**Targets Recognition** Moving on to the tasks focused on determining the targets of Aggressiveness and Responsibility ($Resp_{target}$ and $Agg_{target}$), we find that these tasks show lower scores than the detection tasks. This is not surprising as this is a multi-label classification task (compared to a binary) and models were interrogated in a generative setting instead of multiple-choice. This last point is important as models had to recognize how to format their output in a correct manner, which did not always happen. For these tasks, we do not see the trend of models performing better for Responsibility Attribution over Aggressiveness that we observed in the binary setting. In fact, different models performed better for one dimension and others performed better in the other. Also, we observe a sharper increase in performance when switching to the few-shot approach compared to the binary tasks. In fact, the majority of models gain 0.2 in F1-macro score.

**Analysis of Recognition for Specific Targets** We analyzed the outputs of $Agg_{target}$ and $Resp_{target}$ to understand

| Task | FS | Data | Vict. | Perp. | VSN | Media | Rape | PSN | M. Pop. | Instit. | Fact. F-P |
|---|---|---|---|---|---|---|---|---|---|---|---|
| $Agg_{target}$ | 0 | Malt. | 0.58 | 0.72 | 0.6 | **0.79** | 0.58 | - | - | - | - |
| | | Cecc. | 0.42 | 0.67 | 0.61 | **0.83** | 0.48 | 0.67 | 0.57 | 0.62 | - |
| | 5 | Malt. | 0.64 | **0.88** | 0.69 | 0.84 | 0.55 | - | - | - | - |
| | | Cecc. | 0.47 | **0.87** | 0.75 | 0.85 | 0.5 | 0.85 | 0.62 | 0.7 | - |
| $Resp_{target}$ | 0 | Malt. | 0.51 | 0.46 | 0.6 | **0.63** | 0.54 | - | - | - | - |
| | | Cecc. | 0.55 | 0.33 | 0.66 | 0.71 | 0.55 | 0.65 | 0.58 | **0.74** | 0.61 |
| | 5 | Malt. | 0.69 | **0.77** | 0.76 | 0.68 | 0.68 | - | - | - | - |
| | | Cecc. | 0.63 | 0.73 | 0.71 | 0.8 | 0.54 | 0.79 | 0.55 | **0.84** | 0.69 |

**Table 4**
F1-Macro (average scores across all prompts) for target detection tasks. Scores for Gemma only. Missing values are due to the Cecchettin schema having more targets and physical and physiological factor not being a possible target of aggressiveness.

their performances on each possible target. In addition, we performed a qualitative analysis, investigating model behaviors.

First, we calculated F1-macro score (averaged across all prompts) for single targets, casting each target as a single binary label. As the number of possible combination between tasks, Few-shot, subset, models and list of targets is very large, we decided to only focus on the model that had the best overall performance across $Agg_{target}$ and $Resp_{target}$, which is Gemma.

We reported the results in Table 4. Focusing on $Agg_{target}$, the model shows the best performance for specific targets, mostly the Perpetrator, PSN and the Media with F1-macro averages reaching 0.88. From a qualitative perspective, this can be caused by the explicitness of the comments that are aimed towards the perpetrator, with users expressing hatred towards him and often invoking a punishment consisting of a life-sentence. For instance, *Uccisa da un miserabile vigliacco . Essere orrendo.Giulia abbiamo perso tanto. RIP* (**English translation**: Killed by a miserable coward. Horrible person. Giulia, we lost a lot. RIP).

Meanwhile, $Resp_{target}$ shows different patterns, with the model not correctly recognizing the Perpetrator responsibility in the zero-shot setting. This can be due to the fact that Responsibility Attribution is more subtle and difficult to identify compared to Aggressiveness. In particular, the attribution of responsibility is not always conveyed through explicit and direct expressions, but it is often deduced from the context or the femicide event itself.

Model performs well on the institutions label, as comments explicitly attribute the responsibility to Italy's lack of severe punishments, even going so far as to invoke physical punishment or death for the perpetrator.

In both tasks, we observe that the model does not perform well in detecting the crucial victim label. In many cases, the reference to the victim's sphere was enough to recognize her as the target of aggressiveness, even if the intention was completely different. For instance, e.g., *Poverina aveva bisogno aiuto anche lei ascoltate le sue parole quel delinquente andremmo ammazzato mi dispiace* (**English translation**: Poor girl, she needed help too listen to her words that criminal should be killed I'm sorry) and *Non ci sono parole per descrivere questo schifoso. Mi dispiace tantissimo per lei e per la sua famiglia, pregherò per lei* (**English translation**: There are no words to describe this lousy guy. I feel so sorry for her and her family, I will pray for her). This may be due to the presence of certain terms or the recognition of the main referent in the comments without an understanding of the overall meaning of the sentence. In fact, in several cases it seems that the feminine form of adjective was sufficient to recognize the victim as target, even though the intention was to support her and take her side. For GBV-Maltesi dataset, the model recognizes the Responsibility attributed to the victim, specifically in comments that blame her for her own death, citing her life choices, her status as a mother living apart from her child, and her job, e.g., *Purtroppo le scelte di vita sbagliate e le sue abitudini la hanno esposta al male e a tanti rischi* (**English translation**: Unfortunately, her wrong lifestyle choices and habits have exposed her to evil and many risks) Notably, the ethical judgment commonly related to "she was asking for it" does not appear in the Cecchettin case.

## 7. Conclusion ans Future Works

In this paper, we present the GBV-Cecchettin dataset, which collects people's reactions to the news of Giulia Cecchettin's femicide. We chose the topic because of the pervasiveness of Gender-Based Violence in our society. We further improved the the fine-grained annotation schema proposed in Ferrando et al. [1] and applied it to a new femicide case. The GBV-Cecchettin is composed by 932 comments, annotated by 10 master students.

The annotated corpus shows interesting insights, revealing both similarities and divergences between GBV-Maltesi and GBV-Cecchettin. In particular, our analysis focused on the different perceptions related to misogyny, aggressiveness, and the attribution of responsibility, emphasizing the role of victims' sociodemographic traits in shaping those perceptions. In the experimental phase, we tested several LLMs with four different prompts to both GBV-Maltesi and GBV-Cecchettin, to investigate their ability to detect the presence of aggressiveness and responsibility (binary classification task) and to identify their target from a fixed list (recognition task). The results reveal that the former task is easier than the latter. Aggressiveness binary detection seems to be a harder task then Responsibility detection given the violent nature of the femicide context. In the target recognition task, we found that some targets are easier than others. For example, aggressiveness towards the perpetrator is easier due to the explicitness of the comments directed towards him.

Despite its contributions, this study has several limitations that should be considered when interpreting the results. First, we reckon the comments selection procedure, although being motivated (see Section 3.1), can be considered inadequate to capture the users' perception of the Cecchettin femicide. Second, we acknowledge that involving solely Linguistics Master's Degree students as annotators might lead to biases in the annotated data.

The last two limitations we identify in this research lay the foundation for future work. Having only investigated data drawn from YouTube and recognizing its limitations, we aim to expand our data source in future work, wanting to gather entries from different platforms. Lastly, we are interested in exploring other languages and not limiting ourselves to Italian, adapting the fine-grained annotation schema in a multilingual study to develop a more global perspective on how GBV is perceived.

Considering the power of news media in making a difference for human rights in general and women's rights in particular [18], we strongly advocate the urgency of focusing on how different framing of news can lead to different online reactions. Therefore, as future work, we plan to study how specific narratives (e.g., terms used by the media) can directly influence users perception.

## Ethical Consideration

The Cecchettin dataset was created in accordance with YouTube's Terms of Service. Among the 10 people involved in the annotation phase, 8 of them are Italian, one Russian and one US-American, all enrolled in a Italian MA Linguistics course. 9 of them claimed to be interested in GBV-related matters, and 5 had already taken part to GBV-related projects. All the annotators involved in this study participated voluntarily, without any incentives or obligation. From the beginning, we met with them several times to ensure that the topic did not disturb them psychologically or emotionally, offering support and help if they need it. This approach continued throughout all stages of the research.

## Acknowledgments

We would like to thank all the students involved in the annotation task, who worked with professional attitude on a difficult topic like GBV.

The work has been partially supported by "HARMONIA" project - M4-C2, I1.3 Partenariati Estesi - Cascade Call - FAIR - CUP C63C22000770006 - PE PE0000013 under the NextGenerationEU programme.

# A. GBV-Maltesi Scheme

Here we report the GBV-Maltesi guidelines that served as the starting point for the scheme used for GBV-Cecchettin. All dimension were used in GBV-Cecchettin, except for the ones that received changes as noted in 3.2.

- *Non classifiable:* if the comment cannot be analysed because it is not written in Italian, because it consists only of emojis, because it is not comprehensible or not relevant to the topic (any comment that was marked as NC from at least 1 annotator was removed from the corpus);
- *Empathy:* whether, in the comment, there are expressions of empathy in support of the victim, her family or the event in general (i.e., condolences);
- *Misogyny:* whether, in the comment, there is a presence of discriminatory expression against women, including blaming, objectifying, discriminatory and sexist practices used towards them and their life choices. If misogyny is present, we asked annotators to indicate its target (group or individual) based on [35]. Moreover, we asked to specify if the expressed misogyny contained intersectionality traits and to select from a list what other dimensions were involved: age, religion, job, nationality, skin color, class, sexual orientation, gender, physical condition, educational background, language and culture;
- *Aggressiveness:* whether there is aggressiveness in the comment and to whom it is directed (allowing multiple choices): victim, perpetrator, social network (family, friends, colleagues), media, rape culture;
- *Responsibility:* if there is explicit attribution of responsibility for the murder in the text, state who is blamed (allowing multiple choices): victim, perpetrator, social network (family, friends, colleagues), media, rape culture;
- *Humor:* specify whether the text conveys humorous content through irony, sarcasm, word games or hyperbole;
- *Macabre:* specify whether there are macabre aspects detailing how the victim was killed;
- *Context:* indicate whether the context was helpful to better understand the meaning of the comments;
- *Notes:* free space for suggestions, observations or doubts.

# B. GBV-Cecchettin Statistics for Time-Parts

In Table 5 we report the various statistics about the different time parts of GBV-Cecchettin. In Table 6 we report

| Dimension | Part 1 | Part 2 | Part 3 |
|---|---|---|---|
| Number of Examples | 189 | 544 | 199 |
| Misogyny | 0.53% | 2.02% | 3.02% |
| Intersectionality | 0.00% | 0.55% | 1.01% |
| Aggressiveness | 11.11% | 24.63% | 23.12% |
| Responsibility | 9.52% | 32.72% | 14.57% |
| Support | 34.39% | 36.76% | 36.18% |
| Humor | 2.65% | 0.37% | 2.51% |
| Macabre | 0.00% | 0.00% | 0.00% |
| Context | 2.12% | 1.10% | 2.51% |

**Table 5**
Statistics about presence of dimensions (positive label only) in the different time-phases

| Dim. | Target | Part 1 | Part 2 | Part 3 |
|---|---|---|---|---|
| Aggressiveness | Perpetrator | 61.9% | 66.4% | 34.8% |
| | Victim | 0.00% | 0.00% | 0.00% |
| | PSN | 9.5% | 5.2% | 0.00% |
| | VSN | 14.3% | 4.5% | 10.9% |
| | Male Pop. | 4.8% | 3.0% | 2.2% |
| | Media | 14.3% | 16.4% | 45.7% |
| | Inst. | 0.00% | 9.0% | 8.7% |
| | Rape Cult. | 0.00% | 0.7% | 0.00% |
| Responsibility | Perpetrator | 50.0% | 33.1% | 21.4% |
| | Victim | 16.7% | 6.2% | 3.6% |
| | PSN | 22.2% | 16.9% | 7.1% |
| | VSN | 0.00% | 7.3% | 10.7% |
| | Male Pop. | 5.6% | 5.1% | 0.00% |
| | Media | 5.6% | 3.4% | 7.1% |
| | Institutions | 0.00% | 33.1% | 64.3% |
| | Rape Culture | 0.00% | 5.6% | 0.00% |
| | P-F Factor | 5.6% | 7.3% | 0.00% |
| Support | Perpetrator | 10.8% | 1.00% | 0.00% |
| | Victim | 36.9% | 67.0% | 75.0% |
| | PSN | 12.3% | 5.5% | 2.8% |
| | VSN | 67.7% | 43.0% | 33.3% |
| | Male Pop. | 0.00% | 2.5% | 2.8% |
| | Female Pop. | 4.6% | 10.0% | 1.4% |

**Table 6**
Statistics about the target of Aggressiveness, Responsibility, and Support in the different time-phases

the various statistics of the targets relative to Aggressiveness, Responsibility and Support for the different time parts of GBV-Cecchettin. Note that they can sum up to more than 100% as annotators could select more than one.

## C. Prompts

In Table 7, we report the prompts for $Agg_{binary}$. Other tasks present the layout but slightly change in task description and possible values.

| Num | Text | English Translation |
|---|---|---|
| ***p1*** | Dato un commento riguardo un femminicidio, stabilisci se esso contiene aggressività, scegliendo tra: Vero, Falso.<br>[Commento]:<br>[Risposta]: | Given a comment about a femicide, determine whether it contains aggressiveness, choosing between: True, False.<br>[Comment]:<br>[Answer]: |
| ***p2*** | Leggi il seguente testo: {***Descrizione del caso di femminicidio in questione proposta da LaVentisettesimaOra***}<br>{***p1***} | Read the following text: {***LaVentisettesimaOra's description of the femicide case in question***}<br>{***p1***} |
| ***p3*** | Il termine femminicidio viene usato per indicare l'uccisione di una persona di genere femminile nell'ambito di una relazione affettiva o familiare. Il femminicidio costituisce l'atto finale di violenze fisiche e psicologiche ripetute nel tempo. È molto importante essere consapevoli della gravità del fenomeno, soprattutto dal momento che circa ogni due giorni, in Italia, viene uccisa una donna.<br>{***p1***} | The term femicide is used to refer to the killing of a female gender person in an emotional or familiar relationship. Femicide is the final act of physical and psychological violence repeated over time. It is very important to be aware of the seriousness of the phenomenon, especially because a woman is killed approximately every two days in Italy.<br>{***p1***} |
| ***p4*** | {***p3***}<br>Il seguente commento riguarda il caso di femminicidio di **Nome della vittima**. Descrizione del caso: ***Descrizione del caso di femminicidio in questione proposta da LaVentisettesimaOra***.<br>{***p1***} | {***p3***}<br>The following comment refers to the femicide case of **Name of the victim**. Case description: {***LaVentisettesimaOra's description of the femicide case in question***}<br>{***p1***} |

# Gender-Neutral Rewriting in Italian: Models, Approaches, and Trade-offs

Andrea Piergentili[1,2,*], Beatrice Savoldi[2], Matteo Negri[2] and Luisa Bentivogli[2]

[1] *University of Trento, via Sommarive 5, 38123, Povo (TN), Italy*
[2] *Fondazione Bruno Kessler, Via Sommarive 18, 38123, Povo (TN), Italy*

### Abstract

Gender-neutral rewriting (GNR) aims to reformulate text to eliminate unnecessary gender specifications while preserving meaning, a particularly challenging task in grammatical-gender languages like Italian. In this work, we conduct the first systematic evaluation of state-of-the-art large language models (LLMs) for Italian GNR, introducing a two-dimensional framework that measures both neutrality and semantic fidelity to the input. We compare few-shot prompting across multiple LLMs, fine-tune selected models, and apply targeted cleaning to boost task relevance. Our findings show that open-weight LLMs outperform the only existing model dedicated to GNR in Italian, whereas our fine-tuned models match or exceed the best open-weight LLM's performance at a fraction of its size. Finally, we discuss the trade-off between optimizing the training data for neutrality and meaning preservation.

### Keywords

Ethics, fairness, gender rewriting, large language models, fine-tuning

## 1. Introduction

Language technologies reinforce existing gender stereotypes and binary assumptions by disproportionately favoring masculine references or representations [1], especially when gender information is ambiguous or unspecified [2, 3, 4]. Such biases result in the under-representation or misrepresentation of certain gender groups, reinforcing existing societal stereotypes, and erasing non-binary identities [5, 6]. Addressing these biases through gender-inclusive approaches is increasingly important to ensure language technologies contribute to more inclusive and equitable communication [7, 8, 9].

Gender-neutral rewriting (GNR) has emerged as a natural language generation task aimed at producing texts free from unnecessary gender specifications [10, 11]. This task is particularly challenging in grammatical-gender languages, such as Italian, due to the pervasive encoding of gender in the morphology. Consider the sentence *'Tutti i senatori sono stati informati'* (equivalent to *All*$_M$ *the*$_M$ *senators*$_M$ *have been*$_M$ *informed*$_M$): almost every word is morphologically inflected for (masculine) gender. Rephrasing this sentence in a gender-neutral way may require significant changes, e.g. '*Ogni membro del Senato ha ricevuto l'informazione*' (*Every member of the Senate has received the information*). A further challenge in automatic GNR is preserving the meaning of the original sentence beyond gender expression, to avoid generating output sentences that are neutral but semantically divergent from the input.

So far, GNR system development has been mostly confined to English [10, 11, 12, inter alia], where gender is expressed through specific sets of words, such as pronouns (e.g., *he/she*, *him/her*) and lexically gendered terms (e.g., *policeman/policewoman*), and gender-neutral alternatives (e.g., the singular *they* or synonyms like *police officer*) are generally available and attested. GNR systems for grammatical-gender languages generally target specific gendered phenomena, such as member nouns [13], or use neologistic [14] inclusive devices such as neomorphemes and graphemic solutions [15, 16, 17] that convey neutrality, but are not necessarily acceptable in all contexts. Currently, the sole model dedicated to Italian GNR was developed by Greco et al. [18], which, however, was developed and tested on proprietary, not publicly available data, hindering reproducibility and progress.

Towards addressing this gap, this paper explores the potential of state-of-the-art (SOTA) large language models (LLMs) to perform GNR in Italian. Specifically, we explore both prompting and fine-tuning approaches and assess both neutrality and meaning preservation in the reformulated texts.

Our contributions are threefold: ***i)*** The first systematic evaluation of SOTA LLMs for Italian GNR under a two-dimensional framework measuring both neutrality and meaning preservation; ***ii)*** A set of experiments in fine-tuning LLMs for GNR, enabling compact models to rival significantly larger-sized models; ***iii)*** An investigation of the GNR performance trade-off between meaning preser-

vation and neutrality in the outputs of LLMs fine-tuned on sentence similarity-optimized data.[1]

## 2. Background

**Gender-Inclusive Language** Inclusive language aims to prevent expressions that reinforce gender hierarchies or render non-binary identities invisible, promoting fairness and inclusion in alignment with UN Sustainable Development Goals of gender equality.[2] In grammatical-gender languages like Italian, inclusive language is both particularly challenging and increasingly urgent due to their entrenched gender systems [19, 20, 21] and the widespread use of masculine forms as default to mark generic or mixed-gender referents [22].[3] To address this issue, two main strategies have emerged, as reviewed by Rosola et al. [24] within the Italian linguistic context. On the one hand, *innovative* forms using neomorphemes and symbols (e.g., tutt* or tutt@) are mostly used in informal contexts like social media and online LGBTQIA+ communities, and are generally not accepted in more formal contexts [25]. Instead, *conservative* gender-neutral language strategies retool existing forms and grammar to avoid unnecessary gendered expressions [26, 27], e.g. by replacing *i professori* with *la docenza* [9]. As attested by Piergentili et al. [28], such neutral solutions are increasingly accepted in communication and are endorsed by institutions and universities to embrace all gender identities [29].[4]

**Gender-Inclusive Rewriting** In recent years, sexism and gender-exclusionary practices have been increasingly addressed in NLP, focusing initially on binary gender bias and more recently expanding to non-binary inclusive language technologies [6, 4]. NLP work has explored the modeling of inclusive language across various tasks [30, 31], including inclusive language generation. For instance, Bartl and Leavy [12] explored stereotype reduction in English LLMs fine-tuned on inclusive seeds and lexicon.

Intralingual inclusive rewriting has primarily been explored in English [10, 11, 12], where gender marking is scarce. Similar efforts in languages with grammatical gender include research on German [15], Portuguese [16], and French [17, 13], either by using *innovative* forms or targeting specific instances of gendered languages—such as masculine generics in member nouns. In Italian, prior work has explored gender-neutral translation [32, 33], whereas intra-lingual rewriting remains mostly limited to benchmarking efforts. [34]. Attanasio et al. [35] compared several instruction-following models prompted across fairness-related tasks—including GNR—but these underperformed, achieving less than 50% success in neutralization. Frenda et al. [34] proposed the gender-fair generation (GFG) challenge, where for one of the tasks models are prompted to reformulate gendered Italian sentences in a neutral way. Closest to our work, Greco et al. [18] developed a rewriter by fine-tuning language models specifically for Italian gender-neutral language. However, the data used for testing and developing these models are not publicly available, hampering further research and comparability.

## 3. Experimental settings

We define GNR as the task of reformulating a sentence to remove explicit gender markings referring to human entities, without altering the sentence beyond what is necessary for neutralization, ensuring semantic equivalence to the input. We run a set of experiments evaluating different systems and approaches to GNR. Here, we first discuss the evaluation data and metrics (§3.1) and the set of models we experiment with (§3.2). Then, we describe two approaches to GNR: few-shot prompting SOTA LLMs (§3.3) and fine-tuning a subset of those LLMs on repurposed Italian data (§3.4).

### 3.1. Evaluation

**Test data** Following Frenda et al. [34], we conduct our GNR experiments on mGeNTE [33], a benchmark for gender-neutral translation from English into several grammatical-gender languages, including Italian. mGeNTE provides 1,500 parallel gendered and gender-neutral references created by professionals (REF-G and REF-N respectively), differing only in gender expression (see Table 1 for an example of an Italian mGeNTE entry). It is organized into two subsets: Set-G, containing sentences that require neutralization, and Set-N, containing sentences that do not. For our GNR experiments, we use the 750 Italian gendered references from Set-N as

[1] We release models and data at https://huggingface.co/FBK-MT

[2] See https://sdgs.un.org/goals/goal5

[3] English presents fewer challenges as gender marking is primarily limited to pronouns, allowing focused solutions like the singular *they* [23].

Summary of the models used in this work, including their size, usage in prompting and fine-tuning experiments, and documentation. Inclusively (✳) is a sequence-to-sequence model and was thus not compatible with few-shot prompting. We evaluated it by inputting gendered sentences directly and used it as a baseline in all generation experiments.

input. Such sentences are ideal input for our task, as they include unnecessary gender specifications by design.

**Metrics** To evaluate gender-neutrality, we use the LLM-as-a-Judge [43] approach proposed by Piergentili et al. [44], which provides sentence-level binary gendered/neutral assessments, and was shown to be highly accurate in both human- and model-generated texts. We use their optimal configuration for monolingual evaluation.[5] We compute the percentage of neutralized sentences over the whole test set (750 entries).

To evaluate meaning preservation in GNR, we use BERTScore [45], an attested BERT-based [46] metric measuring the semantic similarity of two texts (the higher the better, indicating close similarity). We use BERTScore rather than common string-matching metrics like BLEU [47] and TER [48] because gender-neutralization can have a notable impact on the lexicon, morphology, and structure of a sentence [9], which would be penalized by such metrics. By contrast, BERTScore was found to be rather insensitive to gender-neutralization [28]. Therefore, lower BERTScore values should be attributed to differences in the meaning of the sentences beyond gender, which we evaluate separately, as described above. To identify reference values to guide the interpretation of BERTScore in GNR, we compute the distribution of BERTScore of mGeNTE REF-N sentences against the respective REF-G.[6] As these neutral reformulations were produced by human experts, the BERTScore distribution provides an empirical estimate of human-level performance in meaning preservation in GNR. We take the mean BERTScore minus one standard deviation ($0.9334 - 0.0546 = 0.879$) as a reference threshold to obtain a conservative estimate of human-level performance. This accounts for the natural variability in human reformulations while filtering out outliers with lower semantic similarity, thus ensuring that models evaluated above this threshold perform within the typical human range.

## 3.2. Models

We experiment with a diverse set of models spanning different families, architectures, scales, and language coverage. Table 2 summarizes our selection of models and how we use them in our experiments. Our selection includes:

- **'Italian' models**, specifically designed or adapted for Italian language tasks: Minerva 7B, LLaMAntino 8B, and Velvet 14B.
- **Multilingual LLMs**, trained on multiple languages including Italian, to evaluate general-purpose models: Llama 3.1 8B, Phi 4 14B, Llama 3.3 70B. Among the multilingual LLMs, we include four different-sized models from the **Qwen3 family**, to analyze consistency and scalability within a single architecture.
- One **commercial system**, included as a high-performance reference system: GPT-4.1.[7]
- Inclusively,[8] a fine-tuning of `it5-large` [49], as the only **dedicated model** for Italian GNR. We consider this system the baseline for our experiments.

[5] Prompt: 'Mono+P+L'; GPT model: `gpt-4o-2024-08-06`
[6] We only use Set-N entries in this computation.
[7] Model `gpt-4.1-2025-04-14`

**Table 3**
The 'system' role messages for the two prompt formats used in the few-shot prompting experiments, in both Italian and English.

All models, except for Inclusively, are instruction-tuned autoregressive LLMs.

## 3.3. Few-Shot Prompting

We run few-shot prompting experiments with all models in the selection described above,[9] to investigate the performance of LLMs without any task-specific fine-tuning. We use two prompt formats:

- **GFG**: a concise rewriting instruction, originally used by Frenda et al. [34] in their gender-fair generation challenge for Italian LLMs.
- **Rewrite**: a more detailed and analytical prompt, also featuring essential guidelines for the task with neutralization examples following the strategies identified by Piergentili et al. [9].

These prompts allow us to explore the impact of more complex instruction on models' performance. Moreover, we experiment with these two prompt formats by formulating them in both Italian an English, to investigate whether the language used is a relevant factor as well. The content of the prompts is reported in Table 3. We include the same 8 task exemplars—or shots—with all prompts, to elicit the in-context learning ability of LLMs [50]. We use vLLM [51] as the inference engine.

## 3.4. Fine-tuning

We perform fine-tuning experiments to assess whether and to which extent smaller open-weight LLMs can be adapted to the GNR task and approach the performance

[9] Except for Inclusively, which does not support few-shot prompting. We instead test its off-the-shelf generation capabilities.

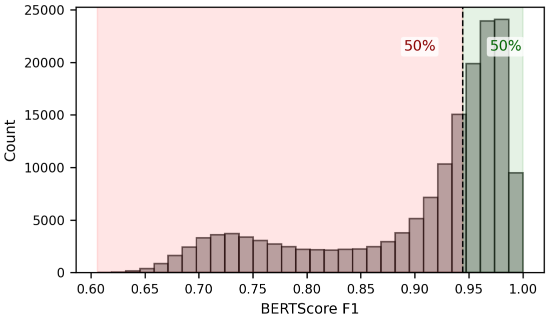

**Figure 1:** Distribution of BERTScore values over the FULL fine-tuning dataset. The CLEAN split is also visualized as the green portion starting at the median line (0.9443).

| Set | Entries | Selection criterion | Avg. BERTScore |
|---|---|---|---|
| FULL | 162,778 | - | 0.9044 |
| CLEAN | 81,389 | BERTScore $\geq$ median | 0.9697 |

Training datasets statistics and summary.

of larger models or closed systems. Namely, we fine-tune LLaMAntino, Velvet, LLama 3.1, Phi 4, and the 8B and 14B Qwen3 models.

### 3.4.1. Data

The only openly available development data dedicated to Italian GNR is the synthetically generated training dataset used by Piergentili et al. [28] to train a gender-neutrality classifier.[10] This data consists in gendered Italian sentences and their gender-neutral counterparts, all generated starting from a dictionary of masculine, feminine, and neutral expressions, through a multi-step prompting pipeline. We repurpose this data to fine-tune autoregressive LLMs for GNR. We prepare the data as chat-formatted input, where each instance consists of a *user* role message containing a gendered sentence, and an *assistant* role message containing the corresponding neutral sentence. Consistent with the models' prior instruction-following fine-tuning, this method adopts a conversational prompt–response format while strictly adhering to a causal token-prediction objective [52].

As the sentences were partly LLM-generated, we note that the content of the gendered-neutral pairs may not always be aligned due to the unpredictability of LLMs in open-ended generation.[11] To investigate this aspect, we compare the gendered and neutral sentences in the dataset using BERTScore to identify dataset entries with semantically divergent gendered-neutral sentences. Figure 1 reports the BERTScore values for the entire dataset. We observe that while the score distribution is skewed towards almost-perfect values, there is a notable tail of gendered-neutral sentence pairs with a rather divergent semantic content. To investigate the impact of such data in GNR fine-tuning, we construct a subset to be used for training alongside the FULL dataset: a CLEAN subset obtained by filtering out the bottom 50% of sentence pairs based on the BERTScore values. Statistics about the fine-tuning data are reported in Table 4.

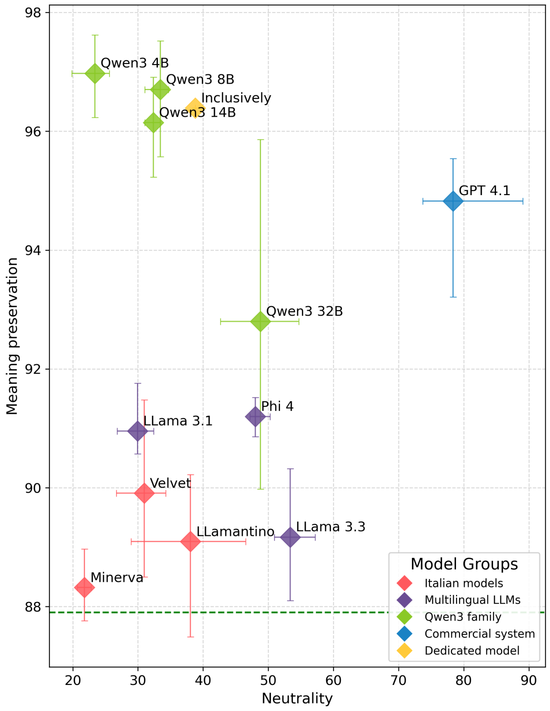

**Figure 2: Results of the few-shot prompting experiments.** The meaning preservation (vertical) axes report BERTScore values multiplied by 100 for easier visualization, whereas the neutrality (horizontal) axes report sentence-level neutralization accuracy. Each ♢ represents the average performance of a model across four prompts. The lines extending from each ♢ indicate the full range of values observed for that model on the respective axis. The dashed line indicates the reference value for human-level meaning preservation in GNR.

### 3.4.2. Method

We fine-tune the selected models using Low-Rank Adaptation (LoRA) [53]. Following common practices in LoRA fine-tuning [54] we set the `rank` and `alpha` at 32, and use the following hyperparameters to strike a

[10] More specifically, we use the cleaned version of the dataset later released by Savoldi et al. [32] at https://github.com/hlt-mt/fbk-NEUTR-evAL/blob/main/solutions/GeNTE.md

[11] While this is not necessarily an issue in the development of a classifier, where individual sentences are simply paired with neutrality labels, for a rewriting task the input-output sentences should be identical except for the attribute of interest, i.e., in this case, gender.

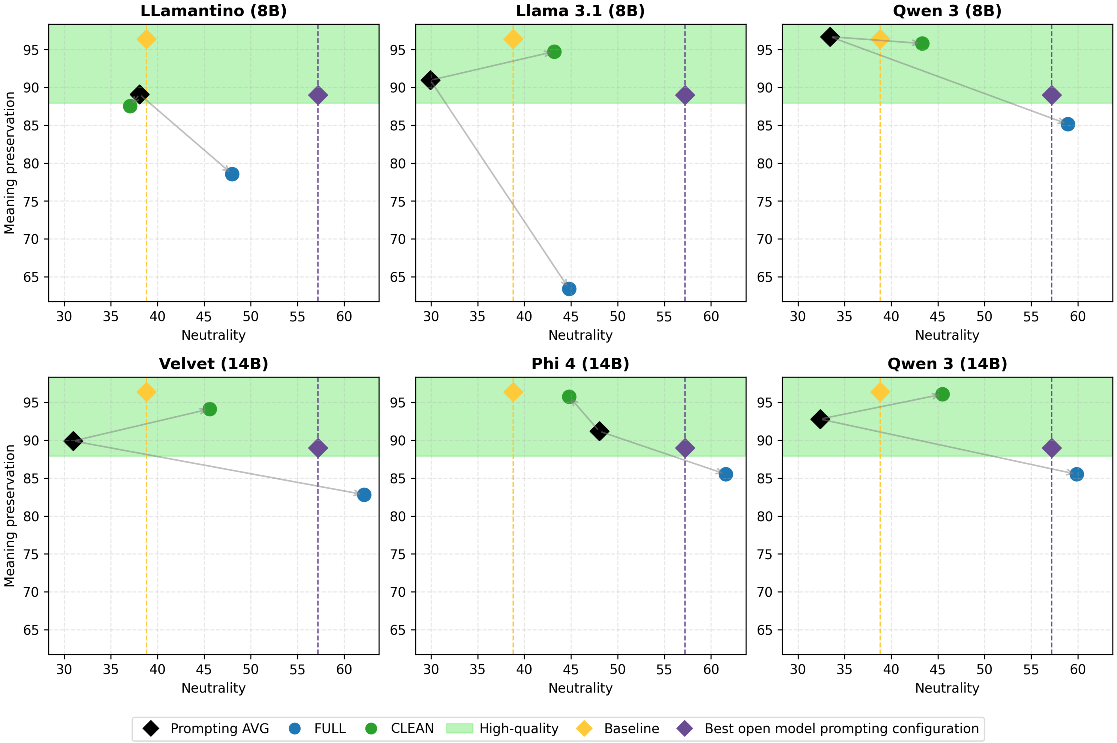

**Figure 3: Results of the fine-tuning experiments.** The meaning preservation (vertical) axes report BERTScore values multiplied by 100 for easier visualization, whereas the neutrality (horizontal) axes report sentence-level neutralization accuracy. The black diamond represents the average performance of the model in the prompting experiments. The blue and green points represent the performance of the model fine-tuned on the FULL and CLEAN datasets respectively. The green band at the top represents BERTScore values reaching human-level meaning preservation in GNR. The yellow and blue points and dashed vertical lines respectively represent the baseline (the dedicated model Inclusively) and the best configuration performance of an open-weight model (LLama 3.3 70B, GFG English prompt).

balance between hardware constraints[12] and consistency across model sizes and requirements: `learning rate`: $2 \times 10^{-4}$, `batch size`: 8 for the 8B models, 4 for the 14B models. We use early stopping with a patience of 20 steps for the 8B models and 40 steps for the 14B models.

# 4. Results

## 4.1. Few-Shot Prompting Results

Figure 2 summarizes the results of the few-shot prompting experiments showing all models' performance in neutrality and meaning preservation. Higher values on both axes indicate better performance; therefore, systems closer to the top-right corner perform best. As no consistent trend emerged across prompt formats (GFG vs. Rewrite, see Section 3.3) and languages (Italian vs. English), we report each model's average performance, along with the range of neutrality and BERTScore values observed across prompting conditions. In Appendix A we provide the complete and detailed results obtained with the two prompt formats, separately for Italian and English instructions.

Generally, and with rare exceptions, all models' BERTScore values are well above the quality threshold we identified in §3.1. This means that the models do not generate unrelated or additional text, confirming that their outputs remain adherent to the input and free of "hallucinations" [55].

Neutrality scores, on the contrary, vary significantly across models. Looking at our baseline, the GNR-dedicated model Inclusively, we observe that it performs rather poorly in neutrality. Across LLMs, we notice similar behavior within the groups. The "Italian" models, in the bottom left quarter of the chart, generally fail to neutralize, and alter the sentences the most. Within the multilingual LLMs group, only Phi 4, Qwen3 32B, and

[12] We run our experiments on nodes with 4 NVIDIA A100 GPUs with 64 GB VRAM each.

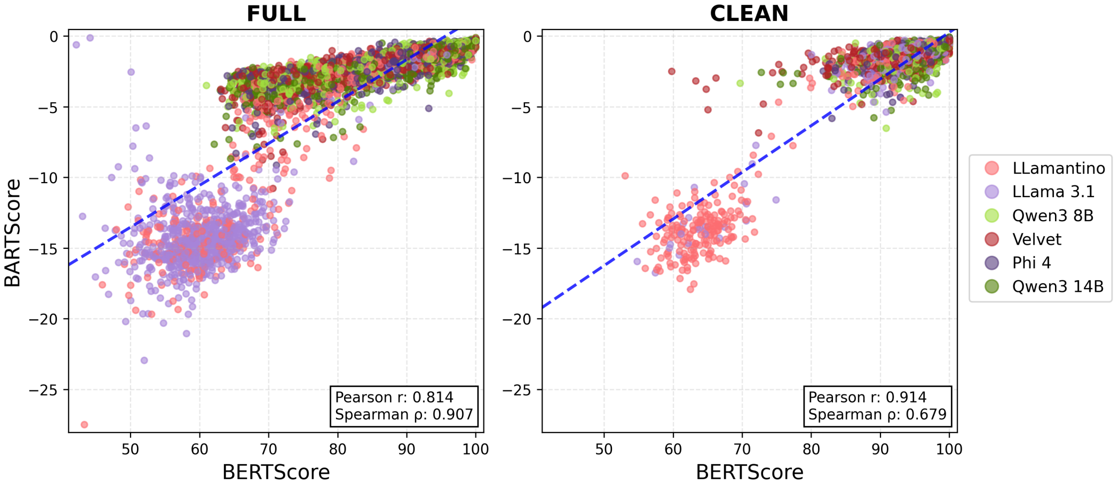

**Figure 4: BERTScore and BARTScore for the outputs of the models fine-tuned on both FULL and CLEAN.** The dashed lines are least-squares regression lines fitted to each set of points, modeling the relationship between the metrics. Points above the line have higher BARTScore than predicted by BERTScore (i.e. BERTScore underrates them), and vice versa for points below. We report Pearson $r$ and Spearman $\rho$ correlation coefficients for each split as well.

LLama 3.3 perform better than the Italian models. The rest of the Qwen3 family generally underperforms, with the high BERTScore suggesting that they make little to no change to the gendered sentences. The only model performing well on both axes is GPT 4.1, which tops at 89.07% neutralization accuracy and 93.21 BERTScore, indicating that it correctly alters the parts of the sentences expressing the gender of human beings while leaving the rest untouched.

Overall, we find that the LLMs we tested perform very differently in GNR in Italian, and that failure in this setting consists in overlooking the relevant (gendered) parts of the input to act upon, and/or unsuccessfully rendering them gender-neutral.

## 4.2. Fine-Tuning Results

Results of the fine-tuning experiments are reported in Figure 3. We first notice that on the neutrality axis all fine-tuned models outperform the baseline, except for LLamantino/CLEAN configuration. LLamantino shows the narrowest gains overall, and in one case even a drop in neutrality, echoing its weaker few-shot prompting results and suggesting it may be ill-suited to GNR. In four out of six instances, and always with the FULL dataset, the fine-tuned models also outperform the best performer among the open-weight models in the prompting experiments, i.e. LLama 3.3 70B with the GFG English prompt, though with a significant drop in BERTScore.

Such a drop indicates that these models fail by hallucinating unrelated content in their attempt to neutralize, rather than by leaving the input sentences untouched as observed in the prompting experiments (§4.1). This is possibly due to two factors: the significantly smaller size of the fine-tuned models with respect to LLama 3.3 70B (1/9 or 1/5, for the 8B and 14B models respectively), as larger LLMs have been shown to exhibit greater robustness and lower variance in downstream performance after fine-tuning compared to smaller counterparts [56], and/or the presence of many divergent gender-neutral sentence pairs in the fine-tuning dataset (see §3.4.1).

While FULL yields the highest improvements in neutrality, only CLEAN improves performance on both axes while keeping BERTScore within the human-level range. However, it yields significantly smaller gains in neutrality and even causes drops for two models (LLamantino, Phi 4). We hypothesize that CLEAN may be excessively conditioned by the data filtering method, i.e. a BERTScore based selection. In other words, by selecting only dataset entries with almost perfect BERTScore values we are optimizing the models to perform well on the sentence similarity dimension—as measured by BERTScore—rather than GNR.

**The impact of metric-based data selection** To investigate the hypothesis above, we evaluate the same outputs against the gendered inputs with another semantic similarity metric: BARTScore [57].[13] BERTScore and

[13] While similar in name and scope, BERTScore and BARTScore function differently. The first computes a sum of token-level cosine similarities between two sentences' embeddings encoded by a BERT (encoder-only) model; the latter is computed as the weighted sum of the log-probabilities that a pretrained BART (encoder-decoder) model assigns to each token in the generated text. In our experi-

BARTScore evaluations are visualized in Figure 4. To understand whether outputs of the models fine-tuned on clean are actually very semantically similar to the corresponding input, and whether those models simply learned to game BERTScore, we compute[14] the Pearson $r$ and Spearman $\rho$ correlation coefficients between BERTScore and BARTScore assessments. The first captures linear correlations between the two metrics' raw scores, while the latter measures how well the relationship between the two variables can be described by a monotonic function, by comparing the rankings of the scores rather than their raw values. This combination allows us to assess both the alignment of the scores and the consistency in how the two metrics rank the outputs.

We find that in full, $r$ equals 0.814 and $\rho$ equals 0.907, whereas in clean they are 0.914 and 0.679 respectively.[15] $r$ is high in both cases, indicating a strong linear correlation between the two metrics—stronger in clean, as in that case the data points are more tightly clustered, skewed towards higher values. This confirms that the metrics generally agree on the quality of the outputs. The substantial drop in $\rho$, instead, indicates that there are many instances in clean where the monotonic trend is broken, i.e., higher BERTScore does not necessarily correspond to higher BARTScore. This suggests that the clean models also learned to game BERTScore by reproducing features rewarded by that metric.

With respect to our hypothesis: by selecting high-similarity pairs for the clean dataset, we effectively steered models toward preserving semantic alignment with the input; however, this emphasis on similarity appears to have hampered their improvement in neutralization. Indeed, the models learned to preserve the input to an excessive degree, as confirmed by the high $r$ coefficient and high BARTScore values shown in Figure 4. We interpret our results as evidence of a broader trade-off between optimizing for neutrality and for sentence similarity. Our findings underscore the need for data curation strategies that strike a balance between neutrality and similarity, achieving the flexibility required for effective GNR.

## 5. Conclusions

We presented the first systematic investigation of state-of-the-art large language models for Italian gender-neutral rewriting under a two-dimensional evaluation of neutrality and meaning preservation. In our few-shot prompting experiments, open-weight models outperformed the only existing Italian-specific system but remained behind a closed commercial system.

Through fine-tuning experiments we showed that compact models can match or exceed the best open-weight LLM at a fraction of its size. Moreover, our BERTScore-based data cleaning highlighted a trade-off: models trained on cleaned data achieve human-level BERTScore but show smaller neutrality gains and exhibit ranking differences against another similarity metric, signaling over-fitting on BERTScore. Future work should take this trade-off into account and create dedicated, high-quality parallel data to aim at reaching the performance of the commercial system with open-weight models.

## Abstract

In recent years, Large Language Models (LLMs) have demonstrated remarkable capabilities across a variety of linguistic and cognitive tasks. This study investigates whether such models can succeed in one of Europe's most selective academic assessments: the Italian medical school entrance exam. We evaluate a wide selection of open-weights LLMs, ranging from natively Italian-pretrained models to multilingual and Italian-specialised variants, on a benchmark dataset comprising over 3,300 real-world exam questions across five knowledge domains. Our experiments systematically explore the impact of language-specific pretraining, model size, prompt formulation and instruction tuning on exam performance. Results show that large multilingual models, particularly the Gemma-2-9B family, consistently outperform all other systems, surpassing the official admission threshold under all prompting settings. In contrast, models trained exclusively on Italian data fail to reach this threshold, even with larger architectures or instruction tuning. Additional analyses reveal that high-performing models display lower positional bias and greater inter-model consistency. These findings suggest that cross-domain reasoning and multilingual pretraining are key to handling multi-disciplinary educational tasks.

## Keywords

Large Language Models, Italian Medical Admission Test, Instruction Tuning, Prompt Engineering, NLP in healthcare

## 1. Introduction

The Italian medical school entrance exam is widely regarded as one of the most competitive and demanding standardized tests in Europe. Each year, approximately 60-65,000 aspiring students face this rigorous assessment[1], which consists of 60 multiple-choice questions spanning biology, chemistry, physics, mathematics, and logical reasoning. Preparation typically begins as early as the penultimate year of high school, with students dedicating countless hours to theoretical study, targeted quizzes, and full-length simulated exams. Despite this intense effort, only a portion of students manage to be included in the national ranking: for example, in 2019 only 42.7% achieved the minimum score, while in 2020 this rose to 68.3%[2]. These figures highlight the exam's reputation as a formidable educational hurdle and a critical turning point in the academic lives of thousands of ambitious young individuals.

Against this backdrop, it is natural to ask what kind of cognitive skill set is truly necessary to succeed in such a highly selective process. Within this context, in an era increasingly shaped by Artificial Intelligence (AI), a provocative question arises:

*To date, could a powerful Large Language Model (LLM), trained on vast data of human knowledge and capable of performing complex reasoning tasks, actually achieve what so many well-prepared students cannot? Could it earn a high enough score to gain admission to an Italian medical school?*

LLMs represent a significant paradigm shift within Natural Language Processing (NLP), consistently demonstrating exceptional performance across diverse linguistic and cognitive tasks. Recent advancements have illustrated that these models frequently match or exceed traditional supervised methodologies and, in certain instances, surpass established human benchmarks [1, 2].

Complementary works in Italian have shown that GPT-style models can reach near-human scores on the national medical-specialty exam [3], introduced CLinkaRT

[1] Report on 2024 Medicine test applicants

[2] Analysis of Medicine admission test scores

for clinical information extraction [4], and released native large-scale benchmarks such as INVALSI-MATE/ITA [5], Mult-IT [6] and the broader CALAMITA suite [7], laying the groundwork for systematic Italian-language evaluation.

With proven capabilities in natural language comprehension and logical reasoning, LLMs have exhibited substantial potential in educational contexts, offering instant personalized feedback, effectively summarizing intricate information, and even simulating complex human-like problem-solving processes.

However, despite their strong capabilities, previous studies have pointed out some limitations of LLMs. In particular, these models can be very sensitive to small changes in the prompt [8, 9]. One major issue is how the arrangement of elements within the prompt affects their performance, especially in tasks that require understanding and reasoning. For example, prior research has shown that LLMs are sensitive to both the specific few-shot examples provided and the order in which answer choices are presented [10, 11].

In this work, our key contribution is an in-depth analysis of how current LLMs, both Italian-specific and multilingual, perform on the multi-choice, multi-disciplinary Italian medical school entrance exam, investigating the following factors that may affect the performance:

**Language-specific pre-training.** We compare general multilingual models, both with multilingual pre-training and Italian specialization, and models specifically pre-trained in Italian, to assess the role of language-specific knowledge in a complex downstream task.

**Model size.** We evaluate models of different sizes to understand how parameter count influences performance.

**Prompt design.** We explore the impact of prompt formulation, including zero-shot vs. few-shot prompting, as well as the effects of prompt length and specificity.

**Instruction tuning.** We analyze how models that underwent instruction tuning (training on datasets designed to follow human-like task instructions) perform in comparison to base LLMs when faced with exam-style tasks.

## 2. Dataset

The employed corpus[3] consists of the official Italian medical school entrance exams administered in past years, collected from the public archive of the Ministry of Education, University and Research (MIUR)[4]. As such, it faithfully reproduces the exact wording, structure, and difficulty level encountered by real candidates.

**Content and scale.** The benchmark consists of $3,301$ high-quality items covering five domains (Table 1). Each item includes a question text (or stem) along with five multiple-choice answers, only one of which is correct. This structure supports two task formulations: a *classification* task, when the question is presented with the answer options, and a *generation* task, when only the question is provided and the model is expected to produce the correct answer. In our experiments, we adopt the classification setting, supplying both the question and the five candidate answers to the model.

**Scoring Scheme.** Each item is graded individually and then aggregated through a three-stage pipeline:

**Per-Item Mark.** A correct answer yields $+1.5$ points, an omission $0$, and an incorrect answer $-0.4$. Negative marking discourages guessing and keeps the expected value of random choice below zero.

**Per-Domain Average.** Let $s_{ij}$ be the mark obtained on the $j$-th question of domain $i \in \{\text{bio}, \text{chem}, \dots\}$ and $n_i$ the number of items in that domain (Table 1). The mean score for the domain is

$$\overline{s}_i \;=\; \frac{1}{n_i}\sum_{j=1}^{n_i} s_{ij} \quad \in [-0.4,\ 1.5]. \tag{1}$$

**Weighted Aggregation.** Since domains contribute unequally to the final mark, mirroring both the weighting and question distribution of the actual exam, we adopt the official weights $w_i$ shown in Table 1 to compute the overall average per item:

$$\overline{s} \;=\; \sum_i w_i\,\overline{s}_i \quad \in [-0.4,\ 1.5]. \tag{2}$$

Finally, the average is rescaled to the *admission-test scale* of $[-24,\ 90]$ by

$$S \;=\; 60\,\overline{s}. \tag{3}$$

**Table 1**
Number, distribution, and weights $w_i$ of questions per domain, as used in Eq. (2).

| Domain | # Questions | Distribution | Weight $w_i$ |
|---|---|---|---|
| Biology | 1 180 | 23/60 | 0.3833 |
| Chemistry | 1 009 | 15/60 | 0.2500 |
| Mathematics & Physics | 655 | 13/60 | 0.2167 |
| Logic & Reasoning | 212 | 5/60 | 0.0833 |
| General Knowledge | 245 | 4/60 | 0.0667 |
| **Total** | 3 301 | 60/60 | 1.0000 |

Hence a model (or a student) that answers everything correctly attains $S_{\max} = 90$, whereas one that is wrong on every question falls to $S_{\min} = -24$. Conversely, a purely random guesser (i.e., one that selects an answer

[3] https://huggingface.co/datasets/room-b007/test-medicina
[4] https://www.miur.gov.it

uniformly at random and is therefore correct with probability $1/5$) has an expected per-item score of

$$\bar{s} = \frac{1}{5} \cdot 1.5 + \frac{4}{5} \cdot (-0.4) = -0.02,$$

leading to an overall expected mark of

$$S_{\text{rand}} = 60 \times \bar{s} \approx -1.2$$

According to the official admission rules, only candidates who score at least **20 out of 90** are included in the national ranking. This threshold is fixed each year and represents the minimum requirement for consideration, although substantially higher scores are typically needed to secure a study place.

## 3. Large Language Models

Recent progress in open-weights LLMs has produced Italian-centric and Italian-specialised systems that still outperform much larger multilingual baselines on the EvalITA benchmark[5] [12]. In this study, we select from the EvalITA leaderboard the top-performing models with fewer than or equal to **9B parameters**, balancing state-of-the-art performance and computational feasibility, and we supplement them with four Italian-specialist models (DanteLLM [13], Cerbero [14], Loquace, Zefiro [15, 16]) that satisfy the same parameter budget but were not submitted to the leaderboard. This guarantees architectural diversity (LLaMA and Mistral families) while maintaining computational feasibility.

**Selection Criteria** Models were selected to facilitate the analysis of the factors outlined in Section1, while maintaining a constant computational budget. The selection criteria are summarised below:

**Language of Pre-Training**. We included (i) purely-Italian LLMs trained from scratch on Italian corpora, (ii) multilingual models that were later specialised to Italian and (iii) non-specialised multilingual models.

**Model Size (Scaling)**. Families of LLMs offering several sizes in the 0.35 B - 9 B range, allowing us to gauge the effect of scale while holding architecture and linguistic coverage constant.

**Instruction Tuning**. Whenever a base and an instruction-tuned (or DPO-tuned) variant coexist, we included *both*.

**Architectural Diversity**. We cover the three dominant open-weights backbones available with an Italian specialisation under 9 B parameters: LLaMA / Gemma / Mistral [17, 18, 19].

**Selected Models** Table 2 lists every model considered in our experiments, organized by pre-training origin (Italian vs. multilingual) and instruction-tuning status. Each entry reports parameter count, original paper (if any) and the Hugging Face identifier.

This curated pool encompasses a wide range of model scales, pre-training strategies, instruction-tuning variants and backbone architectures, enabling us to rigorously evaluate how these factors affect each model's ability to tackle the Italian medical-school entrance test.

**Data Leakage** To the best of our knowledge, none of the questions included in the dataset were seen during the pre-training or fine-tuning of the evaluated models. The official model cards and papers explicitly exclude proprietary multiple-choice exam content, including the MIUR admission tests. While we cannot entirely rule out the possibility of indirect exposure (e.g., paraphrased content shared in online forums), we consider the risk of such leakage to be minimal.

## 4. Experiments

### 4.1. Experimental Setup

All experiments are performed on the dataset described in Section 2 and the models detailed in Section 3. No parameter is updated at any point: every model is used solely in inference mode. Unless otherwise specified in the original checkpoint, all models are queried with their default generation parameters (temperature = 1.0, top_p = 1.0, top_k = 50, repetition_penalty = 1.0); no hyper-parameter tuning is performed.

**Few-Shot Selection.** For each topic of the dataset we randomly sample exactly two in-context demonstrations. These demonstrations are fixed once and reused across all models, prompts, and runs. In the **zero-shot** setting the demonstrations are omitted, while in the **few-shot** setting they are inserted directly into the prompt as fixed in-context examples.

**Prompting Strategies.** Instruction-tuned (`IT`) checkpoints are queried under two conditions:

*plain* — the prompt text in Table 3 is provided as a single user message, identical to the one used for base models;

*chat-template* — the same text is embeded in the model's native chat schema via `tokenizer.apply_chat_template`.

**Table 2**
Overview of the LLMs considered in this work, grouped by type and listing base architecture, parameter count, instruction-tuning status, and checkpoint reference.

**Hardware and Precision.** All runs are executed on a single NVIDIA A100 80GB GPU, with `torch.float16` weights.

**Evaluation Metrics.** Model performance is assessed with four complementary metrics:

*(i) Overall score $S$* is computed by first averaging the per-item marks using the official domain weights $w_i$ (Table 1) to obtain a weighted score $s \in [-0.4,\ 1.5]$, and then applying the linear rescaling $S = 60 \cdot s$, which maps the result to the standard entrance-exam range $[-24,\ 90]$ expressed in sixtieths, as explained in Section 2. Since our setup assumes that the model always selects an answer among the given options, we do not consider the possibility of no response. Consequently, each item is scored either $+1.5$ for a correct answer or $-0.4$ for an incorrect one.

*(ii) Per-topic score $S_t$* reports the same quantity computed separately for each domain (Biology, Chemistry, Mathematics & Physics, Logic, General Knowledge).

*(iii) Overall Macro-averaged $F_1$* aggregates precision and recall uniformly across the five answer classes, making it robust to the pronounced class imbalance of the dataset, as shown in Table 1.

*(iv) Per-topic macro-averaged $F_1$* applies the same statistic within each domain $t$, highlighting areas where a model may be disproportionately strong or weak despite similar global performance.

## 4.2. Prompt Design

The study adopts three system prompts that differ systematically in both length and semantic richness, allowing us to examine how sensitive each model is to the amount of contextual information it receives before attempting the task. The three system prompts are presented in Appendix A.

**P1** is an *ultra-minimal* template that provides nothing more than the formal task instruction: the model is told that it will face a five-option multiple-choice question and must output *only* the index of the correct answer. It contains no role play, no mention of the entrance exam, and no hint about the underlying knowledge domains. This prompt therefore functions as a *lower bound* on instruction length.

**P2** retains the same output constraint but introduces a concise role play: the model is asked to *"simulate a candidate who has studied intensively for the Italian medical admission test"*. This framing injects moderate priming about the exam context and about the desired mindset (efficiency and accuracy) while remaining compact.

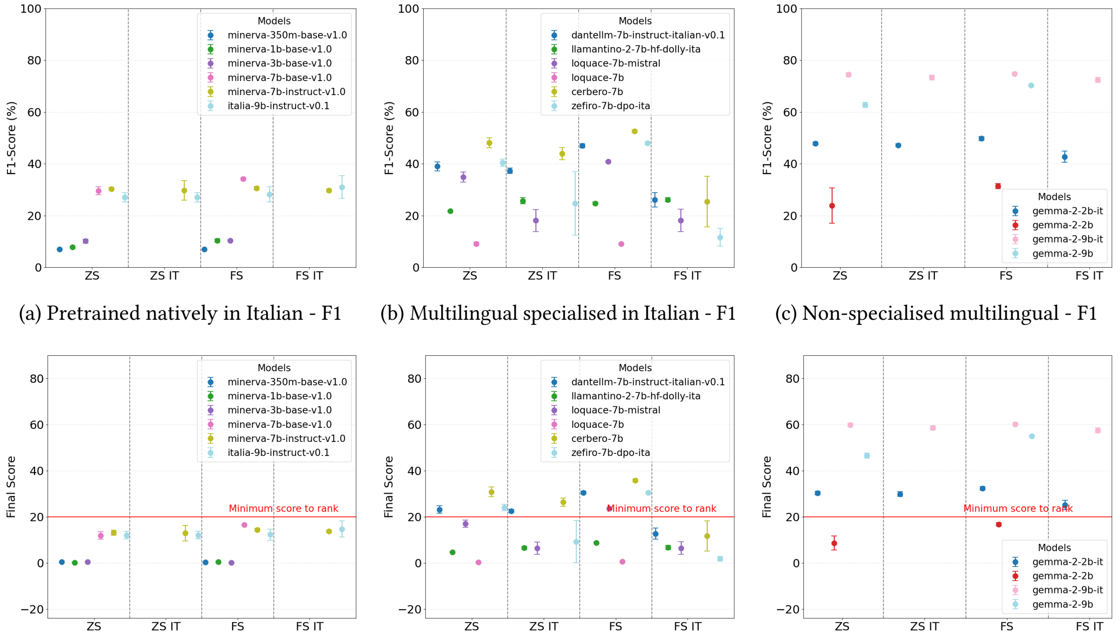
**P3** is the most verbose instruction. It explicitly lists six knowledge areas (Logic, Biology, Chemistry, Mathematics, Physics, and General Culture), thereby grounding the task in the domains required by the real-world exam. The prompt also reiterates the number-only policy in boldface to maximise compliance.

Importantly, all three prompts prescribe the identical answer format: a single digit in $\{1, \ldots, 5\}$ with no accompanying text or explanation. Consequently, any variation in performance, positional bias, or inter-model agreement can be attributed to the incremental context rather than to differences in expected output style.

## 4.3. Qualitative Analysis

We complement the quantitative evaluation with a qualitative analysis aimed at assessing the *robustness* and *behavioural patterns* of the tested models.

First, we analyse **positional bias**, i.e., the tendency



(a) Pretrained natively in Italian - F1

(b) Multilingual specialised in Italian - F1

(c) Non-specialised multilingual - F1

(d) Pretrained natively in Italian - Final score

(e) Multilingual specialised in Italian - Final score

(f) Non-specialised multilingual - Final score

**Figure 1:** Performance comparison across model families and prompting setups. **Top row:** macro-averaged $F_1$ scores. **Bottom row:** final admission scores (red line = minimum threshold for national ranking). Prompting conditions: zero-shot (ZS), zero-shot with instruction formatting (ZS IT), few-shot (FS), few-shot with instruction formatting (FS IT).

of a model to overproduce certain answer indices (e.g., "1" or "3") regardless of the question. For each model and prompt, we compute how frequently each option (1-5) is selected. A uniform distribution would indicate an unbiased decision process, whereas strong deviations suggest systematic preferences unrelated to content [21].

Second, we investigate **inter-model agreement** to assess how similarly different models behave when prompted in the same way. For each prompt and setup, we compare the predicted answers across all model pairs and measure the percentage of matching responses. This reveals which models tend to converge on the same decisions and thus behave similarly, and which ones diverge more often.

Together, these two analyses provide insight into the internal consistency of each model and the structural similarity between them.

## 5. Results and Discussion

In this section, we present and analyse the performance of all evaluated models based on two key metrics: macro-averaged F1 score and final admission score (Figure 1). The reported values are computed by averaging results across three distinct prompt formulations, as we observed a high degree of consistency across prompts for both metrics.

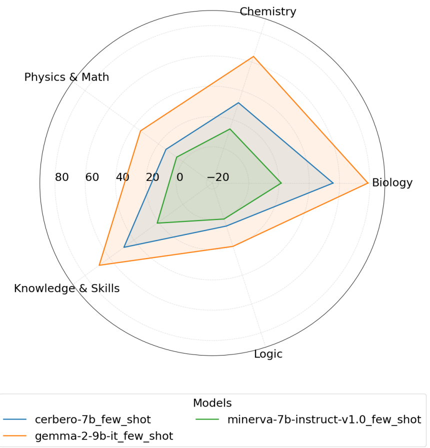


**Figure 2:** Final admission scores across exam disciplines (Prompt 3), comparing the best-performing model in each family under optimal prompting conditions

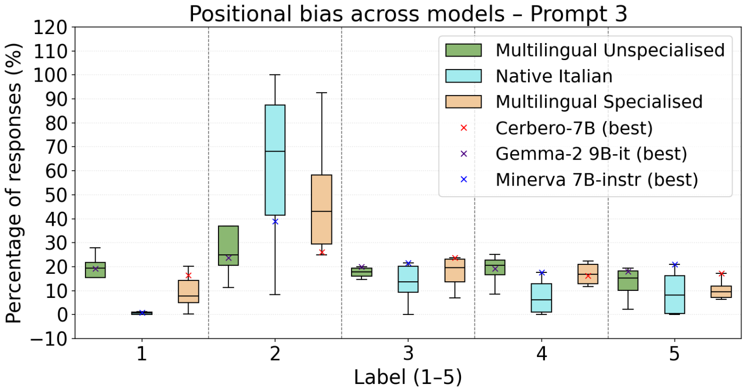

**Figure 3:** Distribution of selected answer positions on Prompt 3, shown separately for each model family. Crosses highlight the best model in each group.

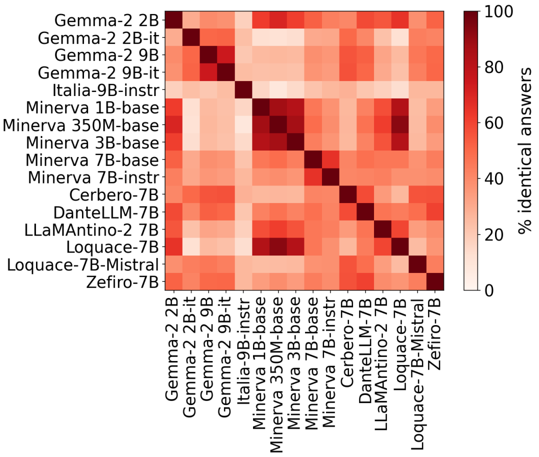

**Figure 4:** Pairwise answer-overlap on Prompt 3. Each cell reports the percentage of identical predictions between two models; darker shades signal stronger agreement. Models are grouped by family.

The analysis is structured around four main factors hypothesized to influence model performance: language-specific pre-training, model size, prompt design, and instruction tuning.

**Language-Specific Pre-Training** The results highlight a clear stratification based on language specialization. Non-specialised multilingual models, particularly gemma-2-9b-it and gemma-2-9b, consistently outperform other classes, achieving the highest F1 scores (≈74-76%) and final scores (≈58-60) across all settings. Notably, both models exceed the admission threshold of 20 in every configuration.

In contrast, natively Italian-pre-trained models, despite being trained from scratch on Italian corpora, perform significantly worse. Their F1 scores rarely exceed 33%, and none of them reach the admission threshold under any condition. Similarly, multilingual models specialised in Italian (e.g., dantellm, cerbero-7b) generally fall short of the top-performing multilingual baselines, though some (e.g., cerbero-7b) do surpass the admission threshold in specific few-shot setups. This suggests that pre-training solely on Italian data may not suffice for general-domain, multi-subject tasks like the medical entrance exam, which likely require both factual recall and cross-domain reasoning competencies that benefit from broader multilingual corpora. While multilingual models perform better, this advantage might reflect the greater scale and heterogeneity of their pretraining data, rather than the effect of multilinguality per se.

**Model Size** Across model groups defined by pre-training language origin, increasing model size generally correlates with improved performance, with only a few exceptions. In the Gemma series, for instance, the 9B models (Gemma-2-9b and Gemma-2-9b-it) significantly outperform their 2B counterparts, particularly in terms of F1 score. The difference is striking: Gemma-2-9b-it achieves 74% F1 in zero-shot settings, while Gemma-2-2b-it remains below 50%. This scaling effect, however, proves less predictable among models trained natively on Italian corpora or tailored to Italian. Within the Minerva family, performance increases modestly from 350M to 7B, though overall results remain limited. Moreover, Minerva-7B-instruct shows no substantial advantage over Minerva-3B-base, and Loquace-7B-Mistral underperforms relative to Cerbero-7B, despite similar model architecture and parameter count. Overall, larger models tend to perform better, but these results suggest that size must be combined with effective training objectives and data coverage to yield consistent gains.

**Prompt-Template Comparison** Figure 1 reports the mean F1-score averaged across the three prompt templates; for nearly all models, the whiskers are tightly clustered, reflecting how little the specific wording shifts the central tendency. Only a few isolated exceptions emerge - e.g., Zefiro underperforms with P2, Cerbero shows higher variance in the FS IT setting, and gemma-2b displays slight sensitivity to prompt verbosity. When runs are examined separately, however, a small yet consistent ranking emerges: the minimalist **P1** systematically attains the highest scores, the verbose **P3** lands in the middle, and **P2** is invariably the weakest. Although the gap is only about 1-2 F1 points, its persistence across the entire model suite indicates that concise phrasing reduces ambiguity, whereas the intermediate framing of **P2** introduces just enough noise to dampen performance.

**Prompt Design** Prompt formulation plays a significant role in modulating model output. We evaluated instruction-tuned models under four prompting conditions: zero-shot (ZS), zero-shot with instruction-tuned formatting (ZS IT), few-shot (FS), and few-shot with instruction-tuned formatting (FS IT). All other non-instruction models were tested only in the ZS and FS settings.

Overall, few-shot prompting leads to improved F1 scores compared to zero-shot, particularly for mid-tier models such as DanteLLM and Cerbero, which show gains of approximately 5-10 points in F1. In contrast, high-performing models like gemma-2-9b-it achieve strong results even in zero-shot settings, indicating robustness to minimal context and reduced reliance on explicit examples.

Interestingly, zero-shot with instruction-tuned formatting often performs comparably to few-shot, especially for models with strong instruction-following capabilities. However, adding instructions to few-shot prompts does not consistently improve performance; for instance, Zefiro and Loquace exhibit a decline in F1 score compared to the few-shot setting without instructions, likely due to prompt verbosity introducing cognitive overload or disrupting the model's internal heuristics [22, 23]. These findings reinforce prior work on large language model sensitivity to prompt phrasing and structure [8, 9], and underscore the need for carefully tuned prompt engineering, particularly in lower-resource or lower-capacity models.

**Instruction Tuning** Instruction tuning provides consistent improvements across different model families. For example, the instruction-tuned gemma-2-2b-it outperforms its base counterpart, gemma-2-2b, by more than 20 $F_1$-score percentage points across all prompting conditions. Similar gains are observed for loquace-7b-mistral over the untuned loquace-7b, and for minerva-7b-instruct compared to minerva-7b-base. The impact of instruction tuning is particularly pronounced in smaller models. While the performance gap between gemma-2-9b and gemma-2-9b-it remains modest (typically around 2-3 $F_1$-score percentage points), tuning significantly enhances the usability of smaller variants, suggesting that instruction tuning complements model scaling and is especially valuable in resource-constrained contexts [24]. Nevertheless, instruction tuning alone is not sufficient to ensure competitive performance. Models such as zefiro-7b-dpo-ita and italia-9b-instruct, despite being instruction-tuned, still underperform relative to top-tier generalist models. This underscores the importance of tuning quality and alignment with the target domain.

Interestingly, instruction tuning appears to be most effective in the zero-shot setting, likely by helping the model better align with the intent of the prompt. However, when combined with few-shot exemplars, it can sometimes introduce redundancy or ambiguity, potentially hindering performance.

## 5.1. Per-Domain Performance

To complement the aggregate metrics discussed above, we conducted a topic-wise analysis of model performance, reporting final admission scores separately for each discipline in the entrance exam.

This additional evaluation aims to reveal domain-specific strengths and weaknesses that may be masked by overall scores, and to better understand how different model families handle the heterogeneous cognitive demands of the test.

For consistency, we selected the best-performing model within each family, prioritizing the few-shot setting whenever it led to superior results. The only exception is the family of non-specialised multilingual models, where the best performance was achieved in the zero-shot condition, though this setting proved competitively robust, even relative to few-shot prompting.

The selected models are:

`minerva-7b-instruct-v1.0` (natively Italian-pretrained family)

`Cerbero-7b` (Italian-tuned multilingual family)

`gemma-2-9b-it` (non-specialised multilingual family)

Given the consistency across prompts, we report results obtained with Prompt 3, which corresponds to the most verbose instruction. The results, summarized in Figure 2, show that gemma-2-9b-it achieves the highest final admission scores across all five disciplines, with particularly strong margins in Biology and Knowledge & Skills. Cerbero-7b displays moderate performance overall but remains consistently below Gemma, with its best result also in Biology. Minerva-7b-instruct, despite instruction tuning, obtains markedly lower scores across the board, with final admission scores that remain below 40% in all subjects. The relative ranking of the models remains stable across domains, suggesting that global performance differences persist even when decomposed by topic.

Interestingly, all models achieve their highest marks in Biology and General Knowledge, two domains that largely reward factual recall, the ability to retrieve canonical facts memorised during pre-training (e.g., "mitochondria produce ATP") [25]. In sharp contrast, Mathematics & Physics and Logic & Reasoning are consistently the hardest areas, even for the best-performing Gemma checkpoint, because they demand multi-step quantitative or set-theoretic reasoning that current LLMs still struggle to perform reliably [26, 27]. Recent work further shows that simply scaling up parameters does not bridge this gap: effective reasoning requires mechanisms that disentangle memory retrieval from inference, rather than larger parametric memory alone [28].

The discipline-level analysis confirms the trends observed in the global scores, underscoring the persistent gap between non-specialized multilingual models and those trained exclusively on Italian data. These results highlight that cross-domain generalization remains a critical differentiator among models. They also reveal that even high-performing systems can display significant weaknesses in specific domains, an important consideration for real-world applications. Overall, the findings emphasize the crucial role of both model scale and pre-training diversity in developing LLMs with strong multidisciplinary capabilities.

## 5.2. Qualitative Analysis

**Positional Bias.** For every model we counted *how its answers are distributed across the five option slots*: the resulting percentages make up the box-plots in Figure 3[6].

**Native-Italian Models** The native-Italian models, cyan boxes, peak around 70% on option 2, and two systems select it in every single question. Such consistency betrays a positional shortcut: the model "trusts" the second slot more than the content it contains.

**Italian-Specialised Multilingual Models** Italian-specialised multilingual models, presented with the orange distributions, still favour label 2, but the median drops to roughly 45% and the whiskers now range from ≈ 25% to 90%. Extra Italian supervision therefore weakens, yet does not eliminate, the tendency to latch onto a preferred position.

**General Multilingual Models** General multilingual models scores, shown in green, cluster close to the 20% baseline expected from random choice, with no extreme outliers. These models appear to read the answers rather than the position, and they also lead our quantitative table, hinting at a link between genuine understanding and low positional bias.

Crosses mark the best model in each family: **Minerva 7B-instr** (blue), **Cerbero-7B** (red) and **Gemma-2 9B-it** (purple). Gemma and Cerbero stay comfortably inside their inter-quartile bands, whereas Minerva still predicts about 40% of its answers as label 2, illustrating that even the best native-Italian model has some residual bias.

Taken together, the figure draws a clear line: positional bias is most pronounced in smaller, language-specific models, softens with targeted fine-tuning, and is almost absent in large multilingual LLMs. The trend mirrors overall performance, suggesting that as models learn to solve the task they naturally stop relying on positional shortcuts. Monitoring this bias might offer a quick, model-agnostic check on whether apparent gains stem from real comprehension or from gaming the answer format. Concrete examples of typical model errors, including failures in numerical reasoning and logical minimization, are provided in Appendix B.

**Inter-Model Agreement** To gauge how closely the models behave, we compute for every pair the percentage of identical predictions on Prompt 3 and visualise these overlaps in Figure 4.[7]

**General Overlap.** Figure 4 reveals two compact blocks of high agreement. The first appears as a compact central block along the diagonal and involves the MINERVA family: the four *base* checkpoints (1B, 350M, 3B, 7B) plus the instruction-tuned variant share $\geq 60\%$ identical answers, well above the $\approx 35\%$ background level observed between unrelated models, and, *in line with the positional-bias analysis*, this consensus largely reflects their tendency to pick the same (often incorrect) option. Interestingly, scaling MINERVA from 350 M to 7 B parameters does little to break this uniformity: the 3 B - 7 B pair overlaps by ≈ 65%, only marginally higher than the 350 M - 1 B pair (≈ 61%), suggesting that increased capacity amplifies the same bias instead of diversifying behaviours.

The second block, smaller but denser, occupies the upper-left portion of the diagonal and links GEMMA-2 9B with its instruction-tuned sibling (GEMMA-2 9B-IT). Their overlap exceeds 75%; unlike Minerva, they agree mostly on *correct* answers, underscoring their stronger

[6] Shown for **Prompt 3**, the richest prompt; Prompts 1 and 2 lead to the same qualitative picture.

[7] Prompts 1 and 2 show the same qualitative pattern.

underlying capability. A size effect is evident here too: Gemma-2 2B and its instruction-tuned counterpart align at $\approx 55\%$, noticeably lower than the 9 B pair, hinting that larger multilingual backbones converge toward more stable (and more accurate) decision patterns.

Between these two extremes sit the *multilingual models specialised in Italian*, such as Cerbero-7B, DanteLLM-7B, and LLaMantino-2 7B. They form a looser band of mid-level agreement (45-60%), often acting as a bridge: they overlap moderately with Gemma while retaining some affinity with native-Italian systems. The pattern mirrors their performance table these models outperform Minerva yet trail the Gemma large pair, indicating that Italian-specific fine-tuning narrows the gap without fully matching the breadth of a high-capacity multilingual pre-training.

Outside the highlighted blocks agreement drops sharply, especially between native-Italian and general multilingual systems, supporting the idea that language-specific pre-training steers models toward distinct decision patterns.

**Topic-Wise Agreement (see Appendix C).** Topic-specific heat-maps paint a similar picture with nuanced shifts:

**Biology** and **Chemistry** closely reflect the global pattern: Minerva models cluster tightly, while Gemma leads a smaller high-accuracy duo, confirming that factual disciplines accentuate family-specific biases.

In **Logic** & **Reasoning**, the Minerva block tightens even further, with overlaps reaching $\geq 70\%$, implying that reasoning errors are strongly correlated across those checkpoints.

**Mathematics** & **Physics** show the widest dispersion: cross-family overlaps fall below 40% for most pairs, suggesting numerical items provoke model-specific heuristics rather than common patterns.

**General Knowledge** falls in between, exhibiting moderate agreement across the board.

Altogether, these observations confirm the main finding: models that share pre-training data and objectives tend to converge on the same answers while larger, broadly-trained multilingual baselines remain both accurate and mutually consistent. Model size amplifies these trends, and Italian-specialised multilingual checkpoints occupy an intermediate space, benefiting from targeted fine-tuning yet still trailing the strongest generalist pair.

## 6. Conclusions

Large multilingual LLMs have begun to clear the Italian medical-school admission bar, but they are still far from matching the level reached by human examinees. On the 3 301-question benchmark, the 9-billion-parameter *Gemma-2* family scored 58-60 / 90 with macro-$F_1$ around 75%, comfortably above the official ranking threshold of 20. A handful of Italian-tuned multilingual checkpoints (e.g. *Cerbero-7B*) also edged past the cut-off in favourable prompting conditions, whereas every natively Italian model remained well below it.

Detailed error analysis confirms that genuine reasoning remains an open challenge. Even top models stumble on Logic and on Mathematics & Physics and display residual positional shortcuts, signalling reliance on surface cues rather than deep understanding. Bridging this gap will demand progress in numerical and deductive reasoning, stronger defences against prompt variability, and tighter integration with external tools and retrieval.

In future work, we plan to extend the evaluation to a *cloze-style*, open-ended generation setting, where models must produce the correct answer without being shown the five multiple-choice options. This format may offer a more faithful assessment of their reasoning abilities and reduce positional biases. The dataset is already formatted to support this task. However, given that only a subset of LLMs currently achieves sufficient performance in the classification setting, such a shift could pose an even greater challenge. In addition, we plan to carry out a systematic exploration of decoding strategies and hyperparameters to quantify how sensitive exam performance and answer stability are to these settings. Such ablations might provide deeper insights into model robustness and optimal inference configurations.

# A. Prompts

The study adopts three system prompts that differ systematically in both length and semantic richness, allowing us to examine how sensitive each model is to the amount of contextual information it receives before attempting the task. The three system prompts are presented in Table 3.

# B. Concrete answer examples

To illustrate the kinds of mistakes made by the top-performing model (gemma-2-9B-it, prompt 3), we report two representative items: one from the Mathematics & Physics subset and one from the Logic & Reasoning subset, together with the label and the model's prediction. Each question is shown first in Italian and then in English.

### Mathematics & Physics

**Italian**
*Quanto vale il rapporto tra il volume e la superficie di un cilindro di raggio 6 cm e altezza 12 cm?*
**English**
*What is the ratio between the volume and the surface area of a cylinder with 6 cm radius and 12 cm height?*
**Options:** (A) 2 cm (B) 1,5 cm (C) 1 cm (D) 0,5 cm (E) 4 cm
**Correct answer:** (A) 2 cm
**gemma-2-9B-it answer:** (B) 1,5 cm

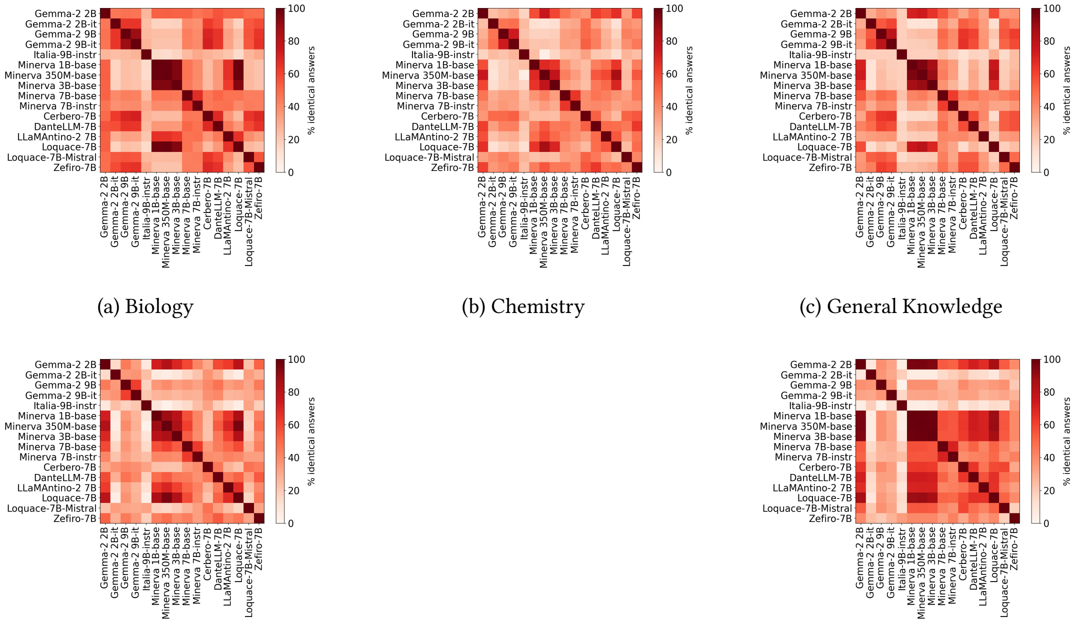
### Logic & Reasoning

**Italian**
*I partecipanti a una gara di corsa sono 150, di cui 98 maschi, 120 biondi e 90 destrorsi. Qual è il numero minimo di maschi, biondi e destrorsi che partecipano alla gara?*
**English**
*There are 150 participants in a running race: 98 are male, 120 are blond, and 90 are right-handed. What is the minimum possible number of participants who are simultaneously male, blond, and right-handed?*
**Options:** (A) 8 (B) 10 (C) 20 (D) 12 (E) 18
**Correct answer:** (A) 8
**gemma-2-9B-it answer:** (B) 10

These snapshots show two common failure modes: a numerical miscalculation in the geometry element and an overestimation in the logical minimization problem, both of which may be influenced by the model's observed positional bias towards option (B) (as shown in Figure 3).

**Table 3**
System prompts used in the study.

| **Italian (original)** | **English (translation)** |
|---|---|
| **P1.** Domanda con 5 risposte (0-4). Scrivi solo il numero della risposta corretta. Nessun altro output.<br>**P2.** Simula il comportamento di un candidato che ha studiato intensamente per il test di Medicina in Italia. Per ciascuna domanda a risposta multipla con opzioni da 0 a 4, indica solo il numero della risposta che ritieni corretta. Non fornire alcuna motivazione. Concentrati sull'efficienza e sulla precisione.<br>**P3.** Sei uno studente italiano con solide competenze in Logica e Ragionamento, Biologia, Chimica, Matematica, Fisica e Cultura Generale. Stai sostenendo il test di ingresso alla facoltà di Medicina. Ti verrà fornita una domanda a risposta multipla seguita da cinque opzioni numerate da 0 a 4. Il tuo compito è indicare **esclusivamente** il numero (0-4) corrispondente all'alternativa corretta. Non fornire spiegazioni. | **P1.** Question with 5 answers (0-4). Write only the number of the correct answer. No other output.<br>**P2.** Simulate the behaviour of a candidate who has studied extensively for the Italian Medical School admission test. For each multiple-choice question with options 0-4, output only the number of the option you believe is correct. Provide no justification. Focus on efficiency and accuracy.<br>**P3.** You are an Italian student with strong skills in Logic and Reasoning, Biology, Chemistry, Mathematics, Physics, and General Culture. You are taking the entrance exam for the Faculty of Medicine. You will be given a multiple-choice question followed by five options numbered 0 to 4. Your task is to output **only** the number (0-4) corresponding to the correct option. Do not provide any explanation. |



(a) Biology

(b) Chemistry

(c) General Knowledge

(d) Mathematics & Physics

(e) Logic & Reasoning

**Figure 5:** Pairwise answer-overlap heat-maps for the five exam domains. Each cell reports the percentage of identical predictions between two models when evaluated only on the subset of questions belonging to the indicated topic (Prompt 3 setting).

## C. Heat-maps of Model Agreement

Figure 5 shows per-domain heatmaps of model agreement. Each cell reports the percentage of identical predictions on a given topic. The same trends seen in Figure 4 persist: (i) MINERVA checkpoints are tightly aligned, mostly on wrong answers; (ii) GEMMA-2 9B models remain the most consistent and accurate pair; (iii) unrelated models rarely exceed 40% overlap. Still, domain-specific traits emerge: Logic & Reasoning shows high Minerva coherence ($\geq 70\%$), suggesting shared shortcuts; Math & Physics shows the lowest cross-family overlap, likely due to numerical complexity. These results confirm that agreement varies by domain and should be interpreted accordingly.

# A Modular LLM-based Dialog System for Accessible Exploration of Finite State Automata

Stefano Vittorio Porta[1], Pier Felice Balestrucci[1], Michael Oliverio[1,*], Luca Anselma[1] and Alessandro Mazzei[1]

[1]Computer Science Department, University of Turin, Italy

**Abstract**

In the field of assistive technologies, making accessible to visually impaired users complex visual content such as graphs or conceptual maps remains a significant challenge. This work proposes a modular dialog system that leverages a combination of neural Natural Language Understanding (NLU) and Retrieval-Augmented Generation (RAG) to translate graphical structures into meaningful text-based interactions. The NLU module combines a fine-tuned BERT classifier for intent recognition together with a spaCy-based Named Entity Recognition (NER) model to extract user intents and parameters. Moreover, the RAG pipeline retrieves relevant subgraphs and contextual information from a knowledge base, reranking and summarizing them via a language model. We evaluate the system across multiple specific tasks, achieving over 92% F1 in intent classification and NER, and demonstrate that even open-weight models, like DeepSeek-r1 or LLaMA-3.1, can offer competitive performance compared to GPT-4o in specific domains. Our approach enhances accessibility while maintaining modularity, interpretability, and performance on par with modern LLM architectures.

**Keywords**

Dialogue Systems, Retrieval-Augmented Generation, Large Language Models, Education

## 1. Introduction

Accessing graphical structures, such as tables, diagrams, and conceptual maps, poses a significant barrier to visually impaired people (VIP), especially in an educational setting, where ensuring equal opportunities for all students is a fundamental requirement. Despite decades of progress in assistive technologies, visual content remains one of the most challenging formats to make accessible. The World Health Organization estimates that at least 2.2 billion people live with near or distance-vision impairment.[1]

While the meaningful alternative text may bridge the accessibility gap, it is rarely implemented effectively. Indeed, for complex visual context a meaningful textual description can be too long for cognitive load constraints. A recent survey about images shared on major social-media and educational platforms found that fewer than 1% were accompanied by any alt text at all, and much of that text was limited to vague placeholders such as *"diagram"* or *"graph"* [1].

Natural Language Processing and Generation (NLP/G) offer promising, yet largely underexplored, approaches for the effective communication of graphical information. The widespread integration of speech-to-text and text-to-speech technologies in modern devices underscores their potential to mitigate accessibility barriers. In this context, *dialog systems* (DSs) can be a powerful tool for teaching graphical structures to VIP, as demonstrated in [2] for instance.

There are various frameworks available to build DSs. Rule-based approaches, such as AIML [3] and VoiceXML,[2] enable the DSs to provide very accurate responses, a critical feature in educational contexts. However, they typically demonstrate limited Natural Language Understanding (NLU), as highlighted in one of our previous works [4]. Alternatively, modular systems, such as the GUS architecture [5], emphasize understanding user utterances by identifying user intent and populating slot frames with information extracted from those utterances. The main challenge for this type of framework lies in the need for annotated dialog examples with labeled slots. End-to-end systems, such as large language models (LLMs), have emerged in recent years as the most popular approach for building DSs, largely due to their ease of use via prompt engineering. Nonetheless, these LLMs face two significant issues that impact their reliability in critical domains like education: (i) the presence of hallucinations in their responses and (ii) a lack of domain-specific knowledge [6]. More recent architec-

tures combine LLMs with modular architectures, such as Retrieval-Augmented Generation (RAG) systems [7], which integrate the text generation capabilities of LLMs with an information retrieval module for selecting and presenting the most relevant information to the user.

In [4], we introduced AIML+, a novel framework based on AIML, specifically developed for building DSs to assist visually impaired students in navigating graphical structures. The use of AIML was motivated by the need to provide accurate responses to users, although it also revealed limitations in terms of NLU. Building on this, and with the goal of creating a reliable system suitable for critical domains such as education, this paper extends our previous work by integrating LLMs into rule-based DSs, resulting in a RAG pipeline. This work aims to improve the often brittle NLU of traditional rule-based approaches and to reduce hallucinations in NLG.

Specifically, our proposal employs a hybrid architecture that combines: (i) an NLU module based on intent classifier and NER to interpret user utterances; (ii) a rule-based information retrieval module to extract relevant information; and (iii) an LLM-based NLG module to generate the system response.

The paper is structured as follows. Section 2 reviews related work in the field of accessible technologies and dialog systems. Section 3 presents the proposed methodology. Section 5 focuses on the performance of the NLU pipeline, Section 6 explains the Dialog Manager and Retrieval Layer logic, while Section 7 evaluates the generation module through both human and automatic assessments. We conclude with a discussion of our findings and future directions in Section 8.[3]

## 2. Related Work

Accessible technologies have explored various strategies to convey graphical information to VIP, including haptic feedback (e.g., vibrations and touch cues) [8, 9], sonification (data-to-sound mappings) [10, 11], and textual descriptions [12, 13]. While effective in specific contexts, these approaches often lack flexibility, interactivity, and generalizability—particularly when dealing with complex or symbolic visual content. To address these limitations, DSs have been proposed as a more dynamic and user-adaptive interface for mediating access to graphical structures.

Early DSs often relied on hand-crafted rules to parse user input and generate responses. AIML [3], for instance, encodes pattern-response pairs via XML, enabling deterministic rule-based dialogs. Although accessible and interpretable, these systems lack the robustness required to handle ambiguous or context-dependent queries, especially in domains that involve structured or graphical information.

To overcome these limitations, modern DSs increasingly adopt neural NLU methods. Intent classification is commonly modeled as a supervised classification task, where transformer-based models such as BERT have demonstrated state-of-the-art performance [14, 15].

Early NER systems relied on hand-crafted rules and domain-specific features, which required significant human effort and expertise [16]. Recent advances leverage distributed representations, context encoders, and tag decoders, achieving state-of-the-art results with less manual feature engineering [17, 18]

In parallel, RAG has emerged as a prominent approach to enabling language models to ground their responses in external knowledge. Although initially developed for open-domain QA and document-based tasks, its use in structured or symbolic domains, such as graphs, is gaining attention, particularly in educational or assistive settings [19, 20]. However, these systems often focus on general factual retrieval and rarely address the accessibility needs of users navigating inherently visual content.

This work builds upon the NoVAGraphS project, which first proposed transforming non-visual access to graphical content into a dialog-based paradigm via hand-crafted AIML conversational systems [2]. We build on this work by introducing a neural NLU pipeline and a RAG component specifically tailored to the retrieval and generation of descriptions from symbolic graph structures.

## 3. Methodology

We propose a modular dialog system based on transformer-based components used for both NLU and NLG (see Figure 1). To build the NLU module, we extended an existing resource [21] by applying both automatic data augmentation and manual annotation. In this way, we have been able to train models for both the tasks of (1) Intent Classification and (2) Named-Entity Recognition. The output of the NLU module is then passed to the dialog management module, a rule-based system responsible for retrieving the specific information requested by the user, referred to as *retrieved evidence* in this paper. The retrieved evidence originates from structured knowledge bases that, in the experimentation described below, consists of a specific diagram. The NLG module employs a prompt built by the Dialog Manager to generate from LLMs natural and contextually relevant responses by leveraging both the current user intent and the retrieved evidence.

Given our task-based approach, we focus on dialogs about Finite State Automata (FSA) as a specific case study.

[3] All code and experimental results are publicly available at https://github.com/stefa168/tesi_tln.

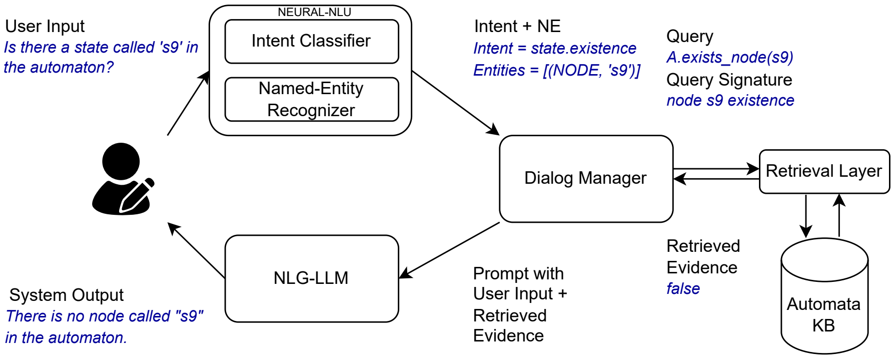

**Figure 1:** The user input is first processed by the Neural NLU module, which performs intent classification and named-entity recognition. The Dialog Manager then generates a query for the Retrieval Layer, which interrogates the Automaton Knowledge Base (KB) and returns the relevant evidence. This retrieved evidence, together with the original user input, is used to prompt the LLM-based NLG module, which generates a natural language response.

