and all novel intents are the second class. Second, the *macro F1-score* with a majority vote on the cluster label. It turns the clustering quality problem into a multi-label classification. In the main part of the paper, we report **AVG** i.e., the average of five metrics over all seeds. AVG increases with clustering quality up to 100%. AVG is the primary metric used for

⁴We publish the code for our metrics: <https://github.com/allegro/ml/tree/main/publications/intent-discovery-metrics/>

Dataset	# intents	# examples	# examples per intent				mean length (characters)	
			mean	min	max	entropy	question	answer
<i>Banking77</i>	77	13.1k	170±33	75	227	0.992	60±40	-
<i>CLINC150</i>	150	22.5k	150±0	150	150	0.999	40±20	-
<i>Purchase</i>	22	2.7k	121±50	29	240	0.972	320±280	1060±400
<i>Delivery</i>	23	3.0k	130±55	57	221	0.973	330±360	860±410
<i>Retail</i>	105	13.8k	133±124	22	664	0.930	160±190	740±830

Table 1: Downstream tasks datasets characteristic. Class imbalance is measured by the average number of examples per intent and the normalized Shannon’s entropy of the intent distribution (which is 1 for the perfectly balanced case and lower in case of class imbalance). Further details are in Appendix A

Method	<i>Purchase</i>	<i>Delivery</i>	<i>Retail</i>
Static	37.0±4.1	31.1±1.3	28.8±0.7
CDAC	50.2±6.6	40.9±4.5	36.5±1.7
Our	83.2±3.2	64.2±6.3	45.4±4.0

Table 2: Static baseline and CDAC representations compared with our framework on novel intent discovery task for real-world data. Our framework combines *TagBERT* pre-trained encoder, CDAC training scheme, and *Conv* method for using the conversation structure. AVG metric averaged over five seeds.

model selection. Additionally, to facilitate comparison with other research, the five metrics are listed separately in Appendix F for all experiments. In Appendix F we give more details on how we compute metrics or test for statistical significance.

4.4 Results

Table 2 shows the AVG metric for our best-performing model. Five individual metrics are listed in Table 8. We significantly improve intent discovery compared with baselines. *Our* model uses *TagBERT* (see Section 3.3.3) as initialization and is trained with the CDAC scheme. While training, we used both question and answer fields and utilized conversational structure-aware encoder *Conv* introduced in Sec. 3.4. The baselines (*Static* and *CDAC*) are based on the general domain *HerBERT* encoder and use the question field only. We improved over the second-best CDAC, depending on the dataset, by 8.9pp to 33pp. The performance gap of *our* framework to the *CDAC* baseline is greater than the superiority of *CDAC* over the naive baseline, *static* embeddings, which is between 7.7pp and 13.2pp.

Initialization	<i>Purchase</i>	<i>Delivery</i>	<i>Retail</i>
<i>HerBERT</i>	65.9±6.2	44.7±3.7	37.2±2.0
<i>AlleBERT</i>	66.4±6.6	49.2±6.4	44.2±2.2
<i>AlleConveRT</i>	73.1±8.8	57.9±5.9	49.3±2.1
<i>TagBERT</i>	83.2±3.2	64.2±6.3	45.4±4.0

Table 3: Impact of initialization for novel intent discovery task. *Conv* conversation structure-aware encoder was trained with the CDAC scheme from different initialization. AVG metric averaged over five seeds with standard deviation.

5 Ablation

We attribute the improvement in performance to all three method components: domain adaptation during pre-training with conversational and weak label signal, state-of-the-art training scheme CDAC, and leveraging of conversation structure with our *Conv* method introduced in Section 3.4.

5.1 Initialization

In this section, we show the effect of initialization on the novel intent discovery task. We trained a conversation structure-aware encoder with a CDAC scheme using four different initializations.

AVG metric is reported in Table 3 and individual metrics are shown Table 9. Comparing *AlleBERT* with *HerBERT*, we can see that domain-adapted initialization improves 1 to 7pp for discovering new intents. Further adaptation of the starting encoder with the loss of ConveRT improves at least 5pp. Summarizing *AlleBERT* and *AlleConveRT* initializations bring gains for all internal datasets. For the CX domain (*Purchase* or *Delivery*), the best initialization was provided by *TagBERT*. Pre-training with weak labels introduced additional training information that turned out to be transferable for the

Training scheme	<i>Banking77</i>	<i>CLINC150</i>	<i>Purchase</i>	<i>Delivery</i>	<i>Retail</i>
Static	41.7±1.0	55.9±1.4	35.5±4.1	31.0±2.4	29.6±0.8
DAC	51.8±1.8	64.6±1.3	24.1±0.7	24.0±0.9	27.3±4.4
Supervised	65.2±2.1	73.2±0.6	38.2±2.1	33.5±2.2	30.1±0.5
CDAC	61.8±2.8	70.4±1.4	52.9±7.3	42.3±3.6	39.2±1.2

Table 4: Evaluation of training schemes for novel intent discovery. We report AVG metric averaged over five seed with standard deviation. Models use *BERT-base* (English datasets) or *AlleBERT* (Polish datasets) encoder and question input only. The best results are in bold.

downstream task. The simultaneous drop in quality on the *Retail* dataset originating from the domain for which we did not have noisy labels confirms this phenomenon.

5.2 Training schemes

We compare two training schemes *Static*, and *CDAC* from Sec. 3.5 with two additional baseline methods *DAC* and *Supervised*. For *Supervised* training scheme, we use Large Margin Cosine Loss (LMCL) (Wang et al., 2018) to learn representation from labels. We discard unlabeled data from the train set. We train the models for all four schemes with question input only and *BERT-base* (Devlin et al., 2019) for English and *AlleBERT* for Polish datasets.

This ablation study is the only case when we can use two public benchmark English datasets from task-oriented dialog systems: *CLINC150* (Larson et al., 2019) and *Banking77* (Casanueva et al., 2020). Unfortunately, public benchmark datasets lack the answer data, a large amount of unlabeled data, and weak labels. However, including them in this ablation study increases the reproducibility of our work and brings interesting insights.

AVG metric is reported in Table 4 and individual metrics can be found in Table 10. For all datasets, there is a gain from using intent labels (*Supervised* and *CDAC*). For public datasets among unsupervised methods, DAC outperforms static representations. However, supervised training is better than semi-supervised CDAC. The results are the opposite for the internal datasets. DAC is better than static representations, and semi-supervised CDAC is better than supervised training. We hypothesize that different real-world and benchmark datasets results might be due to dataset quality and size differences. In general, benchmark datasets are larger and more balanced. Moreover, mail messages from real-world e-commerce are longer and noisier on average. It is an open question how this trend holds

for other real-life datasets.

To sum up, there is a gain from intent labels for all datasets. Optimal solutions for public benchmarks and real-world internal datasets differ. CDAC is the best training scheme that uses intent labels for internal datasets.

5.3 Conversational structure

We examine if any further gains in performance can be obtained from incorporating the answer field signal. We conduct experiments only on the internal datasets. We use only the best training scheme, i.e., *CDAC*. We examine four training configurations: only question representation Q trained with $\lambda = (1, 0, 0)$, only answer representation A trained with $\lambda = (0, 1, 0)$, question-answer concatenation QA concatenation trained with $\lambda_3 = (0, 0, 1)$, using question and answer in a simpler two-headed model QA two heads trained with $\lambda = (\frac{1}{2}, \frac{1}{2}, 0)$ and full three-headed conversational model *Conv* trained with $\lambda = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ described in detail in section Sec. 3.4.⁵

AVG metric is reported in Table 5 and individual metrics can be found in Table 11. The answer alone performs worse than the question alone. We hypothesize that it is due to many non-informative generic answers⁶. Perhaps for other real-world datasets consultant’s answer may be superior to the user’s questions. Passing only the question signal is a strong baseline. Let us check if it is possible to incorporate signals from both question and answer fields in a way that improves performance over Q , question field only baseline. The most straightforward extension, QA concatenation, which requires only inputting different inputs to the same model is slightly better but does not pass the statistical

⁵For multi-headed encoders, we chose the best of all possible final representations (output from any head, or concatenations of outputs from multiple heads).

⁶e.g., *Thank you for your message. Let me check some details and reply later.*

	<i>Purchase</i>	<i>Delivery</i>	<i>Retail</i>
<i>Q</i>	52.9±7.3	42.3±3.6	39.2±1.2
<i>A</i>	51.7±5.5	37.6±4.5	30.5±1.5
<i>QA concat.</i>	55.1±3.8	47.3±3.4	43.4±3.1
<i>QA two head.</i>	56.4±5.9	46.9±5.4	40.2±1.7
<i>Conv</i>	66.4±6.6	49.2±6.4	44.2±2.2

Table 5: Evaluation of conversational structure for novel intent discovery. We report AVG metric averaged over five seed runs with standard deviation. Models use *AlleBERT* initialization, CDAC training scheme, and various inputs, i.e., question *Q*, answer *A*, or both fields (*QA*) in three model variants; *QA concatenation*, *QA two heads*, and *Conv*. The best results are in bold.

significance test. The same goes for the more sophisticated *QA two heads* variant. Only our method *Conv*, a three-headed encoder is better than *Q* with statistical significance. Incorporating both question and answer signal leads to further improvements.

To sum up, after examining multiple ways to include the conversational signal, we conclude that our method *Conv* with a three-headed encoder improves the performance by 5 to 13.5pp.

6 Commercial deployment

6.1 Production pipeline overview

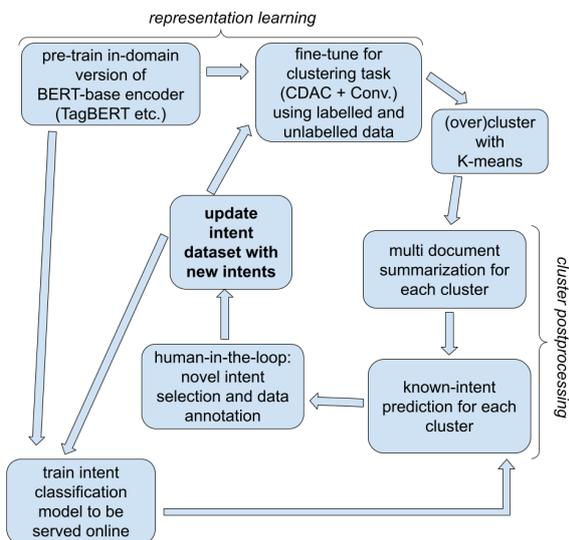

Figure 2: Intent discovery pipeline deployed at *Allegro* with human-in-the-loop carrying out the novel intent selection and data annotation. Representation learning components are subject to experiments in this paper. The main outcome of the pipeline is an updated intent detection dataset, which can be used to train a better intent classification model.

The method we described and verified experimentally is a part of a larger multi-component system for continuous intent discovery deployed commercially, shown in Fig. 2. Here we briefly list the major components of our production pipeline to give the bigger picture:

1. *Representation learning.* Representation learning plays a core role in our pipeline. This component is subject to experiments in this paper and consists of two subcomponents:

- (a) *In-domain pre-training of encoders.* Encoders with *BERT-base* architecture are pre-trained on large chunks of historical data. We include additional signals such as conversational structure (i.e. question and answer) and weak label signal (Section 3.3.2 and 3.3.3). The encoders are reused for the intent classification model.
- (b) *Fine-tuning for the clustering task.* We further train in-domain encoders. If there exists annotated data, we use semi-supervised CDAC with *Conv* (Section 3.4). Otherwise, we use static embeddings.

2. *(Over)clustering with K-Means.* We cluster representations to discover intent groups in the data. The number of novel intents is required by K-Means. We overestimate this value as it is less time-consuming to manually merge clusters with the same intent.

3. *Cluster postprocessing.* Various postprocessing steps make analyzing the clusters by the human annotators more efficient:

- (a) *Multi-document summarization.* The summarization module, provides human-readable candidates for the intent name instead of cluster ids. First, we train a logistic regression classifier with bag-of-words features to predict cluster ids. Then, we identify the most informative sentence in each message using the classifier coefficients (Angelidis and Lapata, 2018). Finally, we select the five most central sentences across all messages (Zheng and Lapata, 2019).
- (b) *Known intent prediction.* We need to distinguish clusters with known intents from clusters with potentially novel intents.

Since the labeled messages are typically a small subset of the training dataset, we infill intents for the unlabeled examples with an intent classifier and present this information to human annotators.

4. *Novel intent selection and data annotation.* Human annotators manually analyze all discovered clusters and choose which novel intents to include in the taxonomy. They annotate all messages from clusters to be included in the labeled dataset to ensure the high coherence of newly discovered intents.

CX intent dataset updated with new intent is the end product of our intent discovery pipeline. Its primary purpose is to train an intent classifier to be served in real-time to CX consultants. It is a complex pipeline of its own. It has similar architecture to the representation learning model in the intent discovery pipeline and it reuses pre-trained encoders. Even though the consultant's answer and the consultant's weak label are not known at the serving time of the intent classification model, we leverage these signals to build a better intent dataset and directly train a better intent classification model.

6.2 Commercial benefits case study

Thanks to the deployed pipeline, we doubled the number of defined intents for customer support within one year. Initially, the taxonomy consisted of 100 classes manually defined by the CX consultants. The commercial deployment of the intent discovery pipeline happened at the moment when the domain experts failed to find any new intents manually. Roughly 50 new intents were discovered thanks to our intent discovery pipeline. The selected clusters were reasonably pure: over 90% (mean and median) of examples from the selected clusters were labeled as the given intent. Additional examples for the new intents were further added (active learning etc.) and at the moment, the examples from the clustering process are at least 40% of all examples for 50 automatically discovered intents. Currently, after extending our taxonomy from other sources as well, our taxonomy has roughly 180 intents.

In addition, the pipeline decreased the time required to define novel intents from weeks to days with the additional benefit of analyzing several-fold more messages. The more comprehensive taxonomy significantly impacts the total benefit from the

automation process, improves user experience by providing faster responses, and saves the cost of hiring additional CX consultants.

7 Conclusions

This paper describes an intent discovery pipeline deployed on a large e-commerce platform. The access to real-life datasets allows extending the established intent discovery models to better leverage vast amounts of unlabelled data, its conversational structure, and additional signals like weak labels. In particular, we learn the following lessons:

1. Among multiple ways to handle conversational data, *Conv*, our generalization of the CDAC model to a three-headed encoder to use all available conversational data (i.e., question and answer) increases the performance of the intent discovery pipeline the most. See Section 5.3.
2. The significant gains also come from pre-training the encoder on an unlabelled in-domain dataset with conversational structure and weak labels (*TagBERT*). See Section 5.1. Therefore, we recommend a system architecture that enables weak labeling by the consultants by design.
3. Even though the consultant's answer and weak labels are not available at the serving time of the intent classification model, they can be used offline for novel intent discovery to build a better dataset and directly improve the intent classification. It happened for our commercially deployed pipeline. See Section 6.
4. Gains from incorporating additional signals (*Conv* method, *TagBERT*) are larger than gains from using state-of-the-art methods (CDAC) on datasets without additional signals. See Section 4.4. We advocate for a shift both in construction and research on intent detection datasets.

8 Limitations

We are aware of two major factors that may affect the generality of our research: shortcomings of the simulated novel intent discovery setup and the assumption that intent detection is a classification problem.

Simulated experiments. In the experimental section, we use small, entirely annotated datasets to analyze different design choices of the representation learning component. We naturally include only already discovered intents (does not mean these are all possible). Our masking procedure that follows research papers (Lin et al., 2020; Zhang et al., 2020) has three drawbacks. Firstly, when we mask most of the dataset, we effectively do few-shot learning, whereas, in reality, the amount of annotated data is much larger. The observed differences between design choices may be mitigated once more data is available. Secondly, real class imbalance may not be reflected in the experimental dataset due to the annotation procedure. Lastly, the ratio between batch size and dataset size is much smaller for real datasets since, in general, we are training with a large amount of unannotated data. It directly affects batch-based pair statistics when using a random sampler in CDAC algorithm. The chance that annotated examples will be present in the batch is low, and effectively we are almost entirely learning from pseudo-pairs during the semi-supervised stage.

Intent detection as classification. We treat the intent discovery as classification i.e. each utterance has only one intent. In reality, users may have more than one goal that transforms the problem into a multi-label scenario. Naturally, we could treat multi-label examples as yet another class, but we do not explore their influence on pipeline performance since they were in a significant minority.

A Dataset details

We further describe real-world internal datasets introduced in 4.1 and compare them to public benchmark datasets. Table 6 exemplifies the domain diversity of the datasets: it contains three sample intent names per dataset.

We visualize the datasets. We use publicly available pre-trained models to enable simple visual comparisons between our real-world internal datasets and any other datasets. Sentence-BERT produces English sentence embeddings by fine-tuning on semantic textual similarity STS pairs (Reimers and Gurevych, 2019). We use a variation of Sentence-BERT trained from MP-Net (Song et al., 2020). Polish version has been obtained following knowledge distillation procedure (Reimers and Gurevych, 2020; Dadas, 2019).⁷ We compute sentence embeddings for the question field or if the answer field is present, for question-answer concatenation. For each example, we compute a partial Silhouette score (using ground truth intents as cluster labels) and average it per intent. Silhouette score, designed originally for evaluating the clustering quality, takes into account the mean intra-cluster distance and the mean nearest-cluster distance for each example. We plot 2D t-SNE mappings of the embeddings, Silhouette score per intent⁸, and intent sizes in Figures 3 and 4 to visualize the datasets and the initial difficulty of the clustering task on general domain pre-trained models.

B Training schemes

B.1 Deep Adaptive Clustering (DAC)

It was introduced in (Chang et al., 2017) for the Computer Vision domain but is easily extended to text. Originally, output representation was interpreted as a probability distribution over unique classes, i.e., they used L_2 normalized features with positive elements. We relaxed this condition and trained real-valued representation for any clustering algorithm. The representation size doesn't have to match a unique number of classes in the dataset (unknown in real scenarios). For a pair of examples i, j the loss function \mathcal{L}_{ij} is

$$\mathcal{L}_{ij} = -R_{ij} \log S_{ij} - (1 - R_{ij}) \log(1 - S_{ij}), \quad (2)$$

⁷Package sentence-transformers, available at <https://sbert.net>, is used with models all-mpnet-base-v2 or sdadas/st-polish-paraphrase-from-mpnet for English and Polish respectively.

# intents	77	150	22	23	105

Table 7: Optimal representation size and batch size vs. a number of annotated intents in the datasets.

where ($R_{ij} = 1$) for positive pairs and ($R_{ij} = 0$) for negative pairs and S_{ij} is cosine similarity of representations. The pseudo-label matrix R is defined in an online fashion for every pair of examples in a batch using current model predictions i.e.

$$R_{ij} = \begin{cases} 1, & \text{if } S_{ij} \geq u(\lambda), \\ 0, & \text{if } S_{ij} < l(\lambda), \\ \text{None}, & \text{otherwise,} \end{cases} \quad (3)$$

where $u(\lambda)$ and $l(\lambda)$ are upper and lower thresholds. Pairs between the thresholds do not take part in the training. This is compensated by adding penalty term $u(\lambda) - l(\lambda)$ to the final loss. The thresholds are updated every epoch according to the formula

$$\begin{aligned} u(\lambda) &= 0.95 - \lambda, \\ l(\lambda) &= 0.455 + 0.1 \cdot \lambda, \end{aligned}$$

where update rule for λ every epoch is $\lambda = \lambda + 1.1 \cdot 0.009$ (Chang et al., 2017). We start with $\lambda = 0$. The training ends when $u(\lambda) = l(\lambda)$. The training resembles curriculum learning: we start with confident examples with very large or low cosine similarity and then introduce more uncertainty. The penalty term also reflects our confidence since it controls the strength of gradient updates.

B.2 Constrained DAC (CDAC)

This extension of DAC to a semi-supervised scenario was introduced in (Lin et al., 2020). In unsupervised case, we only use contrastive objective with pseudo-labels. Once we have annotated examples, we define true positive and negative pairs with labels. The label matrix R has now pseudo-label part (3) and exact part

$$R_{ij} = \begin{cases} 1, & \text{if } y_i = y_j, \\ 0, & \text{if } y_i \neq y_j, \end{cases} \quad (4)$$

where y_i denotes encoded label for i -th example. Since our batch now includes annotated and unannotated examples, we need to redefine pseudo-labels. We consider three cases. Firstly, pseudo-labels can be defined only among unannotated examples. Secondly, we can allow pseudo-labels between pairs of annotated and unannotated examples. Lastly, we can define pseudo-labels for all possible pairs, including a scenario where pseudo-labels are defined among annotated pairs. We chose the second scenario.

Additional modification is alternating training. Even epochs use only annotated data and no threshold penalty. Odd epochs use the whole dataset and pseudo-label matrix as well as exact. The loss in the supervised phase is additionally scaled by the $\delta \geq 1$ hyperparameter to control the weight put on annotated data.

C Metrics⁹.

We choose metrics for our experiments. Three clustering metrics measure the separation of novel intents from each other:

- **Accuracy (ACC)** measures clusters purity. Cluster and ground-truth labels are matched with the Hungarian algorithm.
- **Normalized Mutual Information (NMI)** specifies the amount of uncertainty about class labels given cluster labels.
- **Adjusted Rand Index (ARI)** checks for all sample pairs whether their assigned and ground truth labels are the same.

ACC, NMI, and ARI are calculated only on examples with a novel intent as a ground truth label.

The separation of the novel from the known intents is measured by:

- **Binary F1-score.** It is a macro F1-score with a majority vote on the cluster label calculated on the whole dataset where all known intents are one class and all novel intents are the second class.

Last but not least, there is a metric that measures both the separation between novel intents and the separation of the novel from the known:

- **Macro F1-score** with majority vote on cluster label. It turns the clustering quality problem into multi-label classification.

The macro average is calculated only for novel intents. Examples with any ground truth label may be included¹⁰.

All metrics increase with clustering quality up to 100%. We use five random seeds, which govern intent masking and weight initialization. In

⁹We publish the code for our metrics: <https://github.com/allegro/ml/tree/main/publications/intent-discovery-metrics/>

¹⁰See: https://scikit-learn.org/stable/modules/generated/sklearn.metrics.f1_score.html

the main part of the paper, we report **AVG** i.e., the average of five metrics listed above (which are correlated variables) overall seeds. AVG is the primary metric used for model selection. Whenever in doubt, we confirm that the difference between AVG metrics is statistically significant with correlated T-Test with a p-value=5% threshold. Additionally, to facilitate comparison with other research, for all experiments, the five metrics are listed separately in Appendix.

D Initial fine-tuning

We start our experiments with fine-tuning representation size, batch size, and learning rate hyperparameters for the CDAC training scheme¹¹. For every dataset, we optimize the hyperparameters in two steps: selecting optimal representation size via grid search over the representation sizes {16, 32, 64, 128, 256} and learning rates {1e-05, 5e-05, 1e-04} and then selecting the optimal learning rate and batch size via grid search over batch sizes {16, 32, 64, 128, 256, 512} and the same learning rates as step 1. Tab. 7 shows the relation of the selected hyperparameters to the number of intents. The selected hyperparameters are later fixed in the experiments. Additionally, to improve training stability, we perform an additional learning rate search again within values {1e-05, 5e-05, 1e-04} for every setup which uses *Conv* method separately.

E Pre-trained encoders (details)

To leverage large amounts of historical data, we compare four self-supervised encoders, and one supervised trained on conversational data. The training procedure for each encoder is described in detail below for reproducibility. The encoders are used for experiments in Sec. 4.4.

HerBERT State-of-the-art *BERT-base* language model for Polish (Mroczkowski et al., 2021) trained with Masked Language Model (MLM) objective.

AlleBERT The model is a result of further fine-tuning *HerBERT* on internal unsupervised conversational data. The single training example contains a conversation thread clipped to 512 tokens. We always clip threads to a random subsequence of whole consecutive utterances to persist in a conversational context. *AlleBERT* is trained with the

¹¹We focus on CDAC encouraged by initial good results for CDAC and high cost of fine-tuning each training scheme separately.

MLM objective for 100k steps with the linearly decaying learning rate schedule (peak value 1e-05) and the batch size of 224. The training on four NVIDIA A100 GPUs lasted 2 days.

AlleConveRT The model is a result of further fine-tuning of the *AlleBERT* on the same data but with the mixture of two objectives, MLM loss with the ratio of 0.2 and Conversational Contrastive Loss (CCL). Following ConveRT (Henderson et al., 2020b) we leverage the structure of the conversations with alternately exchanged utterances in a metric learning setup. Positive examples are consecutive messages from a single conversation, and negatives come from answers within the training batch. To reduce the overfitting to specific utterances, we use label smoothing with the value of 0.2 (same as (Henderson et al., 2020b)). To utilize conversational data structure, we add two projection heads on top of the *AlleBERT* encoder, one for the question and answer representations¹². *AlleConveRT* is trained for the 280k steps with the peak learning rate 1e-05 and the batch size of 448. The training on four NVIDIA A100 GPUs lasted 4 days.

TagBERT The model is trained in two-stage fine-tuning of the first version of *HerBERT* (Rybak et al., 2020). In the first stage, we fine-tune the model on internal unsupervised conversational data. We use MLM objective and Message Threads Structural Objective (MTSO). MTSO is Sentence Structural Objective (Wang et al., 2020) tailored to the conversation domain. During training, we swap messages with respect to threads instead of swapping sentences with respect to documents. *TagBERT* is trained for 100k steps with a batch size of 640 and a peak learning rate 8e-05.

In the second stage, we fine-tune the model on the multi-label classification task. The model predicts several of the 512 classes for each thread. The noisy and highly imbalanced labels come from tags that CX consultants add to the conversation threads, roughly identifying the problem solved. The training dataset contains 2.5M messages. *TagBERT* is trained for 38k steps with a peak learning rate of 1.6e-04 and a batch size of 512. The training on sixteen NVIDIA P100 GPUs lasted 8 hours.

F Results (details)

¹²Answers in our data come from two sources: CX consultants and sellers.

¹École Polytechnique, ²Linagora, ³AUEB

Abstract

The rapid development of large pretrained language models has revolutionized not only the field of Natural Language Generation (NLG) but also its evaluation. Inspired by the recent work of BARTScore: a metric leveraging the BART language model to evaluate the quality of generated text from various aspects, we introduce DATScore. DATScore uses data augmentation techniques to improve the evaluation of machine translation. Our main finding is that introducing data augmented translations of the source and reference texts is greatly helpful in evaluating the quality of the generated translation. We also propose two novel score averaging and term weighting strategies to improve the original score computing process of BARTScore. Experimental results on WMT show that DATScore correlates better with human meta-evaluations than the other recent state-of-the-art metrics, especially for low-resource languages. Ablation studies demonstrate the value added by our new scoring strategies. Moreover, we report in our extended experiments the performance of DATScore on 3 NLG tasks other than translation Code is publicly available¹.