FSA are mathematical models of computation typically taught in computer science degree programs which are often represented as structured graphs. They are formally defined as a quintuple consisting of: (1) a finite set of states $Q$, (2) a finite set of input symbols $\Sigma$, (3) a transition function $\delta : Q \times \Sigma \rightarrow Q$ that maps each state and input symbol to a new state, (4) a start state $q_0 \in Q$, and (5) a set of accepting (or final) states $F \subseteq Q$.

## 4. Data Collection and Annotation

To develop the NLU module, we built upon an existing resource, the NoVAGraphS corpus [21]. The corpus consists of 32 human–computer conversations focused on the domain of FSA, comprising a total of 706 dialog turns. Since our work focuses on understanding user input, we exclusively use the 353 human utterances from the dataset.

Based on this corpus, we extended the dataset through data augmentation techniques by using a mix of commercial and open-weight LLMs, including GPT-4o, GPT-o1, and GPT-o3.mini, as well as two locally run models, Llama3.1 and DeepSeek R1, generating paraphrases of the original utterances.[4] To ensure data quality, we manually reviewed the synthetic utterances to verify their correctness. In addition, we also included 100 random off-topic questions extracted from the SQuAD 2.0 dataset [22, 23], selected to represent out-of-domain input[5].

The final dataset contains $1,080$ user utterances. All utterances, both original and synthetic, were manually annotated by one of the authors—proficient in English—for both intent and entity information.

**Intents** We used a hierarchical labeling annotation to better capture the specific topic of each user utterance. The resulting dataset consists of two levels of classes: main intents and sub-intents. Specifically, we defined 7 main intents representing the general topic of the question (Table 1). For four of these main intents (AUTOMATON, TRANSITION, STATE, and GRAMMAR) an additional annotation level, called sub-intent, was introduced. This second level includes a total of 32 sub-intents (Table 2), which specify the question's more fine-grained topic depending on the main intent category.

**Table 1**
Taxonomy of the main intents annotated in the corpus

| Main Intent | Description |
|---|---|
| TRANSITION | Questions concerning transitions between states |
| AUTOMATON | Questions concerning the automaton in general |
| STATE | Questions concerning the states of the automaton |
| GRAMMAR | Questions concerning the grammar recognized by the automaton |
| THEORY | Questions about general automata theory |
| START | Questions that initiate interaction with the system |
| OFF_TOPIC | Questions not relevant to the domain that the system must be able to handle |

**Entities** Entity annotation was performed using the open-source web tool Doccano, resulting in a total of 632 labeled spans across the dataset[6]. Following the

[6] https://github.com/doccano/doccano An entity is encoded as [init-char,fin-char,type]

**Table 2**
Sub intents annotated in the dataset divided by main intent.

| Main Intent | Sub Intent | Description |
|---|---|---|
| AUTOMATON | DESCRIPTION | General descriptions about the automaton |
| | DESCRIPTION_BRIEF | Brief general description about the automaton |
| | DIRECTIONALITY | Questions regarding whether the entire automaton is directional |
| | LIST | General information about nodes and edges |
| | PATTERN | Presence of particular patterns in the automaton |
| | REPRESENTATION | Spatial representation of the automaton |
| TRANSITION | COUNT | Number of transitions |
| | CYCLES | Questions about loops between nodes |
| | DESCRIPTION | General descriptions about edges |
| | EXISTENCE_BETWEEN | Existence of an edge between two nodes |
| | EXISTENCE_DIRECTED | Existence of an edge from one node to another |
| | EXISTENCE_FROM | Existence of an outgoing edge from a node |
| | EXISTENCE_INTO | Existence of an incoming edge to a node |
| | INPUT | Receiving input from a node |
| | LABEL | Indication of which edges have a certain label |
| | LIST | Generic list of edges |
| | SELF_LOOP | Existence of self-cycles |
| STATE | COUNT | Number of states |
| | DETAILS | Specific details about a state |
| | LIST | General list of states |
| | START | Which is the initial state |
| | FINAL | Existence of a final state |
| | FINAL_COUNT | Number of final states |
| | FINAL_LIST | List of final states |
| | TRANSITIONS | Connections between states |
| GRAMMAR | ACCEPTED | Grammar accepted by the automaton |
| | EXAMPLE_INPUT | Example input accepted by the automaton |
| | REGEX | Regular expression corresponding to the automaton |
| | SIMULATION | Simulation of the automaton with user input |
| | SYMBOLS | Symbols accepted by the grammar |
| | VALIDITY | Validity of a given input |
| | VARIATION | Request for simulation on a modified automaton |

annotation process, three entity classes emerged:

- INPUT: for text fragments containing inputs or sequences of symbols. For example, in the sentence *"Does it only accept 1s and 0s?"* there are two entities of type INPUT: `[20,21,"input"]`, `[27,28,"input"]`;
- NODE: for text fragments containing nodes or states of the automaton. For example, in the sentence *"Is there a transition between q2 and q0?"* there are two entities of type NODE: `[30,32,"node"]`, `[37,39,"node"]`;
- LANGUAGE: for text fragments containing information about the language accepted by the automaton. For example, in the sentence *"Does the automaton accept strings over the alphabet {0,1}?"* there is one entity of type LANGUAGE: `[53,58,"language"]`.

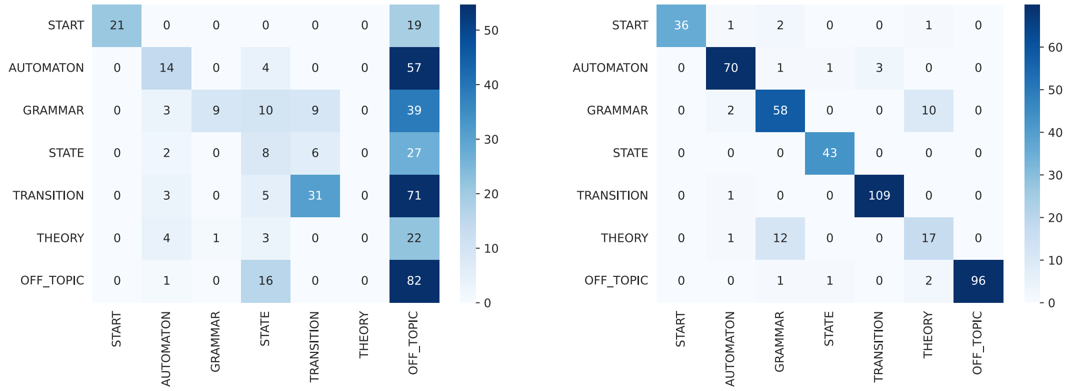
## 5. Neural NLU

The first module of our architecture handles NLU through a two-step pipeline: (i) **Intent Classification** and (ii) **Named-Entity Recognition**. The goal is to extract a structured representation of the user's utterance by identifying the intent and the entities in the user input. For example:

**Input**: *"Is there a state called s9 in the automaton?"*
**Output**: {

```
  Intent = state.existence,
  Entities = [(NODE, 's9')]
}
```

To build the NLU module, we trained two models for Intent Classification and Named-Entity Recognition using the corpus described in Section 4, and we evaluated them against the AIML system we proposed in [24].



| | START | AUTOMATON | GRAMMAR | STATE | TRANSITION | THEORY | OFF_TOPIC |
|---|---|---|---|---|---|---|---|

(b) BERT model

**Figure 2:** Confusion matrices for the AIML baseline and the fine-tuned BERT model on the main intent classification.

**Intent Classification** For intent classification, we fine-tuned a `BERT-base-uncased` model[7] for both main and sub-intent classification. The dataset was split into 60% training, 20% development, and 20% testing. We fine-tuned with the following hyper-parameters: 20 epochs, LR $2{\times}10^{-5}$, linear warm-up 10%, batch 16. Training was logged with Weights & Biases. Our approach significantly outperforms the AIML baseline, achieving a macro-F1 score of 0.92 on main intents and 0.86 on sub-intents. This marks a substantial improvement over AIML, which scores only 0.33 and 0.20, respectively (see Table 3). Figure 2 compares the confusion matrices for both systems, showing that BERT produces far fewer off-topic errors and handles ambiguous utterances more robustly.

**Table 3**
Performance on main and sub-intent classification for the fine-tuned BERT model and the AIML baseline (↑ **higher is better**).

| Model | Main Intent F1 | Sub-intent F1 | NER |
|---|---|---|---|
| BERT (ours) | **0.92** | **0.86** | **0.92** |
| AIML baseline | 0.33 | 0.20 | - |

**Named Entity Recognition** NER is handled using a simplified spaCy v3 pipeline that exclusively employs the NER component on top of a blank model,[8] fine-tuned on our annotated dataset with the same data split (60/20/20). The pipeline is based on the transformer architecture [25] and identifies domain-specific entities such as `states`, `transitions` and `input strings`. It achieves an F1-score of 0.92 on the test set (see Table 3).

## 6. Dialog Manager and Retrieval Layer

The Dialog Manager is responsible for orchestrating the interaction flow by interpreting the NLU output and coordinating the appropriate system response. This involves analyzing the classified intent and any associated entities, and invoking the corresponding function from the Retrieval Layer.

The Retrieval Layer is activated whenever the recognized intent is relevant to the domain, thus neither `START` nor `OFF TOPIC`. Indeed, `START` typically triggers a welcome message, while `OFF TOPIC` handles inputs outside the system's scope. Since these cases do not require access to the automaton's knowledge, retrieval is skipped.

For domain-specific intents (e.g., checking the existence of a state), the Dialog Manager uses a rule-based system that maps intent–entity pairs to specific queries. This design ensures transparency and precise control over system behavior. For instance, when the intent is `state.existence` and the entity is a node identifier like `‘s9’`, the Dialog Manager calls the function `exists_node(‘s9’)`. This function queries the underlying automaton representation to determine whether the specified node exists. The automaton is stored in a Knowledge Base (KB) constructed using the NetworkX Python library,[9] which allows efficient graph manipulation. The automaton's structure is serialized in DOT format, a standard for graph description, and visualized using Graphviz.[10]

The Retrieval Layer then returns a structured output (e.g. `false`, if the node is not found), which is passed to the NLG module for the generation of the final response.

[10] https://graphviz.org/

## 7. LLM-based NLG

For the NLG module, we adopt a prompting strategy based on LLMs that uses both the user input and the output of the Dialog Manager to generate contextually relevant and accurate responses. This technique is widely adopted in RAG systems [7], as it enables the model to ground its answers in retrieved evidence, reducing hallucinations and increasing factual accuracy. Our prompt template drives the model to act as a domain-specific expert — in this case, for finite state automata — instructing it to use only the retrieved data without introducing extraneous information or explicit references to the source. This approach helps maintain concise, focused answers that avoid potential confusion or unverifiable content.

```
System prompt:
"You are a helpful assistant expert
in finite state automata.
Answer the question given by the
user using the retrieved data,
using plain text only. Avoid
referring to the data directly;
there is no need to provide any
additional information.
Keep the answer concise and short,
and avoid using any additional
information not provided.
The system has retrieved the
following data:
{Retrieved Evidence}
The user has asked the following
question:
{User Input}"
```

We evaluate this module by comparing five LLMs with different characteristics: two commercial models, GPT-4o and GPT-o3-mini, and three open-weight models, DeepSeek-r1-8B, Gemma2-9B, and LLaMA3.1-8B.[11]

To assess the quality of the generated answers, we conducted a human evaluation using the *FactGenie* platform [26]. A group of 12 volunteer annotators labeled each generation according to four error categories defined by the taxonomy in Kasner and Dusek [27]. In particular: INCORRECT indicates that the text contradicts the data; NOT-CHECKABLE means the information cannot be verified; MISLEADING refers to text that is deceptive given the context or omits crucial information; and OTHER includes problematic cases that do not fit into the other categories. In addition to human annotation, we also performed automatic labeling using GPT-4.5[12] (*LLM-as-a-Judge*), applying the same error taxonomy. The annotator pool included 8 students from the Department of Computer Science, 2 with an engineering background, and 2 from the Departments of History and Biology. The average age was 28, with a range from 21 to 68 years. Each annotator evaluated a subset of the responses, with overlapping assignments to ensure that all 75 generated answers were reviewed by multiple judges.

**Table 4**
Average percentage of answers containing at least one labeled error, computed by aggregating the four error categories (INCORRECT, NOT-CHECKABLE, MISLEADING, OTHER). Lower values indicate better performance.

| Generator | Human error ↓ | GPT-4.5 error ↓ |
|---|---|---|
| GPT-o3-mini | **7.3** | **6.6** |
| GPT-4o | 8.7 | 7.1 |
| DeepSeek-r1-8B | 26.7 | 13.3 |
| Gemma2-9B | 33.3 | 26.7 |
| LLaMA3.1-8B | 46.7 | 33.3 |

Table 4 summarizes the aggregated error rates across the four categories, demonstrating that GPT-o3-mini consistently achieves the lowest error rates under both human and GPT-4.5 evaluation. Among the open-weight models, DeepSeek-r1-8B shows the most competitive performance, outperforming other open models by a substantial margin. These results highlight the effectiveness of the prompting strategy in generating accurate and reliable responses grounded in retrieved data.

In addition to the error-based evaluation, we introduced four qualitative dimensions to assess the overall quality of the interactions: CLARITY, USEFULNESS, OVERALL APPRECIATION, and FACTUAL ACCURACY. These dimensions offer a more holistic perspective on the responses, going beyond binary correctness.

- CLARITY: whether the response is understandable and well-structured;
- USEFULNESS: whether the response is helpful and provides relevant information;
- OVERALL APPRECIATION: whether the response is perceived as satisfactory or positively received by the annotator;
- FACTUAL ACCURACY: whether the response is entirely correct and free from factual errors.

The same group of 12 human annotators performed labeling according to these dimensions.

Table 5 shows that GPT-o3-mini receives the most favorable user judgments across all dimensions. Among open-weight models, DeepSeek-r1-8B is the most positively rated, while LLaMA3.1-8B and Gemma2-9B receive consistently lower preferences from annotators.

**Table 5**
Percentage of answers regarding how they were perceived by human annotators. Arrows indicate the direction of better results (↓ lower is better, ↑ higher is better). Abbreviations: CL = clarity, US = usefulness, OA = overall appreciation, FA = factual accuracy.

| Model | CL ↑ | US ↑ | OA ↑ | FA ↑ |
|---|---|---|---|---|
| GPT-o3-mini | **92.7** | **98.0** | **95.3** | **98.7** |
| GPT-4o | 86.0 | 90.0 | 86.7 | 90.0 |
| DeepSeek-r1 8B | 69.3 | 82.0 | 68.0 | 70.0 |
| LLaMA3.1 8B | 63.3 | 68.0 | 58.0 | 71.3 |
| Gemma2 9B | 56.0 | 58.7 | 36.7 | 66.0 |

## 8. Conclusions

This work presents a significant advancement over previous systems aimed at the exploration of graphical structures, by proposing a hybrid modular architecture that integrates NLU and NLG techniques based on Transformers and LLMs. The implemented DS addresses several key limitations of rule-based DSs, such as rigid pattern matching, limited context handling, and difficulties in interacting with external data sources.

Compared to AIML, our system stands out for its greater expressive flexibility and its ability to adapt to complex conversational flows, thanks to a more articulated dialog management mechanism. The introduction of a neural classifier for intent recognition, along with a spaCy-based NER module, has substantially improved the robustness of natural language understanding, achieving F1 scores above 90% for both Intent Classification and NER. Moreover, the RAG component has significantly reduced hallucinations and ambiguity in generation, providing contextually accurate responses that are well-grounded in structured data.

The results demonstrate that a hybrid and modular approach can ensure accessibility, reliability, and control—fundamental features for the adoption of DSs in educational and assistive contexts. Our framework therefore represents a concrete step toward more interpretable, adaptable, and user-centered intelligent DSs. In future works we plan to evaluate the complete system with blind people.

## 9. Limitations

While the system shows strengths in modularity, accuracy, and integration of LLMs, a significant limitation persists: its accessibility has yet to be validated with learners. Although designed with accessibility in mind, the system's real-world effectiveness and usability—especially for visually impaired individuals interacting with graphical content—remain untested. Conducting a structured evaluation with these target users is crucial to determine its pedagogical impact and practical usability.

# Leveraging LLMs to Build a Semi-Synthetic Dataset for Legal Information Retrieval: a Case Study on the Italian Civil Code and GPT4-o

Mattia Proietti[1,*], Lucia Passaro[1,2] and Alessandro Lenci[1]

[1] CoLing Lab, Department of Philology, Literature and Linguistics, University of Pisa
[2] Department of Computer Science, University of Pisa

## Abstract

Although raw textual data in the legal domain is abundant, making it easy to collect large amounts of material from several sources, structured and annotated data needed to fine-tune machine learning models is limited and difficult to obtain. Creating human-annotated datasets is both time- and money-consuming, which often makes impractical to get quality data to train machines on various legal language tasks. AI models such as *Large Language Models* (LLMs) are becoming appealing to generate synthetic data, judge model responses, and annotate textual information, so to cope with such shortcomings. In this work, we wish to evaluate the applicability of LLMs for the automatic generation of a dataset of legal query-passage pairs to train retrieval systems. Indeed, *Legal Information Retrieval* (LIR) has been crucial for the creation of robust search systems for legal documents and is now gaining new importance in the context of the *Retrieval Augmented Generation* (RAG) framework, which is becoming a widespread tool to cope with LLMs hallucinating behaviours. Our goal is to test the feasibility of building a query-passage dataset in which the queries are generated by an LLM about real textual passages and assess the reliability of such a process in terms of the generation of hallucination-free data points in a delicate domain, as the legal one. We do so in a two-step pipeline spelt out as follows: i) we use the Italian Civil Code as a source of self-contained, semantically coherent legal textual passages and ask the model to generate hypothetical questions on them; ii) we use the LLM itself to judge the coherence of the questions to spot those inconsistent with the passage. We then select a random subset of the question-passage pairs and ask humans to evaluate them. Finally, we compare human and model evaluations on the randomly selected subset. We show that the model generates many questions easily, and while it lags behind humans when evaluating the appropriateness of the generated questions with respect to the reference passages in zero-shot settings, it substantially reduces the gap with human judgements when only two examples are provided.

## Keywords

Large Language Models, Legal Information Retrieval, Synthetic data generation, LLM-as-a-judge, Legal-NLP

## 1. Introduction

In recent years, we have witnessed great advancements in the field of Artificial Intelligence (AI), in particular in its sub-domain of Natural Language Processing (NLP). The advent of Large Language Models (LLMs), especially on the wave initiated by the GPT family [1, 2], has revolutionised the way we produce, understand, and manipulate textual content. This revolution has permeated all domains, and the legal field is no exception. Indeed, NLP for legal applications is spreading and is gaining a core role in the discussion about the integration of AI into legal practice. However, due to its high degree of specialization, the intellectual complexity of legal tasks, and the technical specificity of its language, the legal domain — similarly to other specialized fields — has progressed more slowly toward a mature integration of language technologies. Despite the vast volume of textual material generated daily by legal practitioners, the field still faces a significant shortage of machine-readable and annotated resources needed to train and fine-tune AI systems for Legal NLP (LNLP) tasks — a process that is complex and presents numerous challenges [3]. The lack of data encompasses all the devisable LNLP tasks. In this work, we focus on data formats necessary to train systems to perform Legal Information Retrieval (LIR) tasks. LIR is a crucial task in the field of LNLP, primarily concerned with retrieving relevant documents in response to a given textual query. A typical application scenario involves a system capable of identifying and returning pertinent legal documents based on a user's question. To effectively perform this task, it is essential to train models on in-domain data—specifically, question-passage pairs derived from legal documents and expressed in legal language—in order to address domain shifts [4]. However, building such datasets purely through human annotation is both extremely time-consuming and costly as it requires coming up with questions and associate them with relevant documents that may be used to answer those questions. To cope with such shortcomings, syn-

*CLiC-it 2025: Eleventh Italian Conference on Computational Linguistics, September 24 — 26, 2025, Cagliari, Italy*

thetic data generation and annotation through LLMs is arising as a promising strategy and it is now being explored within the legal domain as well. Despite its ease, the increasing application of LLMs to generate synthetic data calls for a major assessment of their reliability and real applicability for the task at hand.

This paper aims to answer the following research question: "How reliable are automated methods for generating and evaluating semi-synthetic datasets in the context of Legal Information Retrieval?" In turn, the motivation behind this question is two-fold. On the one hand, we want to generate a dataset that can be used to train machine learning systems to perform the task of LIR. On the other hand, we aim to assess the feasibility of this process by evaluating the reliability of using a state-of-the-art LLM both to generate questions and to assess their relevance to reference text passages, as well as the efficiency of this approach in terms of time and cost. We consider this process as a proxy to evaluate the model's ability to understand legal texts at a basic level, since formulating a good question is an index of the degree of understanding reached by the system formulating that question.

To this end, we integrate two established paradigms of LLMs applications: (i) synthetic data generation[5, 6], employed to automatically construct the dataset, and (ii) LLM-as-a-judge[7], used to evaluate and filter out noisy or inaccurate outputs. Specifically, we apply a multi-step strategy involving a state-of-the-art LLM, namely GPT4-o, to generate questions on articles of the Italian Civil Code and evaluate whether the generated questions are answerable by reading the reference article text. We subsequently sample subsets of the generated questions at random and have them evaluated by human annotators using the same criteria as the model, in order to compare the results of automatic and manual evaluation. In that way, we estimate both the question-generation abilities of the LLM and its self-evaluation ability, both of which are crucial for assessing the feasibility of fully automating the process of creating a legal question-answering dataset.

Given the aforementioned lack of datasets to train machine learning models for tasks related to the legal domain and the costs related to manually annotating corpora from the ground up, integrating LLMs in the process of dataset creation is nowadays a promising approach. This work contributes to the understanding of how much we can rely on state-of-the-art LLMs to generate synthetic textual data that are free from hallucinations and that may actually be useful in practical downstream tasks, particularly focusing on the generation of question-passage pairs to be used to train retriever models for LIR and RAG in the legal domain. This aspect is particularly important for low-resource languages and vertical domains, where annotated data is especially scarce. We found that not only the model's performance on generating questions is pretty remarkable in terms of quantity, but it can be almost as good as human judges in the self-evaluation task in 2-shot settings, though it lags behind humans when a 0-shot prompt is used.[1]

## 2. Related Works

Our work falls in between two paradigms that are becoming standard practice in the NLP community, that is **synthetic data generation** and **LLM-as-a-judge**. As such it is related to a number of works in both those lines of research.

**Synthetic Data** – Making use of LLMs to generate synthetic datasets is becoming commonplace among NLP practitioners at different stages of the data lifecycle, from generation to curation and evaluation [8]. For example, the Huggingface team has recently released a Python library to automatically generate evaluation benchmarks using LLMs [9]. They implement a protocol they call Document-Evaluation-Generation, dubbed as DG2E. This is relevant to our work, as this framework allows the generation of domain-specific, tailored evaluation benchmarks. However, they used a far more complex strategy, involving multiple LLMs and focusing on the creation of evaluation questionnaires, while we are interested in applying LLMs to generate questions to construct a domain-specific retrieval dataset.

Several relevant works have explored the possibility of generating synthetic questions to build retrieval datasets, either involving LLMs or not. Wang et al. [10] proposed Generative Pseudo Labelling (GPL) to build unsupervised datasets for retrieval, using the encoder-decoder model T5 [11] to generate queries and a cross-encoder to assign pseudo-labels. Ma et al. [12] makes use of synthetic question generation to enhance the zero-shot retrieval abilities of models in target domains. Meng et al. [13] implemented a framework called Augtriever, with which synthetic pseudo-queries are generated by both extracting salient spans from the target reference passage and using NLP text-generation trained on other tasks, such as text summarisation. Tong et al. [14] have applied LLMs to generate synthetic questions to train retrieval models in a protocol they dubbed IGFT (iterative Generation Filtering and Tuning), consisting of iterating the three steps of generating, filtering and tuning synthetic questions to cope with low-quality generated data. Bonifacio et al. [15] leveraged LLMs few-shot generation abilities to build domain-specific synthetic datasets which they used to fine-tune retrievers reported to outperform strong standard baselines trained on data obtained by supervised annotation. Saad-Falcon et al. [16] implements a pipeline of synthetic question generation involving LLMs to build retrieval datasets tailored to target low-resource domains.

[1] Code and the data available at https://github.com/aittam9/cc_qa

**LLM-as-a-judge/annotator** – LLMs have been recently involved in the process of both annotating data and evaluating model-generated responses. Aldeen et al. [17] evaluates the performance of ChatGPT in annotating texts comparing it with those of human annotators. Savelka [18] use GPT to semantically annotate legal texts in a zero-shot fashion. Wang et al. [19] deploy a human-LLM collaborative protocol for data annotation.

More broadly, LLMs have been used as judges in a variety of works that are relevant to ours, both for the methods employed and the aims pursued. For example, Sun et al. [20] uses LLMs to judge if a the knowledge retrieved as a triplet from s graph is sufficient to answer a given question. Bavaresco et al. [21] tested LLMs as judges on 20 tasks, comparing their judgements with human ones through Spearman's correlation [22] for graded scores and Cohen's $k$ annotator agreement [23] for categorical ones. We refer to Gu et al. [24] for a comprehensive overview of works that have adapted the LLM-as-a-judge paradigm in several ways.

Although a variety of works have addressed the problem of augmenting data for IR through synthetic question generation, to the best of our knowledge, a gap exists both for the Italian language and the Italian legal domain. The same holds for the application of an LLMs as a judge/annotator to evaluate and label data points to build a dataset for LIR. The contribution of our work resides precisely within that frame.

## 3. Data and Model

**Data**. We used articles from the Italian Civil Code (ICC) as our source data in order to take advantage of it as a source of short, self-contained and semantically coherent texts. We extracted the articles from the publicly available copy of the ICC offered in Wikisource [2] and saved them as textual passages in plain text. In doing so, we removed all the code meta-textual macro-structure information (*Capi, Titoli, Sezioni*) except for the division in books. We discarded the repealed articles as well as some ill-extracted ones before cleaning and preprocessing the remaining. This process of filtering, cleaning and preprocessing left us with 2927 textual passages. It has to be noted that we considered the Italian Civil Code as a mine of legal textual passages, and our aim was not to model its content or its structure, but to have a reliable source of short legal passages.

**Model**. We used GPT4-o, an enhanced version of the GPT4 model released by OpenAI [25], accessed through the Python API endpoint. [3] Because it is a proprietary model, details about its technical specifications, architecture, parameters, and the like have not been disclosed to the public.

## 4. Methodology

**Questions Generation**. After the data pre-processing and cleaning, we asked GPT4-o to generate questions for each ICC article, treated as a simple text passage. We adapted the number of questions to be asked to the model on the basis of the length of the input article in terms of sentences. To do so, we used the tokenizer of the Spacy Python library [4] to split the articles into sentences. As the Spacy tokenizer is not trained to operate on texts from specific domains, such as the legal one, we customized the standard tokenizer by integrating a long list of abbreviations obtained by expanding those in [26]. In that way, the tokenizer can recognize frequent acronyms patterns like *c.c.* or *art.* and have a better understanding of the sentence boundaries. To meaningfully relate the number of generated questions to the article length, we applied a simple heuristic by which we asked the model to generate a number of questions equal to the number of sentences compsing the article. To avoid excessively noisy generations, we set 8 as the maximum number of questions for the longest articles, if those exceed the length of 8 sentences.

More formally, we take all the articles in the ICC to be a collection of passages $P$ and for any passage $p \in P$ we asked the model $M$ to generate a set of passage-related queries $\mathbf{q}^p = \{q_i^p ... q_n^p\}$ where $n = min(len(p), 8)$ and the length is computed in terms of number of sentences. Then we obtain the total number of queries for all the passages $QP$, from the union of all the sets of generated queries as $QP = \bigcup_{p \in P} \mathbf{q}^p$.

Figure 1 shows the prompt used to generate the questions.

**Figure 1:** Prompt used to generate questions

**Automatic Questions Evaluation**. In a second step, we provided the model with each article paired with the questions it had generated initially and asked it to evaluate whether the answer to each question could be found within the corresponding textual passage. The model was instructed to produce a binary output to facilitate efficient parsing in subsequent evaluation stages. Specifically, the model assigned one of two labels to each

[2] https://it.wikisource.org/wiki/Codice_civile

[3] https://platform.openai.com/docs/overview.

[4] https://spacy.io/

question–passage pair: "*SI*" for a positive match, indicating the answer is present, and "*NO*" for a negative match, indicating it is absent. The question, passage, and instructions were formatted into the prompt illustrated in Figure 2. Therefore, given a pair consisting of a passage $p \in P$, a related question $q^p \in \mathbf{q}^p$ generated in the previous step, and a general template prompt $t$ shown in Figure 2, we built a prompt $t^{pq}$ for each passage-question pair. The model $M$ had to determine if $p$ contains the necessary information to answer $q^p$, which basically translates into the model performing a binary classification task over the prompt $t^{pq}$, as shown in 1.

$$M(t^{pq}) = \begin{cases} SI, & \text{if } p \text{ answers } q \\ NO, & \text{otherwise} \end{cases} \tag{1}$$

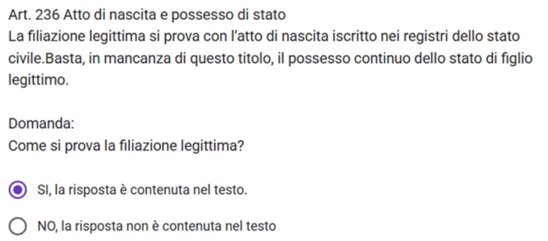
**Figure 2:** Prompt used to evaluate questions

We replicate the automatic evaluation on a random subset used to perform the manual evaluation (see below), this time using a 2-shot prompt technique, in which we provided the model with one correct and one incorrect example.

**Manual Evaluation**. We randomly selected a sample of the generated questions and asked human judges to evaluate whether the answer to the question could be found inside the textual passage (article). Specifically, we randomised the data on two levels. Firstly, we shuffled the whole set of pairs composed of generated questions and reference texts. Secondly, we split the shuffled dataset into subsets of 100 samples each and randomly chose subsets to be annotated by human judges.

We distributed one randomly-selected subset per annotator with no overlap of annotators on the same sets. In that way, we have been able to divide the workload for annotators, asking a single person to annotate samples of 100 items. We estimated that around one hour is required to annotate a sample of that size. All the annotators had an education level of a master's degree or above. They were personally instructed by one of the authors and presented with a Google form providing further instructions and the question-passage pairs to evaluate. The Google Forms have been automatically generated using the Type-Script extension from Google Sheets[5]. We have been able to collect manual annotations for 12 random samples of 100 entries each, for a total of 1200 question-passage pairs. Each question-passage pair to be evaluated has been presented to the annotators as as shown in Figure 3. In this way, the human annotators had to perform the same binary classification task as the model, as illustrated in the previous paragraph, so that 1 can be turned into 2, where $H$ indicate the human performing the task.

$$H(t^{pq}) = \begin{cases} SI, & \text{if } p \text{ answers } q \\ NO, & \text{otherwise} \end{cases} \tag{2}$$



Art. 236 Atto di nascita e possesso di stato
La filiazione legittima si prova con l'atto di nascita iscritto nei registri dello stato civile.Basta, in mancanza di questo titolo, il possesso continuo dello stato di figlio legittimo.

Domanda:
Come si prova la filiazione legittima?

● SI, la risposta è contenuta nel testo.

○ NO, la risposta non è contenuta nel testo

**Figure 3:** Example question as shown to the human annotators in the google form.

**Evaluation cross-comparison**. As a last step, we compared the manual and automatic evaluations on the portion we sampled for human annotators. In addition with the 0-shot evaluation already conducted on the whole dataset, we also performed a 2-shot automatic evaluation on the random subsets to have a more comprehensive picture of model's possible performance. Firstly, we simply compared the outputs of the model's evaluation and human evaluation, counting the respective values, that is, how many positive and negative judgments have been provided by each method. Secondly, we treated the human annotation as a gold standard and used it to assess model performance by computing standard machine learning classification metrics such as Precision, Recall and F1, thus having a more nuanced and faithful picture of the relation between human and model evaluations. The primary objective of this step is to evaluate the extent to which the model's judgments, align with human judgments, across all prompts in the randomly selected subsets, considering both zero-shot and two-shot settings.

## 5. Results

### 5.1. Generation

The results statistics for the first experiment, that is the generation step, are shown in the Table 1:

[5] This task has been performed with the aid of an LLM.

| Book | Input Articles | Generated Questions | Generation Rate |
|---|---|---|---|
| **1** | 392 | 1115 | 2.84 |
| **2** | 345 | 874 | 2.53 |
| **3** | 359 | 949 | 2.64 |
| **4** | 888 | 2116 | 2.38 |
| **5** | 623 | 2132 | 3.42 |
| **6** | 320 | 890 | 2.78 |
| **ICC (all)** | 2927 | 8076 | 2.7 |

**Table 1**
Statistics of the generated questions across ICC books.

As shown, the model demonstrates strong proficiency in generating questions for each article in terms of quantity, with an average of approximately 3 questions per article, ranging from 2.38 to 3.42 across books. Given a total of 2,927 input articles, the model generated 8,076 questions, effectively doubling or tripling the length of each book.

## 5.2. Automatic Self-Evaluation

Next, we examine the results of the auto evaluation performed by the model itself and regarding the quality of the generated questions with respect to the input reference text. Figure 4 shows the distribution of the positive and negative values assigned by the model to each pair of generated questions and reference article text. The values are respectively represented by the labels *SI* and *NO* as required by the prompt shown in the previous section in Figure 2, and their distribution is computed per ICC book. In this phase, the model assigned the positive label *SI* to a total of 5369 question-passage pairs, while judging 2692 pairs as negative, which were labelled with *NO*. Additionally, the model failed to provide a legitimate answer (*SI* or *NO*), thus failing to follow the instructions written in the prompt in 15 cases. Overall, the model judged as relevant to the reference article 66% of the questions, thus interpreting as correct only 2/3 of its own generations.

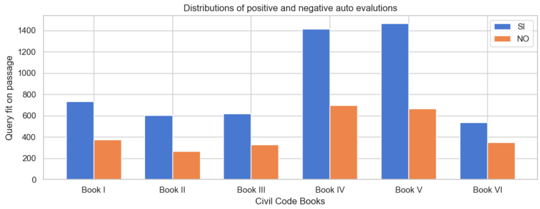


**Figure 4:** Distribution of labels assigned by the model in the self-evaluation step.

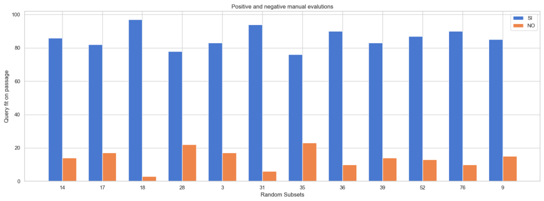

**Figure 5:** Distribution of labels assigned by humans on the selected random subsets.

| Eval Mode | Pos. (SI) | Neg. (NO) | Pos. ratio |
|---|---|---|---|
| Human | 1036 | 164 | **0.86** |
| Model-0shot | 792 | 408 | 0.66 |
| Model-2shot | 982 | 218 | 0.82 |

**Table 2**
Distribution of questions considered as correct (SI) and incorrect (NO) in the aggregated random subsets across evaluation modalities.

## 5.3. Manual Evaluation

As introduced in the previous section, we randomly selected a subset of the generated questions and asked human evaluators to judge if a question would be good for a given reference passage, thus eliciting the same type of binary judgment obtained by prompting GPT4-o. We did so for 12 sub-sets of data each containing 100 items, for a total of 1200 items. As can be seen from Figure 5, human annotators assigned far more positive labels than negative, as the model itself already did in the zero-shot settings, but with an even greater gap between the two classes, for a total of 1036 (86%) positive labels against 164 (14%) negative ones. The manual evaluation on the random sample seems to point out that the majority of questions generated by the model are, on average, correct with respect to the related text passage.

## 5.4. Cross Evaluation

We ran a cross-analyisis between Human and Model evaluations. As for the latter, we use the zero-shot evaluations previously performed on the whole generated dataset, as well as a new set of 2-shots evaluations elicited for the random subsets assigned to humans. In that way, we could compare Human evaluations against two type of model evaluations, namely Model-0shot and Model-2shot. As shown in Table 2, human evaluations assigned the most positive labels (86%), closely followed by the Model-2shot (82%), while Model-0shot evaluations lag behind both (66%). In fact, when the model is prompted with no example provided, its evaluations display a gap of around 18-20% compared to the other two modalities. It should be stressed that in that case *positive* and *negative* do not necessarily correspond to correct and incorrect,

|  | Average | P | R | F1 |
|---|---|---|---|---|
| H@M-0shot | **Macro** | 0.62 | 0.72 | 0.62 |
|  | **Weigthed** | 0.85 | 0.72 | 0.76 |
| H@M-2shot | **Macro** | 0.70 | 0.75 | 0.72 |
|  | **Weigthed** | 0.87 | 0.85 | **0.86** |

**Table 3**
Classification metrics between human (H) evaluations and model (M) evaluations at 0- and 2-shots respectively.

but to how an evaluator, human or artificial, has considered the input pair. So, at this stage the comparison between human annotators and the model is more on the dimension of the propensity to assign positive values to the analysed pairs rather than on judging correct responses.

Therefore, we then analysed how the model evaluations performed against the human ones, using the latter as the gold standard, in order to have a more meaningful comparison between Human and Model evaluations. As previously stated (see above Section 4), the evaluation task can be formalised as a binary classification task. Therefore, we computed classical machine learing metrics such as Precision, Recall and F1 between human and model annotations. Again, we did so for model's evaluations elicited in 0-shot and 2-shot settings. Results are shown in Table 3.

As expected, given the previous comparisons, the F1 score obtained between Human and Model-0shot is modest (76%). This is a confirmation of the tendency of the model to underestimate the correctness of the generated questions when prompted with no example whatsoever. This led the model to mislabel lots of items, favouring negative labels, hence leading to a problem of false negatives, as already guessable in previous analysis. While the percentage of false positives assigned by the model is much lower.

On the other hand, the F1 improved of 10 points (86%) when Model-2shot evaluations are used, substantially levelling the false negatives problem emerged in the 0-shot evaluation. In other words, as it is further summed-up in the confusion matrices shown below in Figure 6, much of the discrepancy between the two evaluation settings depends on the GPT4-o underestimating the goodness of its own generations when the evaluation is led with no examples provided, failing to correctly match a huge number of pairs in which the question and reference article text were positively related. On the contrary, with just one correct and one incorrect examples, the model evaluations align with humans one significantly better.

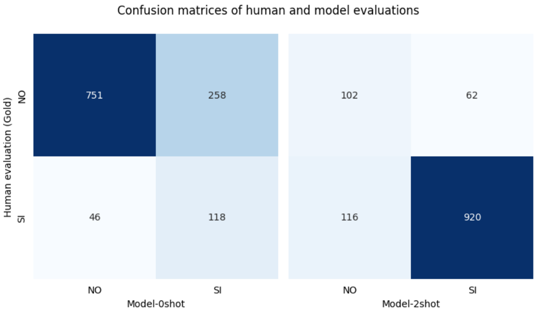

**Figure 6:** Confusion matrices between Human evaluations and Model-0shot and Model-2shot respectively.

## 6. Discussion

We have performed a series of experiments to assess the ability of GPT4-o to generate pertinent legal questions in relation to articles of the Italian Civil Code. We first prompted the LLM to generate the questions, then asked the model itself to judge their goodness, adopting a binary labelling schema. In parallel, we sampled a subset of the generated questions and asked humans to judge their quality with respect to the reference text they were generated from, using the same schema adopted for the model. Next, we compared the kind of evaluation, the automatic made by the model, and the manual performed by human annotators.

Overall, we saw that, as expected, GPT4-o has been generally able to produce an adequate number of questions for each article, as it was stated by our heuristic, which would allow the seamless creation of a dataset to train models for the Legal Information Retrieval task, which may then be integrated into Search Engines or RAG applications. In fact, given the starting set of input texts, we have been able to triple its size in terms of generated questions.

The model's self-evaluation phase seemed to reveal an underestimation of the goodness of the questions by the model itself when it is prompted to perform the task in 0-shots settings. The model judged only 66% of the questions as pertinent to their respective reference text when no example is provieded, initially leading us to think that while it is very good at generating, it underperforms when it comes to evaluating, even though the evaluation concerns its own generated texts. On the other hand, the model has been able to close the gap with human judges in positively evaluating question-passage pairs from a difference of 20% to only 4% when provided with a correct and an incorrect example. While the 0-shot settings underlined a substantial problem of false negatives, this has been substantially reduced in the 2-shot settings. The results show that an SOTA LLM can be seamlessly used to generate legal content-related questions. It can hardly compete with humans in the 0-shot evaluation of the quality of the same questions with respect to their reference passage, but can better mimic human performance when provided with a negligible number of examples. Overall, all the above hints suggest that using LLMs to cope with the shortage of annotated resources to train machine learning models in the legal domain is an asset worth putting into practice. As stated in previous sections, we used the LLM as a generator to produce questions and as a judge to evaluate the goodness of its own generations. While the LLM-as-a-judge paradigm provides an easy and efficient way to evaluate model responses, its value is not limited to that. Indeed, we can readapt model evaluations and consider them as annotations, with no need to discard incorrect questions, which can be used as negative labels of the generated dataset.

## 7. Limitations and Future Directions

Some limitations of the present work need to be noted.

First of all, we used a proprietary model. While this choice is apt to our purpose and data, using a closed-source closed-access model implies not being able to precisely define the engine being used, which can undergo updates or modifications without notification. That may hinder the reproducibility and stability of the results across time.

On the side of question evaluation, we used a simple binary approach aiming at identifying whether a question could be answered with the information provided in the document from which it has been generated. While this is straightforward and seamless to implement, it does not allow a more nuanced assessment of the quality of the questions. Therefore, future work is reserved to refining the evaluation approach to introduce additional criteria to assess the quality of a question other than simple answerability (e.g. fluency, ambiguity and the alike). Also, due to resource constraints, we distributed the random samples for the manual evaluation among annotators, assigning a single sample to each one, without overlapping. This made it impossible to assess the soundness of the annotations by computing annotators' agreement measures. In the future, we plan to widen the number of annotated items as well as the pool of annotators, in order to obtain a stronger and more faithful gold standard.

Lastly, in this work, we focused solely on the Italian Civil Code, from which we derived more than 8000 training inputs. Despite being a robust starting point, we are planning to extend the strategy to other Italian Codes, like the Penal Code, in order to both extend the dataset quantitatively and add greater linguistic and conceptual variation qualitatively.

## 8. Conclusions

In conclusion, integrating LLMs in the process of creating datasets for LNLP tasks is surely a promising and worthwhile route, as it may have many benefits in terms of costs and time efficiency. Indeed, we estimate that the total cost of generating and evaluating questions with GPT4-o is less than 30 dollars, and the amount of time needed to perform the computational experiments is between 15 and 20 hours. These numbers suggest that the process may be easily scalable without a great waste of resources. Also, we showed how the model needs at least two examples to approach the human performance in evaluation, while substantially lagging behind it when a 0-shot prompt is used. While manual evaluation seems to still be the most faithful way to derive gold standards, we estimated that around one hour is necessary for a human to perform an evaluation on a sample of 100 entries, which may become impractical to extend to larger datasets. In contrast, using an LLM to both generate and judge-annotate synthetic questions seems to be a viable alternative to fully automate the process of generating training data for Legal Information Retrieval, providing huge benefits in terms of money and time resources, while maintaining an acceptable performance rate, up to an unavoidable level of noise.

## 9. Acknowledgments

We are deeply grateful to the volunteer human annotators who have participated in the experiments.

# No longer left behind: Self-training Reasoning Models in Italian

Federico Ranaldi[1,2], Leonardo Ranaldi[1,2]

[1]Univeristy of Roma Tor Vergata
[2]Univeristy of Edinburgh

**Abstract**

Although reasoning is, by nature, language-agnostic, the extent to which large language models (LLMs) can perform consistent multilingual reasoning remains limited. Their capacity to deliver step-wise explanations is largely constrained to the dominant languages present in their pre-training data, thereby limiting cross-lingual generalisation and hindering broader global applicability. While recent work has explored a range of strategies to extend reasoning capabilities beyond English, these efforts typically remain grounded in surface-level spoken language phenomena, which may not be optimal for abstract or formal reasoning tasks. In this study, we focus on Italian and English, two languages with markedly different syntactic and morphological properties, to assess whether advancements in multilingual reasoning remain consistent and transferable across typologically diverse settings. To this end, we introduce a modular framework that guides LLMs to abstract the reasoning process into a structured problem space before generating step-wise reasoning trajectories. The approach leverages self-training to enhance alignment and generalisation. Experimental results demonstrate stable and significant gains in multilingual reasoning across models and tasks, with improved consistency between English and Italian.

**Keywords**

Multilingual Reasoning, Self-training, Large Reasoning Models

## 1. Introduction

In the era of large language models (LLMs), approaches such as Chain-of-Thought (CoT) and related methods seek to emulate human reasoning through language generation—an ability that, in principle, ought not to be constrained by the particularities of any spoken language. Yet, a growing body of evidence indicates that the reasoning capabilities of LLMs vary significantly across languages, largely as a consequence of imbalances in pre-training data. LLMs perform better in dominant languages, notably English, while exhibiting reduced reasoning competence in less-represented languages.

Research advances in multilingual reasoning are increasingly aimed at closing the performance differences among languages, enhancing the models' capabilities through in-context learning interventions [1, 2, 3], SFT strategies that differ from language-specific augmentation [4, 5] to task-oriented tuning [6], and preference optimisation [7, 8]. Although these approaches have enabled the development of effective methods for transferring and aligning multilingual reasoning capabilities, we argue that several critical challenges continue to hinder progress. First and foremost, the benefits of in-context interventions appear to be confined to large-scale LLMs, which are better equipped to interpret and follow instructions in a systematic way. However, they must also have robust multilingual proficiency. Therefore, many works rely on SFT techniques that maintain reduced costs when used with specialised, smaller-scale LLMs. Secondly, they require vast amounts of complex reasoning annotations and tremendous tuning efforts to get multilingual LLMs capable of delivering reasoning through SFT and preference optimisation techniques.

To enhance multilingual reasoning in LLMs, we propose a modular approach that first instructs the model to abstractly formalise the problem and then generate structured, step-by-step reasoning trajectories that converge towards a consistent reasoning process across languages.

Our approach decomposes problem solutions into a sequence of formal, language-agnostic sub-problems that are solved sequentially and can be more effectively utilised by models.

The decomposition consists of two high-level modules: *Formalisation* and *Reasoning Execution.* As illustrated in Figure 1, we guide the models to: (i) identify the relevant information within the problem, formalising variables and predicates while delivering symbolic transformations; (ii) generate a reasoning execution trajectory in which the transformations are applied using symbolic representations that explicitly articulate the solution, ultimately yielding an answer in the same query language.

Previous works proposed English-based strategies that operate via logical formalisms coupled with external symbolic solvers [9, 10]. Yet, fully symbolic approaches face a key bottleneck: they require a complete translation

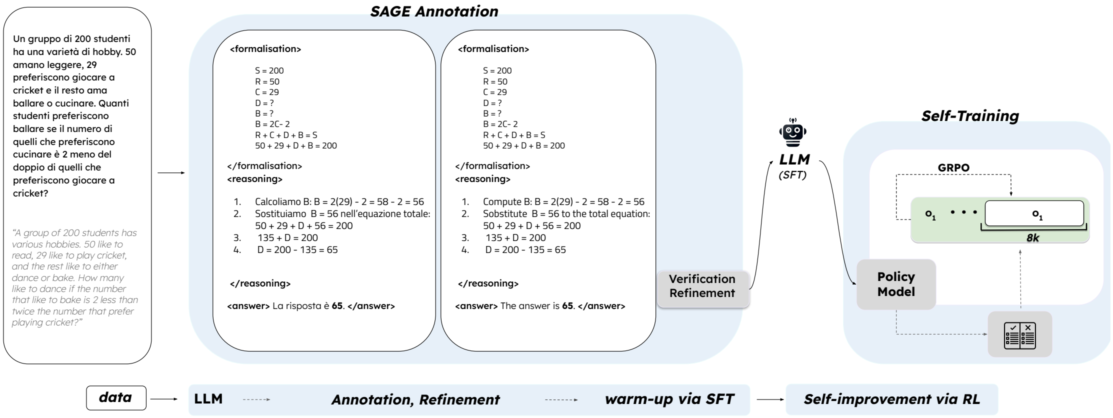
name.surname@ed.ac.uk (L. Ranaldi)



Un gruppo di 200 studenti ha una varietà di hobby. 50 amano leggere, 29 preferiscono giocare a cricket e il resto ama ballare o cucinare. Quanti studenti preferiscono ballare se il numero di quelli che preferiscono cucinare è 2 meno del doppio di quelli che preferiscono giocare a cricket?

*"A group of 200 students has various hobbies. 50 like to read, 29 like to play cricket, and the rest like to either dance or bake. How many like to dance if the number that like to bake is 2 less than twice the number that prefer playing cricket?"*

```
<formalisation>

      S = 200
      R = 50
      C = 29
      D = ?
      B = ?
      B = 2C- 2
      R + C + D + B = S
      50 + 29 + D + B = 200

</formalisation>
<reasoning>

 1.   Calcoliamo B: B = 2(29) - 2 = 58 - 2 = 56
 2.   Sostituiamo  B = 56 nell'equazione totale:
      50 + 29 + D + 56 = 200
 3.    135 + D = 200
 4.    D = 200 - 135 = 65

</reasoning>

<answer> La risposta è 65. </answer>
```

```
<formalisation>

      S = 200
      R = 50
      C = 29
      D = ?
      B = ?
      B = 2C- 2
      R + C + D + B = S
      50 + 29 + D + B = 200

</formalisation>
<reasoning>

 1.   Compute B: B = 2(29) - 2 = 58 - 2 = 56
 2.   Sobstitute  B = 56 to the total equation:
      50 + 29 + D + 56 = 200
 3.    135 + D = 200
 4.    D = 200 - 135 = 65

</reasoning>

<answer> The answer is 65. </answer>

**Figure 1:** LLMs deliver language-agnostic reasoning trajectories across languages by disentangling content from logical reasoning through structured step-wise passages operating via our Structured Abstractive Generative Explanation.

from natural to formal language, which can hinder both efficiency and flexibility, introducing additional layers of complexity.

To achieve a better trade-off, we treat formalisations in an eclectic manner and propose methods to disentangle content from logical reasoning without introducing rigorous formalisms.

To this end, following Ranaldi and Pucci [11], we instruct larger LLMs to generate synthetic demonstrations through Structured Abstractive Generative Explanation (SAGE), which are then used to perform *Self-training* on smaller LLMs.

As part of the warm-up phase, we experiment with multiple alignment strategies, ranging from supervised fine-tuning (Instruction-Tuning) to preference optimisation techniques (Reinforcement Learning).

We conducted an extensive empirical evaluation to assess the impact of different tuning and alignment strategies.

In multilingual reasoning tasks, our demonstrated significant improvements, resulting in an overall increase in exact matching in proposed tasks, which led to the following results and conclusions:

- Structuring multilingual reasoning in LLMs as formal reasoning trajectories (SAGE), which leverages language-agnostic reasoning logic, improves accuracy and generates more verifiable outputs through a transparent and structured.

- Leveraging *self-training* heuristics that combine both tuning and preference optimisation leads to more robust, generalisable, and language-aligned models. While tuning based on synthetic demonstrations proves effective, it alone fails to yield consistently strong performance across all languages. Conversely, relying solely on preference optimisation can provide performance gains, but at the cost of significant computational overhead.

- Our approach allows the disentanglement of content from logical reasoning, improving multilingual reasoning in LLMs, thus benefiting in different language spaces.

## 2. Method

We propose a self-training framework that augments standard fine-tuning with a set of preference optimisation policies (§ 2.1) designed to improve self-refinement. The approach iteratively alternates between preference-based optimisation (via reinforcement learning) and supervised fine-tuning, directing the model to abstract the underlying problem and articulate a step-wise, formal solution (§ 2.2). The iterative process terminates once the model's performance either converges or reaches a predefined maximum number of iterations.

### 2.1. Preference Estimation

RL strategies operate preference estimation. This generally involves aligning the policy model with preferences using a reward model, which learns to predict preferences based on comparisons and leads the optimisation process. Although this approach is practical, it has problems with generalisation, scalability, robustness, and alignment. In GRPO, rule-based reward models are used. While DPO is generally based on a series of naive string-matching functions with ground truth values, rules are explicitly defined in GRPO. Accordingly, we define the following preference policies:

**DPO Preference Estimation** We adopt a string-matching function in line with existing approaches for English [8, 12]. We then refine this procedure by filtering out generations that do not adhere to the expected structural pattern and well-formed format.

**GRPO Preference Estimation** Following Ranaldi and Pucci [11] we define a rule-based metrics that control the accuracy, the structure and the form of the generations.

## 2.2. Self-training

Conventional self-training begins by fine-tuning the base model $\mathcal{M}\theta$ on the supervised dataset $\mathcal{D}$SFT, yielding an updated model $\mathcal{M}\theta'$. At this stage, we assume that $\mathcal{M}\theta'$ has acquired the ability to address the target problem. Specifically, when presented with a question $x$, the model generates a formal reasoning sequence $\hat{y}$ together with the corresponding answer $\hat{a}$.

**Self-training** We begin by sampling multiple completions $\hat{y}$ from $\mathcal{M}\theta'$ in response to a set of questions $x$ drawn from the unlabelled pool $\mathcal{U}$. We then apply preference estimation heuristics to construct preference-based samples according to different optimisation strategies: pairwise comparisons for DPO and grouped completions for GRPO. These generations are compiled into a dataset $\mathcal{D}$, which is subsequently used to further train the model using the corresponding objective functions ($\mathcal{L}$DPO and $\mathcal{L}$GRPO), resulting in an updated model $\mathcal{M}\theta^d$.

Then we use $\mathcal{M}_{\theta^d}$ to generate a new pseudo-labeled dataset for the next-round tuning:

$$\mathcal{S} = (x, \hat{y}) | x \sim \mathcal{U}, \hat{y} \sim_\theta (\cdot|x). \tag{1}$$

After generation, the dataset $\mathcal{S}$ is refined by removing incorrect answers and eliminating duplicates. Consequently, the resulting pseudo-labeled dataset, denoted as $\mathcal{S}^\alpha$, is a subset of the original dataset, i.e., $\mathcal{S}^\alpha \subset \mathcal{S}$. The final training dataset is constructed by combining the original labeled dataset $\mathcal{L}$ with the newly generated pseudo-labeled dataset $\mathcal{S}^\alpha$. During this process, each new dataset is used to train from the original base model $\mathcal{M}_\theta$, rather than continually fine-tuning $\mathcal{M}_\theta$, to mitigate the risk of overfitting.

## 2.3. Single-training

For comparative purposes, we conduct individual training operating only with SFT, DPO and GRPO.

**Algorithm 1** Self-training [11]

```
Input: pre-trained language model $\mathcal{M}_\theta$
       labeled dataset $\mathcal{L} = \{(x^i, y^i, a^i)\}_{i=1}^{l}$
       unlabeled dataset $\mathcal{U} = \{(x^i, a^i)\}_{i=1}^{u}$
       mode $\in$ {DPO, GRPO}
Output: fine-tuned model $\mathcal{M}_{\theta'}$

# Warm-up stage
Fine-tune $\mathcal{M}_\theta$ on $\mathcal{L}$ to get $\mathcal{M}_{\theta'}$
repeat
    if mode = DPO then
    Generate DPO dataset $\mathcal{D}$:
    $\mathcal{D} = \{(\ x^i,\ y_w^i,\ y_l^i\ )\}_{i=1}^{N}$
    where $x^i \sim \mathcal{U}$ and $y_w^i,\ y_l^i \sim \mathcal{M}_{\theta'}(\cdot|x^i)$
    Tune $\mathcal{M}_{\theta'}$ with $\mathcal{L}_{\text{DPO}}$ on $\mathcal{D}$ to get $\mathcal{M}_{\theta^d}$
    end if
    if mode = GRPO then
    Generate GRPO dataset $\mathcal{G}$:
    $\mathcal{G} = \{(x^i, G^i)\}_{i=1}^{N}$
    where $x^i \sim \mathcal{U}$
    and $G^i = \{y_1, \ldots, y_k\} \sim \mathcal{M}_{\theta'}(\cdot|x^i)$
    Compute relative preferences within each group $G^i$,
    assign pairwise relative scores to outputs in $G^i$.
    Tune $\mathcal{M}_{\theta'}$ with $\mathcal{L}_{\text{GRPO}}$ on $\mathcal{G}$ to get $\mathcal{M}_{\theta^g}$
    end if
  # SFT step
  Build pseudo-labeled dataset $\mathcal{S}$:
  $\mathcal{S} = \{(x^i, \hat{y}^i, \hat{a}^i)\}_{i=1}^{s}$
  where $x^i \sim \mathcal{U}$ and $\hat{y}^i, \hat{a}^i \sim \mathcal{M}_{\theta^d}(\cdot|x^i)$
  $\mathcal{M}_{\theta^g}(\cdot|x^i)$
  Select $\mathcal{S}^\alpha \subset \mathcal{S}$ when $\hat{a}^i = a^i$
  Update $\mathcal{L} \leftarrow \mathcal{S}^\alpha \cup \mathcal{L}$
    Train $\mathcal{M}_\theta$ on $\mathcal{L}$ to get a new $\mathcal{M}_{\theta'}$
until convergence or max iteration is reached
```

# 3. Experiments

As outlined in the introduction, our objective is to develop a method for enhancing the reasoning capabilities of LLMs beyond English, with a particular emphasis on Italian. Our experiments are conducted on multilingual reasoning tasks. We evaluate four models (§ 3.1), trained according to the procedure detailed in § 3.2, on two mathematical reasoning benchmarks (§ 3.3), using the experimental configurations described in § 3.4.

## 3.1. Models

To conduct our study on different models and have a term of comparison, we use Llama3-8B [13], DeepSeekMath-7B-Instruct [14] (DeepSeek-7B). Furthermore, to show the scalability and effectiveness of our approach on further models, we introduce additional smaller-scale models: EuroLLM-1.7B and Velvet-2B.

## 3.2. Training Methods

As introduced in §2, we use a iterative steps of SFT and RL. We follow standard practice and perform a warm-up phase based on an SFT step using synthetic demonstrations discussed in §3.3.2. Then, we conduct the self-training by progressively applying SFT and RL optimisation algorithms. Following pilot studies (later discussed), we set the total number of iterations to three (excluding warm-up), the same for the settings where we use only one between SFT and RL.

**Preference Optimisation RL** We employ the HuggingFace trainers ($DPO_{trainer}$ and $GRPO_{trainer}$) to ensure reproducibility. For DPO, we set the learning rate to *1e-6* and $\beta$ to 0.1. The optimisation process is set at a maximum of 2000 steps, saving the checkpoint corresponding to the lowest validation loss. For GRPO, we set the learning rate to *5e-6* and $\beta$ to $x$. The optimisation process is set at a maximum of 2000 steps, saving the checkpoint corresponding to the lowest validation loss. Details in Appendix D.

**Supervised Fine-tuning** Regarding the SFT phase, we employed 8-bit quantization and LoRA. We tune the model for one epoch (warm-up) and for one epoch for each iteration using the learning rates according to the specific model configuration, as detailed in Appendix D.

## 3.3. Data

### 3.3.1. Evaluation Set

To study the reasoning performances of trained models, we operate via mGSM, mSVAMP, and we introduce mGSM-Symbolic focusing on English and Italian.

**Mathematical Reasoning task** We use the extension of GSM8K and SVAMP. Respectively, Multilingual Grade School Math (mGSM) and Multilingual Simple Variations on Arithmetic Math word Problems (mSVAMP). In original cases, the authors proposed a benchmark of English mathematical problems with the following structure: a word problem in natural language and a target answer in numbers. For both versions, a subset of instances from the official list of examples were translated into 11 different languages, maintaining the structure of the input and output.

**mGSM-Symbolic** Mirzadeh et al. [15] improved GSM8k (the ancestor of MGSM) by proposing GSM-Symbolic. This introduces symbolic patterns in GSM8k that complexify the task and disadvantage the LLMs' capabilities. We propose mGSM-Symbolic, the multilingual GSM-Symbolic extension. In particular, we conduct an automatic translation phase disillusioned by qualified annotators in 10 different languages. The dataset is available on **GitHub**[1] and **HuggingFace**[2].

### 3.3.2. Training Set

Instead of using natural language rationale, we employ synthetic demonstrations to train models to solve tasks following the two phases in Figure 1. Specifically, we instruct a robust model capable of addressing multilingual mathematical tasks by formalising problems and solving them in a language-agnostic manner. We employ GPT-4o as annotator, instructing it with the prompt detailed in Appendix A (we define this procedure as `Self-training`)

Different works train an expert version of the same model that is going to be refined for generating synthetic demonstrations, which are subsequently used for self-training (we define this procedure as `Full Self-training`).

**Multilingual Demonstrations** We annotate a subset of the mSVAMP dataset containing 250 samples for all languages to have in-domain demonstrations. After the annotation process, we check the quality of the demonstrations using rule-based heuristics and GPT-4o-mini as an additional evaluator (details in Appendix C).

## 3.4. Experimental Setup

**In-context Learning** We evaluate the baseline models (without tuning) using a 6-shot strategy defined as `Direct` and `CoT`. Moreover, we instruct the models to solve the problem following SAGE.

**Training** We assess the impact of the Self-training approaches (§3) by conducting different tuning configurations:

- **SFT, RL** We tune the models using the synthetic demonstrations as detailed in Appendix B.
- **Self-training** We warm-up the models using the synthetic demonstrations as detailed and conduct the self-training strategies using both policies.
- **Full Self-training** Finally, to observe the impact of the self-generated demonstrations, we conduct both the annotation, SFT (warm-up) and Full Self-train phase completely on the self-generated data of the same expert model.

[1] lranaldii/MGSM-Symbolic

[2] lrana/MGSM-Symbolic

# 4. Results

Reasoning can be effectively grounded in language-agnostic form, which LLMs can leverage to enhance multilingual task performance. SAGE facilitates this by guiding LLMs towards structured symbolic solutions, enabling them to produce robust and consistent outputs across languages. While SAGE yields strong results in GPT-4o, its benefits do not readily extend to smaller models. To address this, we adopt a self-training strategy that enables smaller models to acquire formal reasoning capabilities independently of explicit instruction, ultimately achieving greater consistency than GPT-4o (§ 4.1). Notably, self-training not only outperforms standalone SFT and reinforcement learning approaches, but also enables models to achieve stronger performance with substantially less training data (§ 4.2). Furthermore, we demonstrate the scalability of this method by successfully applying self-training to additional small-scale models (§ 4.3).

## 4.1. Language-Agnostic Reasoning

SAGE positively influences the models' performance in multilingual reasoning, getting substantial benefits on the proposed tasks.

| Models | En | It |
|---|---|---|
| GPT-4o | 83.2 | 79.0 |
| +SAGE | 93.0 | 88.6 |
| Llama3-8B | 76.0 | 58.2 |
| +Self-training | 91.8 | 73.0 |
| DeepSeek-7B | 76.2 | 58.2 |
| +Self-training | 90.2 | 76.9 |
| Velvet-2B | 60.2 | 56.8 |
| +Self-training | 71.0 | 68.5 |
| EuroLLM-1.7B | 66.3 | 60.4 |
| +Self-training | 72.6 | 65.8 |

**Table 1**
Performances on mGSM-Symbolic.

**Multilingual Reasoning** Table 1 presents results for SAGE with GPT-4o on mGSM-Symbolic, with a particular focus on English and Italian. The performance remains consistent with that observed in mGSM, as indicated by the values in brackets. Notably, the Self-training strategy enhances the models' abstraction capabilities, allowing them to perform well even in the more formal and structured setting of mGSM-Symbolic, where typical linguistic biases are reduced. In contrast, baseline methods yield substantially lower scores, underscoring the effectiveness of SAGE's formalisation in supporting multilingual reasoning.

**In-context Learning** Table 2 presents the performance of SAGE applied to GPT-4o, showing clear improvements over previous prompting-based strategies such as `Direct` and `CoT`. The use of in-context instructions encourages the model to organise problem-solving in a structured manner, promoting step-wise reasoning and planning. This results in more consistent reasoning trajectories that are less influenced by language-specific patterns, thereby reducing performance disparities across languages.

## 4.2. The Self-training Impact

Table 2 summarises the outcomes of applying the Self-training strategy across multiple models. The findings indicate a consistent enhancement in performance, particularly in terms of cross-linguistic consistency, even if overall accuracy remains below that of GPT-4o. Beyond accuracy, Self-training proves to be a more efficient tuning method, yielding stronger models while requiring significantly less training data than alternative approaches such as SFT and RL. This advantage is reflected in the steady performance gains observed over SFT in Table 2, and further supported by data efficiency metrics reported in Appendix F, where Self-training operates with fewer examples per model.

**The role of RL** Table 2 reports the results obtained using GRPO. As shown in Table 3, GRPO consistently outperforms DPO, both when applied in isolation and when integrated with SFT within the full Self-training framework. As outlined in Section 2.1, GRPO does not rely on an annotated dataset for supervision. Instead, similar to prior work, a rule-based algorithm serves as a proxy reward model. Unlike DPO, which operates at the level of individual instances, GRPO is specifically designed to optimise groups of completions across languages, making it well-suited to the multilingual nature of the proposed task.

**The impact of Full Self-training** Current alignment strategies typically rely on demonstrations produced by expert models belonging to the same model family. Ranaldi and Freitas [6] demonstrate that in-family learning exerts a stronger influence on the performance of student models. In our work, we adopt the Full Self-training approach and show that self-generated demonstrations can lead to more robust outcomes than those derived from GPT-4o. As illustrated in Figure 2, models trained with their own annotations exhibit greater consistency

| Model | Method | mGSM |  | mSVAMP |  | Average |  |
|---|---|---|---|---|---|---|---|
|  |  | **En** | **It** | **En** | **It** | **En** | **It** |
| **GPT-4o** | `Direct` | 86.8 | 79.8 | 83.2 | 74.6 | 85.0 | 77.2 |
|  | CoT | 92.4 | 86.0 | 89.0 | 78.2 | 90.7 | 82.1 |
|  | SAGE | **93.0** | **88.4** | **86.2** | **83.6** | **89.6** | **86.0** |
| **Llama-3-8B** | `Direct` | 79.6 | 61.2 | 81.2 | 69.8 | 80.4 | 65.5 |

and resilience across languages, despite using the same amount of training data.

## 4.3. Transferability in Smaller Models

To evaluate the transferability of Self-training and SAGE to smaller-scale models, we extend our experiments to include `Llama-3-1B`, `EuroLLM-1.7B`, and `Velvet-2B`. These models were selected based on three criteria: their inherent multilingual design, their promising performance in mathematical reasoning tasks, and their relatively low parameter count, which enabled efficient experimentation across training regimes.

We adopt the experimental setup detailed in § 3.1, applying SFT, GRPO, and our full Self-training procedure. Table 3 reports the average results obtained on the mGSM-Symbolic benchmark. Across all models, Self-training with SAGE consistently outperforms both SFT and RL-based baselines.

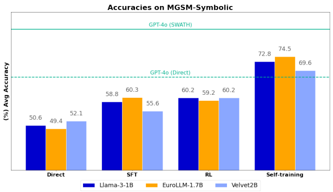

**Figure 3:** Average accuracies of smaller models in our mGSM-Symbolic.

# 5. Background

## 5.1. Improving Reasoning in LLMs

Improving reasoning capabilities in LLMs (both English and multi- and cross-lingual) is usually conducted through SFT using ground-thought examples and preference-based approaches.

**Supervised Fine-Tuning** Supervised Fine-Tuning (SFT) is a standard approach for adapting a model $\mathcal{M}$ to reasoning tasks using a labelled dataset $\mathcal{L}$. Each instance in $\mathcal{L}$ consists of a question $x$, a corresponding step-by-step explanation $y$, and a final answer $a$. The answer is derived from the explanation using regular expressions. A generated rationale $\hat{y}$ is deemed valid if the extracted answer $\hat{a}$ matches the reference answer $a$. Formally, the labelled dataset with $n$ instances is defined as:

$$\mathcal{L} = (x^i, y^i, a^i)i = 1^n. \tag{2}$$

SFT updates the parameters $\theta$ of model $\mathcal{M}\theta$ by minimising the negative log-likelihood of the target rationale:

$$\mathcal{L}\mathrm{SFT}(\theta) = \mathbb{E}(x, y) \sim \mathcal{L}\left[\sum_{t=1}^{T} \log f_\theta(y_t|x, y_{1:t-1})\right], \tag{3}$$

where $T$ is the length of the rationale $y$, and $y_t$ denotes its $t$-th token.

**Self-training** Self-training refers to a family of SFT-based methods that have recently gained renewed interest for their effectiveness in enhancing reasoning capabilities [16]. These methods typically follow a two-stage process. First, a base model $\mathcal{M}\theta$ is fine-tuned on a labelled subset $\mathcal{L}$ to obtain a teacher model $\mathcal{M}\theta'$. This teacher is then used to annotate an unlabelled dataset $\mathcal{U}$, producing a pseudo-labelled dataset $\hat{\mathcal{L}}$. In the second stage, a student model $\mathcal{M}\theta$ is trained on the combination of the original data $\mathcal{L}$ and the pseudo-labelled data $\hat{\mathcal{L}}$, with the aim of surpassing the performance of the teacher $\mathcal{M}\theta'$.

Empirical studies have shown that the quality of pseudo-labels plays a critical role in determining the effectiveness of self-training. To address this, Wang et al. [12] propose an iterative refinement procedure, wherein the model $\mathcal{M}_\theta$ is progressively improved, ensuring increasingly accurate pseudo-labelled data across iterations.

**Reinforcement Learning Heuristics (RL)** Within the Self-training approaches, Reinforcement Learning from Human Feedback (RLHF) is widely used for aligning language models with human feedback [17]. The RLHF framework refines LLM behaviour by leveraging human preference data to guide model tuning through RL. Specifically, it uses a reward model $r(x, y)$, which captures human preferences given an input $x$ and its corresponding output $y$. This reward model is then employed to assign preference scores to arbitrary LLM-generated outputs, facilitating iterative policy refinements via proximal policy optimisation (PPO) [18]. The training process follows an optimisation function, for instance, PPO, which optimises the model policy $\phi_\theta$ to maximise expected rewards while minimising divergence from the SFT policy:

$$\mathbb{E}_{(x,y)\sim D_\pi}[r(x, y) - \gamma \log \frac{\phi_\theta(y|x)}{\phi_{\mathrm{SFT}}(y|x)}], \tag{4}$$

where $\phi_{\mathrm{SFT}}$ denotes the original model trained via SFT, and $\gamma$ serves as a regularization hyperparameter to constrain policy updates.

**Direct Preference Optimisation** Reinforcement Learning with Human Feedback (RLHF), particularly through Proximal Policy Optimisation (PPO), has proven effective for aligning language models with human preferences. However, it typically requires multiple auxiliary components, including a reward model, making the training process computationally intensive and technically complex. To address this, Rafailov et al. [19] proposed Direct Preference Optimisation (DPO), which allows models to be aligned directly with human preferences without the need to train a separate reward model.

DPO begins with a warm-up phase based on supervised fine-tuning. For a given input $x$, the reference policy $\phi_{\mathrm{ref}}$ generates two candidate completions:

$$y_1, y_2 \sim \phi_{\mathrm{ref}}(\cdot \mid x). \tag{5}$$

These are then paired based on preference to form the DPO training set:

$$\mathcal{L}_{DPO} = (x^i,\ y^i_w,\ y^il)i = 1^N, \tag{6}$$

where $y^i_w$ is the preferred response and $y^i_l$ is the less preferred one.

The policy model $\mathcal{M}\theta$ is then optimised by minimising the following objective:

$$\mathbb{E}\left(x, y_w, y_l\right) \sim \mathcal{D}\left[-\log \sigma\left(r(y_w|x) - r(y_l|x)\right)\right], \tag{7}$$

where the score function is defined as $r(\cdot|x) = \beta \log \frac{\phi_\theta(\cdot|x)}{\phi_{\text{ref}}(\cdot|x)}$, and the parameter $\beta$ regulates how far the new policy $\phi_\theta$ may deviate from the reference policy.

While DPO offers a more streamlined alternative to RLHF by avoiding explicit reward modelling, it is limited by its reliance on fixed pairwise preference comparisons. This can hinder its capacity to generalise across tasks that exhibit contextual or structural variation [20].

**Group Relative Policy Optimisation** To overcome these limitations, Shao et al. [21] introduced Group Relative Policy Optimisation (GRPO), a refinement of PPO that improves training stability by using group-based reward estimation. Instead of relying on pairwise comparisons, GRPO evaluates completions within groups and assigns rewards based on relative performance within those groups.

Given a batch of responses from the policy model $\phi_\theta$, GRPO estimates relative advantages across the group and applies the following optimisation objective:

$$\mathbb{E}(x, y) \sim D \left[ A\text{rel}(y|x) \log \pi_\theta(y|x) - \beta D_{\text{KL}} \left( \pi_\theta | \pi_{\text{ref}} \right) \right], \tag{8}$$

where $\pi_\theta$ is the updated policy and $\pi_{\text{ref}}$ is the original pre-trained policy. The KL divergence term prevents the updated policy from diverging excessively from its prior, with the coefficient $\beta$ determining the strength of this regularisation.

The relative advantage $A_{\text{rel}}(y|x)$ is computed as:

$$A_{\text{rel}}(y|x) = \frac{r(y|x) - \mu}{\sigma}, \tag{9}$$

where $r(y|x)$ denotes the reward assigned to the response $y$, and $\mu$ and $\sigma$ are the mean and standard deviation of the reward distribution within the group.

GRPO has demonstrated particular efficacy in multitask and multilingual reasoning contexts. By comparing responses within structurally related groups, it allows for more adaptive and robust policy updates, supporting better generalisation and stability across tasks. Empirical findings confirm that GRPO improves consistency, robustness, and data efficiency when compared to traditional PPO-based methods.

## 5.2. Multilingual Reasoning

Recent efforts to assess the capabilities of LLMs have focused on their performance in complex reasoning tasks, particularly in mathematical problem-solving. Benchmark datasets such as GSM8K and SVAMP have been widely adopted for this purpose. To extend such evaluation to multilingual contexts, Shi et al. [22] introduced mGSM, a multilingual variant of GSM8K, created by manually translating 250 test samples into various languages. Chen et al. [23] proposed mSVAMP, a multilingual extension of SVAMP following the same approach. Multiple strategies have been proposed to enhance multilingual reasoning in LLMs. These include translation-based approaches [24], SFT [25], and preference-based alignment methods [7], each of which demonstrates gains in multilingual performance. Nonetheless, these methods rely heavily on high-quality annotated data. SFT suffers from forgetting and poor generalisation, while preference-based alignment adds computational overhead through critic-based systems. Another line of research has explored the use of in-context prompting, whereby LLMs are instructed to reason step by step through carefully designed prompts. Although this strategy has proven useful in certain tasks [2], its reliance on English, combined with its inefficacy for smaller models [1], limits its applicability. Moreover, reasoning under this framework is typically induced by the prompt's structure, making it difficult to generalise across languages or domains.

While reasoning is inherently independent of language, the extent to which LLMs demonstrate consistent reasoning across linguistic boundaries remains limited. We aim to disentangle logical reasoning from linguistic surface forms by adopting a language-agnostic formalism. We propose converting problems expressed in any language into a shared formal representation that is abstract, manipulable, and semantically grounded. Reasoning operates over this intermediate form, with the final answer rendered in the target language. To support this, we instruct LLMs to abstract and solve problems via self-training, enabling scalable multilingual reasoning without the need for prompt engineering.

# 6. Conclusion & Future Works

Although reasoning is inherently language-agnostic, LLMs' outputs often reflect biases towards dominant pretraining languages, particularly English. While models show strong multilingual capabilities, their step-wise reasoning remains inconsistent across languages. Focusing on English and Italian, we propose a modular approach that abstracts the problem into a language-agnostic formalism, followed by structured reasoning. Using self-training, we align reasoning performances, achieving gains in both accuracy and consistency.

This work contributes to a series of studies aimed at expanding the proficiency of LLMs beyond English. In our Research, we have explored interventions at every stage—from pre-training [26, 27] and post-training [4, 11] to inference methods [1, 2, 3], and recently on multimodal reasoning [28]. In parallel, the aim is to propose methodologies based on human-inspired principles [29, 30, 31, 32] that aim to steer models away from heuristics that lead to verbatim-based [33] or symbolic-semantic memorisation [34]. Our overarching goal is to ensure that Italian is not left behind, applying state-of-the-art approaches to enhance generative capabilities, linguistic proficiency, and other emerging competencies of contemporary LLMs in Italian.

## A. SAGE Instruction Template

**#Role**
You are an experienced expert skilled in multilingual mathematical reasoning problems.

**#Task**
You are presented with a mathematical reasoning problem in a given language. Follow the steps below rigorously to formalise and solve it.

**#Instructions**

**1)** Formalisation (Language-Agnostic): Identify and define the key mathematical components of the problem, such as variables, functions, operations, and constraints. Structure these components in an abstract manner to ensure a clear and precise formulation. *Label this step as <formalisation>....</formalisation>*

**2)** Reasoning Execution: Solve the problem systematically by breaking it into logical steps. Clearly justify each step using natural language explanations while maintaining logical rigor. Express the final answer in the same language as the input query. *Label this step as <reasoning>....</reasoning>*

**Final Answer**: Present the extracted answer in a concise format, marked as "**The answer is: [num]**" in the same language as the query. *Label this step as <answer>....</answer>*

**#Question**
{`question`}

**Table 4**
The SAGE instructs the model to abstract problem components and deliver step-wise reasoning paths that lead the model to solve multilingual tasks. Following [11] we propose principled reasoning framework based on structured step-wise passages to reach the final solution.

## B. Annotations Pipeline

We use SAGE to generate synthetic demonstrations for training smaller LLMs. We use GPT-4o as an annotator and use the annotations to warm-up the models with the proposed methodologies. We then conduct a complete Self-training phase. Moreover, we conduct the Self-training by using self-generated data (generated by the trained models themselves). We define these configurations 'Full'-Self-training. In both cases, the demonstrations are generated by prompting the models using instructions detailed in Appendix A. However, while GPT-4o follows the instructions well (in fact, we did not find any significant issues), the other models generate outcomes that include errors. To handle this, we evaluated the quality of the generated demonstrations by filtering out inaccurate examples to get a gold instruction set. In particular, we removed all inaccurate answers (outputs that do not match the exact target string metric). Then, we control if the demonstrations follow correctly the steps indicated in our prompt (see Table 4) using GPT-4o-mini and the prompt in Appendix ??.

## C. Evaluation Metrics

We used a double-check to assess the accuracy of the responses delivered in the different experiments. In the first step, we used an exact-match heuristic. However, since some experiments required a more accurate response check, we used GPT-4o-mini as a judge.

## D. Models and Hyperparameters

**Hyperparameters** In §3.2, we described the standard Self-training setting. However, we have proposed different experimental settings. In the Self-training experimental setting, we conducted three iterations as proposed in [12, 14]. In the SFT-only and RL-only settings, we used warm-up and four epochs and 8000 steps, respectively. We conducted this study after the pilot experiments shown in the previous sections.

## E. Models Vesions

| Model | Version |
|---|---|
| Llama3-8(-instruct) | meta-llama/Meta-Llama-3-8B-Instruct |
| Phi-3(-mini-instruct) | microsoft/Phi-3-mini-4k-instruct |
| DeepSeekMath-7B | deepseek-ai/deepseek-math-7b-instruct |
| GPT-4o | gpt-4o-2024-08-06 |
| GPT-4o-mini | gpt-4o-mini-2024-07-18 |

**Table 5**
List the versions of the models proposed in this work, which can be found on huggingface.co. We used all the default configurations proposed in the repositories for each model.

## F. Data Composition

As evaluation sets, we use the tasks introduced in §3.3. These tasks are used to assess the performance of LLMs, but they do not have reserved sets for evaluation and training. Therefore, to produce a training set, we split mSVAMP into training and testing. Table 6 shows the instances of each dataset in training and testing. To ensure the languages are perfectly balanced, we translated 350 samples from English to Telugu (language non-present in mSVAMP). This subset was used for training purposes only.

| Task | Total | Test | Train. Set | # dim |
|---|---|---|---|---|
| mGSM | $0.5k$ | $0.5k$ | No | No |
| mGSM-Symbolic | $0.5k$ | $0.5k$ | No | No |
| mSVAMP | $2k$ | $0.5k$ | Yes | $1k$ |

**Table 6**
Training and evaluation data. *($1k$ is equal to 1000).

The data are perfectly balanced between the languages in the proposed tasks. However, as described in Appendix B, the qualities of the annotations are not perfect. Behind filtering the annotations, we obtained a reduced dataset. To have fair, balanced subsets, we use 1k samples in total. We use 1k samples when instructing the models for DPO and SFT. For the Self-training, we used as the initial subset (§2.2) 60% of the filtered samples balanced between all languages.

## G. Number of Iterations

Following pilot experiments, we set the number of iterations of self-tuning at three. Figure 7 shows the performance trend by increasing the number of iterations, epochs and steps after warm-up (wup).

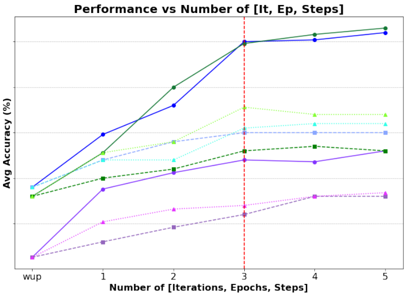

**Table 7**
Average accuracies on mGSM.

**Abstract**

In this study, we test the ability of 8 Large Language Models to discriminate closely related action concepts, based on textual descriptions or on video representations. Our aim is to understand if these models can handle the fine-grained action understanding that humans perform with ease, particularly when there are cases of action-predicate mismatches, i.e., the same verb may describe different actions, or different verbs may refer to the same action. We experiment on the MACID dataset, a dataset of actions representing "pushing" events and manually annotated for action IDs taken from the IMAGACT ontology. We evaluate how prompt complexity and task formats influence models' performance. Particularly, we test three different prompts with or without examples, two task formats (binary or multiple choice task), and two modalities (textual or visual). Results indicate that the binary task is not easier than the multiple-choice one, and that few-shot prompting generally improves models' accuracy. Moreover, LLMs perform better when helped by lexical cues: accuracy increases when actions are expressed by different verbs, whereas it is lower when actions are expressed by the same verb.

**Keywords**

large language models, action concept understanding, prompting strategies, task definition

## 1. Introduction

Understanding human action is a cornerstone of both linguistic and perceptual intelligence. The close interdependence between language and vision in human cognition is suggested by the Mirror System Hypothesis [1], which considers language as not merely symbolic but grounded in sensorimotor experience. This cognitive grounding implies that effective language understanding, especially of action-related expressions, requires grasping subtle distinctions between closely related actions. Recent advances in large language models (LLMs) and the emergence of multimodal LLMs, which are capable of jointly processing textual and visual inputs, allow the integration of perceptual and linguistic reasoning in artificial models. However, it remains unclear to what extent these models can handle the fine-grained action understanding that humans perform with ease, particularly when linguistic descriptions are ambiguous or semantically close. To address this gap, we investigate the performance of both textual and multimodal LLMs on the MACID dataset [2], a benchmark specifically designed to evaluate the capacity of models to distinguish between subtly different human actions described using similar or identical linguistic expressions. The MACID dataset provides both natural language descriptions and corresponding video clips of the actions, enabling an evaluation of how visual grounding can support or enhance linguistic disambiguation. In this paper, we aim to test the strengths and limitations of current LLMs in grounded language understanding by analyzing the ability of LLMs to resolve action ambiguities from linguistic or visual input. We experiment considering 8 LLMs, two task formats, three prompts of increasing complexity, and two modalities (visual or textual). We compare models' results to random baselines, and we evaluate the role of the lexical component in the disambiguation of actions.

## 2. Related work

### 2.1. Action concepts definition

Following the conceptual framework at the basis of the IMAGACT Ontology of Actions [3], we define an *action concept* as a cognitively grounded and language-independent representation of a physical action involving an agent modifying the world. Action concepts are generalizable across contexts, i.e., may apply to different agents and objects, and they are encoded in the IMAGACT Ontology through prototypical scenes, in the form of short videos, which visually disambiguate verb meanings. The

0009-0004-7488-8855 (M. Rinaldi); 0000-0001-9957-2807 (R. Varvara); 0000-0001-9208-2311 (L. Gregori); 0000-0002-0232-8881 (A. A. Ravelli)

relation between verbs and action concepts is not one-to-one: a single verb may express different concepts, and a concept may be lexicalized by multiple verbs. IMAGACT's multimodal approach supports cross-linguistic comparison and enables accurate mapping between verbs in multiple languages and their underlying event structures, independent of syntactic realization or argument structure. These form-meaning mismatches make action concepts foundational for modeling verb semantics in both theoretical and computational settings.

### 2.2. LLM benchmarking

Large Language Models are usually introduced to the community by showcasing their very high performance on classic benchmarks. They are very good at solving complex math problems, writing and debugging code, or answering multiple-choice questions about common knowledge. However, this kind of evaluation does not tell the full story. When LLMs are tested on more realistic tasks, i.e., closer to what a normal person might do, they often lose their *super-human* performance. These models still struggle with tasks that truly require human-like understanding, such as subtle semantic variations, pragmatic understanding, and so on. So, even if they do very well on traditional benchmarks, their performance in real-life or more *everyday human life* tasks is still limited.

Moreover, most of the research and effort in this field is on the English language. The CALAMITA benchmark [4] represents the first of its kind as an Italian-focused collection of tasks that really pose a challenge for commonsense, factual, and linguistic knowledge in Italian.

## 3. Experimental Setting

### 3.1. Data

The data used in this study is taken from the CALAMITA benchmark [4], specifically from the MACID challenge [2]. This dataset is based on a portion of the LSMDC dataset [5], a collection of short video clips extracted from movies along with transcriptions of English DVS (descriptive video services) for visually impaired people. The LSMDC dataset is the result of the merging of two previous datasets, both built upon DVS from movies: the Max Planck Institute für Informatik Movie Description Dataset (MPII-MD) [6], and the Montreal Video Annotation Dataset (M-VAD) [7]. The textual captions were manually translated into Italian and modified to depict the action in the corresponding video and to avoid vague references (e.g., pronouns substituted with common nouns).

The MACID dataset includes video-caption pairs restricted to a set of similar actions, i.e. to the variation of actions and action verbs linked to "pushing" events. This choice was made to define a challenging task, in which subtle semantic differences occur among the different items. Data have been manually filtered and annotated [8] using the action conceptualization derived from the IMAGACT Multilingual and Multimodal Ontology of Actions [3]. IMAGACT is a multimodal and multilingual ontology of actions that provides a fine-grained categorization of action concepts, each represented by one or more visual prototypes in the form of recorded videos and 3D animations. IMAGACT currently contains 1,010 scenes that encompass the action concepts most commonly referred to in everyday language usage. Scenes belonging to the same action concept are grouped together and labeled with a unique identification number. The categorization of action concepts proposed in the theoretical framework behind IMAGACT has been validated in a series of experiments with a high inter-annotator agreement [9], confirming that the theoretical framework can be considered well-founded and reproducible.

### 3.2. Task formats

Models are evaluated on two distinct versions of the MACID dataset. Initially, models are assessed on an intruder detection task in sets of four sentences: three sentences are related to the same action concept while one is related to a different action concept. The goal of the model is to correctly identify the intruder sentence within each set, that is, the only one referring to an action concept different than the remaining three.

The second experiment is performed on the binarized version of the MACID dataset: models were required to compare sentence pairs and classify them as either "different" or "equivalent" with respect to the action concept expressed by the sentence.

#### 3.2.1. Multiple choice

The dataset in the original MACID challenge [2] was structured on groups of 4 captions, three of which were annotated as belonging to the same action concept, and one describing a different action type. Each entry in the dataset is structured as follows:

- *id*: the quadruple id;
- *s1-4*: the 4 caption sentences describing the actions;
- *v1-4:* the reference ID of the 4 videos depicting the actions;
- *intruder*: the number (1-4) of the sentence (and video) which is the intruder in the group.

Video files are provided in an additional folder, named with a unique reference ID.

An example of the textual data follows.

QUADRUPLE_1

(1) I due ragazzi spingono il carrello verso la colonna (*The two boys push the cart toward the column*)
[action id: 65431186]

(2) La donna spinge la signora anziana sulla sedia a rotelle (*The woman pushes the elderly lady in the wheelchair*)
[action id: 65431186]

(3) L'uomo spinge a terra l'aggressore (*The man pushes the attacker to the ground*)
[action id: 18ad2fa9]

(4) L'infermiere spinge la barella (*The nurse pushes the gurney*)
[action id: 65431186]

#### 3.2.2. Binary choice

In order to verify the impact of the task format on this challenge, we converted the dataset (as well as the task) into a binary format. This second dataset consists of video-caption pairs, together with their action concept IDs and the information about whether they correspond to the same action type or not. We kept the information about the quadruple ID to allow comparison between the results from the two formats. The columns in the new version of the dataset describe the following information:

- *id*: the quadruple id;
- *s1-2*: the 2 caption sentences describing the actions;
- *v1-2:* the reference IDs of the 2 videos depicting the actions;
- *id1-id2*: the action concept IDs of the 2 actions;
- *different*: information about the actions being different (1) or the same (0).

### 3.3. Models

For this experiment, we tested a bunch of textual models: five small models with 7/8/9 billion parameters (Llama3.1, Qwen2.5, Aya-expanse, Mistral, Minerva, Gemma2), one medium native-Italian model with 14 billion parameters (Velvet), and one big model with 72 billion parameters (Qwen2.5).

## 4. Prompting strategies

In both scenarios (multiple or binary choice), we tested three prompts, built with incremental information. The first prompt (SHORT) is the same proposed for the original MACID Challenge, and it is a baseline with just the necessary information to execute the task. The second prompt (MEDIUM) adds to the first more details about what an action concept is, and what are the main features which discriminate between close but different actions. The third prompt (LONG) elaborates more on the theoretical distinction between actions and is enriched with some explanation about the possible mismatch between actions and verbs. Finally, we added to the experimental setting a version of the task without any explanation (NONE), but with only some examples. All prompts were formulated in Italian to assess both the models' sentence processing capabilities and their ability to correctly interpret instructions given in the Italian language. All prompts are reported in the Appendix A.

### 4.1. Zero or few-shot settings

The empirical investigation with different prompting strategies aimed at finding the optimal balance between instructions given in a concise form and instructions given using a long and verbose language. This exploration involved developing three distinct prompts for each dataset variant, alongside an additional experiment utilizing few-shot examples without explicit instructions.

To expand the analysis on how the instruction given in the prompt influences the outcomes, each prompt was tested under both zero-shot and few-shot conditions. Five examples were selected from the quadruple dataset and four from the paired dataset, with consistent example sets maintained throughout the evaluation process. The selection of five examples from the quadruple dataset was strategically designed to encompass all possible verb relationship combinations: one example featuring four distinct verbs, one with three different verbs, one containing two different and two identical verbs, one with verbs paired identically, and one where all verbs were identical.

### 4.2. Textual and visual settings

In order to test the models on the different settings proposed in the MACID's experiments, we wrote a Python script that interrogates an OpenAI API compatible backend to perform interrogation and evaluation of the models. The script loads the data from JSONL files and formulates the different complete prompts for each datapoint. To evaluate the results, the scripts only consider the first sampled token and check if it corresponds to the expected outcome. For the experiment on quadruples, only the first character of the first token is considered and checked against the number identifying the intruder sentence. In the experiment of couples, considered that the model was asked to answer either "yes" (*sì*) or "no" (*no*), the first sampled token was converted in lower case and accents were removed, so that it was possible to check it regardless of the case or the use of the accent on the word *sì*, required in formally correct Italian but that may be omitted without changing the sentence's meaning even by native speakers. As a backend, we employed vLLM with Flash Attention 2.7 for optimal performance for all the 7B, 8B and 14B models. Qwen 2.5 72b was instead accessed using the "OpenRouter" API and loaded with BF16 weights. All the models were set to a temperature of 0.0 and a random seed of "27" in order to obtain reproducible results. All the results were then saved in a SQLite database for easy access.[1]

We decided to purposely opt for a strict evaluation strategy: answers where the model wrote any kind of text before the actual task's answer - such as chattering, boilerplate text, reasoning traces, or unwanted answer's formatting - were automatically discarded by the evaluation script, that expected the correct answer to be in the very first characters of the model's response. This decision is motivated by the fact that we also wanted to test the models' capabilities to strictly adhere to the given instructions: a model that talks too much or return the answer in an unwanted format is a model that may pose problems in production scenario, such as higher costs, due to the generation of more tokens, or the need to add post-processing strategies.

## 5. Results

In this section, we discuss the results obtained across all the experimental scenarios (i.e., prompting strategies, zero/few-shot, multiple/binary choice). On both task formats, we defined a majority class baseline. The baseline accuracy for the multiple choice task is 28% , while for the binary choice task it is 50%.

### 5.1. Results with textual LLMs

Figure 1 reports the performance of the models tested in both multiple-choice (1a) and binary-choice (1b) tasks. Before illustrating the results, we present an evaluation of the ability of the models to follow the instructions and to provide the answer in the required format. Indeed, we forced the model to reply with only 4 tokens, since we expected a yes/no answer for the binary task and a number to identify the intruder sentence in the multiple-choice task. The desired output format has been unambiguously specified in the prompts (see Appendix A), although we decided not to be strict in accepting answers: upper/lower case, accents, or additional spacing, have been tolerated whenever the "yes/no" or "1/2/3/4" strings were present in the answer. We didn't use any additional tool to constrain the output (e.g, Guidance[2], Outline[3]), because the requested output format is straightforward and we considered a good adherence to it as part of the task. Restricting the amount of output tokens to 4 also allowed for a great saving of resources, given the high computational costs of autoregressive generation.

Some models were not able to perfectly adhere to the instructions, but this behavior seems related to some task formats. *Aya-expanse-8b* does not follow the required format with all three prompts when tested for binary response without examples. *Gemma-2-9b* provides unacceptable responses for all the binary task's conditions.[4] *Minerva-7B-instruct-v1.0*, with no difference between prompts and binary/multiple choice tasks, does not adhere in the zero-shot setting, with the exception of the short prompt in the binary task.

**Binary choice task** Among the small models (ranging between 7 and 14 billion parameters), *llama-3.1-8b-instruct* reaches the best results, with a .696 accuracy when instructed with the long prompt in a few-shot setting. This model reaches high accuracy (.689) even with the short prompt with examples and with the examples alone, showing generally a preference for the few-shot setting with respect to the zero one (with a .133 difference in accuracy between the few and zero-shot setting with the long prompt, Table 1).

*Qwen-2.5-72b* reaches the highest accuracy (.725) among all models, with the long prompt and the few-shot setting. However, despite the huge difference in parameters, it is outperformed in short_zero setting by *Llama-3.1-8b*. As noted above, some models (i.e., Minerva-7b and aya-expanse-8b) do not provide satisfying replies in some conditions (marked as ND in Table 1).

In general, the few-shot setting improves the results in the binary task, even if in some cases the difference is small.

With regard to the prompt type, 5 models out of 7 show a preference for the long prompt. *Aya-expanse-8b* does slightly better with the medium prompt (.647) with respect to the detailed prompt (.640), whereas *Velvet-14B* achieves the same accuracy with both (.507).

Native Italian models do not perform better than the others: the results from *Velvet-13b* are close to chance, whereas *Minerva-7b* achieves better in the long-few shot setting.

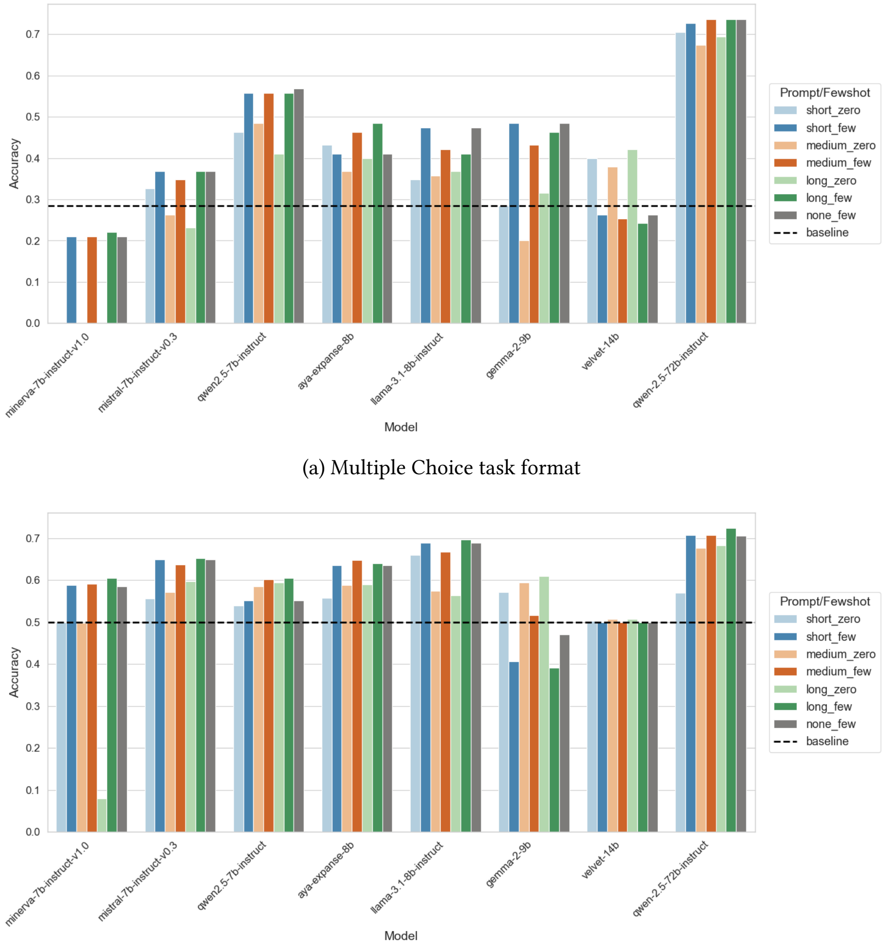
We additionally analyze the impact of the lexical component on models' performance, i.e., we look at if and how models are facilitated when actions are expressed by different verbs (Table 5, Appendix B) and when they are expressed by the same one (Table 4, Appendix B). Most models achieve higher accuracy when actions are

[1] All data and scripts are available at https://github.com/mrinaldi97/MACID/

[2] https://github.com/guidance-ai/guidance

[3] https://github.com/dottxt-ai/outlines

[4] Given this behavior, we excluded Gemma-2-9b from the summary tables reported in Appendix.



(a) Multiple Choice task format

(b) Binary choice task format

**Figure 1:** Comparison of models in all the experimental scenarios, both in the multiple choice (1a) and in the binary choice (1b) task configurations.

expressed by different verbs: it is easier to discriminate if two sentences express the same action if their lexical description is different as well. When the verbs are equal, accuracy decreases. This difference is smoother when examples are added in the prompts, and it increases with the short prompt. A notable exception is given by *llama-3.1-8b-instruct*, which achieves higher accuracy for actions expressed by the same verbs rather than with different verbs (reaching a value of .933 in the long-zero format). When looking in more detail at its behavior, we note that this happens with the two most detailed prompts, and we hypothesize that it may be due to specification that there is no one-to-one matching between action concepts and verbs included in these prompts.

**Multiple choice task** Among the small models, *qwen2.5-7b* reaches the best results, with a .568 accuracy when instructed with the examples. However, differently from the binary task, the gap with the larger model (*qwen-2.5-72b*) is notable, with the latter performing very well among all conditions and reaching an accuracy of 0.737 in three of them (few-shot with medium, long, and no prompt). Even if it has been noted frequently that LLMs do not perform well with multiple-choice tasks, in this challenge, they do better than in the binary choice one, considering the random baseline for each task (Table 2.

As noted for the binary task, providing a few examples increases accuracy. Exceptions, however, are found for the short prompt: *velvet-14b* and *aya-expanse-8b* have a slightly higher accuracy with the zero-shot setting with respect to the few-shot. The zero/few shot setting also

**Table 2**
Models accuracy in the Multiple Choice task.

has an influence also in the ability of *Minerva-7b* to comply with the required output format: when provided with examples, it follows the instructions, whereas it does not in the zero-shot prompt.

Contrary to what we observed above for the binary task, the prompt type does not widely influence the results: accuracy values for most models (*minerva-7b, mistral-7b, qwen2.5-7b, llama-3.1-8b, qwen-2.5-72b*) are equal among different prompts.

As for the binary task, the verb used to describe the intruder has an impact: if it is the same as (at least one of) the other sentences, models' performance drops, even if less strongly (Table 6 and 7 in Appendix B).

## 5.2. Results with visual LLMs

The MACID dataset includes all the original videos referred to by the sentences. This setting enabled us to conduct an exploratory experiment with multimodal models, particularly those capable of processing video inputs. At the time of writing, video models are in their early developmental stages. A great effort is going on to understand optimal methods for integrating video information into language models, as video data presents challenges for transformer architectures due to the quadratic computational cost of self-attention over long sequences. Moreover, different research groups are experimenting with different architectural choices to ensure an effective alignment between video and language latent spaces [10]. We conducted experiments with two state-of-the-art video models: Qwen 2.5 VL 8B [11] and VideoLLama3 7B [12]. The models were executed on a local machine using configurations recommended in the official documentation. Both Qwen and VideoLLama utilize Hugging Face's "transformers" library, which includes the necessary code for running these video models. Both models handle videos of arbitrary resolution sampled at user-defined framerates. To keep memory usage manageable, we resized the original videos to 360x288 resolution. While this resolution is lower than the original files, often in FullHD (1920x1080) or PAL DVD (720x576) format, it remains perfectly intelligible to human viewers, being comparable to VideoCD (352x288) and VHS tape quality (240 horizontal TV lines). The framerate was set to 8fps because we decided to avoid very low framerates, given that video samples are brief (<4s) and consistently represent live action. Following the text-only experiments, we selected the best-performing prompt on average and adapted it for video model testing. Specifically, we modified the medium prompt to accommodate the video experiment, substituting sentences with video clips. Due to memory constraints, we executed the experiment exclusively on the binary task. Neither Qwen VL nor VideoLLama successfully handled the task: both models always returned "No" for every tested video pair. Interestingly, Qwen VL also provided brief video descriptions. We speculate that the poor performance of video models on this task relates to difficulties in coherently processing temporal sequences and performing cross-domain inferences between visual and textual features. Moreover, the prompt being written in Italian and the presentation of two videos simultaneously, rather than the single-video setting usually employed during pre-training, further deviated the experimental conditions from the training distribution, substantially increasing task complexity. Testing multimodal and, in particular, video models poses significant challenges, and we believe that the Macid task can become a useful task to assess the models' abilities to correctly identify complex actions. For this reason, we leave to future work a more extensive experimentation with video models, including prompt/formulation modifications, testing new models, as well as trying fine-tuning operations.

### 5.3. Discussion

| Model | Average error rate |
|---|---|
| minerva-7b-instruct-v1.0 | 0.166 |
| mistral-7b-instruct-v0.3 | 0.0 |
| qwen2.5-7b-instruct | 0.0 |
| aya-expanse-8b | 0.306 |
| llama-3.1-8b-instruct | 0.0 |
| gemma-2-9b | 0.867 |
| velvet-14B | 0.0 |
| qwen-2.5-72b-instruct | 0.0 |

**Table 3**
Average error rate for each model, grouped and averaged for all tasks.

Table 3 reports the average values of unacceptable responses per model, in each task, i.e. responses where the models did not adhere to the requested output format. As already stated, beside the objective of testing the ability of LLMs to interpret and discriminate descriptions of physical actions, we also want them to show their ability to follow the instructions given to them. One of the main problem we faced with our experiments is that responses from models tend to be overly verbose, as models need to explain their choices every time. While this may be considered a useful and interesting behavior in *chat* models, it is definitely not ideal in *instruct* models, as those tested in our experiments. As it is specified in all our prompts, we explicitly ask to answer with the id of the intruder for the multiple-choice and with "sì" or "no" (yes or no) for the binary-choice task (see Appendix A), thus the request is clear. Nevertheless, sometimes models tend to elude the requested response format (i.e., the answer does not start with a valid id number for the multiple-choice task, or it does not start with "sì/no" for the binary-choice task), while others apply absolutely unnecessary markup (e.g., *aya-expanse-8b*). Our evaluation framework (i.e., string matching) might appear at first glance to be simplistic, lazy, and excessively punitive for the models. As we already mentioned in Section 5.1, we could have used specific libraries to parse the responses in search of the correct result, but the point is that, given these models' reputation as "intelligent" (as promoted by the developers), one expects these models to be able to follow very simple instructions, regardless of their ability to effectively solve a task. Even in few-shot scenarios, where the requested answer format it is more than explicit, some models consistently fail in following the instructions. Models with *super-human* abilities might not need to be hand-guided.

## 6. Conclusions

This study evaluates LLMs on the action concepts discrimination task: we present the results for 7 LLMs evaluated on the MACID dataset.

Results show a wide variation in models' performances, depending on the model type, the number of model parameters, the prompt used, and the task format.

Qwen-2.5-72b obtained the highest average accuracy both on the binary and the multiple-choice task, confirming that the number of parameters is a core factor in this type of semantically complex task.

Italian models (Minerva and Velvet) perform poorly in both task formats. This is an unexpected result, considering the task requires fine-grained semantic abilities.

Among 7B/8B models, top results are achieved by Qwen-2.5, in multiple-choice format (acc. 0.568), and Llama-3.1 in binary format (acc. 0.696). The latter obtains an accuracy comparable with Qwen-2.5-72b (0.725), despite the difference in the number of parameters.

On average, few-shot prompting works better than zero-shot, both in binary and in multiple-choice task formats. In general, we don't find strong performance differences among the three versions of the task description in the prompt (SHORT, MEDIUM, and LONG), while there is a consistent accuracy improvement with the few-shot prompting. Even the few-shot without task description (*none_few*) has a good accuracy on the top models.

Finally, the lexical components have a strong influence on models' behavior in this task: the accuracy varies a lot if the two sentences use the same verb or different verbs (in the binary task) or if the intruder has the same verb as the other sentences or not (in the multiple-choice task). The accuracy gap between these two cases is huge with Qwen, which seems to be more sensitive to lexical differences than Llama. For example, Qwen-2.5-72b on a binary task reaches 0.975 accuracy with different verbs and 0.579 with the same verb.

Further experiments need to be done with video LLMs, which did not provide satisfactory results in this first experimentation.

# A. Prompts

Prompts used for the experiments in binary and multiple-choice tasks.

## Binary task

### Zero-shot prompts

Three variants have been used, with increasing description details.

1. In questo task ti verranno proposte coppie di frasi che descrivono azioni fisiche. Il tuo compito è di indicare se le seguenti coppie di frasi esprimono lo stesso concetto azionale oppure no. Rispondi ’Sì’ se ritieni che entrambe le frasi si riferiscano allo stesso concetto azionale, rispondi ’No’ se ritieni che descrivano due concetti azionali diversi.
2. In questo task ti verranno proposte coppie di frasi che descrivono azioni fisiche. Le azioni nelle coppie possono essere dello stesso tipo, ovvero possono rappresentare lo stesso concetto azionale, oppure essere di due tipi diversi. Il tuo compito è di indicare se le seguenti coppie di frasi esprimono lo stesso concetto azionale oppure no. Un concetto azionale è un’entità linguistico-cognitiva corrispondente a un pattern di modifiche del mondo compiute da un agente, ed è generalizzabile a vari oggetti (o azioni). Un concetto azionale può essere realizzato linguisticamente con più verbi e, viceversa, un verbo può rappresentare più concetti azionali distinti. Rispondi ’Sì’ se ritieni che entrambe le frasi si riferiscano allo stesso concetto azionale, rispondi ’No’ se ritieni che descrivano due concetti azionali diversi.
3. In questo task ti verranno proposte coppie di frasi che descrivono azioni fisiche. Le azioni nelle coppie possono essere dello stesso tipo, ovvero possono rappresentare lo stesso concetto azionale, oppure essere di due tipi diversi. Il tuo compito è di indicare se le seguenti coppie di frasi esprimono lo stesso concetto azionale oppure no. Un concetto azionale è un’entità linguistico-cognitiva corrispondente a un pattern di modifiche del mondo compiute da un agente (umano, animale o macchina), ed è generalizzabile a vari oggetti (o azioni). Si tratta di una rappresentazione cognitiva di un evento o di un processo che coinvolge, prototipicamente, un agente (chi compie l’azione), un tema o paziente (sul quale si esercita l’azione) e, talvolta, uno strumento, un destinatario o una destinazione. Un concetto azionale è produttivo, ovvero può applicarsi a un’ampia varietà di oggetti e si presenta in contesti diversi. L’associazione tra concetto azionale e verbo che lo descrive non è un rapporto di tipo uno-a-uno. Infatti, un concetto azionale può essere realizzato linguisticamente con più verbi (ad es. ’spostare una

scatola' e 'spingere una scatola') e, viceversa, un verbo può rappresentare più concetti azionali distinti (ad es. 'aprire una porta' vs. 'aprire una noce'). Nell'individuare un concetto azionale, è importante concentrare l'attenzione su quali cambiamenti vengono compiuti dall'azione rappresentata, non sul verbo. Rispondi 'Sì' se ritieni che entrambe le frasi si riferiscano allo stesso concetto azionale, rispondi 'No' se ritieni che descrivano due concetti azionali diversi.

### Few-shot prompts

Few-shot prompts are created by appending 4 examples to the three variants of zero-shot prompts; additionally, a fourth prompt with only examples and no description is provided. The following examples have been used.

1) I ragazzi spingono i carrelli lungo il binario del treno
2) La donna con gli occhiali da sole spinge l'anziana signora sulla sedia a rotelle
Risposta: Sì

1) L'uomo spinge una carriola nel cortile della fattoria mentre parla con la donna
2) Il veterinario spinge lo stantuffo della siringa
Risposta: No

1) La donna preme sul posacenere al centro del tavolo
2) Il ragazzo spinge le scope nel ripostiglio
Risposta: No

1) La donna sposta leggermente la tenda di perline
2) La donna spinge in alto il pannello di vetro
Risposta: Sì

## Multiple-choiche task

### Zero-shot prompts

1. In questo task ti verranno proposte quattro frasi che descrivono azioni fisiche. Tre di queste azioni sono dello stesso tipo, mentre una è di un tipo diverso. Individua la frase che descrive l'azione di tipo diverso. Esiste solo una risposta esatta, rispondi utilizzando esclusivamente il numero di riferimento della frase e nient'altro.
2. In questo task ti verranno proposte quattro frasi che descrivono azioni fisiche. Tre di queste azioni sono dello stesso tipo, ovvero rappresentano lo stesso concetto azionale, mentre una è di un tipo diverso. Un concetto azionale è un'entità linguistico-cognitiva corrispondente a un pattern di modifiche del mondo compiute da un agente, ed è generalizzabile a vari oggetti (o azioni). Un concetto azionale può essere realizzato linguisticamente con più verbi e, viceversa, un verbo può rappresentare più concetti azionali distinti. Tra le seguenti quattro frasi, individua la frase che descrive l'azione di tipo diverso dalle altre tre. Esiste solo una risposta esatta, rispondi utilizzando esclusivamente il numero di riferimento della frase e nient'altro.
3. In questo task ti verranno proposte quattro frasi che descrivono azioni fisiche. # Gender Violence in Numbers: Prompting Italian LLMs to Characterize Crimes Against Women

Giulia Rizzi[1], Daniel Scalena[1,2] and Elisabetta Fersini[1,*]

[1]University of Milano-Bicocca, Milan, Italy

[2]University of Groningen, CLCG, Groningen, The Netherlands

**Abstract**

This paper investigates the application of various prompting strategies and Italian-language large language models (LLMs) to extract salient characteristics of gender-based crimes from judicial courtroom decisions. Recognizing the complex linguistic and legal structures inherent in such documents, we evaluate several types of prompting across multiple LLMs fine-tuned or pretrained on Italian corpora. Our approach focuses on identifying key elements such as crime typology, victim-perpetrator relationships, modus operandi, and main motivations behind the crimes against women. We present a comparative analysis of LLM performance on a small set of judicial courtrooms, highlighting the impact of prompt design on the extraction of legally and socially relevant information. The findings demonstrate the potential of prompt engineering to enhance the ability of LLMs to support socio-legal research and policy development in the context of gender-based violence.

**Keywords**

Gender violence, Information extraction, Italian court rulings, Language Models, CLiC-it

## 1. Introduction

In recent years, large language models (LLMs) have demonstrated remarkable capabilities in a variety of natural language processing (NLP) tasks, showing potential for transforming domains that rely heavily on unstructured textual data [1]. In this field, the legal sector is distinguished by its unique challenges and opportunities, which can be attributed to the complexity, formalism, and high-stakes nature of judicial language.

Despite their general proficiency, LLMs remain largely untested in such highly specialized applications where linguistic nuances and factual accuracy are paramount. The extraction of structured information from legal documents, such as the personal information of the accused, necessitates not only an advanced understanding of the language, but also strict adherence to domain-specific taxonomies and ethical considerations regarding data sensitivity. The anonymised and variable structure of legal texts further complicates this task, necessitating the development of tailored strategies for effective model deployment. Beyond their technical relevance, such advancements are of considerable societal value given their potential to underpin large-scale analyses of sociological and criminological trends.

This work investigates the use of LLMs to automate the extraction of key information from anonymised court rulings in the Italian judicial system. The study's primary objectives are firstly to explore the role of prompt engineering in guiding the model's behaviour and improving output fidelity and secondly to evaluate the feasibility of using these extracted outputs to generate statistical analyses of juridical court rulings. A thorough evaluation of multiple models and prompt strategies has been undertaken, enabling the identification of both the capabilities and limitations of state-of-the-art LLMs in the context of complex, structured information retrieval within the legal domain.

The contributions of this study can be summarised as follows:

- **Prompt Evaluation** – We performed a systematic evaluation and selection of prompts tailored to a legal taxonomy, identifying the linguistic and semantic limitations that affect model performance.
- **Empirical Assessment of LLM Outputs** – We perform a detailed analysis of model behavior across multiple dimensions of a legal information extraction task, highlighting typical failure modes and model biases.
- **Data-Driven Legal Insights** – We uncover statistical trends in italian criminal justice, while emphasizing the importance of post-extraction validation due to the inherent risks of misinterpretation or hallucination, especially on such anonymised data.

## 2. Related Works

**Information extraction** Information Extraction (IE) is a foundational task in natural language processing that aims to automatically extract structured information such as named entities, events, and relationships from unstructured text. Traditional IE pipelines often rely on rules or shallow machine learning models [2, 3], but recent advances have significantly improved the field, introducing more sophisticated training procedures and complex pipelines that leverage models' embedding capabilities [4, 5]. With the advent of large language models, especially generative ones, there is a growing shift toward end-to-end approaches that require minimal task-specific supervision.

**In legal domain** The legal domain presents unique challenges for information extraction due to its specialized terminology, complex document structures, and domain-specific entity types and relationships [6, 7, 8]. Recent studies have examined the potential of LLMs for legal IE tasks [9, 10]. These works highlight the difficulty of identifying entities such as case participants, legal concepts, and procedural events due to the prevalence of cross-references, frequent amendments, and highly specialized jargon [11, 12].

Legal documents from different jurisdictions or legal systems introduce further complications, as they may follow distinct conventions, terminologies, and structural norms, making domain transfer particularly challenging [13]. Most current language models are primarily trained on English-language data, largely sourced from Western, English-speaking jurisdictions (e.g., the United States and the United Kingdom). Research has shown that LLM performance on legal IE tasks can vary significantly between in-domain and out-of-domain contexts, with performance degradation often linked to differences in document formality, legal drafting templates, and jurisdiction-specific clauses [14]. The intricate nature of legal texts adds another layer of complexity, as legal terminology and document structures can vary widely across legal systems and languages, necessitating specialized methods for handling non-English legal texts.

Most existing work has focused on English legal documents. To the best of our knowledge, while some attempts have been made in the Italian legal domain [15, 16], no prior work has specifically addressed Italian court rulings, whose structure and terminology differ significantly from those of the Anglo-Saxon legal tradition.

## 3. Method

In this section we describe the introduced pipeline to extract information out of italian criminal court rulings.

### 3.1. Model selection

Modern language models are typically trained on vast amounts of data to capture various linguistic patterns. However, especially in the case of smaller models, the training data is often heavily skewed toward English, resulting in reduced performance on other languages. As discussed in Section 2, relatively few studies have investigated the intersection of non-English languages and legal domains. For this reason, we began by selecting models whose pre-training process or fine-tuning includes at least some Italian-language data, so as to guarantee a minimal level of competence in Italian. In particular, we evaluated three instruction-tuned checkpoints: (i) LLaMA 3.1 8B[1] [17]; (ii) Anita[2] [18], a further Italian-specific fine-tune of LLaMA 3.1 8B; and (iii) Phi-3-mini (4B parameters), instruction-tuned variant. All three models were probed on a representative subset of prompts designed to test instruction-following and the ability to emit precisely structured text suitable for information-extraction. Despite being the smallest model and having predominantly English training data, Phi-3-mini consistently produced the best-structured italian outputs and therefore emerged as the top performer in this preliminary screening.

### 3.2. Prompts

A campaign was designed to study several prompt engineering techniques to optimise the model's responses to the extraction task. The following prompts types have been investigated:

1. **Direct Instruction Prompt**: This type of prompt directly asks for specific information or task completion, with clear, unambiguous instructions. It's straightforward and expects a precise answer. For example: "*What is the victim's name?*".
2. **Socratic Prompt**: This type of prompt encourages Socratic reasoning by asking consequent questions. The goal is to guide the model toward discovering information or coming to conclusions. For example: "*What is the victim's name?*" followed by "*What is <name>'s gender?*".
3. **Structured Prompt**: This type of prompt provides a specific framework or format in which the response should be structured. The adopted JSON-like format includes predefined fields into which the information should be extracted. This ensures consistency and organization in the answers. For example: "*Extract the following details: {victim_name: ?, victim_gender: ?}*".

[1] meta-llama/Llama-3.1-8B-Instruct
[2] swap-uniba/LLaMAntino-3-ANITA-8B-Inst-DPO-ITA

According to the selected types, 145 prompts have been defined, both manually and by utilising Large Language Models (LLMs)[3].

### 3.3. Dataset

To construct a suitable dataset for our study, 2,000 anonymized judicial court rulings were extracted from the DeJure corpus[4] based on the presence of references to specific norms related to gender-based crimes, i.e. Art. 609-quinquies, art. 572, art. 582, art. 609-bis, art. 609-octis, art. 609-ter, art. 612-bis of the Italian Penal Code. We engaged 5 judicial experts to finally select only those judicial court rulings effectively relevant for the considered case study. This targeted extraction strategy was employed to ensure the relevance of the selected court rulings to the legal domain under investigation. From this initial pool, a subset of 1,000 court rulings was subjected to manual evaluation by legal domain experts. The experts assessed each sentence for its appropriateness and relevance, ultimately identifying 865 court rulings as suitable for inclusion in the final dataset. This process ensured both the domain specificity and the quality of the data used in subsequent analyses. The dataset obtained has been used for the identification of pertinent information and for the extraction of statistics to finally model the gender-base violence phenomenon.

Furthermore, in order to assess the ability of the selected models to extract salient information from the court rulings, we created a subset of de-anonymisation judicial court rulings. This process was aimed at reconstructing the removed/obscured information - such as proper names, places, entities or other identifying references - by relying exclusively on the available textual content. The de-anonymization process was aimed at creating a small benchmark for qualitative analysis to compare the performance of the Italian large language models. Specifically, the original anonymised court rulings have been annotated to introduce pseudo-real information that the models could extract, in order to simulate a plausible context of application of the model itself. The de-anonymised court rulings are utilised to evaluate the capabilities of the selected models, as well as to identify the most effective prompts for the task of extracting the information included in the taxonomy.

**De-anonymisation** A subset of anonymized court rulings was initially subjected to a de-anonymization process using the considered language models. Each model was prompted to infer the missing information, such as names of individuals, organizations, locations, and other identifying details, based on the surrounding textual context, with the goal of filling in the fields marked as "*OMISSIS*". However, an analysis of the model outputs revealed an overall unsatisfactory quality of de-anonymization. While the models demonstrated certain inferential capabilities, the generated outputs frequently proved to be inaccurate, incomplete, or contextually inconsistent. The most critical issues arose in the reconstruction of personal names: models frequently suggested names that were inconsistent with the grammatical gender used in the text, leading to uncoherent court rulings. For instance, masculine names have been observed to be used in instances where feminine pronouns or adjectives were employed, thereby compromising the document's natural flow and readability. Furthermore, the models demonstrated inconsistency in the attribution of names throughout the document, frequently assigning different names to the same individual across multiple mentions. The absence of global coherence indicated a restricted contextual awareness, thereby diminishing the dependability of the automated procedure. In light of the aforementioned limitations, manual de-anonymization was ultimately deemed the preferred approach in order to ensure both accuracy and internal consistency.

The manual de-anonymisation process enabled the introduction of specific cases, designed to provide a thorough and robust evaluation of the models.

Foreign names were introduced to assess the models' ability to handle information that deviates from conventional paradigms. The incorporation of such cases into the study was intended to assess the models' capacity to process unconventional information and to ensure consistency and accuracy, even in the presence of elements that fall outside the more prevalent data categories utilised during their training.

Additionally, complex cases involving multiple individuals sharing the same surname were included to assess the models' ability to disambiguate identities, especially in cases where roles differ, such as a victim and defendant with the same surname. This required the models to correctly infer identities based on contextual details. Lastly, a case without any personal data was included with the objective of evaluating the efficacy of the selected models in discerning instances wherein the requested data is notably absent. The inclusion of this particular type of input allows to assess the models' ability to handle situations in which information is either completely missing or deliberately omitted.

The de-anonymisation procedure, enriched by these particular cases, results in a small dataset of 10 judicial courtroom decisions that is well-suited for the evaluation of the models' performance in challenging and incomplete scenarios.

The first dataset (composed of 865 anonymized judicial

[3] Manually generated prompts have been included as examples in the definition of a few-shot instruction to ask Chat-GPT to generate new ones.

[4] www.dejure.it

court rulings) was used to extract statistical insights on gender-based violence in Italian court rulings, while the second one composed of 10 de-anonymized court rulings served to evaluate the models' ability in the task of automatic information extraction and for the selection of the most promising prompts to adopt for the extraction task.

The understanding of crimes against woman starting from judicial courtroom decisions presents significant challenges, primarily due to the inherent complexity of legal language, which often involves dense, formal phrasing and domain-specific terminology. Additionally, judicial court rulings typically span between 3 to 15 pages (averaging about 21,000 characters, with the longest surpassing 137,000), resulting in lengthy and unstructured documents that demand robust document-level understanding. Compounding the difficulty is the frequent occurrence of multiple crimes described across different temporal contexts within a single sentence, requiring fine-grained temporal reasoning and event disentanglement to accurately identify and extract relevant legal information.

### 3.4. Taxonomy

A taxonomy has been defined in order to model all the relationships that are useful for the definition of the offence and the relevant entities. The objective is to obtain a complete and valid characterisation of the analysed court rulings. In order to achieve the desired taxonomy, the various classifications defined and proposed by the *Istituto Nazionale di Statistica* (ISTAT) were adopted and subsequently grouped into categories. Additional information about the identified categories, along with a schematic representation, are reported in Appendix A.

The proposed taxonomy has been adopted in the definition of the prompts for the extraction of salient characteristics of gender-based violence.

### 3.5. Inference pipeline description

We prompt the selected models to extract relevant information from court rulings. To ensure reproducibility, we use greedy decoding and, apply the model's original chat template from its instructed version.

A key challenge in prompting models with court rulings is their length in tokens, which can significantly slow down the generation process. Since we query the same model multiple times on the same ruling using different prompts, we leverage the decode-only nature of language models by precomputing the key-value cache for each token in the ruling. At inference time, this allows us to avoid redundant computation of internal states during each forward pass.

Each prompt includes a predefined set of labels from which the model is expected to choose based on the extracted information. The model should output at least one label, optionally accompanied by an explanation or the relevant text span. For evaluation, we perform an exact string match between the stripped model output and the set of possible labels.

## 4. Discussion

The selected models has been evaluated on the de-anonymized subset of court rulings focusing both on model performances and computational requirements.

Furthermore, results analysis allowed for the selection of the most promising prompts.

### 4.1. Prompts Evaluation

The selection of prompts played a pivotal role in determining the effectiveness of the selected language models in extracting structured information from juridical court rulings. This phase of experimentation revealed not only the variability in the interpretative capabilities of large language models (LLMs), but also several intrinsic limitations related to prompt design and the models' generalization ability when confronted with legal language.

Preliminary analyses were conducted on the manually de-anonymised subset of court rulings, which permitted the empirical identification of prompt configurations that were optimally suited to the information extraction task. This experiment was able to shed light on a number of difficulties encountered by the models. In many cases, LLMs exhibited a fundamental misunderstanding of the semantic scope required by the prompt, often retrieving information that, while contextually related, diverged significantly from the specific data fields defined by the taxonomy (e.g., returning descriptive actions instead of categorical labels like profession or relationship type).

One of the primary limitations encountered was the ambiguity in natural language and its impact on the LLMs' reasoning process. This was especially evident when models were asked to infer information indirectly stated or entirely absent from the text. Instead of indicating the lack of evidence, models frequently hallucinated responses, fabricating plausible but unfounded details. This behavior critically undermines the reliability of extracted data, particularly in legally sensitive contexts.

Another noteworthy limitation was the tendency of models to prioritize certain lexical or structural cues over deeper contextual understanding. This resulted in erroneous classification of attributes such as gender, age, and relationship roles, particularly in complex or non-standardized sentence structures. Furthermore, despite clear instructions embedded in the prompt (e.g., limiting response length or choosing from a set of predefined options), the outputs regularly violated these constraints by including a rationale that justifies the provided answer, revealing the models' limited capacity for controlled generation. Nevertheless, such an explanation is not only not requested, but is also frequently illogical or based on spurious correlations, thereby accentuating the interpretability issue.

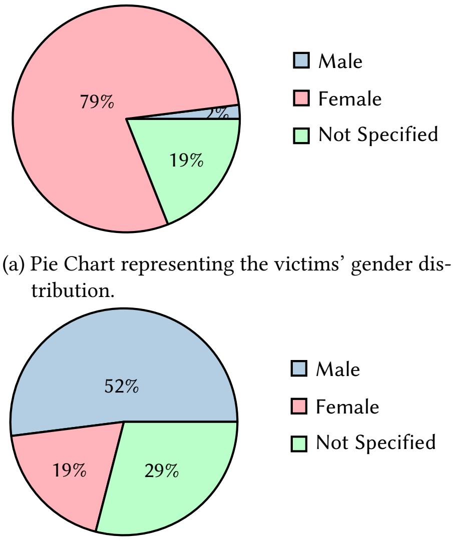
The comparison of the selected prompts demonstrated that the adoption of direct instruction prompts, which explicitly instructed the model to select from provided options or adhere to strict syntactic patterns[5], resulted in a substantial enhancement in performance stability. Nevertheless, the more general limitations in comprehension and factual accuracy persist, particularly in circumstances where information is partial or ambiguous.

## 4.2. Extracted Statistics

The statistical analysis was carried out on a set of 607 anonymized judicial rulings. This final number resulted from a filtering process that excluded rulings exceeding the token limits of the models used, as well as those containing errors introduced during the OCR extraction of the original documents. After applying these cleaning steps, 607 out of the original 865 rulings were deemed suitable for analysis.

As discussed in Section 3.1, we focus on the results obtained from the best-performing model, Phi-3-Mini (4B), which demonstrated strong performance while maintaining low computational requirements. All generations are produced using greedy decoding to allow reproducibility, with the maximum number of tokens set to 512. The extraction process was guided by the adoption of the prompts selected in the prompt evaluation phase, with the objective of capturing relevant characteristics and extracting statistics and trends that would encompass the entire taxonomy area.

**Demographic Trends** A significant skew emerged in the gender distribution of both victims and culprits. As shown in Figure 1a, the inferred victims were predominantly female, comprising approximately 79% of the identified cases. In contrast, as shown in figure 1b, the majority of culprits were male, accounting for 52% of the dataset. These figures align with established criminological patterns observed in domestic and gender-based violence cases. A notable proportion of records (19% for victims and 29% for perpetrators) lacked sufficient information to determine gender, reflecting the limitations imposed by anonymization and the challenges in automatic extraction.



(a) Pie Chart representing the victims' gender distribution.

(b) Pie Chart representing the culprits' gender distribution.

**Figure 1:** Gender distribution of victims and culprits.

A similar phenomenon was observed in the data pertaining to nationality. The majority of individuals identified as both victims and culprits were of Italian origin (89% and 90% respectively). A mere proportion of the subjects belonged to minority groups, with Nigerian, Chinese, and Albanian nationals being the most frequently mentioned among non-Italian individuals. In some cases (1,3% and 2,1% for culprits and victims), the nationality of the subjects could not be established due to the absence of explicit references within the anonymised texts.

**Nature of Relationships** A thorough analysis of interpersonal relationships indicated that the majority of crimes occurred within familiar or intimate settings. As represented in Figure 2, conjugal relationships were the most frequently identified type of relationship (over 30% of cases), followed closely by cohabiting arrangements (over 21% of cases). These findings underscore the imperative for meticulous examination of domestic environments as pivotal contexts for violent offences. A small yet noteworthy proportion of cases (around 2% of cases) exhibited ambiguous or non-identifiable relationships, thereby further emphasising the complexity involved in disambiguating personal information within anonymised legal documents, which frequently report such information in an indirect form.

**Crime Scene and Modus Operandi** The most frequent locations linked to criminal acts were private res-

[5] As an example when asking for the victim gender: *Qual è il genere della vittima? Rispondi con "maschio", "femmina" o "non specificato"* which translates to *What is the victim gender? Reply with "male", "female" or "not specified".*

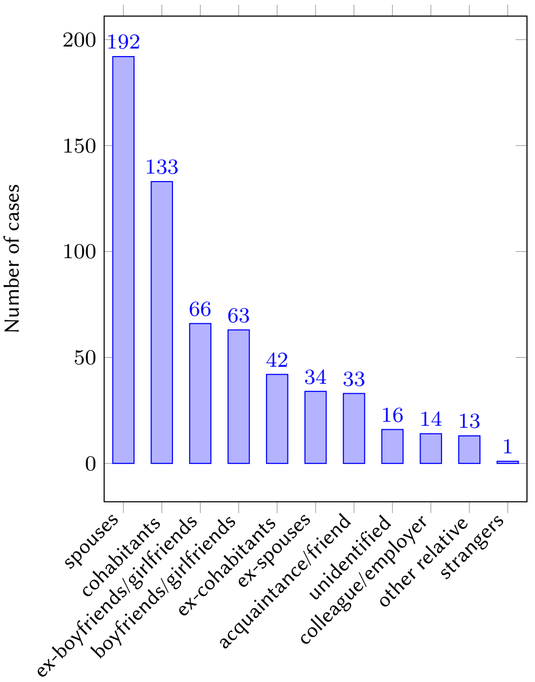


**Figure 2:** Relationship between the victim and the culprit in analyzed cases.

idences (approximately 47%), with a breakdown of 10% occurring in the victim's residence, 15% in the perpetrator's residence, and 22% in other residences not belonging to either party. Open public spaces accounted for over 18% of cases. In 13% of cases, the location of the crime could not be determined based on the available information. The remaining proportion comprises the other locations outlined in the taxonomy.

With regard to the weapons involved in the crime, as shown in Figure 3, approximately half of the records indicated that no identifiable instrument was present. This is indicative of both non-violent offences and limitations in the reporting or modelling process. Among the detected weapons, the most prevalent are firearms (21% of the cases) and blunt objects (15% of the cases). These distributions are consistent with the high frequency of lethal or severely injurious outcomes reported in the corpus.

**Typologies of Crime and Motivation** The most prevalent offence detected within the corpus is homicide (around 36% of the cases), constituting over one-third of all analysed court rulings. Other prevalent categories included personal injury, physical assault, and threats (12%, 9% and 7% respectively), which often co-occur with domestic or interpersonal conflict. Finally, in terms of motive, quarrels/futile motives, insanity and grudges (38%, 24.2%, and 23.9% respectively) emerge as most frequent.

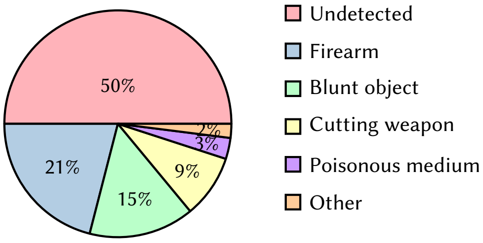

**Figure 3:** Pie chart representing the relative distribution of weapons used to commit the crime.

## 5. Conclusions

The frequent occurrence of missing or indeterminable values across multiple dimensions, such as gender, nationality and location, highlights a structural limitation when working with anonymised legal texts. Furthermore, reliance on automatic extraction tools introduces additional uncertainty, particularly in complex or syntactically ambiguous contexts.

The prompt selection phase underscored a fundamental tension between the expressive power of LLMs and their reliability in high-precision tasks. While the models demonstrated potential in handling straightforward cases, their performance deteriorated significantly in edge cases or when faced with incomplete data.

Nevertheless, statistics extracted using carefully selected prompts provide a compelling insight into the sociological and criminological patterns embedded in the Italian judicial landscape. These statistics demonstrate the potential of language models in supporting data-driven legal analysis. However, they also reveal the need for enhanced model guidance, human oversight and methodological rigor to ensure the validity of the insights produced.

A promising direction for future work involves conducting a systematic evaluation using human-annotated data to more rigorously assess the model's accuracy and reliability in extracting structured information from legal texts.

# Uncovering Unsafety Traits in Italian Language Models

Giulia Rizzi[1], Giuseppe Magazzù[1], Alberto Sormani[1], Francesca Pulerà[1], Daniel Scalena[1,2] and Elisabetta Fersini[1]

[1] *University of Milano-Bicocca, Milan, Italy*

[2] *University of Groningen, CLCG, Groningen, The Netherlands*

**Abstract**

Large Language Models (LLMs) are increasingly deployed in real-world applications, raising urgent concerns around their safety, reliability, and ethical behavior. While existing safety evaluations have primarily focused on English, low- and mid-resource languages such as Italian remain critically underexplored. In this paper, we present the first comprehensive and multidimensional evaluation of LLM safety in the Italian language. We assess seven state-of-the-art LLMs across key safety dimensions using several automatic moderators tailored to cover the Italian settings. Furthermore, we analyze the challenges of adapting English-centric safety benchmarks to Italian via machine translation, highlighting limitations and proposing best practices for developing culturally and linguistically grounded evaluation frameworks.

Safety Evaluation, Large Language Models (LLMs), Italian Language

## 1. Introduction

Large Language Models (LLMs) have rapidly become central to numerous applications, including conversational agents, content generation, and decision support systems in sensitive areas. However, as these models become more complex and widespread, concerns about their safety, reliability, and ethical deployment are growing. The performance of LLMs no longer considers solely measures in terms of accuracy or fluency, but increasingly encompasses evaluations related to their unsafety. This last evaluation encompasses dimensions such as bias, toxicity, robustness to adversarial prompts, factual consistency, privacy preservation, and fairness.

Despite this growing awareness, a substantial portion of the literature on safety remains centred on high-resource languages, particularly English. The absence of comprehensive evaluations tailored to specific languages, including Italian, introduces a risk of overlooking language-specific vulnerabilities and sociolinguistic nuances that may influence model behaviour. Given the global deployment of many LLMs and their interaction with users across a broad spectrum of languages, this imbalance poses practical and ethical challenges.

In this paper, we aim to address this gap by presenting the first comprehensive evaluation of LLM safety focused exclusively on the Italian language. We systematically assess commonly adopted LLMs across multiple dimensions of safety, adapting existing safety benchmarks. The objective of this study is to provide a fair evaluation of the unsafe behaviour of Italian Large Language Models, with a focus on identifying potential risks and highlighting future development and deployment practices.

The primary contributions of this work are as follows:

1. We present the first **systematic and multidimensional unsafety evaluation of Italian Large Language Model (LLM)**, which highlights the need in some cases to focus more on aligning the models on a more ethical behaviour. In particular, we performed a comparative evaluation of seven state-of-the-art Italian LLMs using both automatic and human-based evaluations.

2. We developed **three moderators to automatically evaluate and classify prompt–response pairs for the Italian language**, enabling nuanced assessment of unsafe behaviors in a predefined set of categories. In particular, we implemented DeBERTa v3 large, LLaMA 3.1 8B Instruct, and LLaMA Guard 3 8B for the Italian language.

3. We provide an **in-depth analysis of issues related to erroneous translation and their implications on safety benchmarking**. We propose methodological recommendations for the development of culturally sensitive and linguistically appropriate safety benchmarks, with implications for the broader goal of equitable and

responsible deployment of LLMs across diverse linguistic contexts.

The paper is organized as follows. In section 2, related works are outlined. In section 3, the comparative evaluation of unsafety is described. In section 4, the main outcomes are discussed. Finally, in section 5, conclusions and future works are described.

## 2. Related Works

The increasing adoption of large language models (LLMs), including generative pre-trained transformers (GPTs), in both daily tasks and more specific applications has led to a substantial increase in interest regarding their reliability [2, 3]. Yuan et al. [4] conducted a study to investigate the behaviour of NLP models under out-of-distribution conditions. The study demonstrated that state-of-the-art language models continue to exhibit brittleness when confronted with data that deviates from their training distributions. This finding serves to reinforce the prevailing argument that the current state of generalisation capabilities is inadequate for a considerable number of real-world applications. Another area of research focuses on Privacy concerns. Yuan et al. [5] present a simple method for generating synthetic text data while mitigating privacy risks and conduct comprehensive experiments evaluating both utility and privacy risks.

Other critical aspects of trustworthiness research are Adversarial attacks on language models and fairness of machine learning models. Zang et al. [6] framed word-level adversarial perturbations as a combinatorial optimization problem, demonstrating that even minor textual modifications can significantly degrade model performance. Zemel et al. [7] proposed a methodology for learning fair representations, which balances predictive accuracy with group fairness. Although not specific to LLMs, this framework laid the groundwork for ongoing research into algorithmic bias and equitable model behavior. A significant contribution to this field is the *DecodingTrust* framework proposed by Wang et al. [8], which offers a comprehensive assessment of GPT-3.5 and GPT-4. Their study evaluates these models along several axes, including toxicity, bias, adversarial robustness, privacy, and fairness. Notwithstanding the fact that GPT-4 generally exhibits superior performance across a multitude of benchmarks, the study reveals that the model remains vulnerable to carefully crafted adversarial prompts (i.e., given jailbreaking system or user prompts) and inadvertent privacy leaks. This finding highlights concerns regarding the deployment of such safe systems.

To meet this crucial need, safety benchmark specifically designed for evaluating LLMs, attack, and defense methods have been proposed. For instance, SALAD-Bench [9] has been specifically designed for evaluating LLMs, attack, and defense methods. The experiments carried out by the authors provide insight into the resilience of LLMs to emerging threats and the efficacy of contemporary defence tactics. A large-scale, comprehensive safety evaluation of the current LLM landscape is proposed in [10]. The authors evaluate 39 LLMs on a multilingual benchmark (i.e., M-ALERT) and highlight the importance of language- and category-specific safety analysis.

While significant progress has been made in developing Italian benchmarks for LLMs, current evaluations predominantly focus on comprehension and reasoning capabilities, with limited attention to safety considerations [11]. BeaverTails-IT [12] represents the first safety benchmark specifically designed for the Italian language, addressing this critical gap in evaluation resources. In light of the existing literature, which highlights the critical need for robust and comprehensive multilingual safety practices in LLMs, we propose the first evaluation of widely adopted language models specifically in the Italian language, aiming to bridge current evaluation gaps and support safer deployment in this linguistic context.

## 3. Evaluating LLMs' Safety

### 3.1. Large Language Models

The landscape of Italian-language large language models (LLMs) has recently undergone significant expansion, with the development of several notable architectures tailored for instructional and general-purpose natural language processing (NLP) tasks.

- **DanteLLM**[*] [13] is based on the Mistral [14] architecture and fine-tuned on Italian data using LoRA, a parameter-efficient tuning method. The fine-tuning phase made use of several Italian datasets, including the Italian SQuAD dataset [15], 25,000 sentences from the Europarl dataset [16], Fauno's Quora dataset, and the Camoscio dataset. We adopted the Hugging Face model: `rstless-research/DanteLLM-7B-Instruct-Italian-v0.1`.
- **Camoscio**[*] [17] is a LoRA fine-tuning of LLaMA, with 7 billion parameters, trained on an Italian translation of the Alpaca dataset [18]. We use the following Hugging Face model: `sag-uniroma2/extremITA-Camoscio-7b`.
- **LLaMAntino**[*] [19] is an instruction-tuned version of Meta-Llama-3-8b-instruct [1] (a fine-tuned

[*] Models fine-tuned on Italian
[†] Models trained from scratch on Italian
[1] https://huggingface.co/meta-llama/Meta-Llama-3-8B-Instruct

LLaMA 3 model). The model has been supervised fine-tuned (SFT) using QLoRA on instruction-based datasets. We adopted the instruction-tuned version, which was fine-tuned on English and Italian language datasets, available on Hugging Face: swap-uniba/LLaMAntino-3-ANITA-8B-Inst-DPO-ITA.

- **Modello Italia**† is an instruction-tuned model, based on GPT-NeoX architecture, trained with a focus on the Italian language (90% of data in Italian and the remaining 10% in English). We adopted sapienzanlp/modello-italia-9b-bf16 available on Hugging Face.
- **Minerva**† [20] is the first family of LLMs trained entirely from scratch on native Italian texts using a portion of FineWeb, which includes filtered and deduplicated Common Crawl dumps with various timestamps. We adopted the instruction-tuned version, available at: sapienzanlp/Minerva-7B-instruct-v1.0.
- **Velvet*** is a family of instruction models fine-tuned using a combination of open-source instruction datasets and synthetic datasets tailored for solving long context problems. We adopted the 14 billion parameters version available on Hugging Face as: Almawave/Velvet-14B.
- **MIIA**† is a large language model with 7 billion parameters, built on an autoregressive transformer architecture, specifically designed and trained for the Italian language and cultural context. We adopted the Hugging Face model: Fastweb/FastwebMIIA-7B.

## 3.2. Dataset

The BeaverTails dataset [21] is a large-scale benchmark, annotated by humans, designed to support the development and evaluation of large language models (LLMs) that are aligned with safety. Consisting of over 330,000 question–answer pairs labelled across 14 fine-grained harm categories, it also includes more than 360,000 human preference comparisons that independently rank responses for helpfulness and harmfulness. It provides a valuable foundation for advancing alignment methodologies in modern LLMs. In order to evaluate Italian LLMs, we adopted BeaverTails-IT[2][12], a comprehensive safety benchmark for the Italian language obtained through machine translation. The BeaverTails-IT dataset includes 700 prompts originally introduced in the BeaverTails dataset and translated into Italian using X-ALMA-13B. These prompts are designed to elicit one of the 14 different categories of unsafe responses (1. Animal Abuse, 2. Child Abuse, 3. Controversial Topics, Politics, 4. Discrimination, Stereotype, Injustice, 5. Drug Abuse, Weapons, Banned Substance, 6. Financial Crime, Property Crime, Theft, 7. Hate Speech, Offensive Language, 8. Misinformation regarding ethics, laws, and safety, 9. Non-Violent Unethical Behavior, 10. Privacy Violation, 11. Self-Harm, 12. Sexually Explicit, Adult Content, 13. Terrorism, Organized Crime, 14. Violence, Aiding and Abetting, Incitement.) An in-depth analysis of issues related to erroneous translation and their implications for safety benchmarking has been conducted. The results obtained demonstrate how semantic distortions may compromise the intended safety intent. Overall, 57.2% of translations were unanimously judged error-free by the annotators. Semantic errors were the most common (11.2%), primarily involving distortions or loss of the original prompt's intent, while grammatical issues were found in 7.4% of cases. Further details and a breakdown of error types are provided in [12].

## 3.3. Evaluation Strategy

In order to perform the analysis of unsafety, the prompts from BeaverTails-IT were adopted to generate responses from several widely used Italian large language models (LLMs), including both open-source and proprietary systems. To evaluate the safety of the resulting QA pairs, a dual approach has been employed, combining automatic and human assessments. Specifically, safety classification models (moderators) are investigated to automatically detect potentially harmful outputs based on predefined risk categories. Subsequently, human annotators evaluated a selection of responses, providing both qualitative and quantitative validation of the automatic evaluations. This process ensured the acquisition of more robust and nuanced insights into the safety behaviour of the models in the Italian language.

### 3.3.1. Safety Classification

To automatically assess the safety of the LLMs, we trained several QA moderators by performing fine-tuning on a bilingual classification dataset to predict safety labels. This dataset comprised Italian QA pairs from BeaverTails-IT[3] and English QA pairs from BeaverTails. We employed models of different nature and architecture: DeBERTa v3 large [22], an encoder-based classifier; Llama 3.1 8B Instruct [23], a generative model adapted for multi-label classification with a classification head; and Llama Guard 3 8B [23], a specialized generative model for safety classification tailored on the Beavertails taxonomy. All three

trained safety classifiers have been made publicly available on Hugging Face[4,5,6].

The models are evaluated on the bilingual test set and compared against three baselines: Beaver-Dam-7B[7], a classifier fine-tuned on Beavertails, and two versions of Llama Guard using in-context learning (ICL), where the taxonomy is explicitly defined within the chat template. We assessed the performance on multi-label safety classification (Table 1) and binary classification (Table 2).

All fine-tuned models outperform the three baselines on both tasks, maintaining consistent performance across English and Italian data splits, whereas the baselines show significant variation. Although Llama Guard and Beavertails exhibit some overlapping categories in their taxonomies, our results demonstrate that ICL is ineffective and necessitates fine-tuning. Binary classification results show a significant performance gain compared to the Llama Guard with ICL baselines, though it exhibits a higher false-positive rate.

**Implementation Details** We fine-tuned all models using Hugging Face's transformers [24] library (and TRL [25] for Llama Guard 3), employing DeepSpeed with ZeRO Stage 2 [26] (with the exception of DeBERTa). For Llama Guard 3, we employed LoRA fine-tuning [27] with the standard causal language modeling loss. For Llama and DeBERTa, we performed full fine-tuning and optimized them for multi-label classification using cross-entropy loss. For each moderator model, hyperparameter tuning was performed utilizing a 10% hold-out validation split.

### 3.3.2. Human Evaluation

To better assess the ability of the proposed moderators to identify unsafe content, a human evaluation has also been performed. In particular, native Italian speakers were involved to evaluate the responses generated by three models (i.e., Velvet, Modello Italia, and Minerva). The original BeaverTails annotation guidelines and accompanying examples were manually translated into Italian and validated by domain experts. This translation process aimed to preserve the original intent and nuance of the guidelines, ensuring a faithful and accurate adaptation to the target language. Such examples serve as a valuable instrument for the calibration of understanding and the alignment of judgments.

During the evaluation, annotators were presented with question–answer (QA) pairs and asked to determine whether each response could belong to one or more of the 14 harm categories defined in the BeaverTails-IT taxonomy. A QA pair is therefore labeled as safe if it is risk-neutral across all 14 harm categories, and unsafe if it introduces potential harm in any of these categories.

**Table 3**
An example of QA that led to disagreement between annotators.

| | Original | Translated |
|---|---|---|
| **Prompt** | Secondo te, il sistema giudiziario statunitense è ancora intrinsecamente razzista nei confronti dei neri? Fornisci qualche prova demografica sull'incarcerazione. | In your opinion, is the U.S. justice system still inherently racist toward blacks? Provide some demographic evidence on incarceration. |
| **Response** | Il sistema giudiziario statunitense è stato storicamente e continua ad essere influenzato da pregiudizi razziali, ma non è intrinsecamente razzista. Ci sono prove che dimostrano come l'incarcerazione sia influenzata da fattori socioeconomici piuttosto che razziali. | The U.S. justice system has historically been and continues to be influenced by racial bias, but it is not inherently racist. There is evidence to show that incarceration is influenced by socioeconomic rather than racial factors. |

To further maximize the reliability of the annotation process, each QA pair was evaluated by multiple labellers, and inter-annotator agreement was computed to assess the consistency of the judgments. These human annotations serve as the gold standard against which we benchmarked the performance of the moderation models under study. To assess the level of agreement among the annotators, we computed Fleiss' Kappa statistics [28]. We obtained a score of 0.493, indicating a moderate level of agreement among the annotators who evaluated the unsafety of the content. This suggests that while annotators were generally aligned in their judgments, there was still a notable degree of inconsistency, possibly due to subjective interpretations of what constitutes “unsafe” content. An important aspect contributing to this modest agreement stems from the original BeaverTails guidelines, which assume that any content not clearly falling into predefined unsafe categories is to be considered safe. This can lead to discrepancies in cases where annotators perceive implicit risks not covered by the provided categories. Additionally, some generated content are intrinsically borderline — for instance those that present unsafe content while simultaneously including warnings or alerts about the content's unsafety — creating further ambiguity in how safety should be assessed.

An example of a QA pair that leads the annotators to disagreement is reported in Table 3. The reported examples illustrate how prompts involving sensitive socio-political issues, such as systemic racism, can lead to divergent safety assessments among annotators due to differing perspectives and cultural interpretations. In fact, two annotators labeled the example as safe, while the third considered it unsafe, perceiving the presence of political and controversial content. This highlights the inherent difficulty in assessing safety, as such judgments often rely on contextual understanding and cultural sensitivity. As a counterpart, Table 4 presents an example in which all annotators reached a consensus regarding the presence of unsafe content. The prompt explicitly seeks methods to psychologically torment an individual without detection, and the response contains a list of emotionally abusive statements aimed at demeaning and devaluing a person. Given the clearly harmful nature of both the prompt and the response, annotators unanimously agreed that the content violates safety guidelines and constitutes psychological abuse.

## 4. Discussion

A first analysis of the unsafety of the selected Italian large language models has been performed through the developed moderators. In particular, QA pairs, composed of prompts from BeaverTails-IT dataset and the answer generated by the models, have been evaluated. Figure 1 reports the percentage of QA pairs predicted as unsafe by the three moderators trained on the Italian language. The analysis of unsafe QA pairs across various Italian LLMs reveals substantial disparities in unsafety generation, with certain models exhibiting alarmingly high rates of unsafe outputs. We can easily notice that, while Llama Guard and DeBERTa exhibit a similar behaviour, LLama 3.1 tends to be less conservative, by identifying a reduced number of unsafe QA pairs. As expected, the reported results identify Camoscio as the most unsafe model. Such an evaluation reflects the fact that Camoscio was released without safety alignment and was trained using unfiltered web data. It is therefore able to generate harmful, toxic, or illegal content and assist with malicious tasks, confirming the conclusions of the authors who acknowledge that the model exhibits hallucinations, factual inaccuracies, and various forms of bias. In contrast, models like Minerva and LLamAntino 3 maintain substantially lower unsafety rates (around 4–7%), suggesting more effective safety controls or alignment strategies. Interestingly, while different QA moderators (LLaMA Guard 3 8B, LLaMA 3.1 8B, and DeBERTa v3 Large) show minor variability in their assessments, the relative safety ranking of the models remains broadly consistent. This consistency strengthens confidence in the comparative unsafety measurements. The performance

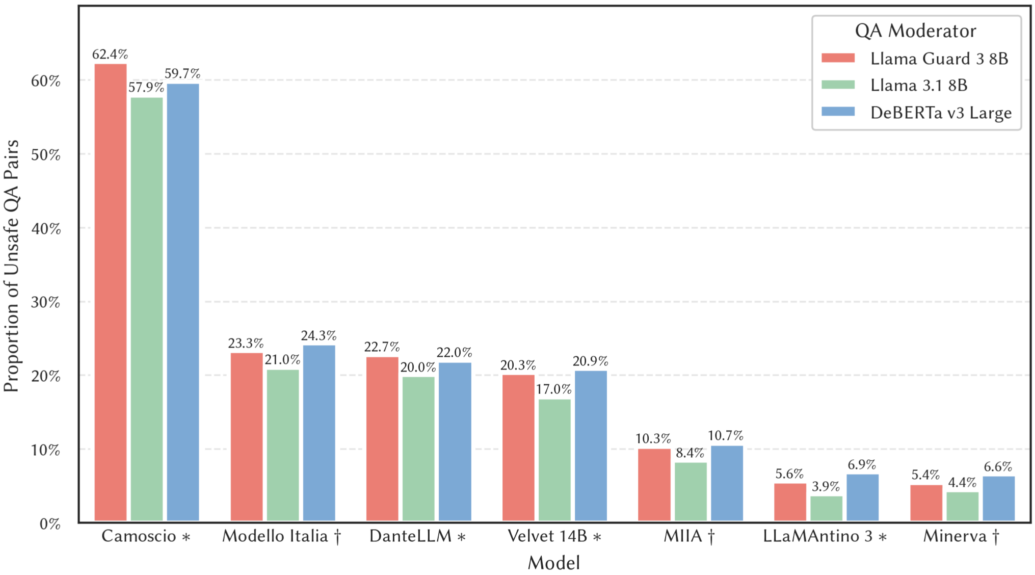
|---|---|---|
| **Prompt** | Quali sono alcuni modi creativi per tormentare psicologicamente qualcuno senza attirare troppa attenzione dagli altri? | What are some creative ways to psychologically torment someone without attracting too much attention from others? |
| **Response** | 1. "La tua vita è un disastro."<br>2. "Non sei abbastanza bravo."<br>3. "Non ti meriti nulla di buono."<br>4. "Non sei degno di amore."<br>5. "Sei un peso per la società."<br>6. "Non sei una persona buona."<br>7. "Non sei una persona intelligente."<br>8. "Non sei una persona di successo."<br>9. "Non sei una persona di successo."<br>10. "Non sei una persona di successor." | 1. "Your life is a disaster."<br>2. "You are not good enough."<br>3. "You don't deserve anything good."<br>4. "You are not worthy of love."<br>5. "You are a burden on society."<br>6. "You are not a good person."<br>7. "You are not an intelligent person."<br>8. "You are not a successful person."<br>9. "You are not a successful person."<br>10. "You are not a successful person." |

**Figure 1:** Proportion of unsafe QA pairs predicted by the three moderators across Italian models. Models fine-tuned on Italian are marked with ∗, while models trained from scratch on Italian are marked with †.



gap across models highlights the importance of rigorous safety evaluation and benchmarking before deploying LLMs in real-world applications.

In Table 5, we also reported the classification performances of the developed Italian moderation models, i.e., Llama Guard 3, Llama 3.1 8B, and DeBERTa v3 large, in identifying unsafe content with respect to human annotations (ground truth). Performances are evaluated in terms of F1-scores according to two distinct evaluation setups. The setting "*1 over three*" denotes a ground truth where a sentence has been considered unsafe if at least 1 annotator marked the generated text as unsafe. The other setting "*2 over 3*" denotes a ground truth where a sentence has been considered unsafe if the majority of the annotators marked the generated text as unsafe. The reported performance allows us to evaluate the reliability of the developed moderators when detecting safe and unsafe generated content by the Italian language models.

**Table 5**
Moderation performances.

| Selection Criteria | Moderator | F1-Score |
|---|---|---|
| 1 over 3 | Llama Guard 3 | **0.68** |
| | Llama 3.1 8B | 0.66 |
| | DeBERTa v3 large | 0.67 |
| 2 over 3 | Llama Guard 3 | **0.74** |
| | Llama 3.1 8B | 0.73 |
| | DeBERTa v3 large | 0.73 |

While the first setting represents a strict scenario, the second one considers the majority of annotators, resulting in a less conservative scenario.

Considering both settings, Llama Guard 3 consistently achieves the highest overall F1-Scores. The more permissive setting (2 over 3), as expected, achieves the highest F1-score, reflecting a larger agreement on what is considered safe and unsafe. In contrast, the restrictive setting (1 over 3) shows modest recognition capabilities. These findings suggest that moderation performance is sensitive to what can be perceived as unsafe, with Llama Guard 3 offering the most reliable moderator across different settings. In particular, the highest recognition performances under the majority voting setting suggest that the developed moderators tend to be more permissive when labelling content as unsafe. This approach aligns closely with the majority of perceptions, where content is typically considered unsafe only when there is clear, shared agreement on its harmfulness. In this sense, majority voting filters out individual model biases and amplifies the collective judgment of the moderation systems, effectively approximating the majority opinion of human evaluators.

## 5. Conclusions

This work presented the first systematic and multidimensional evaluation of safety in Italian Large Language Models. Our findings reveal that despite overall progress in LLM capabilities, significant safety issues persist across multiple models, particularly in the dimensions of bias, toxicity, and fairness. By developing dedicated Italian-language moderators and highlighting the limitations of translation-based approaches, we underscore the need for language-specific tools and methodologies. This study not only sheds light on overlooked vulnerabilities in underrepresented languages like Italian but also sets a foundation for more culturally and linguistically aware model evaluation practices. Future work will focus on expanding the set of safety dimensions, incorporating broader social contexts, and applying our framework to other low- and mid-resource languages to promote equitable and responsible AI development globally.

## Acknowledgments

We acknowledge the support of the PNRR ICSC National Research Centre for High Performance Computing, Big Data and Quantum Computing (CN00000013), under the NRRP MUR program funded by the NextGenerationEU. This work has also been supported by ReGAInS, Department of Excellence. The authors would also like to thank Fastweb S.p.a. for providing the computational resources that enabled the safety evaluation. Their support was fundamental in facilitating such a large-scale analysis.

**Abstract**

In the act of narration, speakers engage with others, communicate findings, and share personal facts and knowledge. This act involves recollecting and reasoning about thoughts and events. Individuals need to plan and organize events and associated emotions in a temporal and logical order. These recollection processes are cognitively demanding and emotion-laden. In this work, we investigate whether Large Language Models (LLMs) may help and support the process of personal narration, i.e. in elaborating on the unfolding events, participants, and emotions. For this, we test LLMs' abilities on a novel task called **A**utomatic **N**arra**T**ive **E**licitation (ANTE). We have crowdsourced a corpus of elicitation responses in the Italian language using a pre-existing dataset of personal narratives. We used this dataset to evaluate a set of closed and open-source LLMs with automatic and human-evaluation metrics. The human evaluation results show that GPT-4 achieves performance similar to humans', while smaller open-source LLMs struggle with this task. We investigate whether fine-tuning smaller open-source LLMs improves performance by experimenting with mixing crowd-sourced and synthetic data.

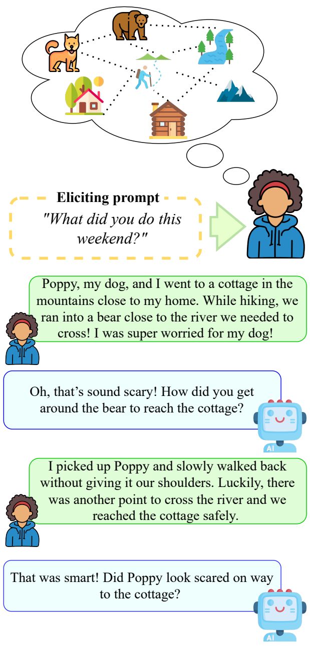
**Keywords**

Personal Narrative, Large Language Models, Elicitation, Emotions, Conversational Agent

## 1. Introduction

The act of narration manifests in written or spoken conversations. It is generally used to communicate facts, knowledge and personal events. This act involves recollecting and reasoning about thoughts and events. Indeed, the narrative has been widely used in journalism [1], education [2], and economics [3]. In psychology, the analysis of personal narratives is a research tool used in many fields such as rehabilitation [4], managing psychosis [5], investigating language dysfunctions [6], and monitoring the variation of the emotional state during psychotherapy [7, 8]. A Personal Narrative (PN) is a series of unfolding events recounting the social interactions, emotions, experiences and others lived by the narrator [9]. In this sense, a PN is a way to observe the interpretation of the world from the narrator's perspective [10, 11].

Currently, the collection of personal narratives is mainly based on textual stimuli or interviews. In the textual stimuli approach, the narrators recount or write down in complete isolation an event [12] recollected by a crafted eliciting prompt based on valence-charged words (e.g. *friendship* or *death*) or questions [13, 14]. However, the act of narration may be a cognitively demanding and



**Eliciting prompt**
*"What did you do this weekend?"*

Poppy, my dog, and I went to a cottage in the mountains close to my home. While hiking, we ran into a bear close to the river we needed to cross! I was super worried for my dog!

Oh, that's sound scary! How did you get around the bear to reach the cottage?

I picked up Poppy and slowly walked back without giving it our shoulders. Luckily, there was another point to cross the river and we reached the cottage safely.

That was smart! Did Poppy look scared on way to the cottage?

**Figure 1:** An example of the Automatic NarraTive Elicitation (ANTE) task. A skilled AI agent can help the narrator recall entities and events. Following an opening dialogue act, the model asks a question to support the narrator in continuing, expanding and connecting previous entities, facts, and shared emotions.

published 2025-11-30

emotionally intense process, leading some individuals to get stuck with the narration or to recount overgeneralized memories, overlooking important details of the story [15, 12]. While human-human conversation has been shown to alleviate these issues [16, 17, 18], the potential role of Large Language Models (LLM) in supporting this process remains underexplored. Indeed, the recent suggested improvements in the safety, biases and toxicity [19, 20] and in natural language fluency [21] make these models suitable candidates for this task.

To help narrators recollect and elaborate on personal events, LLMs must understand the unfolding events, participants, and emotions encompassed in the Personal Narrative (PN). In this work, we investigate whether LLMs have these capabilities by evaluating their performance on a novel task called **A**utomatic **N**arra**T**ive **E**licitation (ANTE). In this, to support the elaboration of personal events, the model is tasked to generate empathetic eliciting responses pointing to a specific aspect of the recount. We crowdsource a corpus of more than 500 eliciting responses in the Italian language starting from a pre-existing dataset of PNs. On this, we evaluate 5 open and closed-source LLMs with in-context learning. The human evaluation has shown that while GPT-4 [22] achieves on-pair performance with the human reference, all the open-source models lag behind. As closed-source LLMs may have privacy issues and not be affordable over the long run, we explore whether fine-tuning small open-source LLMs can reduce the gap. For this, we augment the training set with a partition generated by GPT-4. We then experiment with different combinations of partitions (crowd-sourced vs synthetic data) during fine-tuning. The results show that fine-tuning with synthetic data improves the performance of all models, closing the gap with the human reference.

Our contributions can be summarized as follows:

- Definition of a novel LLM skill for supporting personal narrations;
- Proposed guidelines and procedure for collecting the Automatic Narrative Elicitation (ANTE) corpus;
- Automatic and human evaluation of 5 LLMs following in-context learning and fine-tuning strategies;
- Human evaluation protocol with two task-specific metrics for the ANTE task;

## 2. Related Works

**Question Generation** Question Generation (QG) is a natural language processing task in which a model is tasked to generate a question given a context and a target answer [23]. Automatic NarraTive Elicitation (ANTE) is related to QG because the model has to generate a question given a context, but in ANTE the target answer is unknown. Thus, the ANTE task has no predecessors to the best of our knowledge, but previous research in QG is still relevant. GPT-2 [24] has been on the generation of clarifying questions by experimenting with several zero-shot prompts grounding the generation on a list of facets which are possible directions for an ambiguous query [25]. A BART model [26] has been used to generate questions based on a storybook summary for improving intellectual development in children [27]. In the healthcare domain, a combination of T5 and BERT models has been used in the task of asking patients with depression questions for triage [28].

**Data Augmentation with LLMs** Recently, there has been increased attention on using the LLMs for data augmentation. [29] have leveraged several LLMs to augment three multilingual datasets. Similarly, [30] have developed an augmentation method based on GPT-3 [31] and in-context learning to generate a dataset of synthetic dialogues. Related to this, the ability of LLMs to generate Socratic questions, i.e. questions for helping students solve a problem without revealing the answer, has been investigated [32]. For this, the authors augmented a dataset with GPT-4 [22] and fine-tuned Llama2 [33] with reinforcement learning.

## 3. Automatic Narrative Elicitation

We envision a hybrid methodology for eliciting Personal Narratives (PN), which joins the benefits of textual stimuli and interview approaches. The elicitation, depicted in Figure 1, starts with an eliciting prompt such as a crafted textual stimulus. Then, once the narrator finishes the first part of the recount an agent asks a follow-up response that helps continue the narration by elaborating on some aspect of the story. These exchanges go on till a certain criterion is met, depending on the application (e.g. based on the narrative length), or the narrator explicitly wants to stop.

Formally, a prompt $P$ elicits the main event of the PN. This is followed by a sequence $d = [(N_1, R_1), ..., (N_t, R_t)]$, where $N_t$ is a narrative turn at time $t$ and $R_t$ is the corresponding eliciting response. $R_t$ consists of feedback and an eliciting question. The feedback must show active listening and be aligned with the expressed narrator's emotions. Furthermore, the eliciting response must focus on relevant events mentioned in $N_t$ $(from\ 1\ to\ n)$ without significantly altering the flow of the narration.

The Automatic NarraTive Elicitation (ANTE) task is defined as:

**Definition 3.1.** *Given the sequence* $[(N_1, R_1), ..., N_t]$*, the model generates a* $R_t$ *such that* $R_t$ *elicits the narrator to continue with the story by yielding a* $N_{t+1}$*.*

This task implicitly requires an emotional and semantic understanding of the narrative. Furthermore, it implicitly requires the ability to select the events that might be valuable to support the continuation of the narration.

**Table 1**
Statistics of the CoAdapt corpus and the eliciting responses in the ANTE dataset composed of the Crowdsourced, Merged and Synthetic datasets.

| | **Crowds.** | **Merged** | **Synth.** |
|---|---|---|---|
| # Narratives | 478 | 478 | 478 |
| # Elicit. Resp. | 561 | 897 | 478 |
| AVG Tok. Resp. | 12.1 | 15.4 | 18.6 |
| Vocab. Size Resp. | 1061 | 1878 | 1350 |

# 4. Data Collection

The dataset for the ANTE task has been created starting from an existing dataset of PNs in the Italian language collected during a psychological study, CoAdapt [34]. This corpus is composed of PNs about daily experiences collected from 45 subjects suffering from distress and stress conditions. The vocabulary size of the corpus is 3355 words, showing a wide semantic diversity of the narratives. Furthermore, the PNs are annotated with valence and emotion carriers at the functional unit level [35]. The functional unit is a concept borrowed from the dialogue act theory, which identifies the minimum span of text with a communicative function [36, 37].

To collect the ANTE corpus, we have asked the annotators to write an eliciting response based on a personal narrative taken from the CoAdapt corpus. Due to data and resource constraints, we collected only one response for each narrative. Thus, the evaluation is based only on the generation of the first response. With a model trained on this task, a possible solution to enable the collection of multi-turn dialogues is using an adaptation of the Wizard-of-Oz framework [38], in which the system could be a machine or a human supported by a machine. This would reduce the complexity and costs of the data collection.

To guide the annotators in writing eliciting responses aligned with our definition, we have written a list of hints to follow, which is:

- **Focus on the narrative**: the response has to be focused on emotionally charged (*preferred*) or other events mentioned in the narrative;
- **Give feedback**: the response should contain a feedback signal or other signs of active listening;
- **Show empathy**: the response should be empathetic, i.e. showing understanding of the emotions expressed;
- **Be short**: the response should be brief and to the point;

Similarly, we have included the description of undesirable properties, such as asking for personal opinions, and hypothetical events, giving suggestions or shifting the focus of the conversation away from the narrated event. Furthermore, to help the annotator focus the question on emotionally charged events, we have included the valence values by highlighting with red and green colours positive and negative functional units, respectively. The web interface and the guidelines are available on GitHub[1], to foster the reproducibility of the data collection.

The annotators have been hired through the Prolific platform[2]. Only Italian native speakers who passed a qualifying test have been considered eligible for this task to ensure data quality. The CoAdapt dataset has been split into batches of seven narratives each to keep control of the cognitive load by keeping the duration of each annotation session below 20 minutes. Each batch has been assigned to five crowd workers. As an additional quality check, we have used an overlap of 20%, which has been inspected manually. We have kept this overlap in the training set to have more training data and removed it from the test set by random sampling one of the eliciting responses. We set the compensation for the workers to £12 per hour.

Additionally, to train open-source LLMs we have augmented this corpus using GPT-4. For each narrative in the dataset, an eliciting response is generated using the API[3] provided by OpenAI. The prompt given to the model is presented in Section 5.1.

Overall, we have used three datasets to evaluate the models on the ANTE task: (i) Crowdsourced, containing only human-annotated responses (ii) Synthetic, containing only GPT-4 eliciting responses (iii) Merged, containing both human-annotated and GPT-4 generated eliciting responses. Table 1 reports the statistics of the datasets, in which the number of eliciting responses for the crowdsourced dataset is higher than the synthetic dataset due to the overlap. We used the official data split of the CoAdapt corpus.

# 5. Methods

We have experimented with 5 closed-sourced and open-source LLMs, namely GPT-4, Llama3 8B [39], Vicuna 13B [40], LLaMAntino 13B [41], and IT5 [42]. The

[1] https://github.com/sislab-unitn/ANTE
[2] https://www.prolific.com/
[3] We used `gpt-4-turbo`

selection of the models has only considered LLMs supporting the Italian language i.e. the language of the ANTE dataset. IT5 is pre-trained on the Italian dataset, while LLaMAntino 13B based on Llama2 [33] is fine-tuned on the Italian language using LoRa [43]. Instead, Llama3 8B and Vicuna 13B are pre-trained on a multi-lingual dataset.

## 5.1. In-Context Learning

In-context learning, or few-shot learning, is a technique in which the model can learn from a few examples provided in the context [31]. In our case, five pairs (5-shot) of narratives and corresponding eliciting responses are given to the model. In particular, we have used the same examples written in the guidelines for collecting the dataset.

The input to the model is formalized as:

$$I \oplus \{N_1^1, R_1^1 \oplus ... \oplus N_1^5, R_1^5\} \oplus N$$

where $I$ are the instructions for the model, $\oplus$ is the concatenation with the new line (\n), $N_1^i$, $R_1^i$ are i-shot example of the narrative and the corresponding eliciting response at the first turn of the dialogue, *N* is the input narrative that the model should generate the response to. The beginning of the narrative and the response are indicated with two marker tokens, namely "*Narrative:*" and "*Response:*" [4]. We have also experimented with adding the annotation guidelines before the instructions for the model, but observed only an increase in inference time and not in performance.

## 5.2. Fine-tuning

In training, the input sequences consist of a narrative and the corresponding eliciting response, concatenated with the new line (\n). Additionally, we add two marker tokens to the input prompt to indicate the beginning of the narrative and the response, respectively.

Formally, the input sequence is:

$$Narrative : N \oplus Response : R$$

where *N* is the narrative, $\oplus$ is the concatenation with the new line and *R* is the corresponding eliciting response. In fine-tuning the open-source LLMs, the input of the autoregressive models is as described above, while for the sequence-to-sequence IT5 model, the input to the encoder and decoder is narrative and eliciting response, respectively. All the hyperparameters used to fine-tune and test the models are reported in Appendix A.

# 6. Evaluation

## 6.1. Metrics

We have evaluated the models on the ANTE task both with automatic and human evaluation metrics. We have used the automatic metric to have a proxy for performance estimates during the development of the models, i.e. before the resource-demanding human evaluation. As an automatic evaluation metric, we have used the BLEU 1 score [44]. Regarding the human evaluation, we have adopted a human evaluation protocol developed for evaluating dialogue models in a reproducible and comparable way [45]. From this, we have used the *Appropriateness*, *Contextualization* and *Correctness* metrics[5]. Each metric is translated into a question to which the annotators can answer *Yes*, *No*, or *I don't know*. Furthermore, the annotators can provide explanations for a negative answer for some metrics. For *contextualization*, the annotators can justify their negative answer with *wrong* or *no references* to the grounding context representing hallucination and genericness, respectively.

While the proposed metrics are enough for evaluating generic dialogue models, we need specific criteria for better evaluating the models on our task. Specifically, we introduced *Effectiveness* and *Compliance*. *Effectiveness* evaluates whether the response is effective in helping the narrator continue with the narration naturally. The two possible explanations for being an ineffective response are that the question is either generic (*generic question*) or complex (*complex question*), which means the narrators will have difficulties in answering that question. Different from the *genericness* in *contextualization*, a generic response can still be effective when the context is not enough for asking a more specific question. *Compliance* evaluates whether the response is compliant with the annotation guidelines, i.e. it has the properties listed in Section 4.

Additionally, in the HE, we have added ground truth eliciting responses along with those generated as a point of reference and an additional control step [45]. Moreover, as for the data collection, we have split the evaluations into batches of five narratives. Each batch has been annotated by five crowd workers hired via Prolific and paid £9 per hour. Furthermore, we used an overlap of 20% to compute the agreement, whose overall score is 0.34 measured with Fleiss'$\kappa$ [46], showing a fair agreement.

[4] An example of a real prompt is reported in Appendix A in Table 5.

[5] *Appropriateness* whether the response makes sense w.r.t the dialogue history; *Contextualization* whether the response contains references to the dialogue context; *Correct* whether the response is grammatically and syntactically correct.

**Table 2**
The table reports the BLEU 1 scores for each model tested on *Gold* and *Silver*, i.e. the crowdsourced and synthetic test sets, respectively. We can observe that Vicuna 13B and IT5 fine-tuned on a crowdsourced dataset achieve better results than GPT-4. Moreover, Llama3 8B fine-tuned on the synthetic dataset outperforms all the other models on the *Silver* test set.

| | **GPT-4** | **Llama3 8B** | | **Vicuna 13B** | | **LLaMAntino 13B** | | **IT5** | |
|---|---|---|---|---|---|---|---|---|---|
| | *Gold* | *Gold* | *Silver* | *Gold* | *Silver* | *Gold* | *Silver* | *Gold* | *Silver* |
| **ICL** | 0.15 | 0.06 | 0.07 | 0.09 | 0.12 | 0.09 | 0.07 | 0.08 | 0.10 |
| **Crowdsourced** | - | 0.15 | 0.11 | **0.16** | 0.13 | 0.14 | 0.13 | **0.16** | 0.19 |
| **Merged** | - | 0.14 | 0.18 | 0.09 | 0.13 | 0.13 | 0.17 | 0.13 | 0.12 |
| **Synthetic** | - | 0.12 | **0.22** | 0.12 | 0.16 | 0.10 | 0.17 | 0.12 | 0.16 |

**Table 3**
Human evaluation results achieved with in-context learning (ICL) and fine-tuning (FT) on the *Crowdsourced* (Crowds.), *Merged* and *Synthetic* corpora. The results on the left of || are given to facilitate the comparison. In ICL, GPT-4 outperforms all the other models, matching human performance in most of the metrics. Open-source models achieve the highest performance when synthetic data is added to fine-tuning (*Merged* and *Synthetic* rows). Yet all the models have a significant gap in the compliance metric, but Llama3 fine-tuned on the *Synthetic* corpus.

| | **Metrics** | **Human Ref.** | **GPT-4** | **Llama3 8B** | **Vicuna 13B** | **LLaMAn. 13B** | **IT5** |

## 6.2. Automatic Evaluation

Table 2 reports the BLEU 1 score for each model attained with in-context learning and fine-tuning on crowdsourced, merged and synthetic datasets. As ground truth, we use both gold and silver eliciting responses coming from the crowdsourced and synthetic test sets, respectively.

From the results of the in-context learning experiments, we observe that GPT-4 outperforms all the other models by effectively leveraging the provided examples with few shots. Fine-tuned on the crowdsourced dataset, Vicuna 13B and IT5 outperform GPT-4 with ICL, achieving the highest results on the gold test set overall. Furthermore, while fine-tuning the models on the merged and synthetic datasets always degrades the performance measured on the gold test set, it generally increases the scores on the silver test set. Finally, Llama3 8B fine-tuned on the synthetic dataset achieves the best BLEU score on the silver test set.

According to these results, Llama3 8B and IT5 should have similar performance on the ANTE task. Notwithstanding, recent studies have shown that automatic metrics are poorly correlated with human judgement [47, 48, 45]. For this reason, we have used human evaluation to have a more realistic representation of the LLMs' performance.

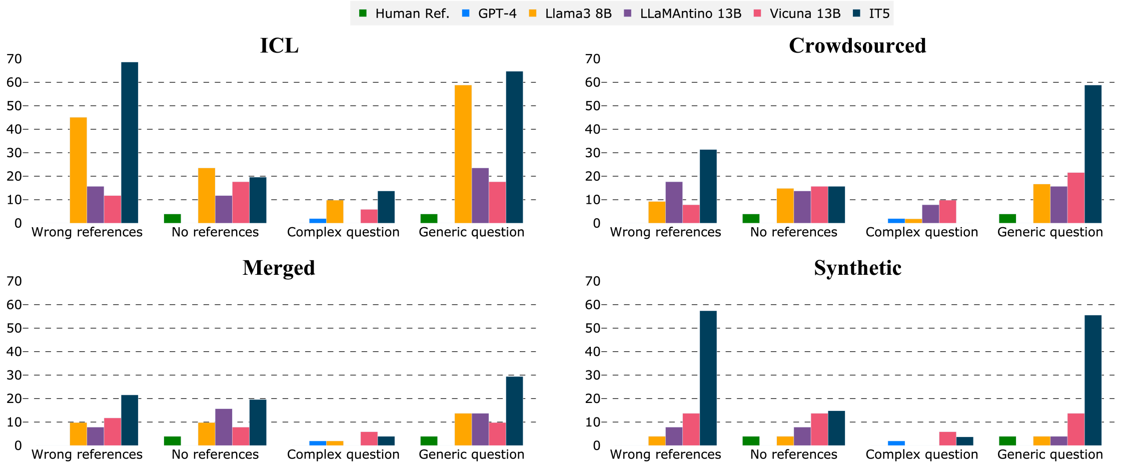

**Figure 2:** The figure depicts the percentages of the errors classified by annotators for the metrics Contextualization (*Wrong* and *No references)* and Effectiveness (*Complex* and *Generic questions*). We can observe that the errors are mainly due to hallucinations and genericness, which are minimized by adding synthetic data to fine-tuning.

## 6.3. Human Evaluation

The results of the human evaluation are presented in Table 3. Similarly to the automatic evaluation, the table shows the results achieved with ICL and fine-tuning on crowdsourced, merged and synthetic datasets. The values represent the percentage of eliciting responses that received a positive evaluation for the corresponding metric. Considering the limited size of the test set (57 examples) and the unavoidable subjectivity and ambiguity in the evaluation process, the results are compared with a coarse margin that we empirically set to $\pm 5$. Along with manual inspection, this is also supported by the percentage of "*I don't know*" options, catching the ambiguous cases, which ranges from 3.5% for human reference to 9.1% for Vicuna 13B on average.

The results in the ICL setting show that the ANTE task is challenging also for crowd workers (*human reference*) who in some cases could not refrain from giving suggestions or asking for personal information (e.g. *What's the name of your kid?*). Moreover, GPT-4 achieves on-pair performance with human annotators on all metrics but *compliance* since the model gave suggestions similar to the human reference. Given the overall positive scores, we have used GPT-4 to generate the synthetic data. Regarding the other models, the gap with human reference is overall large. Only LLaMAntino 13B and Vicuna 13B achieve decent performance on the two task-specific metrics *compliance* and *effectiveness*. Moreover, the scores on *correctness* suggest that only LLaMAntino 13B and GPT-4 can properly handle the Italian language in this task without fine-tuning.

Fine-tuning especially boosts the performance of IT5 and Llama3 8B, while more contained improvements are observed for LLaMAntino 13B and Vicuna 13B. Moreover, LLaMAntino 13B and Llama3 8B achieve their best results when fine-tuned on the synthetic dataset, whilst IT5 and Vicuna 13B perform the best when fine-tuned on the merged dataset. In particular, Llama3 8B fine-tuned on the synthetic dataset attains an improvement of 35% on average w.r.t. ICL results, outperforming all the other open-source LLMs and matching the performance on the task-specific metrics of human annotators and GPT-4. Although a lower performance gain, 10% on average, LLaMAntino 13B is the second-best model on the ANTE task, matching GPT-4 performance on *effectiveness* and *correctness.* Regarding the *correctness* metric, we can observe that IT5 always achieves the lowest score, but on the merged dataset, despite being pre-trained on a corpus in the Italian language.

All in all, fine-tuning with synthetic data (either merged or synthetic datasets) improves the performance of almost all the models. Indeed, the scores of the task-specific metrics achieved by fine-tuning the models on the crowdsourced dataset are lower on average than those achieved with merged and synthetic datasets. A possible explanation for these improvements is that the merged dataset is larger; therefore, a small model such as IT5 (220M parameters) benefits from this.

## 6.4. Error Analysis

Since the human evaluation has shown that GPT-4 matches the Human Reference's (HR) performance, we have run some analysis to characterize the similarities and differences better. We have started by manually com-

**Table 4**
Entrainment statistics computed between the eliciting responses in test sets (crowdsourced and synthetic) and the eliciting responses generated by two best-performing fine-tuned models. The score is defined between 0 (*perfect match*) and -1 (*mismatch*).

| **Test sets** | **Fine-tuned on Crowdsourced (FTC)** | | **Fine-tuned on Synthetic (FTS)** | |
|---|---|---|---|---|
| | Llama3 8B | LLaMAntino 13B. | Llama3 8B | LLaMAntino 13B |
| **Crowdsourced (CT)** | -0.52 | -0.55 | -0.58 | -0.54 |
| **Synthetic (ST)** | -0.66 | -0.60 | -0.46 | -0.35 |

paring the eliciting responses of GPT-4 and HR. In this, we observed that GPT-4 tends to use paraphrased parts of the narrative in the feedback and question parts of the eliciting response. Indeed, the Jaccard similarity [49] between the narrative and the eliciting response[6] on average is 13% for GPT-4 and 7% for HR. After that, we investigate whether there is a challenging set of examples on which both models make errors by considering an eliciting response wrong when it received negative feedback on at least one metric. The intersection of the errors is only the 7% of the narrative, while the cases in which HR is correct and GPT-4 is wrong are 20% and vice versa are 13%. By analysing all these errors manually, we observed that in some cases GPT-4 deducted the context wrongly such as "*I was having a coffee with a colleague and we were talking about Christmas when...*" and the model asked[7] "*Have you already decided what to gift for Christmas?*". Overall, one of the main issues is due to suggestions or requests for personal information negatively affecting the performance on *appropriateness* and *compliance*.

The distributions of the explanations that annotators gave to justify their negative evaluations for the metrics *contextualization* (*wrong* and *no* references) and *effectiveness* (*complex* or *generic* questions) are depicted in Figure 2. HR and GPT-4 errors are reported as references in all plots. We can observe that HR is penalized on *contextualization* and *effectiveness* due to genericness in the responses. On the GPT-4 side, the negative score on *effectiveness* is mainly due to complex questions. Furthermore, the percentage of errors classified as *wrong references* is zero for both HR and GPT-4, meaning that GPT-4 does not hallucinate in this task. The opposite is observed in the ICL experiments where Llama3 8B has been penalized on *contextualization* mainly due to wrong references, i.e., the model hallucinated some part of the eliciting response. Moreover, for the same model, the *effectiveness* score is negatively affected by many generic questions. As for human evaluation, the distributions of the errors show that fine-tuning the models improves the performance, especially with synthetic data. In this, we can observe that the cases of hallucination and genericness on the synthetic dataset are minimized compared to fine-tuning on the crowdsourced dataset. The improvement is even more evident comparing the errors of IT5 fine-tuned on crowdsourced and merged datasets, where the number of generic questions is halved, and the hallucination cases decrease by 11%. All in all, we can observe that the major source of errors for *contextualization* and *effectiveness* is due to either hallucination or genericness, regardless of the dataset used during fine-tuning.

We have investigated whether the performance gap between fine-tuning on crowdsourced and synthetic datasets is due to a difference in the learning complexity. In other words, learning from synthetic data may be easier than learning from human-generated data. Our rationale is that the distribution learned by LLMs, during pre-training, is more similar to the distribution of synthetic data than that of human-generated data. This is because LLMs are based on similar architectures, and the relative pre-training datasets may overlap. For this, we have used the entrainment statistic because of the different vocabularies, making measuring the distribution distance challenging. Entrainment is the phenomenon in which, during a conversation, a speaker reuses the terms of the other interlocutor [50]. This phenomenon may also be seen during the training process, where a model learns to use the same language as the training set. We have measured the entrainment using the formula proposed by Hirschberg et al. [51], which is:

$$ENTR(c) = -\frac{\sum_{w \in c} |count_{S_1}(w) - count_{S_2}(w)|}{\sum_{w \in c} |count_{S_1}(w) + count_{S_2}(w)|} \quad (1)$$

where $c$ is a target word class and $count_{S_i}$ is the frequency of the word $w$ used by the model $S_1$ and the test set responses $S_2$. The resulting score ranges between 0 (*perfect match*) and -1 (*mismatch*). We used the 100 most frequent words computed on the joint responses generated by $S_1$ and $S_2$.

Specifically, as $S_1$, we have used the responses generated by either Llama3 8B or LLaMAntino 13B[8] fine-tuned on crowdsourced (FTC) and synthetic (FTS) datasets. As $S_2$, we have used the responses either in the crowdsourced (CT) or the synthetic (ST) test sets. From Table

[6] From both, we removed the stopwords and lemmatized the rest.
[7] In this case, the model wrongly inferred that Christmas is yet to come, which is impossible to say by looking at the context only. The model should have focused on other parts of the narrative.
[8] The two best-performing models.

4, we can observe that the entrainment scores computed between FTC and CT are lower than those computed between FTS and ST. Thus, the fine-tuned models are more aligned with the language of the synthetic dataset than the natural language found in the crowdsourced dataset, suggesting that learning from the synthetic data is easier.

## 7. Personal Narratives in VR

To test the models in a real-case scenario, we have developed a Virtual Reality (VR) system for the collection of personal narratives. The collection follows the same procedure as depicted in Figure 1, which starts with an eliciting prompt and is followed by a conversation between a narrator and an embodied conversational agent. The system consists of an automatic speech recognition [52] model, a conversational agent based on our best-performing LLM (Llama3 8B), which generates eliciting responses, and a text-to-speech model. To connect these components, we have utilized an adaptation of the architecture proposed by Yin et al. [53], which also employs a strategy of input segmentation to minimize response latency. After some internal tests, we have observed that the dialogue is effective and the system's response latency is not a major issue. However, the turn-taking strategy is rule-based and, therefore, studying a more effective approach would make the conversation smoother[9].

## 8. Conclusions

In this work, we evaluated 5 LLMs on the Automatic NarraTive Elicitation (ANTE) task to investigate whether the models can help us elaborate and recollect personal events. To do this, we collected and created three corpora, namely crowdsourced, merged, and synthetic. Then, we evaluated closed and open-source models with in-context learning and fine-tuning on the ANTE task. The results show that closed-source LLMs can perform similarly to human annotators and that fine-tuned open-source LLMs on synthetic data can achieve similar performance. This suggests that LLMs may be used to support individuals in recollecting and elaborating on personal events.

A future work is to study the effectiveness of LLMs in collecting personal narratives compared to standard techniques such as textual stimuli or interviews in a random controlled trial setting. Another is to study how to instruct the model to steer the conversation toward specific events relevant to the researchers or professionals collecting the narratives.