1 Introduction

Massive pretrained language models have brought significant improvement to NLG tasks (Lewis et al., 2020). Recent systems can even generate texts of higher quality than human-annotated ones (Peyrard, 2019). At the same time, standard metrics, such as BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004), for translation and summarization respectively, have not evolved for the past two decades (Bhandari et al., 2020). These metrics rely on surface lexicographic matches, making them particularly unsuitable for evaluating modern systems operating with embeddings at the semantic level that often generate paraphrases (Ng and Abrecht,

2015). To address this issue, many metrics have been proposed (Sai et al., 2022), but none of them were widely adopted until the release of BERTScore (Zhang et al., 2019) and MoverScore (Zhao et al., 2019). These metrics take advantage of large pretrained language models like BERT (Devlin et al., 2019), which are now being used in nearly all NLP tasks (Qiu et al., 2020; Min et al., 2021).

In this work, we focus on the task of evaluating machine translation. We propose an extension of BARTScore (Yuan et al., 2021), a recent metric exploiting the BART seq2seq language model (Lewis et al., 2020) to evaluate the quality of generated text from various aspects. BARTScore covers four evaluation facets: Faithfulness, Precision, Recall, and F-score, derived from different generation directions between the *source* text, the *hypothesis* (the text generated by a system given the source), and the *reference* (the reference text for the generation, often provided by human annotators). The scores are obtained by pairing the three entities differently at the input or the output side of a trained seq2seq model for fetching conditional generation probabilities.

Based on BARTScore, and motivated by the general idea and positive effect of data augmentation techniques, we found that adding augmented, translated copies of the source and reference texts in BARTScore, can greatly help evaluate the quality of the hypothesis translation. We also propose two novel score averaging and term weighting strategies to improve the original score computing process of BARTScore. Results and ablation studies show that our metric DATScore (Data Augmented Translation Score) outperforms the other recent state-of-the-art metrics, and our new scoring strategies are effective. Moreover, the performance of DATScore is also reported on three other NLG tasks than translation: data-to-text, summarization, and image captioning.

To the best of our knowledge, no prior work has

¹https://github.com/moussaKam/dat_score

been done on leveraging data augmentation techniques for untrained NLG evaluation metrics. Our work will help fill this gap. Our contributions include:

- 1) Inspired by BARTScore, we developed DATScore, incorporating augmented data translated from the source and reference texts. DATScore is an untrained and unsupervised translation evaluation metric that offers a larger performance boost in evaluating low-resource language generation. In contrast to other widely adopted metrics, DATScore can efficiently incorporate both the source and reference texts in the evaluation.
- 2) We introduced a novel one-vs-rest method to average the scores for different generation directions with different weights, which improves over the simple arithmetic averaging method used in BARTScore.
- 3) We proposed a novel entropy-based scheme for weighting the target generated terms so that higher informative tokens receive more importance in accounting for the score, which outperforms the naive uniform weighting employed in BARTScore.

2 Related work

2.1 Translation evaluation metrics

BLEU (Papineni et al., 2002) is the de facto metric for evaluating machine translation. It simply calculates n -gram matching between the reference and the hypothesis using precision scores with a brevity penalty. METEOR (Banerjee and Lavie, 2005) was developed to address two drawbacks of BLEU. It is F-score based (thus taking recall into account) and allows for a more relaxed matching, based on three forms: extract unigram, stemmed word, and synonym with WordNet (Miller, 1994). Apart from the above word-based metrics, some approaches operate at the character level. For example, chrF (Popović, 2015) computes the overall precision and recall over the character n -grams with various values of n . More recently, static word embeddings (Mikolov et al., 2013) have enabled capturing the semantic similarity between two texts possible, of what the historical metrics are incapable. Several metrics have been proposed to incorporate word vectors. For example, MEANT 2.0 (Lo, 2017) evaluates translation adequacy by measuring the similarity of the semantic frames and their role fillers between the human and machine translations.

Lately, pretrained language models have become popular, because they provide context-dependent

embeddings. This proved beneficial to all NLP tasks, but also to evaluation metrics. For example, using a modified version of the Word Mover’s Distance (Kusner et al., 2015), the Sentence Mover’s Similarity (Clark et al., 2019) measures the minimum cost of transforming one text into the other as the evaluation score, where sentences are represented as the average of their ELMo word embeddings (Peters et al., 2018). BERT_R (Mathur et al., 2019) computes approximate recall based on the pairwise cosine similarity between the BERT word embeddings (Devlin et al., 2019) of two translations. UniTE (Wan et al., 2022) proposes a unified framework for modeling three evaluation prototypes: estimating the quality of the translation hypothesis by comparing it with reference-only, source-only, or source-reference-combined data. UniTE is built upon XLM-R multilingual language model (Conneau et al., 2020).

Among several alternatives, BERTScore (Zhang et al., 2019) and MoverScore (Zhao et al., 2019) have received more attention, and have been adopted for reporting results in recent NLG publications (Lin et al., 2022; Weston et al., 2022). They both are unsupervised, general-purpose metrics and leverage BERT-like language models, however, with one difference lying in the similarity function for matching the two sequence representations. BERTScore greedily matches each token from one sequence to the single most similar token in the other sequence, in terms of the cosine similarity of their token embeddings. While MoverScore conducts soft one-to-many matching using an n -gram generalization of the Word Mover’s Distance (Kusner et al., 2015).

Finally, the work closely related to ours is BARTScore (Yuan et al., 2021). Unlike all the above metrics trying to match tokens or their embeddings, BARTScore proposes a novel conceptual view. It treats the evaluation of generated text as a text generation problem, with the help of a pretrained seq2seq model BART (Lewis et al., 2020). At the time of writing, this metric represents the state-of-the-art in the NLG evaluation. We will provide more details about it in Section 3.

2.2 Data augmentation

As deep learning models are often heavily reliant on large amounts of training data, a common attempt to get around the data scarcity problem is by applying data augmentation techniques (Shorten

and Khoshgoftaar, 2019). These techniques increase the size of the training set by making slightly modified copies of already-existing instances or by creating new, synthetic ones. Such augmented data have proven to be beneficial to the training of models in a wide variety of contexts, from computer vision (Shorten and Khoshgoftaar, 2019) to speech recognition (Bird et al., 2020), to NLP (Feng et al., 2021), as it acts as a regularizer and helps reduce overfitting (Krizhevsky et al., 2012). For dealing with textual data, a suite of augmentation techniques exists. To name only a few, backtranslation (Sennrich et al., 2016) translates a text into an intermediate language and then back into the original language, as a way of paraphrasing the initial text. Contextual augmentation (Kobayashi, 2018) generates augmented samples by randomly replacing words with others drawn following the in-context word distribution of a recurrent language model. SeqMix method (Guo et al., 2020) creates synthetic examples by softly mixing parts of two sentences via a convex combination.

Data augmentation has also been applied to the field of NLG evaluation metrics. BLEURT (Sellam et al., 2020) is a supervised metric, i.e., it requires to be finetuned on human meta-evaluations. Before finetuning, BLEURT creates an augmented synthetic dataset by perturbing Wikipedia sentences with BERT mask-filling, backtranslation, and random word dropping techniques. The data are then annotated with some automatic numerical and categorical signals as pretraining labels. FrugalScore (Kamal Eddine et al., 2022) proposes the first knowledge distillation approach for NLG evaluation metrics, to alleviate the significant requirement of computational resources by the heavy metrics based on large pretrained language models (e.g., BERTScore and MoverScore). Unlike BLEURT, it is purely trained on a synthetic dataset consisting of pairs of more or less related sentences, created via various data augmentation techniques (e.g., paraphrasing with backtranslation, perturbation then denoising, etc.). The sentence pairs for training the student model are annotated with scores given by the metrics to be learned.

Differences. Note that BLEURT and FrugalScore use augmented data to train their parameterized metric models, while our DATScore is an untrained and unsupervised metric not requiring human judgments for training and using augmented translation

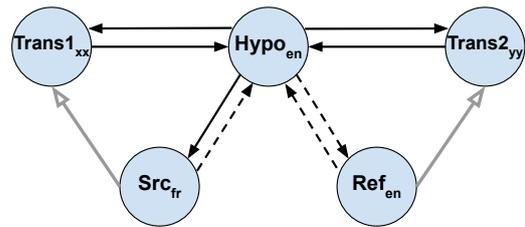

Figure 1: Dashed arrows denote the generation directions covered by BARTScore. Solid black arrows indicate our newly introduced directions for calculating DATScore of the example *hypothesis* in English ($Hypo_{en}$). $Trans1_{xx}$ and $Trans2_{yy}$ represent data *augmented translations* in any languages xx and yy , obtained by applying a translation model (grey arrows) to the example *source* in French (Src_{fr}) and example *reference* in English (Ref_{en}), respectively.

for the sole purpose of scoring.

3 DATScore

As mentioned in Subsection 2.1, BARTScore is not based on matching tokens nor their embeddings as the other evaluation metrics. Instead, it uses a novel approach by framing the evaluation of generated text as a text generation problem. Assuming first a pretrained seq2seq model is “ideal” (e.g., BART), BARTScore directly uses the model’s conditional probability of generating a provided target text Y given a provided input text X , as the evaluation score of the generation direction $X \rightarrow Y$. For example, Y corresponds to a translation hypothesis generated by any system, and X is the reference. If Y is of high quality, then by providing the pair to the pretrained BART model, the estimated conditional generation probability (evaluation score) $P(Y|X)$ should be high.

Therefore, by placing differently the *source* (Src), the *reference* (Ref), and the *hypothesis* ($Hypo$) in pair at the input or the output side of the trained seq2seq model for fetching conditional generation probabilities, BARTScore considers three different generation directions illustrated as dashed arrows in Figure 1. The conditional probabilities associated with the directions are denoted as: Precision ($Ref \rightarrow Hypo$), Recall ($Hypo \rightarrow Ref$) and Faithfulness² ($Src \rightarrow Hypo$). Additionally, an F-score, the arithmetic average of Precision and Recall.

The score (conditional probability) for the gen-

²BART being a monolingual model, faithfulness is only relevant in the context of abstractive summarization, and its corresponding direction cannot be applied to machine translation evaluation.

eration direction from a source sequence $X = \{x_t\}_{t=1}^n$ to a target sequence $Y = \{y_t\}_{t=1}^m$ is calculated as the factorized, weighted log probability over all generation steps:

$$\text{Score}_{X \rightarrow Y} = \sum_{t=1}^m w_t \log P(y_t | X, \{y_{t'}\}_{t'=1}^{t-1}; \theta) \quad (1)$$

where w_t denotes the term importance score to put different emphasis on different target tokens y_t . BARTScore simply employs a uniform weighting scheme (all equal to 1). θ denotes the parameterized seq2seq model.

Our contributions consist of three modifications tailored to machine translation:

Data augmented translations. Unlike BARTScore, we employ M2M-100 (Fan et al., 2021), a non-English-centric multilingual machine translation system as our backbone seq2seq model, due to its superior performance. As our main contribution, we translate the source (e.g., Src_{fr} in Figure 1) and the reference (Ref_{en}) into any languages as our augmented data ($\text{Trans}_{1_{xx}}$ and $\text{Trans}_{2_{yy}}$) for evaluating the hypothesis (Hypo_{en}). In addition to the three directions covered by BARTScore, our metric takes into consideration all generation directions centered on the hypothesis connecting the source, the reference, and the two data augmented translations, i.e., in total 8 directions as the black (dashed and solid) arrows depicted in Figure 1. DATScore is calculated as the weighted average of the scores associated with all the directions:

$$\text{DATScore} = \sum_{X,Y} w_{X \rightarrow Y} \text{Score}_{X \rightarrow Y}; X \neq Y \quad (2)$$

where $w_{X \rightarrow Y}$ denotes the weight of the direction $X \rightarrow Y$, as detailed below.

One-vs-rest score averaging method. We observed empirically that sometimes, one direction score might strongly disagree with the others, likely being an outlier (failed evaluation). This may significantly affect the final DATScore correlations with the human meta-evaluations, if a simple arithmetic averaging method is applied (like BARTScore in computing F-score). To reduce this effect, we weigh each direction with the sum of the Pearson correlations of its scores with the scores of all the other directions:

$$w_{X \rightarrow Y} = \sum_{X',Y'} \text{Corr}(\text{Score}_{X \rightarrow Y}, \text{Score}_{X' \rightarrow Y'}) \quad \text{s.t. } (X, Y) \neq (X', Y') \quad (3)$$

This one-vs-rest method will assign a low weight to the direction score poorly correlated with the rest scores, thus reducing its negative effect on the averaging result.

Entropy-based term weighting scheme. BARTScore gives an equal weight w_t to every token in Equation 1 (uniform weighting). Instead, we introduce a novel scheme to give different importance to different target tokens y_t , based on the entropy:

$$w_t = - \sum_{i=1}^v P_t(z_i) \log P_t(z_i) \quad (4)$$

where v denotes the size of the output generation vocabulary. $P_t(z_i)$ represents the probability of the i -th token in the vocabulary at time step t . We assume that when the model is very confident in generating the target token (low entropy), then this token is non-informative (e.g., stopword). On the other hand, when the model is less confident (higher entropy), the target word is more informative, and then a higher weight should be assigned.

The effectiveness of all our choices regarding the above contributions is shown by our ablation studies (see Section 6).

4 Experiments

4.1 Experimental settings

We benchmark DATScore on two commonly used meta-evaluation datasets for machine translation metrics: WMT17 (Bojar et al., 2017) and WMT18 (Ma et al., 2018) consisting of multiple to_English and from_English language pairs. For each pair, a few thousand examples are available, each being made of a *source*, a *reference*, a *hypothesis* and a *label* produced by human annotators, assessing the quality of the system generated *hypothesis*. Depending on the *label* type, we use Kendall’s Tau τ correlations or absolute Pearson $|r|$ correlations. The former is used when relative ranking is provided, and the latter in the case of direct assessment. We adopt the Kendall’s Tau-like formulation proposed in (Bojar et al., 2017):

$$\tau = \frac{|\text{Concordant}| - |\text{Discordant}|}{|\text{Concordant}| + |\text{Discordant}|} \quad (5)$$

where $|Concordant|$ is the number of examples on which the metric agrees with the human relative ranking, and $|Discordant|$ is the number of examples when they disagree.

To compute DATScore, two M2M-100 models: M2M-100_418M³ and M2M-100_1.2B⁴ are adopted (418M and 1.2B refer to the model sizes). They are finetuned to translate a source text to a target text by providing the source language code (e.g. "fr") at the beginning of the encoder input sequence, and a target language code at the beginning of the decoder input sequence. In our experiments, when English is the target language (to-English), we choose English for Trans1 and Spanish for Trans2 (see Figure 1). Otherwise, whenever English is the source language (from-English), we choose Spanish for Trans1 and English for Trans2. This choice is motivated by the fact that English and

Spanish are the top two represented languages in the training set of M2M-100 (Fan et al., 2021).

4.2 Main results

We compare the performance of our metric against BLEU and three other reference-based unsupervised metrics: BERTScore⁵, MoverScore⁶ and BARTScore⁷ (detailed in Subsection 2.1 and Section 3), using their official implementations. Experimental results are reported in Table 1 and 2. Following their original settings, we use different underlying language models for each baseline metric. For BERTScore and MoverScore, RoBERTa-Large (RL; Liu et al., 2019) and Bert-Base (BB) are used respectively when we evaluate to-English translations, and mBERT (Devlin et al., 2019) for from-English translations. In the case of BARTScore, we use a BART-Large (BL) checkpoint (finetuned on CNNDM (See et al., 2017) and

⁷<https://github.com/neulab/BARTScore>

ParaBank2 (Hu et al., 2019) datasets) for evaluating to-English translations, and an mBART-50 model (Escolano et al., 2021) for from-English translations.

Overall, results show that, on average, across all language pairs, DATScore significantly outperforms all 4 baseline metrics under their original model settings (rows 1a-1d and 2a-2d). Specifically, with respect to the best performing baseline BERTScore (row 1b and 2b), our metric provides a performance boost of 0.7 for to-English case and of 9.8 for from-English case on WMT17 dataset in Table 1, and achieves a gain of 0.7 and of 7.3 respectively on WMT18 dataset in Table 2. These averaging results demonstrate the superiority and applicability of DATScore in evaluating general machine translations of many languages. Moreover, it is interesting to note that our improvement is much more significant in from-English case, which makes DATScore particularly well-suited to evaluate hypothesis translations in non-English languages, often with low resource. We hypothesize that this is due to the inconsistency of underlying language models. The baselines adopt a monolingual model for evaluating English, but a multilingual one for non-English languages. However, DATScore uses a single multilingual M2M-100 model for both cases. It is known that, in general, monolingual models outperform multilingual competitors. Thus, it is reasonable that when comparing multilingual-based DATScore against monolingual baselines in the to-English case, DATScore achieves a smaller improvement than in the other from-English case, where the comparison is fairer (multilingual vs. multilingual).

By looking across specific language pairs and directions, we observe DATScore constantly performs better than 4 baseline metrics with a few exceptions, i.e., de \rightarrow en (-1.6) in Table 1, and de \rightarrow en (-0.1), tr \rightarrow en (-2.6), and zh \rightarrow en (-0.1) in Table 2. Despite these small drops in the performance, DATScore brings a larger margin of improvement in most cases, such as en \rightarrow tr up to 13.8 both on WMT17 and WMT18 datasets.

In the end, for the sake of having a complete comparison, we additionally evaluate BARTScore⁸ with M2M-100_418M and M2M-100_1.2B models (row 1e, 1f, 2e, and 2f) that are used as DATScore’s underlying models. Results show that, only in the

⁸The official implementation of BARTScore is slightly modified to take into account the languages tokens when using a multilingual model.

Table 4: Pearson correlation results on two summarization datasets: REALSumm and SummEval.

from-English case, while they bring an improvement compared to the vanilla BARTScore (row 1d and 2d), they are not able to yield as big of a gain as our metric, indicating that our achieved improvement is not solely due to the underlying language model, but also to taking additional generation directions into account, including those related to data augmented translations.

5 Other NLG tasks

In addition to machine translation, our main focus, we evaluate DATScore on other NLG tasks, including data-to-text generation, abstractive summarization, and image captioning. To work around the different modalities of source inputs represented in these tasks (e.g., not able to create a data augmented translation with an image), we adapt DATScore to only consider 4 generation directions: *Hypo* \leftrightarrow *Ref* and *Hypo* \leftrightarrow *Trans2*.

Data-to-text. Table 3 shows the performance of DATScore compared to the other baselines on the WebNLG data-to-text dataset (Shimorina et al., 2018), which contains 2000 descriptions of structured tables along with their corresponding references. In addition, human assessments covering three dimensions are provided (*semantics*, *gram-*

mar, and fluency). The results show that DATScore significantly outperforms all the other metrics in two settings (grammar and fluency) out of three, while being very competitive in the third setting (semantics). Surprisingly, BERTScore is largely behind DATScore, and MoverScore failed to correlate positively with human judgments in all dimensions.

Summarization. Table 4 shows the evaluation of the different metrics on two summarization meta-evaluation datasets: REALSumm (Bhandari et al., 2020) and SummEval (Fabbri et al., 2021). Both datasets contain a few thousand examples of system-generated summaries and their references. The generated summaries are annotated with *lightweight pyramids* (Shapira et al., 2019) method in the case of REALSumm, while the annotations in SummEval cover four dimensions: *coherence*, *consistency*, *fluency*, and *relevance*. On REALSumm, DATScore has the best performance compared to all the other baselines even when using its smaller version (M2M-100_418M). However, despite its higher correlations compared to BARTScore and MoverScore, DATScore fails to outperform BERTScore on the different dimensions of SummEval.

Image captioning. We consider Flickr8K (Hodosh et al., 2013) and PASCAL-50S (Vedantam et al., 2015), two image captioning datasets. The former is annotated with scores from 1 to 4 assessing the relevance of the captions, and the latter is annotated with relative ranking (i.e., given two descriptions which one is better). Table 5 shows that in this task, DATScore is competitive to BARTScore and BERTScore. Surprisingly, MoverScore significantly outperforms all the other metrics despite its poor performance on the other datasets.

Finally, although not the top-performing metric across all tasks, DATScore showed an overall stable and competitive performance. Conversely, each of the other metrics fails in evaluating generations, at least in one of the tasks. For example, BERTScore and MoverScore have poor performance on the WebNLG dataset. On the other hand, although BARTScore is finetuned on an abstractive summarization dataset, it fails to correlate well with human judgment on REALSumm and SummEval. This finding suggests that DATScore can be safely used to evaluate NLG systems in other tasks for different evaluation dimensions, regardless of being initially designed for machine translation evaluation.

Metric	Model	Flickr8K	PASCAL-50S
		RELE	RR
BLEU	N/A	13.8	8.1
BERTScore	RoBERTa-Large	46.1	33.8
MoverScore	BERT-Base	52.5	33.2
BARTScore	BART-Large+para	44.8	33.1
	M2M-100_418M	34.3	29.6
	M2M-100_1.2B	34.6	26.3
DATScore	M2M-100_418M	42.6	29.6
	M2M-100_1.2B	45.3	31.4

Table 5: Pearson correlation Results on two Image Captioning datasets: Flickr8K and PASCAL-50S.

Entropy-based weighting	One-vs-rest weighting	to_English	from_English
✓	✓	37.2	58.5
✓	✗	37.1	58.1
✗	✓	36.4	55.9
✗	✗	36.4	56.0

Table 6: The average Kendall correlation (to/from)-English when the entropy-based and one-vs-rest weighting are included or excluded. Experiments are conducted on WMT18.

6 Ablation study

To validate our different choices with regard to DATScore, we conducted ablation studies on:

- 1) the contributions of all 8 direction scores, results are illustrated in Figure 2.
- 2) the effectiveness of our *one-vs-rest* score averaging and *entropy-based* term weighting strategies (See Section 3), results are reported in Table 6.

Contributions of all direction scores. From Figure 2(a), we observe that none of the individual directions (horizontal bars) has a better correlation with human judgments than DATScore (dashed vertical lines), which confirms the importance of our ensemble approach. In Figure 2(b), we can see that all variants excluding one direction will lead, in almost all cases, to a drop in the performance, compared to the complete DATScore in which all directions are included. Besides, in the case of to-English translations, we can see that the drop in the performance is almost the same for all exclusions of direction. While for from-English translations, the largest drop in performance is observed when *Hypo*→*Trans2* and *Trans2*→*Hypo* are excluded. This finding highlights the important contribution of our augmented data, especially in the

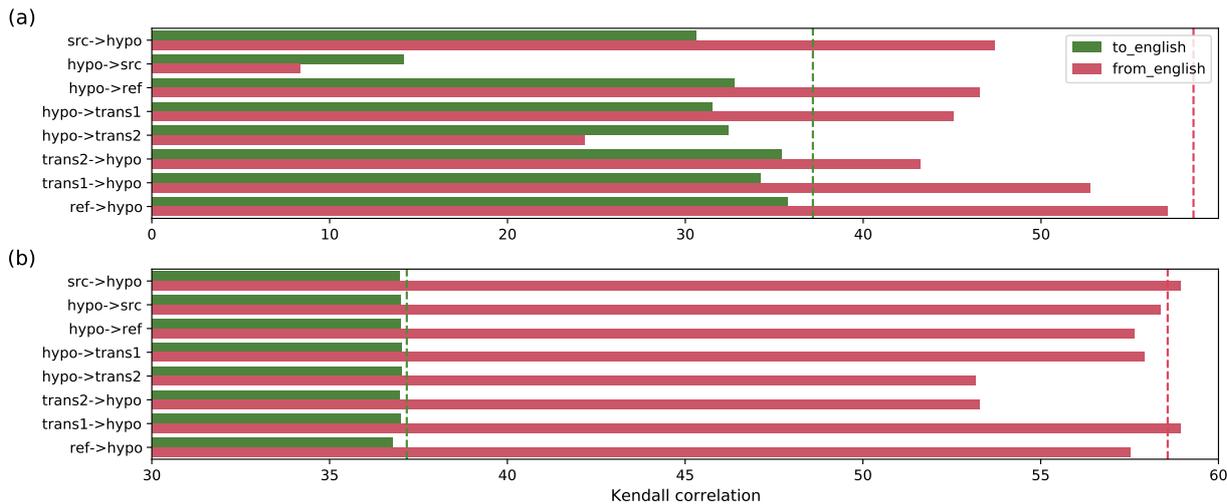

Figure 2: (a): The horizontal bars represent the Kendall correlations of **each individual generation direction**. (b): The horizontal bar represents the Kendall correlation of **a variant of DATScore with excluding the single generation direction** of the line. Both in (a) and (b), the dashed vertical lines represent the Kendall correlation of the vanilla and **complete DATScore**. Correlation results of to-English (in green) and from-English (in red) cases are calculated w.r.t human judgments, and averaged over all languages pairs. Experiments are conducted on WMT18.

low resource language settings (from-English). In the end, we can see that excluding *Src*→*Hypo* or *Trans1*→*Hypo* directions can lead to a slightly better final score. We leave the investigation of the potential negative impact of the two directions to future work.

One-vs-rest and entropy-based weighting strategies. Table 6 shows the performance of DATScore variants with respect to different combinations of applying or not our proposed weighting strategies. Note that when *one-vs-rest* and *entropy-based* weightings are not applied, they are replaced with a simple uniform averaging approach (as used in BARTScore). A performance drop is observed when excluding one of the two weighting strategies, especially for the entropy-based method, whose inclusion leads to an improvement of 2.5 compared to the uniform weighting. This experiment confirms the positive impact of our proposed weighting methods and motivates future work further to investigate a more elaborated approach in this direction.

7 Conclusion

In this work, we proposed one of the first applications of data augmentation techniques to NLG evaluation. To obtain an evaluation score of the translation hypothesis, our developed metric DATScore additionally leverages newly translated copies aug-

mented from the source and reference texts. We also proposed two novel strategies for score averaging and term weighting to improve the original, naive score computing process of BARTScore, on the basis of which our work is built. Experimental results show that DATScore achieved a higher correlation with human meta-evaluations, in comparison with the other recent state-of-the-art metrics, especially for those less represented languages other than English. Moreover, ablation studies show the effectiveness of our newly proposed score computing approaches, and extended experiments showed an overall stable and competitive performance of DATScore on more NLG tasks.

Limitations

In this section, we list some limitations that are worth further investigation in future works:

1) DATScore requires generating additional data augmented translations to perform the evaluation. This process might be time-consuming depending on the adopted backbone seq2seq model, especially if the original text is long. Thus, the performance scalability can be investigated in future complementary experiments.

2) We chose to use English and Spanish to create data augmented translations for the reason that they are the two most represented languages in the training of the M2M-100 model (see Subsection 4.1).