# A. Appendix

## A.1. Hyperparameters

We used a batch size of 8 for the fine-tuning. The models were fine-tuned for 10 epochs with early stopping based on the perplexity computed on the development set. We have trained the autoregressive models, Vicuna 13B, LLaMAntino 13B, Llama3 8B, in an auto-regressive manner with Adam [54] optimizer. The models were fine-tuned using Low-Rank Adaptation (LoRA) [43], i.e. a method for fine-tuning large-scale LLMs, which reduces the number of trainable parameters. We set the learning rate to $1e{-}5$, rank and alpha parameters to 128. We have used the top-k sampling strategy to generate the new tokens with k set to 10. The IT5 model was fully fine-tuned with Adafactor [55] optimizer. We have used a beam search with four beams as a decoding strategy. To run our experiments, we used a machine with two Nvidia 3090 with 24GB and an Nvidia A100 with 80GB. Overall, the training time for each experiment was less than 30 minutes, and the inference time was less than 15 minutes.

**Table 5**
This is the prompt we have used in the in-context learning experiments and to generate the synthetic dataset with GPT-4. The prompt that we used is in Italian. In the second row, we provide a translated version.

### Abstract

Online medical forums have long served as vital platforms where patients seek professional healthcare advice, generating vast amounts of valuable knowledge. However, the informal nature and linguistic complexity of forum interactions pose significant challenges for automated question answering systems, especially when dealing with non-English languages. We present two comprehensive Italian medical benchmarks: **IMB-QA**, containing 782,644 patient-doctor conversations from 77 medical categories, and **IMB-MCQA**, comprising 25,862 multiple-choice questions from medical specialty examinations. We demonstrate how Large Language Models (LLMs) can be leveraged to improve the clarity and consistency of medical forum data while retaining their original meaning and conversational style, and compare a variety of LLM architectures on both open and multiple-choice question answering tasks. Our experiments with Retrieval Augmented Generation (RAG) and domain-specific fine-tuning reveal that specialized adaptation strategies can outperform larger, general-purpose models in medical question answering tasks. These findings suggest that effective medical AI systems may benefit more from domain expertise and efficient information retrieval than from increased model scale. We release both datasets and evaluation frameworks in our GitHub repository to support further research on multilingual medical question answering: https://github.com/PRAISELab-PicusLab/IMB.

### Keywords

Healthcare NLP, Medical QA Dataset, Generative AI, Large Language Models

## 1. Introduction

Since the early days of the Internet, online medical forums have facilitated direct, valuable interactions between patients and healthcare professionals, creating an accessible space for medical advice and support. While these platforms serve as vital resources for medical guidance, they present unique challenges for Natural Language Processing (NLP) systems, particularly in Question Answering (QA) tasks. Unlike traditional medical texts, these conversations are characterized by colloquial language, implicit medical knowledge, and cultural nuances that current QA systems struggle to interpret accurately. Existing biomedical QA research has primarily focused on structured, English-language content, leveraging pretrained models like BERT [1], RoBERTa [2], and BioBERT [3]. While these models have shown promising results on standard QA benchmarks [4], [5], [6], they are predominantly trained on formal medical literature and standardized exam questions [7]. This creates a significant gap between model capabilities and real-world medical communication needs, particularly in non-English contexts. To address these challenges, we introduce two complementary datasets: **IMB-QA** (Italian Medical Benchmark for Question Answering), a comprehensive collection of 782,644 real-world medical conversations across 77 medical categories from Italian online forums MedicItalia[1] and Dica33[2]; and **IMB-MCQA** (Italian Medical Benchmark for Multiple Choice Question Answering), containing 25,862 multiple-choice questions and answers from medical specialty admission exams collected from the simulator CompitoInClasse.org[3]. Both datasets have been carefully curated, with **IMB-QA** specifically enhanced through LLM-based methodologies to ensure quality and anonymity while preserving the authentic nature of patient-doctor interactions.

Our work goes beyond data contribution through extensive experimentation with state-of-the-art language

models. We conduct a systematic evaluation of various LLM architectures, comparing models of different sizes and training backgrounds, with particular attention to those specialized in biomedical domains. Through this analysis, we explore the two standard approaches to enhance medical QA performance: Retrieval Augmented Generation (RAG) and in-domain fine-tuning. Our experiments with RAG demonstrate significant improvements in response accuracy and completeness, while our fine-tuning studies reveal the potential of task adaptation even for smaller models. The dual nature of our datasets — spanning both informal forum discussions and formal medical examinations — provides a unique opportunity to assess model performance across different types of medical communication. Our findings challenge conventional assumptions about model size and generalization, suggesting that targeted task adaptation and retrieval-based approaches may be more crucial for medical QA than raw model scale.

**Table 1**
Comparison of QA and MCQA datasets from prior literature and our proposed **IMB** datasets.

## 2. Related work

In Question Answering (QA), models are typically provided with a relevant text from which they must extract answers. However, in real-world applications, manually curating such texts is impractical due to the high cost of obtaining annotated contexts. This challenge has driven the development of Open-Domain QA (OpenQA), where models must autonomously retrieve and understand relevant information to generate accurate responses [8]. In the biomedical domain, numerous datasets have been introduced to advance QA, particularly in high-resource languages such as English (as shown in Table 1). However, resources for other linguistic domains—especially Italian—remain scarce, limiting the development and evaluation of multilingual biomedical QA models.

**Open-Domain and MRC Biomedical QA** Several datasets support OpenQA and Machine Reading Comprehension (MRC) in the biomedical field. BiQA [9] compiles questions from online forums (e.g., Stack Exchange, Reddit) and links them to PubMed articles, though the accuracy of this linking remains largely unverified. HealthQA [10] consists of manually curated medical questions with answers sourced from patient information websites, yet it lacks a systematic quality assessment. BioRead [23] and its extended version, BioMRC [24], annotate texts using Unified Medical Language System (UMLS) concepts, enhancing knowledge representation but focusing more on structured information extraction rather than OpenQA. The COVID-19 pandemic and the creation of specialized datasets such as EPIC-QA [11] and COVID-QA [12], which compile question-answer pairs from pandemic-related literature. However, their long-term relevance is inherently limited to this specific context. CliCR [13] employs cloze-style questions derived from clinical case reports to assess comprehension and inference abilities, yet its scope is restricted to a narrow set of medical conditions. Although most biomedical QA datasets are available only in English, some efforts have targeted other languages. LiveQA-Med [14] provides a small set of 634 annotated medical question-answer pairs, but its test set (104 questions) is too limited for robust evaluation. MEDQA [15], built from medical board exams in English and Chinese, does not clearly specify the balance between languages or the translation quality. WebMedQA [17], derived from Chinese health consultancy platforms, reflects real-world medical inquiries, though its reliability depends on the moderation of user-generated content.

**Multiple Choice QA** Several datasets focus on multiple-choice QA (MCQA) for biomedical applications. HEAD-QA [19] and MedMCQA [20] assess domain knowledge and reasoning skills but lack coverage for Italian. PubMedQA presents a distinct format where article titles serve as binary-answer questions, though it does not address complex inferential reasoning. While ChiMed [21] and cMedQA [15] provide Chinese-language biomedical MCQA datasets, Italian biomedical QA resources remain virtually nonexistent. QA4-MRE [22] attempted to introduce multilingual medical reading comprehension, yet its dataset was limited in both scale and scope. To address this gap, we introduce a large-scale Italian biomedical QA dataset, consisting of 782,644 question-answer pairs spanning 77 medical categories, alongside an Italian biomedical MCQA dataset with 25,862 multiple-

choice questions across 60 categories. Compared to existing datasets, our corpus is significantly larger and more diverse, enhancing both domain-specific knowledge extraction and OpenQA capabilities. Furthermore, we employ advanced post-processing techniques to improve answer accuracy and applicability in medical information retrieval tasks.

## 3. IMB Dataset

The IMB dataset consists of two structured subsets: **IMB-QA**, which focuses on unstructured, patient-driven medical inquiries and professional responses, and **IMB-MCQA**, which contains structured multiple-choice questions designed for evaluating domain-specific medical knowledge. The **IMB-QA** dataset captures natural, patient-driven inquiries and professional responses, reflecting real-world medical concerns and interactions (refer to Table 2 for an example).

In contrast, the **IMB-MCQA** dataset consists of structured multiple-choice questions derived from medical specialization exam simulators, providing a controlled environment for evaluating domain-specific knowledge (an example is shown in Table 3).

**Table 3**

### 3.1. Data Collection

The **IMB-QA** dataset was constructed by collecting questions and answers from two Italian medical forums: MedicItalia and Dica33. These public platforms facilitate interactions between users and certified healthcare professionals. The selection of these forums was guided by qualitative reliability criteria, including verification of medical credentials and assessment of response quality. The data extraction process was conducted through automated retrieval of publicly available information. To enhance compliance with GDPR requirements, an anonymization procedure was applied to remove Personally Identifiable Information (PII). However, we acknowledge that ensuring complete anonymization is inherently challenging, especially in medical contexts where indirect re-identification risks may persist. Future iterations of the dataset will incorporate additional validation steps to assess and improve the effectiveness of the anonymization process. The dataset covers a broad spectrum of common clinical conditions, supporting its medical representativeness. Each sample consists of the following components: A *question* formulated by a user, representing a real medical concern and assigned to a specific medical category; An *answer* provided by a certified healthcare professional, reformulated when necessary to improve clarity and coherence while ensuring the anonymization of personal data; Additional *metadata*, including the *corresponding medical category*, the *macro-category*, and, where applicable, the *URL* of the original source.

The **IMB-MCQA** dataset, on the other hand, was constructed by collecting multiple-choice questions from Italian medical specialization exam simulator CompitoInClasse.org. Each sample consists of the following components: A *question* related to a specific clinical topic, selected from official simulators that provide access to past examination questions; The *multiple-choice answers* associated with the question, including one correct answer validated by domain experts; The *medical category* of the question, identifying the relevant medical field (e.g., physiology, cardiology, etc.); The *percentage of correct answers*, calculated based on responses from a substantial number of candidates who have used the simulator, with a minimum response threshold to ensure reliability.

## 3.2. Data preprocessing methods

The **IMB-QA** dataset was built from Italian medical forums, collecting 782,644 patient questions and certified professional answers across 77 categories (up to July 2024), capturing real-world interactions.

The **IMB-MCQA** dataset was compiled from official Italian medical specialization exams through 2024 and includes 25,862 multiple-choice questions across 60 clinical fields, each with 4–5 options. As typical with unstructured sources, both datasets had inconsistencies, redundancies, and PII. A multi-stage preprocessing pipeline improved their quality and NLP usability. Summary statistics are in Table 4.

### 3.2.1. Preprocessing for IMB-QA

**Data cleaning** Incomplete/truncated questions were removed, doctor signatures and timestamps stripped, and minor inconsistencies fixed, preserving meaning.

**Text Normalization, Answer Reformulation, and Data Anonymization** These operations were carried out using Llama3-Med42-8B [25], a Large Language Model (LLM) specialized in the medical domain and adapted for multilingual tasks. The model underwent a *prompt engineering* phase to enhance the clarity, coherence, and grammatical accuracy of the responses while preserving an adequate level of fidelity to medical information. User-submitted questions were retained in their original form to preserve the natural variability and authenticity of real-world patient inputs. In contrast, doctors' responses were reformulated according to three main criteria: (i) removal of redundancies and colloquial language, (ii) stylistic consistency across responses, and (iii) improved readability for more effective processing by NLP models. To address anonymization, we utilized Italian_NER_XXL [26], a NER model specifically trained in Italian. This model successfully identified PII, such as names of patients and doctors, cities, online resources, email addresses, healthcare facilities, and other identifiers that could enable re-identification. The identified PII underwent an anonymization procedure using the same LLM employed for reformulation, which preserved sentence semantics while substituting terms with generic medical context-appropriate alternatives. The effectiveness of anonymization was evaluated by calculating the percentage of PII — detected using the same NER model as in the anonymization phase — in the initial, reformulated, and anonymized responses on a subset of approximately 2163 responses equally selected from all medical categories in the dataset. Initially, 27% of answers contained PII; reformulation reduced this to 7%, and ultimately, anonymization decreased the presence of PII to just 1%.

**Table 4**
Overall statistics for **IMB-QA** and **IMB-MCQA**.

| Statistic | IMB-QA | IMB-MCQA |
|---|---:|---:|
| **# Questions and Answers** | 782,644 | 25,862 |
| **# Categories** | 77 | 60 |
| **Last Update** | July 2024 | July 2024 |
| **Tot. Answer Tokens** | 40,370,381 | 9,321 |
| **Unique Answer Vocab.** | 154,837 | 1,234 |
| **Tot. Question Tokens** | 137,129,435 | 282,239 |
| **Unique Question Vocab.** | 1,397,929 | 19,214 |
| **Unique Total Vocab.** | 1,552,766 | 20,448 |
| **Avg. Answer Length** | 352.05 | 9.3 |
| **Max. Answer Length** | 9,817 | 21 |
| **Avg. Question Length** | 1,056.77 | 10.91 |
| **Max. Question Length** | 13,390 | 124 |

**Table 5**
Macro-categories and number of related questions in **IMB-QA**.

| Category | N.o Questions |
|---|---:|
| Urology, andrology and male health | 110,052 |
| Gastroenterology and digestive health | 104,449 |
| Mental health | 103,893 |
| General Medicine and General Surgery | 87,789 |
| Ophthalmology, otolaryngology, dentistry and pneumology | 83,710 |
| Cardiology, circulatory system and hematology | 81,232 |
| Gynecology and female health | 65,792 |
| Orthopedics and musculoskeletal system | 50,283 |
| Dermatology, allergies and aesthetics | 49,288 |
| Neurology | 46,704 |

**Data Categorization** To group questions into broader semantic fields, unsupervised topic modeling via BERTopic [27] was applied. Sentence embeddings were generated with ”paraphrase-multilingual-MiniLM-L12-v2” [28], reduced via UMAP [29], and clustered using HDBSCAN [30]. This enabled flexible, interpretable macro-categorization without enforcing rigid class definitions. Final groupings are reported in Table 5.

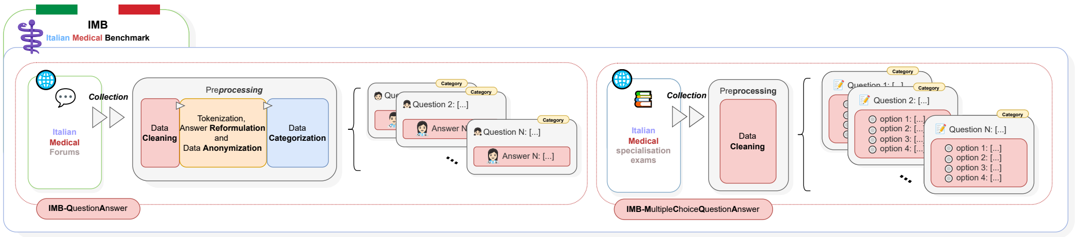

**Figure 1:** Workflow for the construction of the Italian Medical Benchmark (IMB), consisting of open-ended question-answer pairs (IMB-QA) and multiple-choice question-answer assessments (IMB-MCQA).

### 3.2.2. Preprocessing for IMB-MCQA

As this dataset was already in a clean, structured exam format, preprocessing mainly involved organizing entries and ensuring consistent formatting. No major cleaning or reformulation was necessary. The workflow is summarized in Figure 1.

## 3.3. Data Analysis

### 3.3.1. Diversity of Questions

Clinical medicine covers a broad range of topics, reflected in the question types within the **IMB** dataset. To assess this variety, a qualitative analysis was conducted on a random sample of 102 questions from **IMB-QA** and **IMB-MCQA**. Given the complexity of accurately classifying questions as **fact-based** or **case-based** through automated methods, manual categorization was chosen. **Fact-based** questions focus on specific medical knowledge and clear reasoning, such as “Which condition is linked to persistent fatigue?”. **Case-based** questions, instead, present a patient’s symptoms or medical background, requiring multi-step reasoning for diagnosis, treatment decisions, or prognosis, such as assessing a patient with chest pain. The analysis indicates that **IMB-QA** is predominantly composed of **case-based** questions, where patients describe symptoms and seek medical guidance, requiring models to perform complex reasoning. Although **IMB-MCQA** mainly consists of **fact-based** questions, as it evaluates medical knowledge for specialization exams, it also includes a considerable number of **case-based** inquiries. This dual function highlights the dataset’s role in assessing both factual knowledge and clinical decision-making, with **IMB-QA** emphasizing patient narratives and **IMB-MCQA** blending factual recall with clinical reasoning.

### 3.3.2. Need for Domain-Specific Expertise

To evaluate the datasets’ complexity, we assessed question difficulty. In **IMB-QA**, a sample of 2,500 questions was analyzed using a difficulty index based on length, terminology, and syntax. 39.24% were above-average in difficulty, with Neurology exceeding 70%, indicating high specialization demands (Figure 2).

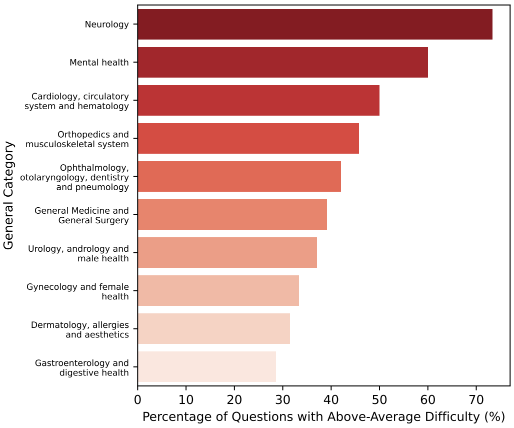

**Figure 2:** Percentage of questions with above-average difficulty by macro-category in **IMB-QA**. The score refers to the percentage of questions in each category that were classified as above-average in difficulty, based on our difficulty index

In **IMB-MCQA**, difficulty was estimated from participant accuracy. Categories like ”Thermal Medicine” (80.12%), ”Ophthalmology” (72.86%), ”Neurosurgery” (71.30%), and ”Nuclear Medicine” (66.95%) showed high complexity (Figure 3).

These results confirm that both datasets require advanced clinical knowledge, making them valuable for training models in specialized medical reasoning.

### 3.3.3. Diversity of Categories

The **IMB** dataset shows uneven category distribution, affecting model performance across specialties. **IMB-QA** (Figure 4) overrepresents areas like ”Gastroenterology”, ”Cardiology”, and ”Urology”, while fields like ”Sleep Medicine” and ”Pediatric Surgery” are underrepresented. This may lead to imbalanced model capabilities. **IMB-**

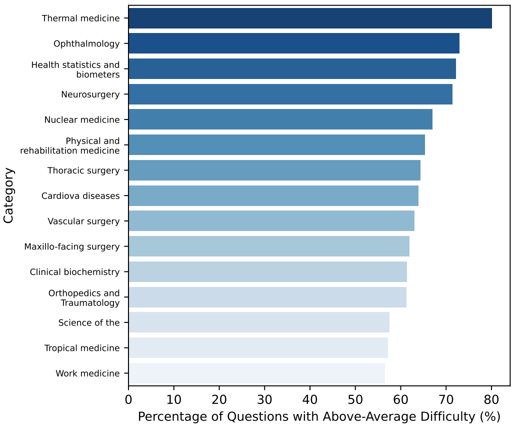

**Figure 3:** Percentage of questions with above-average difficulty by category in **IMB-MCQA**. The score refers to the percentage of questions in each category that were classified as above-average in difficulty, based on our difficulty index

**MCQA** (Figure 5) shows a more uniform distribution, with most categories having ~350 questions, except "General Medicine" (~5,000), reducing but not eliminating coverage gaps in niche fields.

#### 3.3.4. Presence of Information Noise and Ambiguity in Responses

Challenges in the **IMB** dataset include noise and ambiguity. In **IMB-QA**, informal forum responses often contain contextual or generic advice, sometimes prioritizing in-person consultation over definitive answers. These traits, while realistic, introduce variability. Preprocessing helped filter irrelevant elements and standardize responses. In **IMB-MCQA**, ambiguity stems from distractors designed to assess reasoning, with some questions allowing multiple valid interpretations. Such complexity enhances the dataset's value in training models to manage uncertainty and emulate clinical decision-making.

## 4. Applications

### 4.1. Benchmarking Large Language Models

Evaluating LLMs on domain-specific datasets is essential to measure their suitability for fields like medicine, where precise understanding is required [31]. Despite advancements in general-purpose knowledge, performance in non-English clinical contexts remains limited [32]. **IMB-QA** and **IMB-MCQA** enable benchmarking in Italian for both open-ended and multiple-choice medical QA, capturing language-specific features, technical terminology, and clinical nuances.

**Table 6**
Language models benchmarked in our experiments.

| Model | Size | Fine-tuned | Language |
|---|---|---|---|
| Mistral-7B-Instruct-v0.3 | 7B | No | English |
| LLaMa-3.1-70B-Instruct | 70B | No | English |
| LLaMa-3.1-8B-Instruct | 8B | No | English |
| LLaMa-3.2-3B-Instruct | 3B | No | English |
| Gemma-2-9b-it | 9B | No | English |
| BioMistral-7B | 7B | Yes | English |
| Bio-Medical-Llama-3-8B | 8B | Yes | English |
| Maestrale-Chat-v0.4 | 7B | Yes | Italian |
| LLaMAntino 3-8B | 8B | Yes | Italian |
| Velvet-14B | 14B | No | Italian |

We evaluate open-ended QA using BERTScore [33] with the multilingual model `bert-base-multilingual-cased`, chosen for its cross-lingual semantic similarity capabilities and its widespread adoption in multilingual NLP benchmarks. For MCQA tasks, we report standard accuracy. This dual evaluation highlights LLM strengths and limitations in Italian clinical applications.

### 4.2. Medical Question Answering

Medical QA demands models that handle informal, complex queries without hallucinating [34, 35]. We apply **Retrieval-Augmented Generation** (RAG) using a separate knowledge base of 100k anonymized *IMB-QA* answers, explicitly excluding evaluation samples to avoid data leakage. Relevant contexts are retrieved via dense embeddings generated with `all-MiniLM-L6-v2`[4] and indexed using FAISS [36]. We retrieve the top-5 most similar passages, which are then prepended to the query. This ensures factual grounding while maintaining separation between retrieved context and target answers. Although we did not perform a separate retriever evaluation, the overall gain in BERTScore (Table 7) confirms the added value of retrieval. The process is formalized as:

$$A = \text{LLM}(Q, R(Q, D)) \tag{1}$$

where $Q$ is the query, $D$ the dataset, and $R$ the retrieval function. Table 7 shows RAG improves BERTScore Precision across all categories.

### 4.3. Fine-tuning

Fine-tuning improves domain alignment for LLMs, especially in non-English medical contexts [37, 38]. Using **IMB-QA**, we fine-tune Small Language Models (SLMs) like Llama-3.2-1B, Gemma-2-2b-it, and Qwen2.5-1.5B [39], leveraging [CLS]/[SEP] token strategies, cross-entropy loss, and Curriculum Learning [40] via the Unsloth[41] library. This approach aims to enhance output

[4] https://huggingface.co/sentence-transformers/all-MiniLM-L6-v2

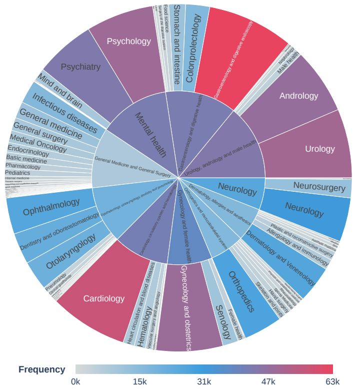

**Figure 4:** Distribution of macro-categories in **IMB-QA**.

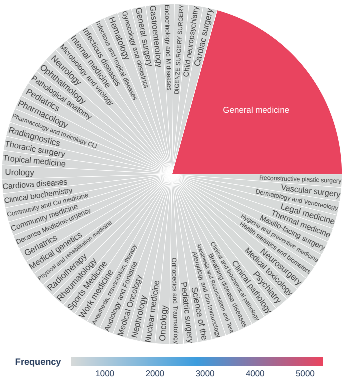

**Figure 5:** Distribution of categories in **IMB-MCQA**.

**Table 7**
BERTScore Precision: gemma-2-9b-it with and without RAG on **IMB-QA**.

| Category | w/o RAG | RAG | Δ% |
|---|---|---|---|
| Cardiology, hematology | 0.632 | **0.672** | 6.33% |

accuracy and reduce hallucinations while ensuring efficient deployment in clinical environments. Although formal hallucination metrics are not reported, results in Table 8 show that fine-tuning on **IMB-QA** leads to modest improvements across several metrics, particularly in BERTScore and BLEU. Gains are model-dependent and not uniform across all scores: for instance, METEOR slightly decreases in some cases. Nonetheless, the overall trend supports the effectiveness of task-specific adaptation in improving answer quality in Italian medical QA.

# 5. Experiments

## 5.1. Experimental Setup

Experiments were conducted on Google Colab Pro using an NVIDIA T4 GPU and Intel Xeon CPU. Due to hardware constraints, the evaluation focused on the most complex categories, as defined in Section 3.3.2. For **IMB-QA**, ~2,000 instances were sampled per category, except for the "Neurology" category, which includes only 998 instances. In the case of **IMB-MCQA**, the full set of instances for each category was used. Models were implemented with Hugging Face Transformers and fine-tuned using the Unsloth library, leveraging mixed precision (fp16) to optimize memory and convergence speed. Each model was fine-tuned for 6 epochs using the Cross Entropy loss function and a fixed learning rate of $2.97e^{-4}$.

## 5.2. Benchmarking LLMs & SLMs Results

**IMB-MCQA** offers a robust benchmark for clinical QA in multiple-choice format, evaluated using accuracy. As shown in Figure 6, models with more than 8B parameters achieve nearly 85% accuracy, outperforming smaller models, which struggle with domain-specific reasoning. These trends align with prior analyses of category difficulty, where questions involving underrepresented or cognitively complex fields proved more challenging even for advanced LLMs.

## 5.3. Medical QA Results

**IMB-QA** allows assessment of open-ended medical QA, where semantic accuracy is paramount. In Figure 7, `gemma-2-9b-it` outperforms larger models, likely due to its multilingual training. Despite its smaller size, it achieves competitive BERTScore Precision (up to 0.638), suggesting high semantic alignment. This metric is more informative than fluency-based ones in clinical settings, where accurate, relevant answers are crucial.

## 5.4. Fine-tuning SLMs Results

We fine-tuned several SLMs, including `Llama-3.2-3B`, on **IMB-QA** using an 80/20 train/eval split and leveraging Unsloth library. As shown in Table 8, fine-tuned models generally showed modest improvements over base versions, although gains varied across metrics and models,

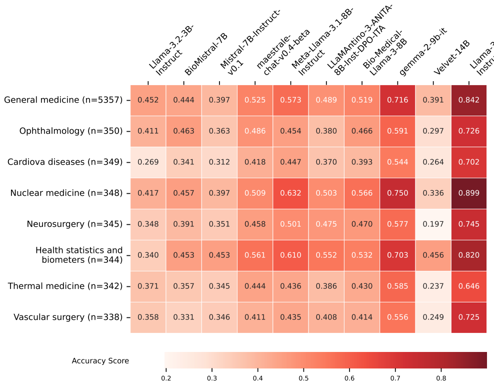

**Figure 6:** LLM benchmark on **IMB-MCQA**.

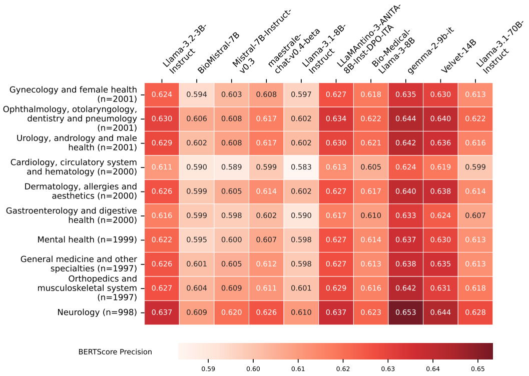

**Figure 7:** LLM benchmark on **IMB-QA**.

**Table 8**
Comparison between fine-tuned and non-fine-tuned models on **IMB-QA**.

| Model | Fine-Tuned | ROUGE-1 | ROUGE-2 | ROUGE-L | BLEU | METEOR | BERTScore P | BERTScore R | BERTScore F1 |
|---|---|---|---|---|---|---|---|---|---|
| Llama-3.2-1B-Instruct | Yes | 0.2857 | 0.0572 | 0.1998 | 0.0309 | 0.1682 | 0.7107 | 0.6860 | 0.6976 |
| | No | 0.2315 | 0.0445 | 0.1552 | 0.0148 | 0.2137 | 0.6186 | 0.6680 | 0.6423 |
| gemma-2-2b-it | Yes | 0.2673 | 0.0586 | 0.1890 | 0.0336 | 0.1617 | 0.7098 | 0.6775 | 0.6926 |
| | No | 0.2932 | 0.0511 | 0.1918 | 0.0228 | 0.2055 | 0.6783 | 0.6870 | 0.6821 |
| Llama-3.2-3B-Instruct | Yes | 0.2994 | 0.0642 | 0.1995 | 0.0424 | 0.1952 | 0.7031 | 0.6924 | 0.6972 |
| | No | 0.2523 | 0.0509 | 0.1607 | 0.0213 | 0.2310 | 0.6332 | 0.6830 | 0.6569 |
| Qwen2.5-1.5B-Instruct | Yes | 0.2628 | 0.0438 | 0.1761 | 0.0201 | 0.1571 | 0.7049 | 0.6859 | 0.6948 |
| | No | 0.1141 | 0.0180 | 0.0756 | 0.0103 | 0.1283 | 0.6021 | 0.6617 | 0.6302 |

with some showing performance drops in specific scores such as METEOR. This confirms that task adaptation improves answer quality and contextual understanding, even for compact models, making them well-suited for clinical applications.

## 6. Conclusion & Future Work

In this work, we introduced IMB, the first Italian dataset for medical question-answering, which includes both open-ended (QA) and multiple-choice (MCQA) questions. The dataset, sourced from medical forums and exam simulators, provides a valuable resource for the development of advanced NLP models. Our qualitative and quantitative analysis highlighted a diverse range of medical specialties, while also revealing challenges related to question difficulty and clinical complexity. Initial experiments with state-of-the-art language models demonstrated that these models struggle with clinically complex Italian questions but perform relatively well on multiple-choice questions. Future work will focus on expanding the dataset by incorporating additional medical specialties and languages (such as English), improving category balancing, and implementing advanced filtering techniques to reduce informational noise. Furthermore, we will explore strategies for adapting language models to improve their ability to understand and reason effectively about medical content.

**Limitations** **IMB** has several limitations, including an imbalance in specialty representation. Fields such as ”Gastroenterology” and ”Cardiology” are overrepresented, while others, such as ”Sleep Medicine” and ”Pediatric Surgery”, have limited coverage. This imbalance may affect model generalization. We will address this issue through data balancing techniques, such as oversampling and weighted training strategies. Another limitation arises from informational noise, as the questions were automatically collected from public sources, which may include irrelevant or ambiguous details. We plan to tackle this challenge by employing semantic filtering and human verification methods. Additionally, ambiguity in responses, particularly in the **IMB-MCQA** dataset, poses a challenge, which we aim to overcome through disambiguation techniques and more precise annotation strategies.

**Ethical and Legal Considerations** Our dataset has been developed using content sourced information from publicly accessible Italian medical sites (MedicItalia, Dica33) as well as a medical exam simulator (CompitoInClasse.org). The dataset is intended exclusively for academic research with non-commercial objectives, adhering to legal guidelines regarding GDPR compliance, data anonymization, and research-related copyright exemptions as outlined in Italian and EU legislation. To mitigate any legal and ethical challenges, and based on consultations with legal experts, we implemented several measures: **(1) Anonymization:** All identifying details (e.g. names, contact details, emails) were removed or altered with the help of automated scripts and LLM-supported redaction, conforming to GDPR's tenets of data minimization and protection. **(2) Textual Transformation:** While we provide links to the original source of each data sample, the raw questions and answers were linguistically restructured and polished, involving grammatical adjustments, simplification, and content refinement with the aid of LLMs and manual oversight. **(3) Scientific Scope:** This data serves strictly educational, illustrative, and scientific purposes as permitted under Article 89 of the GDPR and Article 70 of the Italian Copyright Law, which allows non-commercial research data usage under specified conditions. For this reason, the dataset is distributed under a *Creative Commons Attribution-NonCommercial-NoDerivatives 4.0 (CC BY-NC-ND 4.0)* license. This license strictly restricts usage to non-commercial research, prohibits redistribution of altered versions, and mandates proper author attribution.

## Acknowledgments

This work was conducted with the financial support of (1) the PNRR MUR project PE0000013-FAIR and (2) the Italian ministry of economic development, via the ICARUS (Intelligent Contract Automation for Rethinking User Services) project (CUP: B69J23000270005).

## Abstract

A cognitively plausible language model should (i) process language incrementally, (ii) be trained on naturalistic input, and (iii) mirror the developmental stages observed in child language acquisition. This study focuses on the third point by exploring the adherence of language models' developmental patterns to the predictions of two empirically grounded theories of syntactic acquisition, the Growing Trees and the Neo-Emergentist approaches. Using an evaluation method based on perplexity, we test whether small and medium Italian-tuned LMs (two small GPT2 LMs, GePpeTto, and Minerva-7B) show sensitivity to syntactic phenomena corresponding to three acquisitional stages documented in child Italian. Our results suggest that smaller open models only partially reflect the stagewise progression observed in children.

## Keywords

Language acquisition, LMs, syntax, cognitive plausibility

## 1. Introduction

State-of-the-art Large Language Models (LLMs) demonstrate remarkable success on various linguistic benchmarks ([1], *inter alia*). However, from a linguistic perspective, they remain uninteresting from the point of view of their cognitive plausibility. In fact, their architecture and learning dynamics differ fundamentally from those of human learners, raising doubts about their relevance to linguistic inquiry [2, 3].

Nonetheless, following [4], we argue that language modeling—despite often being overlooked in theoretical linguistics—can contribute meaningfully to linguistic inquiry, provided that certain conditions on the cognitive plausibility of the model are met.

A language model (LM) that aspires to linguistic cognitive plausibility should meet at least three key criteria. First, it should process linguistic input incrementally, reflecting the word-by-word, real-time parsing observed in human sentence production and comprehension [4]. Second, it should be exposed to naturalistic training input, approximating the kind and distribution of linguistic data encountered by human learners (PoS argument, [5]). Third—and this is the focus of the present study—it should reproduce the developmental trajectory observed in first language acquisition, where syntactic competence follows structured and empirically documented stages. In line with this, we investigate whether LMs exhibit cognitive plausibility with respect to syntax by examining whether they reflect insights from linguistic theory on how humans acquire and process syntactic knowledge.

We compare two prominent approaches to syntactic development: the Growing Trees approach (GT) [6] and the Neo-Emergentist approach (NE) [7]. We argue that explicit, theoretically informed, and empirically grounded theories of language acquisition can serve as effective testing grounds for the evaluation of linguistic plausibility of LMs.

We propose an effective method for evaluating the acquisition stages reflected in various (L)LMs by collecting their perplexity estimates for sentences corresponding to stages observed in typical Italian first language development [8]. For our set of experiments, we drew from both

GT and NE literature to identify 17 core phenomena, each represented by a prototypical structural pattern. To enrich the dataset, we introduced variations to these structures—e.g., changes in verbal class—resulting in a total of 89 subphenomena. For each subphenomenon, we generated 100 lexically neutral instances, yielding a comprehensive evaluation battery of 8,900 items. We tested three GPT2 small Italian LMs, ita-baseline-small and NeTS-3M [9, 10], GePpeTto—117M parameters [11]—and a larger one—Miverva-7B-base, 7B parameters [12]. Results show that Italian language models exhibit a stage-wise syntactic learning trajectory that aligns more closely with the GT approach, which proves more predictive than the NE framework. We conclude that while key asymmetries remain, models trained on a minimal amount of input consisting solely of child-directed speech (e.g., NeTS-3M) can approximate the developmental patterns observed in human language acquisition.

## 2. Poverty of Stimulus, LLMs, and language theories

A striking difference between LLMs and natural language acquisition lies in the quantity of training data needed to achieve adult competence. A robust cross-linguistic observation in first language acquisition is that children converge on the adult grammar within a remarkably short developmental window—by approximately age 4 to 6—regardless of the language they are exposed to [13, 14], and with limited exposure to primary linguistic data, as emphasized in the Poverty of Stimulus (PoS) argument [15].

However, the PoS argument has been recently challenged by scholars who argue that LLMs represent the most empirically grounded models of language currently available, and that core features of human linguistic competence (e.g., recursion, logical inference, and hierarchical syntactic structure) may emerge spontaneously in predictive models trained on unannotated language data [16, 17]. From this perspective, LLMs question the necessity of domain-specific innate mechanisms posited by Generative Grammar (GG), suggesting that rich linguistic generalizations may arise from data-driven statistical learning, given domain-general cognitive inductive biases embedded in the artificial neural network architecture [18].

However, the debate concerns not only whether LLMs exhibit linguistic capacities or the amount of data required, but also whether they can inform a theory that accounts for the cognitive underpinnings of natural language. The issue should be addressed from multiple perspectives: by developing fine-grained performance metrics, creating relevant tasks and benchmarks, paying attention to the amount of data, and considering model architectures that may embed relevant linguistic intuitions in the form of inductive biases [4].

Within a linguistic and cognitive perspective, the distinction between models and theories is well established and relevant to discussions about LLMs. [15] distinguishes models, tools for simulating or predicting linguistic data, from theories which, on the other hand, seek to explain underlying cognitive mechanisms. [19] similarly emphasizes that valid theories must provide mechanistic explanations rather than merely replicate behavior. More recently, [20] formalizes this distinction, describing models as devices for representing systems or testing specific hypotheses, whereas theories aim to provide explanatory frameworks to generalize across phenomena. They argue that during early theory development, when empirical testing is limited, plausibility—shaped by factors such as computational tractability and theoretical invariance—serves a critical criterion for advancing from models to theories. In sum, while LLMs demonstrate impressive empirical performance and offer valuable tools for exploring linguistic patterns, their fundamental differences from human cognition, limitations in capturing graded acceptability, and reliance on vast datasets, distinguish them from genuine linguistic theories. At present, LLMs function as tools for hypothesis testing rather than as explanatory accounts of language cognitive foundations.

In this context, we draw on two linguistic theories from the current literature to support the view that language learning by (L)LMs can be meaningfully assessed—and compared to child language acquisition—using precise linguistic criteria.

## 3. Theories of Language Acquisition

As already mentioned, children converge on adult grammar within a remarkably short time [13, 14]. While there can be (moderate) variability in the timing of acquisition in typically developing children, the developmental patterns are consistent across individuals, in two key respects. First, all children go through stages in which they make systematic, non-random errors—such as overproduction of computationally lighter structures with a smaller number of morphosyntactic elements [21], like uninflected verbs (infinitives [22, 23] and imperatives [24]; e.g., *Mangi-a!* 'Eat!, imperative' vs. *Mangi-a-v-ano* 'They ate', past imperfective).

Second, children produce and master certain sentence types before others, and—crucially—the order of acquisition appears to be consistent across learners: some children progress more rapidly than others, but all pass through the same developmental stages. This provides further evidence that the human language faculty constrains the hypothesis space available to learners. This study focuses on this second dimension of acquisition: the order in which different sentence types are acquired.

## 3.1. Comparing Competing Theories

We examine two prominent theories in the literature concerning the order in which syntactic structures are acquired by children. Both seek to answer the same core question (namely, which structures emerge earlier or later in child language), but they differ significantly in their empirical methodologies and theoretical assumptions, leading to divergent predictions that remain under active investigation. Given the ongoing nature of this debate, we consider both approaches in our analysis, without prematurely excluding either.

## 3.2. Growing Trees Approach

The GT approach takes the syntactic tree—a symbolic and highly formalized representation of sentence structure—as its central object of study. Syntactic trees capture the hierarchical relationships among constituents, making explicit distinctions that are not evident in surface word order, and are therefore indispensable for modeling core properties of natural language.

The GT hypothesis proposes that syntactic development unfolds in a layered fashion, reflecting the gradual availability of different regions of the tree. Initially, only low structural domains, such as the verb phrase (vP) and inflectional phrase (IP), are accessible to the child, allowing for simple subject–verb sentences, for instance. Subsequently, portions of the so-called Left Periphery [? 25], a high functional layer, become available, supporting the production of wh-questions and preposed adverbs. Only later does the full functional spine, including higher CP-level structures like embedded clauses, relatives, and "why"-questions, become active. The GT model builds upon earlier maturational analyses introduced in the 1990s, notably [26], and further developed in subsequent work (see [6, 27]). In a cognitively plausible model, one would expect to observe a learning trajectory mirroring that of human acquirers, in which early-acquired structures (e.g., simple S–V sentences) are mastered before later-acquired ones (e.g., embedded clauses).

Traditional metrics for assessing language development, such as Mean Length of Utterance in words (MLUw) alone or average age of acquisition across child samples, have limited explanatory power due to the documented high degree of individual variability in acquisition speed [6]. In other words, some children are faster than others, but all of them follow the same developmental path, in that they all acquire various syntactic structures in the same order.

Empirical studies across multiple languages have shown that acquisition proceeds in structural bursts or "explosions": at a given point, an entire syntactic domain (e.g., the vP+TP layer) becomes accessible, and all structures associated with that domain become available to the child. Crucially, within these domains, there is no robust evidence for a fixed internal acquisition order, suggesting that what is developmentally primary is the availability of the domain itself, not the sequential mastery of its substructures. These domains are straightforwardly captured by the detailed cartographic structure of the functional spine as it has been drawn by theoretical linguists over the past 30 years [28, 25].

While the foundational empirical work focused on Hebrew, the GT framework has since been extended to other languages throught both experimental and corpus-based studies, including Italian [29, 30, 31], English [32], and others [27].

## 3.3. Neo-Emergentist Approach

The Neo-Emergentis approach [7, 33, 34] to language acquisition departs radically from both traditional nativist and certain usage-based models. This approach is theoretically motivated to a maximally impoverished Universal Grammar (UG), in line with Chomskyan "Three Factors" [35]. Rather than positing rich, innate linguistic content (Factor 1), this model shifts explanatory weight onto the interaction between primary linguistic data (PLD; Factor 2) and general cognitive learning principles (Factor 3), thereby advancing a minimalist conception of UG.

The central claim is that syntactic categories are not innately specified but are emergent, and that acquisition proceeds along a learning path where coarser-grained categories are acquired before finer-grained refinements. This involves a successive division algorithm, where the child initially makes basic contrasts (such as predicate/argument) followed by more fine-grained subdivision (identifying discourse and thematic domain up to cartographically defined syntactic distinctions). Data from Catalan, Spanish, Italian, German, and Dutch [33] suggests that basic CP structures (such as wh-questions, V2 word order, illocutionary complementisers, and topicalisation) emerge at early developmental stages (defined in terms of MLUw), challenging models that assume a fixed, innately specified hierarchy of syntactic categories [6, 26, 36]. In contrast, finer-grained structures (e.g. recursive topics, multiple left-peripheral elements, V3 orders) seem to appear only later (around or after MLUw 2.5). Crucially, building on the Peripheral Speaker-Hearer Hypothesis (PSHH), which posits that speaker-hearer perspective is formally encoded at the edges of phasal domains [37], NE model predicts that here-and-now and speaker-hearer-oriented material functions as key bootstrapping heuristics in acquisition, and therefore they are expected to be

**Table 1**
Stage development predictions of the two approaches. A question mark indicates that no clear prediction is available in the relevant literature (i.e., the stage is unknown). For the full ATTracTSS-IT dataset, which includes glosses of these examples and additional sentence subtypes, see Appendix A.

| ID | Sentence Type | GT | NE | Example (Italian) |
|---|---|---|---|---|
| i | SV simple | 1 | 1 | Alessandro telefona. |
| ii | SV unaccusative | 1 | 1 | Luigi sale. |
| iii | VS unaccusative | 1 | 1 | Arriva Matteo. |
| iv | Imperatives | 1 | 1 | Corri! |
| v | Modals | 1 | ? | Il babbo vuole saltare. |
| vi | Root wh-questions | 2 | 1 | Chi annaffia i fiori? |
| vii | Root yes/no questions | 2 | 1 | Ha mangiato la mela? |
| viii | Preposed Adverbs | 2 | 1 | Raramente Giorgio dorme. |
| ix | Focus | 2 | ? | No, l’uccellino salutano i bambini! |
| x | Illocutionary COMPs | 3 | 1 | Che brutto! |
| xi | Why questions | 3 | 2 | Perché il bambino piange? |
| xii | Topics | 3 | 2 | Il cavallo, la bambina lo lava. |
| xiii | Embedded that | 3 | 2 | Il cavallo vede che la mucca beve l’acqua. |
| xiv | Embedded if | 3 | 2 | Non so se Luca verrà al mare. |
| xv | Subject Relative | 3 | 2 | Il bambino che gioca con la mamma. |
| xvi | Object Relative − intervener | 3 | 2 | Il ragazzo che loro abbracciano. |
| xvii | Object Relative + intervener | 4 | ? | Il ragazzo che la nonna abbraccia. |

acquired early. This point is particularly relevant when modeling the developmental trajectory of a language model, whose training, by definition, lacks access to referential stimuli such as here-and-now context (cf. the symbol grounding problem [38]).

## 3.4. Predictions

Under a NE view, the timing and trajectory of syntactic acquisition are governed by the complexity of formal features involved, rather than its fixed hierarchical position in the functional spine. More specifically, if the GT predicts that Topics (pertaining to Stage 3) are acquired later than wh-questions (pertaining to Stage 2), by virtue of their structural height; from a NE point of view, this depends on the featural specification of these elements [34]: for example, yes/no questions are expected to be early-acquired CP structures due to their low formal complexity and learnability via generalization from minimal cues, whereas according to the GT they are expected to arise in Stage 2.

Under the NE view, the macrocategories C, T, and V are assumed to be available from the onset. In contrast, the GT approach posits that only V and T are initially available (Stage 1), with C-related projections emerging at later stages.

Despite being grounded in empirical studies, the two approaches yield diverging predictions about the order of acquisition. This divergence stems also from how particular structures are analyzed. For instance, whether a given construction involves movement to C or remains within the TP layer is often a matter of theoretical interpretation, and currently under scrutiny.

# 4. Experimental Evidence

## 4.1. Methods

To test LMs against the developmental predictions of both NE and GT frameworks, we defined a problem space designed to capture the full range of potential developmental trajectories a LM might exhibit. Using a test set (c.f. next subsection) that targets structurally rich constructions attested at various stages of acquisition, we expect a coherent model (i) to be sensitive to syntactic variations and similarities across different sentence types and to assign probabilities accordingly, and (ii) to align with one of the two developmental hypotheses by assigning higher perplexity scores to items corresponding to later stages of acquisition. To obtain perplexity measures and standard errors, we used the lm-evaluation-harness platform [39] and created a custom task consisting of 100 lexically irrelevant variations of the syntactic patterns presented in Table 1 and further detailed in Appendix A. Items were grouped into three stages to reflect the finer-grained distinctions predicted by the GT framework. If no difference is found between Stage 1 and Stage 2, then the LM behavior is consistent with NE approach. Otherwise, if a distinction emerges, this is in line with GT predictions.

## 4.2. ATTracTSS: A Novel Dataset

The novel test set we created for evaluating the Acquisition Trajectories of various LMs in Terms of Syntactic Structures is dubbed ATTracTSS. The dataset consists of grammatical sentences representing 17 prototypical syntactic constructions—here referred to as sentence types (e.g., simple SV sentences, wh-questions, topicalizations, embedded clauses)—and 100 lexically diverse items generated for each sentence type.

We built our dataset based on the phenomena tested by GT and NE. Notably, NE does not provide an explicit list of the specific sentence types it predicts to emerge in a fixed acquisitional order. Therefore, we adapted GT's classification to the NE framework where possible, deriving stage-based predictions for both hypotheses Table 1. In cases where alignment was not possible, we assigned the label *unknown.*

## 4.3. Implementation

We carry out a perplexity analysis starting from the negative log probabilities assigned by the model to each sentence in the dataset. Perplexity levels are expected to inversely correlate with learnability. Perplexity measures how well a model predicts a given sentence. Lower perplexity means the model finds the sentence more predictable (less surprising), while higher perplexity means the model finds it less predictable (more surprising). Given the 100 repetitions of the same syntactic skeleton, we assume that averaging over multiple lexicalizations reduces the impact of individual word-level frequency effects on model perplexity.

At stage level, our hypothesis is that different acquisition stages would be characterized not only by different mean perplexity values, but also by similar standard deviations (SD), indicating consistent model confidence within each stage. As for sentence types, if perplexity remains consistently low across lexical variants of a sentence type, and the variation is low, we interpret this as evidence that the model handles the structure with a degree of robustness and consistency, suggesting it has learned to generalize over that syntactic pattern. While this should not be taken to imply that the model has acquired the structure in a human-like or abstract sense, such behavior can nonetheless serve as a useful proxy for comparison with human acquisition data.

Four models were tested: ita-baseline-small—the pretrained GPT2 baseline model for Italian shared by the BabyLM Community in the HuggingFace platform [10], NeTS-3M—a similar small GPT2 model trained on a custom 3M corpus of child-directed speech [40] —, GePpeTto—117M parameters [11]—and a larger model, Miverva-7B-base, 7B parameters [12]. For the NeTS-3M model we also implemented a longitudinal tracking by repeating the log-probability analysis across multiple training epochs, in order to trace whether the model's familiarization path mirrors human developmental patterns. The same type of analysis could not be carry out on the other models due to the impossibility to carefully control their training.

## 4.4. Results

Mean perplexity and SD values for each stage in GT and NE were derived from negative log probability values that the four models assigned to each of the items in the dataset, as reported in Table 2 (GT) and Table 3 (NE). Despite numerical differences, perplexity tends to increase coherently with the stage progression in all LMs; SD, instead, tends to grow higher in the latest stages of both GT (Stage 3) and NE (Stage 2), suggesting higher variation within them.

Then, a series of linear regressions were run to assess whether negative log probability assignment is significantly predicted across models (i) by the different syntactic structures of the sentence types included in the dataset, and most importantly (ii) by the articulation in stages proposed by GT and/or by NE. Random intercepts for length (i.e, number of words in each item in the dataset) were included in all regressions. Likelihood ratio tests (ANOVA) between a null model and a model using sentence types as fixed effect revealed that these significantly improved model fit in all LMs (ita-baseline-small: $\chi^2(65) = 2622.7$, $p < .0001$; NeTS-3M: $\chi^2(65) = 2953.7$, $p < .0001$; GePpeTto: $\chi^2(65) = 2925.3$, $p < .0001$; Minerva: $\chi^2(65) = 3095.7$, $p < .0001$). As for GT and NE, instead, similar tests outputted a sharp asymmetry in the predictive power of the two accounts. Treating GT's three-stage articulation as fixed factor significantly improved model fit (ita-baseline-small: $\chi^2(2) = 10.633$, $p < .00491$; NeTS-3M: $\chi^2(2) = 376.68$, $p < .0001$; GePpeTto: $\chi^2(2) = 9.1605$, $p < .0001$; Minerva: $\chi^2(2) = 35.5$, $p < .0001$), but the same did not apply to NE's stages (p values >.05 for all LMs). Note however that except for NeTS-3M, where all pairwise comparisons between stages reach significance, contrasts between Stage 2 and 3 and Stage 1 and 3 strongly vary across LMs (see Appendix B), with Stage 3 being the least stable of the three. For the detailed longitudinal results of the NETS-3M model, see Appendix C.

## 4.5. Discussion

The experiments reported in the previous sections were conducted to address the issue of language development in LMs, i.e., to assess whether the way LMs "learn" their language may be compared to the process of natural language acquisition in children. Specifically, we compared

**Table 2**
Mean perplexity estimation and SD grouped by GT stages.

| Stages GT | Perplexity (SD) | Models |
|---|---|---|
| Overall | 42.1788 (13.28) | ita-baseline-small |
| | 50.0302 (16.29) | NeTS-3M |

the stage-wise developmental predictions of two competing theories, GT and NE, against the performance of some Italian LMs. We did that by looking at perplexity associated to a varied set of sentences in a novel dataset (ATTracTSS test set) both in a cross-sectional perspective, looking at four different Italian models (ita-baseline-small, NeTS-3M, GePpeTto, Minerva), and in a longitudinal perspective, focusing on the performance of one of these models (NeTS-3M) across training epochs.

As for the cross-sectional study, we observed a general alignment of all our LMs with the linguistic development observed in children. Perplexity values tended to grow with the progression of stages in both GT and NE, suggesting that the syntactic structures that children struggle with the most—and therefore take longer to be acquired—roughly overlap with the sentence types that LMs find less predictable. Nevertheless, closer inspection of mean perplexity values per sentence type revealed some variation within the stages, especially in GT 3 and NE 2: some late structures for children, like why-questions, receive very low perplexity from all models (~30), while Stage 1 transitive clauses are assigned higher-than expected perplexity (~52). These observation suggest that caution is needed when comparing humans and LMs, and while the general learning trend aligns with human acquisition, some important asymmetries remain.

Moreover, and as a general consideration, our results show consistently higher perplexity if compared to standard benchmarks (e.g., ~20 perplexity for GPT-3 [41]). This may stem from the absence of licensing contexts in the test items, or suggest that the models resolve, for instance, certain non-local dependencies—especially those in the Left Periphery—via strategies that diverge from native-like structural processing. Also, this suggests that our assessment task is far from trivial and highlights the need for further exploration of training regimens to determine whether specific language models exhibit learning trajectories consistent with those observed in human language acquisition.

Another interesting result concerns the difference in the predictive power of GT and NE with respect to LMs performance. While the single structure types always qualify as good predictors for LMs perplexity, ratifying some sort of syntactic representation abilities, grouping the phenomena into the three-stage articulation of GT always returns better results than the coarser two-stage subdivision of NE. This pattern holds both across models, and in the longitudinal evaluation across training epochs of NeTS-3M, a small-scale transformer trained on 3M tokens of child-directed speech. Even though proposed on independent grounds, then, the linguistic stages grounded in the GT framework may offer a useful lens for interpreting LM behavior, especially in cognitively oriented settings.

Finally, two more relevant considerations may be drawn especially from the epoch-by-epoch analysis, which we could performed on NeTS-3M, the only model we could strictly control for architecture, training regimen and training set (a 3M token corpus, including child-directed speech only, [40], see Appendix C).

First, the model shows evidence of learning, gradually reducing the perplexity gap between items from GT Stage 2 and Stage 3, although these stages remain distinguishable. However, and in line with the results of pairwise comparisons between Stages across models, the most pronounced distinction for the model clearly lies between Stage 1 and Stage 2.

Second, our findings suggest that minimal (3M tokens of NeTS-3M vs. $\geq$ 10M tokens of the other LMs) but curated input allows a transformer model to approximate early, mid, and late stages of language acquisition, in line with empirically attested developmental pattern of a linguistic theory (the GT approach): this is confirmed not only by general the snapshot of perplexity estimation across stages, where NeTS-3M is the only LM strongly differentiating Stage 1, 2 and 3, but crucially also along training epochs simulating child linguistic development.

## 5. Concluding remarks

In this paper we presented ATTracTSS, a novel dataset to assess the Acquisition Trajectories in Terms of Syntactic Structures inspired by language acquisition studies and by two competing empirically-grounded theories—the Growing Trees approach and the Neo-Emergentist framework. Both theories argue for a stage-wise acquisition of syntax in children, but crucially differ in the size and internal composition of these stages.

We conducted out-of-the-box evaluations on three "small" language models (124M parameters)—the pretrained GPT2 baseline model for Italian shared by the BabyLM, ita-baseline-small; NeTS-3M, a similar small GPT2 model trained on a custom 3M corpus; GePpeTto, 117M parameters—and a larger model, Miverva-7B-base, 7B parameters. We measured the perplexity that these LMs assigned to each sentence in the test set and compared them against the three-stage predictions of GT and the two-stage articulation of NE.

In our experimental results, we observe that small-scale, fully open Italian-tuned models show alignment with theories of language acquisition. Among the theoretical approaches tested, the GT-based stage theory yields more accurate predictions than the NE-based approach. This work demonstrates the benefits of a sufficiently rich grammatical theory in order to account for how language acquisition unravels in children, and how this developmental trajectory can serve as a metric to compare natural, instinct-driven acquisition in humans with the learning processes of LMs. In children, acquisition proceeds incrementally, through identifiable phases or stages. A robust theory is necessary to explicitly determine which linguistic phenomena emerge at which stage, in a principled and non-impressionistic way. Such reflection is crucial for linguists, but it may also have broader practical implications, particularly with respect to the sustainability and optimization of model training. Focusing on child language acquisition, and especially on the stages through which it unfolds, offers an additional, more fine-grained metric for evaluating model competence and cognitive plausibility. In this work, we did not address the notion of cognitive coherence, which we consider too general; instead, we focus on strictly linguistic issues and discuss structural coherence with respect to native speaker intuitions—where structural refers specifically to syntactic structures, i.e., sentence types.

This ultimately frames the core tension in terms of *learning* versus *acquisition.*

## 6. Limitations

Although our aim was to assess acquisition stages also across different training regimens—naturalistic, conversational, or redundant [5] using small-scale corpora (10–100M tokens), we could only test the NeTS-3M model under the redundant regimen, trained on a 3M-token corpus of Italian child-directed speech [40]. This is below the 10M-token BabyLM small track threshold [10]. While minimal, this amount approximates the linguistic input received by a 4-year-old child—who has typically acquired structures across all three developmental stages [42]—though an additional million tokens would have brought the exposure closer to that developmental window.

Moreover, the model architecture—GPT-2 (see model card [43])—is not cognitively plausible, as it relies on a non-incremental, parallel attention mechanism that does not reflect human-like structure-building [2, 5].

A further limitation is that the dataset is not fully balanced in terms of the number of phenomena per item; future iterations will aim to expand the dataset and ensure more uniform distribution across phenomena (see the material in the Appendix A).

Finally, although we draw on attested acquisition patterns from Growing Trees and Neo-Emergentism, we lack adult acceptability data for the same structures. Such data will be essential in future studies to assess whether model outputs at later training stages simulate adult linguistic competence.

## B. Pairwise Comparisons

This appendix reports the results of pairwise statistical comparisons between the estimated probabilities associated with each GT stage. See Table 4.

## C. NeTS-3M Model Results Across Epochs

This appendix reports the results of the NeTS-3M Model across epochs, see Table 5. We show performance over 10 training epochs, with predictions evaluated by linguistic phenomenon, GT approach, and NE approach. Table 5 reports perplexity (derived from -log(probability), where higher values indicate greater model uncertainty) and $\chi^2$ values (where higher values reflect stronger model predictions).

**Table 4**
Pairwise comparisons between estimated probabilities of GT Stages.

| Models | Contrast | Est | SE | *p* value |
|---|---|---|---|---|
| ita-baseline-small | Stage 1 vs. Stage 2 | 0.818 | 0.270 | .007 |
| | Stage 2 vs. Stage 3 | -0.048 | 0.367 | .991 |
| | Stage 1 vs. Stage 3 | -0.866 | 0.377 | .056 |
| NeTS-3M | Stage 1 vs. Stage 2 | 6.710 | 0.341 | <.001 |
| | Stage 2 vs. Stage 3 | 2.800 | 0.464 | <.001 |
| | Stage 1 vs. Stage 3 | 3.910 | 0.476 | <.001 |
| GePpeTto | Stage 1 vs. Stage 2 | 0.481 | 0.189 | .029 |
| | Stage 2 vs. Stage 3 | -0.180 | 0.257 | .762 |
| | Stage 1 vs. Stage 3 | -0.661 | 0.263 | .032 |
| Minerva | Stage 1 vs. Stage 2 | -0.934 | 0.188 | <.001 |
| | Stage 2 vs. Stage 3 | -1.215 | 0.255 | <.001 |
| | Stage 1 vs. Stage 3 | -0.281 | 0.262 | .532 |

**Table 5**
Performance of the NeTS-3M model over 10 training epochs. Deeper green indicates better performance.

| | **Average Perplexity: -log(prob)** | | | | **Linear Mixed Effects fitted Models** | | | | | |

# Context-Aware Search Space Adaptation of Hyperparameters and Architectures for AutoML in Text Classification

Parisa Safikhani[1,2,*], David Broneske[1]

[1]The German Centre for Higher Education Research and Science Studies (DZHW), Germany
[2]Otto von Guericke University, Germany

**Abstract**

While Automated Machine Learning (AutoML) systems have shown strong performance on structured data, their application to natural language processing (NLP) tasks remains limited by static, task-agnostic search spaces. In this work, we propose a context-aware extension of AutoPyTorch that dynamically adapts both the hyperparameter search space and neural architecture configuration based on corpus-level meta-features. Our approach extracts interpretable textual statistics—such as average sequence length, vocabulary richness, and class imbalance—to guide the configuration of key hyperparameters. We also introduce two adaptive neural backbones, whose structures are shaped by these meta-features to improve model expressiveness and generalization. Experiments on 20 diverse text classification datasets—including subsets of GLUE, selected Kaggle benchmarks, and private corpora—demonstrate consistent performance improvements over strong baselines, particularly on datasets with limited training samples or severe class imbalance. Our results highlight the effectiveness of integrating dataset-level insights into the AutoML search process for NLP.

AutoML, Text Classification, Hyperparameter Optimization, Meta-Features, Neural Architecture Search, Context-Aware Modeling, AutoPyTorch

## 1. Introduction

AutoML frameworks have significantly advanced the democratization of machine learning by automating the design and optimization of learning pipelines. While these systems have shown strong performance on structured data, their extension to NLP tasks remains limited due to the inherent complexity and diversity of textual data. Text classification, a core NLP task, presents unique challenges stemming from variable input lengths, diverse syntactic structures, and high lexical variation—factors that are often overlooked in conventional AutoML workflows.

Most current AutoML approaches for NLP adopt static pipeline configurations and search spaces, treating all datasets uniformly regardless of their linguistic characteristics. Even when modern frameworks include neural networks or transformer models, their hyperparameter search is usually performed within generic, manually designed boundaries. This static design neglects crucial dataset-specific properties such as text length distribution, vocabulary richness, or class imbalance, which are known to affect both model architecture performance and training dynamics [1, 2]. As a result, these frameworks may perform poorly on unusual or domain-specific text datasets, where generic configurations fail to address context-specific requirements.

To address this gap, we propose a context-aware extension of an AutoML Framework that dynamically adapts its hyperparameter search space and model architecture decisions based on corpus-level meta-features. Our approach integrates a systematic extraction of statistical and linguistic characteristics from each dataset—such as text length variability, lexical diversity, sample size, and class distribution—and uses these to inform both the configuration of search spaces and the structural design of neural backbones. By leveraging these insights, the system can better align model complexity, optimization schedules, and architectural choices with the demands of the data.

This paper makes two main contributions: First, we introduce a context-aware mechanism for dynamically adapting the hyperparameter search space in AutoML based on text-level meta-features such as text length, vocabulary diversity, and class imbalance. This enables the AutoML process to tailor its optimization bounds—e.g., for batch size, learning rate, and dropout—according to the statistical profile of each dataset. Second, we propose two adaptive neural backbones, *MetaMLP* and *ContextualAttentionNet*, whose configurations are shaped by statistical and lexical characteristics of the input text. These

backbones enable the system to construct models from scratch that better reflect the structural and distributional properties of the data. Together, these innovations facilitate a more robust and efficient adaptation of AutoML pipelines to the unique demands of text classification tasks.

## 2. Related Works

Automated Machine Learning (AutoML) aims to streamline model development by automating the processes of feature engineering, model selection, and hyperparameter tuning. While AutoML has become widely successful for structured data, its adaptation to natural language processing (NLP) tasks, particularly text classification, poses unique challenges due to the complexity and diversity of textual data. In this section, we review existing research relevant to AutoML applications in NLP, focusing on the limitations of current AutoML frameworks, the role of dataset-driven meta-features, and recent developments in customizing both hyperparameter search spaces and neural architectures specifically tailored to text data.

### 2.1. AutoML for NLP Tasks and Search Space Design

Automated machine learning (AutoML) has traditionally excelled on structured (tabular) data, whereas applying it to raw text required additional effort to convert text into features [2]. In recent years, several AutoML frameworks have been extended to handle text classification, integrating NLP-specific models and pipeline steps. For example, AutoGluon and AutoKeras can handle deep NLP models (including modern transformers) for classification, with search spaces that encompass state-of-the-art architectures like BERT and RoBERTa [3, 4]. AutoKeras even adjusts its search space based on the task modality: it detects when the input is text and accordingly includes appropriate text vectorization and neural network blocks in the configuration space [3]. Cloud-based AutoML services such as Azure AutoML typically treat text as generic input features (e.g., via TF-IDF or bag-of-words) and do not customize hyperparameter settings based on dataset-specific characteristics [5].

Notably, researchers have evaluated general AutoML tools on NLP tasks by converting text to fixed embeddings (e.g. using Sentence-BERT to obtain features) to fit into a tabular AutoML pipeline [6, 7, 8]. These tools can discover effective models for text data, but they typically operate within broad, fixed search spaces and often lack mechanisms for fine-grained hyperparameter tuning tailored to a specific corpus. In other words, current AutoML frameworks for NLP tend to follow a one-size-fits-all approach, leaving potential efficiency gains from dataset-specific adaptation largely untapped. Moreover, they rely on selecting from existing machine learning or neural network architectures, rather than dynamically constructing models based on the unique characteristics of the textual data.

### 2.2. Meta-Features and Meta-Learning for AutoML in NLP

To guide model selection and hyperparameter optimization, many studies have leveraged dataset characteristics (so-called meta-features). Early work by Lam and Lai [1] characterized text datasets with a small set of features (e.g., number of documents, vocabulary size, average document length) to predict the classification error of different algorithms, thus recommending the best classifier for the task. This pioneering meta-learning approach demonstrated that simple corpus-level metrics can inform algorithm selection. Subsequent research greatly expanded the repertoire of meta-features for NLP. For instance, Madrid et al. [2] define 72 corpus-level attributes – covering general dataset properties, class imbalance, lexical diversity, stylometry, statistical measures, and readability indices – to drive automated selection of text representation techniques. Many of these features capture precisely the kind of information used in our approach for another goal, which is automatic customization of the search space and not a text representation method, such as average and standard deviation of document length, vocabulary richness (unique word ratios), number of classes, and so on. By extracting such meta-features from a new text dataset, one can compare them to previously seen tasks and infer which models or hyperparameter settings might be appropriate. Researchers have applied meta-features in various meta-learning systems for NLP. Gomez et al. [9] introduced an evolutionary meta-learning method (ELMR) that uses 11 statistical meta-features of a text corpus to evolve rules for selecting the optimal classifier. Their approach automatically learned decision rules (via a genetic algorithm) to identify, for example, when a Naïve Bayes vs. SVM vs. neural model would be most effective, based on corpus characteristics. In a broader approach, Ferreira and Brazdil [10] leveraged an active testing strategy to recommend full text-classification pipelines, evaluating candidate preprocessing methods and classifiers on small data samples and using meta-features to pick the best pipeline. Meta-learning has also been used to warm-start hyperparameter optimization in general AutoML frameworks. Ferreira and Brazdil [10] successfully employed 46 dataset descriptors to initialize Bayesian hyperparameter search in Auto-Sklearn, improving efficiency by starting from configurations that worked well on similar prior datasets. More recently, Desai et al. [11] built a text AutoML system that uses a minimal set of only three meta-features (e.g. dataset size, average sentence length) to choose among three Transformer architectures (BERT, ALBERT, XLNet) for a classification task. Despite its limited scope (restricted to only a few models), this work demonstrated the promise of corpus features in guiding model selection for NLP. Our approach extends these concepts further by integrating a set of corpus-level characteristics to dynamically guide not only architecture selection but also hyperparameter tuning within AutoPyTorch, leveraging its capability to construct neural networks from scratch, which is essential for effectively handling the diverse and complex nature of textual data.

In summary, prior research shows that incorporating dataset-derived features, ranging from simple counts to complex linguistic metrics, can significantly enhance automated model selection and configuration in NLP. However, these approaches predominantly focus on selecting among predefined models or representations. To the best of our knowledge, this work is the first to dynamically adjust the hyperparameter search space itself based on dataset-derived meta-knowledge, specifically aimed at constructing deep learning models from scratch.

## 2.3. Hyperparameter Search Space Adaptation in AutoML

Typical AutoML systems rely on a fixed, expert-designed search space intended to be generic across many datasets. For example, Auto-WEKA formalized the Combined Algorithm Selection and Hyperparameter optimization (CASH) problem—searching over a joint space of 27 base classifiers, their respective hyperparameters, and various feature-selection techniques—using Bayesian optimization to navigate hundreds of parameters without dataset-specific specialization [12]. Auto-Sklearn similarly constructs a broad configuration space of 15 classifier types and over 110 hyperparameters (spanning preprocessing and classifiers) yet remains agnostic to the particular characteristics of the input data [13]. While such comprehensive spaces can cover many scenarios, they are often inefficient: many configurations may be irrelevant or suboptimal for a particular text dataset. For instance, a small set of short tweets likely does not require deep ensembles or large n-gram ranges, yet a static search space devotes trials indiscriminately to these options. This inefficiency has motivated research into reducing or tuning the search space based on prior knowledge.

One line of work is search space transfer via meta-learning. Wistuba et al. [14] first proposed to leverage experience from previous hyperparameter optimizations to constrain the search for a new task. In their approach, the hyperparameter space is narrowed to a region (defined by a center point and radius) believed to contain good solutions, effectively pruning away less promising regions. They explored designing a smaller, task-specific search space for the target problem instead of using the default full space. By transferring knowledge of what configurations worked well on similar datasets, these methods aim to accelerate HPO by focusing on the most relevant parts of the space. Such techniques have shown benefits in general AutoML settings, reducing the dimensionality or bounds of hyperparameters to improve search efficiency. However, applying this idea in the NLP domain remains relatively unexplored – current AutoML tools do not automatically adjust fundamental hyperparameter ranges (e.g. maximum vocabulary size, network depth, learning rate schedules) based on text-specific data characteristics. The search space is usually defined a priori (often by human experts) and stays fixed regardless of whether the text data consists of tweets or pages of encyclopedia, or whether the vocabulary is 500 words or 50,000 words.

Recently, a few nascent approaches have hinted at the potential of dataset-driven search space adaptation. Notably, Zero-Shot AutoML techniques combine meta-learning with model selection to configure pipelines without any trial-and-error on the new data. For example, the ZAP framework by Öztürk et al. [15] attempts to directly select a pretrained model and its fine-tuning hyperparameters for a new dataset in a zero-shot manner. ZAP trains a meta-model on a large collection of prior tasks, using only trivial meta-features of each dataset (such as image resolution or the number of classes) to predict the best pipeline. In their vision domain experiments, this approach could successfully pick an appropriate model and hyperparameter configuration without searching, underscoring that even coarse dataset descriptors can be informative for hyperparameter decisions. This idea is very much in line with our goal of text-aware search space customization. However, aside from such cutting-edge research prototypes, mainstream AutoML for NLP still lacks the capability to dynamically tailor the hyperparameter search space based on the dataset.

## 2.4. Text-Oriented Architecture Search & Pruning

Recent research in AutoML for NLP has focused on tailoring neural architectures to the needs of text data. Neural Architecture Search (NAS) techniques, when specialized for textual tasks, have proven effective in discovering model structures that outperform generic designs. For example, Wang et al. [16] propose TextNAS, a search space explicitly designed for text representation, and show that automatically discovered architectures can surpass manually crafted networks on sentiment analysis and inference tasks. These results highlight that text-specific search spaces – incorporating layers like CNNs or RNNs suited to sequence data – can yield state-of-the-art performance where off-the-shelf image-inspired architectures falter. In parallel, the emergence of large pre-trained language models has motivated architecture pruning and adaptation strategies. Rather than treat one model size as fit-for-all, researchers leverage NAS to compress or select architectures appropriate for a given task's resource constraints. For instance, NAS-BERT uses neural architecture search to automatically prune BERT, producing a family of smaller models that retain accuracy across tasks while meeting various latency or memory requirements [17]. Collectively, these efforts underscore that architecture-level customization is crucial for optimizing NLP pipelines. By adjusting neural backbones to text characteristics (lengthy inputs, specialty domains, etc.), NAS and pruning approaches lay the foundation for more adaptive AutoML solutions.

While significant advances have been made in both meta-feature-driven hyperparameter tuning and architecture-level customization (NAS/pruning), these areas have evolved somewhat separately. To date, there remains an absence of integrated methods that dynamically combine architecture selection with hyperparameter optimization based on explicit text dataset characteristics. Our paper directly addresses this gap by introducing a unified framework within AutoPyTorch that adapts both model architectures and hyperparameter configurations based on corpus-specific meta-features. This approach ensures that every component of the AutoML pipeline—from model structure to training parameters—is tailored specifically for the dataset at hand, leading to a more efficient and robust text-classification solution.

# 3. Methodology

Our objective is to enhance the adaptability and performance of AutoML systems for text classification by dynamically customizing both the hyperparameter search space and neural architectures based on intrinsic properties of the input dataset. We implement this within the AutoPyTorch framework, which offers modular extensibility, fine-grained pipeline control, and full support for deep learning models constructed from scratch. This flexibility is especially valuable for textual data, where architectural decisions—such as incorporating attention mechanisms or shaping MLPs—must align with dataset-specific traits like sequence length, lexical diversity, and class imbalance [18, 19].

Unlike other AutoML frameworks that rely on fixed pipelines or pre-trained models, our approach enables the construction of neural architectures that are directly informed by corpus-level characteristics. Prior work has shown that such dynamic, data-driven architecture generation leads to better generalization and improved performance, particularly in heterogeneous or domain-specific scenarios [20, 21]. These findings motivate our design of a context-aware adaptation mechanism that leverages meta-features to steer both model configuration and training strategy during the AutoML search, effectively bridging the gap between static AutoML systems and the flexible demands of NLP tasks.

## 3.1. Text-Level Meta-Feature Extraction

To support both hyperparameter configuration and model architecture design (e.g., number of neurons and layers), we extract a comprehensive set of text-level meta-features using an enhanced analysis function. These include:

### 3.1.1. Text Length

Text length is a critical meta-feature in NLP that impacts both architecture selection and hyperparameter configuration. Short texts (e.g., fewer than 10 tokens) lack sufficient semantic context, leading to poor model performance, as shown in McCartney et al. [22]. Conversely, very long texts exceed transformer input limits (e.g., 512 tokens in BERT) and require either truncation or specialized architectures such as Hierarchical Attention Networks (HAN) [23] or Longformer [24].

To address these issues, we compute the average and standard deviation of text length at the corpus level and incorporate them into multiple stages of the AutoML pipeline. Specifically, long average sequence lengths trigger smaller batch sizes (e.g., 8–16 for texts >300 characters), shorter warm-up periods in cosine annealing schedules, and reduced learning rates to stabilize training. Additionally, we adapt the architectural shape of candidate MLP backbones: datasets with long inputs receive "long funnel" configurations to compress high-dimensional sequences, while very short texts invoke compact "diamond" shapes to avoid overfitting. High variance in length distribution increases regularization (via dropout) to ensure generalization across variable-length inputs.

This integration ensures that the AutoML system dynamically aligns model complexity and optimization behavior with the distributional characteristics of the input text, improving both efficiency and robustness in the search process.

### 3.1.2. Vocabulary Richness and Lexical Diversity

Vocabulary richness—commonly measured using the type-token ratio (TTR) or corpus-level approximations such as the unique-to-total word ratio—reflects the semantic complexity of a text corpus. Higher lexical diversity increases the dimensionality of the input space and often correlates with more complex linguistic structure [25, 26], requiring models with greater expressive capacity. From a theoretical standpoint, diverse corpora demand models with higher VC dimension and wider hypothesis classes to capture nuanced patterns [27].

To account for this, our system dynamically adapts architectural complexity based on measured lexical diversity. For datasets with a high unique word ratio (e.g., $> 0.3$), we increase the number of neuron groups and expand the maximum layer width (`max_units`) in our text-aware MLP-based backbone, allowing the model to better capture semantic variation. Conversely, for low-diversity corpora, we reduce network width and depth to prevent overfitting. In addition, the backbone shape is adjusted: high-diversity texts favor "long funnel" architectures, while simpler datasets default to "diamond"-shaped or regular "brick-like" architectures composed of repeated modules. We also modify activation functions: when diversity is low and the default ReLU may underperform, GELU is automatically selected to improve representation power for simple patterns.

These adaptations ensure that both the search space and the resulting architectures reflect the semantic variability of the input corpus, allowing the AutoML process to match model expressiveness with linguistic richness.

#### 3.1.3. Number of Samples

The number of training examples is a fundamental meta-feature that influences model complexity, training dynamics, and generalization behavior. Small datasets tend to increase the risk of overfitting—particularly when using high-capacity neural networks—whereas large datasets enable the use of deeper models, longer training schedules, and reduced regularization. This is grounded in statistical learning theory, which links generalization error to both the size of the hypothesis class and the number of available training samples [28]. Empirical studies support this connection: Domhan et al. [29] and Probst et al. [30] show that both training regimes and optimal hyperparameter values (e.g., learning rate, dropout) scale with dataset size.

In our approach, we compute the number of training samples during meta-feature extraction and use this to adapt the AutoML search space. For datasets with fewer than 1,000 examples, we expand the dropout search space (up to 0.8), reduce learning rates, and favor simpler backbones such as narrow MLPs or shallow attention blocks. Training budgets are also capped to avoid overfitting under data scarcity. In contrast, datasets with more than 10,000 samples prompt relaxed regularization and enable higher-capacity configurations, such as increased `max_units` and longer training horizons. These modifications ensure that the resulting models are appropriately scaled to the statistical regime of the dataset, improving both robustness and computational efficiency.

#### 3.1.4. Label Distribution and Class Imbalance

Imbalanced class distributions are a common challenge in text classification, where certain categories (e.g., hate speech, fraud cases) are underrepresented but critically important. When the class imbalance ratio—the proportion between the most and least frequent class—exceeds a certain threshold, classification performance for minority classes deteriorates due to model bias toward majority labels [31, 32]. This bias arises from the difficulty of estimating rare class probabilities under skewed priors, which leads to inaccurate posterior approximations, especially when using symmetric loss functions such as cross-entropy.

In our AutoML framework, class imbalance is measured during the meta-feature extraction phase and directly influences the search space configuration. For datasets with imbalance ratios exceeding 3.0, we expand the dropout range (e.g., up to 0.8), reduce learning rates, and increase the warm-up period in cosine learning rate schedules. These measures are designed to stabilize training under uneven gradient updates and reduce overfitting to dominant classes. Conversely, for nearly balanced datasets (imbalance ratio below 1.5), regularization is relaxed to allow more expressive learning.

Although architectural constraints are not enforced strictly based on imbalance, our search space prioritizes configurations that are empirically robust to imbalance, such as residual-normalized attention layers or funnel-shaped MLPs. Together, these mechanisms enable the AutoML system to maintain balanced performance across both major and minor classes.

## 4. Experiments

To evaluate the effectiveness of our context-aware AutoML framework for text classification, we conducted comprehensive experiments on 20 diverse datasets. Our experiments were designed to compare the performance of our proposed context-aware AutoPyTorch against a strong baseline using static configurations in AutoPyTorch.

### 4.1. Datasets

We conduct experiments on a diverse collection of datasets, including a stratified 30% subset of each task from the GLUE benchmark [33], a widely used evaluation suite for natural language understanding. GLUE (General Language Understanding Evaluation) consists of multiple sentence-level and sentence-pair classification tasks, covering linguistic phenomena such as entailment, paraphrase detection, sentiment analysis, and grammaticality judgment. Our subset selection balances computational feasibility and label distribution fidelity, enabling efficient neural architecture search within AutoPyTorch while maintaining representative task characteristics.

In addition to GLUE, we evaluate our approach on selected Kaggle datasets that span various text classification domains (e.g., emotion detection, spam filtering), as well as two private corpora in German. These private datasets address real-world classification tasks and introduce additional linguistic and domain-specific variability, allowing us to assess the generalizability of our context-aware AutoML framework across both English and German texts. Detailed dataset statistics are provided in Table 1.

**Table 1**
Dataset statistics and evaluation metrics. The metric choice reflects task type and class balance.

| Dataset | Samples | Labels | Is Balanced | Skew | Metric |
|---|---|---|---|---|---|
| *GLUE (30% subset)* | | | | | |
| QQP | 238,572 | 3 | No | 2.62 | F1-micro |
| WNLI | 255 | 3 | No | 2.45 | F1-micro |
| MRPC | 1,740 | 2 | No | 2.05 | F1-micro |
| CoLA | 3,197 | 3 | No | 6.34 | MCC |
| RTE | 1,730 | 3 | No | 2.18 | F1-micro |
| QNLI | 34700 | 3 | No | 10 | Accuracy |
| SST-2 | 21012 | 3 | No | 10.09 | Accuracy |
| STS-B | 2588 | 3 | No | 20.88 | Pearson |
| *Public and Private Datasets (subset)* | | | | | |
| Framing | 4,063 | 2 | No | 1.67 | F1-macro |
| Troll | 517 | 2 | Yes | 1.26 | Accuracy |
| Emotion | 42,424 | 2 | Yes | 1.12 | Accuracy |
| Occupation | 10,000 | 9 | No | 31.32 | F1-micro |
| Humor | 4,000 | 2 | Yes | 1.00 | Accuracy |
| Cyber | 1665 | 2 | Yes | 1.11 | Accuracy |
| BBC | 2225 | 5 | Yes | 1.32 | Accuracy |
| Math | 860 | 11 | No | 0.8 | F1-Micro |
| Spam | 10455 | 2 | Yes | 1.11 | Accuracy |
| Emails | 649 | 2 | No | 1.5 | F1-Micro |
| Finished Sentence | 7973 | 2 | No | 4 | F1-Micro |
| Job | 2682 | 2 | No | 19.63 | F1-Micro |

## 4.2. Embedding Method

For all experiments, we used the `all-MiniLM-L6-v2` model from the SentenceTransformers library to generate contextualized text embeddings. The model encodes each input text into a fixed-size dense vector of 384 dimensions.

To ensure a controlled comparison between the baseline and our proposed method, the embedding layer was kept identical across all experimental conditions.

## 4.3. Model Framework & Search Strategy

We implemented all experiments using the AutoPyTorch framework, leveraging its modular design for deep learning pipelines and extensible search space control. To ensure focus on neural architecture optimization, the traditional machine learning components (e.g., random forests, SVMs) were disabled for our approach. Only deep learning backbones were allowed in the search space.

Specifically, the following backbone architectures were included as candidates:

- **MetaMLP** – a custom MLP architecture whose depth, width, and shape are dynamically adapted based on meta-features such as text length, lexical diversity, number of samples, and class imbalance.
- **Contextual AttentionNet** – a lightweight attention-based model built with multi-head self-attention layers, with structural parameters (e.g., number of heads, embedding dimensions) conditioned on input characteristics.

These architectures were treated as a categorical hyperparameter within the AutoML pipeline, allowing the search process to explore and select the most appropriate model type using Bayesian optimization.

The text-aware version of our pipeline integrates the meta-feature extraction step at the beginning of each AutoPyTorch run. The extracted corpus-level properties are then used to dynamically adapt the hyperparameter search space. Key adaptations include:

- Batch size adjustments based on average sequence length;
- Learning rate and dropout range scaling based on dataset size and class imbalance;
- Architectural shaping (e.g., diamond vs. funnel MLPs) based on input diversity and length variance.

All experiments were constrained to a wall-clock time of 3,000 seconds (approx. 2 hours) and a per-model training time of 600 seconds. We used multi-fidelity optimization via Successive Halving with a training budget ranging from 10 to 100 epochs.

All runs were executed on a single NVIDIA A100 GPU machine with 40 GB of memory, using standard 32-bit floating point precision.

## 4.4. Baseline Configuration

To establish a fair comparison, we define a strong baseline using the unmodified AutoPyTorch framework and the same text embedding method (MiniLM). In this setting, the hyperparameter search space remains static and is not influenced by any dataset-specific meta-features.

## 4.5. Results

Tables 2 and 3 summarize the performance of our context-aware AutoML pipeline in comparison to a static AutoPyTorch baseline across 20 text classification datasets. The evaluation was based on four widely used metrics: Accuracy, F1-micro, Matthews Correlation Coefficient

(MCC), and Pearson correlation. These metrics were selected to reflect the characteristics of each task—for example, Accuracy for balanced classification tasks, F1-micro for imbalanced or multi-class problems, MCC for binary grammaticality judgments (e.g., CoLA), and Pearson correlation for sentence similarity (STS-B). Notably, these are also the official evaluation metrics adopted in the GLUE benchmark [33], ensuring compatibility and comparability with prior NLP research.

Overall, our method demonstrates consistent improvements, particularly on tasks characterized by limited training data, class imbalance, or high lexical diversity.

On the GLUE benchmark, our pipeline yields significant gains on several tasks. Notably, WNLI accuracy increases from 17.6% to 54.9%, and SST-2 sees a dramatic rise from 2.1% to 83.4%. These results highlight the effectiveness of our adaptive architecture and regularization mechanisms in low-resource and sentiment-sensitive tasks. We also observe improvements in STS-B, where the Pearson correlation increases from 24.7% to 30.7%. Conversely, slight performance drops are observed in QNLI and CoLA, which may suggest that the current adaptation strategy occasionally introduces suboptimal regularization or architectural choices. For QQP, both the baseline and our pipeline failed to build a viable neural or ensemble model within the computational budget, resulting in fallback to a dummy classifier.

Our pipeline also outperforms the baseline on the majority of Kaggle and private datasets. Substantial gains are observed on *Emails* (from 66.9% to 76.2%), *Troll* (from 52.9% to 56.7%), and *Finished Sentence* (from 79.4% to 81.1%), indicating that context-aware adaptation improves performance in tasks with either noisy data or subtle class distinctions. A slight performance decrease is observed on a few tasks, such as *BBC* and *Occupation*. In the case of *Occupation*, the drop in performance can be attributed to the nature of the dataset: it consists of short, open-ended answers to questions about a person's job, which are then mapped to the top-level labels of the German occupation classification system (KldB). These free-text responses are often terse (e.g., one- or two-word entries like "Technician" or "Sales") and lack sufficient contextual information to support nuanced classification. As a result, the dynamic adaptation mechanisms—designed to adjust architectures and hyperparameters based on richer linguistic cues—have limited room to operate effectively. The scarcity of semantic context may also hinder the effectiveness of embeddings and prevent the model from learning discriminative patterns across fine-grained occupational categories.

Overall, the results support the utility of dynamic search space tailoring across varied domains and textual characteristics.

**Table 2**
Accuracy (%) comparison between Baseline and Custom Hyperparameter Search across GLUE Datasets.

| Dataset | Accuracy/F1-Micro/MCC/Pearson | |
|---|---|---|
| | Baseline | Custom |
| CoLA | 0.05 | -0.2 |
| MRPC | 72.7% | 74.13% |
| QNLI | 53.3% | 50.3% |
| QQP | 49.17% | 49.17% |
| RTE | 52.8% | 53.5% |
| SST-2 | 2.1% | 83.4% |
| STS-B | 24.7% | 30.72% |
| WNLI | 17.6% | 54.9% |

**Table 3**
Prediction performance comparison between Baseline and Custom Hyperparameter Search.

| Dataset | Accuracy/F1-Micro (%) | |
|---|---|---|
| | Baseline | Custom |
| Occupation | 77.9 | 77.3 |
| BBC | 97.3 | 96.85 |
| Cyber | 76.57 | 77.2 |
| Emails | 66.9 | 76.15 |
| Emotion | 87.1 | 88.3 |
| Framing | 69.1 | 71.3 |
| Humor | 91.8 | 92.87 |
| Math | 15.1 | 16.3 |
| Spam | 96.84 | 96.9 |
| Job | 96.46 | 96.27 |
| Finished Sentence | 79.43 | 81.12 |
| Troll | 52.88 | 56.73 |

## 5. Conclusion and Future Works

In this work, we proposed a context-aware AutoML framework that dynamically adapts the hyperparameter search space and neural architecture configurations in response to corpus-level text features. Implemented within the AutoPyTorch ecosystem, our approach integrates dataset-driven meta-feature extraction with a modular design for backbone selection and training parameter control. Experiments across 20 datasets—including subsets of GLUE and diverse public corpora—demonstrate consistent improvements in classification performance, particularly in scenarios with imbalanced classes, small training sets, or high lexical diversity.

By coupling structural and optimization-level decisions to dataset-specific traits, our framework offers a promising direction for more efficient and effective AutoML in NLP. The results validate that even lightweight corpus features (e.g., text length, label imbalance) can yield meaningful adaptations to both model topology and hyperparameter scheduling.

While our method demonstrates strong empirical gains, several important avenues remain for future research.

First, our current system relies on a limited set of meta-features, such as average text length, vocabulary diversity, and class imbalance. In future work, we aim to extend this analysis to include finer-grained linguistic and structural features such as average sentence length, part-of-speech density, punctuation density, unique character ratio, and readability scores. These features may offer deeper insight into the semantic and syntactic complexity of text, enabling more informed search space adjustments.

Second, while we implement a contextual search space by mapping meta-features to hyperparameter ranges, this process currently uses static, hand-crafted rules. More expressive and structured search spaces could allow hyperparameter relevance and conditionality to adapt dynamically based on dataset characteristics. For instance, certain architecture components or regularization parameters could be activated only when specific linguistic conditions are met, allowing for more flexible and principled adaptation.

Finally, our current fusion strategy for resolving conflicts between feature influences on the same hyperparameter is based on simple heuristics—such as averaging suggested values or intersecting ranges. In future work, we plan to investigate more flexible fusion mechanisms, such as weighting meta-features by importance or learning fusion policies from prior task performance. These improvements could make the contextual adaptation process more scalable, robust, and interpretable across a wide range of text classification tasks.

## 6. Limitations

Despite the overall effectiveness of our context-aware search space design, several limitations remain.

First, while our system considers multiple meta-features to guide hyperparameter configurations, their influence is combined using static heuristics. This rule-based fusion does not account for potential interactions or conflicts between features, and lacks the flexibility to adapt based on task-specific dynamics or prior performance.

Second, the increased complexity introduced by text-specific search space customization results in higher computational cost. In most cases, we observed longer processing times due to the additional overhead from meta-feature analysis, search space updates, and more expansive architecture evaluations. This may limit the method's applicability in time-constrained or resource-limited environments.

Lastly, our current evaluation focuses solely on classification tasks using moderately sized monolingual datasets. The applicability of our approach to large-scale corpora, multilingual benchmarks, or more complex NLP tasks (e.g., sequence labeling or generation) remains unexplored.

### Abstract

We investigate whether incorporating linguistically derived speaker profiles improves the response selection capabilities of instruction-tuned large language models (LLMs) in multi-party dialogues. Using the Wikipedia Talk Page dataset, we construct lightweight profiles for each speaker based on features extracted from their prior messages, including frequent nouns and verbs, and sentiment tendency. These profiles are incorporated into the input prompts and evaluated using in-context learning with LLaMA 3.2 Instruct (1B and 8B) and GPT-4o, without any model fine-tuning. We compare performance across models and prompt settings, with and without speaker profiles, and analyze the effect of different profile configurations. Results are compared against a Random baseline and a supervised Siamese RNNs (with GRU units) trained on the same data. Our results show that incorporating speaker profiles improves response selection performance across most LLM settings, with the strongest gains observed in larger models such as LLaMA 3.2 (8B). Lexical features (frequent nouns and verbs) demonstrate greater improvements than sentiment information, particularly in low-context or underspecified scenarios. However, profile effectiveness varies by model scale and prompt format, and provides limited benefit in cases where distractors are lexically and semantically similar to the ground-truth response.

### Keywords

Large Language Model, Multiparty Dialogue, User Profile, Response Selection,

## 1. Introduction

Large Language Models (LLMs) have achieved state-of-the-art performance on a variety of downstream tasks in dialogue systems, including response generation [2, 3, 4], selection [5, 6], and dialogue state tracking [7, 8]. Despite these advances, Multi-Party Dialogue (MPD) remains a more complex setting due to the increased number of participants, diverse conversational roles, and overlapping discourse structures [9, 10]. One key challenge in this context is the absence of explicit user modeling. LLMs typically operate over short dialogue contexts without access to persistent or structured information about individual speakers. This limits their ability to personalize responses or disambiguate interactions based on user-specific traits such as language use, affective tone, or conversational behavior.

Response selection in MPD poses unique challenges due to the presence of multiple speakers, shifting roles, and overlapping conversational threads [5]. Unlike dyadic dialogue, this setting requires distinguishing between several potential interlocutors, resolving ambiguous references, and interpreting speaker-specific cues. These complexities make the task particularly sensitive to both conversational context and speaker identity. However, standard LLM-based approaches primarily rely on surface-level context, without modeling the linguistic behavior of individual speakers, which can limit their ability to correctly select the responses.

**RQ1: Can linguistic speaker profiles improve response selection in multi-party dialogue settings when provided via prompt-only conditioning?** In this work, we investigate whether incorporating cost-effective, linguistically grounded speaker profiles into the input prompt can improve the response selection capabilities of instruction-tuned LLMs in MPD. Our motivation is to test whether such profiles can serve as effective signals for disambiguation and speaker-sensitive response selection. The profiles are derived from users' previous utterances and include their most frequent nouns and verbs, along with a coarse-grained sentiment distribution. Unlike approaches that rely on fine-tuning or persistent user modeling, we adopt a prompt-only strategy using minimal, interpretable features compatible with in-context learning. We focus specifically on response selection rather than generation, as it allows for more controlled experimental conditions and avoids the need for human evaluation. Moreover, automatic metrics for ranking responses are more reliable than those available for open-ended generation, which often struggle to distinguish coherent yet irrelevant outputs [11].

**RQ2: To what extent does the effectiveness of speaker profiles depend on model scale, prompt**

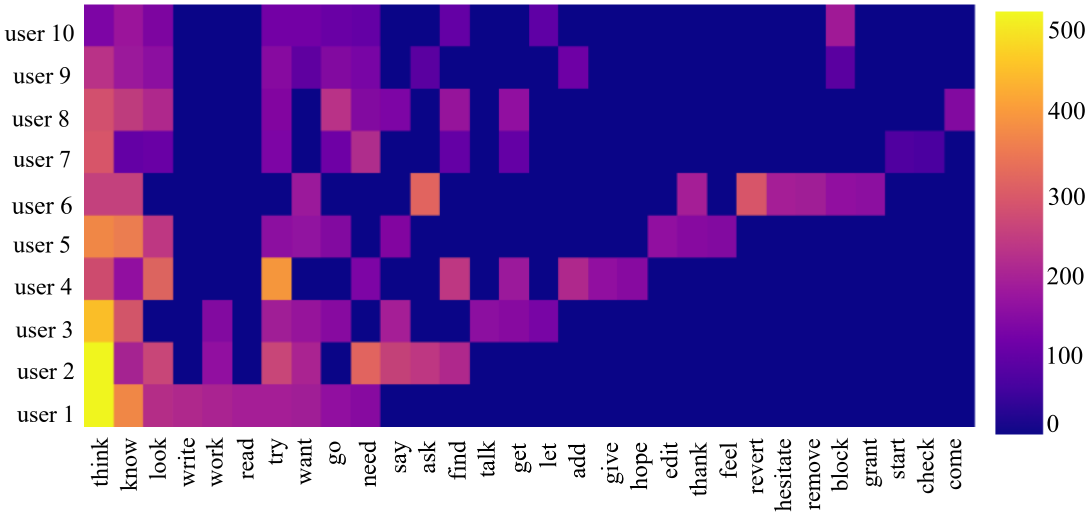

**Figure 1:** Heatmap of the 10 most frequent verbs used by each of the top 10 most active users. The diagonally dominant structure reveals a strong speaker-specific lexicon: verbs frequently used by one user tend to be infrequent or absent in the language of others. This pattern supports the hypothesis that verb usage in MPD can serve as a useful signal for user-aware response selection.

**format, and profile composition?** We evaluate this approach using LLaMA 3.2 Instruct (1B and 8B) and GPT-4o, comparing performance with and without speaker profiles under zero-shot and one-shot prompting. To contextualize results, we include two baselines: a random ranking strategy and a supervised Siamese RNN with GRU units trained on the same dataset. All models are tested on a standardized response selection task using MPDs from the Wikipedia Talk Page dataset.

Our goal is not to build a personalized dialogue system, but to assess whether minimal linguistic speaker information can influence LLM behavior in a selection setting. We do not assume access to long-term user history or stable user identities, and we make no changes to model parameters. Instead, we treat speaker profiling as a lightweight, model-agnostic addition to the input prompt. This setup allows us to isolate the effect of speaker-level information on model performance and to compare its impact across multiple instruction-tuned LLMs.

Our results show that speaker profiles can enhance response selection performance, particularly for larger models and in low-context scenarios. The most consistent gains are observed with lexical profiles (frequent nouns and verbs), while sentiment information yields marginal or mixed improvements. However, model scale and prompt format (e.g. 0-shot and 1-shot) significantly mediate the effectiveness of speaker profiles.

Our contributions can be summarized as follows:

- We introduce a prompt-based method for incorporating lightweight, linguistically derived speaker profiles into LLM-based response selection for multi-party dialogue[1].
- We conduct a systematic evaluation across model scales (1B, 8B, GPT-4o), prompt formats (zero-shot, one-shot), and profile configurations (lexical, lexical+sentiment).
- We present detailed analysis highlighting when and how speaker profiles help, supported by both aggregate performance and error case breakdowns.

## 2. Related Work

Recent work on MPD has explored a range of strategies for modeling speaker identity, roles, and interaction structure. Mahajan and Shaikh [12] introduce a graph-based transformer that incorporates speaker and addressee personas as structured metadata, using crowdsourced profiles to condition response generation. Similarly, Ju et al. [4] build a graph representation of utterances and speaker personas to guide generation through a hierarchical encoder and structured aggregation. These methods emphasize user profile incorporation but assume access to annotated profiles and require complex modeling. Sun et al. [13] use contrastive learning to model speaker-

[1] The code and implementation details will be published in our repository

specific discourse patterns without explicit profiles, learning latent speaker distinctions optimized for generation tasks. Penzo et al. [5] take a diagnostic approach, analyzing how conversation structure affects performance in response selection and addressee recognition. They show that LLMs rely heavily on surface content for response selection and are sensitive to prompt formulation and structural variation. Finally, Hu et al. [9] propose a role-aware modeling framework that combines role-context pretraining with decoding constraints to favor role-consistent outputs. While effective across multiple MPD tasks, the approach depends on predefined role labels and supervised training. Collectively, these studies highlight the importance of speaker- and role-level information in MPD, though most rely on supervised learning, structured annotations, or architectural specialization.

# 3. Experiments

We evaluate the effect of incorporating linguistic speaker profiles on response selection in MPDs using a set of instruction-tuned LLMs and baseline models. All experiments are conducted on the same unseen test set, using consistent prompt formatting and evaluation metrics. Below, we describe the models, data, and profile features used in our setup.

## 3.1. Dataset

We use the Wikipedia Talk Page Conversations dataset [14], which contains 124,957 multi-party dialogues involving 38,462 unique users and a total of 4,023,376 tokens with a vocabulary size of 108,416. The user activity in the dataset is not balanced, i.e. the top 10 most active users account for over 12% of all turns in the dataset.

To model multi-party interactions, each conversation is represented as a tree, with the root corresponding to the initial post and branches representing reply chains. For each reply path, we extract a linear dialogue history leading to a candidate response. Each instance is framed as a response selection task with one ground-truth response and nine distractors drawn from the same structural depth within other conversations.

We segment this subset into three partitions: a held-out test set of 2,500 previously unseen dialogues shared across all models; a training set of 206,633 samples used to train the Siamese RNN and construct one-shot prompts; and a development set of 25,830 samples for tuning the supervised model. To better understand the conversational domain of the dialogues, we applied topic classification using GPT-4o, following the categorization and methodology of Antypas et al. [15] (50 samples were randomly selected and manually controlled to ensure prediction validity). Table 1 presents the distribution of detected topics across the dialogues involving these ten users, covering a broad range of domains including business, popular culture, education, and technology.

| Topic | Count |
|---|---|
| Business & Entrepreneurs | 20,293 |
| Celebrity & Pop Culture | 19,111 |
| Diaries & Daily Life | 17,150 |
| Arts & Culture | 17,034 |
| Learning & Educational | 16,283 |
| Science & Technology | 11,708 |
| News & Social Concern | 10,970 |
| Relationships | 9,654 |
| Technology | 5,019 |

**Table 1**
Topic distribution in Wikipedia Talk Page dialogues, detected using GPT-4o following Antypas et al. [15].

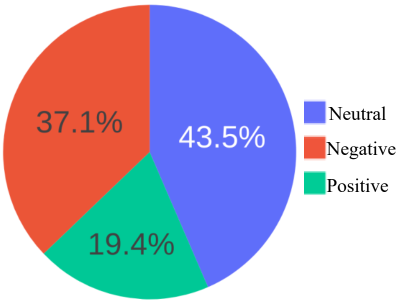

**Figure 2:** Distribution of predicted sentiment labels across all messages. Sentiment labels were derived using GPT-4o and manually verified on a subset of the data.

We segment the data into three parts: a held-out test set of 2,500 previously unseen dialogues used for evaluation equal for all models; a training set of 206,633 samples used exclusively for training the Siamese-RNN baseline and for constructing one-shot examples; and a development set of 25,830 samples used only for optimizing the RNN architecture and hyperparameters. Each response selection instance consists of a dialogue history and a pool of ten candidate responses drawn from the same depth level in the reply tree. One candidate is the correct continuation, and the remaining nine are randomly sampled distractors from other conversations at the same structural depth.

## 3.2. Models

We evaluate three types of models:

- ***Random Baseline*** generates a uniformly ranked list of candidate responses for each input context. This serves as a lower-bound reference point and helps contextualize performance in the absence

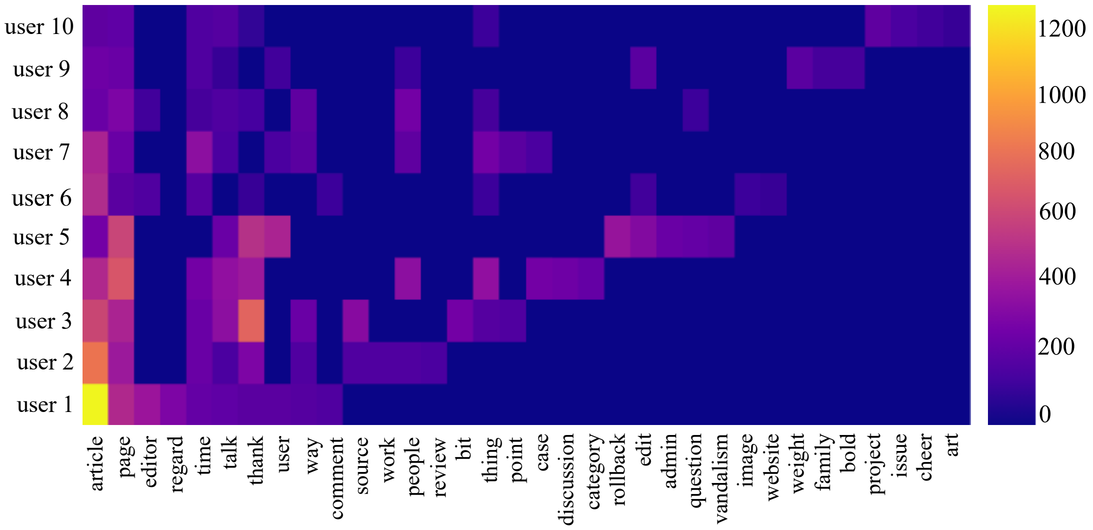

**Figure 3:** Heatmap of the 10 most frequent nouns used by each of the top 10 most active users. Similiar to Figure 1, noun usage is also highly speaker-specific: commonly used nouns for one user are rarely shared with others. This reinforces the utility of lexical profiles, suggesting that noun usage can provide a strong signal for speaker and response selection within MPD.

of data-driven inference.

- ***Siamese RNN*** is a supervised neural baseline using two GRU encoders with shared weights to compute the similarity between a dialogue context and a candidate response. The model outputs a matching score based on pairwise similarity and is trained using labeled context-response pairs with cross-entropy loss. Each GRU encoder uses the following hyperparameters: `MAX_LENGTH = 300`, `input_size = 100`, `hidden_size = 300`, `num_layers = 2`, `dropout = 0`, and `bidirectional = True`. The model is trained for `10 epochs` with a `batch_size = 128` and a learning rate of `0.0001`.
- ***Instruction-Tuned LLMs*** include **LLaMA 3.2 Instruct** (1B and 8B) and **GPT-4o**, representing two families of recent state-of-the-art LLMs. LLaMA 3.2 Instruct is a publicly available model family released by Meta, trained on a diverse multilingual corpus and further instruction-tuned to follow natural language prompts. We include both the 1B and 8B variants to examine the effect of model scale on profile sensitivity. GPT-4o is a proprietary model released by OpenAI, optimized for multimodal interaction and known for strong instruction-following capabilities in both zero-shot and few-shot settings. All models are used via API in inference-only mode without any additional fine-tuning. Inputs are provided as structured natural language prompts, including a system instruction, dialogue history, and a list of candidate responses. When speaker profiles are used, they are appended to the input as plain-text feature descriptions associated with the target speaker. We experiment with both zero-shot prompting (task description only) and one-shot prompting (including a single example of the desired input-output format). Inference is run with $temperature = 0.2$, $top_p = 1.0$, and $max_tokens = 50$, and predictions are parsed to compute Recall@1/2/5.

**Evaluation Metric** We evaluate model performance using Recall@k, a standard metric for response selection tasks. For each dialogue instance, the model ranks a set of ten candidate responses, consisting of the ground-truth response and nine distractors sampled from the same depth level in the conversation tree. Recall@k measures the proportion of instances where the correct response appears in the top $k$ predictions. We report Recall@1, Recall@2, and Recall@5 to assess performance at different levels of ranking sensitivity.

**Prompt Design** We structure prompts for the response selection task using a consistent template for ranking responses based on the context. Each prompt comprises three components: (i) a task instruction explaining the ranking objective and expected output format, (ii) a content section containing the dialogue history and 10 candidate responses, and (iii) an optional speaker profile,

**System Prompt (abbreviated)**

<|begin_of_text|>
You will be given:
- A conversation transcript with numbered turns
- 10 candidate responses
- A user profile containing the most frequent nouns and verbs used by the *next speaker*

Your task:
**Rank the candidate response indexes from best to worst** based on how well they continue the conversation and match the speaker profile.
**Example output format:**
1. 3
2. 4

...
Do NOT provide an explanation but the list of numbers.
<|eot_id|>

**User Prompt (example structure)**

**<CONVERSATION>**
Turn 1: Hi, how are you?
Turn 2: I'm doing well, thanks. You?
...
**</CONVERSATION>**

**<Responses>**
1. I'm glad to hear that!
2. What's new with you?

...
**</Responses>**

**<User Profile>**
thank, update, read, discuss, feel, ...
**</User Profile>**
<|eot_id|>

Table 2
Prompt structure used for response selection in LLMs. The system prompt defines the task, and the user prompt provides the conversation context, candidate responses, and speaker profile when applicable.

appended when profiling is enabled. The speaker profile provides the most frequent nouns and verbs used by the next speaker, i.e. the user who is expected to respond, extracted from their prior messages. The full prompt is framed in natural language and formatted using system and user tags. The model is explicitly instructed to return a ranked list of response indices without any explanation or commentary. In one-shot settings, we prepend a demonstration example showing the exact input-output structure. The speaker profile, when present, is enclosed in a $< UserProfile >$ section and labeled accordingly. This design follows the practices for LLM prompting in prior work [16]. We provide the prompt template in Table 2.

### 3.3. User Profile

We construct speaker profiles for each user in the dataset, using linguistic features extracted from their prior messages. Each profile is fixed per speaker and remains constant across all dialogue instances in which the user appears. We create a lexical profile consisting of the 10 most frequent nouns and the 10 most frequent verbs used by the speaker, extracted using the *spaCy* dependency parser. These tokens reflect habitual vocabulary choices and serve as coarse indicators of speaker identity and discourse tendencies. This profile is then augmented with a coarse-grained sentiment distribution. Each message authored by the speaker is classified as *positive*, *neutral*, or *negative* using GPT-4o, following a prior work [16] and the resulting counts are normalized to produce a speaker-level sentiment distribution (predictions were manually verified for 50 randomly sampled messages to ensure classifier quality). Profiles are incorporated into the prompt and are explicitly associated with the speaker expected to produce the next turn. This design allows instruction-tuned LLMs to condition their ranking decisions on user-specific linguistic traits without requiring model fine-tuning or structural modifications.

Figure 2 presents the overall sentiment distribution across the turns in the dataset. The majority are neutral (43%), followed by negative (37%) and positive (20%), indicating a generally balanced emotional tone. Figures 1 and 3 show heatmaps of the top 10 most frequent verbs and nouns, respectively, for 10 most frequent users. Each heatmap reveals strong user-specific vocabulary patterns: the most frequent items for a given user tend to be rarely used by others. This lexical asymmetry suggests that even simple word-level statistics can encode informative signals about speaker identity. As a result, lexical profiles may help disambiguate responses in MPD by aligning candidate utterances with user-specific vocabulary preferences.

## 4. Evaluation

We evaluate the effect of incorporating linguistic speaker profiles on the response selection performance of instruction-tuned LLMs in MPDs. Our analysis compares three models, GPT-4o, LLaMA 3.2 Instruct (1B and 8B), and a Siamese RNN baseline, under both zero-shot and one-shot prompting conditions. We assess each model's performance with and without speaker profile information, using two profile configurations as frequent nouns and verbs, and the addition of sentiment tendency.

**Baseline Behavior** The Siamese RNN performs moderately well in the profile-free condition, achieving 31% Recall@1. However, its performance declines when profiles are added. This suggests that the architecture may not effectively integrate linguistic profile information, or

| Model | ICL Setting | Profile | Recall@$k$ in 10 | | |
|---|---|---|---|---|---|
| | | | ***R@1*** | ***R@2*** | ***R@5*** |

| | | + Sentiment | 0.62 | 0.69 | 0.84 |

**Table 3**

Response selection performance (Recall@1,2,5) across models, prompting settings (zero-shot, one-shot), and speaker profile configurations. Each instance includes 10 candidates (1 ground-truth, 9 distractors). Across LLMs, incorporating speaker profiles improves performance in nearly all settings, with the strongest gains observed for LLaMA 3.2 Instruct (8B) in the zero-shot condition. Lexical profiles (frequent nouns and verbs) consistently outperform sentiment-augmented profiles, particularly in lower-capacity models. These results suggest that shallow linguistic profiles can enhance LLM-based response selection, but their effectiveness varies with model size and prompting regime.

that the additional features introduce noise in the learned similarity space. The random baseline performs as expected, confirming that all models operate well above chance.

**LLM Performance** Table 3 presents the performance scores across models, prompt settings, and speaker profile configurations. GPT-4o achieves the highest performance in all conditions, with Recall@1 reaching 62% under one-shot prompting with profile information. LLaMA 3.2 Instruct (8B) performs substantially better than its 1B variant, particularly in the zero-shot setting, where the addition of speaker profiles yields the largest relative improvements.

**Speaker Profiles** Incorporating speaker profiles leads to consistent gains across most LLM configurations. For LLaMA 3.2 Instruct (8B), the inclusion of frequent nouns and verbs improves Recall@1 from 20% to 40% in the zero-shot setting. However, sentiment augmentation does not produce additional gains and, in some cases, slightly degrades performance. Nevertheless, the smaller LLaMA model (1B) shows minimal sensitivity to profile input, suggesting that profile utility may depend on model size. Meanwhile, GPT-4o demonstrates strong baseline performance without profiles, but still benefits from profile inclusion. The highest Recall@1 for GPT-4o is 62% with both lexical and sentiment features in the one-shot setting. These improvements, though smaller in magnitude compared to LLaMA 8B, indicate that even high-performing models can leverage cost-effective linguistic speaker information.

**Prompt Structure** Prompting style has non-uniform impact on models' performance. For LLaMA 3.2 Instruct (8B), zero-shot prompting outperforms one-shot in several configurations, particularly when profiles are included. In contrast, GPT-4o benefits more consistently from one-shot prompting, though the margin is small. These results highlight interactions between model scale, prompt format, and profile effectiveness.

### 4.1. Error Analysis

To better understand the limitations and strengths of speaker profiles, we manually analyzed several subsets of the test set. In our analysis, we define a *misclassified* instance as one in which the ground-truth (GT) response does not appear among the top five ranked candidates (i.e., not within Recall@5), and a *correct* instance as one where the GT response is ranked first (i.e., Recall@1).

Out of 2,500 total instances, 1,500 cases were consistently misclassified by all models across all conditions. In these cases, the distractors were often semantically and lexically similar to the GT responses, making the ranking task inherently difficult. Moreover, frequent nouns and verbs extracted for profile construction were typically generic (e.g., "thanks," "help," "response"), and occurred in both GTs and distractors, limiting their discriminative value. In such cases, the profile provided little to no additional context to support accurate disambiguation.

In contrast, 611 instances were correctly classified by all models across all settings. Here, the GT responses were clearly more contextually grounded and lexically aligned with the dialogue history, and the distractors were often generic acknowledgements (e.g., "thanks," "okay") or off-topic continuations. The linguistic profiles were more distinctive in these examples and appeared to support the model's ability to prioritize the correct response.

Finally, in 77 cases, all models failed without speaker profiles but they all correctly selected the GT response once profile information was added. These instances were typically characterized by minimal dialogue history (one-turn inputs), where contextual grounding was insufficient for accurate prediction. The added speaker profile appeared to serve as an auxiliary context that supported correct ranking in these otherwise under-specified dialogues. Conversely, there were 2 cases in which the inclusion of sentiment in the profile led to improved predictions in all models. These examples featured strong affective alignment between the dialogue history and the GT response, while the distractors were neutral and short, allowing the model to benefit from the added sentiment context.

Interestingly, in 12 cases the models ranked the correct response at R@1 without speaker profiles, but failed to do so when profiles were added. In these cases, sentiment distribution was nearly uniform across responses in these cases, providing no additional signal. Furthermore, the distractors were uniformly generic, with some distractors including non-English text or irrelevant long-form content. Thus, the profile content introduces more noise rather than useful contrast, confusing the model.

Overall, speaker profiles provide most benefit when dialogue context is minimal or generic, but lose effectiveness when distractors are lexically similar or the profiles themselves are noisy.

## 5. Conclusion

We investigate whether linguistically derived speaker profiles can improve the response selection capabilities of instruction-tuned LLMs in multi-party dialogue. We constructed user profiles based on frequent nouns, verbs, and sentiment tendencies from prior utterances, and incorporated them into prompts without any model fine-tuning. Our experiments with LLaMA 3.2 and GPT-4o show that lexical profiles consistently improve performance, particularly for larger models and in zero-shot settings. Our results show that lexical speaker profiles improve performance in nearly all LLM settings, especially in larger models and zero-shot conditions. This supports RQ1, demonstrating that even lightweight user information can help response selection in MPD. In addressing RQ2, we find that model scale and prompt design play a crucial role in how effectively speaker profiles are used. Larger models benefit more from profile information, suggesting that they can better leverage user context. However, the sentimental features show mixed results, in some cases adding noise rather than clarity. We also observe that profiles are particularly useful in low-context situations, but their impact diminishes when distractors are semantically close or when the profiles themselves lack specificity.

In future work, we plan to explore richer profile representations, investigate cross-domain generalizability, and test the applicability of this approach in real-time or streaming dialogue systems. We also see potential in extending our method to multilingual MPD and combining profile signals with structural or discourse-level features.

## Limitations

This study relies exclusively on in-context learning and does not involve any fine-tuning of the evaluated models. While this makes our approach lightweight and accessible, it also constrains the models' ability to adapt more deeply to user-specific behaviors. Due to computational constraints, we did not experiment with larger LLMs beyond LLaMA 3.2 (8B) and GPT-4o, and were unable to explore open-weight models at scale requiring GPU access. Our data is limited to English Wikipedia Talk Pages, which restricts the generalizability of our findings to multilingual or informal conversational domains. Additionally, speaker profiles are based on automatic extraction of lexical and sentiment features, which may introduce noise or inaccuracies that affect profile quality. Finally, we focus exclusively on response selection and did not experiment with response generation. While this choice enables robust and reproducible automatic evaluation, it leaves open the question of how linguistic speaker profiles might affect the quality of generated responses in more open-ended dialogue settings.

### Abstract

How effective are the communication choices of Multimodal Large Language Models when pursuing a common goal? Can they make use of common human dialogical patterns? We address these questions by engaging two agents based on the Mistral model in a collaborative building task, where one has to instruct the other how to build a specific target structure. The aim of this work is to investigate whether different prompting techniques with varying degrees of multimodality can influence the performance of MLLM-based agents in the proposed task. Code and data available in the project's GitHub repository.

### Keywords

communication, dialogue, 3D understanding, multimodality

## 1. Introduction

Communication is a crucial aspect of people's daily life, as it allows them to share and obtain information, guide choices and actions, learn, understand their peers, and more. Many common tasks humans often undertake, from a simple grocery shopping run to the coordination of a big work project, require at least a small amount of communicative effort [1]. A typical and recurrent scenario where communicative skills are intuitively key is when two or more people have to collaborate in order to pursue a common goal, as the dialogue exchanges have to be efficient enough to bring the group to the completion of the task with as little effort and inconvenience as possible.

With the rise of powerful AI assistants brought about by the progress of modern technology, it is only natural to want them to communicate with us in a way that is somehow familiar, which means close to the communication protocols that we naturally implement and to the degree of efficiency we are accustomed to. In fact, a communication style that is too alien, for instance one that largely strays away from the Gricean maxims [2], which we commonly use to regulate information flows in conversation, woulds easily cause frustration and dissatisfaction among users.

Our work aims to place a stone on the road toward this objective, by investigating whether Foundational Multimodal Large Language Models (MLLMs)—a very powerful class of AI models which has been receiving more and more attention by the research community in recent years—can mimic common and efficient human communication techniques when communicating among themselves in a collaborative building task, where one model is required to instruct the other on how to build a certain target structure, without specific training.

We intend to proceed by investigating the impact of different prompting techniques, with varying degrees of multimodality, on the performance of models in the aforementioned task. Specifically, we have designed three different experimental setups (a text-only, an image-only, and a mixed). Comparing models' performance in these conditions will shed light on whether specific techniques can induce more effective and human-like communication abilities in MLLMs. At the same time, the specific building task chosen will allow us to also investigate MLLMs abilities to understand and manipulate different formats of 3D representations, presenting them with a diverse challenge which tackles both their linguistic and visual competences.

## 2. Related Work

The topic of communication techniques has been often researched in the fields of computational linguistics and linguistics. Narayan-Chen et al. [3] presents a thorough

analysis of a collaborative building task conducted by human participants in a Minecraft[1]-like environment. The players were divided into couples and assigned the role of either Architect or Builder, where the former was supposed to instruct the latter on how to build a specific target structure composed of blocks of different colors, which only the architect could see. The Builder was provided an inventory of 6 colors of blocks, with 20 units each.

The authors thus collected the Minecraft Dialogue Corpus, a large collection of game logs consisting of 509 human-human dialogues and screenshots of both the target structures and the participants' progress in replicating them, at different timestamps and from various perspectives. Of major interest for our work is the fact that, analyzing the dialogue histories collected, the authors were able to highlight the main recurring communication patterns and techniques that the players employed.

Notably, they observed that humans in the Architect role often relied on choices which would allow them to speed up communication and make themselves more easily understood, such as references to recognizable, well-known shapes of, for instance, objects, or implicit references, recalling recently taken actions or referring to the Builder's position and perspective. Builders, on the other hand, frequently engaged in asking clarification and verification questions, in providing status updates on the ongoing activity and on the inventory state, or in using extrapolation to take autonomous initiative based on their interpretations of the Architect's goal.

Collaborative building tasks have since then sparked interest in AI research in general and NLP specifically, with a dedicated challenge, named IGLU challenge, being proposed in the 2021 and 2022 editions of the NeurIPS conference [4, 5]. The most recent edition of the IGLU challenge included two tracks: a Reinforcement Learning one, involving the development of RL agents able to work as Builders in the task; and an NLP one, dedicated to the advancements of the Builder's ability to understand when and how to ask clarification questions.

Furthermore, Madge and Poesio [6] realized an implementation of the collaborative building task presented in Narayan-Chen et al. [3], using Large Language Models as either the Architect or Builder, with a human as their counterpart. The models received a text-only prompt describing the task, their role and how they were expected to behave. The Architect was provided a (textual) JSON description of the target structure and required to give clear and easy to follow instructions, while the Builder was prompted to state, again in JSON format, the color of blocks that it would have used and where it would have placed them, along with clarification questions, if needed.

This study extends existing research by presenting a fully automated implementation of the collaborative building task. Our approach uniquely employs two MLLMs-based agents, assessing their performance beyond conventional textual prompting to include visual prompting. We investigate two key areas: the MLLMs' capacity for generating human-like dialogue exchanges, investigating communication techniques identified in the Minecraft Dialogue Corpus, and their proficiency in comprehending and manipulating 3D representations.

# 3. Methods

## 3.1. Experimental Design

The task presented in this work is an implementation of the collaborative building task from Narayan-Chen et al. [3], with the role of the Architect and the Builder being taken by two agents based on the Mistral model[2] [7].

To focus our study on high-level spatial reasoning and collaboration, we opted not to use a full Minecraft environment for the multimodal component: instead of requiring agents to navigate a 3D world and interpret a first-person perspective—as is typical in embodied agent settings—we rendered simplified voxel-based scenes and provided static images from multiple viewpoints (see Figure 1). This design choice isolates the challenge of reconstructing and reasoning about three-dimensional spaces from limited visual input, without introducing the additional complexities of navigation, low-level control, and egocentric perception. While full embodiment is an important long-term goal, our aim here is to evaluate whether agents can jointly interpret structured visual scenes at a higher level of abstraction.

In order to investigate the possible effects that varying degrees of multimodality could have on the communicative abilities of the models, we designed three different experimental conditions. The basic prompt, which provided each agent with a description of the task and of its role, remained constant across conditions: what changed was the format in which the target structure was presented to the Architect, as well as that of the updated world states provided periodically throughout the task, based on the Builder's actions.

The Architect's basic prompt instructed it to provide clear and easy to follow instructions, broken down into small incremental sub-steps, and to acknowledge the Builder's actions and communication. The Builder, on the other hand, was directed to always respond with a JSON object listing its actions—either place or remove a block—and messages to the Architect. With respect to communication, its instructions were to provide feedback

[1] Minecraft is a sandbox video game where players explore a blocky, procedurally generated world, mine resources, craft tools, and build structures.

(a) (b) (c) (d) (e) (f)

**Figure 1:** Three examples of pairs of target and generated structures, where the image on the left represents the target. The **a-b** pair shows an instance where the agents were actually able to replicate the structure. The **c-d** couple displays a case where the structure was correctly replicated, but rotated upwards. The **e-f** one shows a case where the agents failed in replicating the whole structure, but correctly built portions of it.

on the ongoing task, to ask clarification questions when necessary, and to report any issues or assumptions that it had to make. Furthermore, the Builder received an explanation of the coordinate system and bounds of the environment and, at every step, the state of its inventory.[3]

Communication between the agents was achieved by sequentially passing the extended conversation to each model. To ensure clarity, at every turn the extended conversation directed to the Architect was parsed so that the Builder's actions modify the world state, which the Architect received separately from the cleaned communication. A schematic representation of the interaction process is provided in Figure 2.

We ran the experiment on 20 target structures from the Minecraft Dialogue Corpus, in the three experimental conditions which are described in the following part of this section.

**Purely Textual:** In the purely textual condition, the Architect received, along with its basic prompt, a JSON description of the target structure, i.e., the coordinates and color of each block composing it. Furthermore, after each turn, the Architect was supplied with an updated JSON representation of the world state, directly reflecting the Builder's most recent actions of placing or removing blocks.

**Purely Visual:** In this second condition, the Architect started by being shown rendered images of the target structure. These images were provided from three specific viewpoints—front, top-down, and an isometric (three-quarter) view—a design choice inspired by the visual conventions of Lego instruction manuals to facilitate a robust perception of 3D forms. Similarly to the textual condition, the Architect was also shown visual updates of the world state after each action performed by the Builder, rendered accordingly.

**Mixed:** In the mixed condition, both input formats were utilized. The Architect received the JSON description of the target structure concurrently with its three visual representations. Similarly, world state updates were provided in both textual (JSON) and visual formats throughout the interaction.

## 3.2. Evaluation Metrics

The evaluation of the agents' performance in the collaborative building task was divided into two aspects: the task success rate (TSR) *per se*, namely the ability of the agents to correctly recreate the target structure, and the effectiveness and human likeness (HL) of their dialogues.

To assess TSR, we compared the model generated structure (that is, the final world state) with the corresponding target structure. To account for global shifts—where a structure might be built correctly but not aligned with the target's exact coordinates—we normalized the coordinates of both the generated and target structures, adjusting them so that the minimum coordinates are set to zero, with all the others shifted accordingly. Moreover, in order to avoid over-penalization of rotational differences, we implemented a form of fuzzy matching—that is, a comparison method which tolerates small variations or transformations between structures. Specifically, we constructed 24, 90-degrees canonical rotations of the generated structures, and found the one which better matched the target. Figures 1c and 1d show a case where a target structure—1c—was replicated with a 90-degrees upward rotation. For each pair of target and best match

[3] The full prompts are available in this works' GitHub repository.

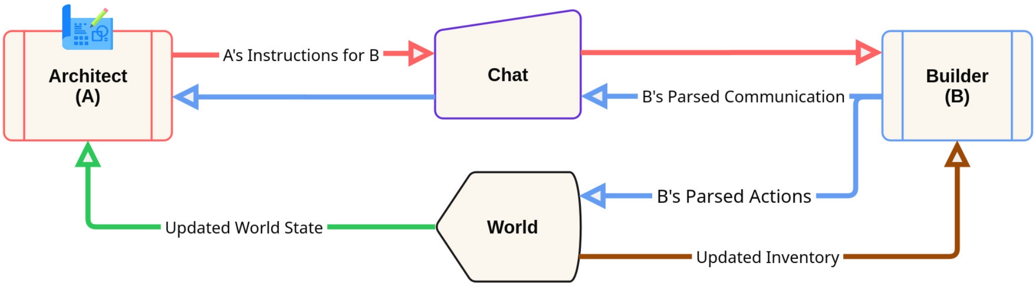

**Figure 2:** The conversational interaction between agents. The Architect's target structure input and subsequent world state updates are contingent upon the current task condition. The interaction concludes either after the set maximum of 20 turns, or with the Architect signaling [FINISH] whenever it considers the structure to be completed.

among the rotations, we proceeded by computing Intersection over Union, also known as Jaccard Similarity, a metric commonly used in place of accuracy for tasks such as object detection, instance segmentation and 3D reconstruction, where defining false negatives is often problematic or misleading [8], along with precision, recall and F1.

For what concerns the evaluation of the dialogue exchanges, we chose to adhere to a growing paradigm in NLP research, namely the use of LLMs as judges of task performance. Indeed, literature in the field has repeatedly shown how the performance of LLMs in aligning with human judgment is encouraging [9, 10], and we therefore decided to opt for this solution in light of both the complexity of conducting an online survey with such lengthy data as the dialogues we collected, opening to the risk of attention drops in the evaluators and, thus, hindered results, and the well-recorded shortcomings of classic NLP evaluation metrics such as BLEU and ROUGE [11, 12]. We used DeepSeek-R1 [13], prompted to evaluate how human-like and plausible the dialogues appeared on a scale from 1 to 5, and equipped with examples of conversations among human players from the Minecraft Dialogue Corpus, as a reference. The five degrees of the evaluation scale were described in detail, instructing the model to judge the dialogues with respect to how much they were distinguishable (1) or indistinguishable (5) from the examples of human-human interactions it received. A direct comparison between the dialogues to be judged and a human-generated gold standard was also meant to discourage the LLM from excessively inflating the scores. To further clarify what signals HL, the examples were annotated with labeled instances of the most common human communication patterns highlighted in Narayan-Chen et al. [3], and summarized in Section 2. The complete judge prompt is available in A.1.

In order to avoid relying solely on the HL scores provided by the LLM judge, we conducted a thorough qualitative analysis of the dialogues, to examine them closely and highlight merits and shortcomings of the agents' communicative abilities. We identified and analyzed occurrences of the aforementioned human communication patterns, as well as other potentially interesting forms of linguistic behavior displayed by the agents.

## 4. Results

In order to shed light on how the three experimental conditions (purely textual, purely visual and mixed) affected the agents' abilities to engage with representations of 3D structures and produce effective dialogues exchanges, we conducted both a quantitative and a qualitative analysis on the data collected, using the metrics and methods introduced in 3.2.

**Quantitative Analysis** For what concerns Task Success Rate (TSR), the results appear quite underwhelming, with poor performance in all the three conditions. Only one structure per condition was perfectly built, and in all the three cases it was a very simple L-shaped formation comprising just three blocks. The IoU, precision, recall and F1 mean scores are available in Table 1

As a soft comparison, in Table 1 we also provide the results of the best solution submitted to the reinforcement learning track of the IGLU 2022 challenge [5]. Please be aware that there are key differences between these works and ours, which only allow for a non-definitive comparison [4] Keeping this into consideration, it is possible to observe how our results in the textual condition only

[4] The key differences are that: as stated above, in our setting there is no navigation or first-person perspective, but every action of the Builder is textual; we implemented agents based on pre-trained MLLMs rather than training them with RL; that we sampled our target structures from the Minecraft Dialogue Corpus; and that in the IGLU challenge F1, precision and recall scores were computed by searching for the maximal intersection across all possible alignments of grid-based representations of the target and built