However, this leaves a question about the performance of DATScore with augmentations varying in other languages (e.g., Chinese). Moreover, for the sake of simplicity, we decided only to include a single translated copy of the source text and the reference text. However, this can be easily extended, and more augmented translations can be created in more languages. We expect to see an improvement in performance with diminishing returns.

3) BARTScore only considers the 8 generation directions centered on the hypothesis connecting with the source, the reference, and the two data augmented translations (see Section 3). However, other connections exist between these entities, such as $Src \rightarrow Ref$ and $Trans1 \rightarrow Src$ (see Figure 1). Therefore, future research could be dedicated to discovering the effect of these other directions and potentially leveraging them to improve the performance of DATScore.

4) Since our focus was on evaluating machine translation, we naturally chose translation for augmenting the data. However, other data augmentation techniques could seamlessly integrate into DATScore, such as using a text paraphrasing model (Bandel et al., 2022).

How do decoding algorithms distribute information in dialogue responses?

Abstract

Humans tend to follow the Uniform Information Density (UID) principle by distributing information evenly in utterances. We study if decoding algorithms implicitly follow this UID principle, and under what conditions adherence to UID might be desirable for dialogue generation. We generate responses using different decoding algorithms with GPT-2 on the Persona-Chat dataset and collect human judgments on their quality using Amazon Mechanical Turk. We find that (i) surprisingly, model-generated responses follow the UID principle to a greater extent than human responses, and (ii) decoding algorithms that promote UID do not generate higher-quality responses. Instead, when we control for surprisal, non-uniformity of information density correlates with the quality of responses with very low/high surprisal. Our findings indicate that encouraging non-uniform responses is a potential solution to the “likelihood trap” problem (quality degradation in very high-likelihood text). Our dataset containing multiple candidate responses per dialog history along with human-annotated quality ratings is available at: https://huggingface.co/datasets/saranya132/dialog_uid_gpt2.

1 Introduction

The Uniform Information Density (UID) hypothesis states that humans distribute information in their utterances evenly for optimal communication (Jaeger, 2010; Fenk and Fenk, 1980). Consequently, language generation has benefitted from UID-based objectives and regularization (Meister et al., 2022; Wei et al., 2021). Specifically, Meister et al. (2020) argued that UID can be optimized for machine translation using beam search. Yet, the effect of different decoding algorithms on information density distributions of generated text are unknown, as is UID’s broader role in neural response generation in the special case of dialogue

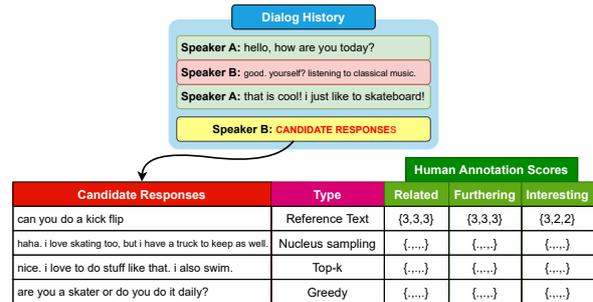

Figure 1: Our dataset contains 4 candidate responses for every dialog history, along with human annotations for 3 qualitative measures.

models. Here, we investigate (i) if different decoding algorithms follow the UID principle, and (ii) if following the UID principle is beneficial for dialogue response generation, and (iii) collect human annotations of qualitative measures for multiple candidate responses to dialog histories generated using different decoding algorithms (Figure 1) to study the relationship of dialog response quality and UID. We operationalize UID as the variance of surprisal and measure its correlation with automatic metrics (e.g., BLEU, METEOR, BERTScore) as well as human judgments on qualitative measures of response quality and find that adherence to UID correlates negatively with human judgments when the responses have very low/high surprisal.

Language production in humans. Spreading information content evenly in utterances is a marker of optimally strategized responses, and humans follow this UID principle as a means to state their thoughts clearly and to make themselves intelligible (Frank and Jaeger, 2008; Levy and Jaeger, 2007). The probability of a sentence has been associated with the cognitive load it incurs (Hale, 2003). As a means to avoid salient variations in the information content (surprisal, i.e., negative log probability) of responses, speakers maintain UID through linguistic choices such as that at the

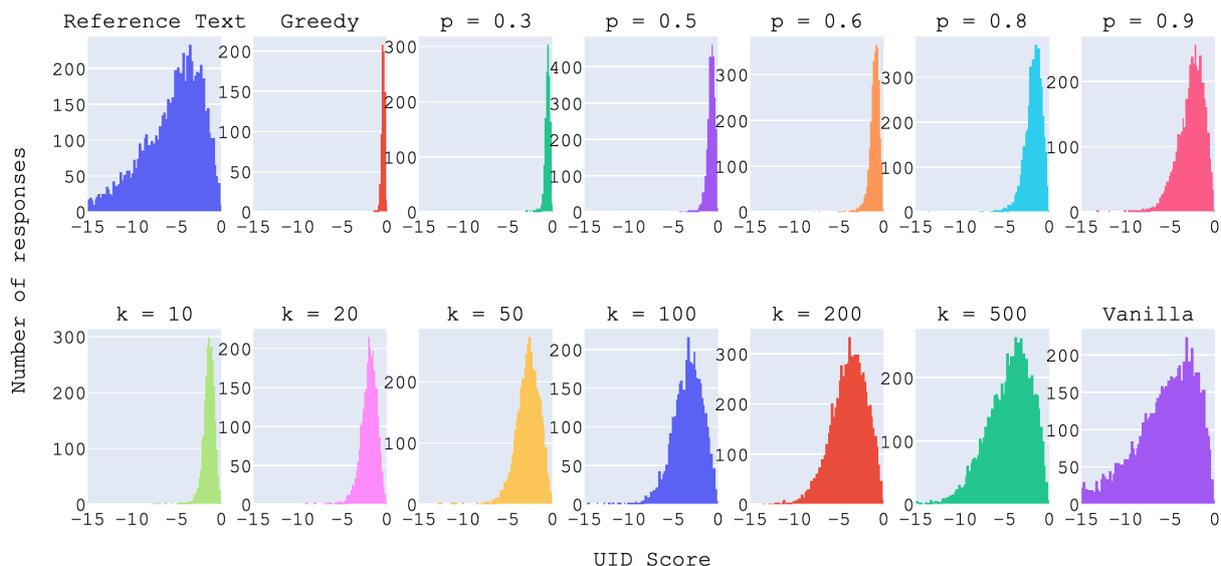

Figure 2: Histogram of **UID Scores** of responses generated using different decoding algorithms. The farther the UID score from 0, the less uniform or more non-uniform the response. Human-generated reference text (left-top) has a higher frequency of non-uniform responses as compared to any model setting as can be seen from the wider spread of scores away from 0. Also, as the values of p and k increase (left to right), the information density distribution slowly approaches reference text-like non-uniformity.

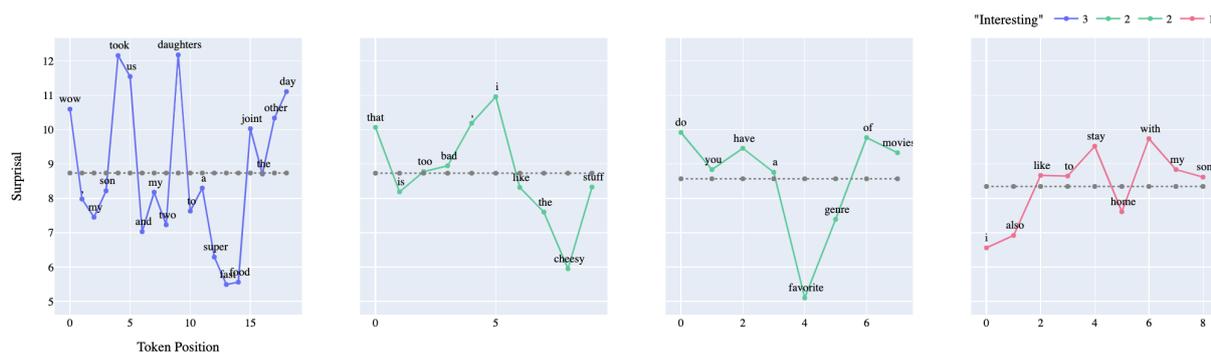

Figure 3: Surprisal at every token in candidate responses to the same dialog history, color-coded with human annotated **interesting** scores. Plots (left to right) are arranged in increasing order of uniformity (i.e. variance along y-axis). Less uniform the surprisal (left-most), better the score.

phonetic (Aylett and Turk, 2004), syntactic (Jaeger, 2010) and lexical level (Mahowald et al., 2013).

Response generation in machines. While large-scale pre-trained language models provide a rich prior for dialogue response generation, the choice of decoding algorithm used at the time of generation is crucial for the quality of generated responses (Holtzman et al., 2020; Zhang et al., 2021a; Nadeem et al., 2020; Golovanov et al., 2019; Oluwatobi and Mueller, 2020). While vanilla sampling often tends to produce incoherent text, greedy decoding leads to safe and repetitive responses. More recently, top- p /nucleus (Holtzman et al., 2020) and top- k sampling (Fan et al., 2018) are used to tune values of p/k to balance the diversity-

quality trade-off (Zhang et al., 2021a; Li et al., 2016).

The UID principle and decoding algorithms.

Both the UID principle and decoding algorithms can be seen as guiding mechanisms for dialogue response production in humans and generation in machines, respectively. UID’s role in machine-generated dialogue is not well understood, with previous work mainly focused on machine translation and language modeling (Wei et al., 2021; Meister et al., 2021, 2020). To address this gap, we present a comparative study of decoding methods to develop a deeper understanding of the role of UID in dialogue response generation.

2 Experimental Details

2.1 Model & dataset

We use the fine-tuned GPT-2 (Radford et al., 2019) model provided by HuggingFace and use their data preprocessing and response generation scripts¹. We used the Persona-Chat (Zhang et al., 2018) data split provided by the ConvAI2 challenge (Dinan et al., 2020)². We then generated responses for 7500 dialogue histories randomly picked from 7801 validation set examples using vanilla, top- p , top- k sampling and greedy decoding.

Decoding algorithms. *Vanilla sampling* randomly picks the next token from the model’s probability distribution, including many long-tail samples. *Top- k* samples from the k most probable tokens; *Greedy decoding* is Top- $k = 1$ decoding, always selecting the most probable next token. *Top- p* (*Nucleus*) sampling selects the next token from the top p portion of the probability mass.

2.2 Uniform Information Density score

We measure UID as the variance of the surprisal (negative log likelihood) of each token in the response (Jain et al., 2018; Wei et al., 2021; Meister et al., 2020). This measure is able to capture any sudden variations in the surprisal of the tokens in the sentence. UID Score is formulated as follows: the dialogue model learns a conditional probability p parameterized by θ to predict the next token (y_t) in the sentence. The surprisal (u) of the next token y_t is,

$$u(y_t) = -\log(p_\theta(y|x, y < t)), \quad (1)$$

for $t \geq 1$ where $y_0 = \langle EOS \rangle$, $t =$ time step, and $x =$ dialogue context. Higher the surprisal, lower its probability and vice-versa. Thus, surprisal indicates how unexpected or surprising a token is in a given context. Average surprisal of a sentence (y) is defined as,

$$\mu(y) = \frac{1}{|y|} \sum_t (u(y_t)) \quad (2)$$

Finally, the *UID score* of a sentence (y) is defined as the negative normalized variance of the surprisal:

$$\text{UIDscore}(y) = -\frac{1}{|y|} \sum_t (u(y_t) - \mu)^2 \quad (3)$$

¹<https://github.com/huggingface/transfer-learning-conv-ai>

²<https://github.com/DeepPavlov/convai/tree/master/2018>

From this formulation, a perfectly uniform sentence would have a variance equal to 0 (i.e. the surprisal of every token in the sentence is equal). Since we take the negative of the variance, the higher the absolute value of UID score, the more non-uniform its information density.

2.3 Response evaluation

Automatic metrics. We measure the quality of responses using length (number of tokens), BLEU³ (Papineni et al., 2002), METEOR³ (Banerjee and Lavie, 2005), character level F-score (chrF)³ (Popović, 2015), BLEURT⁴ (Sellam et al., 2020), a RoBERTa (Liu et al., 2019) based text similarity score⁵ (Reimers and Gurevych, 2019), BERTscore⁴ (Zhang et al., 2019) and SacreBLEU⁴ (Post, 2018).

Human evaluation. To study the effect of adherence to UID on the perceived quality of generated responses beyond n-gram, reference-based and learned automatic metrics, we collected human judgments along 3 measures – **related** (to the dialogue history), **furthering** (if a response keeps the conversation going/is encouraging for the dialogue partner) and **interesting** (if the response provides engaging/new information). We provide screenshots of the task interface (Figure 6), instructions (Figure 7) and details about the MTurk study design in Appendix A.

3 Findings

3.1 Information density of model responses

We plot the histograms of UID scores computed for all of the generated responses in Figure 2. The information densities of human-generated responses have a wider spread than responses produced by the models. Overall, the human-generated reference text has more non-uniform sentences than all model-generated responses. We notice a very high and narrow peak in the case of greedy decoding. This is not surprising as responses sampled using greedy search maximize the probability of the next token (minimize surprisal). Consequently, such responses would have very low surprisal at almost every word, hence lower variance. Vanilla

Table 1: Pearson’s correlation coefficient (r) between **UID score and automatic metrics** of dialog responses generated using different decoding settings. All p -values < 0.05 .

sampling uses the probability distribution learned from the training data, which might be why it is also closer to the validation set (reference text) distribution. With increase in p and k , we see that the information density distribution spreads across a larger range and includes more non-uniform responses, slowly approaching that of the reference text.

Surprisal interval	n	Pearson’s r between UID score and qualitative metrics		
		Related	Furthering	Interesting
(0.8, 1.2)	24	.17	-.03	-.30*

Table 2: Pearson’s r between **UID score and human judgments** of qualitative measures for dialog responses bucketed by surprisal [Surprisal interval = the ranges of surprisal values used for bucketing responses, n = number of responses in each surprisal interval, * p -value $< .05$]

3.2 UID score & automatic metrics

We present the correlation between UID scores and automatic metrics calculated for the generated dialogue responses in Table 1. UID scores have a weak correlation with RoBERTa-based similarity scores

for two settings of nucleus sampling. Other than that, UID scores are not correlated with automatic metrics of response generation. We take this to be an indication that if UID scores do capture any aspect of response quality, it goes beyond what is measured by such metrics and might provide for a better evaluation criteria.

3.3 UID score & human Judgments

Motivated by the fact that UID score is derived from surprisal, we test if surprisal is a confounding factor and find that, indeed, UID scores were highly correlated with average surprisal (Table 3). To tease apart the effect of UID scores on response quality, we controlled for surprisal by grouping or bucketing responses into 12 intervals of surprisals (within a range of 0.4 units as shown in the first column on Table 2). Within these intervals, surprisal had no correlation with generation quality (Table 5). Once we control for surprisal i.e. analyse dialog responses with similar surprisals but varying UID scores, we observe that UID scores negatively correlate with human judgments, to varying degrees of strength, for responses in very low or high surprisal intervals (see Table 2). Thus, for the extremities of the surprisal range, UID scores indicate that better rated responses are non-uniform.

4 Discussion

Contrary to our expectations, we find non-uniformity to be a more desirable property in machine-generated responses. Overall, UID scores and surprisal do not correlate with human judgments (Table 4). But when controlled for surprisal,

we observe that UID score is correlated with human judgments for certain intervals (examples in Figure 3 and Table 6). Our results suggest that optimizing UID to generate uniform text might not be the right objective for regularizing decoding algorithms. Instead we find that non-uniform information density could be a potential solution to the “likelihood trap” problem according to which models generate lower quality text (as per human judgments) when sampling from the extremities of their likelihood space (Zhang et al., 2021b). Consequently, we suggest that decoding algorithms be tuned to follow the information density patterns of human-generated non-uniform data when generating responses outside of the “safe” likelihood range as a means to generate higher quality responses across the entire likelihood space.

5 Limitations

While we present a study of multiple decoding settings, we generate all machine responses using the same transformers based model architecture. Thus, the presented work does not yet explore individual differences between different model architectures. Additionally, due to limited resources we were not able to collect large-scale human annotations across multiple corpora and acknowledge the same as part of future efforts.

6 Ethical considerations

In this work, we collected human annotations on dialogue response quality using MTurk. Each HIT in our MTurk study contained one dialogue history and four candidate responses. The annotators could read the history and rate the responses that followed using mouse clicks on their response choices. We provided an additional feedback field for annotators to write comments in. We received very positive feedback on the task from all the annotators who used this feature. There were no restrictions on the minimum or maximum number of examples the annotators had to rate. From a pilot study on MTurk, we found the average time to complete one HIT to be slightly under 2.5 minutes. After considering the average time required and the task difficulty (expressed to be clearly and easily understood by annotators in their comments) we set the payment amount to \$0.5 per HIT for an hourly rate of about \$12 per hour.

A Human evaluation study details

Raters were selected based on the criteria that they be located in the US, and had attempted a minimum of 500 HITS at an accepted work rate greater than 97% on MTurk. We asked raters on MTurk to answer if a candidate response satisfied each of the qualitative measures (interesting, furthering and related) and gave them three response options: "Yes", "Somewhat" and "No". In a pilot study of 360 responses, we also included a measure for fluency. All of the responses were rated "Yes" by majority vote and we removed this measure from further analysis as all the generations in this study were fluent as indicated by the pilot study and from our observation. For correlation calculations, we assign integer score values to each of the three re-

Table 5: Pearson’s r between surprisal and human judgments of qualitative measures for dialog responses bucketed by surprisal [Surprisal interval = the ranges of surprisal values used for bucketing responses, n = number of responses in each surprisal interval, $*p$ -value $< .05$]

sponse options as 3 for "Yes", 2 for "Somewhat" and 1 for "No". Thus, the higher the score, the better the response is rated. Following the pilot study, for 194 dialogue histories, we showed the raters 4 candidate dialogue responses (total of 776 dialogue responses) and collected ratings on all *3* measures from *3* raters per dialogue history. In all, we obtained a total of 776*3, i.e., 2328 total response-rating pairs. To calculate the score for each response along every measure, we take the mean of all ratings as the score. For cases where at least 2 out of 3 raters agree, we take majority vote as the final score. This constituted (2018 out of 2328) 86.68% of all the ratings collected. We show the overall distribution of qualitative scores for all the response-rating pairs in Figure 4. We verified the rater responses by checking if they were rating human-generated responses highly as those came from a trusted source (Persona-Chat). We also manually inspected a random subset of dialog history-candidate response sets and found the results to be in accordance with our intuitions.

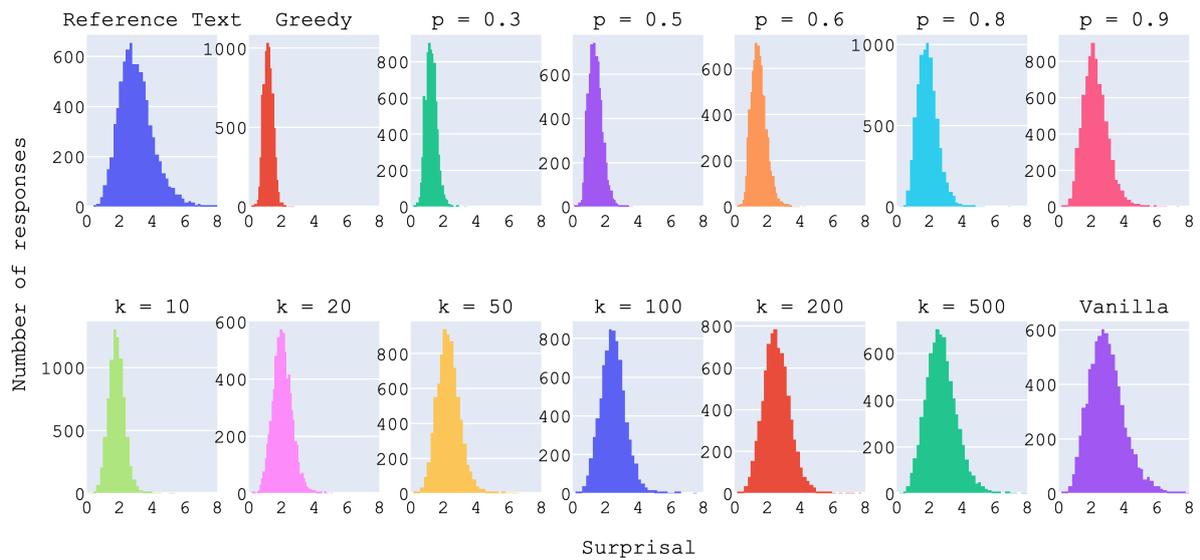

Figure 5: Histograms of **average sentence surprisal** for responses generated using different decoding settings and human-generated reference text (left-top).

Instructions
Examples

Please read the following **conversation history** & rate the responses that follow *as if you were a participant in this conversation*:

Speaker A: its all tedious at first dear , but i know it will get better for you .
 Speaker B: i guess it just really want to be out on my red bike .
 Speaker A: sounds like a true joy . i'm retired now , so you are inspiring me to try that .
 Speaker B: awesome . maybe we could go out riding together .
 Speaker A: i would love that . life is too short to miss out on making new friends .

Rate each of the **4 candidate responses** (1st column) on the **3 quality measures** (2nd column onwards) based on how well each response satisfies the quality description.

You will be entering a total of 12 responses. Fill the responses one row at a time, i.e. first read the response in a row, and rate it on all 3 qualities before moving to the next row.

Instructions		Examples	
Candidate Responses	Quality Measures & Description		
	Related	Furthering	Interesting
	Is it on topic with the conversation history?	Does it encourage the conversation to continue?	Does it present engaging or new information?
me to. life is a great tool to have!	Yes Somewhat No	Yes Somewhat No	Yes Somewhat No
that is true. you guys should come ride with me!	Yes Somewhat No	Yes Somewhat No	Yes Somewhat No
you are right. that is true. i am just happy to have someone who loves me.	Yes Somewhat No	Yes Somewhat No	Yes Somewhat No
i have to go, talk to you later.	Yes Somewhat No	Yes Somewhat No	Yes Somewhat No

Please provide any comments or feedback here.

Submit

Figure 6: Screenshots of our MTurk study interface for collecting human judgments on 4 candidate responses per dialogue history, along 3 quality measures.

1. Read the given conversation history carefully.
2. Then, rate the quality of 4 candidate responses as potential next responses to the conversation history along 3 quality measures (12 responses in total):

Note: Respond as though you are a participant in the conversation. For example, do not mark a response as uninteresting due to personal preference. Instead, consider how a person in the conversation might find it.

Quality Measure	Description
Related	Does the response follow the conversation history's general topic and is a valid continuation of the dialogue?
Furthering	Does the response encourage the conversation to keep moving forward? This might be through a question or a response that can be easily followed-up on.
Interesting	Does the response present new or engaging information?

(a) Detailed instructions that MTurk raters could expand at any time.

The following table contains examples of candidate responses corresponding to each rating option (Yes/Somewhat/No) for all 3 quality measures for the given conversation history:

Conversation History:

Speaker A: I do enjoy trying out different cuisines.
 Speaker B: Oh, nice. What's your favorite food?
 Speaker A: I like Peruvian food quite a lot. What about you?

Quality Measure	Rating	Response Example
Interesting	Yes	Oh, I recently made Ceviche at home! But I'm more into Mexican street food.
	Somewhat	I like Peruvian too.
	No	Nothing much.
Furthering	Yes	What do you like about it?
	Somewhat	I'm more into Mexican street food actually.
	No	I'm not into it.
Related	Yes	I do like it, but it's so hard to cook at home.
	Somewhat	Me too! What else do you enjoy?
	No	I go for runs all the time.

(b) Examples responses for each measure and rating category shown to MTurk raters.

Dialogue history

Speaker A: hi, i m susie. how are you?

Response type	Response text	UID Score	Interesting
Reference Text	i'm good. just got back from some volunteering. how are you doing?	-1.99	3
Candidate 1	hi. i am very good. just enjoying my favorite pastime. how are you?	-1.43	2
Candidate 2	i am great! i volunteer at a soup kitchen and watch movies with my kids.	-1.19	2
Candidate 3	i'm doing well. how are you?	-0.18	1

**Speaker A: that's cool. my dad made us italian food tonight.
 Speaker B: oh nice, i love italian food. my favorite is the garlic bread. what is yours?
 Speaker A: pasta, my son loves pizza though!
 Speaker B: i like that too, have to eat lots of carbs for my training.**

Response type	Response text	UID Score	Interesting
Candidate 1	wow, my son took us and my two daughters to a super fast food joint the other day	-4.83	3
Candidate 2	that is too bad, i like the cheesy stuff.	-2.08	2
Reference Text	do you have a favorite genre of movies?	-1.73	2
Candidate 3	i also like to stay home with my son.	-0.88	1

**Speaker A: hello i hope your sunday is great , what is your favorite kind of music?
 Speaker B: hey there . been a relaxed sunday . yours ? music eclectic.
 Speaker A: my sunday has been exciting ! i enjoy death metal.
 Speaker B: death metal . cool . i spent the morning volunteering.
 Speaker A: i volunteer too , at the local pool to be a swim coach.**

Response type	Response text	UID Score	Furthering
Candidate 1	nice. such a nice day. how long have you been coaching?	-9.99	3
Reference Text	that is great! we both volunteer! mine is rescuing bunnies.	-7.59	2
Candidate 2	that's cool. i donate my pay to the local zoo. humane societies.	-3.89	2
Candidate 3	sick sick. beautiful color, navy blue is my favorite.	-2.79	1

Speaker A: have you heard about the juggalos? weird.

Response type	Response text	UID Score	Furthering
Reference Text	what are those? do they juggle balls?	-6.88	3
Candidate 1	no i have not. i like that band myself	-5.19	2
Candidate 2	we will not tell. do you like comics?	-4.27	2
Candidate 3	i have not heard of them. i've dolls too.	-2.8	1

**Speaker A: hello, how are you today?
 Speaker B: good. yourself? listening to classical music.
 Speaker A: that is cool! i just like to skateboard!**

Response type	Response text	UID Score	Related
Reference Text	can you do a kick flip?	-14.11	3
Candidate 1	haha. i love skating too, but i have a truck to keep as well.	-11.28	3
Candidate 2	nice. i love to do stuff like that. i also swim.	-10.25	3
Candidate 3	are you a skater or do you do it daily?	-9.05	2

**Speaker A: i hope it is a healthy snack. i am doing well, just moved here.
 Speaker B: it is. i am vegan. just moved here too! where from?
 Speaker A: i too am vegan from germany. have you seen lafer! lichter! lecker! on tv?
 Speaker B: oh yes! i love shows like that and watched it back home a lot.**

Response type	Response text	UID Score	Related
Reference Text	they do amazing things with the hummus. where is back home for you?	-6.86	3
Candidate 1	you must have a lot of fun watching them.	-4.53	2
Candidate 2	they have the best new vegan cookbooks, but i am more adventurous.	-2.93	3
Candidate 3	i do love the sky diving, too! i have seen the first few seasons.	-2.47	1

Table 6: Examples of dialogue histories followed by 4 response candidates arranged by increasing UID score i.e. from more non-uniform to uniform responses and their corresponding human judgment scores.

Benchmarking Long-tail Generalization with Likelihood Splits

Ameya Godbole and Robin Jia
University of Southern California
{ameyagod, robinjia}@usc.edu

Abstract

In order to reliably process natural language, NLP systems must generalize to the long tail of rare utterances. We propose a method to create challenging benchmarks that require generalizing to the tail of the distribution by re-splitting existing datasets. We create ‘Likelihood Splits’ where examples that are assigned lower likelihood by a pre-trained language model (LM) are placed in the test set, and more likely examples are in the training set. This simple approach can be customized to construct meaningful train-test splits for a wide range of tasks. Likelihood Splits surface more challenges than random splits: relative error rates of state-of-the-art models increase by 59% for semantic parsing on SPIDER, 93% for natural language inference on SNLI, and 33% for yes/no question answering on BOOLQ, on our splits compared with the corresponding random splits. Moreover, Likelihood Splits create fairer benchmarks than adversarial filtering; when the LM used to create the splits is also employed as the task model, our splits do not unfairly penalize the LM.

1 Introduction

Success on in-distribution test data does not necessarily show that a system has solved the underlying task at hand. Systems can achieve artificially high accuracy by exploiting dataset-specific shortcuts, such as spurious feature-label correlations that hold in the data but not in general (Gardner et al., 2021). In many datasets, a large proportion of test examples are similar to training examples, further inflating in-distribution accuracy (Lewis et al., 2021; Czarnowska et al., 2019; Orr et al., 2021). Out-of-distribution (OOD) evaluation paints a clearer picture of a system’s ability to perform the task.

Prior work has proposed a variety of methods to test OOD generalization, each with their own strengths and weaknesses. Task-specific behavior tests (Ribeiro et al., 2020; Naik et al., 2018; Gardner et al., 2020) give insights into model be-

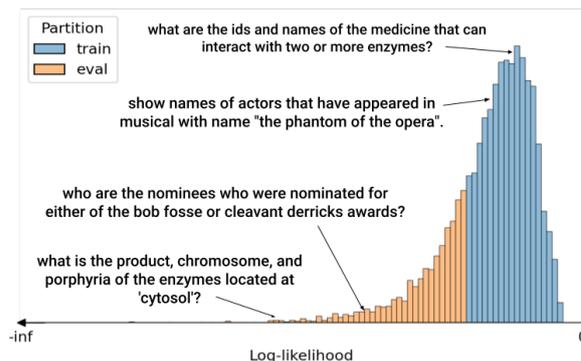

Figure 1: **Likelihood Splits**: We propose to partition the dataset based on likelihood under a language model. The high-likelihood “head” of the distribution becomes the training set while we evaluate generalization to the low-likelihood “tail” of the data. Shown here are queries from the SPIDER dataset in different likelihood buckets: one possible tail generalization could be the handling uncommon entities with known query types.

havior but require significant manual (often expert) effort to create. Adversarial data collection, in which annotators try to fool high-performing models (Nie et al., 2020; Potts et al., 2021), also collects challenging examples, but runs the risk of focusing only on a narrow subset of model weaknesses (Bowman and Dahl, 2021; Kaushik et al., 2021). Adversarial filtering removes easy examples from existing datasets (Sakaguchi et al., 2021), but can disproportionately penalize the model used during filtering (Phang et al., 2021). Domain generalization tests transferability to new data domains (Fisch et al., 2019; Miller et al., 2020), but there is no guarantee that generalizing to a given new domain is possible—out-of-domain examples may require skills that are not learnable from the training data (Geiger et al., 2019). Other approaches create dataset splits that test for specific skills, such as length generalization (Lake and Baroni, 2018) and compositional generalization (Shaw et al., 2021), but they only apply to a narrow subset of tasks.

In this work, we propose **Likelihood Splits**, a general-purpose method to create challenging OOD splits for existing datasets. The principle behind Likelihood Splits is that any system that claims to reliably process natural language must be able to generalize from more common utterances seen during training to the long tail of rare utterances at test time. Generalization, not merely memorization, is necessary because even a very large training dataset cannot exhaustively cover all possible long-tail examples that may be encountered in the real world. Moreover, standard annotation procedures tend to over-sample examples from the head of the distribution, further ignoring the challenge posed by infrequent examples. We identify tail examples using the likelihood under the GPT-2 language model (Radford et al., 2019). Examples with low likelihood under GPT-2 are placed in the held-out evaluation sets and the high likelihood examples are used as the training set (see Figure 1).

Likelihood Splits are a novel, widely applicable strategy that can create interesting generalization benchmarks at no additional annotation cost. They are more challenging than a random split across a wide range of tasks: error rates relative to random splits increase by 59% for T5 (Raffel et al., 2020) on SPIDER (Yu et al., 2018), 93% for ELECTRA (Clark et al., 2020) on SNLI (Bowman et al., 2015), and 33% for ROBERTA (Liu et al., 2019) on BOOLQ (Clark et al., 2019). Moreover, the proposed splits do not unfairly penalize the GPT-2 model used to create the splits when it is used as a task model, thus avoiding one of the downsides of adversarial filtering. We identify many independent challenges required by Likelihood Splits, including generalizing to rare words, complex programs, and syntactically complex sentences. We encourage future benchmark creators to release Likelihood Splits as a complementary evaluation to the standard IID evaluation to better test out-of-distribution generalization performance. We will release the splits discussed in this work along with the code to easily create Likelihood Splits of other datasets.¹

2 Related Work

Generalizing to the long-tail. Evaluating systems on long-tail phenomena is important, especially because many datasets over-sample the head of the distribution. For example, some question-answering (QA) datasets limit their purview to pop-

ular web-pages (Yang et al., 2018) or frequent user queries (Kwiatkowski et al., 2019). Lewis et al. (2021); Liu et al. (2021) demonstrate that models trained on these datasets often fail on examples that do not match the most frequent training cases. Similar observations have been made in entity linking to rare entities, (Orr et al., 2021; Chen et al., 2021), information retrieval for open-domain QA (Sciavolino et al., 2021), relation extraction for rare relations (Sabo et al., 2021) and lexicon induction for rare senses in machine translation (Czarnowska et al., 2019). Zero-shot performance of large LMs on numerical reasoning and factoid questions is also correlated with the frequency of occurrence of the facts in the pre-training corpus (Razeghi et al., 2022; Kandpal et al., 2022; Elazar et al., 2022). While we do not test whether models can memorize long-tail knowledge, we instead test whether models can process long-tail sentences. Naik et al. (2022) note that it is challenging to catalogue and evaluate generalization along micro-level dimensions and instead propose benchmarks that vary along macro-level dimensions (such as the language and domain) as a proxy. We hypothesize that LMs learn which micro-level phenomena are rare, as this would improve their overall language modeling objective. In this work, we present a recipe that leverages LMs to evaluate tail generalization for any language task.

Task-specific test sets. Ribeiro et al. (2020) use templated queries to evaluate model performance under various linguistic perturbations. This method requires dataset designers to define phenomena of interest and axes of perturbation along which labels may be preserved or changed. Naik et al. (2018) analyze model errors and instantiate tests that explicitly evaluate models on more examples from each error class. Gardner et al. (2020) check for model consistency under local perturbations of test set examples. All of these approaches require annotators to create new examples, whereas we propose a method to resplit existing datasets.

Adversarial approaches. Søgaard et al. (2021) argue that random splits over-estimate model performance on new in-domain data and recommend the use of adversarial and heuristically challenging splits to estimate generalizability. Adversarial data collection promotes the creation of difficult examples by encouraging annotators to fool a model-in-the-loop (Nie et al., 2020; Potts et al., 2021;

¹github.com/ameyagodbole/long-tail-likelihood-splits

Kiela et al., 2021). Similarly, Adversarial Filtering removes examples that are easy for a given task model in order to create more challenging benchmarks (Sakaguchi et al., 2021; Yang et al., 2018). However, Kaushik et al. (2021) and Bowman and Dahl (2021) point out that adversarially collected or filtered examples may focus on a narrow set of skills that the “in-the-loop” model lacks, instead of covering all the abilities required for the underlying task. Additionally, the “in-the-loop” task model is disproportionately penalized by the adversarial test sets (Phang et al., 2021). We show in §4.3 that Likelihood Splits do not suffer from this issue.

Domain shift. In NLP, domains can be characterized by the changes in vocabulary and distribution of word use, styles used by authors, and the intended audience. Fisch et al. (2019) pose the challenge of developing QA systems that need to generalize to unseen domains. Miller et al. (2020) show that QA models trained on SQUAD show a performance drop on new domains (while human baseline performance remains unchanged); Miller et al. (2021); Hendrycks et al. (2020) inter alia perform similar analyses of domain shift. SPIDER (Yu et al., 2018) and GRAILQA (Gu et al., 2021) evaluate semantic parsing on unseen table and knowledge base domains respectively. Domain shift is an orthogonal axis of generalization; we focus on generalizing to rare utterances in the same domain.

Out-of-distribution detection. Previous work in OOD detection has used high generative model perplexity as a sign of outliers (Arora et al., 2021; Ren et al., 2019; Lee et al., 2018). Our intuition is similar: low likelihood (high perplexity) is an indicator of rare examples. However, only our work uses likelihood scores for benchmark creation. Moreover, in our setting all examples have been collected under the same data collection protocol, so none of the examples are truly OOD.

Compositional generalization. The ability to “compose” the meaning of a new utterance from the known meaning of its parts (Fodor and Pylyshyn, 1988) is an important aspect of language understanding. The deterministic grammar of programming languages makes semantic parsing, the task of translating a natural language utterance into a logical program, a good testbed for evaluating compositional generalization (Lake and Baroni, 2018; Kim and Linzen, 2020; Hupkes et al., 2020; Keysers et al., 2020; Shaw et al., 2021). However, for

tasks where the constituent blocks are not clearly defined, it is unclear how to create such evaluation splits of the data. We compare against compositional generalization splits of the semantic parsing dataset SPIDER (Yu et al., 2018) in §4.

3 Capturing the Tail of the Distribution

In order to find the tail within a dataset, we approximate likelihood of an utterance in the real distribution with its likelihood under a language model (LM). Our method can be easily modified to create meaningful splits for any language task. We demonstrate this by creating Likelihood Splits for:

- SPIDER, a semantic parsing dataset (Yu et al., 2018) consisting of natural language questions and corresponding SQL programs;
- SNLI, a natural language inference dataset (Bowman et al., 2015) consisting of premise and hypothesis sentences paired with labels denoting that the hypothesis is entailed by/neutral to/contradictory to the premise;
- BOOLQ, a question-answering dataset (Clark et al., 2019) consisting of a passages, associated questions, and binary yes/no labels.

3.1 General Approach

We consider language tasks where models must map an input x to an output y (e.g., a SQL query or a label). The input x may be either a single sentence (e.g., semantic parsing) or a pair of sentences (e.g., natural language inference), in which case we write $x = (x_1, x_2)$. Given a dataset D of (x, y) pairs and desired proportion p of evaluation examples, our method partitions D into subsets D_{train} and D_{eval} where $|D_{\text{eval}}| \approx p \cdot |D|$. More specifically, we will first assign a likelihood score $s(x)$ to each $x \in D$, then choose D_{eval} to be the $\lfloor p \cdot |D| \rfloor$ examples in D with lowest value of $s(x)$, and choose $D_{\text{train}} = D \setminus D_{\text{eval}}$. In §3.2, we describe a few different ways to define s . In §3.3, we describe a modification to this procedure that controls for varying length between examples. Finally, we describe task-specific adjustments in §3.4.

3.2 Assigning Likelihood Scores $s(x)$

We use the total log-likelihood over the query tokens assigned by the GPT-2 language model as the score $s(x)$ for every example. There are two ways to use the LM: (1) prompting a frozen LM or (2) fine-tuning the LM on the dataset.

Task	Prompting	Fine-Tuning
SPIDER	write a database question: {query}	< endoftext > {query}
BOOLQ	Passage: {passage} Ask a question about the passage: {question}	
SNLI	Premise: {premise} This hypothesis is {entailed/neutral/a contradiction}: {hypothesis}	

Table 1: Input formats for single-sentence and sentence-pair tasks in the prompting and fine-tuning settings. Values in curly braces are plugged in from the example. For SNLI, we provide the label in the prompt to prime the LM to the class of hypothesis. The LM is trained (when fine-tuning) and evaluated on generating the query in blue.

Past work has shown that prompting i.e. prepending a task-specific string to the query, helps GPT-2 generalize zero-shot to new tasks (Radford et al., 2019). We use simple prompts that describe the task and prime the LM to the text we expect it to generate (see Table 1). For sentence pair tasks (such as SNLI and BOOLQ), it is necessary to compare the relation between two pieces of text and not just each piece in isolation. Thus, it is intuitive to describe unlikely examples by the conditional likelihood of x_2 given x_1 . We demonstrate the flexibility of our approach by providing the label in the prompt if it adds additional information about the text to be generated (e.g. in SNLI).² We will refer to this setting which uses the prompted LM with the tag *ll_split pt* in the rest of the work.

The dataset curator may also choose to fine-tune the LM to better capture the task distribution. We fine-tune the GPT-2 LM to maximize either the probability of x for single sentence tasks or the conditional probability of x_2 given the prompt for sentence-pair tasks. When fine-tuning the LM on the dataset, we need to ensure that it is not used to assign scores to the examples it is trained on. Given the dataset D , we first randomly partition D into k folds. For each fold, we fine-tune an LM on the remaining folds and use it to assign log-likelihood scores to examples in the held-out fold. We refer the reader to Appendix A.2 for fine-tuning details. We will refer to this setting as *ll_split* henceforth.

3.3 Controlling for Length

Since the likelihood of an utterance is negatively correlated with its length, we create a split that explicitly controls for the effect of length. After assigning a likelihood score to every utterance, the examples are bucketed based on length (defined by tokenizing the utterance with NLTK (Loper and

²We include the label in the prompt for SNLI but not BOOLQ because the resulting prompts seemed most natural for each dataset. This choice was made before assessing downstream behavior.

Bird, 2002)). For single-sentence and sentence-pair tasks, we use the length of the query (x and x_2 respectively) over which log-likelihood was computed. Within each bucket, a fraction p of the examples with the lowest $s(x)$ are put in the evaluation set; aggregating examples from all buckets, $|D_{\text{eval}}| \approx p \cdot |D|$. We will refer to this control setting with the modifier (*-len*) henceforth.³

3.4 Dataset-specific Choices and Details

SPIDER. We follow Shaw et al. (2021) and swap examples between the train and evaluation sets such that every logical program atom in the evaluation set appears at least once in the train set. This ensures that the model is not required to generalize to unseen function names and declarations.

SNLI and BOOLQ. We ensure label balance in our splits (as in the original data) by splitting the examples for each label separately, then combining the resulting train and evaluation sets.

Development sets. Csordás et al. (2021) show that without development sets that are in-distribution to challenging test sets, models are prone to over-fitting, which under-estimates their ability to generalize. Thus, after dividing the data into train and evaluation sets, we randomly divide the evaluation set into a development set and test set. Other details are reported in Appendix A.1.

4 Experiments

Next, we benchmark task models on our Likelihood Splits. Splits created using GPT2-medium will be the focus of our analysis. We will briefly study the effect of switching the LM to GPT2-large in §4.4.

When creating Likelihood Splits, the number of folds k for fine-tuning the LM (§3.2) can be chosen by the dataset curator. For results in §4 and §5, we set $k = 3$ arbitrarily. We analyse the effect of

³We also considered using perplexity, which normalizes for length, but it led to an over-correction where short examples were filtered into the evaluation set.

choosing a different value of k in Appendix A.3. Our results show that the trends and observations discussed here hold true for other values of k .

4.1 Benchmarked Models

One of the goals of this work is to expose long-tail generalization as a challenge to state-of-the-art models; SotA models on the considered benchmarks are all pre-trained models. We make efforts to show that models with different pre-training data and objectives are similarly affected by our proposed splits. Hyperparameters and training details for the reported models are in Appendix A.2.

Semantic parsing. Following Shaw et al. (2021), we benchmark the competitive T5-base model (Raffel et al., 2020) on all splits of the SPIDER dataset. In order to test whether these splits are adversarial to the data splitting language model, we additionally fine-tune GPT2-medium models for the semantic parsing task. To study the effect of model size, we fine-tune T5-small and GPT2-small variants.

SNLI and BOOLQ. We fine-tune two competitive models (ROBERTA (Liu et al., 2019) and ELECTRA (Clark et al., 2020)) at two model sizes (*base* and *large*). Additionally, following Poliak et al. (2018), we train a ROBERTA-large model to perform the task given just the hypothesis. The performance of a hypothesis-only model estimates the degree of spurious correlations that exist in the dataset which give away the label.

4.2 Alternative Splits for Semantic Parsing

We compare the difficulty of the Likelihood Splits with past work on heuristic challenges splits.

Length. Past work has established that text generation models trained on short inputs struggle to generalize to longer inputs at test time (Lake and Baroni, 2018; Hupkes et al., 2020; Newman et al., 2020). We create *Length* splits by placing examples with the longest input queries in the evaluation set and the remaining examples in the training set.

TMCD. Systematicity is the ability to compositionally derive the meaning of an utterance from the known meaning of its parts. Past work studying systematicity in semantic parsing has defined “atoms” as the smallest constituents of the grammar (e.g. variables and function names) and “compounds” as complex structures formed by composing atoms (e.g. multi-argument functions and nested function calls) (Keysers et al., 2020). Following Shaw

Split	T5 base	T5 small	GPT-2 medium(Δ)	GPT-2 small
Random	78.6	75.2	69.3 (9.3)	64.7
Length	50.0	44.5	39.9 (10.1)	34.0
Template	60.1	60.0	51.4 (8.7)	45.1
TMCD	66.2	64.1	56.2 (10)	51.4
Split LM: GPT2-medium				
<i>ll_split</i>	66.0	64.2	57.2 (8.8)	51.8
<i>ll_split</i> (-len)	71.3	67.3	59.9 (11.4)	57.3
<i>ll_split</i> pt	60.6	59.7	50.9 (9.7)	45.9
<i>ll_split</i> pt (-len)	73.5	68.4	64.5 (9)	58.3
Split LM: GPT2-large				
<i>ll_split</i>	61.8	61.8	53.7 (8.1)	48.3

<i>ll_split</i> pt	63.0	58.3	51.4 (11.6)	45.7
<i>ll_split</i> pt (-len)	72.0	70.1	63.4 (8.6)	57.5

Table 2: SPIDER: Exact sequence prediction accuracy for Likelihood Splits created by GPT2-medium and GPT2-large, and other challenge splits. Likelihood Splits are more challenging than random splits while not being adversarial to GPT2-medium. Δ marks the performance drop from T5-base to GPT2-medium.

et al. (2021), we create TMCD (Target Maximum Compound Divergence) splits of SPIDER by maximizing the divergence between the distributions of compounds in the train and evaluation sets.

Template. These splits test the ability of parsers to generate unseen program templates (canonicalized programs formed by anonymizing all variable names and standardizing syntax). We group examples in the SPIDER dataset based on templates defined by Finegan-Dollak et al. (2018). To create the evaluation set, we randomly pick groups of examples till the target set size is reached; the remaining groups form the training set.

4.3 Model Performance on Likelihood Splits

In Table 2, we report exact match accuracy⁴ on the data splits using the SPIDER evaluation suite. For SNLI and BOOLQ, we report the accuracy of benchmarked models in Table 3. We create 3 random splits and report mean and standard deviation of accuracy of models trained on each split.

Likelihood Splits are more challenging than random splits. On SPIDER, for example, T5-base accuracy on *ll_split* is 12.6 points lower than the random split accuracy. Likelihood Splits lead to drops in performance that are comparable to the

⁴This metric accounts for the fact that SQL statements are invariant to certain shuffling and change in variable names.

System	SNLI					BOOLQ				
	Random	ll_split		$ll_split\ pt$		Random	ll_split		$ll_split\ pt$	
		(-len)		(-len)			(-len)		(-len)	
ROBERTA-base	89.6 \pm 0.4	79.3	77.1	82.6	81.7	74.9 \pm 0.4	71.6	71.2	72.4	71.9
ROBERTA-large	90.5 \pm 0.5	82.4	79.2	85.0	84.3	84.4 \pm 0.6	79.3	78.9	82.3	80.6
ELECTRA-base	90.5 \pm 0.2	80.1	78.4	82.9	82.8	78.8 \pm 1.1	74.1	74.3	75.2	73.6
ELECTRA-large	91.0 \pm 1.3	82.6	81.6	85.9	84.9	85.5 \pm 0.6	82.6	82.1	83.7	81.9
ROBERTA-large (Hypothesis-only)	70.2 \pm 0.3	64.6	64.6	67.2	69.6	-	-	-	-	-
Human Accuracy	88.7 \pm 0.8	83.6	84.4	85.2	86.4	-	-	-	-	-

Table 3: SNLI and BOOLQ: Accuracy for various splits and model sizes. Likelihood Splits lead to decreased model performance. Controlling for length further increases the difficulty.

alternative challenge splits. Only Likelihood Splits focus on challenges derived from input language variation; we analyze these challenges in §5.1.

On SNLI and BOOLQ, Likelihood Splits are also more challenging than random splits. For example, ELECTRA-large accuracy decreases by 8.4 points on SNLI and 2.9 points on BOOLQ. On SNLI, the performance of the hypothesis-only baselines on Likelihood Splits is lower than that on the random splits, which indicates that our splits are less easily solved by modeling spurious statistical cues.

Controlling for length preserves challenging nature of splits. Likelihood is negatively correlated with length, so Likelihood Split test data contains longer examples. On SPIDER, generalizing to longer utterances is challenging, so controlling for length makes the Likelihood Splits less challenging. However, these splits are still much more challenging than random splits. For T5-base, ll_split (-len) is 7.3 points harder and $ll_split\ pt$ (-len) is 5.1 points harder than the random split. By controlling for length, we identify examples that are more challenging for other reasons (discussed in §5.1). Fitting the dataset distribution with a fine-tuned LM reduces the correlation between length and likelihood on SPIDER. Accordingly, $ll_split\ pt$ poses a stronger length generalization challenge than ll_split , and thus is more challenging: T5-base accuracy drops by 18 points on $ll_split\ pt$ compared with the random split.

Conversely, for SNLI and BOOLQ, controlling for length makes the Likelihood Splits slightly harder compared to their uncontrolled versions (ELECTRA-large accuracy drops by 1% from ll_split to ll_split (-len) on SNLI, and by 0.5% on BOOLQ). This suggests length is not a reason that Likelihood Splits are harder for these datasets. Relatedly, $ll_split\ pt$ is easier than ll_split here.

Likelihood Splits do not unfairly penalize the scoring LM. The difference in accuracy between T5-base and GPT2-medium are comparable across all splits (Δ in Table 2). This shows that the Likelihood Splits do not unfairly penalize GPT2-medium, the model used to create the Likelihood Splits. Thus, benchmarks based on Likelihood Splits will be fairer to model class of the LM used.

Human accuracy is less affected. We estimate human accuracy on the evaluation sets using the \sim 10% of examples that were annotated with 5 labels in the original SNLI dataset. Human accuracy is at most 5.1% lower on our proposed splits than on the random splits. Model performance drops more severely than the smaller drop in human accuracy; models that were previously superhuman are now worse than the estimated human performance (except for ELECTRA-large on $ll_split\ pt$). In comparison, adversarial filtering (Le Bras et al., 2020) has a larger drop in human accuracy from 88% on the standard split to 78% on their most challenging split. Thus, our method does not as heavily emphasize mislabeled or ambiguous examples.

4.4 Effect of the LM on Likelihood Splits.

We study the effect changing the language model by using a GPT2-large model to create the Likelihood Splits of SPIDER. The log-likelihood scores assigned to the examples by GPT2-medium and GPT2-large are highly correlated; Pearson correlation coefficient (r) between log-likelihood scores from fine-tuned models is 0.96 while it is 0.99 for the pre-trained models. Accounting for swapping of examples in order to meet the atom constraint, the evaluation sets differ in 16% of examples in the ll_split setting, and 10% of the examples in $ll_split\ pt$ setting. ll_split is more challenging when using GPT2-large; T5-base accuracy drops an additional

System	Random	<i>ll_split</i>		<i>ll_split reverse</i>	
		(-len)		(-len)	
SPIDER					
T5-base	78.6	66.0	71.3	83.9	81.5
SNLI					
E-base	90.5 \pm 0.2	80.1	78.4	96.6	97.4
E-large	91.0 \pm 1.3	82.6	81.6	96.7	97.4
BOOLQ					
E-base	78.8 \pm 1.1	74.1	74.3	77.8	78.1
E-large	85.5 \pm 0.6	82.6	82.1	85.8	86.8

Table 4: Accuracy on SPIDER, SNLI and BOOLQ when training on the unlikely (tail) queries and evaluating on the likely (head) queries (*ll_split reverse*). The model accuracy on the reverse splits are comparable to or higher than accuracy on the random split. This supports the claim that generalizing to rare instances is a significant challenge. (E-base and E-large are ELECTRA models)

4.2% compared to the *ll_split* with GPT2-medium. The other splits are comparable with accuracies differing by 1-2% across all models (see Table 2). Thus, we expect splits created with different LMs to demonstrate similar characteristics.

4.5 Are Reverse Likelihood Splits Difficult?

We wish to test whether the decrease in task accuracy is driven by rarity of the instances or whether any likelihood based distribution shift is challenging. We test this hypothesis by creating a setting that requires generalizing from the tail of the distribution to the head. Using the same likelihoods as before, we create reverse splits where the more likely (head) of the distribution is used as the evaluation set instead of the unlikely (tail). From Table 4, we see that the accuracy of ELECTRA-large on SNLI increases from 81.6% on the Likelihood Split to 96.7% on the reversed split. For comparison, this is more than the accuracy on random splits of SNLI (91%). We see similar trends on BOOLQ and SPIDER where the reverse splits are as easy as or easier than the corresponding random splits. We conclude that generalizing specifically to the tail is what makes our splits difficult.

5 Analysis of Data Splits

In order to highlight the challenges posed by our proposed splits, we analyze how the development sets (to ensure unseen test sets) differ from the training sets in each split. Our splits require models to simultaneously excel at many different skills be-

lieved to be important for language understanding.