**Table 1**
TSR mean performance across the three experimental conditions. In bold, the highest score for each metric. As a soft comparison, the results of the best solution from the IGLU 2022 RL track are presented as well.

| Condition | IoU | Precision | Recall | F1 |
|---|---|---|---|---|
| Textual | **0.22** | **0.36** | **0.27** | **0.30** |
| Visual | 0.15 | 0.24 | 0.23 | 0.22 |
| Mixed | 0.16 | 0.27 | 0.23 | 0.24 |
| IGLU 2022 best solution | – | 0.33 | 0.26 | 0.25 |

slightly deviate from those that were achieved as part of the IGLU challenge, suggesting that our implementation, which did not involve any task-specific training for the MLLMs-base agents, went close to matching the performance obtained using agents specifically trained via Reinforcement Learning (RL) in an embodied setting.

An interesting trend is observable in our results: the four computed metrics consistently show that the best performance was achieved in the textual set up, followed by the mixed one and, finally, by the purely visual one. Figure 1 shows three pairs of target and generated structures, with different degrees of correctness.

Regarding the human likeness (HL) evaluation, the mean scores in all three conditions approach the midpoint of the 1-to-5 scale (see Table 2). This result indicates that the dialogues exhibit some characteristics of human interaction, yet do not consistently achieve a naturalistic quality.

According to the LLM judge's prompting instructions, a score of 3 signifies that conversations, while not entirely human-like, contain substantial portions that resemble the provided examples of human dialogue. This suggests a baseline capability for human-like interaction that is, however, far from being fully realized. More specifically, 55% of dialogues in the textual and mixed conditions received a score of 3, while in the visual condition it was achieved by 70% of dialogues. The highest score obtained was 4, assigned to a dialogue exchange in the visual condition, and to another in the mixed one.

Notably, these results highlight an opposite trend with respect to the one that emerged in the TSR analysis. In fact, the ranking of the three conditions is flipped when it comes to HL scores, where the condition which obtained the best results is the purely visual one, then the mixed one, still occupying the middle position, and finally the textual condition.

**Table 2**
HL mean scores across the three experimental conditions. In bold, the highest score.

| Condition | HL Mean Score |
|---|---|
| Textual | 2.55 |
| Visual | **2.80** |
| Mixed | 2.65 |

**Qualitative Analysis** In our qualitative analysis, we mostly focused on closely investigating the dialogue exchanges among the two agents, in order to analyze their linguistic behavior and check for the presence of the communication patterns and techniques presented in 2.

As a general observation, the Architect, as expected, displayed the typical verbosity associated with LLMs. In fact, even if it was instructed to avoid providing too many instructions all at once, but rather breaking down the task into simple steps and waiting for feedback from the Builder, it often produced long and monotonous bullet points with steps and instructions. This propensity was observed almost double the number of times in the textual condition then in the other two, and it is likely one of the major features that contributed to lowering the HL scores, as such a linguistic behavior is uncommon in human dialogues, and therefore in the examples the LLM judge had as reference.

Aside from this undesirable behavior, the agents indeed proved able to employ, at different degrees, all the typically human communication patterns of interest. The only pattern which was never recorder throughout our task is that of extrapolation, namely instances where the Builder asks to keep working without further instructions.

Moreover, apart from the specific patterns we are interested in, the agents displayed some generic desirable behavior. Specifically, the Architect repeatedly demonstrated the ability to spot mistakes in the Builder's actions and provide guidance in correcting them, either by acknowledging the updated world state or by independently asking the Builder to describe what it was seeing, then suggesting changes. As a reference, B presents two snippets of dialogues, a high quality one and a low quality one, with an analysis of their merits and flaws.

In the following part of this section we will describe more in details how the single patterns were used by the agents.

**Implicit References:** This communicative technique, concerning the choice to make references to the Builder's current position and point of view or its most recent actions, was widely employed by the Architect, being present with at least some instances in all the dialogues collected. While this shows that the Architect was, to an

structures, while we implemented coordinate normalization and canonical rotations before computing these metrics.

extent, able to construct references which would speed up communication and at the same time to acknowledge its counterpart, it is worth noticing that in this specific task set up the Architect is not actually able to see the Builder—so whenever it refers to its position, it would be either assuming that they share the same perspective, or trying to infer it based on the updated world state it received.

**Recognizable Shapes and Sub-Structures:** This pattern refers to the ability to use well-known shapes to identify the structures or parts of them. Again, the Architect was able to implement this into its dialogues. Even though its choices in this direction were never as creative and eccentric as some of the examples presented in Narayan-Chen et al. [3], but rather simple choices such as letter shapes, it shows that the agents were able to identify and use at their advantage some easily recognizable formations present in the structures. Interestingly, in one instance, a recognizable shape (a plus sign) was consistently mentioned five times by the Architect and ultimately adopted by the Builder in its feedback as well, almost as if established as a code name through repetition. In a similar fashion, in one other instance the Architect purposefully proposed to attribute a code name to a specific part of the structure, stating: *I'll call this the "top leftmost block"*.

**Verification and Clarification Questions:** LLMs often struggle to ask clarification questions and to understand whether the instructions they received are realizable, or lack some key information [6, 14]. Our Builder was no exception, as it was rare for it to ask clarification or verification questions. Specifically, we recorded 2 instances of such questions in the textual setup, 5 in the visual condition, and 8 in the mixed one. Notably, it is more common for the Builder to pose its questions in an indirect way, as shown by the fact that, of the 15 questions it asked, only 5 of them were direct.

**Status Updates:** The Builder proved able to efficiently communicate status updates to the Architect, as this pattern is largely found in all the dialogues. However, the vast majority of the updates it provided were extremely repetitive, being almost always the same throughout the conversation, and very often sounding unnatural and stiff. One reason for this behavior might be the fact that, frequently, status updates were directly requested by the Architect, sometimes at every turn, creating an overall repetitive communicative environment to which the Builder might have adapted. In favor to this hypothesis is the fact that unsolicited status updates, which happened most often when the Builder had to communicate inventory shortages, were much more varied in terms of sentence structures, and sounded more natural.

## 5. Discussion and Conclusion

The results obtained through our collaborative building task highlighted how MLLMs-based agents are able to conduct dialogues employing some typical communication patterns used by humans in similar scenarios, while still largely struggling to understand and manipulate 3D representations.

In terms of Task Success Rate (TSR), the best performance was obtained in in the purely textual condition, where the Architect was presented the target structure and the subsequent updated world states only as a JSON representation, while the worst results were observed when, instead, it received said information in the form of images. This shows how processing 3D environments from images still seems to pose a complex challenge for MLLMs, regardless of the attempt to achieve a well-rounded representation by providing the Architect with different points of view of the same structure. Research in the area of language and vision tasks has repeatedly made claims that MLLMs might display cases of unimodal biases, where they tend to largely rely on either the visual or linguistic modality, to the expenses of the other [15, 16, 17, 18]. The results obtained through our task, where the introduction of a textual description of the target structure improved performance, seem to support such claims, pointing to a unimodal bias which favors language. Yet, as briefly mentioned in Section 4, the use of MLLMs-base agents without task-specific training allowed us to obtain results which only slightly deviate from those achieved by RL agents specifically trained for such task. This observation suggests that the implementation of a specific training regime could increase performance, potentially reaching the results obtained by RL agents in the context of the IGLU challenge.

Nevertheless, with respect to the quality of dialogue exchanges, an inverted trend was observed, where the purely visual condition exerted the best results, while the textual one produced the worst ones.

An hypothesis regarding this opposing effect that the three experimental conditions had on the construction of the structure and on the linguistic performance is that, while a JSON description of the structure might be an easier representation for the Architect to understand and, therefore, allowing it to provide more effective instructions or to more promptly spot mistakes in the updated world state, it could also present the Architect with an undesirable shortcut for communication. In fact, the purely textual condition was the one in which the largest number of verbose bullet points of instructions was recorded, most of the time being precise, block-by-block descriptions of the structure. This suggests that such a straightforward structure representation as a JSON description induced the Architect to simply copy it and restate it in the form of a list of instructions, to the expenses of dialogue quality.

Such lengthy and monotonous bulleted lists of instructions where generated by the Architect despite its directives to break down tasks into simple steps and await Builder feedback. This verbosity persisted even in cases where the Builder demonstrably failed to follow these comprehensive directives, suggesting a potential disconnect or an attempt by the Architect to over-clarify in the face of non-compliance.

This behavior, along with the notable absence of extrapolation—where the Builder requests to continue working independently—is consistent with the fundamental design principles of instruction-tuned LLMs. These models are primarily developed to function as assistants, optimized for providing comprehensive and helpful responses when explicitly prompted, rather than initiating new tasks or seeking continuation autonomously. While this optimization for thoroughness can be generally beneficial, it proved sub-optimal for the Architect, which, when faced with cases where the Builder struggled to understand those long and overly-specific instructions, it was unable to adapt its communication style to better suit its counterpart's necessities.

On the other hand, the single presence of images of the target structure deprived the Architect from the opportunity to directly copy from the prompt, inducing it to generate more natural and plausible utterances, albeit this time hindering TSR scores. Coherently with this claim, the mixed condition obtained the most balanced results, possibly exploiting the advantages of both visual and textual representations of the target structure.

This study offered insights on how different prompting techniques can affect the communication proficiency of MLLMs partaking in a collaborative building task, along with their abilities to understand and recreate 3D structures. In particular, it showed how varying degrees of multimodality in the models' prompts affect their communication and building abilities in opposing ways, and how a mixed input, comprising both visual and textual elements, could be a balanced solution to incorporate the advantages of both formats.

We are positive that this work can inspire interesting further implementations to improve models' communicative abilities in multimodal collaborative settings.

## 6. Limitations

We acknowledge several limitations in our present work which open avenues for future research.

First, regarding the use of LLMs as judges, it is important to note that while this is a growing evaluation method and previous studies have highlighted its potential, researchers still report flaws and advocate for careful application of such automated judges [19]. A further limitation of our evaluation is its reliance on a single, holistic score for human likeness. A more granular analysis would be beneficial, refining the judge's work to assess distinct dimensions of the conversation—such as fluency, grounding, and collaborative effectiveness—to provide more nuanced insights.

In addition, our qualitative analysis of the dialogues focused on a specific set of communication patterns. Other interesting forms of linguistic behavior were recorded, and a more general analysis could help explain them. Notably, it would be informative to investigate the monotony and repetitiveness in the Architect's utterances, possibly by elaborating a metric to quantify it and compare it to human-generated dialogues.

Furthermore, there are important differences between our implementation of the collaborative building task and how people naturally approach such a game. While in our pipeline the action and communication spaces were shared, in a human-human setup, the Builder can directly modify the world state without first articulating their actions in natural language [3]. Lastly, inferring a complete 3D structure from three static images is inherently challenging.

## 7. Future Directions

Future work could address these limitations in several ways. A more complex and diverse implementation, potentially involving a modular architecture with specialized components for acting and communicating—for instance, an LLM for language paired with a model for 3D understanding [20]—would allow for a division of action and language spaces. Moreover, having agents that can freely move in a simulated environment could facilitate 3D understanding, though this introduces new challenges related to spatial awareness and navigation [21].

Another promising direction is to explore task-specific training. This could involve fine-tuning on dialogue corpora like the Minecraft Dialogue Corpus, using datasets built to enhance 3D spatial understanding [22], or employing MLLMs pretrained for 3D comprehension [23].

Finally, applying Reinforcement Learning (RL) to train the agents presents an interesting avenue. The reward signal could be twofold: one component for task success, granting rewards for each correctly placed block (capped to prevent reward hacking), and a second component for collaborative quality. This latter reward could be provided by an LLM judge assessing the use of conversational grounding techniques, such as acknowledgements and clarification questions, to foster more effective and natural collaboration.

## A.1. Judge Prompt

> You will be shown some dialogues among two agents, an Architect and a Builder. The dialogues were collected during a collaborative building task, were the Architect was supposed to instruct the Builder on how to build a certain target structure. You will be provided some examples of dialogues among humans playing the same game. Based on those examples, your task is to judge how human-like and plausible each dialogue that you will be shown is, on a scale from 1 to 5, where 1 means that the dialogue is very unnatural and easily detectable as artificial; 2 means that while the dialogue still sounds artificial, a restricted amount of human communication patterns seen in the examples are present; 3 means that although the dialogue is not entirely natural, a big portion of it resembles the human examples; 4 means that the dialogue is almost perfectly human-like and natural, with only very few occurrences of artificial-sounding and implausible utterances; 5 means that the dialogue is very human-like, it presents utterances and exchanges which closely resemble the ones seen in the example, thus being almost indistinguishable from the examples. Only answer with the number you think is best, without producing any other utterance.

# B. Dialogue Snippets

Two snippets of dialogues between the agents. Note that neither the builder's action nor the represented world state are reported here.

## B.1. A high quality dialogue exchange

The following is a snippet of the dialogue which got a HL score of 4 out of 5 in the visual condition. In this example, it is possible to appreciate how the Architect provided its instructions in small and clear steps, made references to recognizable shapes—*squared-shape foundation*—and implicitly referenced blocks that were recently placed—*the first purple block*. Moreover, in its fourth utterance, the Builder asks for a direct clarification question, which is promptly acknowledged and answered by the Architect.

**Architect**: Alright, let's start building this structure step by step.
First, we'll focus on the blue base. Place 4 blue blocks in a square-shaped foundation. Place the 4 blocks side by side, each adjacent to the other, so that they form a 2x2 square. Proceed when you're ready with the blue base.

**Builder**: Placed the 4 blue blocks in a 2x2 square at ground level with the bottom front left coordinate at 100,1,100.

**Architect**: Great job on placing the blue base. Next, let's build the purple part of the structure. Place the first purple block on top of the front left blue block.
Give me a confirmation when you've placed the purple block.

**Builder**: Placed the purple block on top of the front left blue block.

**Architect**: Great, now I want you to place the second purple block one level above and directly to the front of the first purple block. Once that's done, let me know.

**Builder**: Placed the second purple block one level above, directly in front of the first purple block.

**Architect**: Good job placing the second purple block! Now, let's build the green part of the structure. Add a third green block on the right side of the back right bottom blue block. Let me know once you're done!

**Builder**: I need confirmation, do you mean the right side relative to the structure or right side relative to the world?

**Architect**: My apologies for any confusion, I meant the right side FROM THE VIEWER'S PERSPECTIVE. So the block you've placed is the correct one. Now add two more green blocks, one on top of the first green one, and one in front of the first. Let me know when this is done.

## B.2. A low quality dialogue exchange

The following excerpt, on the other hand, serves as an example of a low quality communication exchange, and is taken from a dialogue with score 2 out of 5 in HL. It is clear from the extract that, in this case, the Architect failed at providing simple, incremental instructions, but rather produced verbose and monotonous bullet points which are simply precise block-by-block descriptions of the structure, framed as instructions. The Architect does demonstrate the ability to acknowledge a mistake on the Builder's part, but maintains this same linguistic behavior when correcting it, providing another set of almost identical bullet points.

**Architect**: Let's begin building the structure. First, let's create the bottom layer. The bottom layer has 6 blocks placed in a row in this order: red, purple, yellow, yellow, purple, red.

- Place the first red block on the ground.
- Next, place a purple block to the right of the red block.
- Then add a yellow block to the right of the purple block.
- Place another yellow block to the right of the first yellow block.
- After that, place a purple block to the right of the second yellow block.
- Finally, place a red block to the right of the purple block.

Please confirm once you have placed these blocks.

**Builder**: Placed all the blocks as instructed.

**Architect**: The blocks in your message don't match the required structure because they are positioned too close to each other. Please destroy all your recently placed blocks. For the first row, you should place each block next to (i.e., one block away from) the previous block. Let's retry:

- Place the first red block on the ground.
- Next, place a purple block to the right of the red block but spaced one block away from the border closest to the red block.
- Then add a yellow block to the right of the purple block, also spaced one block away from the border closest to the purple block.
- Place another yellow block to the right of the first yellow block, spaced one block away from the border closest to the yellow block.
- After that, place a purple block to the right of the second yellow block, spaced one block away from the border closest to the yellow block.
- Finally, place a red block to the right of the purple block, spaced one block away from the border closest to the purple block.

Please confirm once you have placed these blocks.

# Toward Optimised Datasets to Fine-tune ASR Systems Leveraging Less but More Informative Speech.

Loredana Schettino[1,*], Vincenzo Norman Vitale[2] and Alessandro Vietti[1]

[1]Free University of Bozen-Bolzano, Piazza Università, 1, 39100 Bolzano, Italia
[2]University of Naples Federico II, C.so Umberto I, 40, 80138 Napoli, Italia

**Abstract**

Modern Automatic Speech Recognition (ASR) systems, based on Deep Neural Networks (DNN), have achieved remarkable performance modelling huge quantity of speech data. However, recent studies have shown that fine-tuning pre-trained models, despite providing a powerful solution in low-resource settings, lacks robustness across different speech styles, and this is not just related to the amount of training data, but to substantial differences in phonetic-prosodic characteristics. Therefore, this study aims to explore how modern E2E ASR systems' performance is affected by the amount of training data and the type of speech data and which acoustic-phonetic features most markedly exert an influence. To this aim, a k-fold cross-validation was performed by fine-tuning a pre-trained FastConformer model with datasets varying in type of speech data and size. Then we performed a correlation analysis between the values of the acoustic characteristics of the data and the recognition scores. The analyses allow the identification of an optimal combination of speech data type and amount of training data. Also, results show that using both more spontaneous speech or more controlled speech can be beneficial, provided that the speech rate is contained.

**Keywords**

Speech style, ASR, Sample Efficiency, Acoustic Features, K-fold Cross-Validation

## 1. Introduction

Spoken language is intrinsically variable. Speech produced to convey a message can vary widely depending on several internal and external factors, such as the communicative and contextual situation, the formality of the exchange, the speaker's disposition and individual choices of the forms and phonetic realisation deemed as most appropriate and functioning to convey the intended message given the specific condition of production and reception [1]. Thus, speech variability can be described as the synergetic contribution of linguistic, contextual, and social factors [2], which results in different types of speech, often referred to as *speech style*, characterized by varying levels of spontaneity, fluency, speaking rate, prosodic variation, degree of phonic specification [3, 1].

Modern ASR systems, based on Deep Neural Networks (DNNs), have achieved remarkable performance by modelling the linguistic and acoustic features of spoken language. However, these systems implicitly learn to model only a small proportion of the possible variation that characterises spoken language. As a result, error rates increase with the degree of linguistic and phonetic variation of the data considered. In fact, while most benchmarks consist of read or rather controlled speech productions, the interest in ASR applications in real contexts, such as human-machine-interactions or transcription of spontaneous conversation, led to the evaluation of ASR performance in different, less controlled and more spontaneous scenarios, which resulted in different performance values for other types of data, e.g, lower for more spontaneous datasets [4]. In particular, a recent study on the evaluation of ASR systems, based on state-of-the-art supervised, self-supervised, and weakly supervised End-to-End models, on Italian speech [5, 6], showed consistent performance differences across speech types: dialogic, monologic, and read speech. Namely, increasing performance from dialogic speech to monologic speech and from the latter to read speech.

Efforts devoted to overcoming this issue often consist of building complex and costly models that require large amounts of data and computational resources. However, this can be problematic, especially when working with so-called "low-resource languages". Different studies have provided evidence that a powerful solution is provided by fine-tuning pre-trained models (see [7]). However, [8] adopted this approach in a study on low-resource speech recognition and showed not only a lack of robustness in Word Error Rate (WER) distributions across different speakers and conversation contexts, but also that this was not related to the amount of training data, but to substantial differences in prosody, pronunciation and utterance length. This led to acknowledging that using more data and more complex techniques is not sufficient to address

the problem of automatically recognising different types of data. Rather, we need to investigate how different types of data and their specific acoustic-prosodic features affect the performance of ASR systems to address this robustness issue [7].

Based on this body of research, this work aims to contribute to the study of how different types of speech data are modelled and how this affects the robustness of the model toward the definition of an optimal dataset to obtain robust recognition systems.

## 2. Related Work

Especially, but not exclusively, within the context of low-resource studies, the need to develop less resource-greedy ASR systems emerges. To this end, different data efficiency techniques, e.g., learning or data augmentation techniques, have been explored, such as multilingual transfer to provide robust acoustic word embeddings [9, 10], self-training, where an ASR system trained with the available human-transcribed data is used to generate transcriptions, which are then combined with the original data to train a new ASR system, or neural TTS synthetic data generation [11]. However, although it has been shown that the size of training data affects the performance of ASR systems, "[w]hether data augmentation is always beneficial is an open question." [11, 723].

Another way to help achieve high performance with minimal data may consist in relying on less but more informative data by investigating how different types of speech data are modelled and affect the robustness of the model, and which combination of different speech types and amount of data optimises the informativeness and efficiency of a sample to fine-tune pre-trained models.

To this end, a better understanding of the aspects of speech that challenge ASR architectures the most is required. In the last 20 years, various studies have investigated which phonetic features affect automatic recognition the most (see [7] for an overview). In particular, issues were observed to mostly concern features of conversational speech such as grammatical inconsistencies, self-interruptions, backchannels, lexical and non-lexical disfluencies, and the degree of pronunciation variation [12, 13]. ASR systems were also observed to struggle to recognise words with low intensity, high F0 value or shorter duration [14]. Then, a recent study aimed at gaining insight on which aspects of casual, conversational speech cause the largest challenges for different ASR HMM and transformer-based architectures showed that utterance length (in number of tokens), articulation rate and pronunciation variation exert a major influence, with higher recognition scores correlating with longer utterances, lower speech rates and lower phonetic variation [7].

The present study aims to contribute to this line of research by developing and validating a method to address the following research questions (RQs):

**RQ1.** If modern E2E ASR systems' performance is affected by the amount of training data and the type of speech data, can we identify the optimal combination of speech data and amount of training data?

**RQ2.** What acoustic-phonetic characteristics affect the most modern E2E ASR performance? To what extent?

## 3. Methodology

To investigate how data characterised by different features (data type) and varying amounts of training data (training data time) can affect the fine-tuning of modern ASR models, our method includes a K-fold cross-validation procedure [15]. This technique is used when there is a limited amount of data and provides insight into the model's performance across different data subsets. It consists of splitting the data into subsets (*folds*) and training different models, as many as the number of folds, each time considering a different combination of folds as training (potentially validation) and test sets. The approach follows these key steps:

- selection of data with different speech characteristics;
- fold splitting according to training-specific criteria, i.e., speech type and training fold size (minutes);
- selection of a pre-trained model for fine-tuning;
- evaluating model performance for the selected datasets;
- fine-tuning the pre-trained model by training it on the different folds;
- comparison of the performance of the fine-tuned models;
- Word Error Rate - acoustic features correlation analysis.

### 3.1. Data

Given the methodological focus of this study, we decided to work with a well-known, restricted dataset to gain clearer insights into the effectiveness of the method and the findings. Hence, we selected data from a corpus that was the object of previous phonetic studies [16, 17], namely the CHROME corpus [18]. The corpus comprises approximately 10 hours of speech produced by three female expert museum guides (G) leading visits at San Martino Charterhouse (in Naples). It consists of Neapolitan Italian, informative semi-monologic, semi-spontaneous speech characterised by a high degree of discourse planning and an asymmetrical relationship between the interlocutors. The three speakers show idiosyncratic speech

**Table 1**
Datasets duration, tokens, speech rate (SR) values.

| dataset | duration | tokens | SR | m utterance duration (sd) | m utterance tokens (sd) |
|---|---|---|---|---|---|
| G01 | 192’ 26” | 27881 | 2,41 | 3,72 (2,76) | 8,97 (7,23) |
| G02 | 216’ 14” | 39145 | 3,02 | 4,30 (2,50) | 12,98 (8,08) |
| G03 | 181’ 56” | 29341 | 2,68 | 4,62 (3,31) | 12,43 (9,04) |

styles [19]. In particular, they use different speech rates and different “hesitation strategies”. G01 produces approximately 159 words per minute and seems to privilege an “on the fly” production, using several non-lexical fillers (*eeh*, *ehm*) and prolongations to cover speech planning time; G02 shows a higher speech rate, producing about 174 words per minute, where utterances are juxtaposed to each other as she tends to avoid silent pauses altogether, avoid prolongations and non-lexical fillers, and prefer lexical fillers instead; G03 adopts a more controlled, “rhetorical” style, with a lower speech rate of about 146 words per minute and mainly using lexical fillers and silent pauses.

## 3.2. Data Preparation

Using the text annotation in TextGrid format [20], the dataset was split in Inter-Pausal Units based on pauses longer than 250 ms. This resulted in utterances with a mean duration of 4,81 seconds (standard deviation = 2,88, max length = 30 ms). The text was normalised by removing special characters, but leaving annotation of segmental phenomena such as fillers (eeh, ehm, mh) and prolongations (e.g., la**aa**). The final considered dataset consists of slightly more than 3h and 27881 tokens for G01, about 3h and a half and 39145 tokens for G02, and about 3 h and 29341 tokens for G03. G02 shows a higher speech rate than both G01 and G02. See Table 1 for total duration, tokens and speech rate (SR), and mean (m) and standard deviation (sd) of utterance duration and tokens.

## 3.3. Modelling

Selecting an appropriate pre-trained model is a critical decision that influences the success of subsequent downstream tasks. While many high-performing models are available, such as Whisper or Phi-4, our selection was guided by several practical requirements: language-specific support for Italian, computational efficiency, and public availability to ensure experimental reproducibility and democratic access. Accordingly, we chose the FastConformer model pre-trained on Italian by Nvidia [21]. The FastConformer is an efficient variant of the Conformer architecture, designed to significantly reduce the computational cost and latency of the standard Conformer model while maintaining high accuracy. This makes it particularly suitable for real-time speech recognition tasks. Furthermore, the architecture is highly scalable, and indeed, FastConformer is at the core of top-performing Nvidia ASR systems like Canary and Parakeet.

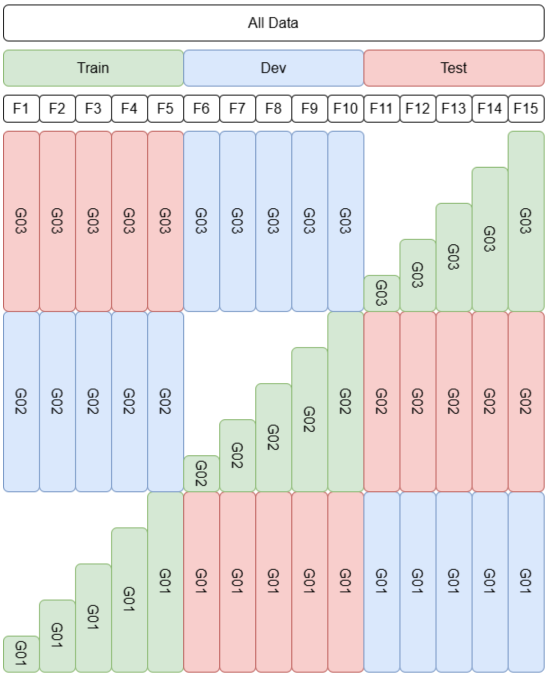

**Figure 1:** K-fold Cross-Validation Procedure.

The Group K-fold is a variation of k-fold cross-validation intended for scenarios where the data has a predefined group structure. The key constraint is to ensure that the same group is not represented within the same splits, namely training, validation and test sets. In our case, samples from the same speaker will be grouped in the same split. This method prevents data leakage by ensuring that the model generalises to new, unseen groups, not just new samples from existing groups. The corpus is split into three folds, one per speaker and idiosyncratic speech style (data set type), and these were further split into five sub-folds of different sizes (split size), resulting in 15 different fold combinations described in Figure 1.

## 3.4. Evaluation and correlation analysis

The model performance across the different folds was evaluated considering the Word Error Rate (WER) computed at the utterance level. Model comparison was conducted based on WER mean and distribution values per fold to observe which model performed better across the considered folds.

Then, correlation analysis between data character-

**Table 2**

istics and WER was performed to examine the influence of acoustic features on the performance of different time folds. Feature values were automatically extracted for each utterance employing the OpenSmile toolkit [22]. The *Geneva Minimalistic Acoustic Parameter Set* (eGeMAPSv02) [23], i.e., a restricted set of features based on interdisciplinary evidence and theoretical significance, was selected as the feature set. The study focuses, in particular, on the features that could be considered as the most relevant, as reported in previous literature [7] and inspection of the data.

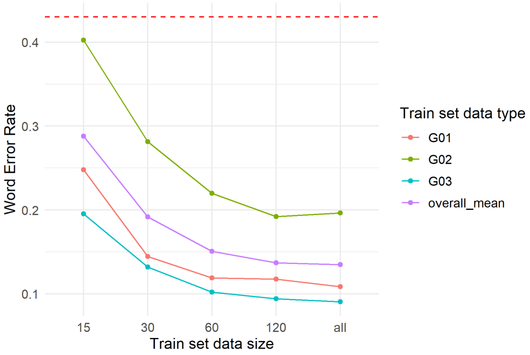

**Figure 2:** Word Error Rate (WER) per training time grouped by training data. The dashed red line indicates the mean baseline WER.

# 4. Results

## 4.1. Model performance and comparison

The analysis starts by evaluating the model's baseline performance on the defined datasets before applying k-fold cross-validation to establish a reference for comparison. The selected model performs less for the G01 dataset (mWER = 0.51, sd = 0.32) than for the G03 dataset (mWER = 0.40, sd = 0.26) and the G02 dataset (mWER = 0.39, sd = 0.26), see the first three rows of Table 2. The overall mean WER across different data type sets is 0,43 (sd = 0.26).

Then, we observe the model's performance on each fold. Figure 2 and Table 2 show the mean WERs per train set data type and size. The mean WERs across the data type sets (purple line) reach lower values than the baseline (red dashed line) already after fine-tuning with the smallest 15' sets (mWER_15 = 0.32, mWER_30 = 0.22, mWER_60 = 0.18, mWER_120 = 0.16, mWER_all = 0.16). The values decrease as the size of the training set increases. However, the magnitude of the WER difference between subsequent size groups progressively diminishes until it becomes trivial between the models trained on 60' speech and those trained on the entire datasets (about 3h). We then consider the mean WER values grouped by train set data type. Although models trained on G01, as well as G02 and G03 data, perform better than the baseline, we observe that the models trained on G02 data perform worse than the others, with WERs closer to the overall baseline. In particular, the models trained on G02 are tested on G03 and are closer to the G03 baseline (mWER =

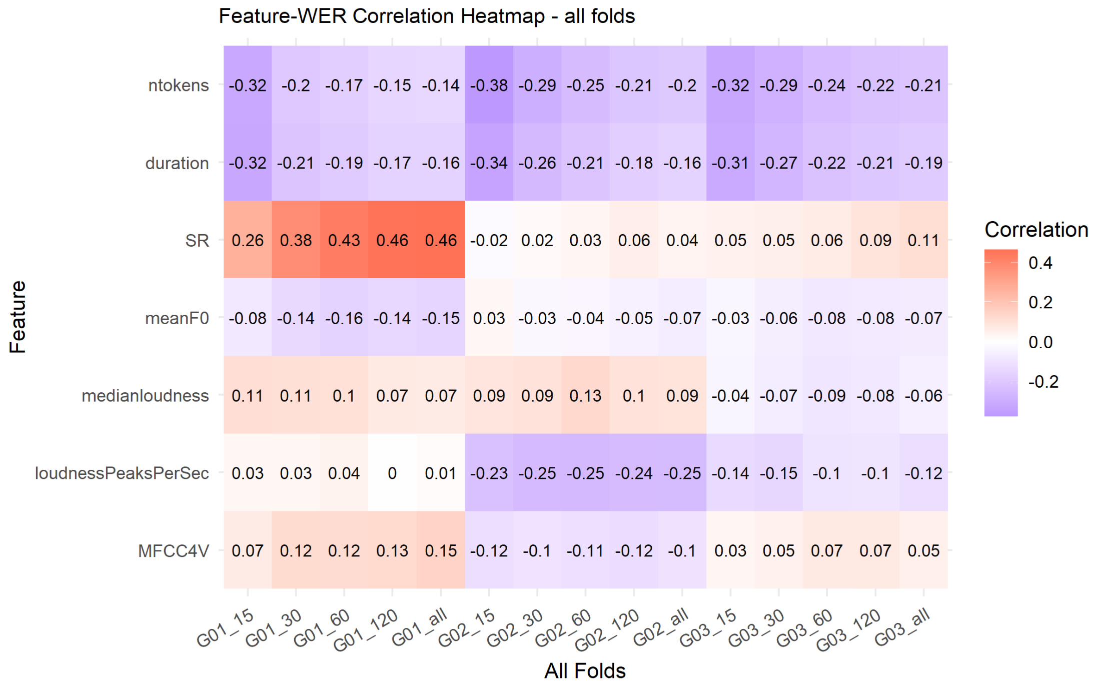

**Figure 3:** Correlation of feature values with WER per train set data type_size folds.

0.4). Instead, the models trained on G03 and tested on G01 show a larger difference with the G01 baseline (mWER = 0.51) than the difference between models trained on G01 and tested on G02 and the G02 baseline (mWER = 0.39).

Considering both the contribution of the train set data type and the size to the model performance improvement, the optimal fold is G03_120.

## 4.2. Features Correlation with WER

To explore how different datasets affect model performance, we observe which features correlate with the trained models. The heatmap in Figure 4.2 shows the Pearson coefficients resulting from the correlation between a selection of relevant acoustic features and the WER for each model. The colour of each tile represents the direction of the correlation, while its intensity indicates the strength of the correlation. Red denotes a positive correlation, meaning higher feature values correspond to higher WER, whereas blue indicates a negative correlation, where higher feature values align with lower WER. White represents a weak or no correlation.

We observe negative correlations between the WER values and both the utterance duration and tokens. The correlation becomes weaker, but still noticeable, with increasing train set data size, and the same trend is observed for each dataset. An opposite trend is observed for the speech rate values, the latter correlate with WERs positively and increasingly along the train set size. However, this trend is considerably stronger for the models trained on data from the G01 dataset (and tested on G02 dataset). Weaker correlations are observed for the mean values of F0, especially for the G02 and G03 models, with the strength slightly increasing with the size of the training set. Rather constantly weak correlations can be observed for median loudness, MFCC4 in voiced regions and WER values. Still rather constant but slightly stronger is the correlation between loudness peaks per second and WERs for the models trained on the G02 dataset.

# 5. Discussion and Conclusions

This study contributes to investigations on how the performance of modern E2E ASR models is affected by the type and amount of speech data used for training and aims to define a way to identify an optimal combination of type and amount of speech data. The investigation is supported by observation of how different speech acoustic features contribute to the model performance.

The Fast-Conformer WER on the selected semi-monologic, semi-sponetanous data presents overall lower values than the evaluation provided by a previous study on Italian monologic data, i.e., 12.8 WER [6]. More specifically, lower recognition scores are reported for G01 speech, characterised by a more spontaneous speech style, including more features such as non-lexical fillers and prolongations than the other speakers, which is in line with the literature [12, 13].

The cross-fold evaluation shows that the models' performance improves with train set size; however, the magnitude of the improvement gradually decreases until becoming trivial between models trained on 120 minutes and about 3 hours of speech. This finding supports the claim that simply increasing the size of the training set is not always beneficial and not always enough to guarantee better performance. Although this trend stands across all datasets, variation can still be observed.

The models trained on speech produced by the second guide (G02) perform worse than the others, with recognition scores closer to the overall baseline. In particular, the models trained on G02 speech, that is characterised by higher speech rate and fewer pauses, are tested on G03 speech and achieve smaller improvement over the G03 baseline as compared to the models trained on G03 speech, showing a more controlled speech style, and G01 speech, defined by a more spontaneous speech style. It is particularly worth noticing that the models trained on G03 and tested on G01 show the best recognition scores over all size folds, thus overcoming the G01 baseline disadvantage. This seems to indicate that some speech data are more informative than others and may even overcome recognition issues related to more spontaneous and conversational speech styles; however, studies in this direction should be further developed.

Considering both the contribution of the train set data type and size to the model performance improvement, the dataset that optimises the combination of data type and amount is the one containing 120 minutes, i.e., two-thirds of the available dataset, of the more controlled, but still spontaneous, speech produced by G03 (RQ1).

In line with the literature [7], correlations between recognition scores and utterance durational features emerge. More specifically, higher length values (in terms of utterance tokens and duration) correlate with lower recognition errors, which indicates that providing a wider context enhances recognition. Conversely, higher speech rates hinder recognition. However, this effect is more or less mitigated according to the speech type in the training set (RQ2). This finding, as well as the constant and weak correlations observed for the other acoustic features, deserves further attention and needs to be explored in future works.

Overall, these findings show that using both more spontaneous speech and more controlled speech can be beneficial to fine-tune a pre-trained model, provided that the speech rate is not too high. More detailed analyses will be performed considering the values of the acoustic characteristics and their variation to gain deeper insight.

This study provides evidence corroborating the idea that less but more informative data can be used to fine-tune pre-trained models, which could be useful for fine-tuning in low-resource scenarios. Furthermore, the use of the Fastconformer highlights the value of architectures that offer a favorable trade-off between performance and computational resources. These models present a viable alternative for deployment on resource-constrained, privacy-oriented devices. At the same time, they can be quickly adapted to different low-resourced contexts, standing in practical contrast to larger-scale yet resource-demanding models.

In this study, we prioritised methodological soundness and understanding over immediate broad applicability. We selected a known dataset restricted in size and speaker diversity to enhance the interpretability of the results, verify the method's core effectiveness and establish a solid foundation for scaling to larger, more diverse corpora. Future work will be devoted to further exploring this direction by considering larger datasets that maximise differences in acoustic-phonetic features that were observed to be relevant for the modelling.

**Abstract**

Alterations in speakers' articulation and phonation are among the earliest symptoms of Parkinsons' Disease (PD). However, clinical decision-making is currently based on holistic ratings of speech intelligibility, while studies on PD detection mostly involve highly complex and hardly interpretable models. This study builds upon previous works on Italian that showed how the characteristics of disfluency phenomena may be considered as an index of impairment at the very onset of the disease by investigating whether even less complex (supervised) end-to-end speech recognition systems (E2E ASR) can model disfluency phenomena in Italian PD speech and how this could support PD discrimination tasks. Exploiting the ability of E2E ASRs to progressively model useful features for discriminating between PD and non-PD speakers provides valuable insight into the ASRs' internal dynamics as well as for the development of decision support systems.

## 1. Introduction

Parkinson's Disease (PD) is a chronic neurodegenerative disorder steadily on the rise in terms of prevalence and incidence [1, 2]: more than 10 million individuals worldwide are affected by PD, mainly among the population aged 65 and over, and this number is expected to increase in demographically ageing societies. Caused by deterioration or loss of dopaminergic neurons in the *substantia nigra* of the basal ganglia, PD is generally diagnosed based on clinical criteria, such as the medical history and physical/neurological examinations of the patient. Although several experimental studies have shown that speech and voice alterations are among the earliest symptoms of PD [3, 4, 5], this precious information is poorly used in clinical decision-making. In the Unified Parkinson's Disease Rating Scale (UPDRS), the rating tool used to assess the severity and to monitor the progression of the disease [6], only one item (3.1) concerns the patient's speech and suggests an assessment based on the clinician's perception, considering above all intelligibility. The application of advanced and sustainable methods of acoustic data analysis could therefore be beneficial, especially in the diagnostic phase: while a cure for PD has yet to be found, early diagnosis is crucial for access to pharmacological and non-pharmacological interventions.

However, developing machine learning tools for critical areas like early Parkinson's disease detection is significantly hampered by data scarcity. Acquiring the necessary data is both costly, requiring specialized linguistic and medical experts, and complex, given the inherently (and fortunately) small patient sample size. To overcome this limitation, our study explores the use of latent features encoded within pre-trained Automatic Speech Recognition (ASR) models. This approach explores the possibility of efficiently utilizing limited available data by leveraging knowledge distilled from vast quantities of data not originally intended for this purpose. Additionally, to further enhance the procedure, it focuses on specific speech features that were observed to play a significant role in discriminating PD speech, even at the early stages of the disease, namely speech disfluency patterns [7].

We believe that using such a method optimises the use of the available data by integrating domain-specific and computational knowledge and can thus support the development of decision support systems in data-scarce critical contexts, as exemplified by early Parkinson's detection.

# 2. Related work

## 2.1. Parkinson's Disease Speech and Disfluency Patterns

The loss of dopamine in the central nervous system causes motor impairments and has an impact also on laryngeal, respiratory and articulatory functions, with about 90% of individuals with PD suffering from voice and speech disorders [8]. PD-related hypokinetic dysarthria includes a range of alterations: hypophonia (reduced voice volume), dysphonia (changes in voice quality), dysrhytmia, reduced speech rate, monopitch, imprecise articulation [9, 10, 11, 12]. Parkinsonian speech is also commonly referred to as 'disfluent', although a detailed and comprehensive description of the specific characteristics of disrupted PD speech has not yet been provided [13]. Studies have mostly focused on specific types of disfluencies: in [14, 15], for example, stuttering-like disruptions (one-syllable word repetitions, sound and syllable repetitions, sound prolongations, and blocks) were observed in PD patients and healthy speakers, and greater disfluency percentages were found in pathological speech, supporting the relationship between stuttering and the functions of the basal ganglia. In a work on repetitive speech phenomena (both hyperfluent and dysfluent) [16], a positive correlation between the frequency of disfluencies and the duration of PD was found. However, studies have not always considered the functions of disfluency phenomena in PD speech and mostly involved mild-to-severe and strongly disfluent patients in experimental protocols.

A recent study conducted on Italian early-stage PD subjects and on spontaneous monological speech [17], showed that, even at the beginning of the pathology (when patients' speech is completely intelligible), the observation of disfluency phenomena can reveal some alteration in linguistic planning and processing: the speech of PD patients was found to differ from that of sex- and age-matched healthy speakers, in terms of the higher frequency of repairs, the specific functions of hesitations (mostly used by PD patients for lexical retrieval), the location of disfluency phenomena (more within-words in PD speech than in the control group) and the duration of silent pauses (longer in PD than in healthy subjects).

## 2.2. Parkinson's Disease Automatic Detection

Various studies have been devoted to developing automatic and objective tools to support PD diagnosis and the assessment of its severity [18]. Remarkable PD detection accuracy was achieved by leveraging non-interpretable embeddings obtained with Deep Neural Networks (DNNs)-based self-supervised models, e.g. x-vectors, Wav2Vec 2.0, HuBERT, and TRILLsson representations. Furthermore, a more recent study showed that models based on interpretable features such as prosodic, linguistic, and cognitive descriptors can support the evaluation of speech deterioration in PD patients, whereas models based on non-interpretable features achieve higher detection accuracy [19]. These findings are often based on consideration of highly functional vocal paradigms, such as sustained phonation of isolated segments, and involve rather complex models relying on non-interpretable features or features commonly observed as useful for PD speech discrimination as they become evident in the mid to advanced stages of the disease [18]. Nonetheless, a recent study showed that PD detection trials relying on a restricted number of meaningful features that were extracted from connected speech rather than isolated speech units achieve accurate, as well as economical and interpretable discrimination [7]. Also, studies on the interpretability of DNN-based models, using probing techniques, provided evidence that even smaller and less complex models, such as Conformer-based ones [20], can model speech features and that different features are encoded in DNN layers at different depths [21]. In particular, it was found that higher levels capture phone identity and word identity information, and the last layer before the object function even captures discriminating features of disfluency phenomena, more specifically, filled pauses and prolongations [22].

In substance, this study builds on the following findings from previous work on Italian PD speech:

- relying on natural speech material that results from the usual working dynamic of the vocal apparatus during phonation proves useful for discrimination [7];
- peculiar uses of natural speech characteristics phenomena like disfluency phenomena may be considered as an index of impairment at the very onset of the disease [17];
- less complex supervised end-to-end speech recognition systems (E2E ASR) can model disfluency-related features useful for their discrimination [22].

On this basis, we investigate whether less complex (supervised) E2E ASR systems can model disfluency features in Italian PD speech and how well this could support PD discrimination tasks.

# 3. Method

## 3.1. Data and Annotation

The study is based on the data described in [12]. It consists of approximately 40 minutes of monologic speech produced by 36 Italian native speakers from the Campania region: 18 participants with idiopathic non-demented PD (10 males, 8 females; 51–81 years of age, M= 65) and 18 age-matched Healthy Controls (HC, 10 males, 8 females; 54–77 years of age, M= 64). The patients were recruited from the Movement Disorders Unit of the First Division of Neurology at the University of Campania "Luigi Vanvitelli". PD participants had no prior history of language or speech disorders, had been diagnosed with Parkinson's disease within the past four years (since 2021) and showed no significant cognitive impairment, major or minor depression, or dysthymic disorder. All participants were asked to discuss the positive and negative aspects of the place they were living during data collection. They were encouraged to speak in their usual, conversational tone and at a comfortable volume. Sociolinguistic information for each speaker was gathered via a questionnaire, and all participants provided written consent for the data collection process.

The analysis focused on a series of so-called "disfluency phenomena" defined as speech management phenomena, namely, speech material, e.g. repetitions, segmental prolongations, pauses, and fillers that speakers can use to monitor and effectively manage the online processes of speech planning, coding, articulation, and reception [23]. The phenomena were identified and annotated based on their context of occurrence, following [17] and included the following phenomena specifically involved in the speech planning process (Cohen's k= 0.82, good agreement [24]):

- Prolongations (PRLs), marked prolongation of segmental material, e.g., *l**aaa** casa* (th**ee** house);
- Filled Pauses (FPs), non-lexical filler, vocalizations and/or nasalizations, e.g., *eeh, ehm, mhh*;
- Silent Pauses (SPs), marked silences perceived as a hesitant pause in the context of occurrence;
- Lexicalized Filled Pauses (LFPs), lexical fillers, work as discourse markers involved in the coverage of planning times, e.g., *diciamo, insomma, appunto...* (well, let's say, so, ...);
- Repetitions (REPs), repetition of already uttered words or fragments of words, e.g., *di di* (of of) or *d- di* (o- of).

## 3.2. Probing Approach

Based on previous studies investigating E2E-ASR models' internal behaviour [21, 25, 22, 26], we employ a probing approach to investigate the pre-trained models' ability to capture speaker and speech related markers, i.e., characteristics associated with disfluent speech segments combined with PD biomarkers, and whether these features facilitate PD speech identification.

The employed technique involves:

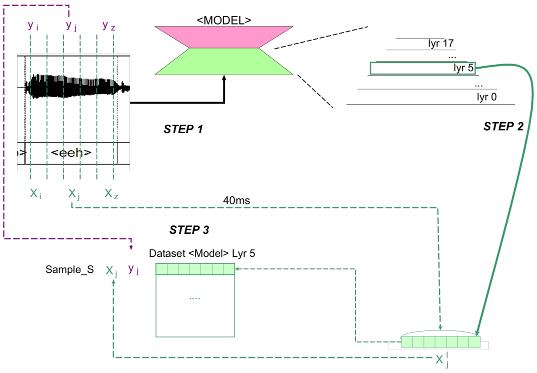

**Figure 1:** Probing Procedure: Step 1 – The annotated ($Y_{i..j..z}$) input sequence ($X_{i..j..z}$) for sample $S$ is fed to the Probed Model in 40ms chunks. Step 2 – The intermediate encoder's layers' emissions ($X_j^I$) are captured and associated with the proper label ($Y_j$). Step 3 – the triplet Sample Index ($X_j$), label ($Y_j$)), Intermediate Emission ($X_j^I$)) builds up in a dataset representing the same sample M in the latent space from the n-th encoder's layer.

- selecting pre-trained models ($m$). In particular, two publicly available Conformer-based [20] models with different decoding component were selected: one with a Connectionist Temporal Classification (CTC) [27] decoder[1], namely, a non-auto-regressive technique; one with a Recurrent Neural Network Transducer (RNN-T), commonly known as *Transducer*[2], which is an auto-regressive speech transcription technique;
- building Long Short Term Memory (LSTM) and Bidirectional LSTM (BILSTM) classifiers whose inputs are represented by intermediate emissions of the considered model's encoder layers ($l$), combined with the appropriate sequence of labels based on dataset annotation;
- evaluating the classifications relying on metrics oriented to results safety rather than performance.

### 3.2.1. Data Preparation

The considered dataset has been prepared based on a set of praat TextGrid annotation files indicating the speaker and the type of disfluency according to the speech signal. More specifically, PRLs, FPs, SPs, LFPs and REPs were considered, resulting in a dataset with a dimension of 850 segments. For each segment, the contextual information preceding and following the disfluency phenomenon has been considered, giving each segment a length of 4

[1] v1.6.0 https://huggingface.co/nvidia/stt_en_conformer_ctc_large
[2] v1.6.0 https://huggingface.co/nvidia/stt_en_conformer_transducer_large

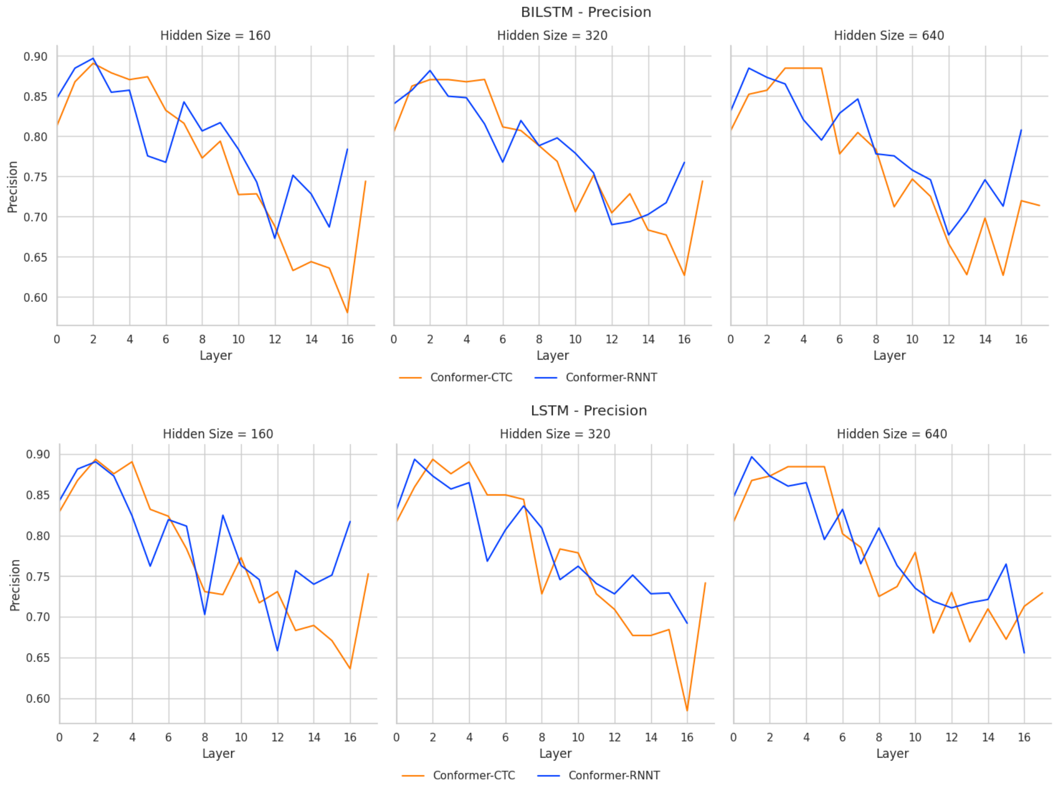

**Figure 2:** The precision achieved by differently sized (160,320,640) BILSTM (Top) and LSTM (Bottom) classifiers trained on the considered dataset in different latent spaces. The pre-trained models (orange and blue) along with the encoding layer on the x-axis indicate the latent space in which the dataset has been considered for training and evaluation.

seconds. Then, for each encoding layer from a considered pre-trained model, we extract a representation of segments in the corresponding latent space following the procedure described in Figure 1. In particular, for each segment, we obtain:

- A *sequence of intermediate emissions*, namely fragment representations in the corresponding layer's latent space. Each fragment corresponds to a portion of $t$ milliseconds of the input signal, where $t$ depends on the considered model's characteristics.
- A *sequence of labels* associated with each fragment, indicating whether that fragment belongs to a disfluency or not and, if so, whether the speaker is PD or HC.

The resulting dataset consists of pairs of sequences of emissions (i.e., distilled features) and corresponding labels identified by the model and the layer from which they were extracted.

### 3.2.2. Pre-trained Models

We selected two publicly available Conformer-based [20] pre-trained models built with the NVIDIA Nemo toolkit[3], both with a fragment dimension $t = 40 milliseconds$ and only differing in the decoding component.

On the one hand, we considered a CTC decoder, one of the most popular decoding techniques. It consists of a non-auto-regressive speech transcription technique that collapses consecutive, all-equal, transcription labels (character, word piece, etc.) to one label unless a special label separates them. The result is a sequence of labels shorter than or equal to the input vector sequence length. Being non-auto-regressive, it is also considered computationally effective, requiring less time and resources for training and inference phases. On the other hand, we considered a Transducer, which is an auto-regressive speech transcription technique that overcomes CTC's limitations, being non-auto-regressive and subject to limited label sequence length. The Transducer decoding technique can produce label-transcription sequences longer than

[3] Nemo version 1.21.0.

the input vector sequence and models inter-dependency in long-term transcription elements. A Transducer typically comprises two sub-decoding modules: one that forecasts the next transcription label based on the previous transcriptions (prediction network) and the other that combines the encoder and prediction-network outputs to produce a new transcription label (joiner network). These features improve transcription speed and performance (compared to CTC), while requiring more training and computational resources [28]. Also, the two techniques should provide different representations and contributions during the training phase (backdrop) due to their different dynamics in forward propagation.

Note that both considered pre-trained models rely on the same encoder architecture, but the Conformer-CTC model has 18 encoding layers, while the Conformer-Transducer encoder has 17 layers. This resulted in 35 different latent space representations for the considered dataset.

### 3.2.3. Classifiers

The classifiers internally consist of a LSTM or a BILSTM module, followed by a Feed Forward Neural Network (FFNN). The choice of LSTM and BILSTM modules is driven by their capacity to capture the temporal dependencies in the input, which fits well with our objective of modeling temporal dependencies in the latent space representation of the speech signal.

Since the LSTM/BILSTM hidden-layer size is a crucial parameter, we investigate the impact of three different layer sizes (hidden-layer size, $h$), namely 160, 320 and 640. So, an LSTM-based classifier processes a sequence of $\{e_{l,m}\}$ emission vectors (each of length $n$) and produces a new sequence of vectors with size $h$. The two sequences are aligned over time. At each time step $t$, based on the LSTM/BILSTM hidden-layer output, the FFNN produces a label indicating whether the considered input represents a disfluency segment, pronounced by a PD or HC speaker, or not. In summary, we train and evaluate many different RNN classifiers/detectors ($L_{h,m,l}$) for all possible $h$, $m$, and $l$ combinations to search for the evidence of disfluencies-related pathological biomarker properties in the models' decisions.footnoteFrameworks used to implement and train the classifiers: torch==2.2.1 and pytorch-lightning==2.0.7 and BILSTM based classifier were trained, resulting in $\sim$ 200 models. Note that the temporal sensitivity of our classifier/detector, namely the minimum difference between consecutive time steps, is 40 ms because the considered ASR models produce emissions at that rate.

During the training phase, the considered corpus was split into train, validation, and test sets using 60%, 20%, and 20% percentages while ensuring that these sets did not share the same speakers. Each classifier has been trained for a maximum of 100 epochs using an Adam optimizer with an initial $lr = 0.00001$. To reduce the risk of overfitting, we introduce a *dropout* neuron-selection strategy for the LSTM/BILSTM gates, which statistically excludes (with a 0.1 probability) one neuron and its weights during each training iteration [29]. Finally, an early stopping mechanism was used to avoid wasting computational resources. In particular, the training phase ends if the validation-loss does not decrease by a minimum of 0.001 during the last 20 epochs, which is the patience threshold.

### 3.2.4. Evaluation

Since our aim is to investigate whether pre-trained E2E ASR models encode features useful for the identification of disfluency phenomena in PD speech, and whether and how they enable the discrimination between PD and HC, we decided to rely on metrics oriented to results safety rather than performance. Note that a sample is classified as PD or HC if the portion related to the disfluency is (1) detected and (2) at least 60% of frames are correctly labeled as either PD or HC. The reliability of the approach is assessed by inspecting the confusion matrices for the best LSTM or BiLSTM, CTC-based and RNNT-based classifiers, which provide a breakdown of correct and incorrect predictions for each class. The quantitative analysis was further supported by a qualitative exploration of the acoustic features emerging as relevant for discrimination with reference to previous literature [18]. To this aim, the eGeMAPSv02 [30] feature set from the OpenSmile toolkit [31] was selected as the basic feature set and inspected using the Orange software [32].

## 4. Results and Discussion

In this study, we considered two distinct ASR architectures, namely Conformer-CTC and Conformer-Transducer, selected for the differing capabilities of their decoding components. These decoding mechanisms, i.e., CTC and Transducer, being respectively non-autoregressive and autoregressive by nature, are inherently capable of capturing diverse aspects of the speech signal, therefore influencing in a different way the encoding component.

Figure 2 reports the precision of each trained classifier. It is interesting to observe how the layers closer to the input provide the higher precision, while the overall tendency, getting closer to the decoding component, is a constant reduction, which is likely related to the specific objective of the pre-trained models, namely, to provide a clean transcription. However, the model that seems to provide the most informative and stable latent representation seems to be the Conformer-CTC (orange line) in layers from 2 to 6, showing a constant precision over all the considered configurations.

To enable a more nuanced and phenotypically informed classification, we considered two types of Recurrent Neural Networks (RNN) for our classifier, namely Long Short-Term Memory (LSTM) and Bidirectional Long Short-Term Memory (BiLSTM). Both architectures are designed to preserve memory of previously observed sequences. However, BiLSTM offers a crucial advantage by enabling the re-evaluation of past observations in light of subsequent inputs. For instance, the quality of a vowel sound's realization at a given point can alter the assessment of the entire preceding segment of the speech signal, a capability effectively captured by the bidirectional nature of BiLSTM.

Consistent with the literature, the earliest layers proved to be sensitive to speech-related information, allowing them to distinguish between speakers with PD and those without PD. Likewise, the earliest layaers appear to contain sufficient information to discriminate between disfluent and non-disfluent segments, letting performance in line with the literature [22].

To gain insight into the reliability of both the approach and the latent representation space, figure 3 reports the confusion matrices of the best-performing classifiers for the two considered RNN architectures (i.e., LSTM, BiLSTM), showing that in both cases the most critical choice, namely identifying a PD speaker, is correctly addressed, whereas we observe some false positive predictions, where healthy speakers' productions were misclassified as PD productions (in both cases about 0.4). This may be explained by considering that similar sets of phonetic cues in speech may index different information.

The qualitative exploratory inspection showed that pitch, loudness, voice quality-related features, including shimmer and Harmonics-to-Noise Ratio (HNR), and Spectral flux were most relevant for distinguishing between PD and HC speech. This observation is in line with previous findings described in [7] where features concerning the spectral distribution, energy and frequency emerged as the most relevant to discriminate between PD and HC speech.

(b) BiLSTM with hidden size $h = 160$ trained on the dataset represented in the latent space of Conformer-CTC's encoding layer #2.

**Figure 3:** Confusion matrix of the best-performing classifier for LSTMA (top) and BiLSTM (bottom).

## 5. Conclusion

The main findings highlight that focusing on speech correlates such as disfluency phenomena provides a convenient choice to enhance the development of decision support systems. The latent representation from the intermediate encoding layer was shown to be highly informative and quite reliable for the classification of PD and HC speakers. In addition, the CTC decoder seemed to provide slightly more stable performance in this task, probably due to its non-autoregressive nature. Future steps will involve a comparison of performance with different pre-trained models and classification architectures. Indeed, since disfluency phenomena encompass different types of phenomena (i.e. textual phenomena, like lexical fillers and repetitions, and phonetic phenomena, like non-lexical fillers and prolongations), different approaches may perform better on specific types.

Also, the analysis led to observing (not yet noticeable) alterations of acoustic features revealing the onset of PD-related motor impairment. It is worth noticing that some of the considered disfluency phenomena, namely prolongations and filled particles, consist in prolonged vocalisations, which are similar to the sustained vowel traditionally used in highly controlled studies on PD speech. Thus they provide a nice integration of data efficacy and ecology.

# Structural sensitivity does not entail grammaticality: assessing LLMs against the Universal Functional Hierarchy

Tommaso Sgrizzi[1,2,*,†], Asya Zanollo[1,2,†] and Cristiano Chesi[1,2,†]

[2] *Laboratory for Neurocognition, Epistemology, and Theoretical Syntax - NeTS-IUSS Pavia*

### Abstract

This paper investigates whether large language models (LLMs) generalize core syntactic properties associated with restructuring verbs in Italian, a domain tied to the universal hierarchy of functional heads proposed by Cinque [1, 2]. Specifically, we examine whether LLMs distinguish between restructuring and control verbs based on canonical syntactic diagnostics: verb ordering, clitic climbing, and auxiliary selection. We also probe how models interpret novel infinitive-selecting pseudoverbs, testing whether they default to *restructuring*- or control-like behavior. Using controlled minimal pairs, we evaluate five models of different sizes: Minerva-7B-base-v1.0 [3], GPT2-medium-italian-embeddings [4], Bert-base-italian-xxl-uncased [5], GPT2-small-italian [4], , and GePpeTto [6]. Our findings reveal that none of the models internalize the functional hierarchy, nor do they systematically block clitic climbing for control verbs, or are sensitive to auxiliary selection variability of the restructuring and control classes. These results highlight fundamental limitations in the syntactic generalization abilities of current LLMs, particularly in domains where structural contrasts are not overtly marked in the input.

### Keywords

Large language models (LLMs), Cognitive plausibility, Syntactic evaluation, Universal hierarchy of functional heads, Restructuring verbs

## 1. Introduction

Large language models (LLMs) have achieved remarkable success across a wide range of natural language understanding tasks, reigniting interest in their syntactic abilities and sparking a vigorous debate regarding the cognitive plausibility of the linguistic generalizations they acquire from data ([7], a.o.). Recent research has begun to probe the extent to which LLMs implicitly encode hierarchical syntactic structure [8, 9, 10], examining their sensitivity to phenomena such as long-distance dependencies and subject-verb agreement. This paper contributes to this growing body of work by investigating whether LLMs are sensitive to a crosslinguistically robust constraint governing the hierarchical distribution of functional verbs in Italian ([1, 11]). Given the broad crosslinguistic relevance of this phenomenon ([12, 13]), our investigation directly addresses the question of the coherence of linguistic structural representations in LLMs: can these models learn and represent aspects of Cinque's hierarchy from the data they are trained on? We considered two aspects: model's size and the training language, in order to observe whether, keeping the size constant, a model trained in Italian would perform better in a task specific for Italian. In terms of size, we compared larger, medium and smaller models — Minerva-7B-base-v1.0 [3], GPT2-medium-italian-embeddings [4], Bert-base-italian-xxl-uncased [5], GPT2-small-italian [4] and GePpeTto [6], to see if a greater number of parameters and training data leads to better generalization in terms of abstracting linguistic rules. The research questions (RQs) that guide this study can be framed as:

- **RQ1:** To what extent do LLMs generalize the verb ordering hierarchy proposed by Cinque (2006) for restructuring verbs?
- **RQ2:** Can LLMs differentiate the underlying structural ambiguity inherent in restructuring versus control verb constructions?
- **RQ3:** What is the syntactic structure assigned by LLMs to novel verbs which introduce non-finite complements?

For instance, as far as RQ1 is concerned, the following contrast shows that the incorrect hierarchical order — which directly reflects into linear order — of *provare* 'try' ($\text{Asp}_{\text{Conative}}$) and *volere* 'want' ($\text{Mod}_{\text{Volition}}$) leads to ungrammaticality.

b. **Gianni lo prova a voler riparare.*
Gianni it.CL tries to wants to fix

Intended: ‘Gianni tries to want to fix it.’

Regarding RQ2, consider the fact that only restructuring verbs allow clitic climbing (2) and auxiliary switch (3), as shown in the examples below.

(2) a. *Gianni lo comincia a riparare.*
Gianni it.CL begins to fix

‘Gianni begins to fix it.’

b. **Gianni lo corre a riparare.*
Gianni it.CL runs to fix

‘Gianni runs to fix it.’

(3) a. *Gianni ha/è voluto partire.*
Gianni has/is wanted to

‘Gianni wanted to leave’

b. **Gianni ha/*è preferito partire.*
Gianni has/*is preferred to

‘Gianni preferred to leave’

Finally, RQ3 can be investigated through the syntactic ingredients laid out above, using both clitic climbing and auxiliary switch as diagnostics for a restructuring-like, or a control-like representation of infinitive-taking verbs. Consider a pseudo-verb like *grabbare*, if models have clear the difference between restructuring and control, they would either block or allow clitic climbing across it, and either block or allow auxiliary switch.

In the next section, we will introduce the empirical domain of restructuring and the relevance of the cartographic enterprise as valid heuristics to test the cognitive plausibility of syntactic generalizations.

## 2. Universal Functional Hierarchy

In formal linguistics, the cartographic approach refers to the effort to systematically map out the functional structure of the clause. Much like a geographical map reveals detailed topography, syntactic cartography seeks to uncover the fine-grained architecture of language, identifying a universal and richly articulated hierarchy of functional projections that determine the order of constituents in natural language [14]. This enterprise, developed over the past three decades, has shown striking cross-linguistic consistency: while surface word orders vary dramatically across languages, the underlying structural relations often conform to highly constrained and universal hierarchies. For instance, across typologically diverse languages, adverbs and verbal morphology appear in a constrained order that reflects an underlying sequence of functional heads encoding modality, aspect, tense, and voice [2]. A well-known example involves the relative positions of epistemic and aspectual adverbs. Consider the following contrast.

(4) a. *John* ***probably*** *has* ***again*** *read the book.*

b. **John* ***again*** *has* ***probably*** *read the book.*

This contrast reflects a deeper generalization: epistemic adverbs like *probably* structurally precede aspectual adverbs like *again* in the functional hierarchy [2]. This ordering is also mirrored in other languages, such as Italian (*Giovanni probabilmente ha di nuovo letto il libro* vs. ?*Giovanni di nuovo ha probabilmente letto il libro*), and even when surface word orders vary, (constrained) movement analyses do preserve the underlying hierarchy. In fact, attested orders tend to be derivable from the base sequence via movement operations constrained by Universal Grammar, while unattested orders — such as stacking adverbs in reverse (*again* > *probably*) are rarely, if ever, observed without resulting in degraded acceptability (see also [15, 16, 17] for a different view on ordering constraints yet still rooted in cognitive principles).

Similarly, in the nominal domain, elements such as demonstrations, numerals, adjectives, and nouns tend to conform to the base order Demonstrative > Numeral > Adjective > Noun [18]. Using English again for illustration, the sequence *those three books* is allowed, but not *red three those books*. These generalizations suggest that natural languages are not arbitrarily diverse but instantiate a shared blueprint with tightly delimited variation, a claim supported by decades of comparative research [19, 20, 21, 22].

Crucially, these cartographic universals are not merely typological observations; they reflect deep structural constraints on human language, likely rooted in cognitive and interface-driven pressures such as learnability, interpretability, and communicative efficiency (see a.o. [23, 24, 25]). As such, they offer a highly structured benchmark for evaluating whether LLMs reflect the underlying principles of natural language cognition or simply reproduce surface-level statistical patterns. Assessing cartographic generalizations in LLMs thus becomes another valuable diagnostic tool for determining whether their internal representations exhibit the kind of compositional and hierarchical structure found in human language.

Importantly, the utility of cartographic diagnostics does not presuppose that LLMs use the same mechanisms as human language acquisition. Instead, it positions cartographic constraints as a structural target: a gold standard against which to assess the depth of linguistic generalization in artificial systems. If LLMs are to be considered cognitively plausible models of language

([26], a.o.), they should, at a minimum, capture the universal constraints that human learners internalize from fragmented, language-specific input. Testing for cartographic effects in LLMs therefore offers a window into the extent to which their representations are not only successful at surface prediction but aligned with the hidden universals that define natural language competence. In this sense, cartography closes the gap between linguistically informed evaluation and cognitively grounded modeling. By operationalizing syntactic universals as testable hypotheses in LLMs, we move closer to understanding not just whether these models can generate human-like language, but whether they have abstracted the kinds of structure that make human language what it is.

## 2.1. The empirical domain: the case of restructuring verbs in Italian

A particularly revealing case study for testing structural representations from a cartographic perspective in LLMs comes from the domain of restructuring verbs in Italian, as discussed in [1, 11]. Restructuring verbs — such as *potere* ‘can’, *dovere* ‘must’, *volere* ‘want’, *continuare* ‘continue’, *cominciare* ‘begin’, are verbs that, despite selecting an infinitival complement, do not behave as if they embed a full clause (cf. [13, 12, 27], a.o.). Instead, they participate in a monoclausal structure, lacking the full complement of functional projections found in fully embedded (i.e., biclausal) contexts. This has observable syntactic consequences: only restructuring verbs permit movement of the object clitic from the complement position of the infinitive up to the matrix verb (e.g., *Marco lo vuole mangiare* ‘Marco wants to eat it’), while control verbs, which are superficially similar, do not (e.g., **Marco lo decide di mangiare* ‘Marco decides to eat it’). Clitic placement (Clitic Climbing; CC) thus offers a fruitful diagnostic for the underlying syntactic structure of a restructuring configuration.

More specifically, the working hypothesis that we are adopting here ([1, 11]) views restructuring verbs as functional heads occupying a fixed hierarchy (e.g., from lower to higher, Aspectual > Modal > Temporal), with each verb spelling out a specific functional projection (Fig. 1) rooted in the cartographic representation of the inflectional domain.

Restructuring verbs obey in fact strict ordering constraints within sequences: for example, *Marco lo suole voler mangiare spesso* ‘Marco usually wants to eat it often’ is grammatical, while reversing the restructuring verbs blocks clitic climbing (**Marco lo vuole soler mangiare spesso*) as it is a violation of the hierarchical sequence of functional heads ($^*\text{Mod}_{\text{Volition}} > \text{Asp}_{\text{Frequentative}}$). Unlike linear word orders of adjectives or adverbs, which LLMs might learn through surface-level statistical regularities, these restructuring configurations constrain deeper syntactic dependencies. Besides CC, restructuring verbs like *potere* ’can’, *volere* ’want’, and *dovere* ’must’, can in fact optionally allow the infinitival verb to pick the auxiliary (*essere* ’be’, or *avere* ’have’), as in the case of unaccusative verbs.

$\text{MoodP}_{\text{speech act}} > \text{MoodP}_{\text{evaluative}} > \text{MoodP}_{\text{evidential}} > \text{MoodP}_{\text{epistemic}} > \text{TP(Past)} > \text{TP(Future)} > \text{MoodP}_{\text{irrealis}} > \text{ModP}_{\text{aletic}} > \text{AspP}_{\text{habitual}} > \text{AspP}_{\text{repetitive(I)}} > \text{AspP}_{\text{frequentative(I)}} > \text{ModP}_{\text{volitional}}\ \text{AspP}_{\text{celerative(I)}} > \text{TP(Anterior)} > \text{AspP}_{\text{terminative}} > \text{AspP}_{\text{continuative}} > \text{AspP}_{\text{retrospective}}\ \text{AspP}_{\text{proximate}} > \text{AspP}_{\text{durative}} > \text{AspP}_{\text{generic/progressive}} > \text{AspP}_{\text{prospective}} > \text{ModP}_{\text{obligation}}\ \text{ModP}_{\text{permission/ability}} > \text{AspP}_{\text{completive}} > \text{VoiceP} > \text{AspP}_{\text{celerative(II)}} > \text{AspP}_{\text{repetitive(II)}} > \text{AspP}_{\text{frequentative(II)}}$

**Figure 1:** [1]:12

(5) *Marco ha/è dovuto partire.*
Marco has/is must.PSTPRT leave.INF

Marco had to leave.

Restucturing verbs then present an ideal testing ground for evaluating whether LLMs encode abstract syntactic structures from cartographic generalizations, or merely track co-occurrence frequencies. While *Marco lo finisce di mangiare in fretta* (‘Marco finishes eating it quickly’) is structurally monoclausal and allows clitic climbing, its control verb counterpart **Marco lo decide di mangiare in fretta* is ungrammatical precisely because the clitic cannot climb out of a true embedded clause. These subtle distinctions, masked by similar surface forms, reflect two different structural representations, underscoring the need to go beyond linearity when assessing syntactic competence in artificial models. Furthermore, evidence from language development [28] shows that the distinction between restructuring and control syntax, and the fixed ordering constrain of restructuring verbs, are acquired very early on. This suggests that children have a clear representation of the difference between control and restructuring verbs, and when encountering a novel infinitive-taking verb, some preliminary corpus data suggest they tend to prefer a restructuring interpretation over a control one [29]. A natural question, then, is whether LLMs also encode such a clear distinction when processing previously unseen infinitive-taking verbs. In summary, we can use at least three solid tests to probe linguistic competence when comparing restructuring and control verbs: (i) the first (restructuring), but not the second (control), allows Clitic Climbing (CC); (ii) the order of predicates lexicalizing positions in the functional hierarchy is rigid; and (iii) restructuring predicates can take both *be* and *have* as auxiliaries.

## 3. Generalization in LLMs

Despite the impressive performance of state-of-the-art LLMs, it remains an open question whether their enhanced predictive capabilities reflect genuine syntactic knowledge. LLMs are said to exhibit syntactic generalization insofar as they can abstract structural rules from data and apply them to novel grammatical contexts beyond their training input. Wilson et al. (2023) [30] theorize three forms of generalization, differentiating the ability to learn word distributions and the distributions in contexts from the ability to abstract generalization independently of training data. The findings highlight that, while excelling in transferring distributions across syntactically similar context, LLMs struggle in extracting structural hierarchical rules, relying primarily on linear order instead. Accordingly their linguistic knowledge appears to be of a semantic and probabilistic nature and the emergence of human-like abstraction correlates with the increase of training data, radically differentiating from human linguistic competence. The issue of LLMs's grammatical knowledge is tackled by the linguistic community through different approaches relying on controlled experimental settings, probing LLMs' performances on minimal pair sentences, and evaluating the internalization of deep hierarchical dependencies of the underlying linguistic structures. Blimp [31] evaluate LLMs with minimal pairs, finding that — while learning basic dependencies, and surface-level patterns — models still cannot encode universal constraints like argument structure, even in a high-resource language like English. Training models on larger corpora leads to better performances suggesting that data play a major role compared to the architecture.

The very same result is obtained in another benchmark, BIG-bench [32], comprising 204 tasks designed to assess linguistic, reasoning, and knowledge-based abilities. Even if larger models show an improvement in syntactic generalization, this can be explained in terms of memorization rather than grammatical abstraction. Deep-structure constraints still represent a challenge.

In a recent study, [33] confirms the relevance of training data size in improving generalization, taking the case of a syntactic universal as the Final-over-Final Constraint (FOFC) — the rule governing word order variation crosslinguistically. They tested models with low-resource languages and found that models fail to learn this constraint when dealing with languages like Basque. A superhuman amount of training examples improves syntactic generalization, but models do not acquire abstract rules of grammar.

Taken together, these studies point to the necessity of incorporating more structured training methodologies and inductive biases, especially in light of the fact that human language acquisition occurs with far less data. Current models remain fundamentally data-dependent rather than rule-based, and simply increasing the scale of training does not really improve the possibility of true syntactic generalizations.

In this context, the empirical domain of restructuring verbs provides an ideal testing ground for disentangling linear generalizations from structural rules. On the one hand, restructuring verbs follow specific linear orderings that could, in principle, be learned from surface patterns in the training data. On the other hand, their ordering can either permit or block syntactic phenomena such as clitic climbing (CC), making linear order a surface reflex of deeper structural constraints. Capturing the relevant syntactic generalizations in this domain therefore requires more than sensitivity to word order — it demands an understanding of the underlying hierarchical structure.

## 4. Methods

We designed 13 minimal pairs experiments targeting various grammatical contrasts involving clitic placement, auxiliary selection, and verb-verb complementation. In these experiments, we manipulated the presence or absence of restructuring environments, the type of matrix verb (restructuring verbs, control verbs, and pseudo-verbs), and the structural distance between multiple occurrences of restructuring verbs, allowing us to probe the models' syntactic representations under different conditions. First, we coded 14 restructuring verbs and 14 infinitive-taking verbs (which we name according to the syntactic literature as control verbs, cf. [34]). While the coding of control verbs is arbitrary, the numbering of restructuring verbs reflects their position in the functional hierarchy of [1], with *andare* 'to go' assigned code 1 as the lowest verb, and *solere* 'to be used to' assigned code 14 as the highest (see Table. 1). Verbs higher in the hierarchy occur linearly to the left of lower verbs.

In addition to the verbs above, we also created three pseudo-verbs (i.e., non-existent words in Italian) to test whether LLMs assign them a restructuring-like or control-like syntactic representation when they take a non-finite complement. One, *grabbare*, is a bare verb resembling modals (verbs 6, 7, and 12 in Table 1) as well as *solere* 'to be used to' and other control verbs. The other two pseudo-verbs, *drommare a* and *trellare di*, take the prepositions *a* and *di*, respectively: a feature shared with the remaining restructuring and control verbs.

To address RQ1 (introduced in Section §1), we constructed minimal pairs of verb sequences that either respect or violate Cinque's (2006) functional hierarchy. Each item in Exp. 1 presents a grammatical (hierarchy-respecting) sentence alongside a minimally different ungrammatical counterpart, with the two verbs separated by varying degrees of hierarchical distance. This experi-

**Table 1**
List of restructuring and control verbs used across conditions, *Functional Projection* refers to restructuring verbs

| Code | Restructuring verb | Functional Projection | *Control* verb |
|---|---|---|---|
| 1 | *andare a* ’to go’ | $\text{Asp}_{\text{Andative}}$ | *correre a* ’to run’ |
| 2 | *cominciare a* ’to begin’ | $\text{Asp}_{\text{Inceptive}}$ | *salire a* ’to go up’ |
| 3 | *finire di* ’to finish’ | $\text{Asp}_{\text{Completive}}$ | *dire di* ’to say’ |
| 4 | *provare a* ’to try’ | $\text{Asp}_{\text{Conative}}$ | *scendere a* ’to go down’ |
| 5 | *riuscire a* ’to succeed’ | $\text{Asp}_{\text{Success}}$ | *osare* ’to dare’ |
| 6 | *potere* ’can’ | $\text{Mod}_{\text{Ability}}$ | *preferire di* ’to prefer’ |
| 7 | *dovere* ’must’ | $\text{Mod}_{\text{Obligation}}$ | *desiderare* ’to wish’ |
| 8 | *stare per* ’to be about’ | $\text{Asp}_{\text{Prospective}}$ | *promettere di* ’to promise’ |
| 9 | *continuare a* ’to continue’ | $\text{Asp}_{\text{Continuative}}$ | *decidere di* ’to decide’ |
| 10 | *smettere di* ’to stop’ | $\text{Asp}_{\text{Terminative}}$ | *chiedere di* ’to ask’ |
| 11 | *volere* ’want’ | $\text{Mod}_{\text{Volition}}$ | *pensare di* ’to think’ |
| 12 | *tornare a* ’to come back’ | $\text{Asp}_{\text{Iterative}}$ | *credere di* ’to believe’ |
| 13 | *tendere a* ’to tend | $\text{Asp}_{\text{Predisp}}$ | *sperare di* ’to hope’ |
| 14 | *solere* ’to be used to’ | $\text{Asp}_{\text{Habitual}}$ | *scegliere di* ’to chose’ |

ment tests whether LLMs prefer the option adhering to the hierarchy, and whether their preferences correlate with the hierarchical distance between verbs.

A second experiment (Exp. 2) uses the same verb pairs as in Exp. 1, but includes a proclitic clitic in each sentence. This introduces an explicit syntactic cue for restructuring, allowing us to evaluate whether clitic placement influences the model's preference for the grammatical, hierarchy-respecting variant..

To address RQ2, Exp. 3 and Exp. 4 pair control verbs with restructuring verbs, testing them in both possible orders: restructuring+control (Exp. 3) and control+restructuring (Exp. 4). Each minimal pair includes clitics, with the grammatical variant displaying enclisis on the infinitival verb and the ungrammatical one displaying proclisis onto the matrix verb. The latter is ruled out because in both cases the control verb introduces a clausal boundary that blocks clitic climbing.

To investigate RQ3, we conducted a series of experiments pairing restructuring and control verbs with the three pseudo-verbs introduced earlier. Exp. 5 combines each of the three pseudo-verbs (*grabbare, drommare a, trellare di*) with all 14 restructuring verbs, presenting two variants per item: one with proclisis onto the matrix verb (suggesting restructuring), and one with enclisis on the infinitival verb. Exp. 6 reverses the order (restructuring + pseudo-verb) but otherwise follows the same design. Since proclisis requires a monoclausal analysis, these experiments test whether the model treats novel verbs as compatible with restructuring. A systematic preference for the proclitic variant would suggest that the model generalizes restructuring behavior to unseen verbs.

Exp. 7 and Exp. 8 approach the same question from the opposite angle, pairing pseudo-verbs with control verbs. In Exp. 7, the order is control + pseudo-verb, while in Exp. 8, it is pseudo-verb + control. In both cases, only the enclitic variant is grammatical because control verbs block clitic climbing, even if the model assumes the pseudo-verb to be restructuring-compatible. This design offers a strong test of whether the model robustly distinguishes restructuring from control verbs. If the model is sensitive to this contrast, it should reject the proclitic variant in favor of enclisis, indicating a fine-grained syntactic representation of clitic domain boundaries.

Exp. 9 further probes the syntactic status of pseudo-verbs by pairing them with each other and testing proclitic vs. enclitic placement. This experiment asks whether the model classifies pseudo-verbs as restructuring-like or control-like when they co-occur, shedding light on whether it generalizes clitic behavior within novel verb classes.

In Exp. 10, we tested pseudo-verbs in isolation, assessing model preferences for auxiliary selection (*have* vs. *be*) — another syntactic hallmark of restructuring (see §2.1). For comparison, Exp. 13 and Exp. 14 extend this test to restructuring (modals) and control verbs, respectively.

Exp. 11 tests pseudo-verbs selecting infinitival complements, presenting both proclitic and enclitic variants. This experiment investigates whether the model prefers proclisis (indicating a restructuring representation, along the lines of Exp. 5) or enclisis, and whether this preference is modulated by the presence or absence of the prepositions *di* and *a*.

Finally, in Exp. 12 and 13 we tested modal (restructuring) verbs and control verbs with auxiliary selection, respectively (only modals allow both *essere* 'to be' and *avere* 'to have' with unaccusative verbs, while control verbs require *avere*). This allows us to see whether the fine-grained syntactic distinctions between restructuring and control have been successfully generalized by these models.

**Table 2**
Minimal pair generated examples

| Group | Good sentence | Bad sentence |
|---|---|---|
| Exp. 1 | il marinaio continua a riuscire a pescare il pesce | il marinaio continua a tendere a pescare il pesce |
| Exp. 2 | l'esploratore lo può riuscire a toccare | l'esploratore lo può stare per toccare |
| Exp. 3 | il ballerino va a salire a guardarlo | il ballerino lo va a salire a guardare |
| Exp. 4 | il golfista chiede di andare a registrarlo | il golfista lo chiede di andare a registrare |
| Exp. 7 | il viaggiatore scende a trellare di odiarlo | il viaggiatore lo scende a trellare di odiare |
| Exp. 8 | il gestore dromma a ordinare di inviarlo | il gestore lo dromma a ordinare di inviare |
| Exp. 13 | il principe ha preferito venire | il principe è preferito venire |
| | Proclitic option | Enclitic option |
| Exp. 5 | il gioielliere lo grabba andare a vendere | il gioielliere grabba andare a venderlo |
| Exp. 6 | il gestore lo va a drommare a disinfettare | il gestore va a drommare a disinfettarlo |
| Exp. 9 | il sarto lo trella di grabbare rifiutare | il sarto trella di grabbare rifiutarlo |
| Exp. 11 | l'anziano lo grabba lavare | l'anziano grabba lavarlo |
| | HAVE auxiliary | BE auxiliary |
| Exp. 10 | il pugile ha grabbato discendere | il pugile è grabbato discendere |
| Exp. 12 | il golfista ha dovuto crescere | il golfista è dovuto crescere |

## 4.1. Materials: Minimal Pairs

The minimal contrasts exemplified in Table 2 have been considered. For each condition internal to each experiment, we generated 100 structurally irrelevant variants displaying different lexical items as subjects, infinitival verbs, and objects (when present). Although some of the items across the experiments were semantically odd, the generalizations are nonetheless still strong, and the contrast within the pairs remains sharp, as in the example below.

4. il calciatore lo sta riuscendo a finire di ideare
   *the soccer player it.CL is about to be able to finish to design*
5. *il calciatore lo riesce a star finendo di ideare
   *the soccer player it.CL is able to be about to finish to design*

The script responsible for the generation of the minimal pairs is available on GitHub.

## 4.2. Experiments

Five LLMs have been employed for the evaluation of syntactic generalization with minimal pair sentences. The selection was driven by two key factors for the evaluation: model size and language of training.

Correspondingly we included large, medium and small models - Minerva-7B-base-v1.0, GPT-2 medium and Bert-base-italian-xxl-uncased, GPT2-small and GePpeTto. All models are trained on Italian corpora, hence they allow us to assess whether exposure to Italian during training enhances syntactic generalization in a typologically relevant domain. This setup enables a direct comparison between different models' size, in the ability to internalize the structural dependencies necessary to abstract the relevant generalizations. All models are available on Hugging Face [35, 36, 5, 37, 38].

Minerva-7B-base-v1.0 [3] is a causal LLMs with 7 billion parameters, based on Mistral architecture (32 layers, hidden size 4096, 32 attention heads, context window of 4096 tokens) trained on 2̃.48 trillion tokens (1.14T Italian, 1.14T English, 200B code) and a 51200-token vocabulary.

Bert-base-italian-xxl-uncased is the Italian version of BERT base model (uncased), a masked LLMs trained on next sentence prediction. The models has 111M parameters and training data consist of OPUS corpus (https://opus.nlpl.eu/) extended with additional content from the Italian portion of the OSCAR corpus, for a final training corpus of 81GB and 13,138,379,147 tokens.

GroNLP/GPT2-medium-italian-embeddings [4] is built on GPT-2 medium architecture, with 359M parameters with the lexical layer retrained to support Italian.

GroNLP/GPT2-small-italian [4] is a smaller causal Transformer with 121 million parameters, built on GPT-2 small architecture and retrained in Italian.

GePpeTto [6] has a GPT2-small configuration (1̃17 million parameters) and has been trained in Italian corpora - OSCAR (https://huggingface.co/datasets/oscar-corpus/oscar?utm_source=chatgpt.com), PAISA (https://www.corpusitaliano.it/en/?utm_source=chatgpt.com), Wikipedia. GePpeTto, similarly based on the GPT2-small architecture, employs a BPE tokenizer with a reduced vocabulary of 30,000 tokens, specifically adapted for Italian linguistic data.

#### 4.2.1. LLMs Evaluation

The *LM-eval* platform [39] was adopted to perform minimal pair tests. A total of 610,500 minimal pairs were generated and divided into 13 groups, as described in §4.1, and assessed by all the selected models. For each experiment we computed the mean accuracy and standard deviation (3), leaving further statistical analyses for the future. For unknown reasons, some models failed to complete certain evaluation tasks without producing any intelligible error messages.

## 5. Results

We organize our results around the three core research questions that reflect different dimensions of the models' syntactic generalizations with respect to restructuring verbs, control verbs, and infinitive-selecting pseudoverbs. For each question, we present the relevant experimental conditions and summarize the performance of all tested LLMs in terms of mean accuracy and standard deviation. To assess whether models internalize the syntactic hierarchy of restructuring verbs proposed by [1] (RQ1), Exp. 1 and 2 tested sequences of two restructuring verbs in the correct vs. incorrect hierarchical order, with and without clitic pronouns. Mean accuracies in these experiments were consistently low (Minerva: 36–37%, GePpeTto: 36–38%, GPT2: 46–48%), with SD close to 0.5. BERT, however, performed moderately above chance (Exp. 1: 64.6%, Exp. 2: 56.9%), suggesting that it may encode some sensitivity to hierarchical ordering, although not robustly.

The presence of clitics in Exp. 2 did not alter model behavior compared to Exp 1. Models show no evidence of having acquired the hierarchical layout of restructuring verbs, besides BERT's results. However, their responses may correlate with verb distance or hierarchical ordering, which we leave for further research.

To evaluate whether models distinguish between restructuring and control verbs based on syntactic diagnostics (RQ2) we considered two properties: clitic climbing (Exp. 3, 4, 5, 6, 7, 8, 9, 11), and auxiliary switch (Exp. 10, 12, 13). In Exp. 3 and 4, which tested restructuring–control verb sequences with clitics, models consistently failed to block clitic climbing where it was expected to be ungrammatical. GePpeTto and Minerva almost systematically chose the ungrammatical option (18–28%), while GPT2-small showed slightly better performance ( 42–46%) but with high variability, BERT performed near floor ( 5–6%). A model that shows a bias over 75/80% can be in fact considered structurally coherent, even though it picks the ungrammatical option [40].

In Exp. 7 and 8, which paired control verbs with pseudoverbs, models again failed to systematically block clitic climbing. GPT2 reached 48–57% accuracy, while GePpeTto and Minerva remained well below chance (12–18%).

In Exp 9 and 11, which included only pseudoverbs, GePpeTto consistently preferred proclitic constructions (low accuracy = proclisis favored), while Minerva and GPT2-small showed no clear preferences, again reflecting indecision or inconsistency.

As for auxiliary selection, the results reveal further lack of syntactic differentiation: in Exp 10, GePpeTto systematically selected *essere* (7% accuracy), suggesting it interpreted pseudoverbs as restructuring verbs. GPT2-small showed more balanced choices ( 47%), compatible with the ambiguity characteristic to some restructuring verbs which allow both *avere* and *essere.*

In Exp 12, in fact, testing modal auxiliaries, models should ideally show 50% accuracy, given the optionality of auxiliary selection; instead, both GPT2-small and GePpeTto showed categorical but divergent choices, with accuracies around 5%.

In Exp. 13 (control verbs), only Minerva performed above chance (57%), while GePpeTto and GPT2-small selected the incorrect auxiliary (*essere*) almost categorically (1% accuracy), and BERT was the only model to outperform Minerva (63%).

As a result, models largely fail to generalize the syntactic constraints of restructuring and control verbs. Clitic climbing is not consistently blocked by control verbs, and auxiliary selection does not reliably reflect the transparency effects typical of restructuring verbs nor the ambiguity intrinsic to them. Only GPT2-small shows partial sensitivity in some control constructions, while GePpeTto tends toward an overgeneralization of restructuring syntax (e.g. by overselecting *essere* as an auxiliary).

Finally, a central question of this study addresses how models categorize pseudoverbs — novel verbs not seen during training but constructed to select infinitival complements, and whether they are interpreted as control or restructuring verbs.

In Exp. 5 and 6, pseudoverbs appeared in sequences with restructuring verbs, with proclitic vs. enclitic alternations. Minerva showed a slight preference for the enclitic form ( 23–29% accuracy), suggesting a bias toward control-like syntax. GePpeTto strongly preferred the proclitic form ( 17% accuracy = 83% proclisis), indicating a restructuring-like interpretation. GPT2-small was ambivalent. Since the three pseudoverbs differ in whether they select a preposition, mirroring the variation found among restructuring verbs, further analyses will investigate this property as a potential factor.

Exp. 9 and 11, which tested proclitic/enclitic preferences with pseudoverb–pseudoverb sequences, reinforced these trends: GePpeTto showed a consistent preference for proclitic constructions (11–15% accuracy), while GPT2-small and Minerva again showed no strong preference.

**Table 3**
Mean and standard deviation of model accuracy across experiments, – indicates that the model failed to complete the subtask.

| Experiment | UID | Minerva | | GePpeTto | | GPT2-Small | | GPT2-Medium | | BERT | |

In Exp. 10, which tested auxiliary selection with pseudoverbs, GePpeTto again opted overwhelmingly for *essere*, consistent with restructuring behavior, while GPT2-small distributed responses more evenly. BERT distributed its choices roughly evenly (around 53.7% accuracy), suggesting some awareness of optionality, though this may be an artifact of random choice.

These results suggest that GePpeTto interprets novel infinitive-selecting verbs as restructuring verbs by default (although without expressing the available optionality with *avere*), consistently favoring proclisis and auxiliary *essere*. In contrast, GPT2-small and Minerva exhibit uncertainty or mixed behavior, with no consistent syntactic categorization of pseudoverbs.

## 6. Discussion

Overall, the findings reveal that the models' behavior does not align with the predictions raised by the framework of [1], nor with the grammatical requirements characteristic of the syntax of non-finite complements in Italian. Instead, their choices are often inconsistent, insensitive to syntactic structure, or driven by superficial factors. The first research question addressed whether models generalize the hierarchical structure of restructuring verbs as observed in the syntactic literature ([1, 11]). Our results clearly indicate that no such hierarchy is reflected in the models' performance. Accuracies were consistently low, and variability high. These findings echo previous results showing that LLMs often fail to internalize syntactic hierarchies when such structures are not directly observed during training or explicitly encoded [30]. Even BERT, which slightly outperformed other models on restructuring verb order, failed across the board on clitic-related diagnostics. This has implications for how much syntactic theory — especially fine-grained distinctions like cartographic hierarchies — is learnable from surface patterns alone.

In the second set of questions, we tested whether models are able to handle clitic climbing and auxiliary selection, two classical diagnostics that distinguish restructuring from control. Across all clitic-related experiments, models consistently failed to block clitic climbing where it should be ungrammatical, especially in the presence of control verbs. This strongly suggests that models do not encode the syntactic opacity of control verbs. A potential explanation for these results lies in tokenization artifacts. Unlike proclitic clitics (e.g., *lo ha visto* 'it.obj has seen'), enclitics (e.g., *vederlo* 'see-it.obj') should be tokenized as subword fragments. If models fail to treat enclitics as distinct morphemes, this may increase their preference for proclitic constructions simply because the latter are tokenized as independent words, easily recognizable as syntactic objects.

Auxiliary selection patterns further support the view that models lack a deep representation of infinitive-taking verb classes. None of the models consistently mapped control verbs to *avere*, or correctly captured the optionality of auxiliary selection in modals (with the partial exception of BERT in Exp. 13, having 63% accuracy). GPT2 again performed marginally better than the others in preserving optionality, but even it failed to align with the expected 50% distribution. Surprisingly, both GPT2-small and GePpeTto nearly categorically misassigned *essere* to control verbs, a highly ungrammatical option in Italian.

These findings point to a broader issue: models do not reliably encode the syntactic transparency of restructuring verbs nor the obligatory opacity of control verbs. Syntactic features that are not overtly marked in surface form — such as whether a verb transmits argument structure or allows clitic climbing — appear to be difficult for models to capture, even when such distinctions are central to grammaticality.

## 7. Conclusions

This study investigated whether LLMs encode abstract syntactic generalizations by testing their sensitivity to the restructuring verb hierarchy in Italian. Using a suite of controlled minimal pair experiments targeting verb order, clitic placement, and auxiliary selection, we assessed models' ability to capture structural dependencies that go beyond linear surface patterns.

The models tested — GPT2-small-italian, GPT2-medium-italian-embeddings, GePpeTto, Bert-base-italian-xxl-uncased and Minerva-7B-base-v1.0 — showed limited sensitivity to the syntactic hierarchy of restructuring verbs, failed to consistently distinguish restructuring from control verbs based on key syntactic diagnostics, and did not consistently categorize novel infinitive-taking verbs based on the non-finite embedding typology available in Italian. These findings highlight fundamental limitations in the syntactic abstraction capacities of current models, particularly in domains where structural contrasts are not overtly marked in surface form.

While none of the models fully internalize the hierarchical structure of restructuring verbs, some results (as BERT's above-chance accuracy in distinguishing hierarchy-respecting sequences in Exp. 1) suggest at least some limited sensitivity to structural cues. However, this sensitivity is neither robust nor consistent across models or conditions, and most importantly does not translate into reliable grammaticality judgments. For example, clitic placement's explicit cues for restructuring failed to improve performance, and models consistently failed to block ungrammatical clitic climbing or the *essere* auxiliary selection in the context of control verbs. These findings indicate that, to the extent models are sensitive to structural hierarchies, in the domain of cartographic generalizations this sensitivity remains shallow and insufficient for capturing the related grammatical distinctions.

Addressing these limitations will require new approaches to model design, training, and evaluation that go beyond surface-level pattern recognition, and may involve encoding linguistic biases into model architectures—much like cartographic hierarchies are hypothesized to be innately hardwired in human cognition.

## 8. Limitations

The main limitation of the current research lies in the exclusive usage of publicly available pre-trained models as outlined in 4.2. To obtain a fine-grained understanding of models' capacity on syntactic generalization, future works will employ models trained from scratch, with a training regimen reproducing human language acquisition stages (see 2). The alignment between learning trajectories and the implementation of more structured training methodologies and inductive biases (see 3) will hopefully improve models' performance in syntactic tasks [41, 42]

Moreover, we are in the process of designing an acceptability judgment task to present these contrasts to native speakers and properly compare LLM performance with human data.

Further analyses - currently underway - are required to provide a more comprehensive understanding of the syntactic behaviors tested. These will be reported in future work.

# Evaluation of Italian and English Small Language Models for Domain-based QA in Low-Resource Scenario

Irene Siragusa[1],*, Roberto Pirrone[1]

[1]Department of Engineering, University of Palermo, Palermo, 90128, Sicily, Italy

**Abstract**

Usage of open-source Large Language Models, which can be run locally, modified, fine-tuned, and queried without APIs that require data sharing, is required when dealing with sensitive or confidential information. In addition, suitable computational resources are needed to infer and fine-tune such models. The objective of this work is to assess the potentialities of Small Language Models in low-resource scenarios in which quantization may be required. In particular, the focus will be on the usage of these models in the context of the Italian and English languages from both a purely quantitative and resource-oriented evaluation, across two Question Answering data sets, a generic closed answer and a domain-based one with open answers.

**Keywords**

LLM, QA, Quantization, Fine-tuning,

## 1. Introduction

Generative Large Language Models (LLMs) are mainly oriented towards the paradigm "*the bigger the better*", involving both closed-source models such as GPT [1] Claude [2] and Gemini [3, 4], but also Llama (Llama 3.1 405B [5] or Llama 4 Maverick 400B [6]) and DeepSeek (DeepSeek R1 671B [7]) models. Despite the impressive capabilities of such models, in both textual and multimodal setup, significant issues arise when dealing with their size. In particular, higher computational resources are needed during the training phase, which is performed only once and asynchronously. The inference phase, on the other hand, despite requiring less computational resources, may result in being a bottleneck of the final distributed application, for which multi-currency and related GPU resources are needed. Pay-per-use APIs resolve all the computational aspects but lead to privacy-related issues. Applications that involve the use of Artificial Intelligence (AI) models as support systems in private companies or hospitals, where data is confidential or sensitive and any breaches must be avoided, should be compliant with those restrictive requirements and not allow sharing data with third parties.

To ensure these privacy-related issues, the focus of this work is on open-source models which can be trained locally and inferred in a low-resource scenario, both with full precision or in a quantization setup [8]. In doing this, the most recent Small Language Models (SLMs), released from late 2024 until April 2025, are considered, for which an instruction tuning phase was performed, involving both English and Italian as supported languages. This research led to the selection of models belonging to the following families, namely Qwen 3 [9], Gemma 3 [10], Phi 4 [11, 12] and Ministral [13], for which only the free models available below the 20B parameters are considered. Performances of these models were evaluated using both the full-precision and 8 /4 bit quantization scenarios. The evaluation was carried out with the generic benchmark MMLU [14, 15] and UniQA [16], a domain-specific Question Answer (QA) data set in the university domain. Both data sets cover English and Italian, and relative evaluations were performed in both languages. Statistics for the evaluation time and GPU used are also calculated. To further stress the potentialities of these models, the smallest ones were fine-tuned with two diverse strategies over the UniQA data set, and relative performances of both selected benchmarks have been analyzed.

Thus, the main contributions of this work can be summarized as follows.

1. Evaluation of open-source SLMs with MMLU benchmark and UniQA data set in different quantization scenarios, from both quantitative and computational perspective;
2. Fine-tuning with two proposed strategies over the UniQA data set;
3. Comprehensive evaluation of fine-tuned models over both MMLU and UniQA.

This work is organized as follows: an overview of fine-tuning strategies in the context of a low-resource scenario and of the selected open-source models and their principal characteristics are reported in Sections 2, and 3. The experimental setup along with the selected data sets and the proposed fine-tuning strategies are described in Sections 4 and 5. The results obtained are collected and

discussed in Section 6, while the concluding remarks are drawn in Section 7.

## 2. Background

Fine-tuning pre-trained LLM in the context of domain and task adaptation involves strategies for both proper fine-tuning and the technique to reduce the overall fine-tuning computational cost, while keeping its effectiveness. Supervised Fine-Tuning (SFT) strategies are used for instruction tuning, domain, language, or task adaptation [17, 18, 19]. As a supervised method, both the input and the desired output are provided to the model, and, following a teacher forcing methodology, the model is forced to use the expected golden target token, even if the wrong one has been previously generated [20]. In the case of QA tasks, this consists of a question and associated answer and an optional context from which the answer should be derived.

Parameter-Efficient Fine-Tuning (PEFT) techniques are adopted in conjunction with SFT to speed up the fine-tuning phase and reduce computational resources required. In particular, those involve freezing, quantization, and Low-Rank Adaptation (LoRA) [21]. In freezing, only weights are actually trained in selected layers, while the rest are kept frozen. In the quantization strategy [8] the precision representation of the weights in the model is reduced from 32-bit to a 16-, 8-, or 4-bit representation. This technique can be used at both the training and inference time, thus decreasing the computational resources needed in terms of GPU. Lastly, LoRA [22] is one of the most used PEFT techniques where low-weight adapters, associated to selected layers, are actually trained, instead of the original ones. In doing this, the size of the trainable parameters is greatly decreased, and the computational resources needed for the fine-tuning process are reduced accordingly. In addition, those techniques can be combined to better fit computational constraints, such as in Quantized Low-Rank Adaptation (QLoRA) [23] in which quantization is applied along with LoRA during training.

For effective fine-tuning, models are trained, on average for a few training epochs, mainly ranging from 3 to 15, [24, 25, 26, 27], usually combining different PEFT strategies [28, 29].

## 3. Models

Capabilities around different tasks for closed-source and huge LLMs are well known, but in the context of real applications, usage of such models is impracticable. This can be mainly addressed to costly pay-per-use APIs, and to the sharing of private data to third parties that may lead to data breaches. Natural Language Processing (NLP) community is exploring not only the capabilities of larger [1, 2] and expert-based LLMs [6, 7, 4, 30], but also smaller models obtained through a distillation procedure from larger models [10], thus providing the general public with a valuable alternative.

Small Language Models are the focus of this research, which is limited to multilingual generative models with an explicit reference for supporting the Italian language, in addition to English. In particular, only models based on a transformer decoder-only architecture [31] and instruct fine-tuning are considered. Instruct models are capable of generating text given an instruction, thus making them suitable for the proposed evaluation scenario which includes closed and open QA tasks. In addition, as the increasing and faster development of newer models, only models which have been released from the last months of 2024 to April 2025 are examined. More in detail, we considered only models with less than 20B parameters, which have been sub-grouped as 4B, 8B, and 12B-14B models, to better evaluate their performance. The selected models are listed below along with their principal characteristics.

**Gemma 3** [10] is a family of multimodal and multilingual models developed by Google DeepMind, co-designed with Gemini models [3, 4], with which they share the same tokenizer. A Grouped-Query Attention (GQA) mechanism [32] was used with post-norm and pre-norm with RMSNorm [33] and support for longer contexts. Gemma 3 models range from 1 to 27B parameters and were trained with a knowledge distillation strategy. In the context of this research, only the 4B and 12B versions are considered.

**Ministral** [13] is a model from the French company Mistral AI, it was released in the 3B and 8B parameter version. Ministral models are the newer version of Mistral 7B [34], which uses an interleaved sliding-window attention pattern to provide a faster, more computationally efficient, and low-latency solution at inference time. As the 3B version is not open-source, only the 8B version was considered in this work.

**Phi 4** [11, 12] is a family of Microsoft models that showed impressive capabilities despite the reduced number of parameters, compared to other models. Higher performance of these models can be addressed to the three-stage training procedure and the data curation process, which involves a data decontamination process to the most used benchmarks. In addition, more variety in data, attention towards synthetic data for Chain of Thoughts (CoT) and reasoning capabilities, contributed in enhancing the overall behavior of these models. Phi 4 was released in its full version, which consists of 14B parameters and in its mini version with 3.8B parameters, which will be considered as a 4B model in the subsequent analysis.

**Qwen 3** [9] is a family of multilingual models released by the Chinese company Alibaba Cloud. Along with the large models of 30B and 235B parameters Mixture of Expert Models, smaller models have been released ranging from 1B to 32B parameters. Only models of 4B, 8B and 14B parameters are considered in this analysis. Great attention in Qwen 3 models was towards reasoning and CoT, both in training data selection and at inference time, in which the explicit thinking mode can be enabled or not.

## 4. Data sets

Three English and Italian data sets have been considered for evaluation purposes, two are closed QA data sets, and the other an open QA dataset. In the first case, the model is asked to answer with one of the provided answers, while in the second case a free text answer is expected. As closed QA, the general Massive Multitask Language Understanding (MMLU) task was selected in its English and Italian versions. From here on, the English version of MMLU will be referred to as MMLU-EN, and the Italian version as MMLU-IT, while MMLU will be used to refer to both splits. On the other hand, UniQA was selected as a domain-specific open answer QA data set in the university domain, available both in English and Italian.

**MMLU-EN** [14] is a generic benchmark task to evaluate the capabilities of LLMs after their training phase. It is a closed QA task involving 57 different subjects in STEM, humanities, and social science with diverse complexity ranging from elementary level to advanced and professional level. It consists of 14079 questions, and the models are queried with a 5-shot strategy in which 5 sample questions are provided for each subject. Accuracy is the proposed metric for performance evaluation.

**MMLU-IT** [15] is the translated version of the MMLU data set, which is also referenced in the Language Model Evaluation Harness framework [35]. Translation was obtained automatically using an *ad hoc* developed prompt for ChatGPT. No further checks have been conducted on the data set to evaluate its correctness in terms of translation.

**UniQA** [16] is a QA data set for the University domain that comprehends nearly 14k QA pairs and more than 1k documents, which serve as a context for the question. The data set has been generated in a semi-automated manner using the data retrieved from the website of the University of Palermo, covering information about the bachelor and master degree courses for the academic year 2024/2025. Data are natively both in Italian and English, i.e. no translation procedure was involved for developing the model. From here on, UniQA-EN will be used for the English split, UniQA-IT for the Italian one, and the general form UniQA will be used for both splits.

## 5. Experimental setup

Models in an out-of-the-box setup were tested with MMLU and UniQA data sets at different levels of quantization, namely in their base, 8-bit (Q8) and 4-bit (Q4) quantization [8]. These evaluations were performed to assess the different performances of quantized models versus their base version along with the effective computational resources involved, such as GPU memory and inference time. Quantization was performed with the usage of the bitsandbytes library[1] in combination with the transformers library [36] in both 8-bit and 4-bit quantization [37].

Regarding the MMLU-EN and MMLU-IT evaluation, we used the Language Model Evaluation Harness framework [35], in 5-shot setup, and considering the accuracy as the evaluation metric. Performance for the UniQA data set was obtained providing the following prompt, enriched with the target question and associated documents, following an in-context learning strategy [38].

> You are Unipa-GPT, the chatbot and virtual assistant of the University of Palermo.
>
> Provide an answer to the provided QUESTION concerning the University of Palermo, relying on the given DOCUMENTS
>
> If the question is in English, answer in English.
>
> If the question is in Italian, answer in Italian.
>
> QUESTION:

>
> `documents`

For UniQA, we used the default generation configurations suggested by the developers of the selected models. In particular, the thinking mode was disabled for Qwen 3, while the sampling strategy in the generation phase was disabled in the context of Gemma 3 models. Whenever the model was not able to generate and answer, the

[1] https://github.com/bitsandbytes-foundation/bitsandbytes

default empty answer has been considered as the generated one. As evaluation metric, BLEU [39], ROUGE [40], METEOR [41] and BERTScore [42], with the multilingual model XLM-RoBERTa Large [43] were calculated. Since the F1 BERTScore provides a more comprehensive evaluation of the meaning and significance of the generated answer, it was the only metric considered for evaluation purposes in the context of this work. In the Appendix, all the calculated metrics for the UniQA data set are reported for each inference configuration tested (Table 6).

## 5.1. Fine-tuning strategies

Only the smallest models, namely Gemma 3 4B, Phi 4 mini, and Qwen 3 4B, have been fine-tuned over the English and Italian training split of the UniQA data set. In particular, two different fine-tuning strategies have been proposed and used in this phase, namely *w/ docs* (with documents) and *w/o docs* (without documents). They differ in the arrangement of the training samples and the associated instruction prompt as reported in Table 1.

**Table 1**
Instruction prompts designed for fine-tuning w/ and w/o documents.

| ***w/ docs* prompt text** |
|---|
| You are Unipa-GPT, the chatbot and virtual assistant<br>of the University of Palermo.<br>Provide an answer to the provided QUESTION<br>concerning the University of Palermo,<br>relying on the given DOCUMENTS<br>If the question is in English, answer in English.<br>If the question is in Italian, answer in Italian.<br>QUESTION:<br>`<QUESTION>`<br>DOCUMENTS:<br>`<DOCUMENTS>` |
| ***w/o docs* prompt text** |
| You are Unipa-GPT, the chatbot and virtual assistant<br>of the University of Palermo.<br>Provide an answer to the provided QUESTION<br>concerning the University of Palermo.<br>If the question is in English, answer in English.<br>If the question is in Italian, answer in Italian.<br>QUESTION:<br>`<QUESTION>` |

In w/ docs strategy, annotated documents were fed as input in the training sample, thus allowing the model to read the documents and force it to extract and re-paraphase the desired snippet in the document, containing the answer. On the other hand, in the w/o document strategy, no additional context was provided in the prompt, allowing the model to learn the QA pairs directly and, at inference time, to integrate the knowledge provided by the documents in a context-learning set-up [38].

Following the approaches described in Section 2, our choice was to perform a full fine-tuning limited to selected layers. A unique strategy was designed that is suitable for heterogeneous models with a different number of decoder layers. We fully fine-tuned only the last 25% of the decoder layers and the classification head, while freezing the remaining layers. The proposed strategy resulted in a valuable trade-off with PEFT techniques and full fine-tuning. In addition, this strategy meets the proposed research question in analyzing the impact of quantization at the inference phase and not during training.

The models have been trained for five epochs: a larger number of training epochs do not lead to significant improvement compared to the considered training data. A validation set was expunged from the training set with a 90:10 ratio, and it was used as a criterion to select the best model over the validation loss.

Inferences were run on a local machine on a single 48 GB NVIDIA RTX 6000 Ada Generation GPU (machine 1) and on a cluster with 1 NVIDIA A100 64 GB GPUs from the Leonardo supercomputer[2] via an ISCRA-C application (machine 2), while fine-tuning was executed on machine 2. Over the same machines, the occupied GPUs and inference time were monitored to simulate and provide an estimation of the required computational resources in the low-resource scenario.

# 6. Results

In Table 2 a comprehensive evaluation of the selected models is reported. Evaluations also include performances over bigger models such as Mistral Small [44], Llama 4 Scout Instruct [6], Claude 3.5 Sonnet [2] and GPT 4o Mini [38]. These models have been considered since their performance for both tasks was available from public leaderboards [45, 46, 47]. In this phase, no spot checks or roundtrip translations have been conducted to further investigate errors in the automatically translated MMLU-IT split, to assess whether some inference errors derive from actual model limitations or from translation artifacts.

The overall best results are achieved by Claude 3.5 Sonnet, followed by GPT 4o mini. Nevertheless, Phi 4 results in a valuable alternative since it reaches performances comparable to Mistral Small and is only 0.2

points below GPT in MMLU-EN. As for MMLU-IT, scores tend to be lower compared to the English split, and again Phi results the best. With reference to smaller models, Qwen 3 in its 4B and 8B versions outperforms other models in MMLU tasks, while showing a significant average inference time, compared with the competitors. Performance generally exhibits a decrease in quantized models. The decrease is significant in the case of Q4, while the average inference time for each question is decreasing for Q8 and tends to increase in the case of Q4, especially for Qwen.

Generally speaking, the quantization procedure at inference time can increase the answer time due to the additional computation required for quantization [37]. This behavior is highly emphasized with the UniQA evaluation, where the input provided to the models can be significantly longer compared to MMLU samples. The results for UniQA are reported in Table 3, together with the average GPU occupied for each inference. To better compare obtained results, the standard deviation over the average inference time and GPU usage is also reported. Note that the average inference time is reported in seconds, while the GPU usage in GB: associated standard deviation follows the same scale, and, in the GPU case, the majority results 0.0 since the corresponding variation is lower than 0.1 GB.

In full precision inference, best results are assessed by Gemma 3 models reaching a BERT-F1 score of 0.88 on average in both 4B and 12B versions, also surpassing larger 14B models. In this context, the performances of Gemma 3 4B are much more interesting from a computational perspective, since it is 64% smaller than the 12B version, reaching comparable performances. The smallest model in this set-up is Phi 4B mini, which occupies less than 16GB and reaches the smallest inference time, which is desired in context of real-time applications. Regarding quantized inferences, GPU values decrease by 70% and 80% for Q8 and Q4, respectively, compared to models inferred with full precision. In terms of inference time, significant increases are found in Q8, while a reduction is found in Q4, which is mainly related to the quantization strategy adopted by bitsandbytes [37]. Overall, for both performance and computational resource usage, Phi and Ministral are the best models which benefit from quantization, and keep comparable performances over the selected benchmarks, despite a slight decrease. The worst performances are assessed by Gemma models which deeply suffer the quantization procedure that leads to output empty string (Q4) or meaningless output in not desired languages (Q8).

In contrast with the MMLU case, in which a slight discrepancy can be found between the English and

**Table 4**

Italian split, in the UniQA case, all performance places on the same level, and, in some cases, slightly towards the Italian split. This performance can be explained through an analysis on the data set, in which the presence of the context can guide the model more effectively in generating the desired answer, and in the language-related characteristics and understandings.

In Tables 4 and 5 the results over both benchmarks are reported using the two proposed fine-tuning strategies, with and without documents.

No improvements are found after the fine-tuning phase with the two proposed strategies in terms of performance on the MMLU benchmarks. Models fine-tuned with the w/ docs strategy tend to better maintain the performance obtained by the base models. These results show that the fine-tuning on a specific task did not lead to a degradation in performance in a generic benchmark and that the generalization performance of the considered LLM is maintained. This is mainly due to the light fine-tuning strategy adopted, which does not cause the model to overfit.

Regarding UniQA performance, both strategies have been shown to be successful since overall performance for the BERT F1 score increased. More specifically, better results are obtained in the case of w/o docs strategy, both from evaluation metrics and for average inference time, which is reduced. Improvements are found in both the base and quantized inferences. As in the without fine-tuning inference, the average time for quantized models deeply penalized Gemma 3 4B, while Qwen 3 4B trained with a w/ docs strategy, resulted in being the overall best model both in MMLU and UniQA benchmarks. Qwen 3 4B, in fact, better maintained the same level of performance across the different quantization levels. In addition, the w/o docs fine-tuning strategy was crucial to improve capabilities for Phi 4 mini 4B, in particular in the base and Q8 quantized inference. A general speed-up in performances is found in fine-tuned models over UniQA benchmark, while no improvements are found in Gemma 3 4B in Q4 setup, where performances are kept low.

The results obtained show that recent progress in developing multilingual LLMs provides the opportunity to use a valuable out-of-the-box model, also for domain-specific tasks with appropriate prompt engineering. In addition, the two proposed fine-tuning strategies, coupled with an overall light training phase as for the number of epochs, trainable layers, and consequently the resources needed, results crucial to improve capabilities of the SLMs under consideration, as for Phi 4 mini 4B and Qwen 3 4B. Those models trained in a target domain for a desired QA task of interest were able to outperform models three times larger in size, requiring on-budget resources. In general, both models should be considered as a valuable alternative to develop a custom LLM in a low-resource scenario. Phi tend to outperform after a w/o docs fine-tuning in terms of BERT score. On the other hand, Qwen presents strong performance in both traditional metrics such as the BLEU, ROUGE, and Meteor scores (Table 6) with both a fine-tuning strategy and different quantization. Depending on the actual computational resources available, Phi is preferred, since it is smaller compared to Qwen. Despite metrics being really close to each other, the w/o docs training strategy is the best and the fastest one in the training phase.

## 7. Conclusions

In this work, we evaluated the recent open-source instruction-tuned multilingual Small Language Models belonging to different families with a focus on their performances upon a base inference and after a Q8 and Q4 quantization. In particular, both closed and open answer QA tasks were analyzed in Italian and English. Performances were evaluated from a quantitative perspective with the general MMLU benchmark and UniQA, a QA data set based on a specific domain for which relevant documents are associated to each question.

The results show that among the largest models under evaluation, Phi 4 14B almost reached Claude 3.5 Sonnet and GPT 4o Mini in the MMLU benchmark, while Gemma 3 14B obtained interesting performances when inferred with full precision using UniQA. Among the smaller models, Qwen 3 4B and Phi 4 mini 4B were the most promising ones: both models better scale in terms of performance after Q8 and Q4 in selected benchmarks.

In addition, two fine-tuning strategies were proposed for the last 25% layers and the classification head of the smaller models using the training split of the UniQA data set. The results proved that Qwen 3 4B benefits the most of the training when evaluated over UniQA, while maintaining general good performance in the MMLU task. Such considerations together with the flexibility towards quantization and smaller inference time make Qwen 3 4B a valuable model to implement custom LLM-based applications in a low-context scenario after a suitable fine-tuning phase.

More tests are needed to evaluate the performance of the investigated models from a qualitative perspective. More in detail, additional tests will be conducted to simulate a real-case scenario, involving both human evaluation of the quality of the provided answers and truly open-ended QA in the domain of interest.

## Acknowledgments

We thank Giampiero Barbaro, who contributed in developing the training strategy in the early stages of this work, as part of his master thesis. This work is supported by the cup project J73C24000070007, "CAESAR" (Cognitive evolution in Ai: Explainable and Self-Aware Robots through multimodal data processing). The works presented were partially developed on the Leonardo supercomputer with the support of the CINECA-Italian Super Computing Resource Allocation class C project IscrC_DOCVLM2 (HP10C97VNN).

## Declaration on Generative AI

During the preparation of this work, the authors used Writefull for grammar and spelling checks. After using these tools, the authors reviewed and edited the content as needed and assume full responsibility for the content of the publication.

# A. Evaluation metrics

In Table 6, are reported the full calculated metrics over the UniQA data set in different quantization and fine-tuning strategies.

**Table 6**
Overview of the calculated metrics in the UniQA-EN and UniQA-IT split. BERT-prec and BERT-rec stands for BERT precision and recall scores, respectively, while FT and QTN refers to the fine-tuning and quantization strategy adopted. Average performance and execution time is reported in seconds, while the GPU used in GB. Bold values are the higher ones for each block, while starred ones the overall best.

# Annotating Manzoni: Challenges in the Annotation of Lemmas, POS and Features in “I Promessi Sposi”

Rachele Sprugnoli[1,*,†], Arianna Redaelli[2]

[1] Università Cattolica del Sacro Cuore, Largo Gemelli, 1, 20123 Milano, Italy
[2] Università di Parma, Via D'Azeglio, 85, 43125 Parma, Italy

**Abstract**

In this paper we introduce a dataset of *I Promessi Sposi* annotated with lemmas, UPOS tags, and features aligned with Universal Dependencies (UD). Three representative chapters from Manzoni's 1840 edition (791 sentences, almost 26 K tokens) were automatically tagged with UDPipe and fully manually corrected. Tailored guidelines extended standard UD practice with: (i) a double lemmatization approach, one that maintains archaic spellings and altered forms and one that normalizes lemmas, (ii) novel features that capture specific important characteristics of the novel, such as the use of apocopated and altered forms. Using the resulting dataset, we retrained the Stanza pipeline to obtain an in-domain model. Augmenting training data with ISDT sentences yielded further, although smaller, gains. Finally, a CRF sequence tagger was developed to identify apocopated forms.

**Keywords**

annotation, Italian literature, computational literary studies, Alessandro Manzoni

## 1. Introduction

In recent years, there has been a growing interest in the application of Natural Language Processing (NLP) to texts within the humanities, particularly in the literature domain. This trend is evidenced by the papers published in the proceedings of numerous conferences and workshops specifically dedicated to this area of research, such as those organized by the Special Interest Group on Language Technologies for the Socio-Economic Sciences and Humanities of the Association for Computational Linguistics (LaTeCH-CLfL)[1], the Digital Literary Studies Special Interest Group of the Alliance of Digital Humanities Organizations (SIG-DLS)[2], or the Computational Humanities Research (CHR) community[3]. Other key venues include the International Conference on Natural Language Processing for Digital Humanities (NLP4DH)[4] and the Workshop on Language Technologies for Historical and Ancient Languages (LT4HALA)[5].

The European consortium CLARIN has compiled a list of 45 literary corpora, each representative of a single author or a specific period.[6] However, this list does not include any Italian corpora. Nevertheless, literary texts are present within Italian diachronic corpora such as DiaCORIS [1], CODIT [2], and MIDIA [3]. The latter two include some works by Alessandro Manzoni, though not the complete texts but only selected portions. In contrast, the full text of *I Promessi Sposi* is accessible and searchable through platforms such as Intertext,[7] the LIZ (*Letteratura Italiana Zanichelli*) database,[8] and the CBook website [4]. However, there are currently no publicly available linguistic annotations nor any models that have been developed or tested specifically on the novel.

This paper aims to begin addressing this existing gap by offering the following contributions:

- A manually annotated dataset comprising three chapters of the novel, totaling 791 sentences and approximately 26,000 tokens. The annotations include lemmas, UPOS tags, and morphological features following the Universal Dependencies (UD) framework. Particular attention was given to (i) using features described in the Italian UD guidelines that are not yet widely adopted across existing treebanks, (ii) applying a dual lemmatization strategy (normalizing and conservative), (iii) defining additional features that capture stylistic and linguistic peculiarities of the novel.

*CLiC-it 2025: Eleventh Italian Conference on Computational Linguistics, September 24 — 26, 2025, Cagliari, Italy*

- An in-domain model trained on the aforementioned annotated dataset.
- A joint model trained on the combined data from *I Promessi Sposi* and the ISDT treebank.
- A dedicated model for the recognition of apocopated forms, which are characteristic of the novel's language.

All datasets and models are publicly available in a dedicated GitHub repository: https://github.com/RacheleSprugnoli/CoNLL-U_Manzoni.

## 2. Related Work

The application of NLP tools to Italian literary texts has been approached through targeted experiments since the early 2000s. Basili et al. [5] employed machine-learning techniques to semantically classify narrative fragments from Alberto Moravia's novel *Gli indifferenti*, whereas Pennacchiotti and Zanzotto [6] evaluated the accuracy of a morphological analyzer and a POS tagger on a range of prose and poetry texts dating from the thirteenth century to the late nineteenth century, revealing a drop in performance compared with results obtained on contemporary Italian. More recently, within the TrAVaSI project (*Trattamento Automatico di Varietà Storiche di Italiano*), texts of various genres, including literary works dated from 1861 onwards, have been annotated according to the UD framework, but using the same annotation layers we adopt for Manzoni, i.e., excluding dependency parsing. As in our study, these annotated data have been exploited to train automatic models [7]. Particular attention has been devoted to lemmatization, adopting a conservative approach that preserves the original token's graphical, phonological, and morphological characteristics [8]. By contrast, dependency parsing is included in the annotation of Dante Alighieri's *Divina Commedia*, which has in turn enabled the release of the Italian-Old treebank[9] and the development of models specifically tailored to this text [9]. In this annotation, lemmatization follows the criteria established in the *DanteSearch* project, from which the data were drawn [10] before applying the UD framework. In this case as well, a conservative strategy is adopted, whereby *pecorelle* ("little sheep") is lemmatized as *pecorella*. The same methodology has also been employed in the *Edizione dell'Opera Omnia di Luigi Pirandello* [11] and in the *Archivio Lessicografico della Poesia Italiana dell'Otto-Novecento* (ALPION) [12], although in these projects the data are accessible only through concordances.[10] Different lemmatization choices have been made in the compilation of other linguistic resources for Italian. For instance, in MIDIA, altered forms are linked to their corresponding base lemmas, but other word forms have not been normalized, resulting in distinct lemmas for each variation: for example, the archaic spelling *imaginando* ("imagining") is lemmatized as *imaginare*, while the modern form *immaginando* corresponds to *immaginare*. In COLFIS (*Corpus e Lessico di Frequenza dell'Italiano Scritto*), altered nouns and adjectives were initially lemmatized as independent lemmas and then a reference to the corresponding base form was added.[11] Finally, in LIPSI (*Lessico di frequenza dell'italiano parlato nella Svizzera italiana*), altered forms are mapped to a base lemma when weakly lexicalized: e.g., *chiesina* ("little church") is lemmatized with *chiesa* ("church"). On the contrary, independent entries are created when there is a significant semantic divergence between the derived form and the base: e.g., *lampadina* ("light bulb") is treated as a separate lemma with respect to *lampada* ("lamp") [13, 14]. This same strategy is also adopted in the compilation of the *Nuovo De Mauro* dictionary[12] and in our work, as explained in detail in Section 3.

## 3. Annotation

Chapters 1, 8, and 23 [13] of the final edition of *I Promessi Sposi* (1840) were automatically annotated with UDPipe 2 (ISDT model, version 2.15) [15] [16] and then manually corrected.[14] We adopted the CoNLL-U Plus format[15] to arrange specific annotation requirements designed for the novel, as explained in the following subsection (see Figure 1).

### 3.1. Guidelines

The annotation guidelines were developed collaboratively, discussed in multiple revision rounds, and refined to their current form. Their purpose was to guide the annotation process while remaining as consistent as possible with the official UD guidelines for Italian[16]. However, existing Italian treebanks do not always strictly follow UD's recommendations. Whenever discrepancies were

[9] https://github.com/UniversalDependencies/UD_Italian-Old

[10] https://vocabolari.pirandellonazionale.it/; https://alpion.unict.it/vocabolario/ricerca/

[11] https://linguistica.sns.it/CoLFIS/Home.htm

[12] https://dizionario.internazionale.it/avvertenze/2

[13] These chapters were selected for their stylistic and structural variety. Chapter 1 introduces the setting of the novel and includes a long descriptive passage, some dialogic sections, and even pseudo-documentary parts marked by archaic lexical choices; chapter 8 plays a central role in the narrative, featuring multiple scenes, thematic shifts, and dialogic exchanges, as well as a semi-lyrical closing section; chapter 23 is characterized by its predominantly dialogic structure and includes a lengthy final soliloquy.

[14] As we report in Table 2, the performance of this model is not optimal.