5.1 Properties of the Proposed SPIDER Splits

TMCD-related properties and length. Following Shaw et al. (2021), we report atom and compound divergences of the various splits in Table 13 of Appendix A.4. Divergence measures how much the distribution of atoms/compounds differs between the train and evaluation set. Our approach leads to splits with higher than random atom divergence, which shows that our split poses the challenge of **generalizing to rare atoms**. Similarly, a greater than random compound divergence emerges from the resulting split. This means that the split also requires some amount of **compositional generalization**. From Figure 6 in Appendix A.6, we see that log-likelihood preferentially puts the longer queries in the test set and the corresponding length variation is closer to that of the length split than the other splits. Hence, it naturally requires some aspect of **length generalization**. As expected, by controlling for length of the utterances, we can remove the challenge of length generalization.

Program difficulty. SPIDER assigns a rating of ‘easy’, ‘medium’, ‘hard’, or ‘extra hard’ to every SQL program. From Figure 2, we see that the evaluation sets of the Likelihood Splits contain more examples from the harder categories than the training sets. Controlling for length reduces this effect but does not completely remove it (see Appendix A.5 for more details). Note that this skew emerges even though we do not consider the programs when creating these splits.

Rare words. On the input side, we first analyze the distribution of rare words. We define rare words as all English words⁵ in the SPIDER dataset that occur at most 1 time per million words according to SUBTLEXus (Brysbaert and New, 2009). This results in a list of 561 words. We report the fraction of words in the development set that are rare. This metric automatically controls for the length of the examples; longer examples are more likely to contain rare words by chance. To estimate the distribution of this fraction under random splits (null distribution), we create 500 random splits and plot the distribution of values observed. From Figure 3, we observe that the Likelihood Splits have more rare words in the test set, especially for the *ll_split*

⁵We filter out incorrect spellings using the word list at <https://github.com/dwyl/english-words>

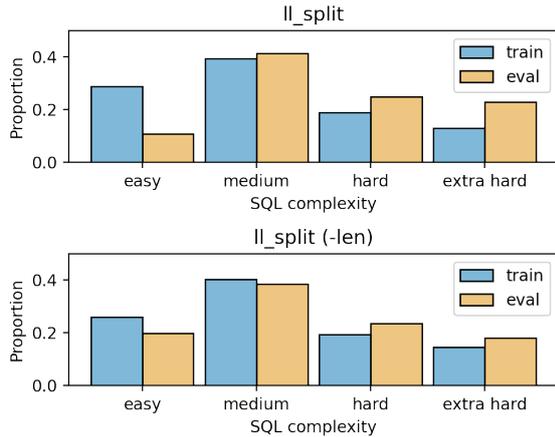

Figure 2: SPIDER: Distribution of SQL programs of varying complexity in the train and development set of Likelihood Splits. These splits show a skew towards training on easy examples and evaluating on harder examples.

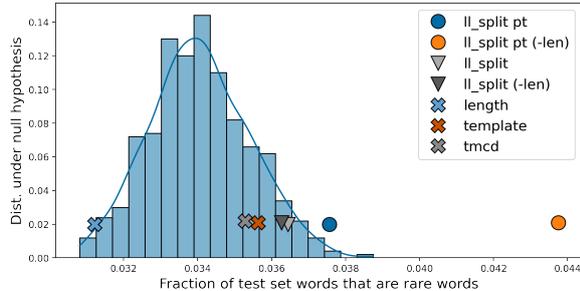

Figure 3: SPIDER: Statistics of the fraction of dev set words that are rare for various splits. This is plotted against the distribution of values observed for 500 random splits of the data. *ll_split* variants retain a larger fraction of rare words in the test set. Controlling for length finds shorter examples with more rare words.

pt setting. Controlling for length puts shorter examples in the evaluation sets, but a larger fraction of the words are rare. The other challenging splits considered do not focus on the input language variation and hence the fraction of development set words that are rare is closer to random.

Input syntactic complexity. We also study the query parse tree structures in various splits of the dataset in Figure 8. We measure the complexity of the parse tree based on mean and max depth as well as Yngve score (Yngve, 1960) which is a measure of syntactic complexity. We see that more complex queries tend to be assigned lower likelihood and correspondingly put in the evaluation set. The effect of the complexity is also correlated with length and balancing for length reduces the gap between

Category	Random	<i>ll_split pt</i>
Easy	92.3% (.225)	81.3% (.077)
Medium	82.3% (.409)	71.6% (.435)
Hard	78.4% (.201)	60.1% (.233)
Extra Hard	62.9% (.164)	52.5% (.254)
Dev set Acc	80.6%	64.8%
Projected Acc		77.15%

Table 5: SPIDER: Accuracy of T5-base aggregated by the SQL hardness rating for random and *ll_split pt* dev sets. The number in brackets is the fraction of dev set examples that fall in each bucket. The examples in the dev set of *ll_split pt* are skewed towards harder examples. However, performance of T5-base on *ll_split pt* is lower than performance on random split in every bucket. Projecting and re-weighting the random set accuracies using the fraction of examples in each bucket in *ll_split pt* over-estimates dev set performance.

the complexity of the train and test set. We refer the reader to Appendix A.7 for more details.

Effect on accuracy. In Appendix A.8 and Table 5, we show that the higher frequency of both novel compounds (i.e., compounds not seen during training) and harder programs each partially explain the higher difficulty of *ll_split pt* for T5-base. For example, 16% of dev examples in the random split have ‘extra hard’ programs, compared with 25% in *ll_split pt*. On the random split, T5-base gets 63% of these examples correct, compared with 81% dev accuracy overall, so these examples are indeed more challenging. On ‘extra hard’ examples in *ll_split pt*, T5-base has an even lower accuracy of 53%. Thus, the mere fact that *ll_split pt* has more ‘extra hard’ examples does not fully explain why it is harder; other factors must also be playing a role.

5.2 Properties of the Proposed SNLI Splits

For SNLI, we study the variation of premise and hypothesis length (A.9), distribution of rare words (A.10), Yngve score (Yngve, 1960) for syntactic complexity (A.11), and Flesch-Kincaid (Kincaid et al., 1975) reading grade-level (A.12). Evaluation sets of Likelihood Splits of SNLI are more complex than their corresponding training sets on all 4 variations; evaluation set examples tend to be longer, tend to contain more rare words, are more syntactically complex, and have higher reading levels.

Controlling for length removes length variation, and slightly decreases the skew in reading level. Surprisingly, the Yngve scores of evaluation examples are skewed to being less complex than the

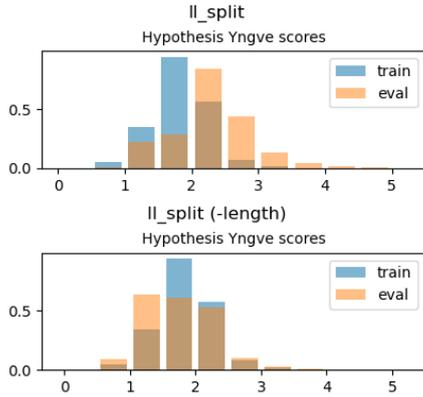

Figure 4: SNLI: Distribution of Yngve scores computed on the parse tree of the hypothesis. The evaluation sets for *ll_split* contain more complex utterances. Normalizing for the length surprisingly reverses the skew.

corresponding training set (see Figure 4), even though the length controlled variants of SNLI are more challenging than the corresponding Likelihood Splits. Some of the difficulty when controlling for length can be explained by the increased proportion of rare words.

We analyze the errors of ROBERTA-large on the development set of *ll_split (-len)*, the hardest SNLI split (see Appendix A.13 for concrete examples). We find several instances of examples that require common-sense or world knowledge to be solved correctly. These include knowledge of terms such as crowd-surfing and lincoln logs (a type of toy), and facts like zip-lining is an exciting activity. We find that a small fraction of the errors are caused by ambiguous or incorrect labels. There are several instances of spelling mistakes, a few of which change the meaning of the sentence.

6 Conclusion

With the saturation of static, single-metric leaderboards, there is growing consensus for the development of holistic evaluation benchmarks. This includes evaluation of systems on aspects of performance beyond just single error rate on in-distribution data; aspects such as performance on out-of-distribution data (Linzen, 2020), and evaluating generalizability, robustness and fairness (Ethayarajh and Jurafsky, 2020). In this work, we describe an approach to benchmark long-tail generalization, a necessary skill for NLP systems that truly understand language. We demonstrate the challenge posed by our splits to state-of-the-art models on several tasks; standard evaluation overestimates

model performance on long-tail utterances. Instead of releasing a random split as the only metric on official benchmarks, our simple method can be used, for a wide range of tasks, to expose additional challenges in the collected data at no annotation cost. Benchmarking long-tail generalization, in this manner, can test model behavior on a broad set of generalization challenges, which may be missed by evaluations that test specific skills in isolation.

Limitations

Evaluating a proposed benchmarking method such as ours is challenging, as there is no community consensus on what properties characterize an ideal benchmark. While we have argued that Likelihood Splits have a number of desirable properties, ultimately we intend Likelihood Splits to *complement* other options for creating benchmarks, not replace them. In particular, we do not aim to replace methods that require additional annotation and domain knowledge discussed in §2. In situations where previously collected datasets contain no or very few examples of a particular type, creating new data may be the only way to test models on that type of example. We view our approach as one lightweight option that dataset curators can choose to create a more holistic benchmark.

The properties of the Likelihood Splits that we have studied in this work do not fully explain what makes the Likelihood Splits harder. Dataset splits that explicitly test specific skills like length generalization and compositional generalization are good at exposing specific weaknesses in models. While it is hard to pinpoint the source of difficulty, our approach is complementary in that it can test a much broader set of skills that a narrow test may miss.

The difficulty of out-of-distribution generalization is higher in low resource languages, however, we show that the problem is yet not solved for NLP tasks even in the high resource English language. Our approach has the flexibility to use any autoregressive LM to score the utterances; large multi-lingual LMs such as BLOOM (Scao et al., 2022) can be used if appropriate.

The model performance gaps between random split and Likelihood Splits are small (2-4%) on some datasets (e.g. BOOLQ). We cannot guarantee that Likelihood Splits for a new dataset will be much more challenging than random splits. In such a situation, other complementary evaluation strate-

gies may be recommended to more strenuously challenge models.

Our approach has multiple knobs to control the properties of the splits created: (1) prompting/fine-tuning the LM, (2) controlling length variation, and (3) dataset specific choices such as label balancing. This choice gives dataset curators a lot of control to modify the approach. It is possible that the behaviour of the splits might be inconsistent under some changes. In our experiments, we find that qualitative findings are largely consistent, even across changes such as using a different language model.

Finally, there is no guarantee that the challenge posed is a fair generalization task (Geiger et al., 2019); we cannot guarantee that all skills needed to solve the test set can be learned from the training set. Nevertheless, since our approach partitions data that was collected under a single consistent protocol, it is more likely to be fair than methods that rely on an additional, separate annotation process to create test data.

Acknowledgements

We thank Xiang Ren for discussions and feedback in the initial stages of the work. We thank Rajarshi Das and colleagues at USC for feedback on drafts of this work. This work was funded in part by a gift from Open Philanthropy.

A Appendices

A.1 Dataset Statistics

Refer to Table 6 for final split sizes. When creating the splits, we first partition the available data into train and evaluation (combined size of dev + test) sets using the methodology of each split (e.g. TMCD maximizes compound divergence, Likelihood Splits sort by an LM score and then partition the data). Then the evaluation set is randomly divided into dev and test sets.

Dataset	Train	Dev	Test	Total
SPIDER	5,966	1,034	1,034	8,034
SNLI	549,018	10,000	10,000	569,018
BOOLQ	7,617	2,540	2,540	12,697

Table 6: Sizes of train/dev/test sets for the dataset splits

The public release of the SPIDER dataset consists of 7000 training examples and 1034 validation examples (it also contains 1659 additional examples from older datasets which we do not use in our work). We use these 8034 examples to create all our splits. Shaw et al. (2021), one of the alternative splits that we compare against, use a subset of 4000 examples from the 7000 training examples. Hence, our results are not directly comparable to performance reported by them. The SQL programs for 6 (of 8034) examples in the dataset cannot be parsed uniquely and thus we cannot define compounds on these examples. We drop these examples when creating the TMCD split i.e. the training set of TMCD split contains 6 fewer examples.

The SNLI data contains 550152 training examples, 10000 dev examples and 10000 test examples for a total of 570152 examples. We drop examples where the gold label cannot be determined by majority vote. We also drop examples where the premise was labelled ‘Cannot see picture to describe.’ or the hypothesis is empty. This results in a filtered dataset of 569018 examples from which we create our splits.

The public release of BOOLQ contain 9427 labeled training examples, 3270 labeled development examples, and 3245 unlabeled test examples. Thus we create our splits from the 12,697 labelled train and development examples. We maintain the approximate 60/20/20 train/dev/test proportions of the original dataset when creating the splits.

A.2 Model Hyperparameters

We use the Transformers library (Wolf et al., 2020) for training and evaluation. All models were trained on Nvidia Quadro RTX 6000 GPUs (24GB GPU Memory).

We report hyperparameters for fine-tuning GPT-2 to create the Likelihood Splits in Table 7. We select the best checkpoint based on lowest perplexity by validating on 10% of the training data in each fold.

Hyperparameters for SPIDER models are in Table 8, for SNLI models in Table 9 and for BOOLQ models in Table 10. Note that we evaluate check-

Hyperparameter	Value
train batch_sz	32
lr_scheduler	constant
learning_rate	2e-5
optimizer	AdamW
eval steps	64
	SPIDER: 2000
max steps	SNLI: 15000
	BOOLQ: 3000

Table 7: Hyperparameters for fine-tuning GPT-2 (both medium and large) on the dataset folds to create Likelihood Splits

	T5	GPT-2
train batch_sz	8	2
grad acc steps	16	16
max_steps	10000	10000
lr_scheduler	constant	constant
learning_rate	1e-3	2e-5
optimizer	Adafactor	AdamW
max src_length	512	512
max tgt_length	256	256
src prefix	-	database question for table
tgt prefix	semanticparse:	generate the sql parse:
eval batch_sz	8	1
eval steps	256	128
num_beams	5	5

Table 8: Hyperparameters for the models trained on SPIDER.

points (see hyperparameter ‘eval steps’) during training to select the best checkpoint at the end of training.

For SPIDER, we follow Shaw et al. (2021) and tune the learning rate, batch size and maximum training steps for a T5-base model (Raffel et al., 2020) on a random split of the SPIDER dataset. Once we have found a hyperparameter setting, we apply the same setting on the all splits. We also report performance of a T5-small model on all splits trained with the same hyperparameters.

For SNLI and BOOLQ, we follow the default hyperparameters suggested by the original works. Additionally, we perform early stopping when performance on the validation set fails to improve for a specified number of evaluations.

A.3 Effect of k on Likelihood Splits

When creating Likelihood Splits, the number of folds k for fine-tuning (§3.2) is a choice left to the creator of the benchmark. In our work, we

set $k = 3$ as an arbitrary choice prior to running the task models i.e. it was not tuned based on task model performance. We conduct additional experiments to test the effect of changing the value of k by setting $k = 5$ and generating new splits.

On SPIDER, when $k = 5$ instead of $k = 3$, Likelihood scores are highly correlated with a Pearson’s r of 0.90. However, the process of balancing atoms (described in §3.4) causes the evaluation sets to look more different. When controlling for length, 77% of the evaluation set examples are the same; 80% of the evaluation examples are the same otherwise. We report the accuracy of T5-base (the most competitive baseline model on SPIDER) on the new splits with $k = 5$ in Table 11. The new splits are more difficult by about 2%. We observe the same trend where controlling for length makes the splits less challenging.

On BOOLQ, when using 5 folds instead of the 3 folds, Likelihood scores are highly correlated with a Pearson’s r of 0.96 and 89% of the evaluation set examples are the same. Accordingly, the ELECTRA-large accuracy only changes slightly from 82.6% to 83% on the new test set and is still lower than the random split accuracy. While there exists an indication that controlling for length makes the ll_split (-len) splits more challenging, the effect of controlling for length becomes more pronounced when $k = 5$. We report the effect of k on BOOLQ performance in detail in Table 12.

We report the effect of changing k on SNLI accuracy in Table 12. Since the SNLI dataset is an order

of magnitude larger than the SPIDER and BOOLQ datasets, the number of folds has less of an impact on the LM fine-tuning. As a result, Likelihood scores for $k = 3$ and $k = 5$ are highly correlated with a Pearson’s r of 0.99. When controlling for length, 89% of the evaluation set examples are the same; 92% of the evaluation examples are the same otherwise. Accordingly, we see much smaller differences in model performance on the new splits; the ROBERTA model accuracies change by at most 0.9% on the new test sets.

A.4 SPIDER: Variation of TMCD Related Properties

Past work by [Keysers et al. \(2020\)](#) has established the terms of atom and compound “divergence” to quantitatively describe the extent to which the distributions of the atoms and compounds differ between the train and evaluation sets. They used the Chernoff coefficient ([Chung et al., 1989](#)) to measure distribution similarity:

System	SNLI					BOOLQ				
	Random	ll_split (k=3)		ll_split (k=5)		Random	ll_split (k=3)		ll_split (k=5)	
		(-len)	(-len)	(-len)	(-len)		(-len)	(-len)		
ROBERTA-base	89.6 ±0.4	79.3	77.1	78.4	75.0	74.9 ±0.4	71.6	71.2	71.1	70.3
ROBERTA-large	90.5 ±0.5	82.3	79.2	82.1	79.0	84.4 ±0.6	79.3	78.9	78.4	78.3
ELECTRA-base	90.5 ±0.2	80.1	78.3	80.1	77.6	78.8 ±1.1	74.1	74.3	75.0	73.9
ELECTRA-large	91.0 ±1.3	82.6	81.6	84.0	80.6	85.5 ±0.6	82.6	82.1	83.0	80.6
Human Accuracy	88.7 ±0.8	83.6	84.4	83.0	84.0	-	-	-	-	-

Table 12: Effect of k on the difficulty of Likelihood Splits of SNLI and BOOLQ. There are some accuracy differences on BOOLQ, however the values are comparable and significantly lower than the accuracy on Random splits. The accuracy differences are less pronounced on SNLI.

$$C_\alpha(P \parallel Q) = \sum_k p_k^\alpha q_k^{1-\alpha} \in [0, 1] \quad (1)$$

where p_k and q_k are the probability of a particular atom/compound k being in the train and test set respectively. The divergence is then $1 - C_\alpha$. The ‘‘atom’’ divergence uses $\alpha = 0.5$ as a symmetric divergence score. The ‘‘compound’’ divergence used $\alpha = 0.1$ to give more importance to the occurrence of a compound in the train set rather than trying to make the distributions of train and test set similar.

Split	Atom	Compound
Random	0.077	0.046
Length	0.120	0.092
Template	0.105	0.089
TMCD	0.296	0.322
ll_split	0.083	0.054
ll_split (-len)	0.081	0.049
ll_split prompt	0.093	0.056
ll_split prompt (-len)	0.094	0.052

Table 13: Atom and Compound divergence (on the logical form side) between train and dev sets of various splits. Although we ensure every atom appears at least once in the train set, a high atom divergence demonstrates the challenge of learning rare atoms. A greater than random compound divergence emerges denoting a need for compositional generalization.

A.5 SPIDER: Variation of SQL Hardness

We use a tool provided by the SPIDER dataset creators to evaluate hardness. The tool assigns a rating from easy, medium, hard or extra hard to every example based on the complexity of the SQL parse. Complexity is evaluated in terms of the number of join and aggregation operations, and nested SQL statements. We find that the Likelihood Splits are skewed towards putting more complex examples

in the evaluation set compared to the test set (see Figure 5).

A.6 SPIDER: Input Length Variation

As expected, the likelihood assigned by the language model (LM) is negatively correlated with sequence length meaning i.e. longer sequences tend to have lower likelihood. This can be seen from Figure 6, where ll_split and ll_split_pt tend to put longer utterances in the lower likelihood evaluations set. Accounting for length by dividing the data within buckets makes the distribution of train and test sets align better and remove the added difficulty of length generalization. The $length$ split poses this challenge which has been established to be a difficult ability for generation models to acquire (Newman et al., 2020). Note that the distributions do not match exactly since examples need to be swapped between train and evaluation set to meet the atom constraint (evaluation cannot contain any unseen atoms).

A.7 SPIDER: Variation of Query Parse Structure

We analyze the complexity of the parse structure of the queries. Following Wallace et al. (2021), we parse the queries using the Benepar parser (Kitaev and Klein, 2018) based on T5 small (Raffel et al., 2020). We report the distributions of mean and max parse tree depth as well as the syntactic complexity of the utterance based on the Yngve score (Yngve, 1960; Roark et al., 2007). The Yngve score essentially measures the average number of left branches on the path from the root of the parse tree to every word in the sentence and can be thought of as measuring the number of spans that need to be coordinated.

We can see that the dev set of the ll_split is on average more complex than its train set along all 3

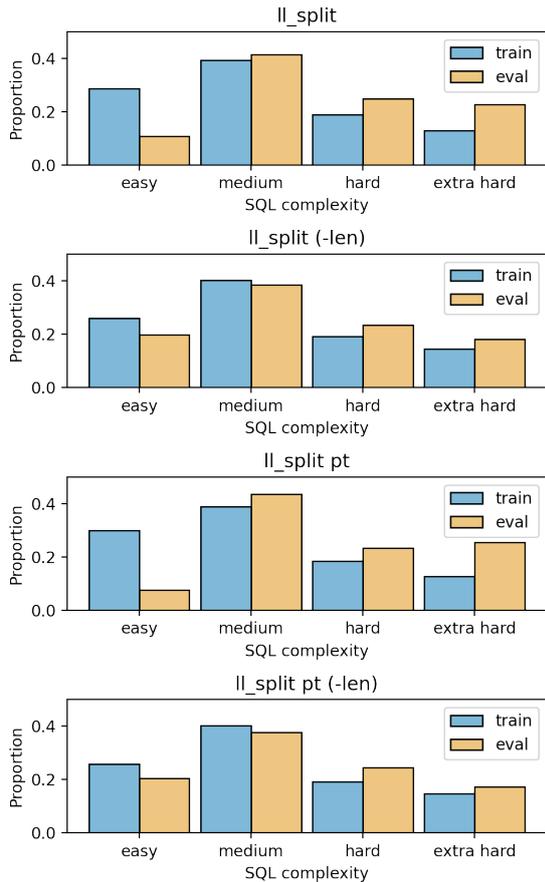

Figure 5: SPIDER: Distribution of SQL programs of varying complexity in the train and development set of various splits. Likelihood Splits show a skew towards training on easy examples and evaluating on harder examples.

metrics considered (see Figure 8). Moreover, these metrics are correlated with utterance length, and controlling for it in the *ll_split (-len)* split makes the difference less pronounced.

A.8 SPIDER: Error Analysis

We analyze the performance of T5-base on the development set of *ll_split pt*. In particular, we test whether the presence of novel compounds and SQL query hardness are sufficient to explain the difficulty.

We call compounds in the SQL programs of the development set as ‘novel’ if they do not occur in the training set of the split. 25.5% of the dev set examples in the random split contain at least one novel compound as opposed to 43.6% of the dev set examples of *ll_split pt*. From Table 14, we see that T5-base performance is lower in both categories of examples. Projecting for expected performance on dev set of *ll_split pt* assuming the examples

Split	Random	<i>ll_split pt</i>
Percent. of examples with a novel compound	25.5%	43.6%
Acc on examples with novel compounds	61.4%	45.5%
Acc on remaining examples	87.1%	79.8%
Acc on the dev set	80.6%	64.8%
Projected accuracy		75.9%

Table 14: SPIDER: The presence of novel compounds alone does not explain the difficulty of the *ll_split pt*. Projecting the random set accuracies using the percentage of examples with novel compounds in *ll_split pt* over-estimates dev set performance.

were as difficult as examples from the random split over-estimates the performance of T5-base.

We report performance of T5-base on the dev sets grouped by the SQL hardness metric (described in Appendix A.5) in Table 5. We see that accuracy on *ll_split pt* is lower than the accuracy on the random set within each SQL complexity bucket. If the sole source of difficulty was the larger proportion of harder examples, projecting the random set accuracies would correctly estimate dev set performance on *ll_split pt*. However, the projection is an over-estimate. Thus, the hardness metric alone does not explain the difficulty of the proposed split.

A.9 SNLI: Input Length Variation

From Figure 9, we see that the Likelihood Splits put longer premises and hypotheses in the evaluation set. Controlling for length completely removes this skew while increasing the difficulty of the splits (Table 3). This means that if we remove the factor of length from likelihood, the remaining examples have lower likelihood for other reasons; reasons that contribute to difficulty.

A.10 SNLI: Distribution of Rare Words

We report the fraction of test sets words that are rare for various splits in Figure 7. This evaluation combines the premise and the hypothesis i.e. it considers the full task input. In order to remove typographical errors, we only consider words that occur in a wordlist of English words (<https://github.com/dwyl/english-words>). We define rare words as words that occur at most 1 time per million words statistics collected in SUBTLEXus (Brybaert and New, 2009). This process results in a list of 13478 low frequency words that occur in the SNLI dataset. We find that Likelihood Splits

put examples with a significantly large fraction or rare words in the evaluation set. Controlling for length increases the fraction of rare words since length is removed as a factor from likelihood.

A.11 SNLI: Variation of Syntactic complexity

We compute Yngve scores for premise and hypothesis of examples as described in Appendix A.7. The complexity of premise and hypothesis in developments sets of Likelihood Splits is higher than in the corresponding train sets (see Figure 10). Controlling for length removes this skew in the premise. However, the length controlled splits tend to have less syntactically complex hypotheses in the evaluation sets. This is surprising because the length-controlled variants are actually more difficult for the model; human performance is higher on length-controlled splits.

A.12 SNLI: Variation of Reading Level

We compute the Flesch-Kincaid reading level (Kincaid et al., 1975) for premise and hypothesis of examples. This score takes into account the number of syllables per word in the sentence. The reading grade (complexity) of premise and hypothesis in developments sets of Likelihood Splits is higher than in the corresponding train sets (see Figure 11). Controlling for length does not fully remove this skew and the evaluation examples retain more complex sentences than in the training set.

A.13 SNLI: Error Analysis

In Table 15, we present some examples from the development set of *ll_split (-len)* where the fine-tuned ROBERTA-large model predicts incorrectly. We divide them into categories: examples requiring external world knowledge, examples where a typo changes the meaning of the example, and examples with ambiguous or incorrect labels.

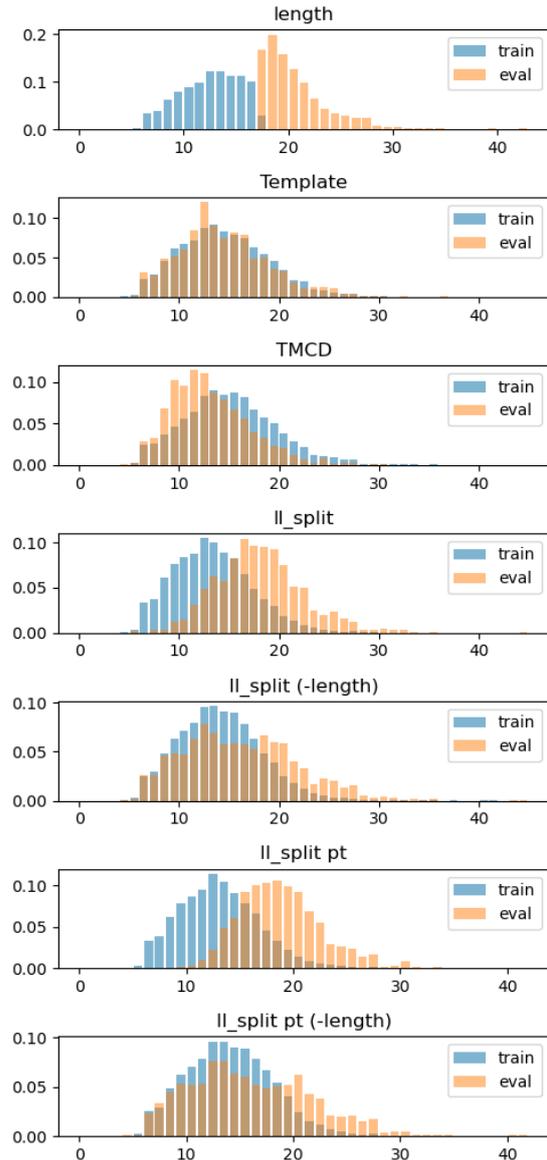

Figure 6: SPIDER: Input length variation for the splits. Y-axis is the distribution of examples within each length bucket of the X-axis

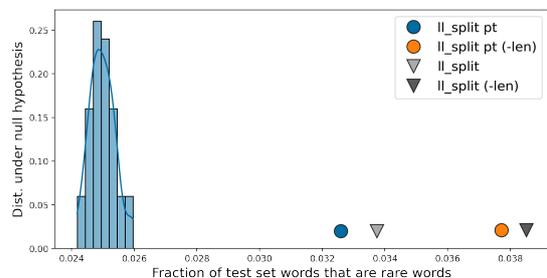

Figure 7: SNLI: Fraction of development set words that are rare in the premise and hypothesis of various splits. The dev sets for *ll_split* seem to contain a larger fraction of rare words than random splits. Normalizing for the length seems to retain more rare words.

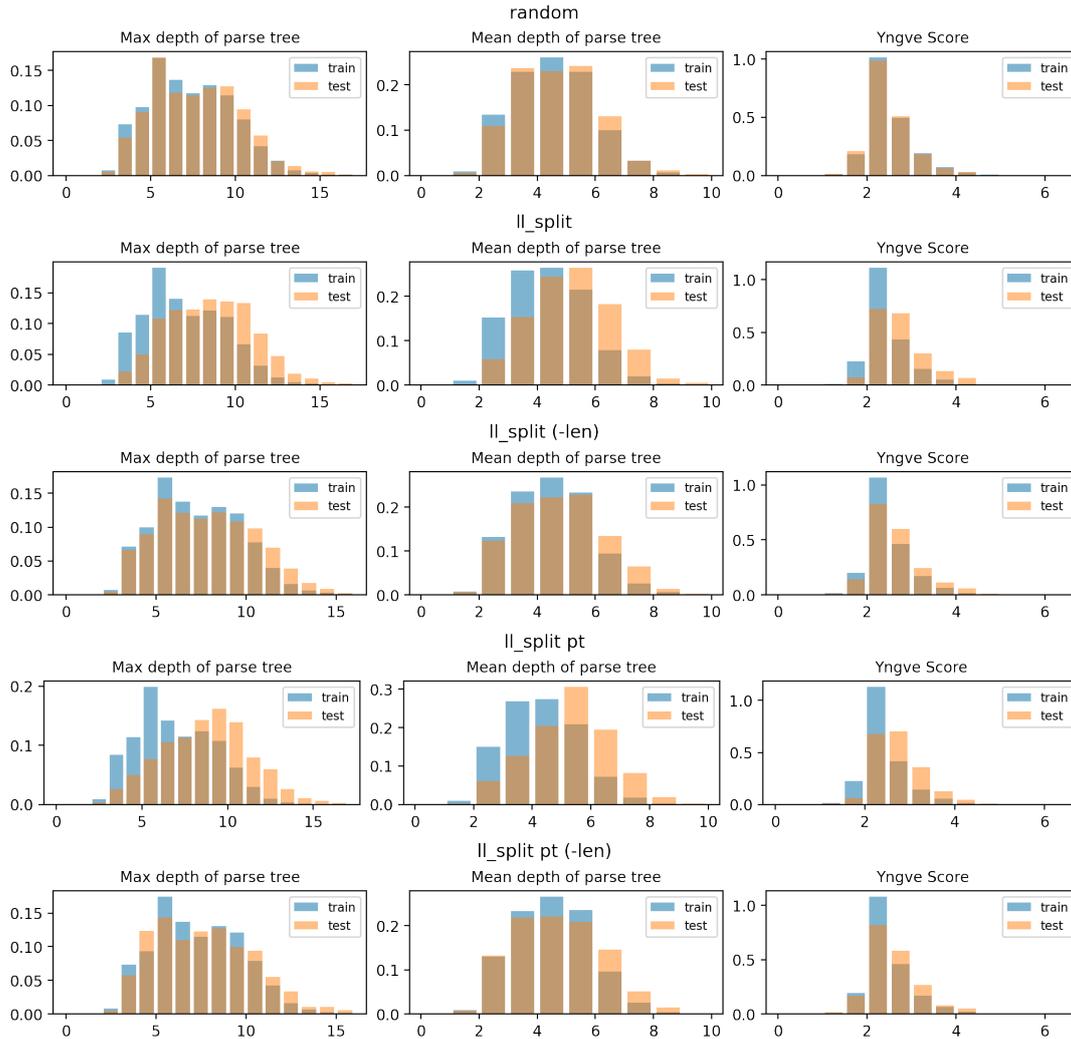

Figure 8: SPIDER: Distribution of features computed on the parse tree of the input query. The dev sets for *ll_split* seem to contain more complex utterances across all 3 metrics considered. Normalizing for the length seems to reduce the effect. The metrics are mean and max depth of parse tree and Yngve score which is a metric

Error Type	Premise	Hypothesis	Gold Label	Predicted Label
Requires External Knowledge	A young boy is holding on and riding a zip line down a hill.	A exciting adventure!	entailment	neutral
	A young child is watching a toy construction brick construct.	A child is using lincoln logs.	neutral	contradiction
	A performer is jumping off the stage into a crowd of fans.	The artist is crowdsurfing.	entailment	neutral
	A couple holds up their child on a series of large steps while others are also traversing the steps.	A fourteen year old is restrained from the museum.	contradiction	neutral
Typo	Martial artists perform in front of a crowd outdoors.	There is a crown outdoors.	entailment	neutral
Ambiguous / Incorrect Labels	Technicians working in underground.	People work underground while dinosaurs attacked	neutral	contradiction
	A young gentlemen with a blue tie talking into a microphone.	High winds will interfere with microphone recording.	entailment	neutral

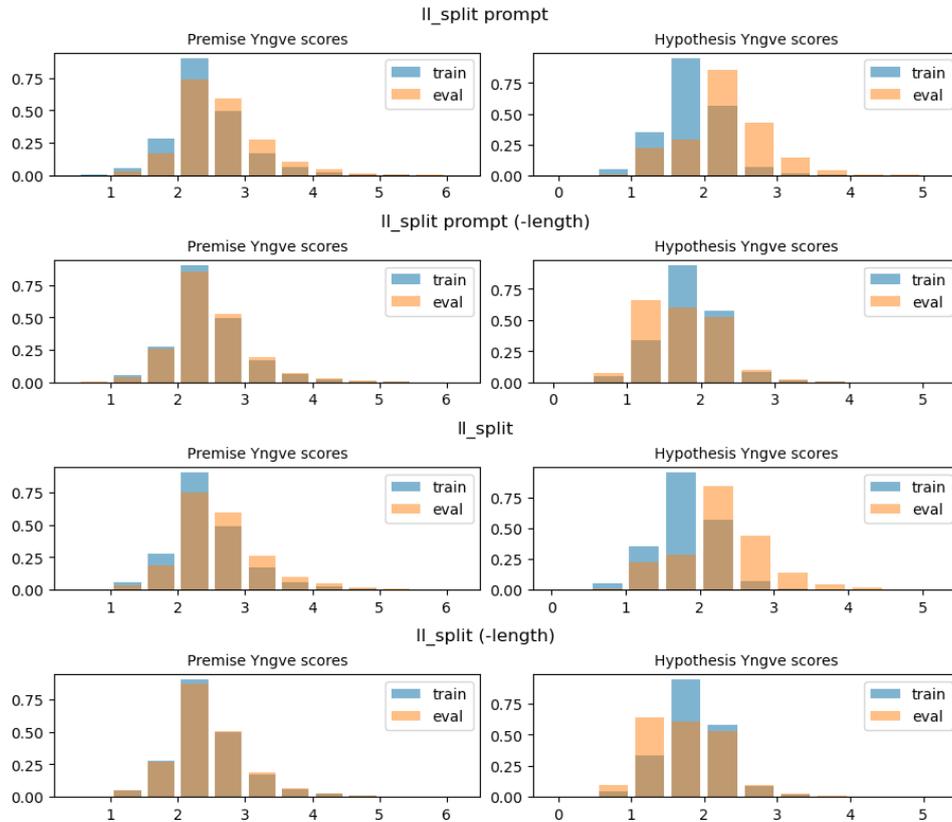

Figure 10: SNLI: Distribution of Yngve scores (syntactic complexity) computed on the parse tree of the premise and hypothesis. The dev sets for Likelihood Splits contain more complex utterances.

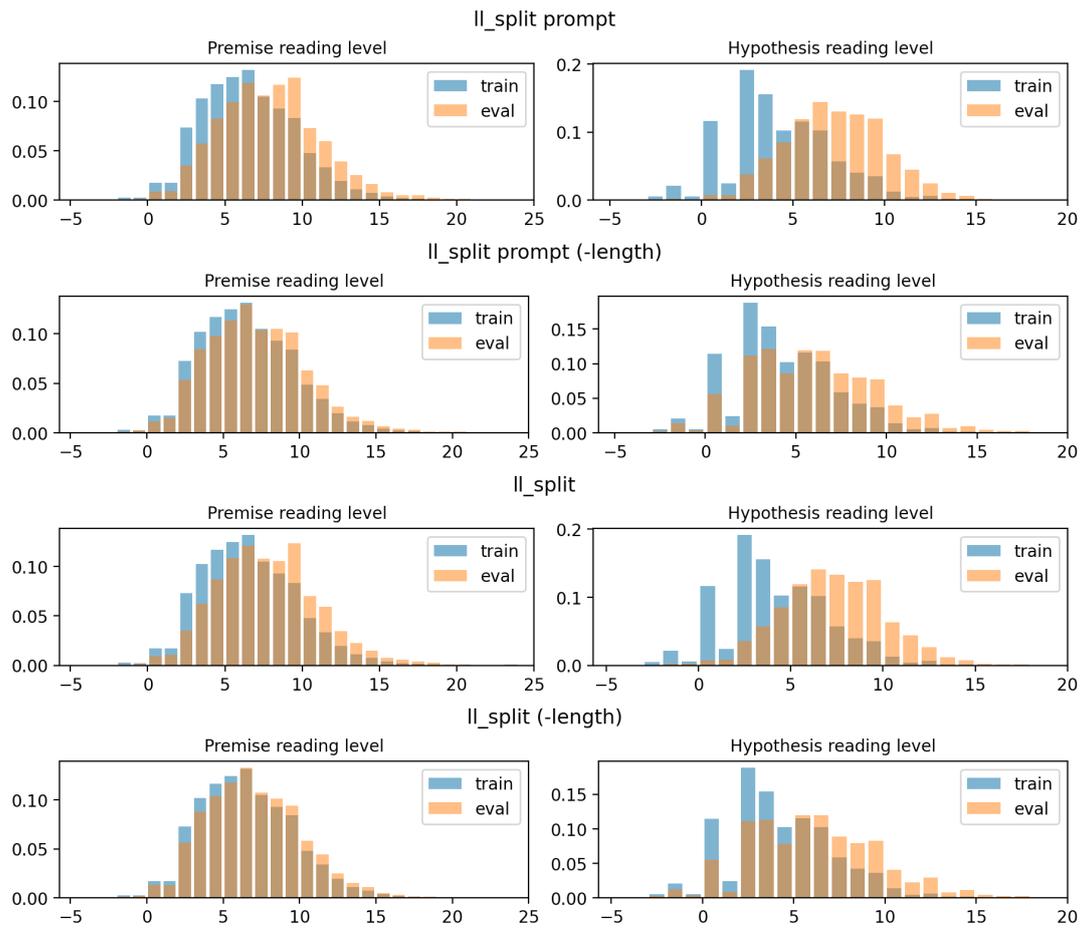

Figure 11: SNLI: Distribution of Flesch-Kincaid reading level for the premise and hypothesis in various splits. The dev sets for *ll_split* seem to contain more complex utterances. Normalizing for the length seems to reduce but not remove the effect.

Despite being highly effective, a common weakness of this family of approaches is that they synthesize code-switched sentences using word lexicons - opening up several potential quality issues in the pretraining data. For instance, the SOTA algorithm AA as well as other related works (Lin et al., 2020; Li et al., 2022a) use non-contextual, one-to-one word translations obtained from MUSE lexicons (Lample et al., 2018) -- which can be problematic in a variety of cases. Firstly, failing to factor sentence-level context can cause violations in linguistic agreement, such as gender, case, tense and verb agreement. Secondly, AA cannot adequately handle contextual synonyms or polysemes (often estimated to constitute up to 80% of English words (Miller, 1998; Geeraerts, 1993)), with Lin et al. (2020) and Pan et al. (2021) assigning random word senses (and thus, translations) for polysemes -- regardless of context. Thirdly, one-to-one word translations create further issues, including the handling of multi-word expressions (eg. ``get out") and multi-word entities (eg. ``New York") -- with these problems aggravating for agglutinative languages. Finally, the bilingual MUSE lexicons themselves have been shown to be of dubious quality across a variety of languages (Kementchedjheva et al., 2019), and using these for multilingual code-switching can propagate such errors manifold. This is illustrated in Figure 1, which shows an example of AA noising taken directly from Pan et al. (2021). With 6 errors in a sentence of 14 words (refer Appendix A.1 for a detailed examination of these errors), we contend that these limitations could cause significant corruption in the pretraining corpus.

We, thus, hypothesize that although AA has been effective in a variety of scenarios, the raised issues could lead mRASP2 to underperform. For this reason, we propose Contextual Code-Switching (CCS) - a novel approach for extracting contextual, many-to-many word translations, leveraging massive² NMT models, and then using these for noising the pretraining corpus. We conduct experiments on 3 different language families: Romance, Uralic, and Indo-Aryan, and report significant average improvements across the board, with gains of up to +5.5 spBLEU. We also find that CCS models narrow the gap with or outperform massively multilingual models like mBART50 (Tang et al., 2021)

²-'massive' in this work signifies the size of pretraining data, while 'large' refers to the large Transformer architecture (with 12 encoders and 12 decoders)

and mRASP2, despite using a tiny fraction of the data and compute. Lastly, we conduct ablation studies to analyze some of the most important factors to consider when synthesizing code-switched text for multilingual NMT pretraining - which constitutes another key, novel contribution of this work.

Our major contributions are, thus, as follows:

1. Firstly, we show that improving the quality of synthetic code-switching can significantly enhance pretraining of multilingual NMT models across various high, medium, low-resource and agglutinative language pairs (3.4.1).
2. Secondly, we demonstrate how massively multilingual NMT models can be harnessed to pre-train smaller models that yield comparable or better performance -- all while using a fraction of the training data and compute (3.4.2).
3. Thirdly, we empirically analyze and discuss some of the key factors that can enhance NMT pretraining on code-switched data - including context, many-to-many substitutions, code-switching language count, and fine-tuning - furthering scientific understanding (3.5)
4. Finally, for greater scalability of our approach, we propose useful variations of CCS that could alleviate potential resource dependencies (3.4.3) and increase efficiency (8.1) -- all while maintaining comparable performance.

2 Approach

2.1 Definitions

Given a set of N languages $L = L_1, L_2 \dots L_N$, multilingual NMT is defined as the task of learning a many-to-many mapping function θ from source language L_a to target language L_b . Code-switching refers to the phenomenon of shifting between two or more languages in a sentence. This work explores functions C that can synthetically code-switch corpora for pretraining multilingual NMT models.

2.2 Aligned Augmentation

Aligned Augmentation constructs synthetically code-switched datasets using multilingual lexicons. These lexicons are generated by interlinking bilingual MUSE dictionaries through a pivot language, English. Given a sentence S , a code-switched sentence $C_{AA}(S)$ is created by looking up word translations in the lexicon and, if available, substituting with replacement ratio r . A bilingual lexicon is used to code-switch parallel corpora and the multilingual one for monolingual data, with $r = 0.9$.

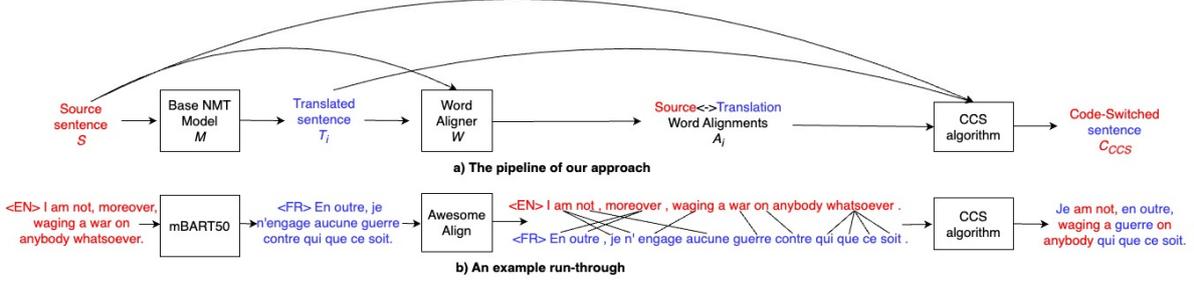

Figure 2: a) The pipeline of, and b) an example illustrating our approach. Alignments between punctuation marks have been omitted for ease of illustration. Color coding signifies language in the code-switched sentence $C_{CCS}(S)$. $C_{CCS}(S)$ is later fed to a Transformer and trained using Cross Entropy and Contrastive Loss (Section 2.4).

2.3 Contextual Code-Switching

Contextual Code-Switching (CCS) seeks to obtain contextual, many-to-many word translations, later used for code-switching parallel and monolingual corpora. Given a source sentence S , we generate the code-switched sentence $C_{CCS}(S)$ as follows:

1. Use a 'base' NMT model M to translate S in n languages ($n \geq 1$) to obtain translations $\{T_1 \dots T_n\}$. Here, $M_{L_i}(S) = T_i$ where $M_{L_i}(S)$ is translation of S by M to L_i
2. Use word aligner W to align S with translations $\{T_1 \dots T_n\}$ and obtain word alignments $\{A_1 \dots A_n\}$; where $W(S, T_i) = A_i$
3. Generate the 'noised' code-switched sentence $C_{CCS}(S)$ using the CCS algorithm, with S , $\{T_1 \dots T_n\}$ and $\{A_1 \dots A_n\}$ as inputs

The CCS algorithm works by generating "connected components" of aligned words. For a given translation T_i and word alignment A_i , we iterate over each source word w_i in S , extract target words from T_i which are aligned with w_i (as specified by A_i), and then iteratively extract the source words aligned to these target words and vice versa, until convergence. This yields all possible many-to-many word alignment combinations, from which code-switching is carried out through random, iterative substitutions in S until the replacement ratio is reached -- yielding the final sentence $C_{CCS}(S)$. $C_{CCS}(S)$ could be code-switched in one ($n = 1$) or more ($n \geq 1$) languages, which we term Bilingual (BLCS) and Multilingual Code-Switching (MLCS) respectively. Although mRASP2 uses MLCS, we show in Section 3.5 that BLCS mostly performs better and is also more efficient. We illustrate our approach in Figure 3 and provide an example where the many-to-many substitution enables CCS to correctly translate the word *moreover* as *en outre*. Finally, we provide pseudo-code (containing finer

technical details) in Algorithm 1 of Appendix A.2.

2.4 Training

To ensure a fair comparison, we replicate the training conditions proposed by Pan et al. (2021) while training our AA and CCS models. Our training dataset D consists of shuffled parallel and monolingual sentences, noised using the respective code-switching approaches. These code-switched sentences are input to the encoder. Meanwhile, the target sentences are the reference sentences for parallel corpora and the denoised (original) sentences for monolingual corpora. A special token indicating language ID is prepended to all source and target sentences. Finally, the model is trained using a loss function \mathcal{L} that jointly optimizes Contrastive Loss \mathcal{L}_{CON} and Cross Entropy Loss \mathcal{L}_{CE} as follows:

$$\mathcal{L} = \mathcal{L}_{CE} + |s| * \mathcal{L}_{CON}$$

where: $\mathcal{L}_{CE} = \sum_{x,y \in D} P_{\theta}(y|x)$, and

$$\mathcal{L}_{CON} = - \sum_{x,y \in D} \log \frac{e^{\text{sim}^+(\mathcal{E}(x), \mathcal{E}(y))/\tau}}{\sum_{a,b \in B} e^{\text{sim}^-(\mathcal{E}(x), \mathcal{E}(b))/\tau}}$$

Here, \mathcal{E} denotes the average pooled encoder output, 'sim' computes positive and negative semantic similarity for a pair of sentences, as denoted by sim^+ and sim^- respectively. Temperature τ controls the strength of penalties during contrastive learning and is set to 0.1. B denotes the mini-batch in dataset D that (x, y) belong to. As shown by Pan et al. (2021), Contrastive Learning aligns semantic representations of source and reference sentences (x, y) while pushing away all 'negative' targets -- approximated to other reference sentences in the mini-batch for convenience. Finally, $|s|$ is the average sentence length (token count) that balances the token-level cross entropy loss and sentence-level contrastive loss.

3 Experiments

In this section, we seek to answer the following Research Questions:

1. How does CCS perform against the SOTA non-contextual algorithm, AA, and how does this vary across language pairs? (3.4.1)
2. How do small CCS models compare against SOTA massively multilingual models? (3.4.2)
3. How can CCS alleviate its potential resource dependencies and scale beyond? (3.4.3)
4. What are the key factors to consider when pretraining on code-switched text? (3.5)

As part of 3 Case Studies, we evaluate CCS on 3 different language families - namely, the high-resourced Romance, the agglutinative Uralic, and the low-resourced Indo-Aryan - in order to test its efficacy under different scenarios. For each family, we train from scratch small multilingual AA and CCS baselines on its languages. Small models have the benefit of minimizing negative interference, while also satisfying our resource constraints.

3.1 Corpora

Tables 1a and 1b show the training corpora statistics used per language family. We use this data for training all AA and CCS models in this work. For a fair comparison, only languages from each family that are present in the training set of mRASP2 and mBART50, and contain MUSE dictionaries are chosen for training. Portuguese (Pt) is taken as the zero-shot case, explored in Section 3.4.3, so no parallel corpus is used. The datasets constituting the training corpora are detailed in Section A.4.3.

For validation, we choose the last 1000 sentences from the bitext for each language. For testing, we use the latest available WMT test sets for each language into and out of English. Table 2 specifies these test sets, which are used for all experiments in this work. Regarding metrics, following related work, we use spBLEU-101³ (Goyal et al., 2022) to evaluate all baselines in this work, but also provide ChrF++ (Popović, 2017) and COMET (Rei et al., 2020) results in Appendix A.5.1. We observe that these metrics largely agree with each other.

3.2 Preprocessing (CCS)

In order to apply the CCS algorithm (Section 2.3), we first generate 'base' model translations and word alignments using the fine-tuned mBART50 and

³referred to as spBLEU in this work for brevity

Romance		Uralic		Indo-Aryan

(b) Parallel data

Table 1: Statistics of training corpora used in this work

awesome-align (Dou and Neubig, 2021) models respectively. For the former, we use the corresponding multilingual 1-n, n-1, and n-n models (based on the language pair) and generate translations with a beam size of 5. For the latter, we fine-tune awesome-align with a subset (300K parallel sentences) from our training corpus using the Translation Language Modeling and Self-Training objectives, as suggested by Dou and Neubig (2021). Where possible, we attempt to have this subset uniformly distributed across all languages (except in low-resourced Indo-Aryan, where 12K En-Gu and 288K En-Hi sentences are used). This setup of 'base' and word alignment models is used for training all CCS baselines in this work unless otherwise specified (such as in Section 3.4.3).

3.3 Experimental Settings

We use the vanilla Transformer (Vaswani et al., 2017) with 6 encoder and 6 decoder (6e6d) layers to train all models in this work, except in Table 3 - where 'large' CCS baselines with 12 of each (12e12d) are used for fair comparison against massively multilingual models. We use a batch size of 4000 and a learning rate of 0.0001, with a polynomial decay scheduler and 5000 warm-up updates. We use an Adam optimizer with $\epsilon = 1e-6$. For regularization, we use dropout of 0.1 and weight decay of 0.001. We use automatic mixed precision and an update frequency of 4 to speed up training. We conduct validation every 1000 updates and use a patience value of 10 for early stopping. We train each model only once since a random seed of 0 is set everywhere. For tokenization, we use sentencepiece (Kudo and Richardson, 2018). Sentencepiece models using a unigram language model are trained on the corresponding corpora with a vocabulary size of 32000 and character coverage of 1.0. Following Pan et al. (2021), we use a replacement ratio of 0.9 in AA models while for CCS, we use 0.55, 0.75, and 0.1 for the Romance, Uralic and Indo-Aryan

families after grid-search optimization. We detail infrastructure and training costs in Section A.4.

3.4 Results

3.4.1 Comparison with AA

In this section, we compare AA baselines with vanilla CCS models, when trained from scratch under identical conditions. Since Pan et al. (2021) already showed AA is the SOTA pretraining algorithm, we do not recreate other denoising approaches here - however, we do compare against two of the best-performing massive models from related work, mBART50 and mRASP2, in Section 3.4.2. Table 2 shows results for all 3 Case Studies.