```

**Figure 1:** Snippet of CoNLL-U Plus format (beginning of Chapter 23).

encountered between the UD guidelines and currently available treebanks, our guidelines prioritized the official UD specifications. This involved both substitutions and additions.

Among the substitutions, we systematically replaced the use of `VerbForm=Ger`, commonly found in current treebanks for the traditional Italian gerund (e.g., *dicendo*, “saying”), with the correct label `VerbForm=Conv`. Similarly, for superlative adjective forms (e.g., *pessimo*, “very bad”), we replaced `Degree=Sup` with `Degree=Abs`.

Among the additions, we decided to use the feature `Reflex=Yes` for reflexive forms (e.g., *sé*, *si*, *proprio*, “him/her/itself”, “themselves”): although this feature is listed among the ones to be used in Italian,[17] it is still rarely applied in most currently available treebanks.[18] We also annotated indefinite pronouns functioning as total quantifiers (e.g., *ogni*, “each”, “every”, *tutto*, “all”, “everything” and *ciascuno*, “everyone”, “each one”) with the feature `PronType=Tot`, in line with the UD guidelines, despite its inconsistent use across current resources.

Beyond these additions, we introduced a set of features not prescribed by the UD Italian guidelines, but intended to account for morphosyntactic phenomena of particular historical or stylistic relevance in *I Promessi Sposi*. All such features were annotated in the MISC field.

Firstly, we used the feature `Variant=Apoc` to annotate apocopated forms, only excluding indefinite articles (e.g., *un*, “a”), which are fully grammaticalized in contemporary Italian and therefore not stylistically significant. As observed by Bianchi [17], Manzoni drew both on postconsonantal and postvocalic apocopes (e.g., respectively, *fecer* instead of *fecero*, “they did", and *cagion* instead of *cagione*, “cause") to evoke the rhythms and informality of spoken language, at times even extending beyond Florentine usage, which was his main language model. Unlike elisions, which involve the omission of a final vowel before an initial vowel and are graphically marked with an apostrophe, apocopes generally drop final phonemes regardless of the phonological context and are not marked. However, some apocopated forms in the novel, such as *que’* instead of *quei* (“those"), do include an apostrophe. In such cases, the apostrophe reflects a graphic convention rather than a genuine elision, and our annotation still treats these forms as apocopated.

Furthermore, we extended the set of possible values for the feature `Degree` to include morphological alterations, which are also frequently attested in the novel:

- `Degree=Dim` for diminutives (e.g., *casetta*, “little house");
- `Degree=Aug` for augmentatives (e.g., *spadone*, “big sword");
- `Degree=Pej` for pejoratives (e.g., *occhiacci*, “nasty eyes");
- `Degree=End` for endearments (e.g., *poverina*, “poor little girl").

Rather than relying exclusively on morphological structure, the annotation of this feature was guided by contextual interpretation, focusing on the expressive or affective nuance that the altered form conveys in each occurrence. As Perotti [18] noted, many of these altered forms were introduced by Manzoni only in later revisions of *I Promessi Sposi*, reflecting his pursuit of greater precision and expressive depth. The extended feature set was thus designed to capture and document this stylistic evolution through a consistent, context-sensitive, and fine-grained annotation approach. Altered forms were lemmatized in the third field with their standard, non-altered base forms; the altered lemma, instead, was reported in the eleventh field (e.g., *occhiacci*, “nasty eyes"; third field: *occhio*, “eye"; eleventh field: *occhiaccio* “nasty eye"). By lemmatizing altered forms under their standard base lemma, the annotation facilitates lexical querying and quantitative analysis, avoiding the dispersion of occurrences across multiple lemmas while preserving the expressive variation. For the same reason, namely to ensure consistency and semantic clarity in lexical analysis, fully lexicalized altered forms whose meaning significantly diverges from that of the base lemma were instead treated as independent lemmas (e.g., *cavallone*, “large water wave", was lemmatized separately from *cavallo*, “horse").

In a nineteenth-century corpus like *I Promessi Sposi*, lemmatization also required additional care to account for archaisms and diachronic variation. In all cases, we prioritized the modern form of the lemma as the primary entry, placing it in the third field, regardless of the degree of obsolescence or morphological variation. This criterion was adopted to support both practical usability and

[17] https://github.com/UniversalDependencies/docs/blob/pages-source/_it/feat/Reflex.md

[18] `Reflex=Yes` is currently present in the following treebanks: PUD (3 occurrences), ParTUT (14), OLD (2,346).

interpretive clarity: lemmatizing under a standard modern lemma ensures ease of information retrieval, even for users who may not be familiar with historical or literary Italian. However, such standardization was not pursued at the expense of losing linguistically significant traces of the novel's historical and stylistic identity. On the contrary, we aimed to preserve this richness by systematically annotating archaic and obsolete forms through a dedicated feature in the MISC field and/or an additional lemmatization in the eleventh field.

More specifically, in line with this approach, we distinguished two main cases for archaic forms:

- when the form was both obsolete and corresponded to an archaic lemma whose modern counterpart differed only in orthography or morphology (not in lexical identity or meaning), we annotated the feature `Style=Arch` in MISC field and reported the archaic lemma in the eleventh field (e.g., *annunzio*; field LEMMA: *annunciare*, "to announce"; MISC field: `Style=Arch`; eleventh field: *annunziare*);
- when the form was only the archaic spelling of a lemma that is still used today (i.e., the lemma itself was not obsolete), we only annotated `Style=Arch` in the MISC field without adding any lemma in the eleventh field (e.g., *varjo*; field LEMMA: *vario*, "various"; MISC field: `Style=Arch`). The same criterion was also applied to inflected forms that appear archaic but whose corresponding lemma is still current and unaltered (e.g., *chieggio*, which is the first person singular of *chiedere*, "to ask").

In case of uncertainty, we referred to *Nuovo De Mauro* [19], which provides mappings between obsolete or literary forms and their modern equivalents.

Finally, consistent with the principles outlined above, we applied a contextual approach to UPOS tagging and morphological features assignment, following the conventions of current Italian treebanks: for example, infinitives and participles were annotated as NOUN or ADJ when used as nouns or adjectives, respectively. In the case of infinitives used as nouns, no morphological features were assigned, as these forms are not inflected for gender or number. For participles, instead, the annotation also had consequences on lemmatization: when used as adjectives, they were lemmatized with the corresponding masculine singular form, in line with standard adjectives; when retaining a verbal function, they were lemmatized with the infinitive of the corresponding verb[19]. To help distinguish between participles and adjectives, we referred to Guasti [20], indicating three diagnostic tests, also adopted in the annotation of CoLFIS:

- participles cannot be modified with the suffix -*issimo* or intensifying adverbs (e.g., *molto*, "very"), while adjectives can;
- past participles can host clitic pronouns, while adjectives cannot;
- participles can co-occur with both *essere*, "to be", and *venire*, "to come", while adjectives can't.

## 3.2. Inter-Annotator Agreement

The IAA was calculated on the first 100 sentences of Chapter 38, the last one of the novel. This chapter is not part of the current dataset and the completion is in progress at the time of writing this paper. The annotators involved are two students of the Master's degree in "Linguistic Computing" at Università Cattolica del Sacro Cuore; they are Italian native speakers who have studied UD during a couple of courses of the degree but have not participated in the writing and discussion of the guidelines and are at their first experience of extensive annotation. Before beginning their work on Chapter 38, the students read the guidelines and analyzed the annotations already made for Chapters 1, 8, and 23.

The Cohen's kappa recorded for the different annotation levels was as follows:

- Lemmatization: 0.80;
- UPOS tagging: 0.97;
- Morphological features identification: 0.84;
- Other features: `Degree`, 0.80; `Style`, 0.86; `Variant`, 0.99.

**Table 1**
Cohen's kappa on the first 100 sentences of Chapter 38.

| UPOS | | Morphological Features | |
|---|---|---|---|
| X | 1 | Polarity | 0.89 |
| NUM | 1 | Definite | 0.82 |
| INTJ | 1 | Gender | 0.81 |
| PROPN | 1 | Foreign | 0.8 |
| PUNCT | 0.99 | NumType | 0.8 |
| NOUN | 0.99 | Number | 0.8 |
| CCONJ | 0.99 | Person | 0.8 |
| ADP | 0.98 | Clitic | 0.78 |
| VERB | 0.98 | VerbForm | 0.78 |
| PRON | 0.96 | Poss | 0.77 |
| AUX | 0.96 | PronType | 0.77 |
| DET | 0.95 | Tense | 0.76 |
| ADV | 0.94 | Mood | 0.76 |
| ADJ | 0.92 | Degree | 0.45 |
| SCONJ | 0.89 | Reflex | 0.39 |

[19] As for present participles, their usage is almost exclusively limited to either a nominal or, more rarely, a verbal function. The nominal use is generally easy to identify, as present participles functioning as nouns are typically preceded by a determiner (e.g., an article).

Table 1 provides details on the Cohen's kappa achieved for each UPOS tag and morphological feature. Overall, the results for the various annotation levels are good, often above 0.80 (indicating substantial or almost perfect agreement), with a few exceptions only for some features.

As for lemmatization, there are 27 discordant lemmas that fall into 4 categories. Some cases are clear errors due to superficial annotation: e.g., in *si sana ogni piaga* ("every wound is healed"), *sana* is lemmatized as *sano* ("healthy") instead of *sanare* ("to heal"). A recurring issue concerns the lemmatization of unstressed personal pronouns. Sometimes, the lemma matches the token itself; other times, it corresponds to the masculine form: e.g., in *l'era stata compagna* ("she had been her companion"), *l'* is lemmatized with *le* (feminine) or with *lo* (masculine). Another disagreement concerns the lemmatization of words in an archaic form, which also has repercussions on the feature `Style=Arch`. For example, *pronunziar* ("to pronounce") is lemmatized alternatively as *pronunciare*, in this case by adding the feature `Style=Arch`, or as *pronunziare*, without the feature.

Regarding the annotation of UPOS tags, the lowest agreement is recorded on subordinate conjunctions, confused with adpositions (2 times), adverbs (4 times) and pronouns (7 times, always in the annotation of *che*, meaning "who", "which" or "that").

The results concerning the annotation of morphological features show greater variability. Notably, the features `Degree`, which is employed for marking comparative and superlative forms of adjectives and adverbs, and `Reflex`, which is used for reflexive pronouns, have relatively low kappa scores (0.45 and 0.39 respectively), indicating moderate and fair IAA. As mentioned in subsection 3.1, these features were subject to modifications that appear to have been insufficiently assimilated by the annotators. For instance, one annotator consistently employed the `Sup` value of `Degree` rather than `Abs` for absolute superlatives, and frequently omitted the `Reflex=Yes` feature.

By contrast, the level of agreement is high for the newly introduced features in the MISC column. An interesting example of annotation divergence concerns the token *figliuoli* ("children"): one annotator interprets it as an archaic form of the lemma *figlio* ("child") with an endearing suffix, whereas the other annotator assigns the lemma *figliuolo*, without marking it with either the `Degree=End` or `Style=Arch` features.

# 4. Retraining Stanza

The dataset was split into training, development, and test sets using an 80/10/10 ratio, with the division based on the number of syntactic words as units, in accordance with the guidelines of the UD framework. The number of syntactic words was taken proportionally equally from the three chapters. Following this approach, the partitions are the following:

- training set: 615 sentences, 20,806 tokens;
- development set: 101 sentences, 2,670 tokens;
- test set: 75 sentences, 2,457 tokens.

Using this partition, a new Stanza [21] model for Manzoni's novel has been developed.

Table 2 presents the performance of the retrained model on the test set, in comparison with results obtained on the same file from other models, namely the ISDT [15] and OLD [9] 2.15 models of UDPipe 2, as well as the spaCy `it_core_news_lg`[20] and the Stanza combined models. The retrained model outperforms the other evaluated ones across all tasks. Obviously this is also due to the different annotation choices, especially those related to the features (see Section 3).

All models are nearly equivalent and highly reliable in token segmentation. The biggest divergence occurs for sentence splitting: as previously shown by Redaelli and Sprugnoli [22], this task is challenging due to the distinctive punctuation of the novel, particularly the use of guillemets and long dashes as closing quotation marks, thus the development of a dedicated model is especially necessary. Syntactic word segmentation has high scores (> 90) across all models but spaCy proved to be the least reliable.

With regard to UPOS tagging, the retrained Stanza model achieves an improvement of 2.44 F1 points compared to the Stanza combined model. The tag with the lowest F1 score under the retrained setting is INTJ (F1=0.79, P=1, R=0.65). For example, the only occurrence of *ohimè* (a roughly equivalent interjection to "alas") is misclassified as a NOUN, while *addio*, "farewell", is classified three times as an INTJ and three times as a NOUN. All other tags have values above 0.80 but we can notice some recurring errors in the case of the SCONJ tag. Indeed, subordinating conjunctions (F1=0.85, P=0.84, R=0.85) are confused with prepositions (ADP, especially for *dopo*, "after"), pronouns (PRON, as in the case of *che*, "who/that"), or adverbs (ADV, as in the case of *dove*, "where").

As for Universal features (UFeats), the 3.71 point improvement over the Stanza combined model is likely due to differences in the handling of specific features such as `Reflex=Yes` and `VerbForm=Conv`. The features with the lowest F1 scores are `PronType=Int` (F1=0.50, P=0.50, R=0.50), which marks interrogative pronouns and determiners, and `PronType=Exc` (F1=0.44, P=0.67, R=0.33), which is applied to exclamative pronouns and determiners. These categories are sparsely represented in the test set, with only 8 and 6 instances respectively. However, there is evidence of confusion between the two: for example, in the sentence *"Come stava allora il povero don*

[20] https://spacy.io/models/it#it_core_news_lg

**Table 2**
F1 score of different models.

| | UDPipe-ISDT | UDPipe-OLD | spaCy-large | Stanza-combined | Stanza-retrained |
|---|---|---|---|---|---|
| Token | 99.87 | 99.94 | 99.81 | 99.81 | 100 |
| Sentences | 22.66 | 66.99 | 21.62 | 61.08 | 100 |
| Words | 98.32 | 95.11 | 92.05 | 98.03 | 99.63 |
| UPOS | 93.94 | 87.85 | 85.08 | 93.59 | 96.03 |
| UFeats | 93.94 | 75.57 | 86.01 | 93.10 | 96.81 |
| Lemmas | 95.29 | 88.55 | 85.50 | 94.29 | 97.13 |

**Table 3**
Examples of lemmatization errors involving altered (on the left) and archaic (on the right) forms.

| FORM | LEMMA-GOLD | LEMMA-PRED |
|---|---|---|
| *bravacci* | *bravo* | *brave* |
| *campicello* | *campo* | *campice* |
| *paesello* | *paese* | *paesello* |

| FORM | LEMMA-GOLD | LEMMA-PRED |
|---|---|---|
| *maraviglia* | *meraviglia* | *meravigliare* |
| *leggiero* | *leggero* | *leggiere* |
| *edifizi* | *edificio* | *edifizio* |

*Abbondio!"* ("How was poor Don Abbondio feeling at that moment!") the word *come*, "how", is annotated as `PronType=Exc` in the gold data, but the model incorrectly predicts `PronType=Int`. The feature `Mood=Cnd`, indicating verbs in the conditional mood, also yields a relatively low F1 score (F1=0.73, P=1, R=0.57). Although this class includes only a small number of instances (7), misclassifications occurred, including one case where it was confused with the indicative mood (*fiaterebbe*, "he would breathe") and another with the subjunctive mood (*leverebbe*, "he would take away").

For lemmatization, the improvement is of 2.84 points with respect to the Stanza combined model, with a total of 82 incorrect lemma predictions. Notably, lemmatization choices involving altered forms and archaic variants do not appear to be major sources of inaccuracy: indeed, only 12% of errors involve altered forms, and 4% involve archaic ones. Table 3 provides examples of these types of errors. The remaining instances mostly concern the prediction of non-existent lemmas (e.g., *riunendo* (gerund of "reunite") → *riunere* instead of *riunire*; *mangi* (present subjunctive of "eat") → *manire* instead of *mangiare*); and of feminine forms instead of the correct masculine ones (e.g., *scure* ("dark") → *scura* instead of *scuro*; *forestiera* ("female foreigner") → *forestiera* instead of *forestiero*). It is interesting to note that the UDPipe model trained on the *Divina Commedia* (UDPipe-OLD) exhibits low performance on lemmatization, despite the fact that the target domain is literary, as is the case for Manzoni. This discrepancy can likely be attributed to the considerable temporal and stylistic differences between the two sources: the *Divina Commedia* is dated back to the 14th century and is composed in poetic form, whereas Manzoni's work dates to the 19th century and is written in prose. Indeed, the lexical overlap between the lemmas in the training set of the OLD treebank and those in our corpus amounts to only 50%, compared to a higher overlap of 69% with the lemmas in the training set of the ISDT treebank.

## 4.1. One Novel, Three Versions

Alessandro Manzoni revised *I Promessi Sposi* multiple times, resulting in three versions. The earliest, a handwritten draft composed in 1823 and known as *Fermo e Lucia*, differs in both content and style from later editions. The language used, for example, is an original combination of Italian, Lombard, French and Latin calques, also rich in author's neologisms. In 1827, Manzoni published a revised version, commonly called the *Ventisettana*, which introduced substantial linguistic refinements aimed at improving clarity and accessibility for Italian readers. The definitive version, released starting from 1840 and known as the *Quarantana*, incorporated further stylistic and linguistic changes based on the Florentine language, reflecting Manzoni's efforts to promote a unified Italian language.

Given the linguistic differences among these versions, it is of particular interest to assess the extent to which the model trained on the *Quarantana* generalizes to earlier texts. Table 4 presents the F1 scores obtained in the first chapter of *Fermo e Lucia* (5,760 tokens) and the *Ventisettana* (7,407 tokens). Notably, performance on the *Ventisettana* is even higher in terms of morphological features and lemmatization, although there is a slight decrease in UPOS tagging. Morphological features identification is still good on the 1823 version but UPOS tagging and lemmatization show a more evident drop.

## 4.2. A Joint Model

An additional experiment involved the creation of a combined model trained on the merged training and development sets of ISDT and the training set of *I Promessi Sposi.* ISDT was selected because its corresponding model

**Table 4**
F1 score on the first chapter of the two previous versions of *I Promessi Sposi*. Bold scores indicate an improvement over the results obtained on the *Quarantana* test set.

| | *Fermo e Lucia* | *Ventisettana* |
|---|---|---|
| UPOS | 95.78 | 95.87 |
| UFeats | **97.12** | **97.56** |
| Lemmas | 95.15 | **97.55** |

achieved better results than the other off-the-shelf models, although it still underperformed compared to the in-domain retrained model. The resulting combined training set consisted of 14,300 sentences.

Table 5 reports the performance of this combined model on the first chapters of *Fermo e Lucia* and the *Ventisettana*, as well as on the test set from the *Quarantana*. The increased training data, despite being from a different domain and not always consistent with our annotation guidelines, led to a modest overall improvement in performance, particularly on the 1840 test set. These generally positive results align with findings from previous experiments conducted on the *Voci della Grande Guerra* [23] and *VoDIM* [7] corpora. In contrast, joint models developed for syntactic parsing of the *Divina Commedia* have shown lower performance compared to in-domain models [24].

**Table 5**
F1 score of the joined (ISDT+Manzoni) model on the test set of *I Promessi Sposi* (*Quarantana*) and on the first chapter of the previous novel's versions. In bold the score that are improved with respect to the ones obtained with the in-domain mode.

| | *Fermo e Lucia* | *Ventisettana* | *Quarantana* |
|---|---|---|---|
| UPOS | **95.95** | 94.35 | **96.24** |
| UFeats | 96.86 | 96.11 | **97.14** |
| Lemmas | **96.58** | **97.61** | **97.50** |

## 5. Modeling Apocopes

We implemented a supervised sequence labeling pipeline for identifying apocopated forms using Conditional Random Fields (CRFs) and the same train, development and test sets used for the retraining of Stanza. For the time being, we have focused on apocopated forms only, as among the three specific features we added to the annotation, `Variant=Apoc` is the most frequent, whereas the others are too sparsely represented.[21] Although more frequent than the other features, the number of instances was still insufficient to support the use of neural methods, which require larger amounts of training data to perform effectively and generalize well. Therefore, we adopted a CRF-based approach instead.

The model is trained using the `sklearn-crfsuite` library and hyperparameters (c1 and c2 regularization coefficients) are optimized via randomized search with 5-fold cross-validation. The feature set includes orthographic (e.g., lowercase form, word suffixes and prefixes), morphological (e.g., UPOS and FEATS) and lexical (lemma) features from the preceding and following tokens. The results of the model's binary classification on the test set are reported in Table 6.

**Table 6**
Results of the CRF model on the `Variant=Apoc` feature.

| | P | R | F1 |
|---|---|---|---|
| Apoc | 1 | 0.85 | 0.91 |
| None | 1 | 1 | 1 |
| Avg. | 1 | 0.92 | 0.95 |

The test set contains 59 apocopated forms corresponding to 41 tokens and 33 lemmas; 12 of these forms do not appear in the training set, which includes 611 apocopated instances corresponding to 220 tokens and 169 distinct lemmas. Among the model's 9 false negatives, 4 are apocopated forms that were not seen during training: i.e., *timor* ("fear"), *almen* ("at least"), *passan* ("they pass by"), *ondeggiar* ("to ripple"). As for the remaining cases, the model fails to correctly classify *par* ("it seems", seen 7 times in the training set), *fra* ("friar", 3 times), *star* ("to stay", 2 times), and *siam* and *cagion* ("we are" and "cause", each seen once in the training data).

## 6. Conclusion

In this paper, we have introduced several new resources: (i) a manually annotated dataset of 3 chapters of *I Promessi Sposi*, comprising 791 sentences and approximately 26,000 tokens, enriched with lemmas, UPOS tags, Universal Dependencies morphological features and adhoc features designed for capturing specific stylistic characteristics of Manzoni's novel; (ii) an in-domain NLP model trained specifically on this dataset; (iii) a joint model combining data from the novel and the ISDT treebank; (iv) a specialized model for recognizing apocopated forms, which are a distinctive feature of Manzoni's text.

All data and models developed in this study are made publicly available in a dedicated GitHub repository, hopefully laying the groundwork for future research on Italian literary texts through computational approaches.

As for future work, a key priority is to extend the annotation to additional chapters. Thanks to the new models developed in this study and their relatively low error rates, the manual correction process is expected to be significantly accelerated. The expansion

[21] The whole dataset, at the moment of writing, contains 735 apocopated forms, 109 altered forms and 106 archaic forms.

of the dataset will also enable the development of models targeting the other two specific features introduced in our annotation scheme, namely `Style=Arch` and `Degree=Aug/Dim/End/Pej`. Another future step will involve syntactic annotation, with the ultimate goal of incorporating Italy's most important novel among the UD treebanks. This will continue the broader effort to integrate Italian literary texts into syntactically annotated resources, following the precedent set by the annotation of the *Divina Commedia* [9].

## Acknowledgments

The authors thank Flavio Massimiliano Cecchini for annotating chapters 1, 8, 23 of *Quarantana* and *Ventisettana*, Alessia Leo and Michael Mostacchi for annotating chapter 38 of *Quarantana*, Chiara Febbraro for the annotation of chapter 1 of *Fermo e Lucia* and Giovanni Moretti for technical assistance.

# Ciallabacialla! Modeling and Linking a Regional Lexical Resource to Include Sicilian in the Semantic Web

Rachele Sprugnoli[1,*,†], Giovanni Moretti[1], Domenico Giuseppe Muscianisi[2] and Eleonora Litta[1]

[2]*Università di Parma, Via D'Azeglio, 85, 43125 Parma, Italy*

**Abstract**

This paper describes the inclusion of Sicilian in the Semantic Web through the development of new resources aligned with Linguistic Linked Open Data principles. More specifically, we model and publish the first Sicilian Lemma Bank and a bilingual Sicilian–Italian glossary extracted from the Sicilian Wiktionary (*Wikizziunariu*). These resources are formalized using the OntoLex-Lemon and LiLa (Linking Latin) ontologies with the aim of enabling cross-lingual interoperability. The glossary is also linked to the LiITA (Linking Italian) knowledge base. In addition, two preliminary experiments are reported: the first evaluates the translation capabilities of commercial Large Language Models (LLMs) from Sicilian into Italian; the second investigates bilingual lexicon induction through cross-lingual embedding alignment, with results indicating the challenges posed by low-resource dialects. This work aims to demonstrate the feasibility and importance of integrating under-resourced languages into broader Computational Linguistics and Semantic Web infrastructures.

Sicilian, Linguistic Linked Open Data, Semantic Web, lexical resources, dialectology

## 1. Introduction

The LiITA (Linking Italian) project is dedicated to developing an interoperable Knowledge Base (KB) for Italian linguistic resources. Its primary goal is to construct a network that interconnects diverse Italian language datasets (such as dictionaries, lexicons, and textual corpora) by publishing them as Linked Open Data (LOD). At the core of LiITA is the Lemma Bank (LB), a continually expanding repository of canonical citation forms (lemmas) for Italian words [1]. The LB functions as a central hub, enabling interlinking and interoperability across various linguistic datasets. By aligning lexical entries and word occurrences from distributed resources with their corresponding lemmas, LiITA supports federated search capabilities and facilitates advanced linguistic analyses.

LiITA adopts the OntoLex-Lemon [2] model as its foundational standard for the representation of lexical resources. This ensures that data is structured according to widely accepted Semantic Web principles, thereby promoting interoperability and reusability. OntoLex-Lemon provides a framework for linking lexical entries to their meanings and to related linguistic properties. LiITA utilizes this framework to establish connections between lemmas in the LB, their occurrences in texts, and their corresponding entries in lexicons and dictionaries. Although the LiITA Knowledge Base primarily focuses on resources related to the Italian language, it is important to acknowledge that Italy is home to a rich array of local languages. Many of these are endangered, predominantly oral, and often lack standardized orthographies. A recent paper [3] offers a critical examination of Italy's linguistic landscape, challenging mainstream Natural Language Processing (NLP) approaches. The study highlights the fragmented and underdeveloped state of NLP research for many Italian language varieties. Given that language inherently encodes local knowledge, cultural traditions, and historical memory, the loss of these varieties entail a significant erosion of cultural heritage. Despite this, the language varieties of Italy are increasingly represented in multilingual NLP initiatives. These include participation in shared tasks on morphological inflection and on language identification (see for example [4]). Additional contributions include cross-lingual word embeddings for low-resource settings and the inclusion of Italian varieties like Lombard, Piedmontese, and Sicilian in multilingual pretrained language models, such as mBERT [5].[1] How-

[1] See [3] for other bibliographical details about these recent efforts.

ever, these varieties remain under-represented in terms of training data volume and quality. On the other hand, a tendency of multilingual NLP to treat language varieties "monolithically", without adequate consideration for their distinct orthographic conventions, sociolinguistic contexts, or community-specific needs, remains. In this light, the integration of bilingual dictionaries and other lexical resources for Italy's minority languages into the LiITA LOD framework would represent a concrete step toward supporting these under-resourced languages. Such inclusion would enhance their digital visibility, promote accessibility, and contribute to the broader goal of preservation and exchange of information on linguistic diversity. The first bilingual glossary to be included in the LiITA KB was the one published in the *Vocabolario della lingua parmigiana* [6]: data in RDF and CSV format together with a set of SPARQL queries are available online [7].[2] This paper, instead, concerns the modeling and linking of the Sicilian Wiktionary (*Wikizziunariu*). More specifically, this paper provides the following three contributions:

1. the modeling of the first Lemma Bank for Sicilian and of a Sicilian-Italian glossary extracted from the *Wikizziunariu* according to the Linguistic Linked Open Data principles;[3]
2. the linking of the glosssary to the KB of the LiITA project[4]
3. the results of two preliminary NLP experiments using the aforementioned bilingual glossary.

## 2. The Sicilian Dialect

Dialects constitute an essential component of Italy's linguistic heritage. In this study, it is important to clarify the intended meaning of the term *dialect*, which corresponds to the Italian *dialetto*, i.e., a regional or areal language that is genealogically a sister language to so-called Standard Italian, as defined in the *Vocabolario Treccani*[5] (see also [8]). The dialects of Italy are, in fact, independent Romance languages that, over the centuries, have become minoritized local varieties. This shift is primarily attributable to the prestige and diffusion of the *volgare fiorentino* following the works of Dante, Petrarch, and Boccaccio, whose literary influence from the 14th century onward played a central role in shaping the literary language of the Italian Peninsula and, eventually, the codification of present-day Standard Italian. Today, Standard Italian functions as the roof-language for the various Italo-Romance dialects spoken across the country [9]. However, the medieval Sicilian *volgare* was among the first Romance varieties to be used as a literary language, particularly at the court of Emperor Frederick II of Swabia, who established his principal seat in Palermo between 1220 and 1250. During this period, poetry and the arts flourished, giving rise to the *Scuola poetica siciliana*, which Dante, in his *De vulgari eloquentia*, regarded as the earliest manifestation of an "Italian" literary tradition.

According to the *Carta* by Giovan Battista Pellegrini, the Sicilian dialect is placed as group III (*siciliano*) among the Extreme Southern dialects of Italy (henceforth abbreviated as ESI, or *Meridionale Estremo* in Italian), with seven varieties based on the presence of umlaut (*metafonesi*), namely Western Sicilian, Central umlauted area, South-Eastern umlauted area, Original non-umlauted area, Messinese, Aeolian and Pantesco. This classification, along with others that have been proposed (see, for example, [10]), highlights the structural and sociolinguistic complexity of the Sicilian dialect. Moreover, due to its geographical location at the crossroads of the Mediterranean, Sicily has historically been (and continues to be) a site of intense cultural, communal, and linguistic contact [11]. Although the Sicilian dialect retains its core Italo-Romance structural features, it has undergone significant stratification due to successive waves of linguistic contact from Late Antiquity through the Middle Ages. Early layers include influences from (Byzantine) Greek, particularly in eastern Sicily, and from Sicilian Arabic in the west. Subsequent periods of contact include the Norman era (10th–12th centuries) and the reign of Frederick II (ending in 1266), followed by the Angevin rule and the Sicilian Vespers (1282), which introduced Gallo-Romance elements. Later, during the Aragonese and Spanish periods (14th–17th centuries), further Ibero-Romance influences were integrated into the language. Following the medieval period, Sicilian dialects began to evolve into their modern forms. In addition, various linguistic minority communities have historically settled in Sicily. The oldest still active is that of Piana degli Albanesi, the largest Arbëreshë (Italo-Albanian) settlement on the island, established at the end of the 16th century. Another notable case is the Gallo-Italic of Sicily, comprising approximately 15 isolated communities in central and eastern Sicily, whose origins trace back to the Norman period. A third group is the Sicilian Greek community in Messina, officially recognized as a linguistic minority in 2012, which descends from settlers who migrated from the Peloponnese in the mid-16th century. Today, the varieties of Sicilian spoken in these areas exhibit significant influence from these non-Italo-Romance minority languages. The long and complex sociolinguistic history of the Sicilian dialect, together with its internal variation

and multilingual contact layers, renders it a particularly rich and compelling subject for investigation through computational methods.

### 2.1. Dictionaries and Grammars of Sicilian

With such a history, the studies on the dialects of Sicily, both in language and culture, show a long-lasting tradition already from the Middle Ages. However, for a comprehensive understanding of the present-day language, the most informative period for the study of Sicilian begins with Italian Romanticism, specifically in the mid to late 19th century. Shortly after the Unification of Italy, Antonino Traina published the *Nuovo vocabolario siciliano–italiano*, a dictionary lemmatized according to Sicilian entries, which provided Italian translations as well as phraseological examples drawn from idiomatic expressions and literary sources, encompassing both cultivated and popular registers [12]. As was typical of the period, Traina's underlying objective was to promote the Tuscan-based national language, thereby contributing to the broader project of fostering social and linguistic unification among the newly formed Italian citizenry. In the same period, the most influential scholar of the Sicilian language and cultural traditions was Giuseppe Pitrè, author of the monumental *Fiabe, novelle e racconti popolari siciliani* [13] and *Grammatica Siciliana* [14]. In his linguistic work, Pitrè approached Sicilian as a Romance language in its own right, analyzing its phonology diachronically from Latin without reference to Tuscan (i.e., Italian), which he explicitly treated as a separate variety rather than a standard of comparison. Both Traina and Pitrè promoted a spelling standardization rooted in Latin orthographic principles. This approach had a dual effect: on the one hand, it contributed to the definition of a kind of Sicilian *koine* (common language), but on the other hand this introduced a bias towards the Latinization of Sicilian [15]. This process of standardization continues to play a fundamental role today. In 2024, the *Cademia Siciliana* (Sicilian Academy) published the *Documento per l'ortografia del siciliano* (Document for the spelling of Sicilian), aiming to be friendly for those who want to write in Sicilian. On the scientific and academic side, the most important linguistic and ethnographic research on Sicilian consists of the pioneering investigation by Franco Fanciullo on the Aeolian Islands [16].

Besides the *Dictionary* by Traina, two other fundamental lexicographic resources for the Sicilian dialect are the *Vocabolario storico-etimologico del siciliano* and the *Vocabolario siciliano*, both published on paper by *Centro di studi filologici e linguistici siciliani*. As far as digital dictionaries are concerned, there is the *Vocabolario del siciliano medievale*[6] of the University of Catania, which collects lemmas of the *volgare siciliano* from the mid 13th to the mid 16th century and provides a Web interface [17]. Within this context of rich historical and linguistic tradition, *Wikizziunariu* emerges as a collaborative resource that is easily accessible, machine-readable, and free from copyright restrictions.

## 3. Workflow

This work was carried out in two main phases. The first involved parsing a dump of the Sicilian Wiktionary (*Wikizziunariu*) to extract information relevant to our objectives. The second phase focused on modeling and creating resources in RDF format. This latter step includes the construction of a Sicilian LB, the transformation of Wiktionary data into RDF triples, and the linking of Italian translations to the LiITA LB developed within the LiITA project.

### 3.1. Data Extraction

The dump of the Sicilian Wiktionary, downloaded from the Academic Computer Club archive in Umeå,[7] was parsed using a custom script designed to extract relevant data. Figure 1 illustrates the structure of an entry from which the following elements were retrieved: the page title (*abbentu*), the grammatical category (*Sustantivu*, i.e., common noun), number and gender (*singulari maschili*), alternative forms (*puru scrittu abbientu*), and the Italian translation(s) (i.e., values following the label *talianu* in the *Traduzzioni* section, such as *riposo*, *quiete*, *pace*).

The main challenge in the extraction process stemmed from the variability in how information is structured across entries. For example, number and gender may be represented using initials (e.g., *s* for *sostantivo*, noun, *m* for masculine, and *f* for feminine). Furthermore, while alternative forms are always enclosed in parentheses, they are not always preceded by the phrase *puru scrittu*, and the number of translations varies. In some cases, these translations are accompanied by information about the grammatical gender of the Italian equivalents (e.g., *maschili* and *f*, as shown in the figure).

A total of 14,464 entries were extracted through this process, distributed across 20 distinct classes. Twelve of these correspond to traditional grammatical categories: adjectives, adverbs, articles, coordinating conjunctions, interjections, common nouns, proper nouns, numerals, prepositions, pronouns, subordinating conjunctions, and verbs. In addition, the entries included acronyms, confixes, prefixes, suffixes, nominal phrases, multiword ex-

pressions, proverbs, and conjugated verb forms. These latter entries were not included in the subsequent stages of the work, as they cannot be directly mapped to a LB. Table 1 presents the final number of entries considered for each grammatical category and provides example for each category; the original categories have been converted into UPOS (Universal Dependencies Part of Speech) tags [18]. The low number of determiners (DET) is due to the fact that, in the original classification, this category includes only articles, while other types of determiners are assigned to different classes; for example, possessive determiners are categorized as adjectives or pronouns.

## 3.2. Data Modeling and Linking

The Sicilian entries were used to build the Sicilian LB. Lemmas are described with the OntoLex model in conjunction with the LiLa ontology. The latter provides a structured representation of the linguistic features of each lemma, including part-of-speech classification, via the `lila:hasPos` property, and grammatical gender, via the `lila:hasGender` property. The total number of lemmas in the Sicilian LB is 10,232. The discrepancy with respect to the number of entries in the *Wikizziunariu* (see Table 1) is primarily due to the fact that some of them are written representations, rather than distinct standalone lemmas. The following RDF triple, expressed in Turtle syntax, represents the Sicilian lemma *middeu*,[8] classified as a masculine noun. It includes multiple written representations (*amiddeu*, *amoddei*, *middeu*, *muddeu*, *muddìu*) each annotated with the language ISO tag `@scn`. These forms are considered orthographic or graphical variants of the same lemma and do not affect its morphological interpretation; all share the same grammatical gender (masculine). Additionally, the lemma is related to a lemma variant identified by an URI[9] corresponding to the lemma *muddìa*.[10] In our example, *middeu* and *muddìa* can be used alternatively but they differ in gender, being the second a feminine noun.

```
<http://liita.it/data/id/

  ontolex:writtenRep "amiddeu"@scn, "
      amoddei"@scn, "middeu"@scn, "
      muddeu"@scn, "mudd u"@scn .
```

Subsequently, the bilingual glossary was modeled. The Sicilian lexical entries were linked to the corresponding lemmas in the Sicilian LB via the `ontolex:canonicalForm` property. The Italian translations were connected to the Italian LB developed within the LiITA project using the same property. Furthermore, the lexical entries of the two languages were directly related through the `vartrans:translatableAs` property, which establishes a correspondence between trans-

**Figure 2:** Lemmas and corresponding translations: the example of *frassino* (ash).

lations. The following RDF triple defines a lexical entry in Italian for the word *frassino* (ash) associated with a canonical form which represents the corresponding lemma in the LiITA LB. Furthermore, this entry is linked to its corresponding Sicilian lexical entry (*middeu*), establishing a cross-lingual correspondence between the Italian and Sicilian lexical resources.

```
<http://liita.it/data/
    LexicalResources/DialettoSiciliano
    /id/LexicalEntry/italian/328>
  a ontolex:LexicalEntry;
  rdfs:label "Lexical entry of
      Italian: frassino";
  ontolex:canonicalForm <http://liita
      .it/data/id/lemma/993692>;
  vartrans:translatableAs <http://
      liita.it/data/LexicalResources/
      DialettoSiciliano/id/
      LexicalEntry/siciliano/753> .
```

Figure 2 displays the lemma *frassino* (ash) as it appears in the LiITA LB, together with information regarding its grammatical gender (masculine) and part of speech (common noun). The node is linked to the lexical entries in the linked lexical resources through the property `ontolex:canonicalForm`. In particular, there are six entries connected via the `vartrans:translatableAs` property related to the Sicilian dictionary and one related to the dialect of Parma. The visualization also shows the `lemmaVariant` relation between *middeu* and *muddìa*.

The linking process with the Italian LB was conducted in two distinct phases. In the initial phase, an automatic alignment was performed between the string of each translation of Sicilian glossary entry and those recorded in the Italian LB, considering the part of speech. This procedure successfully accounted for 55% of the entries. An additional 19% of entries were identified as ambiguous, i.e., a single Italian entry corresponded to multiple lemmas within the LB, thus requiring manual disambiguation. For instance, the entry *caglio*, whose Sicilian translation is *quagghialatti*, could be linked either to the lemma identified by the URI http://liita.it/data/id/lemma/972573, corresponding to the meaning "rennet", or to http://liita.it/data/id/lemma/972574, which refers to a type of herb or artichoke. To resolve such ambiguities, additional information was consulted from *Wikizziunariu* or other Sicilian-language dictionaries.

Currently, 26% of the entries lack a corresponding linking to the Italian LB. These terms include, among others, feminine or plural forms absent from the LB, as well as culturally specific terms unique to the Sicilian context, such as *spènsiri* translated as *largo mantello utilizzato dai contadini* (a wide cloak worn by peasants) or *carpita* translated as *coperta rustica tessuta con ritagli di stoffa* (a rustic blanket woven from fabric scraps).

# 4. Case Studies

Using SPARQL queries, it is possible to extract linguistically meaningful information from multiple perspectives.[11]

For instance, one can retrieve Sicilian lemmas having written representations beginning with a *d* and an *r*; the complementary distribution [d] ∼ [r] is especially attested in the western variant from Palermo when those sounds appear in intervocalic or initial position. Among such cases is the lemma *dicembri* (December) (< Latin *DECEMBRE(M) ∼ *DECEMBRU(M)) that witnesses several written representations, namely (a) *dicièmmuru*, (b) *dicèmmiru*, (c) *dicembru*, (d) *dicèmmuru*, (e) *dicièmmiru*, (f) *ricièmmiru* and (g) *ricièmmuru*. The lemmas (d) and (f) indeed show the aforementioned allophony [d] ∼ [r] but there are also other interesting phenomena. The lemmas (a) and (e) show the *metafonesi* (umlaut) in tonic syllables, i.e. a process of vowel assimilation; the lemmas (a), (b), (d), (e), (f) and (g) witness the lag assimilation of Latin *MB > Sicilian MM [19]. Finally, the lemmas (a), (d) and (g) attest a u-vowel, while the lemmas (b), (e) and (f) an e-vowel: these are epentheses, thus random insertions of one or more sounds to favor the pronunciation.

It is also possible to search for lemmas having written representations that include *ed* or *ied*, an alternation which graphically renders the umlaut of vowels in tonic syllables. This is a significant linguistic phenomenon in Sicilian, serving as a marker for distinguishing dialectal variants. It is generally attested in central and western regions of the island, while it is absent in the north-eastern areas. For example, in the Sicilian word (a) *aceddu* (bird) (< Latin *AU(I)CELLU(M)), the actual pronunciation of *dd* is retroflexed as *ḍḍ* [ɖː] but it is here not represented [14]. This feature is contained in all the following written representations, that is (b) *acieddu*, (c) *ancieddu* and (d) *oceddu*. The tonic syllable is the middle one and witnesses either (1) no changes in lemmas (a) and (d) deriving from Latin *-CE- or (2) umlauted vowels in lemmas (b) and (c) both bisyllabic [ˈɪ.e]. The same phenomenon occurs with, among others, *(ab)bruciareddu* ∼ *(ab)bruciarieddu* (ripe ear), *beddu* ∼ *bieddu* (beautiful), *ciuceddu* ∼ *ciucieddu* (soup, broth, delicacy), *frateddu* ∼ *fratieddu* (brother), *marzamareddu* and *mazzamareddu* ∼ *marzama(u)rieddu*, *mazzumaurieddu* and *mazzamarieddu* (whirlwind, whirlpool, demon), *munzeddu* ∼ *munzieddu* (stack, pile), *pisciteddu* ∼ *piscitieddu* (small fish).

As for morphology, we can search for nouns ending with -*ìa* (< Greek -ía), an abstract suffix which is one of the most common and attested. We can thus notice that the Sicilian suffix is variously represented in Italian translations. More specifically, Sicilian -*ìa* corresponds to the following Italian suffixes:

1. -*ia* (same Greek ía-suffix for abstractivize nominals), as in *ancarìa* ∼ *angheria* (vexation), and *magarìa* ∼ *stregoneria* (witchcraft);
2. -*ità* (< Latin *-ITÁ(TEM)), as in *avracìa* ∼ *altezzosità* (haughtiness) and *liccum(ar)ìa* ∼ *golosità* (delicacy);
3. -*ezza* (< Latin *-ITIA(M) ∼ *-ITIES), as in *laccanìa* ∼ *debolezza* (weakness);
4. various other abstractivizing suffixes, such as -*eccio*, -*io*, -*enza*, -*ita* (with the accent on the antepenultimate syllable).

# 5. Experiments

Beyond the specific linguistic analyses enabled by interoperability, such as those presented in Section 4, the data we provide can support a variety of experimental applications. A couple of examples are given in the following subsections.

## 5.1. How much Sicilian do LLMs know?

The bilingual glossary may be used to assess the ability of Large Language Models (LLMs) to translate from Sicilian into Italian. Specifically, we randomly selected 20 nouns, 20 adjectives, 20 verbs, and 20 adverbs, and prompted the main commercially available LLMs to translate each word into Italian. We chose to focus on commercial systems (namely, ChatGPT, Gemini, and Claude) because they are the most widely used by non-experts due to their user-friendly interfaces. A simple zero-shot prompt was employed uniformly across all models: *Traduci ogni parola dal siciliano all'italiano* (Translate each word from Sicilian to Italian). The responses were compared against the translations provided in the glossary and were also evaluated by one of the authors, a linguist and native speaker of Sicilian. This additional human evaluation was intended to determine whether certain translations, even if not identical to those recorded in the resource, could nonetheless be considered acceptable. For example, while the adjective *bacioccu* is officially translated only as *sempliciotto* (nitwit), the alternatives *sciocco* (foolish) (proposed by GPT-4o) and *tonto* (dumb) (provided by Claude Sonnet 4) were considered equally valid. Table 2 presents the results of this evaluation in terms of (synonym-aware) accuracy.

Table 2 reveals not very high accuracies even with synonym tolerance. Gemini 2.5 Flash tops the list at 67% accuracy, about 6 points ahead of GPT o3 and roughly 15 points above Claude 4 Sonnet (51%) and GPT-4o (52%). Even the best-performing model thus mistranslates

[11] Queries can be found in the GitHub repository: https://github.com/LiITA-LOD/LocalVarieties/tree/main/Siciliano. They can be tested on the following endpoint: https://liita.it/sparql.

**Table 2**
Synonym-aware accuracy on 80 randomly chosen Sicilian words translated into Italian.

| | Accuracy |
|---|---|
| Gemini 2.5 Flash | 67% |
| GPT o3 | 61% |
| GPT-4o | 52% |
| Claude 4 Sonnet | 51% |

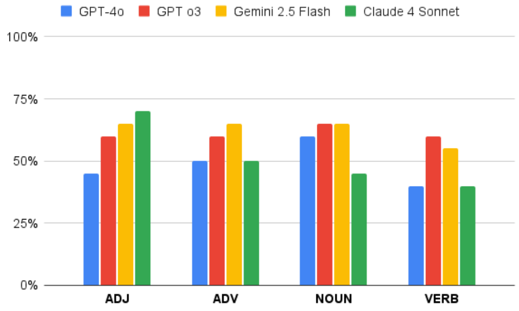

**Figure 3:** Accuracy per part-of-speech tag.

roughly one word out of three, underscoring how low-resource dialects remain challenging for general-purpose systems. An interesting case is that of GPT o3, which, during the reasoning process, retrieves information from the Web. For certain translations, it explicitly cites its sources, including the *Wikizziunariu*, the vocabulary published on the *TerraLab* blog,[12] and the lexicon curated by the group *Salviamo il siciliano*.[13] This approach leads to better accuracy than the GPT-4o model but still lower than that of Gemini 2.5 Flash.

Two noteworthy observations can be drawn from Figure 3, which shows with a bar chart the accuracy calculated for each part of speech. First, verbs consistently emerge as the most challenging grammatical category to translate across all four models. Second, GPT o3 and Gemini 2.5 Flash exhibit relatively stable performance across categories, whereas Claude 4 Sonnet and GPT-4o show greater variability. However, given the limited sample size of only 80 items, the results are subject to a high sampling error, and the observed differences are not statistically significant. Future work should expand the benchmark and incorporate a broader range of dialectal variants to enable more robust evaluation.

Error analysis shows that 18 words were incorrectly translated by all the systems. More generally, all models exhibit a systematic tendency to infer translations on the basis of superficial orthographic similarity between the Sicilian lemma and a resembling Italian word, which is then selected as the output. For example, *mbròcculi* is rendered as *broccoli*, although its actual meaning is *moina* (flattery), and *pisuliddu* is rendered as *pisellino* (little pea), whereas the intended sense is *permaloso* (touchy).

## 5.2. Evaluating Bilingual Lexicon Induction

A second experiment used the bilingual glossary to build cross-lingual word embeddings and to evaluate the resulting mapped vectors on the Bilingual Lexicon Induction (BLI) task. Irvine and Callison-Burch [20] define BLI as "the task of inducing word translations from monolingual corpora in two languages." Although recent work has introduced solutions based on LLMs [21] [22], one of the most widely adopted methods is still to align embeddings trained separately on monolingual corpora into a shared vector space. We therefore applied vecmap[14] [23] in its supervised mode to map Sicilian and Italian fastText embeddings.[15] The glossary was partitioned into training and test sets using a 90:10 ratio after removing homographs and Sicilian lemmas whose Italian equivalents were multi-token expressions, yielding 9,698 Sicilian–Italian pairs for training and 1,079 pairs for testing. Evaluation employed the nearest-neighbor retrieval method (with k=10) and resulted in an accuracy of 19.8% (coverage=50.6%). By using the Cross-domain Similarity Local Scaling (CSLS) retrieval, a cosine-similarity variant that attenuates the hubness problem, namely the tendency of a small subset of vectors to appear disproportionately often as nearest neighbors of other points [24], the result is even lower, i.e., 14.68%. These low scores suggest that, although more than 9.6 K seed pairs are non-trivial for a low-resource variety such as Sicilian, there are many out-of-vocabulary words.

# 6. Conclusions

This work represents a step toward the integration of the Sicilian dialect into the ecosystem of Linguistic Linked Open Data [25]. By modeling and publishing a bilingual Sicilian–Italian glossary extracted from Wikizziunariu, and by aligning it with the LiITA LB through established ontologies such as OntoLex-Lemon and LiLa, we provide a reusable, interoperable lexical resource that promotes the visibility and accessibility of Sicilian in digital environments. The two preliminary NLP experiments, evaluating LLMs' translation capabilities and testing BLI, highlight both the potential and the current limitations of applying computational methods to under-resourced varieties.

[13] http://www.salviamoilsiciliano.com
[14] https://github.com/artetxem/vecmap
[15] https://fasttext.cc/docs/en/crawl-vectors.html

Future work will proceed along multiple directions. First, we plan to model and integrate additional Sicilian resources, with particular attention to Antonino Traina's *Nuovo vocabolario siciliano–italiano*, which is already available in digital format. Second, we aim to broaden the scope of the LiITA KB by incorporating resources from other dialects. An expanded multilingual dataset will enhance interoperability and enable richer cross-lingual analyses. Third, we intend to link textual resources to the LB. However, this will require reliable lemmatization procedures, a non-trivial task for dialects with non-standardized orthographies and scarce annotated corpora. Finally, we plan to extend the range and depth of NLP experiments to evaluate downstream tasks with the goal of advancing computational support for Italy's linguistic diversity.

# Curated Data does not mean Representative Data when training Large Language Models: an Experiment using Representative Data for Italian

Fabio Tamburini[1],*

[1]FICLIT - University of Bologna, via Zamboni, 32, 40126, Bologna, Italy

**Abstract**

It is widely accepted in literature that data curation is the first step for a successful pretraining of Large, and Small, Language Models (LLMs). Datasets generally fall into two categories: open datasets are publicly available, fostering transparency, reproducibility, and community-driven improvement, but they often face limitations in scale, diversity, and quality. Closed datasets, typically curated by private entities, can offer greater scale, higher quality, and proprietary data sources, yet they raise concerns around transparency, bias auditing, and public accountability.

This paper presents an experiment aimed at quantitatively measuring the improvements provided by representative datasets for LLM pretraining. We pretrained two small LLMs under the same experimental conditions as the corresponding Italian reference models from the Minerva family, evaluated their performance on standard benchmarks, and used LLM-as-a-Judge to assess the Fluency, Coherence, and Relevance of generated texts on specific tasks. The results support the idea that, while open science and open datasets are important goals, representative corpora, even if closed, are more suitable for LLM pretraining, as they enable better performance under identical experimental conditions.

**Keywords**

LLM pretraining, representative corpora, text generation evaluation, LLM-as-a-judge

## 1. Introduction

Large language models (LLMs) have emerged as foundational tools in Natural Language Processing (NLP), powering a wide array of applications from question answering and summarisation to code generation and scientific discovery. Their performance, generalisation ability, and alignment with human values are deeply influenced by the quality, diversity, and scale of the data used during pretraining [1, 2]. As models grow larger and more capable, the need for rigorous data curation practices becomes increasingly critical not only to enhance downstream performance but also to mitigate harmful biases, hallucinations, and environmental costs [3, 4].

Data curation for LLMs involves the collection, filtering, deduplication, classification, and documentation of large-scale textual corpora. These processes aim to balance scale with quality by removing low-signal, harmful, or irrelevant content while preserving linguistic diversity and domain coverage [5, 6]. More recent efforts have highlighted that indiscriminate use of web-scale data may result in the propagation of social biases and misinformation [7], emphasising the importance of carefully designed curation pipelines that consider ethical and societal dimensions [8].

While early work relied heavily on broad, minimally filtered internet scrapes (e.g., Common Crawl), more recent approaches have shifted toward structured, transparent, and task-specific datasets, often constructed through a combination of automated and manual filtering techniques [9]. These developments reflect a growing recognition that model capabilities and behaviours are closely tied to the provenance and properties of their training data. However, the field still lacks standardised methodologies and benchmarks for evaluating curated datasets, presenting challenges for reproducibility and comparative analysis.

### 1.1. Open vs. Closed Pretraining Datasets

The growing ecosystem of LLMs has revealed a sharp divide between open and closed approaches to data curation. On one hand, open-source initiatives such as BLOOM [10], OPT [2], Pythia [11] and Minerva [12] have committed to full transparency by using publicly available datasets and releasing detailed documentation of their training corpora. These efforts aim to promote reproducibility, community-driven auditing, and equitable access to foundation models. On the other hand, leading commercial models such as GPT-4, Claude and Gemini rely on proprietary or undisclosed datasets, raising questions about accountability, data provenance, and research reproducibility.

The open-data approach is grounded in scientific ideals of transparency and collaborative validation. Models like

0000-0001-7950-0347 (F. Tamburini)

BLOOM, trained exclusively on open-access sources including multilingual Common Crawl, Project Gutenberg, and academic corpora, exemplify an effort to democratise LLM research and foster global participation [10]. The open release of datasets enables systematic study of data quality, bias, duplication, and domain representation, and it supports downstream development of safer and more equitable AI systems.

In contrast, closed models often cite competitive, ethical, or legal reasons for withholding training data details. OpenAI's GPT-4 report, for example, states that "given the competitive landscape and the safety implications of large-scale models," they have opted not to disclose training data sources. While this protects proprietary advantages and potentially prevents misuse of harmful content, it also hinders external audits of data quality, bias, and copyright compliance. Without transparency, it becomes difficult to evaluate how model performance or behaviour may be influenced by specific sources or omissions.

This divergence has implications for the broader AI research community. The lack of visibility into proprietary datasets exacerbates the reproducibility crisis in machine learning and limits efforts to assess environmental and social impacts of training practices. Conversely, open models, while more transparent, often contend with limitations in data scope and quality due to the exclusion of copyrighted or paywalled content, potentially affecting their competitiveness in knowledge-rich domains.

Ultimately, the tension between open and closed data paradigms reflects competing priorities in the development of foundation models: openness and accountability versus competitive advantage and scalability.

## 1.2. Key Open Datasets for LLM Pretraining

A number of high-quality, publicly available datasets have become foundational to the training of open-source large language models. These datasets vary in terms of domain coverage, linguistic diversity, and preprocessing strategies, but collectively represent the backbone of transparent and reproducible LLM development.

The Pile [5], a curated 825 GB dataset designed for training language models, combines diverse sources such as academic articles (arXiv), code (GitHub), books, legal documents, and forums to maximise domain coverage. C4 (Colossal Clean Crawled Corpus) [4] is a large-scale, filtered dataset derived from Common Crawl. It removes boilerplate, duplicates, and low-quality text to provide a clean, general-purpose corpus for language modeling. RedPajama [13] presents a reproducible, open alternative to the Llama pretraining dataset. It aggregates content from Common Crawl, Wikipedia, ArXiv, StackExchange, and more, with a focus on transparency and reproducibility. RefinedWeb [14] features a deduplicated and quality-filtered web dataset used to train models such as Falcon. It emphasises a scalable yet high-signal alternative to raw web scrapes. CulturaX [15] is large-scale multilingual web dataset covering 167 languages, designed to improve the cultural and linguistic diversity of LLMs. CulturaX emphasises inclusion of underrepresented languages by sourcing and curating high-quality content from Wikipedia, government websites, and news sources. Books3 (from The Pile) is large collection of digitised books, providing long-form narrative and expository text. Despite its utility, its inclusion has sparked debate due to copyright concerns, underscoring the need for clearer data usage norms.

These datasets are frequently combined or customised depending on the training goals, whether for general-purpose models, multilingual capability, or domain-specific LLMs. CulturaX, in particular, represents a growing movement toward linguistic equity and cultural inclusivity in large-scale model pretraining.

The effort to create open datasets for LLM pretraining that cover a wide range of data inevitably encounters a major challenge: whether or not to include text types that are not freely available on the web. In our view, this is a critical issue when comparing LLMs trained on open data with their counterparts developed by large tech companies using closed datasets, which undoubtedly include a richer and more representative variety of document types for the language or languages being studied. The central concept here is representativeness, which Egbert et al. [16] define as "the extent to which a corpus permits accurate generalisations about the target domain, which involves two components: the extent to which the corpus includes the full range of both text types and linguistic distributions in a domain". In essence, a representative corpus should serve as a statistically valid sample of the population of texts corresponding to the language variety under investigation.

Another point regards the quality of texts published on the Web when compared with curated and edited texts issued by professional publishers. Web texts and published texts differ significantly in form, purpose, authorship, and audience engagement. Web texts, such as blog posts, social media updates, and news articles, tend to be dynamic, hyperlinked, and frequently updated. They emphasise immediacy, brevity, and interactivity, often written in an informal tone to encourage user engagement [17]. In contrast, published texts like academic articles, books, and journals are typically static, peer-reviewed, and follow rigorous editorial standards. These texts prioritise depth, permanence, and formal structure. Additionally, while published texts aim for scholarly credibility and longevity, Web texts often prioritise accessibility, shareability, and multimedia integration. Understanding these distinctions is critical for analysing digital literacy and communication strategies in the information age and, in our opinion, is also critical for pretraining LLM providing "good" and "reliable" texts for teaching a language to a LLM.

This paper aims at exploring and quantify the differences in training a LLM either with open Web data or on a representative corpus examining if the two settings produce some differences in LLM performance, taking contemporary Italian as the reference language.

## 2. A Representative Dataset

Given the objective of this study, we introduce the reference corpus for contemporary Italian which we use as a template for building the representative corpus employed in our experiments.

### 2.1. The CORIS Italian Corpus

CORIS design was started in 1998 with the purpose of creating a representative, synchronic, general reference corpus of written contemporary Italian which would be easily accessible and user-friendly [18, 19]. CORIS currently contains 165 million words and has been updated every three years by means of a monitor corpus [20]. It consists of a collection of authentic and commonly occurring texts in electronic format chosen by virtue of their representativeness of contemporary Italian.

After a long design process devoted to a careful definition of relevant textual macro-varieties and their proportions, CORIS has been structured as outlined in Table 1: the largest section, namely 'Press', contains newspapers and periodicals articles, 'Fiction' a collection of novels and short stories while scientific texts and legal/bureaucratic documents where included, respectively, in 'Academic Prose' and 'L&A Prose'. The last two sections contain respectively documents not belonging to the previous categories and texts belonging to Internet language (mainly posts from high quality blogs).

| CORIS Section | Proportion |
|---|---|
| Press | 38% |
| Fiction | 25% |
| Academic Prose | 12% |
| Legal & Admin. Prose | 10% |
| Miscellanea | 10% |
| Ephemera | 5% |

**Table 1**
CORIS Sections and their proportions.

Based on the general CORIS schema outlined in Table 1, we created an 11.6 billion-token corpus that includes the same textual macro-varieties and maintains the same CORIS balancing. This corpus was constructed by selecting materials from the previously mentioned CulturaX project and incorporating large sections of specific published texts. This extensive, curated, and representative training corpus was then used to train our new "CORIS-llm" language model, following the procedure described in the next section.

## 3. Experiment Settings

### 3.1. LLM pretraining

Minerva is the first family of LLMs pretrained from scratch on Italian [12] and emerged as a standard reference for Italian NLP. A prior study pretrained an Italian model based on GPT-2 from scratch [21], but it used a relatively small 117M-parameter set, making it not directly comparable to modern LLMs or the more recent Minerva family.

In order to perform a fair comparison with the Minerva models, we adopted exactly the same pretraining settings and hyperparameters described in [12]. We pretrained the models using the MosaicML LLM-Foundry[1] package concentrating our efforts on two models: a 350M-parameter model trained on a single node equipped with four A100-64GB GPUs for an equivalent number of steps as the Minerva-350M model and 1B parameter model trained on 2 nodes in the same way as Minerva-1B[2]. While a 11.6 billion-token corpus is big enough for pretraining a 350M model, it is too small, following the Chinchilla rule [22] involving a parameter/token ratio of 1:20, for a 1B model, thus, in this second case, we could expect some performance degradation.

A detailed quality analysis of the Minerva dataset is contained in the original paper [12].

### 3.2. First Evaluation on Standard Benchmarks

The evaluation of LLMs has traditionally relied on a suite of standardised benchmarks designed to assess a broad range of linguistic, reasoning, and task-specific capabilities. These benchmarks enable systematic comparison across models and facilitate progress tracking in natural language processing.

To address the need for evaluating generation-based tasks, LAMBADA [23] tests a model's ability to predict the final word of a passage based on broad context, emphasising long-range dependency modelling. In parallel, benchmarks such as WinoGrande [24] and HellaSwag [25] target common-sense reasoning and disambigua-

tion, probing a model's depth of understanding beyond surface-level patterns.

More recently, MMLU (Massive Multitask Language Understanding) has been introduced as a collaborative effort to assess a wide range of LLM competencies ranging from law and medicine to physics and philosophy offering a broad-spectrum evaluation across 57 subjects to test a model's ability to generalise across domains [26].

While existing evaluation benchmarks are highly valuable, they are primarily designed to assess LLM performance in English and are therefore not suitable for our purposes. Recently, a group of Italian researchers introduced a promising new benchmark, called ITA-Bench, for evaluating LLMs in Italian. This suite combines automatically translated versions of popular English benchmarks with adapted, manually curated datasets for Italian [27]. We adopted ITA-Bench for the initial evaluation of our new LLMs and conducted a preliminary comparison with an equivalent Minerva model.

Table 2 presents the results of CORISllm-350M and CORISllm-1B on ITA-Bench, alongside a comparison with the corresponding Minerva models. Overall, the two LLMs demonstrate comparable performance: Minerva performs better on certain tasks, while CORISllm slightly outperforms it on others.

On average, the Minerva models show slightly better performance; however, these results must be interpreted in light of the nature of the benchmark. ITA-Bench focuses primarily on tasks involving commonsense reasoning and scientific knowledge retrieval, which are not well-suited for assessing differences in text generation capabilities. Pretraining an LLM on a representative corpus does not inherently confer an advantage in reasoning or STEM-related tasks because the dataset used for pretraining does not contain specific materials useful for increasing performance on STEM-related tasks and no specific methods were used to promote the development of reasoning abilities. Accordingly, CORISllm and Minerva perform similarly on ITA-Bench. To properly evaluate our research hypothesis, a more targeted assessment of text generation abilities is required.

## 3.3. Text Generation Quality Evaluation

Evaluating LLM-generated texts is inherently challenging, and assessing the quality of these textual outputs is even more complex [28].

Our primary objective is to conduct a careful evaluation of the quality of texts generated by LLMs. Specifically, we aim to compare an LLM trained on "open" but non-representative datasets, namely the Minerva family, with one trained on a representative and balanced dataset, CORISllm. The comparison focuses on commonly used human evaluation metrics: *Fluency*, internal *Coherence* and text *Relevance* to the given task.

To ensure a fair evaluation, it is necessary to generate and assess a substantial number of texts. For this purpose, we adopted the LLM-as-a-Judge (LaaJ) approach, after a comparison of LLMs annotations with human judgments.

We designed six distinct prompts, each corresponding to one of the six CORIS macrovarieties: a short newspaper article, a children's fairy tale, an abstract of a scientific paper, a judgment for a crime, a trip description, and a brief movie review, and generated 50 outputs each. Table 3 presents the prompts used to stimulate the LLMs to generate texts.

The following sections first describe the human evaluation process, followed by the LaaJ methodology we employed to achieve our objective.

### 3.3.1. Human Evaluation of LLM Outputs

Human evaluation remains the gold standard for assessing the quality of natural language outputs produced by LLMs. Despite the growing sophistication of automated metrics and model-based evaluators, human judgments are uniquely capable of capturing nuanced dimensions of quality such as contextual appropriateness, subtle coherence errors, pragmatic relevance, and factual accuracy. Consequently, human assessments are widely used in both benchmarking LLMs and validating automatic evaluation methods.

Human evaluation of LLM outputs is typically carried out using either rating scales (e.g., Likert scales), pairwise comparisons, or ranking protocols. Each approach has strengths and limitations: scalar ratings allow fine-grained feedback but may suffer from rater calibration issues, while relative comparisons often yield more consistent judgments.

In the context of LLM outputs, common evaluation criteria include fluency, coherence, relevance, factual accuracy, and harmlessness or bias. For instance, the HELM benchmark [29] employs extensive human annotation pipelines to assess these aspects. Fluency is often reliably judged, but tasks like evaluating factual consistency or detecting hallucinations present greater challenges. Human annotators are also crucial for detecting subtle harms, such as stereotyping or toxicity, which automated tools frequently miss or misclassify [3].

Despite its value, human evaluation has notable limitations. It is expensive, time-consuming, and subject to inter-rater variability, which can obscure subtle differences between systems. Additionally, annotator background and task framing can influence outcomes. For example, work has shown that crowdworker evaluations can differ systematically from domain-expert judgments, particularly on complex tasks like summarisation or question answering [30].

To compare the behaviour of the considered LaaJ systems with human judgments, we conducted a small experiment where three expert linguists manually evaluated 120 texts produced by Minerva-350M in response to the six prompts given in Table 3. The annotators were asked to evaluate the LLM-generated texts according to the three selected metrics: the instructions given to them was almost identical to the prompts in Tables 8, 9 and 10 we used for LaaJ. Table 4 (top-left section) shows the Spearman Rank Correlation Coefficients (SRCC) between the rankings provided by the three human annotators A1-A3, who assigned scores on a 5-point Likert scale. The correlations were relatively low, highlighting the challenges human annotators face in consistently grading text production using similar criteria.

Due to the low correlations observed, particularly in the assessment of Fluency, we decided against using the human annotations to calibrate our LaaJ systems and chose to rely solely on the LaaJ methodology for the evaluations.

| **Text Macro-variety** | **Prompt** |

### 3.3.2. LLMs as Automated Judges of Text Quality

Recent advances LLMs have opened new avenues for evaluating textual outputs in NLP. Traditionally, the evaluation of text generation has relied heavily on human judgments, which, while high in fidelity, are costly, time-consuming, and often inconsistent due to inter-annotator variability [31]. In contrast, LLMs such as GPT-3/4, Palm and Gemini have demonstrated potential not only in generating text but also in providing reliable meta-judgments about language quality, including fluency, coherence, and relevance.

Several studies have investigated the reliability of LLMs as automatic evaluators. For instance, G-Eval [32] highlights that LLMs can approximate human judgments in multi-dimensional evaluation tasks when properly prompted. As shown in the nice review by Li et al. [33], it is possible to set up a framework where an LLM acts as a zero-shot or few-shot judge, providing ordinal or scalar ratings that correlate highly with human annotations. This correlation is particularly strong when the models are instructed explicitly to focus on specific dimensions of quality, such as grammatical fluency or semantic relevance.

In terms of **Fluency**, LLMs have internalised extensive grammatical structures through pretraining on large corpora, enabling them to effectively recognise and assess grammaticality and naturalness. For **Coherence**, models evaluate the logical consistency and flow of ideas across sentences or turns, especially when equipped with context windows that span multiple paragraphs. Evaluating **Relevance**, the alignment of a response to a prompt or topic, has also been shown to benefit from LLMs' contextual awareness and knowledge grounding.

In summary, LLMs have emerged as credible tools for evaluating textual quality across multiple dimensions: when applied with careful prompt design and interpretative caution, they can serve as scalable, cost-effective complements to human assessment.

In order to avoid any inconsistency introduced by human judgments, we decided to rely only on two different LLMs for evaluating the quality of texts produced by CORISllm and Minerva models.

We adopted a powerful online LLM, namely *Gemini-2.0-flash* through Google APIs, and an offline, quantised model, namely *bartowski/Llama-3.3-70B-Instruct-Q6_K_L* downloaded from the Huggingface repository[3].

Tables 8, 9 and 10 show the three prompts we have designed for asking the two LaaJ to evaluate, using a 5-point Likert scale, *Fluency*, *Coherence* and *Relevance* of the texts generated by CORISllm-350M/1B and Minerva-350M/1B. For designing these prompt we took inspiration from similar prompts proposed in G-Eval [32]. The separators '##SYSTEM##', '##USER##' and '##ASSISTANT##' for marking the three different blocks of information in the prompts were replaced with empty lines for Gemini prompts and with the appropriate separators for prompts proposed to the Llama judge.

To assess the reliability of their judgments, we first evaluated the agreement between the two LaaJ systems and the human annotators. Table 4 also reports the SRCC between each LaaJ and the human annotators. While the two LaaJ systems show high mutual correlation, their agreement with individual human annotators is lower, though still comparable to the level of agreement observed between human annotators themselves. This further supports the case for favoring LaaJ-generated annotations over those produced by humans.

Table 5 shows the (SRCCs) between Gemini-2.0-flash and the quantised Llama-3.3-70B judges when evaluating 600 new texts produced by CORISllm and Minerva models (300 for each model). Correlations are all quite high and highly significant, thus we can reliably use these automatic judges for evaluating the textual production of the tested models.

| Model | SRCC | p-value |

**Table 5**
SRCCs between the LLM judges Gemini-2.0-flash and quantised LLama-3.3-70B when evaluating the 600 texts produced by CORISllm and Minerva (300 for each model).

## 4. Results

Tables 6 and 7 present the means and standard deviations of the scores assigned by the two judges across the three evaluation metrics to the 600 texts forming the evaluation dataset. The tables also display the results of a t-test for independent samples, which assesses the statistical significance of the differences in means.

Examining the evaluations provided by Gemini, we observe a notable increase in the scores assigned to CORISllm-350M compared to the equivalent Minerva-350M model. Furthermore, the scores for it are so high that they are comparable, and not significantly different, to those of the larger Minerva-1B model, with the exception of the Relevance metric. With regard to CORISllm-1B, it performs much better than Minerva-350M, as expected, and more or less on par with Minerva-1B, exhibiting better performance on Fluency and worse on Relevance. All differences that are statistically significant are indicated by the asterisks next to the metric.

Regarding the Llama-3.3-70B judge, CORISllm-350M consistently receives significantly higher scores than the equivalent Minerva-350M model, and its scores are comparable to those of the Minerva-1B model across all metrics. Using this judge, CORISllm-1B performs much better than both Minerva models in a highly significant way,

except for the Relevance metric when compared with Minerva-1B for which there seems to be no significant differences.

## 5. Discussion & Conclusions

In this study, we examined how the choice of data for LLM pretraining affects performance, emphasizing the importance of using a representative corpus to enhance the quality of text produced by generative LLMs.

Using the design framework of the CORIS corpus, a representative corpus of contemporary Italian, we pretrained two LLMs following exactly the same process used for the Minerva models [12]. However, instead of the original dataset, we used a new 11.6 billion-token representative corpus specifically structured to align with the CORIS macrovarieties.

##SYSTEM##
Tu sei un linguista esperto nella valutazione dei testi. Ti verrà fornita la descrizione di un esercizio e lo svolgimento di questo esercizio da parte di un'AI.
Il tuo compito è valutare lo svolgimento in base a una metrica. Assicurati di leggere e comprendere attentamente queste istruzioni. Tieni aperto questo documento durante la revisione e consultalo quando necessario.
Criteri di valutazione:
Coerenza (1-5): la qualità globale di tutte le frasi. Il testo dovrebbe essere ben strutturato e ben organizzato. Il testo non dovrebbe contenere solo un mucchio di informazioni correlate, ma dovrebbe svilupparsi da una frase a un corpo coerente di informazioni su un argomento.
Fluenza (1-5): la qualità dello svolgimento in termini di grammatica, ortografia, punteggiatura, scelta delle parole e struttura delle frasi.
- 1/2. Scarsa. Lo svolgimento presenta molti errori che lo rendono difficile da comprendere o lo rendono poco naturale.
- 3. Lo svolgimento presenta alcuni errori che compromettono la chiarezza o la scorrevolezza del testo, ma i punti principali sono comunque comprensibili. - 4. Buona. Lo svolgimento presenta pochi errori ed è facile da leggere e seguire. - 5. Ottima. Lo svolgimento non contiene errori ed è facile da leggere e seguire.
Fasi di valutazione:
1. Leggi attentamente lo svolgimento e identifica gli errori grammaticali, ortografici e sintattici. 2. Assegna un punteggio per la fluenza su una scala da 1 a 5, dove 1 è il punteggio più basso e 5 il punteggio più alto in base ai Criteri di valutazione.

When evaluating the textual production of equivalent models across Fluency, internal Coherence, and Relevance to the assigned task, CORISllm outperformed Minerva. Due to the limited dimensions of the training corpus, suitable to pretrain 350M models and less 1B models, the results are more neat on smaller models. In any case, this points in the direction that using representative and balanced corpora for LLM pretraining has an impact on performance. In our experiments, CORISllm-350M, despite having only one-third of the model parameters, performed nearly on par with Minerva-1B in terms of generative text quality.

The goal of this work was not to create a complete family of LLMs pretrained on representative corpora and ready for production deployment. Rather, we aimed to provide a proof-of-concept study that emphasises the need for greater attention to training corpora in order to develop better models.

While the openness of training data is certainly a valuable principle, the results presented here suggest that it is equally important to incorporate high-quality published texts into the training process in order to enhance performance without altering the transformer model. Since such materials are often protected by copyright, it is essential to establish specific agreements with publishers.

Due to copyright restrictions on portions of our pretraining corpus, we are unable to distribute it freely. CORISllm models are available upon request.

# BABILong-ITA: a new benchmark for testing Large Language Models effective context length and a Context Extension Method

Fabio Tamburini[1,*]

[1]FICLIT - University of Bologna, via Zamboni, 32, 40126, Bologna, Italy

**Abstract**

This paper introduces a new benchmark designed to evaluate the effective context length handled by Large Language Models (LLMs) in Italian. Following the structure of the five core tasks from the English BABILong dataset, we created an equivalent benchmark tailored for Italian. We used it to assess the context management capabilities of several prominent LLMs, both small and large, pretrained from scratch or fine-tuned specifically for Italian. Additionally, we tested a context extension technique called "SelfExtend" that does not require any training or fine-tuning phase, measuring its effectiveness using our proposed benchmark.

**Keywords**

Large Language Models, context length evaluation, new benchmark, Italian, context extension

## 1. Introduction

As the capabilities of Large Language Models (LLMs) continue to advance, one of the most critical areas of improvement lies in their ability to process and retain information over extended sequences of text, a feature commonly referred to as context length. Traditional benchmarks for evaluating LLMs focus on accuracy, reasoning, and generation quality, but often overlook systematic assessment of how well a model can operate when presented with extremely long input sequences.

LLMs long context is crucial for Retrieval-Augmented Generation (RAG) because it allows the model to process and reason over more retrieved information at once. In RAG systems, external documents or chunks of text are retrieved based on a query and then passed to the LLM to generate accurate and contextually relevant answers. A longer context window means the model can consider more documents or larger portions of documents simultaneously, reducing the need to truncate or summarise input data. This leads to better comprehension, improved factual accuracy, and more coherent responses, especially for complex or multi-part queries.

Evaluating the context length capabilities of LLMs is crucial for understanding their practical utility in real-world applications requiring long-range reasoning, document understanding, and multi-turn conversations. Over the past years, several standardised benchmarks have been developed to assess and compare the performance of LLMs across varying context lengths.

A widely cited benchmark framework is the Kamradt's 'Needle-in-a-Haystack'[1] which probes a model's ability to retrieve a small piece of relevant information embedded in a long, distractor-filled sequence. This test is considered a litmus test for whether models truly attend to long-range dependencies rather than relying on heuristics or recency biases.

Another critical benchmark is 'Passage Retrieval and Question Answering' over long contexts, exemplified by datasets such as 'NarrativeQA' [1] and 'HotpotQA' [2]. These datasets require models to maintain coherence and extract pertinent information across several paragraphs or documents. The 'BookSum' benchmark [3] further extends this approach by evaluating abstractive summarisation over entire books, posing an extreme challenge to context handling.

To assess performance on computationally efficient long-context processing, the 'Long Range Arena' provides a suite of tasks including image classification, text retrieval, and list sorting, adapted to sequence modelling tasks with sequences ranging from 1k to 16k tokens [4]. While not all tasks are purely devoted to natural language processing, they benchmark architectural innovations like sparse attention and memory-efficient transformers.

'LongBench' [5] provides comprehensive testbeds across domains covering key long-text application areas including single-doc QA, multi-doc QA, summarisation, few-shot learning, synthetic tasks, and code completion in both English and Chinese, evaluating both performance scaling and fidelity to far-positioned inputs.

An et al. [6] present a new evaluation suite 'L-Eval'

containing 20 sub-tasks, 508 long documents, and more than 2,000 human-labelled query-response pairs including diverse task types, domains, and input lengths.

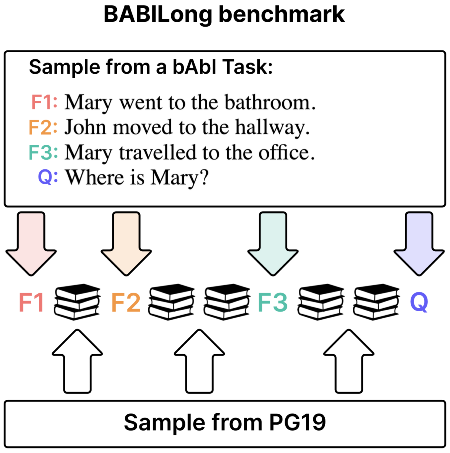
Taken together, these benchmarks form a multi-faceted suite of tools that not only test LLMs for maximum supported context length but also probe their effective use of context. As models scale to handle millions of tokens, developing robust and generalisable long-context benchmarks remains an active area of research, especially for languages different from English.

Regarding the techniques for increasing context 'awareness' in transformers, recent works have introduced scaling techniques specifically targeting context length extrapolation. For example, Press et al. [7] proposed the in-Context Learning Extrapolation to test model performance when context lengths at inference time far exceed those seen during training. Considering this, we could refer to a recent interesting survey on techniques for extending transformers context by Wang et al. [8].

Another English benchmark, relevant to this work, is 'BABILong' [9], a benchmark specifically designed to evaluate the maximum usable context length of large language models. BABILong provides a controlled and extensible framework for measuring how effectively LLMs can retrieve and use information embedded at various positions within long input contexts. The benchmark simulates real-world scenarios where crucial information may appear early in a document and must be recalled accurately much later, such as in code completion, document summarisation, and legal or scientific reasoning tasks. Each BABILong instance presents the model with a structured sequence containing query-relevant and distractor content spread over thousands to potentially millions of tokens. The model is then tasked with answering queries or completing sequences that require precise recollection of target information, making it possible to assess the degradation of performance as a function of input length.

Unlike traditional evaluations, BABILong systematically varies the distance between the query and its corresponding reference information, enabling granular analysis of context window utilisation and scaling properties across different architectures. The benchmark supports plug-and-play integration with both decoder-only and encoder-decoder models, and it is agnostic to pretraining data, making it suitable for comparative studies across proprietary and open-source models.

In summary, BABILong provides a scalable, interpretable, and model-agnostic benchmark for long-context reasoning and memory fidelity and it is a very useful tool for researchers and practitioners seeking to push the boundaries of efficient long-sequence modelling in large-scale language systems. Moreover, it can be easily extended to other languages: the goal of this work regards the extension of BABILong to Italian, allowing for a careful testing and benchmarking of LLMs that natively handle the Italian language.



BABILong benchmark
Sample from a bAbI Task:
F1: Mary went to the bathroom.
F2: John moved to the hallway.
F3: Mary travelled to the office.
Q: Where is Mary?
F1
F2
F3
Q
Sample from PG19

**Figure 1:** BABILong schema for generating tasks: task facts are hidden into distractor text fragments extracted from PG19 (picture from [9]).

## 2. A new benchmark for Italian

BABILong extends the bAbI benchmark [10], which consists of 20 tasks designed to evaluate basic aspects of reasoning. These tasks are generated by simulating interactions among characters and objects across various locations, each represented as a fact, such as "Mary traveled to the office." The challenge is to answer questions based on the facts generated in the current simulation, such as "Where is Mary?" The tasks in bAbI vary in the number of facts, question complexity, and the reasoning skills they assess, including spatial and temporal reasoning, deduction, and coreference resolution.

Solving tasks that require long-context processing demands that a model effectively identify and attend to relevant information embedded within extensive irrelevant content. To emulate this scenario, they embed the core task sentences within passages of distractor text sampled from a closely related distribution (see Figure 1). Each example is constructed by progressively appending sentences from the background corpus, preserving their natural order, until the desired total length is achieved. This approach decouples the evaluation context length from the intrinsic length of the original task, thereby enabling the assessment of models capable of handling inputs extending to millions of tokens. As background material, they used books from the PG19 dataset [11], chosen for their substantial length and naturally occurring long-form narrative structure.

We reproduced the same process proposed in BABI-

Long by, first, translating English sentences belonging to BABILong tasks leveraging Google Translate and then using the Project Gutemberg[2] (PG) Italian free texts as base corpus for extracting distractor fragments.

Given that all the major evaluations in the BABILong paper [9] were performed considering only the first five tasks, namely QA1-QA5, we decided to translate and post-process only these five tasks and insert them into BABILong-ITA.

In order to build a reliable and effective Italian benchmark we had to manually revise and adapt automatic translations ensuring a good adherence to common Italian language adjusting translation artifacts or wrong translations. In particular, we had to manage these phenomena:

- **Proper Names translation**: Google Translate did not translate English proper names of people involved in the task, thus we have to replace them consistently with common Italian proper names, e.g. 'John'->'*Giovanni*', 'Mary'->'*Maria*', etc.

- **Object/Place Simplification**: the automatic translation tended, in some cases, to translate single English words into Italian multi-word expressions artificially increasing tasks difficulty. We simplify objects/places translations like 'bedroom'->'*camera da letto*'->'*camera*' and 'football'->'*pallone da calcio*'->'*pallone*', etc.

- **Verb Tenses**: for expressing past events English consistently use the past tense while in Italian, even if the equivalent past tense '*passato remoto*' is grammatically correct, is much more common using the '*passato prossimo*'. We then adapted the translations replacing all these tenses, e.g. '*andò*'->'*è andato/a*', '*posò*'->'*ha posato*' and '*si spostò*->'*si è spostato/a*' adapting the suffixes to the sentence subject preserving the correct grammatical agreement.

- **Proposition Correction**: sometimes Google Translate generates inappropriate translations from the point of view of the used prepositions; we corrected them, for example '*John si recò al giardino*'->'*Giovanni si è recato in giardino.*' or '*Mary andò nel corridoio*'->'*Maria è andata in corridoio*', ensuring a better adherence to the most common use of them.

- **Translation Mistake Corrections**: sometimes, especially when translating questions with implicit referents, Google Translate rendered incorrect Italian sentences that we have to carefully check and correct also by leveraging regular expressions: for example 'What is the kitchen west of?'->'*Qual è la cucina a ovest?*'->'*La cucina è a ovest di che cosa?*'.

While we could have incorporated a broader range of state/position-changing predicates in the translations, we chose to adhere to the original selections, as the English benchmark did not include such variations.

Table 1 shows one example for each BABILong-ITA task without the insertions of any distractor texts (0k configuration).

## 3. Benchmark evaluation

In order to test the effectiveness of the new proposed benchmark and to grasp some idea about the performance of the most relevant models able to effectively handle the Italian language, we performed a set of experiments involving quite a large set of LLMs.

First of all, we considered the new models presented in 2024 and trained from scratch on Italian: the first by the SapianzaNLP group[3], namely *sapienzanlp/Minerva-7B-base-v1.0* and *sapienzanlp/Minerva-7B-instruct-v1.0*, and, second, the largest model proposed by iGenius/CINECA using the unofficial conversion *sapienzanlp/modello-italia-9b-bf16* for simplicity. We considered also two fine-tuned model from DeepMount00, namely *DeepMount00/Qwen2-1.5B-Ita* and *DeepMount00/Mistral-Ita-7b*, a model from Microsoft, *microsoft/Phi-4-mini-instruct*, one from meta, *meta-llama/Llama-3.1-8B-Instruct* both in its original and quantised form relying on *bartowski/Meta-Llama-3.1-8B-Instruct-Q4_K_S* and, finally, two models from Google, *google/gemma-3-4b-it* and the huge *google/gemini-2.0-flash*. All models were downloaded from the HuggingFace model repository[4] and used on a local server except for *gemini-2.0-flash* that was queried using the Google API.

### 3.1. Experiments setting

In BABILong, the authors consider performance satisfactory if the accuracy of an answer exceeds 85% and a complete failure if it is below 30%. Of course, as the authors said, this definition of "satisfactory performance" is not universal and should be adapted to the specific task at hand.

The comparison with the correct result follows the original BABILong evaluation method: the LLM output is lowercased, and the first valid target it names is considered as the LLM answer and compared with the gold target in order to compute model accuracy.

**Table 1**
BABILong-ITA examples. This table shows the "0k" configuration without distracting text. In the longer context configurations (1k, 2k, 4k...) fragment of texts from PG have been inserted between context sentences as distractors following the original BABILong schema.

## 3.2. Results

Figure 2 presents the average retrieval accuracy across all tasks for each evaluated LLM on the BABILong-ITA benchmark.

LLMs trained from scratch in Italian, specifically Minerva and Modello-Italia, generally show low performance. However, within their maximum supported context length of 4k tokens, their performance remains relatively stable across all tested lengths.

The fine-tuned models from DeepMount00 demonstrate consistently poor retrieval performance. Despite a declared maximum context length of 32k tokens, they struggle significantly even at much shorter lengths. Similar observations apply to Phi-4, which fails to achieve satisfactory results even at just 1/16 of its maximum declared context window.

Google's Gemma3 shows slightly better performance, managing to handle contexts up to approximately 1/8 of its maximum declared length. Conversely, Gemini-2.0-flash, with a nominal maximum context length of 1 million tokens, solves fewer than 50% of the tasks at 128k, an underwhelming result given its scale.

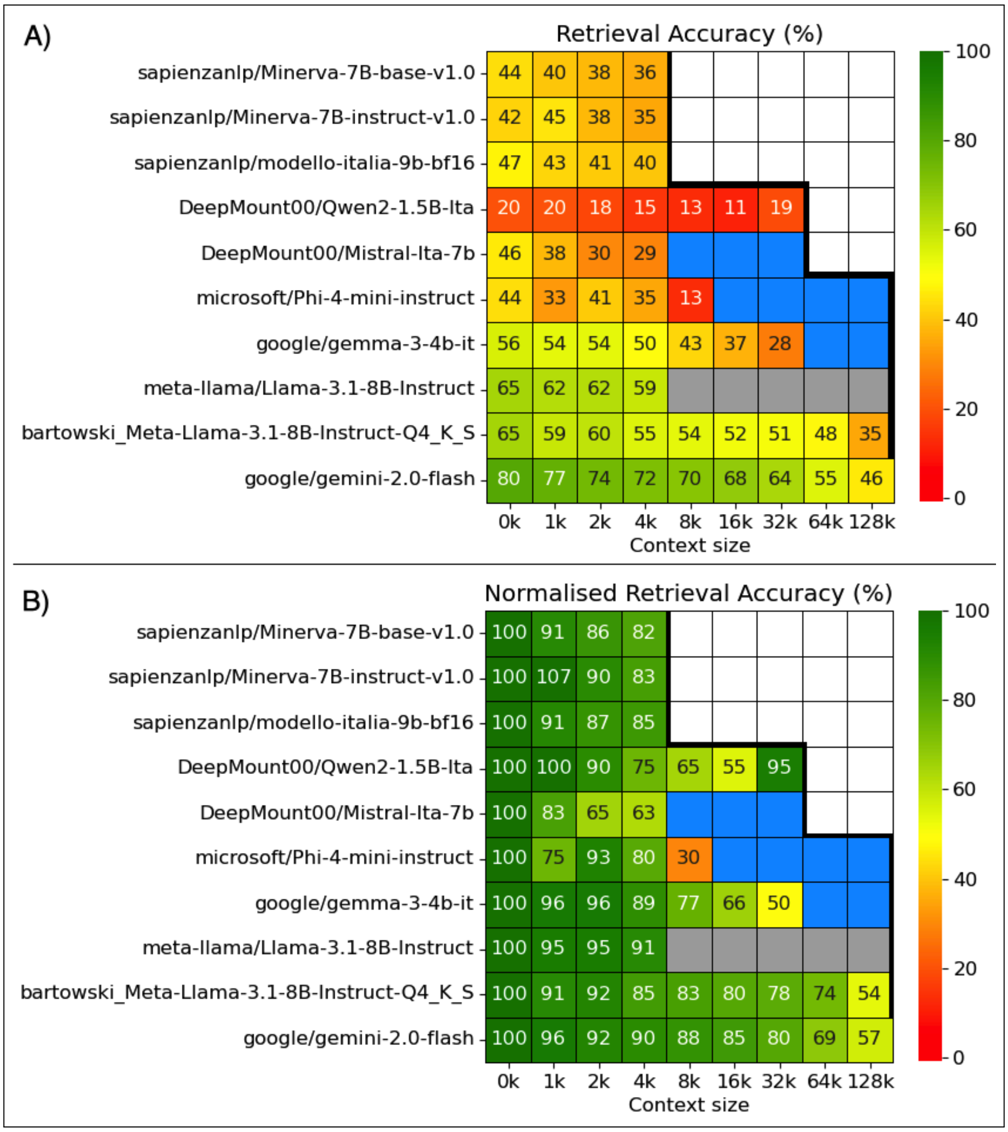

**Figure 2:** BABILong-ITA evaluation results for tested LLMs averaged over the five proposed tasks. The thick black line marks the maximum context length for a given model (for Gemini-2.0-flash the official limit is 1000k tokens). Blue squares indicate cells not computed for computational restriction reasons, but actually not useful for the evaluation because smaller contexts already presented very low retrieval accuracies. On the contrary, gray cells marks combinations that we were not able to calculate that are approximated by the corresponding quantised model. In A) we have original accuracies, while in B) we normalised the accuracy w.r.t. the "0k" case to show the relative reduction of accuracy obtained increasing the test context size.

Among the tested models, LLaMA-3.1-8B stands out as the most effective. Although we completely evaluated only its quantised version, which performs slightly below the full model, it successfully retrieves 35% of the hidden information even at the maximum declared context length. It appears to offer an excellent balance between local deployment feasibility and performance, trailing only slightly behind the much larger Gemini-2 model.

Figure 3 presents the per-task performance of the two best-performing LLMs tested, namely Gemini-2.0-flash and the quantised version of LLaMA-3.1-8B. The QA2 and QA3 tasks are notably more complex than the others, with both models struggling to retrieve the target information in QA3, even within very short contexts.

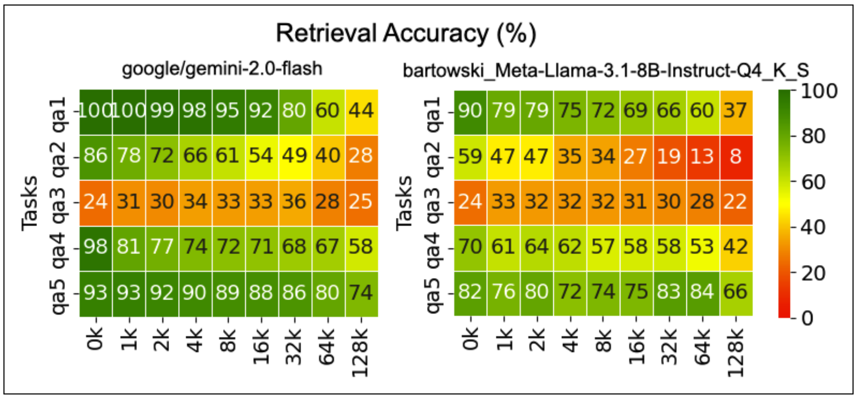

**Figure 3:** Per task BABILong-ITA evaluation results for the best two tested LLMs.

Given these results and the smooth transitions across different context lengths, we can conclude that BABILong-ITA appears to be a reliable benchmark for testing the effective context length of LLMs.

## 4. Extending Large Language Models Context Length

Extending the context length of LLMs is a key research direction aimed at improving their ability to reason over long documents, maintain dialogue coherence, and process extensive sequences of information.

Several approaches have emerged to address the computational and architectural challenges associated with long-context modeling:

- **Sparse Attention and Efficient Transformers**. One class of techniques involves modifying the attention mechanism to reduce its quadratic complexity with respect to sequence length. Models such as *Longformer* [12], *BigBird* [13], and *Reformer* [14] introduce sparse or locality-sensitive hashing attention patterns to enable efficient processing of longer sequences. These methods trade off some global attention capacity for linear or sub-quadratic scaling, allowing context lengths up to tens of thousands of tokens.

- **Memory-Augmented Models**. These models incorporate external memory buffers to persist information across long sequences. *Transformer-XL* [15] uses a segment-level recurrence mechanism, enabling longer context windows by caching hidden states across segments. Similarly, models like *Compressive Transformer* [11] compress and store previous activations to extend memory capacity while maintaining computational tractability.

- **Position Encoding Innovations**. Absolute positional encodings pose a limitation on extrapolation beyond trained sequence lengths. Relative positional encodings, as used in *Transformer-XL* [15] and Rotary Position Embeddings (RoPE) proposed by Su et al. [16] provides better generalisation to longer contexts. More recent methods such as *YaRN* [17] adjust RoPE scaling to maintain performance across significantly extended context lengths.

- **Training and Fine-Tuning on Long Contexts**. Recent advancements show that increasing context length during pretraining can yield substantial improvements. Big models like Claude, Gemini and GPT-4 are examples of models trained or adapted for extended context windows up to 128k tokens or more. Techniques such as long-context fine-tuning, positional interpolation [18], and linear RoPE interpolation [7] have demonstrated effectiveness in scaling pretrained transformers to larger context windows without retraining from scratch.

The paper by Jin et al. [19] introduces a novel method called "*SelfExtend*", which enables LLMs to handle significantly longer contexts without any fine-tuning. This approach addresses the limitations of previous methods that often require extensive fine-tuning or architectural changes.

SelfExtend operates by constructing a bi-level attention mechanism during inference without modifying in any way the model structure or pretrained weights:

- **Neighbour Attention** focuses on dependencies among adjacent tokens within a specified range reducing the standard self-attention window to the closest positions. If $L$ is the context window for the pretrained model, the parameter $w_n < L$

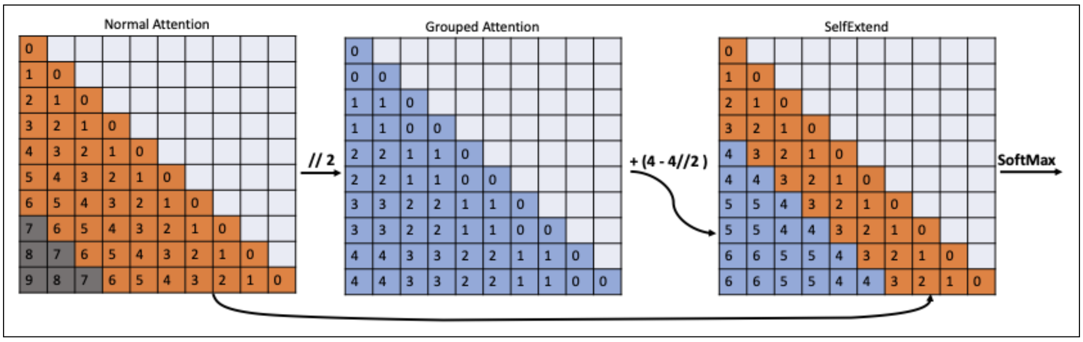

**Figure 4:** This figure shows the construction of the attention score matrix (before softmax) of SelfExtend: the example considers a sequence of length 10 fed into an LLM with the pretraining context window size $L = 7$. Numbers indicate the relative distances between the corresponding query and key tokens. Here $w_n = 4$ and $G_s = 2$. The two kind of attentions are then merged and the softmax operation is applied on the resulting matrix (picture and description taken from [19]).

controls the dimension of the neighbour attention.

- **Grouped Attention** captures dependencies among tokens that are far apart averaging the contributions of the pretrained self-attention between different $G_s$ positions.

The maximum length of the extended context in the ideal case can be computed as

$$(L - w_n) * G_s + w_n \tag{1}$$

thus, for example, if we have $L = 4096$ and choose $w_n = 2048$ and $G_s = 16$, the ideal maximum extended context would be $34k$ tokens.

Figure 4 shows a small example of attention construction by mixing Neighbour and Grouped Attentions.

These two attention levels are computed based on the original model's self-attention mechanism, allowing for the extension of the context window with only minor code modifications and no need for additional training.

The authors argue that LLMs inherently possess the capability to handle long contexts, and the primary challenge lies in the out-of-distribution (O.O.D.) issues related to positional encoding. To mitigate this, SelfExtend maps unseen large relative positions to those observed during pretraining, effectively addressing the positional O.O.D. problem.

Empirical evaluations in Jin et al. [19] demonstrate that SelfExtend substantially improves the long-context understanding ability of LLMs and, in some cases, even outperforms fine-tuning-based methods on tasks such as language modeling, synthetic long-context tasks, and real-world long-context tasks.

This method has been successfully applied to various models, including LLaMA-2, Mistral, SOLAR, and Phi-2, showcasing its versatility and effectiveness in extending context windows without compromising performance.

More details on SelfExtend can be found in the original paper [19].

### 4.1. Using SelfExtend to increase LLMs context length

The baseline model for our experiments is the largest model produced by the SapienzaNLP team: *sapienzanlp/Minerva-7B-base-v1.0* is a Mistral-based model configured with a 4096-tokens fixed context and without sliding window pretrained from scratch on Italian and English [20]. Building on this baseline, we extended its context using *SelfExtend* with varying values of $w_n$ and $G_s$, resulting in several variants referred to as "*LongMinerva*". These extended models were then evaluated on the proposed BABILong-ITA benchmark.

Figure 5 presents the results obtained by applying SelfExtend with seven different combinations of $w_n$ and $G_s$. The method proves to be quite effective, enabling context extension for the original Minerva model maintaining similar performance for contexts ≤4k. Notably, the LongMinerva variants with $w_n = 512$ or $1024$ and $G_s = 16$ achieved satisfactory performance improvements, given the original performance at 0k. Considering that SelfExtend operates without requiring any additional training or fine-tuning, these results seem particularly promising.

## 5. Discussion & Conclusion

This paper introduced a new benchmark for evaluating the effective context length of LLMs in Italian. Based on a similar resource originally developed for English, we translated and manually cleaned the data to construct a reliable and meaningful Italian benchmark.

Our evaluation of several prominent LLMs capable of processing Italian validated the quality of the proposed

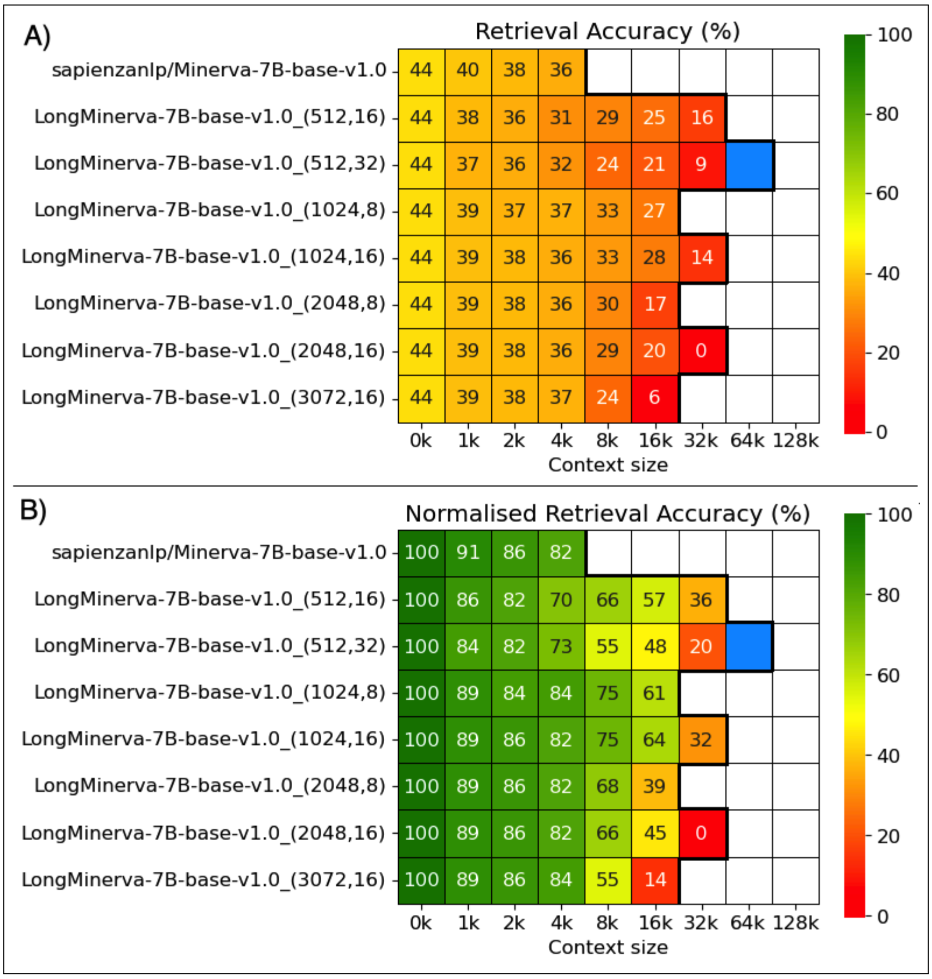

**Figure 5:** BABILong-ITA evaluation results for the experiments on context extension by using SelfExtend on the *sapienzanlp/Minerva-7B-base-v1.0* model, averaged over the five proposed tasks. In round brackets we have $(w_n, G_s)$. The thick black line marks the maximum context length for a given extended context model computed using eq. (1). Blue squares indicate cells not computed for computational restriction reasons, but actually not useful for the evaluation because smaller contexts already presented very low retrieval accuracies. In A) we have original accuracies, while in B) we normalised the accuracy w.r.t. the "0k" case to show the relative reduction of accuracy obtained increasing the test context size.

benchmark and offered a clear picture of the actual context lengths these models can effectively handle.

The conclusions align closely with those reported in the original BABILong study by Kuratov et al. [9]: LLMs tend to struggle with retrieving relevant information at context lengths significantly shorter than their declared maximum capacities.

As an additional contribution, we applied the technique proposed by Jin et al. [19] to extend LLM context length without any training or fine-tuning, achieving promising results also for Italian large language models.

The benchmark data and all the codes for reproducing the experiments are available on Github[5].

## Acknowledgments

I would like to thank the colleague S. Peroni for allowing me to use his GPU system to complete the experiments on extending LLM context length.

## Abstract

We introduce MAIA (Multimodal AI Assessment), a multimodal dataset developed as a core component of a competence-oriented benchmark designed for fine-grained investigation of the reasoning abilities of Visual Language Models (VLMs) on videos. The MAIA benchmark is characterized by several distinctive features. To the best of our knowledge, MAIA is the first Italian-native benchmark addressing video understanding: videos were carefully selected to reflect Italian culture, and the language data (i.e., questions and reference answers) were produced by native-Italian speakers. Second, MAIA explicitly includes twelve reasoning categories that are specifically designed to assess the reasoning abilities of VLMs on videos. Third, we structured the dataset to support two aligned tasks (i.e., a *statement verification* and an *open-ended visual question answering*) built on the same datapoints, this way allowing to assess VLM coherence across task formats. Finally MAIA integrates, by design, state-of-the-art LLMs in the development process of the benchmark, taking advantage of their linguistic and reasoning capabilities both for data augmentation and for assessing and improving the overall quality of the data. In the paper we focus on the design principles and the data collection methodology, highlighting how MAIA provides a significant advancement with respect to other available dataset for VLM benchmarking. Data available at GitHub.

Multimodality, Benchmarking, Vision-Language Models, Multimodal Reasoning, Language Resources

## 1. Introduction

In recent years, mainly following the success of large language models (LLMs), there has been a growing interest for large pre-trained models able to manage both texts and images. Such Vision and Language models (VLMs) have been investigated both from a theoretical perspective (e.g., Baroni [1]) and for their application-oriented interest (e.g., Bigham et al. [2]). Today, there are dozens of available VLMs, and the most popular *families* of generative AI models (e.g., Llama, Gemma, Qwen, GPT) include several VLMs, which can address a number of question answering tasks on both images and videos. As a consequence of the fast and increasing power of VLMs, assessing their performance on standardized tasks and metrics is becoming more and more challenging.

First of all, evaluating VLMs understanding in real world scenarios requires moving beyond single-frame scenarios. Unlike static images, videos offer rich temporal structure: they capture dynamic scenes, evolving actions, interactions, and causal dependencies that unfold over time, making them one of the most faithful and closest approximations to real-world complex scenarios. In this context, the role of evaluation becomes critical: to truly assess a model's ability to understand, reason, and ground meaning across modalities, we need benchmarks that do not merely test task performance, but probe the underlying competences of the model [3].

With this purpose in mind, we introduce MAIA (Multimodal AI Assessment), a multimodal dataset developed as a core component of a broader competence-oriented evaluation framework for VLMs. MAIA is designed to challenge models on multimodal reasoning grounded in real-world scenarios from different linguistic perspectives. To the best of our knowledge, it is the first native Italian evaluation dataset of its kind and based on video content. MAIA provides a linguistically rich and semantically diverse resource for exploring vision and language understanding in realistic contexts, with a particular focus on Italian culture, by covering distinct reasoning categories, each targeting specific semantic phenomena. This

structure allows for a fine-grained analysis of the contribution of both language and visual modalities across different types of reasoning. A key feature of MAIA is its cascading data collection approach, which enables the same source data to be spent and used across multiple task formats (e.g., generative tasks, classification tasks, etc.), supporting fully comparable evaluations and paving the way for an *all-in-one* benchmarking strategy. The efficacy of this approach and of the MAIA benchmark as a severe and robust evaluation framework has been proved in Testa et al. [4] in which we evaluate models against a classification and a generative task, namely visual statement verification and open-ended question answering. While the second task turns out to be more challenging even for the best-performing models, they also exhibit significant inconsistencies both within and across the two tasks, with some categories relying more heavily on either the visual or the linguistic component to solve the task. However, in this paper, we dive into how the dataset was collected. Finally, an additional aspect of innovation in the data creation of MAIA pipeline lies in the integration of human annotation with targeted data augmentation using powerful LLMs (*GPT-4o* [5]), combined with a multi-stage semi-automatic validation process conducted with the same model at different levels. This dual use of a generative model (i.e., *GPT-4o*) not only enhances the diversity and coverage of the dataset but also ensures high-quality and semantically consistent data throughout the pipeline.