We note some interesting trends. Firstly, while significant improvements are observed across all language families, the margin of gain varies. The highest gains are observed for the high-resourced Romance and the agglutinative Uralic families -- while the latter benefits greatly from many-to-many substitutions (Table 6), the former is quite noteworthy given that for Romance languages, MUSE lexicons are available in all directions (not just English-centric) so AA models would be strongest here. Meanwhile, the low-resourced Indo-Aryan family, which is non-agglutinative and suffers from low-quality 'base' model translations (as observed from inspection of mBART50 translations by native speakers), the margin is relatively lower. Nonetheless, on average, CCS still outperforms the SOTA approach AA and, as we shall see in Section 3.4.2, even massive models like mBART50 and mRASP2 - despite using far lesser data overall. Moreover, we show in Table 7 how techniques like BiLingual Codeswitching (BLCS) can further boost CCS by +1 to +2 spBLEU, making the total gap against AA +2 to +3 spBLEU points for the Indo-Aryan family.

Secondly, we observe that CCS mostly performs equally well for En-X and X-En pairs (with few exceptions), but AA varies considerably and performs better for the latter. This could be because X-En is generally an easier translation task than En-X, owing to the abundance of high-quality English target-side data. CCS bridges the gap between these two tasks and improves consistency - likely due to the higher quality codeswitching systematically benefiting cross-lingual representations overall.

Lastly, we note that the spBLEU gains in Table 2 translate to comparably large improvements in ChrF++ and COMET (Table 10)

3.4.2 Comparison with Massively Multilingual Models

We now proceed to compare our CCS systems against two SOTA massively multilingual models mBART50 (Tang et al., 2021), trained on 50 languages, and mRASP2 (Pan et al., 2021), trained on 32 languages; in Table 3. Table 3a contains ratios of the monolingual and parallel data used by the massive models w.r.t. ours, per language family, and can help in a meaningful interpretation of the results in Table 3b. While we use significantly lesser data for the Romance family, we attempt to match the parallel data used by mRASP2 for the Uralic and Indo-Aryan families. This data is comparable to or slightly more⁴ than that used for fine-tuning mBART50. As baselines, we use the AA and CCS models from Table 2 and their large (12e12d) variants. We also include a fine-tuned (ft) version of CCS (large) - created by pretraining on the code-switched monolingual data but leaving the parallel data unnoised for subsequent multilingual fine-tuning. We explore the impact of fine-tuning in greater detail in Section 3.5.

However, considering mBART50 and mRASP2 are massive models designed to scale to a much larger set of languages, we emphasize that Table 3 is *not* intended to be a head-to-head comparison; rather it is meant to position our work against the wider, popular SOTA. Our motive here is two-fold: a) to provide a way to harness massive models for pretraining and perform comparably or better, and b) to estimate the potential impact of scaling up CCS models - thus suggesting a worthy new direction of future exploration for pretraining better massive multilingual models. The first purpose could be especially useful for academics with fewer resources, while the second is likely better suited to groups capable of training massive models, eg. large industrial labs.

We achieve the first purpose by showing that the CCS (large) model performs comparably to mBART50 despite using substantially lesser data (such as in the Romance family), though mRASP2 retains a larger gap. But, when comparable data is used, as in the other families, CCS (large) models consistently outperform massive models by significant margins, despite using lesser monolingual data. The only exception is X-En where mBART50

⁴Relatively speaking here. Note that the overall data gap is still heavily biased towards mBART50, with up to 90x more monolingual data than our CCS models

(b) Results (large = 12e12d, ft = fine-tuned)

Table 3: Data and performance comparison with massively multilingual models. mBART50 (Tang et al., 2021) and mRASP2 (Pan et al., 2021) were taken and evaluated on the given pairs. Our Models were trained and tested only on languages from specific families (4 for Romance, 2 for Uralic and Indo-Aryan) on a much smaller dataset (Table 3a).

performs better, likely due to the wide gap in English monolingual and target-side data. However, the fine-tuned CCS model does close the gap with fine-tuned mBART50, performing comparably or better. We address the second purpose by noting that except for the low-resourced Indo-Aryan case, mRASP2 - which is essentially a scaled-up version of AA (large) trained on more languages - routinely improves over the latter. While 'forgetting' low-resource languages can lead to some performance decline, performance, in general, can be observed to improve on scaling up - likely boosted by improved cross-lingual transfer. Now, when using comparable data, CCS (large) beats both AA (large) and mRASP2. This suggests that scaling up CCS to train a massive model like mRASP2 could reasonably be expected to yield improvements over the latter. We leave this exploration to future work.

Given CCS leverages massive models to pre-train small, high-performing ones, we also explore another interesting auxiliary application of CCS,

Knowledge Distillation (KD), in Section A.5.2, and show how it outperforms traditional KD baselines.

3.4.3 Alleviating Resource Dependencies

	Romance		Uralic		Indo-Aryan	
	En-X	X-En	En-X	X-En	En-X	X-En
CCS (base=ft. mBART50)	29.58	29.85	23.4	23.45	20.45	18.45
CCS (base=from-scratch)	30.05	29.40	23.1	22.95	20.25	19.55

Table 4: CCS with different 'base' model choices. A model trained 'from-scratch' can be used as a substitute for fine-tuned mBART50 with comparable performance.

Scaling beyond mBART50 While the above experiments use mBART50 as the 'base' model, an important question to consider is how to scale to languages beyond the ones included in the same (or, more challengingly, any available massive model). We conduct an alternative set of experiments, where we train up small (6e6d) Transformer multilingual models "from-scratch" on our parallel data (Table 1b) and show in Table 4 that CCS baselines using these as 'base' models consistently perform comparably to those using mBART50 as the 'base'. This

suggests that although massive models are readily available and convenient to use, CCS performance is not dependent on their existence, and small models trained from scratch can be a good substitute.

Zero-Shot Translation: A follow-up question to the previous solution of training models from scratch on parallel data is the zero-shot scenario: i.e. what happens if there is no parallel data available, such as for low-resource languages or non-English centric pairs? Table 5 addresses this scenario. Starting from a random 'from-scratch' baseline trained on the Romance corpus in Table 1b (i.e. no En-Pt data provided), we observe that CCS baselines using the former as a 'base' model introduce large gains over the same and over AA. The latter is a particularly strong baseline since it uses ground-truth MUSE lexicons from Pt to every other Romance language for code-switching. However, the enhanced multilingual code-switching of CCS can potentially achieve superior alignment of the Pt vocabulary with that of the other languages -- making CCS a better alternative than AA even if parallel data is unavailable for a given pair.

	En-Pt	Pt-En
From-scratch	1.30	3.40
AA	3.20	10.30
CCS (<i>base</i> =from-scratch)	4.80	11.00

Table 5: Zero-shot Translation

3.5 Analysis

We now empirically discuss some key factors that enhance code-switched pretraining and hope these would serve as useful pointers for future work.

Impact of many-to-many substitutions Table 6 studies the impact of many-to-many substitutions through an ablation study, comparing against a CCS baseline where only 1-1 aligned words are chosen for substitution. We note a consistent decline in performance across all language pairs, with the largest being for Uralic (about 1.5-2 spBLEU points on average). This is likely due to agglutination in the Uralic family. For instance, 1 Finnish word *jauhelihakeitto* aligns to 3 English words: minced meat soup. This is correlated statistically - the

	Romance		Uralic		Indo-Aryan	
	En-X	X-En	En-X	X-En	X-En	En-X
CCS (1-1)	28.53	28.98	21.50	21.95	18.95	18.00
CCS	29.58	29.85	23.40	23.45	20.45	18.45

Table 6: Ablation study investigating the role of many-to-many substitutions

average word count per sentence in our Fi corpus is 10.66 while for En it is almost double (20.2). Many-to-many substitutions are, thus, crucial for code-switching such agglutinative languages.

Impact of contextual translations Through an example lifted from the Romance corpus, Figure 3 shows how CCS improves pretraining data quality through contextual substitutions. While *man* means *humano* (human) in certain contexts, the French word *homme* is correct here. A similar argument holds for *charge* and *gardes* (*garde* could mean either guard or custody, based on context).

Original:

45-year-old man has been remanded in custody on a firearms charge following a disturbance at a travellers' site on Monday when six people were arrested .

AA:

A 45-year-old humano tem been remanded in gardes sobre one arms débit following una necazuri at una travellers' site habilitado Monday when six people stavano arrested.

CCS:

A 45-anos-old homme ha stato reținut en custodia on a firearms charge urma a disturbión en un viajante 'site del manhá when six persone fueron arrestadas

	Original	✗ AA	✓ CCS
Errors due to non-contextual noising in AA:	man	humano	homme
	custody	gardes	custodia
	charge	débit	charge

Figure 3: CCS produces more contextual substitutions. In this example taken from the Romance corpus, the sentences codeswitch between En, It, Fr, Es, Pt, and Ro

Impact of code-switching language count Pan et al. (2021) use Multilingual Code-Switching (MLCS)⁵ to noise sentences, meaning a sentence could be code-switched in multiple languages. While we reproduce this in vanilla CCS and AA baselines, in Table 7 we explore Bilingual Code-Switching (BLCS), where 1 sentence switches between only 2 languages. Intuitively, this could be easier for the model to denoise. We observe our intuitions are mostly correct -- except for Romance, BLCS consistently improves performance. For the Romance languages, a likely explanation is that these have high lexical similarity (about 80-90% (Eberhard et al., 2022)) and more shared vocabulary, so the denoising task is not as complex and MLCS encourages greater transfer. In contrast, the lexical similarity for Uralic languages is lower than 50% (Jorgensen, 2020), while Hindi and Gujarati

⁵While this term is coined for ease-of-use in this work, it is a slight misnomer, and we discuss this in Appendix A.3

	Romance		Uralic		Indo-Aryan	
	En-X	X-En	En-X	X-En	En-X	X-En
CCS (MLCS)	29.6	29.9	23.4	23.45	20.45	18.45
CCS (BLCS)	28.2	28.58	23.9	23.7	21.45	20.65

Table 7: Comparison between MultiLingual (MLCS) and BiLingual Code-Switching (BLCS)

use different scripts -- leading to reduced vocabulary sharing and increased complexity. This might also explain why BLCS gives the Indo-Aryan family the highest gains, followed by Uralic. We note BLCS is also more time-efficient in Section 8.1, so we suggest future work to use the same when code-switching lexically dissimilar languages.

Impact of fine-tuning While the default variant of CCS follows Pan et al. (2021) and mixes parallel and monolingual code-switched data for pretraining, we explore if pretraining on only the latter and leaving the parallel data 'unnoised' for fine-tuning, might be a better alternative (as is common in other related works). Table 8 confirms this enhances performance significantly, likely due to monolingual data being abundant enough for achieving the cross-lingual transfer desired during pretraining, and fine-tuning more closely resembling the final translation task. Secondly, we note that Multilingual Fine-Tuning (MLFT) beats Bilingual Fine-Tuning (BLFT) in code-switched pretraining too, complementing the findings of Tang et al. (2021) in masked pretraining.

	Romance		Uralic		Indo-Aryan	
	En-X	X-En	En-X	X-En	X-En	En-X
CCS	29.58	29.85	23.40	23.45	20.45	18.45
CCS + BLFT	28.65	28.43	23.55	23.80	16.35	14.50
CCS + MLFT	30.00	29.68	25.20	25.85	23.55	22.35

Table 8: Improvements yielded by fine-tuning

4 Related Work

Denosing-based pretraining: Various noising mechanisms have been proposed for denosing-based pretraining of NMT models in recent times. Inspired by BERT (Devlin et al., 2019), earlier models including MASS (Song et al., 2019) and BART (Lewis et al., 2020) were pretrained on masked monolingual corpora, followed by fine-tuning on large parallel datasets (Tang et al., 2021). In an effort to shift the denosing objective from language modeling to translation, subsequent works adopted code-switched noising. ALM (Yang et al., 2020a) introduced this concept by using statistical phrase

tables to code-switch parallel datasets and training bilingual MT models that showed small improvements for the high-resourced, linguistically similar En-De and De-En pairs. Next, CSP (Yang et al., 2020b) proposed using probabilistic lexicons for code-switching in order to train bilingual models on both monolingual and parallel data. RAS (Lin et al., 2020) extended this trend to multilingual NMT, utilizing MUSE lexicons to code-switch and pretrain the massive NMT model mRASP on parallel corpora from 32 languages. Its successor, Aligned Augmentation (Pan et al., 2021) used a 'multilingual' lexicon (formed by heuristically chaining bilingual MUSE lexicons) to code-switch both monolingual and parallel corpora and pre-trained the mRASP2 model on these using contrastive learning. They reported SOTA scores, beating mRASP and many other strong baselines across a variety of language pairs and tasks. CeMAT (Li et al., 2022b) showed that BART-like masking can complement lexicon-based code-switching.

Different from all these works that only attempt one-to-one, non-contextual code-switching, the key novel contribution of our work is to carefully explore and analyze the performance gains offered by enhanced code-switching that factors context, many-to-many substitutions, code-switching language count, etc. We show how modern NMT models can be utilized to achieve these goals and achieve comparable or better performance while using a tiny fraction of the data and compute.

5 Conclusion

We explore a noising mechanism called Contextual Code-Switching (CCS) that extracts contextual, many-to-many word translations for code-switched pretraining in multilingual NMT. Our experiments, conducted on 3 different language families, show that CCS consistently beats the previous SOTA approach, Aligned Augmentation and also performs comparably or better than mBART50 and mRASP2, based on the quantity of training data provided. We analyse the impact of some major factors responsible for enhancing code-switched pretraining through examples and ablation studies. We hope the findings of this work will be useful to researchers studying NMT pretraining, as well as to academic and industry peers who may be looking for a way to fruitfully leverage massive NMT models, or conversely, to jump-start the training of even larger and better-performing ones.

6 Acknowledgements

This work was funded by UK Research and Innovation (UKRI) under the UK government’s Horizon Europe funding guarantee 10039436. The experiments in this work were conducted using resources provided by the Cambridge Service for Data Driven Discovery (CSD3) operated by the University of Cambridge Research Computing Service⁶, Sulis Tier 2 HPC platform hosted by the Scientific Computing Research Technology Platform at the University of Warwick, and the Baskerville Tier 2 HPC service⁷ operated by Advanced Research Computing at the University of Birmingham. Finally, we would also like to acknowledge Guillem Ramirez for his help in selecting interesting examples for Figure 3.

7 Ethical Considerations

There has been significant concern recently over massive multilingual NLP models learning racial and gender biases during pretraining (Tan and Celis, 2019; Bender et al., 2021). A technique like CCS that leverages massive NMT models could be at risk of propagating any such biases present in the ‘base’ model. While such a limitation is not unique to CCS and could apply to any technique harnessing large models (such as Knowledge Distillation approaches), it is an important ethical concern since model biases that are propagated this way could be harder to detect and control - as compared to data biases. In such a situation, it could be worthwhile to invest effort into curating more ‘unbiased’ data, and then using models trained from scratch on this data as the base models for CCS (see Table 4) - giving a greater degree of control than massive models like mBART50 but potentially yielding comparable performance.

8 Limitations

We now discuss some limitations of our work and suggest some ways to mitigate them.

8.1 Cost

One of the advantages of AA is that it is relatively inexpensive to code-switch using lexicons. CCS, on the other hand, requires translating training data into multiple different languages followed by computing word alignments, which can be very expensive, particularly on scaling up. So, we suggest

⁶www.csd3.cam.ac.uk

⁷<https://www.baskerville.ac.uk/>

Algorithm	Time
CCS-MLCS (<i>base</i> =mBART50)	8h 37m
CCS-BLCS (<i>base</i> =mBART50)	4h 30m
CCS-MLCS (<i>base</i> =from-scratch)	4h 42m
CCS-BLCS (<i>base</i> =from-scratch)	2h 37m

Table 9: Total Preprocessing (base translation+word alignment+CCS) time costs for En-Fi 4M corpus, while using 1 GPU node of 3 A100 GPUs

some ways of reducing the cost, while potentially maintaining comparable performance. One effective way would be to use the BLCS variant, since it only needs one translation and one set of word alignments per sentence. Another way to reduce costs is to use smaller (6e6d) models trained from-scratch as a faster substitute for larger models like mBART50 (Table 4). The effectiveness of these techniques is shown in Table 9, which depicts the total preprocessing costs (for the entire pipeline in Figure 3) for code-switching a 4M En-Fi parallel corpus on a single GPU node (with 3 A100 GPUs). It is worth remembering that the word alignment costs are minimal here (about 30 minutes), so the costs are primarily due to generating translations (with a beam size of 5). We, thus, encourage using standard techniques to improve MT efficiency, like using lower beam size, shortlisting, quantization etc. to further reduce costs.

We will also release the code-switched corpora constructed in this research as part of the camera-ready version of this paper, to ensure greater reuse of the expenditure in our time and resources.

8.2 Resource Dependencies

The CCS models in our work function using mBART50 as the ‘base’ model and the word alignment model, awesome-align. Greater resource dependencies are, thus, another limitation of CCS and it is important to think of viable alternatives in case of non-availability of these. Awesome-align uses representations from mBERT (Devlin et al., 2019) so, it could scale to the languages the latter is pretrained on. For other languages, such as very low-resource pairs, it could be worth exploring low-resource word aligners (Asgari et al., 2020; Poerner et al., 2018) - though we leave the exploration of the same as part of future work. As for the ‘base’ model, we could use models trained from scratch as a viable alternative (see Table 4) and potentially obtain comparable performance. In case of non-availability of parallel data, this approach can scale

well to zero-shot translation when parallel corpora from related language pairs are available. (Table 5)

8.3 Low-Resource Scenarios

As we saw in Table 10, CCS appears to yield relatively lower gains for low-resource languages. While this does beat many SOTA models including mBART50 and mRASP2, further research is needed to adapt CCS better for data-scarce and low-resource scenarios in general. Based on related work, one useful solution could be to leverage data from high-resourced languages and families (eg. mixing Romance language data with Indo-Aryan languages) in a more multilingual and scaled-up iteration of our work. Another way would be to filter out low-quality translations from the 'base' model using its confidence scores, and only use the high-quality ones for code-switching. While we are unable to explore these within the scope of this work, they could make for interesting future directions.

A Appendix

A.1 Examining the Code-Switching Errors in Figure 1

In this subsection, we dissect Figure 1 and detail the mentioned errors, along with their causes⁸. Pre-training a multilingual model like mRASP2 that uses non-English corpora requires code-switching in non English-centric directions as well. Since the MUSE dictionaries (like most lexicons) are largely available in English-centric directions, Pan et al. (2021) attempt to generate a multilingual dictionary by recursively linking the bilingual MUSE lexicons through a pivot language (English). In theory, this would allow dictionary entries from language X to language Y using only X-En and En-Y dictionaries. However, such recursive linking would propagate any existing quality issues even further. We illustrate this point using examples from Figure 1. The Estonian word *annetada* and

⁸We did not include this in the main work since this is auxiliary to our paper's focus on contextual and many-to-many substitutions

the Hebrew word *ויטוריה* are used as substitutions for don't and win respectively -- but they actually mean donate and Vittoria (a city in Spain), both of which have relatively less edit distance with don't and victory. A closer look at the Estonian⁹ and the Hebrew¹⁰ MUSE dictionaries, as well as the multilingual dictionary¹¹ constructed by Pan et al. (2021) confirms that this has been caused by the process of linking noisy bilingual dictionaries. The latter error, for instance, was caused by linking win to victoria (Portuguese), which was then aligned with Vittoria (Italian) and then Vittoria (English) - completely altering the meaning. A similar explanation can be drawn for how the English word *some* is incorrectly substituted with the English word *sometimes* (Figure 1b), despite there being no English-English dictionary.

A.2 The CCS algorithm

The pseudo-code of the CCS algorithm is shown in Algorithm 1, along with finer details we were unable to describe previously.

A.3 A discussion on the MLCS terminology

Multilingual Code-Switching (MLCS), as described in Section 2, is a misnomer. In the work of Pan et al. (2021), code-switching is carried out using a bilingual (English-centric) lexicon for the parallel corpora, and a multilingual dictionary for the monolingual corpora. Thus, they use MLCS in a monolingual corpus with the multilingual dictionary, but only Bilingual Code-Switching (BLCS) in a parallel corpus. They do not explain the reason for this choice. In our work, we attempt to shed some light on this and explore the efficacy of BLCS, which is far more efficient for CCS (refer Section 8.1) and also performs comparably or better (Tables 2 and 3). We use the term MLCS in our AA and CCS baselines, therefore, to contrast with BLCS and for ease of use. It is worth noting, however, that the parallel corpus is still bilingually code-switched in the MLCS baselines, following Pan et al. (2021).

A.4 Experimental Settings

A.4.1 Computational Infrastructure

Due to expiry and low availability of GPU hours, we are forced to conduct our experiments on 3 dif-

return $C_{CCS}(S)$

ferent GPU clusters. To maintain comparability, however, we ensure that we use the same cluster for each case study - thus the training and evaluation of all baselines (be it CCS or AA), including the evaluation of the massive models, for a particular language family is always conducted on the same cluster. Additionally, we also ensure that the same parameters are used across all machines, and libraries with the same versions are installed.

Specifically, for the Romance family Case Study we use Skylake CPU nodes with the maximum memory of 300GB and Ampere GPU nodes with 1000GB RAM and 4 Nvidia A100 GPUs per node, running CentOS8. For the Uralic family, we use nodes with 2 AMD EPYC 7742 (Rome) CPUs and 512GB RAM, while for GPUs we use 3 Nvidia A100 GPUs with 40 GB RAM. For the Indo-Aryan family, we use Intel® Xeon® Platinum 8360Y CPU nodes with 512 GB RAM and GPU nodes with 4x NVIDIA A100 40GB GPUs.

A.4.2 Computational costs

Total preprocessing costs for the En-Fi 4M pair are given in Section 8.1 and, based on the technique used, can be roughly interpolated given our training corpora size (Table 1) to calculate total GPU hours. In practice, the real-world time was much lesser since we: a) used GPU clusters (as mentioned above) to simultaneously process multiple language pairs by submitting multiple jobs, and b) divided large corpora into smaller halves that were simultaneously preprocessed. For example, the 20M English monolingual corpus used in the Uralic family (Table ??) was divided into 2 halves of 10M that were submitted as part of 2 separate jobs.

For training, we only used 1 GPU node (1 Slurm job) per language family with 3 or 4 GPUs, depending on the cluster. Training costs for the Romance model took about 50 hours till convergence, 32 hours for Uralic and 61 hours for the Indo-Aryan models. The discrepancy in time is likely due to the fact that each of these experiments had to be run on separate clusters (as mentioned in A.4.1) with different architectures and different batch sizes, especially given each model took very similar number of steps until convergence (270K-290K updates in total).

A.4.3 Datasets used

All the datasets we use are publicly available, distributed freely with the CC0 license. For all case

studies, News Crawl (Akhbardeh et al., 2021) is chosen to make up the monolingual corpus. For parallel corpora, we use different sources for each language family. For the Romance family, we use the Europarl corpus (Koehn, 2005) as our parallel corpus. For Uralic, we use the WMT (Barrault et al., 2019), EUBookshop (Skadiņš et al., 2014) and the ELITR-ECA (Williams and Haddow, 2021) corpora. Finally, for Indo-Aryan, we use the Samanantar (Ramesh et al., 2022) corpus.

Except for Samanantar, all of these datasets belong to the news domain. While Samantar is a collection of datasets from various domains, given the test set belongs to the news domain, we sample news datasets from this corpus for inclusion in our training data.

A.5 Additional Results

A.5.1 Results on other metrics

We summarize the results of our key models in Table 10, using spBLEU, ChrF++ and COMET metrics. While we were unable to include the same in our main work, we observe that the metrics agree with each by and large and detail it in this section for completeness.

A.5.2 CCS for Knowledge Distillation

While the results in the main work mostly focused on the efficacy of CCS in its primary role as a pretraining mechanism, Table 11 indicates how it could also be effective as a better Knowledge Distillation (KD) technique, with minimal computational overload. We compare against the vanilla KD baseline (Hinton et al., 2015) that trains a small (6e6d) student model to mimic the teacher model (mBART50). CCS models of the same size routinely outperform KD, with the sole exception of X-En (Romance). It is interesting to note that it takes similar computational resources to preprocess and train CCS (BLCS), as it does for the KD baseline: given a translation generated by a teacher model, it appears it is better to use the translation to noise (code-switch) the source sentence and train it using the CCS mechanism, as opposed to using it as a target. The only overhead for CCS would be that of extracting word alignments, and in practice we find that it is relatively small - about 1/16th the time taken for translation generation.

Abstract

Dialogue State Tracking (DST), a crucial component of task-oriented dialogue (ToD) systems, keeps track of all important information pertaining to dialogue history: filling slots with the most probable values throughout the conversation. Existing methods generally rely on a predefined set of values and struggle to generalise to previously unseen slots in new domains. To overcome these challenges, we propose a domain-agnostic extractive question answering (QA) approach with shared weights across domains. To disentangle the complex domain information in ToDs, we train our DST with a novel domain filtering strategy by excluding out-of-domain question samples. With an independent classifier that predicts the presence of multiple domains given the context, our model tackles DST by extracting spans in active domains. Empirical results demonstrate that our model can efficiently leverage domain-agnostic QA datasets by two-stage fine-tuning while being both domain-scalable and open-vocabulary in DST. It shows strong transferability by achieving zero-shot domain-adaptation results on MultiWOZ 2.1 with an average JGA of 36.7%. It further achieves cross-lingual transfer with state-of-the-art zero-shot results, 66.2% JGA from English to German and 75.7% JGA from English to Italian on WOZ 2.0.

1 Introduction

Task-oriented dialogue systems are designed to provide natural conversation with users and assist them in achieving daily goals. With the growth of task-oriented dialogue systems, there is an increasing interest in supporting dialogues among many domains and languages to fit the users’ demands. However, either modelling a multi-domain or multi-lingual dialogue system requires substantial data collected in real scenarios. This data acquisition

procedure is extremely expensive, and it motivates us to resolve this challenge by leveraging dialogue data in rich-resource domains and languages via zero-shot transfer learning.

Dialogue State Tracking (DST) is crucial for accurately extracting user intents and goals over multiple turns within the dialogue. Based on the tracked dialogue states, the dialogue manager makes corresponding next actions with back-end results, where the accuracy of the DST becomes absolutely vital. With a fully predefined ontology, traditional approaches tackle the DST as a classification problem by enumerating every combination of slot-value pairs (Mrkšić et al., 2017; Zhong et al., 2018). Those approaches are strongly limited by their scalability, as some slots (e.g. *name*) have an unbounded set of slot values. Secondly, they are generally not flexible to unseen slot-value pairs, making them more difficult to adapt to zero-shot transfer learning. Moreover, a completely predefined ontology is hard to acquire and not scalable for ToD systems in real applications.

To overcome those challenges, we take inspiration from Gao et al. (2020) and investigate how DST can be tackled by extracting slot values from user utterances directly. In this paper, we propose a domain-independent and transferable dialogue state tracker within an extractive question answering architecture. Our model is responsible for filling the slot value by recognising specially designed domain-slot prompts by span prediction, which extracts answers from the input utterance by predicting the token positions. In addition, we introduce a novel domain filtering strategy in training and an independent multi-domain classifier in evaluation such that we only ask slot questions that appear in predicted domains. For example, given *hotel* as the current turn domain, all questions under the *train* domain are filtered out as there is no overlap between them. This simple but effective filtering strategy significantly reduces the noise from unrec-

* Work done while at UCL.

Code is available at <https://github.com/hanzhou032/xqa-dst>

essary questions in both the training and evaluation phases. Furthermore, we study unexplored impacts of two-stage fine-tuning on DST transfer learning with mono-lingual and multi-lingual question answering datasets.

We call the final model XQA-DST: XLM-R based Dialogue State Tracker in Question Answering. Our main contributions are summarised below:

- We introduce XQA-DST, a novel domain-independent and transferable dialogue state tracker inspired by extractive question answering models. The model is able to recognise slot values by reformulating the task as an answer to a designed domain-slot question prompt by span prediction, which extracts answers from the input utterance by predicting the token positions.
- We enable XQA-DST on question answering by zero-shot domain adaptation scenarios, showing its transferability capabilities. The final model shows state-of-the-art domain adaptation performance with an average JGA of 36.7% for five domains on MultiWOZ 2.1.
- We show that our model is capable of both domain adaptation and cross-lingual transfer learning. We demonstrate its cross-lingual transferability by achieving state-of-the-art zero-shot results, 66.2% JGA from English to German and 75.7% JGA from English to Italian on WOZ 2.0.

2 Related Work

Traditional dialogue state tracking approaches mostly rely on a predefined ontology. Lee et al. (2019) implement a slot-utterance matching module that computes the similarity between the utterance and each slot-value pair. Lai et al. (2020) use BERT (Devlin et al., 2019) as the context encoder and generate the relevance score for every pair. Recently, Lin et al. (2021a) and Feng et al. (2022) include schema graph networks to utilise inter-slot relationships. However, their scalability is strongly limited by the availability of the predefined ontology and schema graphs.

To improve efficiency, span prediction methods have been proposed to tackle DST so that the slot can be filled by directly addressing values in the context. Heck et al. (2020) implement copy mechanisms, but they use independent span projection

layers for each slot, which make their model incapable of inference in new domains. Zhou and Small (2019) and Gao et al. (2020) formulate the DST as a question answering problem, and they prepare questions for asking the model to answer values for every slot. We differentiate from these approaches by disentangling the complex domain information from domain filtering and domain classification strategies.

Generative approaches (Wu et al., 2019; Kumar et al., 2020) provide an alternative way to handle DST. Li et al. (2021) introduce a generative question answering approach, GPT2-m, that leverages an autoregressive language model. Similarly, Lin et al. (2021b,c) propose T5DST, and they study the impacts of slot descriptions and cross-task transfer on domain adaptation. Lee et al. (2021) reformulate DST as prompting states via schema descriptions from language models. Recent end-to-end dialogue models (Peng et al., 2021; Su et al., 2022) also show strong supervised performance on DST.

Cross-lingual transfer learning for DST aims to leverage the labelled data in rich-resource languages and transfer learned knowledge to low-resource languages. Chen et al. (2018) study this problem and propose the XL-NBT teacher-student framework. Liu et al. (2020) introduce an Attention-informed Mixed-Language Training (AMLT) method to build code-switching training sentences. They study the effectiveness of multi-lingual pretrained language models, XLM (Conneau and Lample, 2019) and mBERT (Devlin et al., 2019), with their AMLT approach. Qin et al. (2020) propose a data augmentation framework, which encourages cross-lingual alignment by fine-tuning mBERT on generated code-switching data. Moghe et al. (2021) introduce intermediate fine-tuning on parallel sentences to improve the cross-lingual DST. To the best of our knowledge, we are the first work that studies the effectiveness of a multi-lingual pretrained language model, XLM-R (Conneau et al., 2020), on DST without implementing additional cross-lingual alignment strategies.

3 Multi-Domain and Multi-Lingual DST

To tackle the task of dialogue state tracking, our model reads the current user utterance U_t , preceding system utterance M_t , dialogue history H_t , and the domain-slot prompt Q_t as inputs for each turn. Followed by that, our model is responsible for firstly determining the dialogue domains D_t from

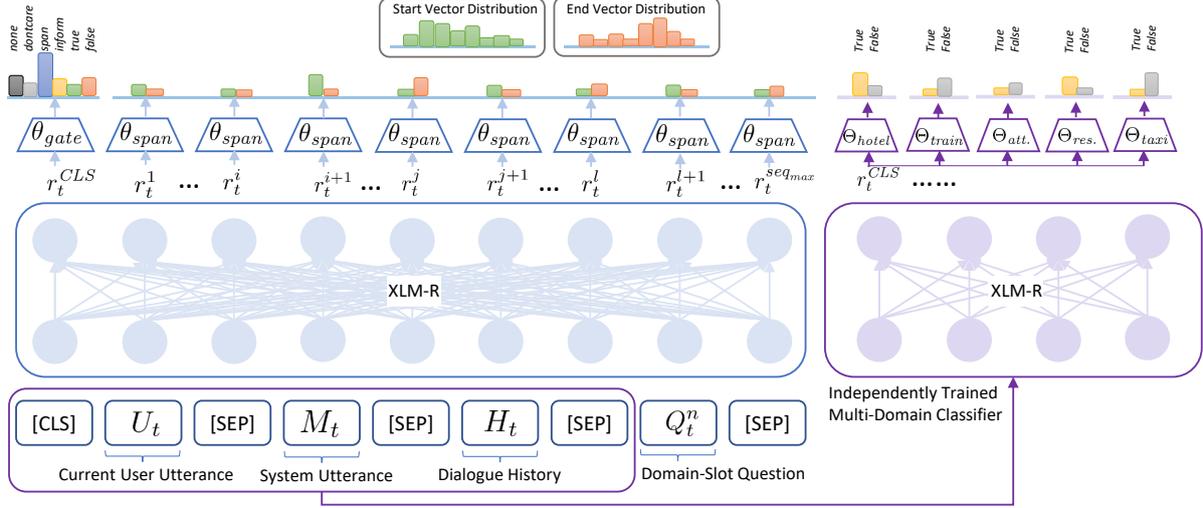

Figure 1: The model architecture of our XQA-DST for multi-domain and multi-lingual DST, where the right part is the independently trained multi-domain classifier that outputs active domains.

the input sequence. Then, it predicts the presence of the answer span in predicted domains given the question. If an answer is present in utterances, the model will predict the value for that domain-slot question using span extraction. Otherwise, its value will be filled in accordance with other predicted types. Finally, our model tracks the dialogue states by a rule-based update mechanism along with the progress of the dialogue across turns.

3.1 Context and Domain-Slot Questions

In extractive question answering, the context is used to provide the background information, and the answer is usually contained in the context. When it comes to DST, it is equivalent to modelling the system message and the user response together as the context for the current turn. The complete context C_t is then collected by concatenating the current user utterance U_t and the preceding system utterance M_t with dialogue history H_t at turn t . We implement XLM-R as the context encoder for the purpose of cross-lingual transfer learning.

Each context is paired with N questions, which iterate through every slot that we are interested in. We append the domain-slot prompt at the end of the context as an analogue question for each domain-slot pair. Hence, the model can learn to correlate different questions to the same context and provide corresponding answers to fill the slot. For the same context with n th question Q_t^n at turn t , the input

sequence S_t^n can be written as:

$$S_t^n = [\text{CLS}] \oplus U_t \oplus [\text{SEP}] \oplus M_t \oplus [\text{SEP}] \oplus H_t \oplus [\text{SEP}] \oplus Q_t^n \oplus [\text{SEP}], \quad (1)$$

where \oplus is the string concatenation, and H_t represents the dialogue history collected in a reversed order, and it is defined as follows:

$$H_t = U_{t-1} \oplus M_{t-1} \oplus \dots \oplus U_1 \oplus M_1 \text{ for } t > 1. \quad (2)$$

To utilise the question as a distinct feature for each slot, we propose the analogue question in the format of a domain-slot prompt. Here, additional special tokens are introduced to assist the model in recognising the domain-slot pair as distinct parts. Moreover, they provide clear signals for the start and end positions for each domain-slot pair. The equation for constructing the domain-slot prompt Q_t^n is defined below:

$$Q_t^n = \langle \text{dom.} \rangle \oplus d_t^n \oplus \langle / \text{dom.} \rangle \oplus \langle \text{slot} \rangle \oplus s_t^n \oplus \langle / \text{slot} \rangle, \quad (3)$$

where d_t^n refers to the name of the domain and s_t^n is the slot name for n -th question at turn t .

3.2 Shared Classification Gate

Our model contains a shared classification gate θ_{gate} for every domain-slot question as shown in Fig. 1. This shared gate provides shared knowledge among various domain-slot pairs, as it is neither domain-specific nor slot-specific.

For each input sentence S_t , this shared gate classifies it to one of six classes as described in three main categories. Special cases, *none/dontcare*, indicate that there is either no observable value from the input sequence S_t or any value that can become the answer for that slot question. Copy mechanism, *span*, indicates that the answer can be extracted from the current user utterance U_t by the span prediction module. Similarly, *Inform* is to copy from the system inform memory that tracks values mentioned in the preceding system utterance M_t . Boolean values *true/false* are used to deal with binary categorical values for Boolean slots where the value cannot be extracted from the utterance.

With these designed classes, it takes the output r_t^{CLS} from the encoder as its only input. It generates a probability distribution $p_t^{\text{gate}} \in \mathbb{R}^6$ over six classes as in the following equation:

$$p_t^{\text{gate}} = \text{softmax}(W_{\text{gate}} \cdot r_t^{\text{CLS}} + b_{\text{gate}}), \quad (4)$$

where W_{gate} represents the weights for our shared gate that is achieved by a linear classification layer, and b_{gate} is the corresponding bias term. The class is then determined by taking the maximal argument of $\text{argmax}(p_t^{\text{gate}})$.

3.3 Shared Span Prediction Layer

If the predicted class for the current input sequence S_t is *span*, the answer for that domain-slot question Q_t will be filled by predicting the start and end positions of the value from the input sequence. We implement the shared span prediction layer for every domain-slot question for the purpose of domain-adaptable design. This is achieved by constructing a linear layer that takes the entire token representations from r_t^1 to r_t^{seqmax} as inputs, and it generates two outputs with two parallel softmax layers for token positions, the start and end position distribution, p_t^{start} and p_t^{end} .

$$[p_t^{\text{start}}, p_t^{\text{end}}] = \text{softmax}(W_{\text{span}} \cdot r_t^i + b_{\text{span}}) \quad (5a)$$

$$\text{start}_t = \text{argmax}(p_t^{\text{start}}) \quad (5b)$$

$$\text{end}_t = \text{argmax}(p_t^{\text{end}}). \quad (5c)$$

The start and end positions of the predicted value are then determined by picking the largest probability from distributions p_t^{start} and p_t^{end} . Followed by that, we sequentially collect the tokens from the predicted start_t position to end_t position, treating any reversed sequence prediction as an empty value. We then detokenize them to form the final predicted value for that domain-slot question.

3.4 Turn-Domain Filtering

For a task-oriented dialogue, the user may shift the domain of conversation across turns so that a dialogue can have multiple domains. We introduce a novel turn-domain filtering strategy that puts a strict constraint and only allows the model to pay attention to currently active domains. Turn-domain filtering indicates that only the slots within the current domains D_t are used to prepare training features since slots are domain-specific. Hence, turn-domain filtering can reduce the potential noises introduced by unnecessary domains. Mathematically, this filtering strategy puts an additional constraint for slot domain d_t^m in Eq. 3:

$$d_t^m \in D_t. \quad (6)$$

3.5 Independent Multi-Domain Classifier

Turn-domain filtering allows the model to answer questions only within the interested domains. However, the domain information is no longer a given feature in the evaluation stage. Here, we propose a multi-domain sequence classifier as shown in Fig. 1. The input sequence is the complete dialogue context C_t without domain-slot questions. We then collect the entire sequence representation r_t^{CLS} by the context encoders as XLM-R(C_t). Followed by that, r_t^{CLS} is fed into $|D|$ softmax layers, thereby allowing a binary prediction that decides whether each domain d_t is present in the input context or not. Finally, we collect the domains that have been assigned to the ‘True’ class, which indicates the presence of that domain in the context.

$$p_t^d = \text{softmax}(W_{\text{MSC}}^d \cdot r_t^{\text{CLS}} + b_{\text{MSC}}^d) \quad (7a)$$

$$d_t = \text{argmax}(p_t^d) \quad (7b)$$

$$D_t = \{d_1, \dots, d_{|D|}\}. \quad (7c)$$

3.6 System Inform Memory and Update Rules

To further reduce the error of our span extractor, we have employed the same inform copy mechanism as Heck et al. (2020). This memory is a simple dictionary that records all values informed by the preceding system utterance M_t into a system inform memory $I_t = \{I_t^1, \dots, I_t^N\}$. Then, the value answer A_t^n for n th question Q_t^n asked at turn t can be predicted by the following copy mechanism, given that $\text{inform} = \text{argmax}(p_t^{\text{gate}})$:

$$A_t^n = I_t^n \text{ for } Q_t^n. \quad (8)$$

We implement a simple rule-based mechanism that is used to update dialogue states across turns

as same as [Chao and Lane \(2019\)](#). In each turn, if the model assigned class for the current input sequence S_t^n with Q_t^n is not *none*, the dialogue state will be updated by obtaining A_t^n from our value prediction modules. On the other hand, if the classification gate predicts that there is no value for S_t^n , the dialogue state will be kept unchanged.

3.7 Two-Stage Fine-Tuning

Our model is designed to be capable of not only DST tasks but also general question answering tasks. Therefore, the transfer learning ability of our base model can be enhanced by firstly fine-tuning it on mono-lingual and multi-lingual question answering datasets as the first-stage fine-tuning. Then, we initialise its weights on DST shared gates and further fine-tune the model on DST datasets as the second-stage fine-tuning. This two-stage fine-tuning strategy maximally brings domain-agnostic knowledge into the field of DST.

4 Experimental Setup

4.1 Dataset

The datasets that we carry out experiments on are WOZ 2.0 ([Wen et al., 2017](#)) and MultiWOZ 2.1 ([Eric et al., 2020](#)) for single-domain and multi-domain task-oriented dialogues, respectively. WOZ 2.0 is a restaurant reservation dataset, and it contains three slots: *area*, *food*, and *price range*. It provides the conversation in three languages: English, German, and Italian. MultiWOZ 2.1 contains multi-domain conversations for more than 10000 dialogues over seven domains. The dialogue domain can change across turns, thereby making MultiWOZ 2.1 the most challenging dataset for task-oriented dialogue systems. We exclude *hospital* and *police* domains with very few dialogues, and the remaining dataset contains five domains (*hotel*, *train*, *attraction*, *restaurant*, and *taxi*) with 30 domain-slot pairs in total. For domain adaptation experiments, we use an extractive QA dataset, SQuAD 2.0 ([Rajpurkar et al., 2018](#)), to provide the intermediate fine-tuning. In cross-lingual experiments, we further use the multilingual QA dataset, XQuAD ([Artetxe et al., 2020](#)), to study the effectiveness of multi-lingual intermediate fine-tuning.

4.2 Implementation Details

We employ the pretrained *XLM-RoBERTa-base* model from the Huggingface library of Transformers ([Wolf et al., 2020](#)), which consists of 12 hidden

layers of 768 units. We also employ the *BERT-base-uncased* model for ablation study and fine-tuned models on SQuAD 2.0 and XQuAD for adaptation experiments. For all implementations, we limit the maximal input sequence length to 180 tokens to save the cost while keeping a reasonable length for including dialogue history. We truncate from the earliest dialogue history when the input sequence length exceeds the limit. The training objective is to minimise the summations of individual loss functions for each module, where each loss is defined as the cross-entropy loss. The loss for each domain module in the multi-domain classifier is equally weighted, where the coefficient for each part of the joint loss of our main model is:

$$\mathcal{L}_{total} = 0.8 \cdot \mathcal{L}_{gate} + 0.2 \cdot \mathcal{L}_{span}. \quad (9)$$

During the training process, we implement the Adam optimiser ([Kingma and Ba, 2015](#)) with an initial learning rate of 10^{-5} . Then, we employ a linear scheduler with a warm-up proportion of 10% so that the learning rate will decay linearly until reaching zero after the warm-up steps. We put a dropout layer with a rate of 30% at the output of our context encoders. We use an early stopping strategy by monitoring the accuracy of the validation dataset until it stops increasing for at least 3 epochs. The batch size is fixed at 16. The multi-domain classifier is trained independently with the same experimental setting, and it is only involved in the evaluation stage. We report the mean of supervised DST and zero-shot experimental results for three runs with different random seeds.

5 Experimental Results

5.1 Zero-Shot Domain Adaptation

We rank our XQA-DST model with prior methods capable of zero-shot domain adaptation. The experiment is used to evaluate the transfer performance of models when tested with dialogues in a completely unseen domain. We train our model on the other four domains by excluding the target domains. We follow the experimental steps reported by [Kumar et al. \(2020\)](#). Since there is a single domain defined in the target domain, the domain classifier is not utilised here because the dialogue domain is given information. Table 1 shows a comparison of our XQA-DST model to baselines and recent approaches, where the JGA is defined as the ratio of dialogue turns that have been perfectly predicted over the number of turns for all dialogues. It is

Models	Type	Hotel	Train	Att.	Res.	Taxi	Avg.
MA-DST (Kumar et al., 2020)	G	16.3	22.8	22.5	13.6	59.3	26.9
SUMBT (Lee et al., 2019)	C	19.8	22.5	22.6	16.5	59.5	28.2
TRADE (Wu et al., 2019)	G	19.5	22.9	22.8	16.4	59.2	28.2
GPT2-m (Li et al., 2021)	G	24.4	29.1	31.3	26.2	59.6	34.1
T5DST* (Lin et al., 2021c)	G	21.2	35.4	33.1	21.7	64.6	35.2
TransferQA (Lin et al., 2021b)	G	22.7	36.7	31.3	26.3	61.9	35.8
XQA-DST w/o two-stage	S	22.9	37.0	24.0	25.7	62.2	34.4
XQA-DST w. SQuAD2	S	24.3	40.0	27.9	28.2	63.2	36.7

Table 1: The joint goal accuracy (%) of zero-shot domain adaptation experiments on each domain with recent models on MultiWOZ 2.1. The abbreviations for model types are: G: Generative; C: Classification; S: Span prediction. *Results from MultiWOZ 2.0 are reported by Lin et al. (2021c).

clear that our model has generated more accurate results than both MA-DST (Kumar et al., 2020) and SUMBT (Lee et al., 2019) baselines by at least 6.2% JGA on average in domain adaptation even without two-stage fine-tuning. SUMBT tracks the dialogue states by classifying every slot-value pair. Hence, it is a classification-based method, whereas our approach is mainly relying on the value filling by the span prediction module. It can be seen that our model has outperformed baselines by a significant (3-9%) margin in the *hotel*, *restaurant*, and *taxi* domains. This is because the classification-based method requires a predefined ontology for its enumeration of values, which inevitably makes it not robust to unseen values in new domains and results in relatively low performance for domain adaptation.

There is another class of methods that utilises generative value filling to handle the DST, including TRADE, GPT2-m, and TransferQA. Given GPT2-m as an example, it is in the framework of generative question answering, which also coincides with the underlying idea of our XQA-DST model but has a decoder to generate candidate values. With the two-stage fine-tuning strategy on the SQuAD 2.0 dataset, our model shows improvements in all domains of 2.3% on average. It shows the highest JGA in both *train* and *restaurant* domains (40.0% and 28.2%, respectively). It also outperforms the TransferQA approach that implements the cross-task transfer learning, which is similar to our two-stage fine-tuning that includes multi-task knowledge. Our results appear as the state-of-the-art results at 36.7% JGA on average for zero-shot domain adaptation experiments.

Furthermore, our approach is designed to be applicable for both domain adaptation and cross-lingual transfer learning, whereas all generative

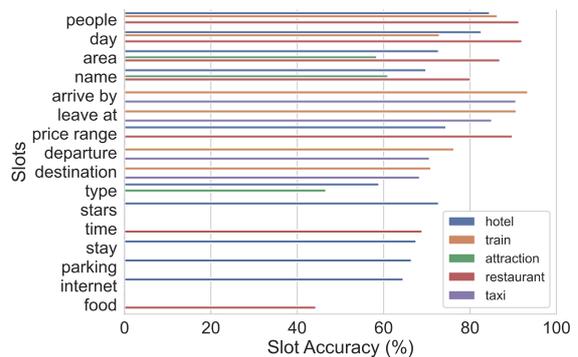

Figure 2: The categorical plot of slot accuracy (%) for each slot over 5 domains for the zero-shot domain adaptation experiment by XQA-DST.

methods listed above can only do mono-lingual learning. Therefore, our XQA-DST model has shown very competitive results in the zero-shot domain adaptation, and we can conclude that it is able to effectively generalise to task-oriented dialogues in new domains by understanding the linguistics behind our domain-slot questions.

5.2 Domain Adaptation Analysis

We analyse the individual slot accuracy for every domain-slot pair in 5 domains to study the impact of shared slots over domains on the performance of domain adaptation. The results are obtained by computing the slot accuracy on each target domain by XQA-DST. The slot accuracy is defined as the ratio of dialogue turns where the value for that slot is correctly predicted. Fig. 2 shows the slot accuracy for 16 slots over 5 domains, where multiple domain bars for the same slot indicate that the slot is shared across these domains.

It is observable that slots that have been shared among multiple domains lead to a relatively higher domain adaptation performance. By contrast, it is

Models	Joint Goal Accuracy (%)	
	GE	IT
XLM-R-DST	20.78	25.39
XL-NBT	30.80	41.20
MUSE + AMLT	36.51	39.35
XLM+CLCSA	48.70	-
mBERT+CLCSA	63.20	61.30
TLM+CLCSA	65.80	66.90
Ours <i>w/o</i> two-stage	64.88	68.63
<i>w.</i> XQuAD	66.16	72.84
<i>w.</i> SQuAD2	66.12	75.66

Table 2: The zero-shot cross-lingual DST results for target languages, German (GE) and Italian (IT), on WOZ 2.0. There are no results on Italian by XLM due to the absence of Italian in its pretraining (Liu et al., 2020).

also distinctive that slots that have not been shared among multiple domains have much lower accuracy. For instance, most slots in the *hotel* domain are not shared with other domains, so the slot accuracy for ‘*parking*’ and ‘*internet*’ slots (66.4% and 64.5%, respectively) are reasonably lower than others. The same rule applies to the ‘*time*’ and ‘*food*’ slots in the *restaurant* domain. Therefore, the number of shared domains for the slot is the foremost factor in achieving a good domain adaptation result. Secondly, we notice that slots with digital values such as ‘*people*’ and ‘*day*’ have very high slot accuracy (91.3% and 92.0% in the *restaurant* domain) even in the zero-shot setting. It validates the effectiveness of our model to domain adaptation for successfully extracting candidate values from the message. Last but not least, due to the wide surface form of location values, it is naturally hard to predict location slots, ‘*departure*’ and ‘*destination*’, that are not categorical with unseen values. Hence, even though they are shared in both *train* and *taxi* domains, they give relatively lower slot accuracy in the set of shared slots. Overall speaking, our XQA-DST model has generated reasonably well domain adaptation results on most domain-slot pairs and has shown a certain level of common knowledge across domains.

5.3 Zero-Shot Cross-Lingual DST

The zero-shot cross-lingual transfer learning is to train our XQA-DST on the source language, English. Then, it is sequentially evaluated on the test sets in German and Italian with labels that are kept in English. Since WOZ 2.0 is a single domain dataset with relatively short dialogues, the dialogue

history is not included as inputs, and the domain classifier is deactivated. To provide a fair comparison to the ground truth, we implement Google Translator (Wu et al., 2016) to translate the values filled by span prediction in the target language back to the source language.

In Table 2, our XQA-DST model with two-stage fine-tuning gives strong zero-shot results in both German and Italian languages (66.2% and 75.7% JGA, respectively). In comparison to recent approaches for cross-lingual DST, our XQA-DST model has generated results that significantly increase the margin by an absolute 8% on Italian. It is worth noting that both XLM+CLCSA and mBERT+CLCSA (Qin et al., 2020) are data augmentation-based approaches on multi-lingual models with the same model architecture as XL-NBT (Chen et al., 2018). TLM+CLCSA (Moghe et al., 2021) also implements two-stage fine-tuning with data augmentation. Even without two-stage fine-tuning, our model in extractive QA still outperforms most of them and appears as the state-of-the-art results in the zero-shot cross-lingual transfer learning on WOZ 2.0.

Besides the above approaches, we include XLM-R-DST as a baseline that we replace the context encoder of BERT-DST (Lai et al., 2020) with XLM-R. Then, we can study the effectiveness of different model architectures in cross-lingual transfer learning. We recall that XLM-R-DST fills the slot values by iterating through every candidate slot value with a relevance scorer. Table 2 shows a huge improvement in our approach by increasing the average JGA on target domains from 23.1% to 66.8% by more than 40%. It indicates that our specially designed extractive QA framework has a strong generalisation ability across languages, whereas the XLM-R-DST appears as only recognising each value as distinct features without understanding the deep semantics behind them. Lastly, we notice that the cross-lingual result on Italian has a higher joint goal accuracy than German in our experiments. We suppose that this is because of the declension in German, which leads to more diverse word forms with the same semantics and introduces noises to the translation process.

5.4 Supervised DST

We perform experiments on the supervised DST configuration and compare our XQA-DST model with prior methods capable of monolingual zero-

Models tested on MultiWOZ 2.1	JGA (%)
TRADE (Wu et al., 2019)	45.60
SUBMT (Lee et al., 2019)	46.70
STARC (Gao et al., 2020)	49.48
MA-DST (Kumar et al., 2020)	51.88
T5DST (Lin et al., 2021c)	52.21
GPT2-m (Li et al., 2021)	52.58
SDP-DST (Lee et al., 2021)	56.66
SOLOIST (Peng et al., 2021)	56.85
PPTOD (Su et al., 2022)	57.10
XQA-DST (our work)	53.21

Table 3: The performance of Supervised DST for our proposed XQA-DST model with prior methods capable of zero-shot inference on MultiWOZ 2.1.

shot domain adaptation on MultiWOZ 2.1. Table 3 comprises the JGA for each method, and we implement the same label mapping as TripPy (Heck et al., 2020) for a fair evaluation. In Table 3, our approach has outperformed most prior methods capable of zero-shot generalisation, including many generative approaches such as TRADE, T5DST, and GPT2-m. Though it is less competitive than the prompt-based SDP-DST model and end-to-end models in the supervised DST setting, its language transferability is still distinctive.