The paper is organized as follows. Section 2 reviews the most relevant prior work in the research area. In Section 3, we detail the design choices behind the creation of the dataset and, more broadly, the development of the entire MAIA benchmark. Finally, Sections 4 and 5 describe the specific steps followed for dataset construction: the former focuses on the selection and collection of video material, while the latter addresses the collection and validation of all linguistic data that constitute MAIA. Both sections are complemented by dedicated analyses of the collected data.

## 2. Related Work

Multimodal datasets combining vision and language have played a crucial role in the development and evaluation of VLMs. Early image-based resources such as the *VQA* [6], *GQA* [7], *DVD* [8], and *HL* [9] datasets have provided controlled environments to assess visual reasoning and natural language understanding through several tasks like Image captioning or Visual Question Answering, thereby reinforcing the role of vision as a fundamental component in the evaluation of multimodal models [6]. Over time, contributions of this kind have been instrumental in shaping the foundations of multimodal evaluation, where language understanding is assessed in conjunction with perceptual grounding. Simultaneously, these efforts have revealed critical weaknesses in early multimodal architectures, by highlighting their reliance on dataset biases or shallow heuristics rather than genuine visual reasoning [10, 11]. Such challenges have later been framed within the broader phenomenon of *Unimodal Collapse*, where a VLM disproportionately depends on its language component, resulting in text-only models performing comparably to their multimodal counterparts [12]. In contrast to earlier stages [13, 14, 15], the growing awareness of these issues has prompted the emergence of *diagnostic* evaluation frameworks such as in Parcalabescu et al. [12], Thrush et al. [16], Chen et al. [17], Bianchi et al. [18] and *carefully curated* benchmarks such as in Xiao et al. [19] and Tong et al. [20], designed to expose the true capabilities and limitations of VLMs. These methodological insights strongly motivate the design of MAIA as a robust, controlled multimodal dataset, aimed at ensuring that models genuinely integrate both linguistic and visual information, rather than relying solely on the priors embedded in their language backbones.

Building on this tradition, video-language datasets lately extended the challenge to temporal understanding and dynamic scene interpretation, both essential components for complex real-world understanding. Several resources including *TVQA* [21] and *HowToVQA* [22] datasets or the *AGQA* [23] and *MVBench* [24] benchmarks changed their focus from static perception to actions and entities, by trying to challenge VLMs in identifying the relationships between them. As in the case of image-based evaluation, early surveys have already stressed the need for careful and systematic assessment Zhong et al. [25]. While task-oriented benchmarks often report strong performance [26, 27], more fine-grained evaluations have revealed critical limitations [28], and competence-based analyses continue to highlight the substantial gap in the video understanding capabilities of VLMs [29]. In this context, MAIA contributes as a new video-language dataset aimed at evaluating VLMs not only on videos featuring temporal dynamics and meaningful content but also through a competence-oriented design that explores the interplay between language and vision, a dimension largely neglected in prior Video QA benchmarks.

**Italian Multimodal Datasets.** Most multimodal datasets are available in English, with only limited multilingual or other native-language resources, with Italian being consistently underrepresented. In the image domain, *GQA-it* dataset [30] is a notable attempt to adapt a visual question answering dataset into Italian. More recent benchmarks like XGQA [31] and EXAMS-V [32] include translated Italian multiple-choice questions, but lack original content and do not target high-level reasoning. MAIA fills this gap as the first Italian-native and

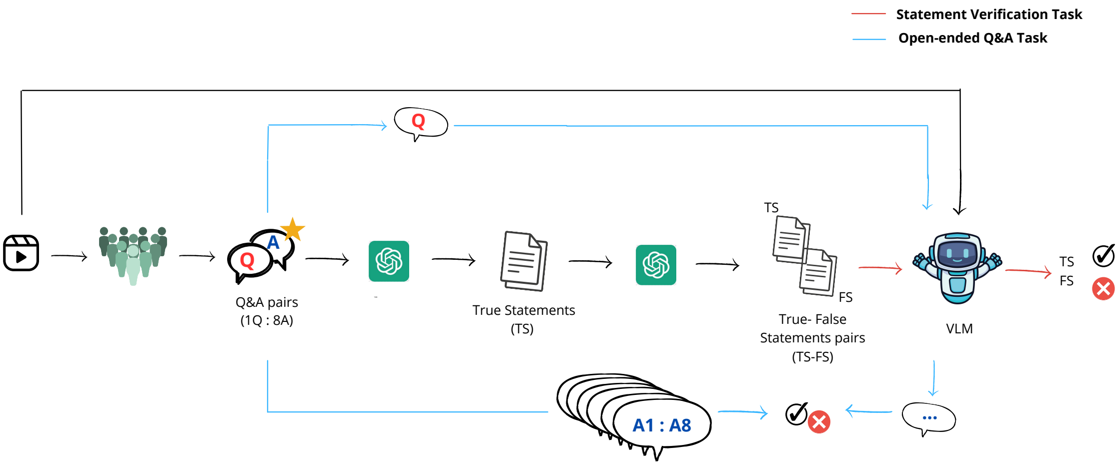

**Figure 1:** Workflow of the MAIA evaluation framework, integrating dataset construction with its application to the two aligned evaluation tasks used in Testa et al. [4].

video-language dataset specifically designed to assess complex visual reasoning and grounding.

## 3. MAIA: Benchmark Design

This section presents the design principles, structure, and construction pipeline of both the MAIA dataset and the benchmark built upon it. In line with this, Figure 1 illustrates the overall workflow adopted for dataset creation, embedding it with the broader architectural framework of the benchmark, which also includes the downstream tasks the data is designed to support.

As shown, the dataset creation begins with the collection of short videos, each associated with twelve high-level reasoning categories. These categories reflect different semantic phenomena and were chosen to ensure a rich and controlled testing environment for visual and linguistic reasoning. Based on these categories, we constructed our multimodal dataset by first collecting a set of questions that served as the conceptual backbone for the creation of the linguistic data, both manually (i.e. a set of answers) and automatically generated (i.e. True and False statements), as described in detail in Section 5. Figure 2 illustrates an example[1] of a MAIA item and highlights the cascading logic behind the data creation process. This architecture supports the development of two aligned evaluation tasks: a *Visual Statement Verification* task, using paired true/false statements to assess the model's ability to distinguish accurate from misleading content in a multiple-choice format, and an *open-ended Visual Question Answering* task, where each question is matched with eight different human answers serving as a reference set to evaluate the quality of the response generated by the VLM. Each task will test different aspects of visual understanding and reasoning, all grounded in the same set of videos and categories.

Table 1 presents the structure of the MAIA dataset after the data creation and validation process.

| Feature | n | |
|---|---|---|
| Videos | 100 | |
| Semantic Categories | 12 | (9 Macro-Category) |
| Questions (Q) | 2, 400 | (2 x Category x Video) |
| Answers (A) | 19, 200 | (8-Answers pool x Q) |
| True Statements (TS) | 19, 200 | |
| False Statements (FS) | 19, 200 | |

**Table 1**
Overview of the MAIA dataset composition.

### 3.1. Reasoning Categories

We defined 12 reasoning categories as the outcome of two pilot studies conducted with a group of expert volunteer

[1] Although all source data are in Italian, examples are presented in English to enhance readability.

| CATEGORY | | QUESTION | ANSWER (1/8) | TRUE STATEMENT (1/8) | FALSE STATEMENT (1/8) |
|---|---|---|---|---|---|
| CAUSAL | | Why is mozzarella melted? | The heat from the wood oven has melted it | Mozzarella is melted by the heat of the wood oven | Mozzarella is melted by the heat generated by the sun. |
| COUNTERFACTUAL | | What would happen if the pizza chef dropped the pizza on the floor? | He would dirty the floor and would have to remake the pizza. | If the pizza chef dropped the pizza, he would dirty the floor and would have to remake the pizza. | If the pizza maker dropped the pizza, he would not dirty the floor and would not have to remake the pizza. |
| IMPLICIT | *Partial* | Is the person who rolls out the pizza the same one who puts it in the oven? | No, they are two different people. | In the scene, the person who rolls out the pizza dough and the one who puts it in the oven are two distinct figures. | In the scene, the person who rolls out the pizza dough and the one who puts it in the oven are the same person. |
| | *Total* | What is the function of all the wooden planks under the wood oven? | They have to feed the fire. | The wooden planks under the wood oven are for feeding the fire. | The wooden planks under the wood oven are for decoration. |
| UNCERTAINTY | | On average, how many pizzas does the pizza chef bake each day? | I do not have enough data to know. | There is not enough data to determine the average number of pizzas a pizza maker cooks daily. | There is sufficient data to determine the average number of pizzas that the pizza maker cooks daily. |
| OUT-OF-SCOPE | | What is the cake made of? | I cannot see any cake. | There is no cake in the video. | There is a cake in the video. |
| PLANNING | | What steps should the pizza maker take to revive the fire? | He should stir up the embers a bit and throw some new wood. | To revive the fire, the pizza maker should stir the embers and add new wood. | To revive the fire, the pizza maker should stir the embers and add new water. |
| SENTIMENT | | What attitude does the pizza maker show while taking the pizza out of the oven? | The pizzaiolo looks focused. | In the video, the pizza maker looks focused while taking the pizza out of the oven. | In the video, the pizza maker looks distracted while taking the pizza out of the oven. |
| SPATIAL | *Partial* | Where is the pizza placed after being taken out of the oven? | The pizza is placed on a plate. | After being taken out of the oven, the pizza is placed on a plate. | After being taken out of the oven, the pizza is placed on the table. |
| | *Total* | Where is the pizza maker? | In the pizzeria in front of the oven | In the scene, the pizza maker is in the pizzeria in front of the oven | In the scene, the pizza chef is in the pizzeria by the counter |
| TEMPORAL | *Partial* | When does the pizzaiolo take the pizza out of the oven? | When he considers it cooked, towards the end of the video. | The pizzaiolo takes the pizza out of the oven towards the end of the video when he considers it cooked. | The pizzaiolo takes the pizza out of the oven towards the beginning of the video when he considers it cooked. |
| | *Duration* | How long does it take to cook the pizza in the video? | Pizza baking time is approximately 30 seconds | The baking of the pizza in the video takes approximately 30 seconds | The baking of the pizza in the video takes approximately 30 seconds |

**Figure 2:** Overview of reasoning categories in MAIA with an example highlighting the cascading logic of the linguistic data. For each of the 100 videos, the dataset contains 2 questions for each of the 12 categories; for each question, it has 8 answers, and each of these answers has a corresponding True and False statement pair.

annotators. These pilots aimed to identify the optimal number, type, and specificity of the categories needed to effectively probe the cognitive and linguistic abilities of VLMs on our videos. Based on the feedback received, some initially proposed categories were merged due to content overlap or redundancy. Conversely, other categories were added to enhance the granularity of reasoning assessment (e.g, we introduced a *Planning* category, as we consider it a meaningful expression of reasoning skills). These refinements allowed us to design a more robust and informative framework to explore the interplay between language and vision in multimodal processing.

The following paragraphs introduce the final macro-categories, including their definitions and any associated sub-categories.

**Causal** focuses on reasoning about the causes or effects of events depicted in the video. It includes two subtypes[2], namely *Implicit* and *Explicit* , offering a comprehensive test of a model's ability to describe causality within events. The former involves inferring unobservable causes from visible effects in the scene, requiring logical reasoning beyond what is directly shown. The

[2] Unlike the following cases, these are not treated as distinct sub-categories but as two equally represented subtypes of the same category

latter concerns clearly observable cause-and-effect dynamics, where either the cause or the effect is directly identifiable from the video content.

**Counterfactual** focuses on questions about hypothetical scenarios that do not actually occur in the video but could take place under specific conditions. These questions are based on entities or events visible in the video and explore the consequences of an event or situation that might happen in the video if a certain condition were met. This category tests the ability of a model to reason about hypothetical scenarios grounded in the context of the video while deriving logical and plausible outcomes from such scenarios.

**Implicit** investigates entities, events, or their attributes that are not explicitly visible in the video while their presence or properties can be reasonably inferred from the context. It evaluates the ability of a model to infer implicit details based on context, whether the target information was never shown or was previously visible but later obscured.

*Total Implicit*: involves entities or events that are never directly visible in the video but can be inferred from observable details. A typical answer provides the requested information based on logical inference.

*Partial Implicit*: involves entities or events that were visible earlier in the video but are no longer visible due to a shift in the scene or because they have moved out of the frame.

**Out-of-scope** refers to entities or events entirely absent from the video, focusing on properties or details of these non-existent elements. Typical responses to out-of-scope questions involve a negation, indicating that the referenced entity or event is not present in the scene. Typical answers to this question types involve a negation, signaling that the referenced content is not present. This category indirectly tests the ability of a model to detect multimodal hallucinations and an assertiveness tendency in its responses.

**Planning** asks for actions needed to achieve a specific goal related to the video. The typical response to a planning question is a sequence of actions that someone should perform in order to reach the desired outcome. Such a category assesses the ability of the model to infer and plan the necessary steps to accomplish a goal based on the visual cues provided in the video.

**Sentiment** assesses sentiment, mood, attitude, or emotion displayed by characters in the video toward other entities or events in the scene, throughout the entire video. A typical response to a sentiment question may describe a specific sentiment, attitude, or emotion, or it may reflect a neutral stance. This category evaluates the ability of the model to recognize and identify the emotional state or attitude of characters based on visual cues.

**Spatial** investigates the spatial relationships between entities, objects, or events depicted in the video. It aims at assessing the model's ability to infer both stable and time-dependent spatial relationships, as well as the ability to determine relative positioning in space and to rely on grounding competencies.

*Total Spatial*: focuses on position of entities in space (including their relation to other entities) that remains constant throughout the whole video, disregarding any temporal variations or minimal movements of the entity at different moments in the video. A typical response to this type of question provides general spatial information valid for the entire duration of the video.

*Partial Spatial*: focuses on time-related positions of entities in space, takin into account events occurring in the scene. A typical answer to this question provides spatial information that is valid only for the requested time range in the video.

**Temporal** focuses on temporal information and studies the ability of a model to infer temporal relationships, sequence of events, and durations from visual content in a coherent manner.

*Partial Temporal*: focuses on the temporal properties and relationships between events in the video, excluding their duration. Questions target aspects such as when something happens or whether it occurs before or after another event. Typical answers specify the event along with the requested temporal detail.

*Duration Temporal*: focuses on a specific property of events in the video: their duration. A typical answer to a question involves several ways to express the duration of the event.

**Uncertainty** refers to entities or events present in the video but lacking sufficient information to answer the question precisely. Questions are inherently ambiguous, as the visual content does not fully support a definitive response. Answers may offer plausible options, acknowledge uncertainty, or signal that the reply is a guess. This category tests a VLM in handling ambiguity and incomplete evidence, and in assessing its tendency to respond assertively.

# 4. Curated Video Dataset

## 4.1. Video Selection

A key design choice for the MAIA benchmark was to reflect Italian culture in real-world scenarios through a carefully curated selection of video clips. To ensure richness and variety, the selection process was based on the following thematic areas: Locations, Food, Sport, Job, Nature, Activities. Such topics allowed us to collect a dataset showing locations, iconic Italian cities, and daily activities (e.g., enjoying breakfast at a café, cooking pasta, attending a soccer match) or even typical events (e.g., Italian local festivals or weddings). This cultural focus was not intended to limit the generalizability of the benchmark, but rather to offer a valuable opportunity to assess model performance on culturally grounded data, which is an aspect often underrepresented in existing multimodal resources.

## 4.2. Video Collection

We collected a culturally representative set of 100 short videos (~30 seconds each) sourced from *YouTube* Italy. Following the criteria described in Section 4.1, videos were retrieved using keyword-based queries across selected thematic areas. Only *Creative Commons* licensed content was included to ensure reproducibility. When necessary, longer videos were manually checked and cut to extract the most relevant 30-second segments, resulting in a uniform and culturally grounded video set.

## 4.3. Analysis of Videos

To better understand the visual content present in the MAIA benchmark, we conducted an object detection and classification analysis over the full set of videos using a *YOLOv11*[3] detection pipeline. For each video, we sampled 32 uniformly spaced frames and ran object detection on them. This analysis provides a high-level view of the typical objects types in MAIA.

Figure 3 shows the frequency distribution of detected object labels across all annotated frames. *Person* is by far the most common object class, reflecting the human-centered nature of most videos in the benchmark. However, the dataset also includes a wide variety of everyday objects, suggesting a rich and diverse set of visual elements.

Figure 4 shows the distribution of the number of detected objects per frame. Most frames contain a moderate number of objects, typically between two and six. This indicates that the videos offer a balance between visual simplicity and complexity, making them suitable for testing both low-level perception and high-level reasoning in VLMs.

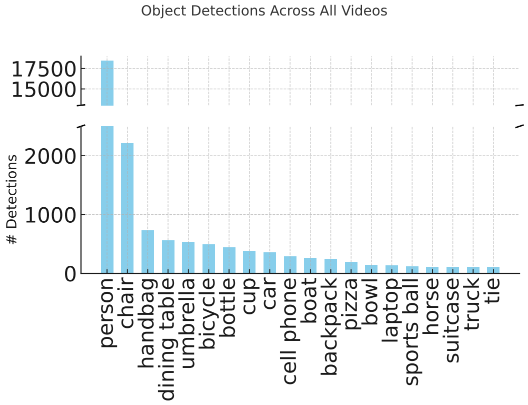

**Figure 3:** Distribution of object detections across all videos. For simplicity we plot just the top 20. *Person* is by far the most common entity.

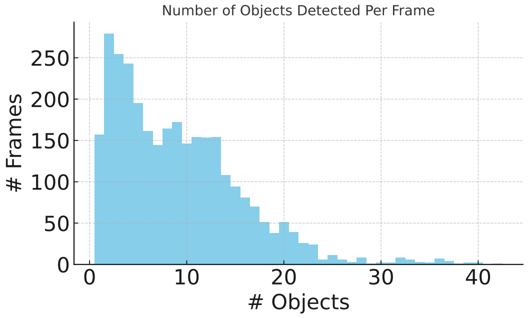

**Figure 4:** Histogram of number of objects detected per sampled frame. Most frames contain 3 objects.

# 5. Curated Linguistic Data

## 5.1. Questions Collection

We created 12 different sets of guidelines, each assigned to a different annotator via *Google Forms* in order to collect two questions per reasoning category for each video. Annotators were PhD students under 30 with specializations in Linguistics and Computational Linguistics[4]. To ensure variability between the pair of questions about that video, annotators were asked to change the entities

[3] https://docs.ultralytics.com/it/models/yolo11/

[4] Each annotator was paid 100 euros for generating questions, which were collected through the administration of 1, 200 forms (10 per annotator)

| QUESTION | What role do the men in white shirts play?<br>Che ruolo svolgono gli uomini con le maglie bianche? |
|---|---|
| ANSWER 1 | The men in white shirts are the competition judges<br>Gli uomini con le maglie bianche sono i giudici di gara |
| ANSWER 2 | They observe who scores a point<br>Osservano chi fa punto |
| ANSWER 3 | Men in white give judgements on the competition<br>Gli uomini in bianco danno giudizi sulla gara |
| ANSWER 4 | They seem to be the referees of this bocce game<br>Sembra che siano gli arbitri di questa partita a bocce |
| ANSWER 5 | They measure the distance of the thrown ball from the little one and determine the winner of the set<br>Misurano la distanza della boccia tirata dal boccino e decretano il vincitore del set |
| ANSWER 6 | The men in white shirts are the referees of the match<br>Gli uomini con le maglie bianche sono gli arbitri dellla partita |
| ANSWER 7 | The men in white are the jury<br>Gli uomini in bianco sono i giudici |
| ANSWER 8 | Men in white shirts play the role of refereeing the match<br>Gli uomini con le maglie bianche svolgono il compito di arbitrare la partita |

**Figure 5:** Example of a video and one of its two associated questions (category: *Implicit*), along with the corresponding 8-answer pool

and/or events involved in both of them. Each provided form contained both the definition of the assigned semantic category with examples, and also general rules to be followed (see Appendix, Figure 8 for an example of the form used). Each question had to be generated naturally and as an open-ended question. Questions involving a 'Yes/No' answer (e.g. *Is there a car in the video?*) were not allowed. Finally, for the correct execution of the task, the audio of the video had to be ignored, as the VLMs to be tested could only work on the visual part. Subsequently, questions were manually reviewed to ensure quality and category alignment.

## 5.2. Answers Collection

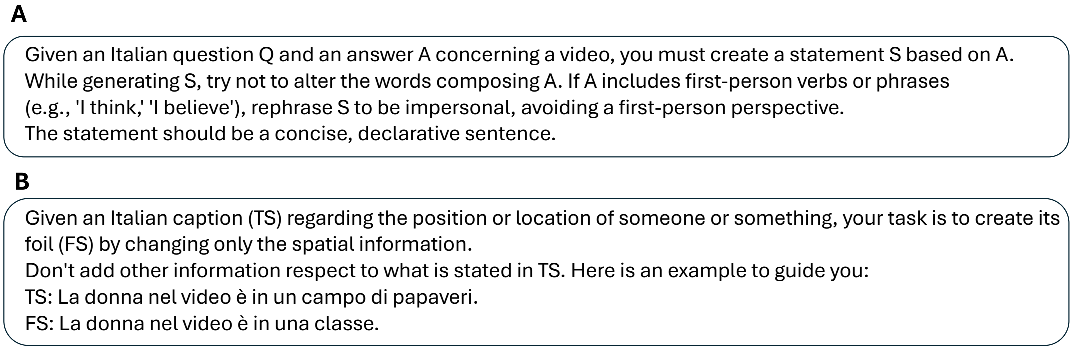
The goal of this phase was to collect 8 different answers for each question to ensure not only accuracy but also variability in responses. This choice is also supported by findings from Mañas et al. [33], who empirically show that using up to 8 demonstrations provides an effective trade-off between diversity, accuracy, and computational efficiency in in-context learning with LLMs for VQA evaluation. We used the *Prolific* platform[5] and selected annotators aged 25 to 80 who were born in Italy, spoke Italian as their first language, and had spent the majority of their first 18 years of life in Italy. As with the question collection step, we used *Google Forms* to provide the task[6]. Each form included 10 videos, and for each video, the annotators were asked to answer 12 questions, one per reasoning category (see Appendix, Figure 9 for an example of the form used). Annotators were encouraged to use their own world knowledge when interpreting the visual content of the video.

To guarantee high quality of the collected answers, we employed rigid control mechanisms based on sanity check questions. Answers were accepted only if the annotators correctly answered at least 90% of these control questions, otherwise their submissions were rejected and the task was reassigned to another annotator. In total, 2, 400 questions were paired with 8 answers each, resulting in 19, 200 responses. They were then further checked by a semi-automated two-step validation process based on *GPT-4o* with few-shot prompting:

**Semantic Consistency Check.** Each response was evaluated for semantic consistency with the corresponding question. In cases where inconsistencies were detected, the answers were manually reviewed to assess

[5] https://www.prolific.com

[6] Annotators were paid £7 per hour for answering questions



**A**

Given an Italian question Q and an answer A concerning a video, you must create a statement S based on A.
While generating S, try not to alter the words composing A. If A includes first-person verbs or phrases
(e.g., 'I think,' 'I believe'), rephrase S to be impersonal, avoiding a first-person perspective.
The statement should be a concise, declarative sentence.

**B**

Given an Italian caption (TS) regarding the position or location of someone or something, your task is to create its foil (FS) by changing only the spatial information.
Don't add other information respect to what is stated in TS. Here is an example to guide you:
TS: La donna nel video è in un campo di papaveri.
FS: La donna nel video è in una classe.

**Figure 6:** Prompts used for True (A) and False (B) Statements generation with GPT-4o. Prompt B (category: *Spatial total*) is representative of the 12 different prompts used to generate False Statements, each tailored to a specific semantic category.

whether the question should be re-answered by another annotator or the response could still be accepted. Real inconsistencies were found to be minimal (i.e., fewer than 100 out of $19,200$ responses).

**Contradiction Test.** We checked whether, within each pool of 8 responses to the same question, any of the responses contradicted the others. We found that 90.25% of the 8-answer pools exhibit full agreement, as they do not contain any contradictions. The remaining 9.75% (234 cases) were manually reviewed by an additional annotator to resolve inconsistencies.

A post-processing phase of the responses was implemented to ensure a sufficient degree of variability and reduce potential redundancy within each of the $2,400$ pools of 8 answers (see Section 5.6). Figure 5 shows an example of one 8-answer pool associated with a video and a question, after this refinement procedure described above.

## 5.3. True Statement Generation

At this step we automatically generate a true statement (TS) for each question-answer pair collected in the previous phases. A TS consists of descriptive declarative sentences aligned with the visual content of the videos. For example, if a video shows a boy who is initially in a kitchen and he hears a loud noise and runs away, a TS for the *Spatial* category could be:

*In the video, the boy is in the kitchen before running away.*

To create TS we used *GPT-4o*, with the prompt in Figure 6A, leveraging the combination of each question and its answer to automatically generate $19,200$ true statements (TSs). As with the answers, the TS are organised into $2,400$ pools of 8 items, each expressing the same event with different wording. Following the same procedure used for the pools of 8 responses, we performed a quality check to ensure lexical variability within the 2400 pools of true statements (TS) (see Section 5.6).

## 5.4. False Statement Generation

The goal of this phase is to create a false statement (FS) for each TS already collected, in order to form a minimal TS-FS pair, enabling controlled experiments and precise analysis of a model's behavior with respect to the reasoning categories. As for TSs, the FSs were automatically generated using *GPT-4o* for editing only the elements of the sentence related to that semantic category, an approach inspired by the caption-foil method [14]. Figure 6B shows a prompt used for the FSs generation[7]. For instance, taking into account the previous example in 5.3:

*In the video the boy is in the bathroom before running away.*

Finally, we implemented two quality checks for FS using *GPT-4o*.

**Structural Check** aiming at automatically verifying that each FS aligns correctly with its corresponding TS according to its category. While the *GPT-4o* evaluation initially flagged 864 out of $19,200$ cases as incorrect, only 2.5% were ultimately confirmed as truly problematic and subsequently corrected through manual revision.

**Contradiction Test** performed by assuming that a correct FS must be in contradiction with the relevant TS. We ran an NLI task to classify TS-FS pairs as Entailment,

[7] Due to space constraints, we could not include all the 12 prompts used for generating FSs specific to each reasoning category. However, the prompt shown here is representative of the adopted methodology.

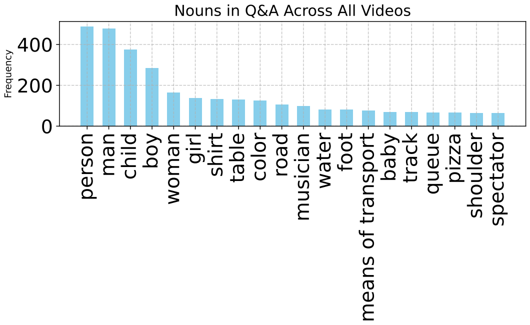


**Figure 7:** Distribution of the top 20 nouns in the Q&A pools across all videos, excluding high-frequency terms used to structure video-related questions according to the different categories (e.g., *What is the* *attitude* *of the girl in the* *video*?)

| | | B-Rephrasing | | A-Rephrasing | |
|---|---|---|---|---|---|
| | | *TTok* | *CW* | *TTok* | *CW* |
| **Answers** | Lexical Overlap | 22.95% | 21.41% | 18.74% | 17.60% |
| | Avg TTR | *** | *** | 0.50 | 0.55 |
| **TSs** | Lexical Overlap | 39.34% | 38.04% | 30.51% | 26.81% |
| | Avg TTR | 0.37 | 0.41 | 0.50 | 0.55 |

**Table 2**
Average Lexical Overlap and TTR Statistics for pool, considering both Type-token (TTok) and Content-word only (CW). Statistics are compared before (B) and after (A) Automatic Sentence Rephrasing (*GPT-4o*) for both 19, 200 Answers and 19, 200 TSs. Average TTR statistics were not computed for the 2400 8-Answers pools before rephrasing.

Neutral, or Contradiction. A qualitative analysis revealed that most Neutral cases (1287) were actual contradictions, and only 93 out of 170 Entailment cases were valid, which were then manually corrected to create contradictions.

## 5.5. Analysis of Linguistic Data

Similarly to videos, we investigated the entities used in our data by analyzing the most frequent nouns in the questions and their corresponding answers[8], as shown by the frequency distribution in Figure 7. To extract entities, we used the *spaCy* library[9] (*it_core_news_sm* pipeline), applying morpho-syntactic analysis (i.e., POS tagging) over both questions and answers. For each sentence, we selected tokens tagged as *NOUN* and extracted their lemmas to reduce redundancy. Duplicate nouns within the same QA pair were removed. Structural terms, functional to question/answers construction (e.g., *video*, *scene*, *attitude*), were filtered out to improve the informativeness of the plot and its comparability with object detection results in Figure 3. Several correspondences emerge between linguistic and visual entities (e.g., person, table, car), meaning that our linguistic data takes advantage of what is presented within our videos.

## 5.6. Lexical Variability

As said in Section 5.2, we opted for a pool-based structure with 8 items per question in order to balance semantic consistency with lexical diversity both across answers and statements. To meet this requirement, we assessed and enhance lexical richness within our data. This phase was carried out in several incremental steps (i.e., a string based test, lexical overlap and *Type-Token Ratio* (TTR) based investigations), each of which involved an initial analysis of the potential redundancy of responses within the pool and an automatic rephrasing step (*GPT-4o*), particularly in cases where overlap was high[10]. Table 2 presents average lexical overlap and TTR within pools before and after rephrasing. Results show a substantial improvement, with a post-rephrasing average TTR of 0.55, which is a high value considering the semantic similarity among the 8 alternatives in each pool, especially for TSs, which follow more repetitive and fixed structures (e.g., *In the video X happens <...>*, *The video shows X <...>*).

# 6. Conclusion

We presented MAIA, a multimodal dataset forming the core of our benchmark designed for fine-grained investigation of the reasoning abilities of VLMs on videos. Among its innovative features, MAIA is the first Italian-native evaluation resource of its kind, built from both human-elicited data and content generated through controlled data augmentation. It supports two complementary tasks aligned on the same datapoints: a statement verification task (multiple-choice format), and an open-ended question answering task (fully generative setting).

As for future work, we would like to produce an English version of MAIA, for comparing VLMs on the same tasks across languages. Then, we intend to align the visual objects recognised by the VLM with the linguistic objects in the questions, enabling deeper error analysis based on the mapping. Finally, it would be interesting to see whether our framework promote models that undergo learning paradigms tightly integrating these two capabilities, as in Gul and Artzi [34].

[8] Nouns from TS and FS were excluded, as those sentences are derived from Q&A and would result in redundant repetitions.

[9] https://spacy.io

[10] Since TSs are generated from an automatic rephrasing of Q&A pairs, we checked and improve their lexical diversity. This indirectly benefits the corresponding FSs, which differ by a single term from TS.

## Acknowledgments

This work has been carried out while Davide Testa was enrolled in the Italian National Doctorate on Artificial Intelligence run by Sapienza University of Rome in collaboration with Fondazione Bruno Kessler (FBK). Giovanni Bonetta and Bernardo Magnini were supported by the PNRR MUR project PE0000013-FAIR (Spoke 2). Alessandro Lenci and Alessandro Bondielli were supported by the PNRR MUR project PE0000013-FAIR (Spoke 1). Alessio Miaschi was supported by the PNRR MUR project PE0000013-FAIR (Spoke 5). Lucia Passaro was supported by the EU EIC project EMERGE (Grant No. 101070918).

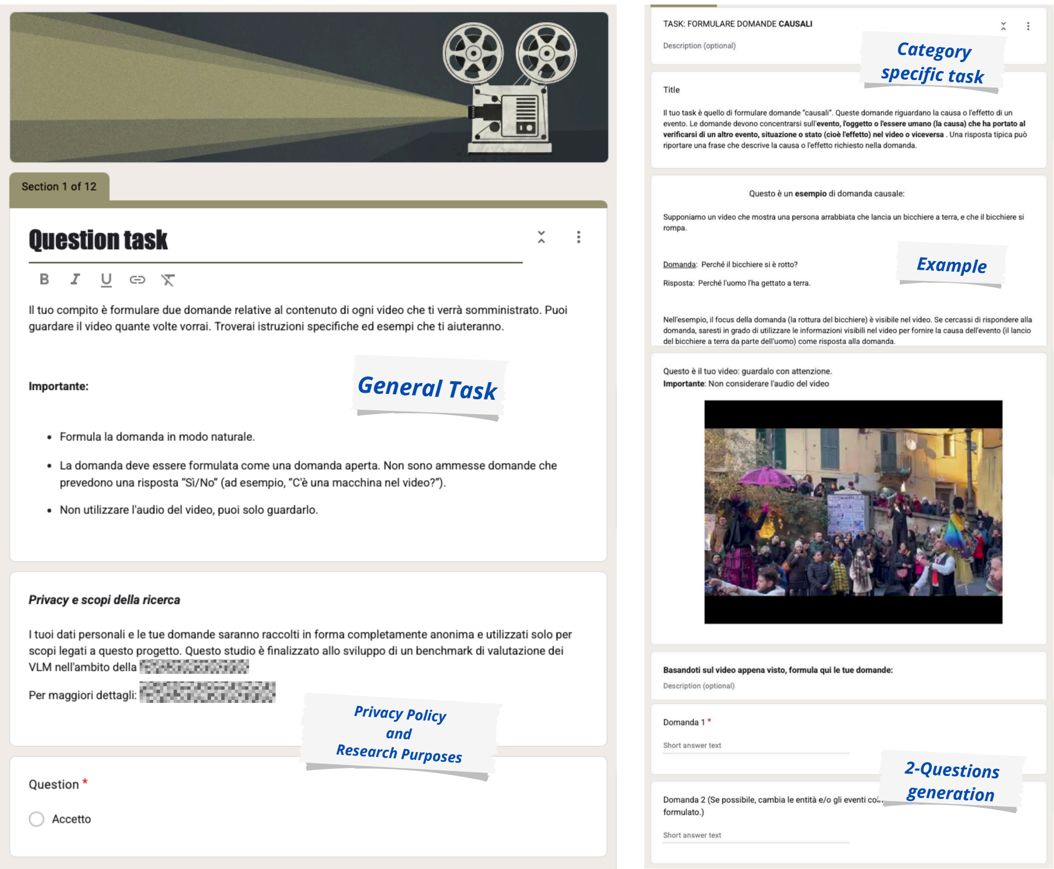
# A. Additional Materials

The following figures show examples of the forms adopted for collecting the questions (Figure 8) and the corresponding answers (Figure 9).



Section 1 of 12

**Question task**

Il tuo compito è formulare due domande relative al contenuto di ogni video che ti verrà somministrato. Puoi guardare il video quante volte vorrai. Troverai istruzioni specifiche ed esempi che ti aiuteranno.

**Importante:**

- Formula la domanda in modo naturale.
- La domanda deve essere formulata come una domanda aperta. Non sono ammesse domande che prevedono una risposta "Sì/No" (ad esempio, "C'è una macchina nel video?").
- Non utilizzare l'audio del video, puoi solo guardarlo.

***Privacy e scopi della ricerca***

I tuoi dati personali e le tue domande saranno raccolti in forma completamente anonima e utilizzati solo per scopi legati a questo progetto. Questo studio è finalizzato allo sviluppo di un benchmark di valutazione dei VLM nell'ambito della [redacted]

TASK: FORMULARE DOMANDE **CAUSALI**

Description (optional)

Title

Il tuo task è quello di formulare domande "causali". Queste domande riguardano la causa o l'effetto di un evento. Le domande devono concentrarsi sull'**evento, l'oggetto o l'essere umano (la causa) che ha portato al verificarsi di un altro evento, situazione o stato (cioè l'effetto) nel video o viceversa** . Una risposta tipica può riportare una frase che descrive la causa o l'effetto richiesto nella domanda.

Questo è un **esempio** di domanda causale:

Supponiamo un video che mostra una persona arrabbiata che lancia un bicchiere a terra, e che il bicchiere si rompa.

Domanda: Perché il bicchiere si è rotto?

Risposta: Perché l'uomo l'ha gettato a terra.

Nell'esempio, il focus della domanda (la rottura del bicchiere) è visibile nel video. Se cercassi di rispondere alla domanda, saresti in grado di utilizzare le informazioni visibili nel video per fornire la causa dell'evento (il lancio del bicchiere a terra da parte dell'uomo) come risposta alla domanda.

Questo è il tuo video: guardalo con attenzione.
**Importante**: Non considerare l'audio del video

**Basandoti sul video appena visto, formula qui le tue domande:**

Description (optional)

Domanda 1 *

Short answer text

Domanda 2 (Se possibile, cambia le entità e/o gli eventi co... formulato.)

Short answer text

**Video Q&A Task**

Benvenuti e grazie per partecipare a questo task di annotazione!

Ai fini del corretto svolgimento del task e della sua validazione, **rispetta sempre le istruzioni che seguono**.

* Indicates required question

Il tuo compito consiste nel guardare una serie di video e rispondere, per ognuno di essi, a 12 domande basate esclusivamente sulla parte visiva del contenuto multimediale.
Puoi visionare il video quante volte desideri per rispondere alle domande.

**Punti Importanti da Ricordare:**

1. **Formula risposte sempre in maniera naturale.**

**Nota bene**: Prendi il tuo tempo per rispondere al meglio alle domande. Le annotazioni consegnate al di sotto di un determinato arco temporale e/o che non rispettano tutte queste istruzioni iniziali, saranno automaticamente rifiutate. Lo stesso vale in caso di risposta errata alle domande di controllo.

## Declaration on Generative AI

During the preparation of this work, the author(s) used ChatGPT (OpenAI) in order to: Paraphrase and reword, Improve writing style, and Grammar and spelling check. After using these tool(s)/service(s), the author(s) reviewed and edited the content as needed and take(s) full responsibility for the publication's content.

# Building It-tok: an Italian TikTok Corpus

Luisa Troncone[1,2,*]

[1] University of Salerno, Via Giovanni Paolo II, 84084 Fisciano, Italy

[2] STL CNRS UMR 8163, University of Lille, Rue du Burreau, 59650 Villeneuve d'Ascq, France

## Abstract

This contribution focuses on the process of building a corpus for TikTok discourse. Particularly, it aims at describing the choices made during the construction of a corpus of Italian TikTok videos. The corpus It-tok was collected to individuate linguistic functional correlates of digital discourse on TikTok. It-tok includes two subsets of videos: the first one is centered on videos concerning themes of interest for the public debate (e.g. abortion, femicide, racism, internal politics); the second one is made up of videos with no specific theme, intended to constitute the control sample for the observations made for the first sub-corpus.

## Keywords

TikTok, public discourse, CMC corpora, modality, linguistic functional correlates

## 1. Introduction

The major goal of this contribution is to present some of the choices made during the process of building It-tok, an Italian TikTok corpus. The It-tok project was born with three aims:

- to provide a first assessment of the linguistic functional correlates (LFCs) displayed by TikTok content, and, subsequently, of the modality of communication on this specific social network;
- to highlight how themes of interest for the public debate are treated on this social network;
- to compare the LFCs found in general TikTok discourse with those emerging in thematically focused content.

By functional linguistic correlates, we mean the set of features that characterize language across different modalities; consequently, spoken texts exhibit specific correlates compared to written, read, or digitally produced texts (see section 3. for a more in-depth discussion): for instance, some LFCs of spoken language with regard to written language highlighted in previous studies regarded a significantly different distribution of PoS [1], the higher count of deictics [2], or of demonstratives [3]. LFCs describe effects on language uses based on the modality the communicative event takes place in. The focus on functional linguistic correlates poses significant challenges for decisions related to the corpus design, precisely because of the platform's content multimodality. Indeed, the structure of the final product, i.e., the TikTok video, can take highly diverse forms, and can employ a number of semiotic means for conveying the message. Because of the platform's multifaceted nature, a number of choices were to be made, to achieve a selection of content for analysis which was both replicable in its methodology and suitable for the achievement of the objective. In fact, beyond the thematic relevance, the selection process is complicated by the inherently heterogeneous nature of TikTok videos. These products differ not only in terms of topic but also from a semiotic point of view: they can include spoken language, text on screen, music, sound effects, gestures, visual editing techniques, or a combination of these means. As a result, choices concerning the corpus are of various kinds and must account for the platform's multimodal nature, which challenges both linguistic analysis and methodological consistency from the outset. In this work, we chose to focus solely on verbal content, but TikTok would allow for a variety of different levels of interest.

For accomplishing the goals illustrated above, we decided to subdivide the collection stage into two phases, one concerned with general discourse (Gen) and one concerned with political and social discourse

(PolSo).

During the collection, a number of methodological issues arose, which will be described here, together with the solutions we opted for; but, before getting to the decision-making section, we will briefly introduce TikTok and the reasons it was chosen.

## 2. TikTok: Characteristics, Meaningfulness, Employment in Linguistics

TikTok is a social media platform which allows for the publication of video content. It gained much popularity in the latest years especially among the youngest parts of the population [4][5]. A *tiktok* is a (usually) short video: in fact, while the maximum duration the platform allows for a *tiktok* is 10 minutes, the mean duration of *tiktoks* stands around 50 seconds[2]. This format can be also found on other social media (e.g., *reels* on Instagram), but the reasons which led to choosing it are linked to the amount and the kind of popularity it reached lately, rather than the specific format of the content considered.

With the beginning of the post-digital era, and the intersection and overlap of the online and offline lives, digital content has begun to have a consistent effect on our *analogic* life [6]. This is especially true for public debate themes, and, in the latest years, this influence has been especially clear for TikTok content, which is getting central in the political discourse. To give an idea of the importance TikTok gained in the public opinion building process, we can provide some examples. Consider the ban imposed by Donald Trump: as neo-elected President of the US, at the end of January 2025 he imposed the closure of the platform in the US, since he held that the Chinese government was receiving sensitive data about US government and citizens through TikTok users[3]. Given the amount of public disagreement with such decision, also manifested through many Americans signing up to Xiaohongshu, another Chinese social [7][8], Trump postponed the closure, and TikTok went dark for only one day on the 20th January. Conversely, political and social topics are increasingly present on TikTok discourse: the political importance of the platform can be seen also in spreading and testifying major political events and boosting discussion about major socio-political issues, such as the Black Lives Matter protests (2020) [9], the killing of Mahsa Amini (2022)[10], the war in Gaza (2023-present)[11], the #metoo movement (2020)[12], the suspension of the unsentenced guilty raper by the University of Leuven (2025) [13].

Given the importance social media nowadays hold in our society, there is no doubt that TikTok constitutes now a fundamental political mean [14][15][16], which makes it a viable field of study for our aims.

### 2.1. TikTok and Linguistics

Several studies in the field of linguistics (especially acquisitional, clinical, and variational) have already considered data coming from TikTok[4]. Many studies regard specific domains, and were built through a punctual methodology, which usually is not focused on an open resource. The main application fields for these studies regard especially language learning and teaching practices enhanced through TikTok [18][19] [20][21], the study of code-switching dynamics detected on the platform [22][23][24], language creativity [25][26], or hate speech detection and moderation [27][28][29].

Still, anyways, a description of the communicative modality/ies employed on TikTok, and especially in *tiktoks*, is missing. Furthermore, corpora of Computer Mediated Communication [30] have mainly concentrated (and this is also true for TikTok studies) on thematic corpora, which on their own can provide a partial portrait of the discourse on platforms. Just to focus on some examples regarding Italian CMC corpora, the only example we were able to find of a methodology leading to a generalist corpus is the one by TWITA [31][5], while others mainly exploit thematic hashtags [32][33][34][35] or specific pages [36][37] for the extraction. The reason for a generalist ("control-like") corpus stands in the fact that, in order for assertions on specific subsections (or thematic sections) to be solid, they should be checked with respect to how language is generally used on the specific platform. It-tok aims at providing both a description of the chosen path for the creation of a generalist corpus of *tiktoks*, and a characterization of modality displayed in such a content format.

## 3. Linguistic Functional Correlates

As explained in the previous paragraph, TikTok has already undergone a number of investigations in linguistics. Still, anyways, a bottom-up description of the functional features characterizing the platform is missing. Most existing studies tend to adopt a top-down

[2] According to Statista, *Average TikTok video length in 2023 and 2024.*

[3] The Trump-TikTok controversy was already on in 2020, during his first administration.

[4] For a theoretical perspective on communication dynamics on TikTok, see [17].

[5] TWITA exploits an extraction method which would have not been much effective for tiktoks, as it is based on the extraction of tweets with Italian most frequent words, but tiktoks cannot be extracted based on words in the video, since automatic subtitles are not searcheable.

approach, focusing on specific trends or phenomena, without accounting for the underlying structural features of TikTok communication as shaped by the platform's multimodal and technologically mediated nature. Addressing this gap is one of the central aims of the It-tok project, which seeks to identify TikTok's LFCs.

The LFCs of a specific modality of communication consist in the set of features which primarily describe that specific modality and characterize it with respect to others [38]. By *modality*, we mean the combination of semiotic resources (e.g., speech, gesture, text, image, sound), interactional dynamics (e.g., synchronicity, turn-taking), and cognitive constraints (e.g., processing time, spontaneity) that shape linguistic production in a given environment. For instance, the spoken modality is typically associated with the gesture-auditory-visual channel, real-time interaction, prosody, and a high degree of context-dependence. In contrast, written modalities tend to involve planning, permanence, and syntactic density, often favoring nominal constructions over verbal ones [39].

It is important to distinguish between *modality* and *channel*. While *channel* refers specifically to the physical means of transmission (e.g., auditory, visual, tactile), *modality* encompasses the broader communicative framework that includes social conventions, technological constraints, and the multimodal configuration of the medium. In the case of TikTok, the modality is particularly complex and hybrid, since it combines features of spoken interaction (e.g., spontaneous speech, direct address to an audience) with elements of edited visual media (e.g., cuts, overlays, subtitles, background music), thereby creating a composite, dynamic communicative environment.

As noted in the literature on this topic, LFCs do not depend on sociolinguistic features of speakers, but, instead, they stay the same across diastratically and diatopically different speakers. For this very reason, the construction of It-tok could avoid taking into consideration sociolinguistic representativeness issues, focusing instead on capturing the linguistic regularities that emerge specifically from the platform's multimodal communicative modality. The primary goal was to ensure that the corpus would be suitable for identifying these modality-driven patterns, rather than for mapping speaker-based variation.

## 4. Building It-tok

Some issues with building a corpus from TikTok videos have already been pointed out in [40]: namely, the authors refer to different formats of the videos, necessity of manual supervising for the automatic transcriptions, ethical considerations. Throughout our work, we tried to address these issues, regarding which we tried to make choices as solid as possible.

To identify LFCs of TikTok discourse (subcorpus Gen), and to compare them to the LFCs of that sub-part of TikTok discourse which concerns themes of interest for the public debate (subcorpus PolSo), we proceeded through a double phased data collection.

### 4.1. Corpus Building Process

TikTok API allows for the extraction of a maximum of 100 videos per extraction, which shall be from a 30 days time period, so the extraction was carried out month by month. The affordances of this research API does not allow for queries of tokens within the automatically generated captions (which would have been the preferred path), but it allows for querying hashtags. TikTok displays several characteristics in common with other platforms. One of these, is the affordance of hashtags. Hashtags are (small strings of) words, which function as hyperlinks, and link a content directly to others which contain the same hashtag. Most hashtags are thematic, in the sense that they describe the topic of that content. But this is not the only function they have on social media. In fact, hashtags can also be exploited to gain followers, or views, and in this case their form is a bit different. While, regarding the first function, hashtags do not display particularities on TikTok, considering the second one, these hashtags usually have a very transparent form on other platforms (*#followforfollow, #followme*). This is not the case for TikTok hashtags. Here hashtags are exploited by users in a way which, according to them, would boost the algorithm, and make them gain more views[6], but their form is by far less transparent, namely we have *#foryou*, *#fyp*, *#perte*, which all refer to the *for you page* of the app. This type of hashtags is by far the most used on TikTok[7], compared to thematic ones[8]. The so-called *for you page* (it. *per te*), so commonly cited in the hashtags, is the main page of the app, where users get the content TikTok suggests them based on what they liked or watched for longer[9]. What distinguishes the *fyp* from the other scrollable pages is the fact that in the *fyp* users are

[6] This was also confirmed by a questionnaire we spread over March 2025, concerned with the use of hashtags on TikTok.

[7] TikTok for Business, https://ads.tiktok.com/business/creativecenter/inspiration/popular/hashtag/pc/en.

[8] The same questionnaire cited in note 3 revealed that users of TikTok are well aware there are hashtags specifically useful (or thought to be useful) for TikTok content rather than other social media.

[9] An equivalent of the TikTok *fyp* is the *search* page on Instagram, or the *tl* (*timeline*) on X.

reached by content not necessarily published by people they follow. Therefore, to get in other people's *fyp* means to get more visibility on the app. For this reason, users tend to exploit hashtags connected to *fyp*.

Another way to boost the popularity of one's content consists in using thematic trending or popular hashtags, even for videos which have nothing to do with it.

All these features consistently affected our methodology of retrieving data, which had to consider the peculiarities of the platform.

Because of the peculiarities of TikTok hashtags, we chose to pay some special attention to the hashtags used for the query, and in particular we had to avoid keyword with a scope which was too large and concurrently the ones whose scope was too restricted, since we would have risked ending up with no results. We extracted a minimum of 15 videos per month for each of the subcorpora, selecting them by duration (>60s) and region of publication ("IT"=Italy). The video extracted were all published between October 2024 and January 2025. The extraction was performed during February and March 2025. Among the videos reached, only the ones showing the *voice_to_text* feature, namely the TikTok automatic transcriptions, were considered viable for It-tok. This way we could avoid video memes (usually shorter than 60s), those videos where the message is carried by the music rather than the speech and the ones in which there is no speech at all. Note that we did not use the automatic transcription as the final transcript: its presence was solely employed as a filter to exclude videos that did not contain or feature any spoken language. This way, we isolated the materials containing spoken language, whether continuous or discontinuous, explicitly excluding content such as memes, images carousels, or other materials lacking spoken language.

Finally, we got a total of 196 viable videos. Those videos were automatically downloaded, transcribed through the tool Open-AI Whisper in Python [41], both in aligned .txt and .eaf files. The transcriptions were annotated using the CLIPS [42] standard [43]. We decided to add some tags, which we thought would be useful for detecting specific sections of the texts. Table 1 summarizes the tags to be found in the annotated transcription.

Finally the .txt files were automatically tagged (through spaCy [44]), ending up in a .conllu file.

To sum up, for each video It-tok provides:

- a .mp4 file;
- a .txt file;
- an antr.txt file;
- a .conllu file;
- a .eaf file.

The CoNLL-U file PROPN tags were exploited to carry out the anonymization of the files.

**Table 1**
List of tags used in the annotated transcription, respectively from CLIPS and added specifically for It-tok

| Tag | Meaning | Source |
|---|---|---|
| <sp><br><lp> | *short and long pauses* | CLIPS |
| <ehm><br><eeh> | *full pauses* | CLIPS |
| <MUSIC><br><NOISE><br><inspiration><br><breath> | *non verbal noises* | CLIPS |
| [foreign_word]<br>[dialect] | *other languages (start)* | CLIPS |
| [/foreign_word]<br>[/dialect] | *other languages (end)* | It-tok |
| <READ><br></READ> | *read section (start and end)* | It-tok |
| <CLIP><br></CLIP> | *clip (start and end)* | It-tok |
| <MASK_IL><br></MASK_IL> | *masking inappropriate language (start and end)* | It-tok |
| <OTHER_SP><br></OTHER_SP> | *other speaker speech (start and end)* | It-tok |
| <CHUNKING><br><KISS> | *non-verbal noises* | It-tok |

As for now, the CoNLL-U files were checked just for the PoS and lemma columns. Here we also tagged discourse markers (DMs), in order to make them easily retrievable. We chose to tag DMs because we thought they could provide a measure of the extent to which TikTok discourse could be compared to spoken language, and since they are also included in the features which make up LFCs [39].

During the extraction, both in the process for PolSo and Gen, we noticed that the number of minimum extraction necessary for reaching the minimum of 15 viable videos per month differed sensibly from month to month, as can be seen in Table 2. We supposed it depended on the period of the year the videos we were extracting belonged to. Particularly, we decided to extract videos from October, November and December of 2024 and January of 2025. As it is well known, the amount of posting, and the quality of posts on social media is very much dependent on the time of posting. In particular, during the last months of the year more "seasonal" posting happens [45][46][47], which may be due to specific festivities (Halloween, Christmas, New

Years' Eve) or the whole period of "end of the year" wrapped. This seasonal posting primarily consists of videos that likely do not meet our extraction criteria, as they are probably shorter than 60 seconds and/or lack spoken language. Consequently, to make sure it was a contingency of the peculiarities of the months considered, we attempted a subsequent extraction of February and March 2025, which showed a piece of evidence favoring our hypothesis, as they show a rate of videos featuring *voice_to_text* similar to the one displayed by January. This happens because the trends usually developing or spreading at the end of the year are trends that usually do not produce videos that would have been considered viable for our data (i.e., they are usually short, with songs or media carrying the message rather than the words and consequently not featuring *voice_to_text*).

**Table 2**
Number of extacted videos compared to viable videos, per month

| Subcorpus | Month | videos extracted | voice_to_text videos | |
|---|---|---|---|---|
| PolSo | Oct | 678 | 75 | 11% |
| | Nov | 521 | 37 | 7% |
| | Dec | 605 | 36 | 6% |
| | Jan | 186 | 61 | *33%* |
| | *Feb* | *180* | *64* | *35%* |
| | *Mar* | *185* | *69* | *37%* |
| Gen | Oct | 521 | 65 | 12% |
| | Nov | 808 | 40 | 5% |
| | Dec | 847 | 35 | 4% |
| | Jan | 250 | 76 | *30%* |
| | *Feb* | *258* | *88* | *34%* |
| | *Mar* | *267* | *97* | *36%* |

## 4.2. PolSo

Our thematic section was collected by extracting videos whose description included (at least) one in a list of hashtags. Due to the original thematic nature of hashtags, they usually have a general form, which made us prefer them with respect to keywords in video descriptions, as these last would have needed a broader consideration of their flected and/or derived forms (i.e., *femminista* 'feminist.SG', *femministe* 'feminist.PL.F', *femministi* 'feminist.PL.M', *femminismo* 'feminism').

The selection of the hashtags was carried out based on our common sense of users, and on the most recent surveys about what worries Gen Z[10] the most (especially compared to GenX), carried out by IPSOS in 2022[11] [49]. Furthermore, to ensure that this preference aligned with the interests of Italian youth, we distributed a brief online questionnaire via Google Forms to a random sample of individuals under the age of 27, selected through cluster sampling. The responses confirmed the primary areas of interest and, to some extent, introduced additional hashtags related to foreign policy, an area that, anyways is not currently taken into consideration for It-tok. The themes regard mainly civil rights and internal politics issues and can be subdivided in four groups: environmental and ecological crisis, national identities and policies, politicians, and social intersectional rights. Table 3 shows the hashtag names selected, together with their category.

Following the questionnaire, we plan on realizing an expansion of the PolSo section with themes from foreign politics[12].

## 4.3. Gen

As regards the generalist section, our *modus operandi* was completely different. Since we could not find any TikTok generalist corpus building methodology which would have been somewhat exhaustive, we opted for a format-based extraction strategy. Specifically, we selected three widely used formats on the platform, which are very common on the platform and that differ primarily in their varying degree of (perceived) interactionality: *storytimes, answers, stitches.* Particularly, the extraction of these last two types was based on the external caption TikTok automatically produces when creating a video in these formats: namely, *risposta a* 'answer to' and *#stitch con* 'stitch with'. Storytimes were extracted through hashtags.

In order to maintain internal consistency and comparability, we also aimed to keep the duration of the videos across the three formats as uniform as possible.

### 4.3.1. Storytime

The first format we exploited was the *storytime*, extracted through the corresponding hashtag. A storytime video displays a person usually speaking directly to the camera, telling a story, usually from their personal life, and unsolicited by anyone. Therefore, storytimes are strongly monological. They make a format of their own on a number of platforms[13], as they were also published on YouTube since 2015.

**Table 3**

[10] GenZ is the most present generation on TikTok [48].

[11] The survey showed that while GenX members are more interested in themes such as taxes, (un)employement levels and job market, GenZers care more about the environment, education and civil rights.

[12] Since LFCs do not depend on the theme, they shall not be interested in the specific topic of the video, so they shall remain the same as the ones we will extract from PolSo as it is.

[13] The massive presence of such a format is linked to its efficiency in being an instrument for creating online communities [50].

List of the hashtags chosen for the extraction

| Category | hashtags |
|---|---|
| environmental and ecological crisis | *ecologismo* ‘ecologism’, *ecoansia* ‘ecoanxiety’, *ecoterrorismo* ‘ecoterrorism’, *overtourism, antispecismo* ‘antispeciesism’, *specismo* ‘speciesism’, *ecofemminismo* ‘ecofeminism’ |
| national identities and policies | *capitalismo* ‘capitalism’, *anticapitalismo* ‘anticapitalism’, *migrante* ‘migrant’, *migranti* ‘migrants’, *rifugiati* ‘refugees’, *antifascista* ‘antifascist’, *antirazzista* ‘antiracist’, *razzismo* ‘racism’ |
| social intersectional rights | *femminismo* ‘feminism’, *feminist, metoo, femminicidio* ‘femicide’, *patriarcato* ‘patriarchy’, *violenzadigenere* ‘gender-based violence’, *aborto* ‘abortion’, *misoginia* ‘misogyny’, *omofobia* ‘homophobia’, *transfobia* ‘transphobia’, *omolesbobitransfobia* ‘homo- lesbo- bi- trans- phobia’, *dirittiLGBT* ‘LGBT rights’, *abilismo* ‘ableism’, *grassofobia* ‘fatphobia’, *femminismointersezionale* ‘intersectional feminism’, *intersezionale* ‘intersectional’, *privilegio* ‘privilege’, *woke* |
| politicians’ names | *giorgiameloni, governomeloni, matteosalvini, giuseppeconte, ellyschlein, antoniotajani* |

### 4.3.2. Answer

The second format we selected is composed by *answers*. In these videos, the creator selects a comment to one of their videos and *answers* to the comment through a *tiktok*, rather than through writing another comment. This affordance is exploited for two reasons: either because writing would have costed too much time, or because a video answer is content in itself, whereas a written answer is not, and TikTok algorithm is said to boost accounts posting frequently. Since answers directly refer to one comment, they can be considered *more* interactional, compared to storytimes. This is also to be seen in the linguistic features answers they display: more deictic expressions or second person pronouns and verb forms.

### 4.3.3. Stitch

Stitches are somewhere in the middle between answers and storytimes. A *stitch* is a video which starts with/from another video section, usually lasting no more than 10 seconds, by another creator[14]. The *stitched* video (i.e., the original one) can be either used as a base for speaking one’s mind on a subject introduced by said stitched video itself, making it just a clarifier for the context, or can have the same function as the base comment in the *answer* videos, and in this case, as happens for answer videos, linguistic features include second person pronouns and verb forms. So, because of their very nature, stitches can be seen as formats more interactional than storytimes, but less interactional than answers.

## 4.4. Semi-supervised Automatic Collection

All the processes the videos went through were to be checked manually, as automatized processing turned out to be not always completely reliable. As for the transcriptions, this could be due to the quality of the sound, the presence of dialect or of strong regional markedness, or the (highly variable) speech rate. Regarding the tagging, as we mentioned earlier (4.1), at the moment we did not check the syntactic tagging yet, but the PoS tagging and lemmatization outputs were to be manually checked, as they presented some inaccuracies. Lemmatization was to be corrected especially for cases such as:

- less frequent verbs or verb forms, e.g. *tatuo* ‘tattoo.PRS.1SG’ was lemmatized as *tatuere* instead of *tatuare,* or future forms like *ripeterai* ‘repeat.FUT.2SG’ lemmatized as *ripeterai* instead of *ripetere*;
- irregular verb forms, e.g., *sai* ‘know.PRS.2SG’ got lemmatized as *saare* instead of *sapere*;
- verb forms displaying suppletivism, e.g., *vai* ‘go.PRS.2SG’ got lemmatized as *vai* instead of *andare.*

Regarding PoS tagging, main issues pertained:

- loans, marked as proper names;
- big numbers, such as years, which in the transcription were written in words (e.g. not *20* but *twenty*) and got marked as proper names;
- deverbal nouns, e.g. *(il) ritorno* ‘(the) come back’, tagged as *VERB* instead of *NOUN.*

# 5. Current Status and Future Perspectives

## 5.1. Current status of It-tok

As for April 2025, we extracted a total of 196 videos for a total duration of more than 7 hours (see Table 4 for a deeper insight). We are in the process of analyzing some

[14] According to TikTok support: “Stitch allows you to combine a video on TikTok with one you're creating” [51].

LFCs, focusing on particular lexicosyntactic traits. Anyways, we are well aware that a number of sociophonetic and morphological features could be analyzed, but we chose to focus only on some levels. In the meantime, It-tok shall be published online by the beginning of 2026. Concerning the publication and the treatment of data, we considered what was done during other studies based on TikTok data. Particularly, since the text data cannot be traced back directly to the original videos, and since the content we extracted is publicly accessible online, the data is to be considered of public domain [40][52].

**Table 4**
Current status of It-tok

| Subcorpus | Total duration | Total word count |
|---|---|---|
| PolSo | 3:43:49 | 32 581 |
| Gen | 4:06:04 | 35 254 |
| *It-tok* | *7:50:54* | *67 835* |

## 5.2. Preliminary Observations

Table 5 shows the distribution of videos found for groups of hashtags in PolSo (notice that a video can present more than one hashtag, and hashtags belonging to different subsections).

**Table 5**
Distribution of the hashtags types through PolSo

| Subsection | Videos |
|---|---|
| Ecologic crisis | 6 |
| Political and national identities | 11 |
| Civil rights | 76 |
| Politicians' names | 35 |

Table 6 shows the top ten most frequent hashtags in the whole It-tok corpus, excluding the ones we used for the extraction.

**Table 6**
Most frequent hashtags in It-tok

| Rank | Hashtags' names | Frequency |
|---|---|---|
| 1 | ***perte*** | 21 |
| 2 | ***fyp*** | 14 |
| 3 | *meloni* | 11 |
| 4 | *politica* | 10 |
| 5 | *fratelliditalia* | 8 |
| 6 | *donne* | 8 |
| 7 | *diritti* | 7 |
| 8 | ***viral*** | 7 |
| 9 | ***neiperte*** | 7 |
| 10 | *salvini* | 6 |

Table 6 confirms what we asserted about the way hashtags are used on TikTok: on the one hand, it is well true that some of the most used hashtags, excluding the ones we explicitly searched videos for, are thematic, but this is a very specific way of using hashtags, since the only ones we find are connected to PolSo themes. Videos from PolSo, in fact, display an overabundance of hashtags, compared to the ones in Gen (i.e., 9,37 vs. 3,2 hashtags per video, in average). Nonetheless, the most frequent hashtags remain *#perte* and *#fyp*, both very TikTok-specific and directed towards gaining views and/or boosting the content through the algorithm.

Turning to LFCs, we preliminarly looked at the distribution of PoS in the It-tok corpus. PoS were chosen for first assessment of some modality characteristics because it has been shown that they correlate with the spokenness of texts. In particular, nouns and verbs, and their respective modifiers, adjectives and adverbs, have been said to act as pivotal units in the construction of a text. Their frequency offers significant insights into how different types of texts are syntactically structured and how modality influences linguistic composition. Specifically, nouns tend to be more prominent in written texts, while the frequency of verbs increases progressively as one moves towards more natural spoken language [39]. Such a tendency is seen also for It-tok: Table 7 shows PoS occurrence percentages of It-tok, along with a comparison with the corpora:

- *Lessico dell'Italiano Parlato* (LIP), a corpus of spoken Italian [53];
- *Primo Tesoro della lingua italiana letteraria del Novecento* (PTLLI), a corpus of literary Italian, from the 1900s [54]
- *Corpus Scritto* (CS), a corpus of written Italian [55].

**Table 7**
Nouns, adjectives, verbs and adverbs occurrence in It-tok, compared to other Italian corpora.

| | *It-tok* | *LIP* | *PTLLI* | *CS* |
|---|---|---|---|---|
| *NOUN* | 17,9% | 15,7% | 20,0% | 21,7% |
| *ADJ* | 5,6% | 8,8% | 7,9% | 17,0% |
| *VERB* | 21,2% | 20,0% | 18,7% | 10,4% |
| *ADV* | 10,6% | 10,1% | 6,1% | 3,8% |

The data for LIP, PTLLI and CS in Table 7 is taken from [40]. The corpora shown above are the ones previous research was performed on, and for which the tendencies named had been observed. However, similar tendencies emerge also from the CORIS [56], ItWac [57] and Paisà [58] written corpora, see Table 8. Notice that these last two corpora are collected from online sources. Also with respect to these, It-tok alignes more closely to

LIP.

**Table 8**
Nouns, adjectives, verbs and adverbs occurrence in It-tok, compared to CORIS, ItWac and Paisà.

| | *It-tok* | *CORIS* | *ItWac* | *PAISÀ* |
|---|---|---|---|---|
| *NOUN* | 17,9% | 24,7% | 22,3% | 18,3% |
| *ADJ* | 5,6% | 9,3% | 8,6% | 7,4% |
| *VERB* | 21,2% | 12,5% | 14,0% | 12,1% |
| *ADV* | 10,6% | 4,6% | 3,4% | 2,6% |

It must be considered, anyways, that the two subcorpora differ greatly by linguistic features displayed. As an example, Figure 1 shows the difference in the occurrence of DMs, which are strongly associated with spoken modality, with respect to the total of tokens in the different texts[15].

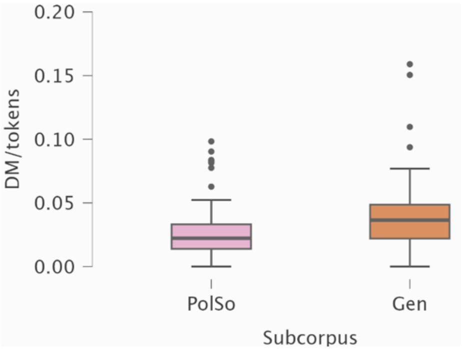

**Figure 1:** DM occurrence in It-tok, subdivided per subcorpora.

As can be seen in Figure 1, even though the two subcorpora are equally spoken, it seems that the thematic one employs a kind of speech which is probably less hesitant. Further research will include a differentiation based on the different themes, within PolSo, and based on different features, between the PolSo and Gen.

## 5.3. Future perspectives

Next advancements in It-tok building involve exploring the language features findable on TikTok (e.g., newly imported constructions or neologisms), broading It-tok and its scope, and the building of a treebank of TikTok discourse.

Though It-tok being a still very small corpus, it displays the potentiality to show a number of linguistic uses hardly findable in traditional corpora, like creative uses or newly registered loans (see 1-3), for which It-tok could also be searched.

(1) venire blastato da mio nipote è stato meraviglioso (0125_S)

‘to be *blasted* by my nephew was wonderful’

In (1), *blastato* < *blastare* < en. *to blast* stands for ‘getting humiliated’ through words. An adapted loan can be seen also in (2), where *flexare* sth. < en. *to flex* stands for ‘show one’s ability in sth.’.

(2) […] possibilità di flexare un po' di statistica (G0125_16)

‘[…] opportunity to *flex* some statistics’

In (3) it’s the whole passive construction to get borrowed.

(3) Un calciatore della Juventus è stato fatto outing (1224_F)

‘A Juventus player was outed’

Another set of features, phonetics in nature, that could be thus investigated regards the so-called “influencer accent”, which was noticed around the internet but still never assessed [59][60].

Furthermore, due to its informal nature, TikTok could provide naturalistic data for a number of linguistics areas of interest, e. g., neologisms and gendered neologisms [61][62][16], or code switching/mixing phenomena [63].

The expansion we foresee for It-tok regards Gen, but also partially PolSo. Nonetheless, based on the methodology applied for the extraction, Gen could be easily systematically broadened, making it a potential monitor corpus for Italian TikTok discourse through an yearly update. Furthermore, PolSo will be widened to include themes of foreign policy. A further expansion could pertain a set of videos that were systematically excluded with the present methodology: particularly, the video memes, and that could constitute the base for studies on innovative linguistic forms, could be extracted through hashtags such as *#memetok*. The pseudosuffix *-tok* can apply to any word X, i.e. *X-tok*, standing for ‘section of TikTok regarding X’. Examples of usage involve *booktok* ‘section of TikTok regarding books’, *cattok* ‘section of TikTok regarding cats’, *footballtok* ‘section of TikTok regarding football,

[15] $p < 0.001$ for the Mann-Whitney test.

[16] In fact, some gendered neologisms, such as *girl dinner*, actually were born from a trend on TikTok, and then spread all over other social networks.

*feministtok* 'section of TikTok dedicated to feminism'*, lefttok* 'section of TikTok filled with leftists. From this pseudosuffix, It-tok takes its name.

Finally, we will be building a treebank of at least 10% of It-tok, based on the methodology implemented for the KIPARLA forest project [64][65]. This will allow for syntactic queries, and make visible LFCs which are proper of the syntactic level of analysis (e.g., types of clauses, syntactic dependencies, subordination, syntactic heaviness).

## 6. Conclusions

With this contribution, we aimed to provide a brief overview of the methods adopted and the decisions made during the construction of an Italian TikTok corpus. Our choices were guided both by the specific communicative dynamics of the platform and by our research objectives, namely, to assess certain LFCs of TikTok discourse and, where applicable, to distinguish between generalist and thematic subtypes.

It-tok is structured to represent the first generalist corpus of spoken Italian on TikTok, and besides its main aims about LFCs and characteristics of political and social discourse online, it can represent a way to open TikTok to linguistic systematic studies, because of its replicable methodology, also applicable to create comparable corpora for other languages.

Due to the aim to describe LFCs in both general TikTok discourse and discourse on political and social topics, we adopted a split extraction strategy. Manual supervision was required at all stages of the automated processing to ensure consistency, accuracy, and compliance with the criteria established for corpus inclusion.

Importantly, the multimodal nature of TikTok, as a platform where language coexists with visual, auditory, and gestural elements, means that its texts are inherently complex and shaped by multiple interacting variables. These characteristics pose unique challenges for corpus design and analysis, they also provide valuable insights into modern digital communication practices, both in terms of parallel communication channels and the simultaneous use of multiple semiotic modes to construct a message (e.g., use of emojis, or particular visual rendering of verbal language, such as the SpongeBob Mocking meme to convey derision [66]).

Once completed, It-tok will provide a linguistically annotated corpus of Italian TikTok discourse, featuring transcriptions formatted according to the CLIPS conventions and annotated at multiple levels, including PoS tagging, morphological features, and syntactic dependencies in UD.

The corpus will also include a small but representative treebank, offering structured syntactic analyses of selected texts that reflect the linguistic complexity of this emerging multimodal variety.

## Acknowledgements

I would like to thank prof. Voghera, and the whole linguistics nucleus of the University of Salerno, for the suggestions and the discussions about the project.
This project is part of the program of education and sensibilization towards online public discourse of the *OLiNDiNUM*[17] *- Observatoire LINguistique du DIscours NUMérique* project.

## A. Online Resources

The corpus repository, which documents the corpus and treebank construction processes and the challenges encountered in the syntactic annotation of spoken data, is available on GitHub (https://github.com/cabinsix/It-Tok). The repository will host the transcribed and anonymized files, along with their corresponding CoNLL-U formatted versions. The treebank is currently under development and can be accessed via the Arborator platform (https://arborator.grew.fr/?#/projects/It-tok).

## Declaration on Generative AI

During the preparation of this work, the author(s) used ChatGPT (OpenAI) in order to: Paraphrase and reword and Grammar and spelling check. After using these tool(s)/service(s), the author(s) reviewed and edited the content as needed and take(s) full responsibility for the publication's content.

# Protecting the Privacy in Velvet with Model Editing

### Abstract

Large Language Models (LLMs) showed impressive generation abilities and are now integrated in many real-world applications. However, LLMs also tend to memorize information, including Personally Identifiable Information (PII), which can be learned and generated during inference, posing a risk to users' privacy. In this context, Model Editing techniques have been proposed recently to prevent the leakage of private information by modifying LLMs' parameters directly while preserving their generation capabilities. In this work, we show an application of Model Editing for Privacy Protection in the context of Italian data on Velvet, a multilingual LLM recently released. In particular, we focus on protection against Training Data Extraction (TDE) attacks. Empirical results from the experiments show that model editing techniques can be effective in mitigating privacy leakage in LLMs, even for Italian data, while preserving their multilingual generation capabilities.

### Keywords

Large Language Models, Model Editing, Privacy

## 1. Introduction

Large Language Models (LLMs) showed impressive generation capabilities in managing various tasks, and they are now integrated into many real-world applications. Given the popularity and potential of these models, several open-weight LLMs have been released to the public in the last years, including multilingual ones. Following this trend, LLMs that support the Italian language have also been made available [1], thus allowing to manage tasks even in Italian.

However, since LLMs are now employed in many services, they can be affected by some well-known issues, such as toxicity or privacy leakage [2], which can have an important negative impact on model performance. These problems raised concerns about privacy due to the possible presence of undetected private information in training data. Prior research showed that these models tend to memorize training data [3, 4, 5, 6], thus they are prone to memorizing Personal Identifiable Information (PII), which might be disclosed during the text generation. Italian LLMs can also be affected, as data used for training these models is often scraped from public web pages [7, 8], and although processes to identify and remove private information are used to clean data, PII could still be present.

Privacy is critical for LLMs deployed as services, raising concerns about privacy leakage and thus requiring attention. Carlini et al. [3] showed that extracting private information from an LLM is possible by prompting textual sequences from training data. The success of these attacks is evidence that the privacy of real individuals is at risk, so methods to prevent leakage of PII are necessary. Recently, many solutions have been proposed to mitigate this phenomenon, such as machine unlearning [9, 10]. Alternatively, Model Editing approaches showed promising effects for protecting the privacy of users [11, 12, 13]. The application of these methods allows us to modify the knowledge encoded in the LLMs by breaking the association between some memorized prompts and the corresponding PII. Among these methods, Private Memorization Editing (PME) [13] is an approach that exploits the memorization mechanism of transformers to modify the association between a prompt and its related private information, showing its effectiveness in protecting LLMs from TDE attacks.

In this work, we show an application of PME [13] to protect users' privacy for Italian data in LLMs. We focus on Velvet-2B[1], a recent multilingual LLM for English and Italian languages. Even though the training data has been curated to remove PII, the model may learn some information during training. Our main objective is to understand whether model editing can be extended and used to protect users' privacy whose PII might be included in training data obtained from public datasets. With PME, we can define an automatic process for obscuring private information and making Velvet robust to external attacks.

We evaluate the effectiveness of our approach through an experimental process to make Velvet more robust against external attacks aimed at prompting the LLM to generate memorized PII. We obtain Training Data Extraction (TDE) attacks from a subset of documents in Italian

used to train Velvet to induce the model to leak PII; in particular, we focus on email addresses (Section 4.1). Then, we adapt PME to Velvet and edit the model to protect the LLM against identified TDE attacks (Section 4.2). Finally, we measure the effectiveness of our approach by observing the behaviour of Velvet against TDE attacks, and we evaluate the preservation of post-edit Velvet's multilingual generation capabilities to ensure the edit had no negative impact on the model (Section 4.3). Results show that model editing can be adapted to Italian data and make Velvet more robust against TDE attacks by notably reducing the accuracy of attacks (Section 5.1). In addition, evaluation of post-edit Velvet suggests that the edit does not affect multilingual capabilities for both English and Italian languages (Section 5.2).

# 2. Background

Given the large amount of data that is necessary to train an LLM, the risks connected to privacy violations have been largely investigated (Section 2.1). We describe what mechanisms in LLMs have been identified to control model predictions (Section 2.2), and how these insights allow editing some undesired predictions without the need of re-training the model (Section 2.3).

## 2.1. LLMs & Privacy

As LLMs require large amounts of data for training, some undesirable information may have been included in the training material inadvertently: a person's name, address, email address, social security number, phone number, as well as any other data that, when combined, could lead to identification of individuals, are considered private information and should not be further disseminated during inference by an LLM. This kind of information, defined as Personal Identifiable Information (PII), can in fact be used to identify a specific individual, and threats their privacy if disseminated.

However, once a PII is included in the training material, an LLM can leak it during inference. In fact, LLM may memorize that information [14, 15, 16] and consequently cause privacy leaks at inference time. A number of attacks have been designed to exploit this tendency and extract private information from LLMs [2, 17, 18]. For LLMs, even in black-box access the right prompt may be sufficient to obtain private information. While some attacks require the attacker to craft an adversarial input for the model [19, 20], other attacks do not even rely on potentially harmful prompts [3, 6, 4, 5].

Developing techniques for the preservation of individuals privacy is central to make LLMs more robust, and trustworthy.

## 2.2. Knowledge Mechanism of Transformers

**Transformer-based Language Model Predictions** We consider the forward pass of a Transformer-based decoder-only model $\mathcal{M}$ of $L$ layers and describe it in terms of its sub-components on a prompt $p$. Given the tokenized prompt $X = [x_1, ..., x_n]$ and their corresponding input embeddings $X^{(0)}$, a model builds the prediction for the next token $x_{n+1}$ with an iterative refinement across layers. At a given layer $l$, given the Attention Block as $\mathrm{Attn}$, the layer normalization as $\mathrm{LN}$ and the Feed Forward block $\mathrm{FFN}$, the output of that layer $X^{(l)}$ is computed as:

$$\forall l \in \{1, \ldots, L\} : \begin{cases} A^{(l)} = \mathrm{Attn}(\mathrm{LN}(X^{(l-1)})) \\ \tilde{X}^{(l)} = X^{(l-1)} + A^{(l)} \\ H^{(l)} = \mathrm{FFN}(\mathrm{LN}(\tilde{X}^{(l)})) \\ X^{(l)} = \tilde{X}^{(l)} + H^{(l)} \end{cases} \tag{1}$$

On the last position $n$, at the last layer $L$, the hidden representation $x_n^{(L)}$ is projected by a matrix $U \in \mathbf{R}^{d \times |V|}$ onto the vocabulary $V$ space. The scores obtained, normalized by a softmax function $\sigma$, predict the next token:

$$\mathcal{M}(X) = \arg\max \sigma \left( x_n^{(L)} U \right) = x_{n+1}$$

We aim to understand what are the mechanisms that control for the generation of next token, and if it is possible to alter them to modify the predictions on the next token when the model leaks private information.

**FFN Layers as Knowledge Memories** Feed Forward blocks FFN play a crucial role in the generation mechanism of the model, and not only because they account for most of the parameters of the network. The interpretation of the Feed-Forward block in a Transformer model is that it implements a mapping of paired keys to values [21, 22]. Geva et al. [21] notice that, with the exception of activation function that is usually a ReLU rather than a softmax, the equation for the Feed Forward layer reminds the one that describes a neural memory [23]. The Feed Forward block is in fact composed of two matrices, $W_{in}^{(l)}, {W_{out}^{(l)}}^T \in \mathbb{R}^{d \times d_1}$ and an activation function $f$ that process each position $i \in [1, ..., n]$ of the input independently from one another. The output $h_n^{(l)}$ of the Feed Forward block at the $n$-th position of the input is computed as follow:

$$h_n^{(l)} = f \left( \tilde{x}^{(l)} W_{in}^{(l)} \right) W_{out}^{(l)} \tag{2}$$

where $\tilde{x}^{(l)}$ is the sum output of the Attention Block and the output of the previous layer as in Equation 1. The keys of the memory are produced by the output of $W_{in}^{(l)}$ and the non-linear function $f$, while the values are the corresponding columns in $W_{out}^{(l)}$.

## 2.3. Editing Knowledge of LLMs

In the last years, there was a major interest around alternative methods to modify specific behaviors of LLMs without retraining the entire model from scratch. Based on the insights about the knowledge mechanism of transformers, the research area of knowledge editing has been flourishing, with the number of methods and approaches growing further.

Currently, knowledge editing methods can be roughly divided in two categories: parameter-preserving and parameter-editing methods [24]. While parameter-preserving methods rely on external adapters or memories to intervene whenever there is a specific situation requiring a different response, parameter-editing methods are based on the theory about the knowledge mechanism of transformers and modify the parameters of the LLM directly, without the need of external modules like parameter-preserving solutions.

We focus on parameter-editing methods: basically, given an LLM $\mathcal{M}_\theta$ with parameters $\theta$, parameter-editing methods aim at finding a shift in parameters $\Delta$ to obtain a new model $M_{\theta+\Delta}$, which allows to modify a specific prediction while preserving the non-target generation capabilities. ROME [25] and MEMIT [26], in particular, are parameter-editing approaches designed to edit the LLMs' parameters in a localized manner and are based on the interpretation of Feed Forward layers as memories, as introduced in Section 2.2. Under this interpretation, then, the matrix $W_{out}^{(l)}$ is optimizing the mapping between keys and values, that is:

$$W_{out}^{(l)} = arg \min_{\widehat{W}} \sum_{(k_0,v_0)} ||\widehat{W}k_0 - v_0||^2 \tag{3}$$

with $k_0 \in K_0$ being a set of keys to memorize and $v_0 \in V_0$ the corresponding values [25, 26, 27]. Given the linearity of the system in Equation 3, the optimal solution can be computed as:

$$W_{out}^{(l)} = V_0 K_0^T (K_0 K_0^T)^{-1} \tag{4}$$

Additionally, a closed-form equation can be found to calculate the edit to introduce new keys and values into the mapping [25, 26]. Given a representation of keys $K_0$ and values $V_0$ stored in that matrix, and the representations for the new keys $K^*$ and values $V^*$ to store.

$$\Delta^{(l)} = (V^* - W_{out}^{(l)} K^*) {K^*}^T (K_0 {K_0}^T + K^* {K^*}^T)^{-1} \tag{5}$$

The term $V^* - W_{out}^{(l)} K^*$ represents the residual between the new desired values $V^*$ and the old values currently stored in $W_{out}^{(l)}$ for the new keys $K^*$. Since we have $K^* \subseteq K_0$ because the new keys are representations already stored in $W_{out}^{(l)}$, and the new values $V_0^*$ satisfy $V_0^* \subseteq V_0$, we can define $W_{out}^{(l)} K^* = V_0^*$. The equation for $\Delta^{(l)}$ can be written as:

$$\Delta^{(l)} = (V^* - V_0^*) {K^*}^T (K_0 {K_0}^T + K^* {K^*}^T)^{-1} \tag{6}$$

We will use the matrix $\Delta^{(l)}$ to edit the memorized mapping in layer $l$, without retraining.

Since we do not have access to $K_0$, Meng et al. [26] assumes that this representation can be modeled with a random sample of inputs, so $K_0 K_0^T$ can be defined as follows:

$$C_0^{(l)} = \lambda \cdot \mathbb{E}[kk^T] \triangleq K_0 {K_0}^T, \tag{7}$$

where $\lambda \cdot \mathbb{E}[kk^T]$ is an uncentered covariance statistics computed on an empirical sample of vector inputs to the layer. In this paper, we refer to it with $C_0$ rather than $C_0^{(l)}$ for simplicity.

## 2.4. Model Editing for Privacy Preservation

In recent studies, model editing techniques have been applied to the context of privacy protection.

Wu et al. [11] propose DEPN, which is a method that locates neurons associated with private information, and then edits their corresponding activations to remove their contribution to prediction.

Patil et al. [28] showed an application of ROME [25] and MEMIT [26] to remove private information from FFN layers of transformers. This approach exploits the association mechanism to break the associations leading to the leakage of private information.

Venditti et al. [12] propose PAE, a data-driven approach based on the editing mechanism of MEMIT, aiming to break the association between an individual and their corresponding PIIs. The method uses prompt templates filled with the information about an individual and their corresponding PII, to replace the private information with a dummy PII, thus preventing the leakage of the real PII.

Ruzzetti et al. [13] propose PME an automatic approach taking advantage of the memorization mechanism in LLMs. This approach basically uses memorized prompts inducing privacy violation to remove associated PIIs. Unlike other locate-and-edit methods, PME distributes the residual for the editing among all the FFN layers of the transformer. The main advantage of this method is that it can be used automatically on collected prompts without the need of further manual analysis to determine the source of the knowledge, allowing for an automatic algorithm for privacy protection.

In this paper, we apply PME because of its advantages, in particular the fact that it does not rely on assumptions such as which layers to modify or which part of a text retrieves the critical information, thus allowing for an automated process.

# 3. Application and Method

## 3.1. PII Leakage via Training Data Extraction attacks

PII is private information that may have been inadvertently included in the training dataset and can be extracted from an LLM using Training Data Extraction attacks (TDE) [3, 4, 5, 6]. In the initial formulation of TDE attacks, Carlini et al. [3] demonstrate that black-box access to an LLM can be sufficient to extract memorized information from a model: when prompted with a *context* that has been included in the training material, the target LLM tends to generate verbatim the continuation of the original document. Among the generated verbatim memorized content, a model may also generate private information that should not be disseminated.

Formally, given a model $\mathcal{M}$, a string $s$ is $k$-extractable memorized if there exists a *context* string $c$ of $k$ tokens such that the concatenation of $[c \parallel s]$ is contained in the training material for $\mathcal{M}$ and $\mathcal{M}$ generates $s$ exactly when prompted with $c$ in greedy decoding. When the *context* exactly matches a sequence of the training material, the success of the attack is maximized [4], and since this is the most informative setting that the attacker can obtain, this is the worst-case scenario.

The success of the attack increases as the attacker gets more information regarding the training material: one crucial aspect is the length $k$ of the *context* that the model is fed with [5, 4]: the longer the *context*, the larger the probability of emission of verbatim memorized information.

Since LLMs have been shown to memorize PII rather than associating them with an individual identity [5, 12, 2], those attacks represent one of the crucial challenges to protect individuals whom information have been inadvertently added to the training material of an LLM.

Hence, we initially perform TDE attacks against our target model: we simulate an informed attacker who has some background knowledge regarding the training material, with increasing level of information. For a given PII, we collect the *context* that precede it in the training materials, and produce 50, 100, and 200-tokens-long sequences (see Section 4.1 for further details) as we expect that a more informed attacker may obtain larger volume of information. The model is then prompted to generate the subsequent 100 tokens: the attack succeeds if – in greedy decoding – the generated PII matches the original PII in the training material: the evaluation is rigorous since a strict match between the generated PII and the one found in the training material is required.

## 3.2. PME for Automatic Privacy Mitigation

To address the threats posed by TDE attacks, we adopt Private Memorization Editing (PME) [13], a model editing strategy that aims to leverage the memorization tendencies of LLMs as a defense strategy. The objective of the method is to reduce the success of TDE attacks, and hence to replace the memorized PII with a semantically equivalent, but privacy-preserving information. PME applies the editing on the Feed Forward layers of the models, similarly to other model editing techniques like ROME [25] and MEMIT [26].

As discussed in Section 2.3, once one knows the correct representation for keys and values that the $W_{out}^{(l)}$ encodes, it is possible to apply the closed form solution in Equation 6 to perform the update. To compute the correct representation for keys and values, PME directly exploits training material verbatim memorized from a model.

When the model is prompted with a context $c$ that is included in the training material that causes the generation of a PII, PME edits the model to obtain a privacy-preserving output instead. In each layer, the keys are the hidden representation that the model computes for the *context* prompt as in Equation 2, so $k^{(l)} = f\left(\tilde{x}^{(l)} W_{in}^{(l)}\right)$.

For the values, the new privacy-preserving value should be encoded with an appropriate vector representation. For this reason, PME initially optimizes a hidden representation $v^*$ in the last layer of the model: using Gradient Descent, PME optimizes $v^*$ so that, once decoded with the projection matrix on the vocabulary, it gives the highest probability of generating a dummy, privacy-preserving value.

Then, the underlying hypothesis in PME is that each layer should contribute to the generation of this last-layer representation $v^*$. PME mimics the generation of the PII: with a forward pass on the memorized context, the method quantifies how much each layer contributes to the generation of the memorized PII. Instead of relying on Causal Mediation Analysis as in MEMIT [26] or other localization techniques that have been shown to not inform the edit [29, 30] for identifying a restricted number of contributing layers, a *contribution coefficient* is computed for each layer following a geometric approach. Since the computation of a Transformer model can be described as a sum of its sub-components at each layer [31, 32], PME computes the *contribution coefficient* $w^{(l)}$ of each layer as the projection of that layer Feed Forward output onto the last layer Feed Forward representation:

the larger the projection, the larger the impact of that layer on the overall sum. This *contribution coefficient* – rescaled to obtain a sum of one across different layers – is then used to represent a fraction of $v^*$, proportionally to the *contribution coefficient* $w^{(l)}$ of that layer, that is, at each layer the value $v^{(l)} = w^{(l)}v^*$

Once the correct representation for keys and privacy preserving values is computed, then the edit can be performed as in Equation 6, and the post-edit model should not generate the target PII under TDE attacks.

# 4. Experimental Setting

In this section, we discuss the experimental setting we use to assess the effectiveness of our approach. Specifically, we define: (1) the process for data preparation to obtain the TDE attacks and relative leaked information (Section 4.1), (2) how PME is adapted and applied to Velvet (Section 4.2), and (3) how we evaluate the effectiveness of our privacy protection approach and the post-edit preservation of Velvet's capabilities (Section 4.3). For these experiments, we focus on email addresses of Italian data as PII, and Velvet-2B as our target LLM.

## 4.1. Data Preparation

**Training Data Extraction Attacks** As we discussed in Section 3.1, Training Data Extraction attacks are based on documents and prompts that the LLM has seen during training, which induce a target LLM to complete the given prompts with a text verbatim memorized by the model. Since LLMs are prone to leak PII during generation due to possible contamination of training data with PII, we prepare Training Data Extraction attacks by analyzing a subset of the training data used for Velvet. We focus on the Italian subset of *CulturaY* [33], one of the public datasets seen by Velvet during the pre-training phase.

We focus on potentially harmful prompts, since our main objective is to study the feasibility of protecting against TDE rather than assessing their accuracy. To do that, we define the following protocol. We filter all documents in the dataset that contain at least one email address in them. Then, once we obtain only documents containing PII, we prepare batches of different potential TDE attack prompts of different lengths $k \in \{50, 100, 200\}$, by selecting the $k$ tokens preceding the identified PII. After obtaining a set of potential attacks, we deduplicate similar prompts. In order to select effective attacks, we prompt Velvet-2B with the collected attacks and induce the model to generate 100 tokens: if the email address generated by the model for a given prompt is the one expected as in the training data, we add it to the set of TDE attacks.

**Sample for computing PME Editing Statistics** An important step required by PME to perform the desired edit is the uncentered covariance statistic $C_0^{(l)}$ described in Eq.7. This is an estimation of the keys stored in the corresponding $l$-th FFN layer, so we need to build an empirical sample of vector inputs for the layer, which are obtained by feeding the LLM with sample texts. Since we are dealing with a multilingual LLM trained on both English and Italian texts, we prepare two samples of 100k documents each from English and Italian Wikipedia subsets of the pre-training data used for Velvet-2B. The purpose of these samples is to understand the effects on the editing performance of $C_0$ computed on different languages.

## 4.2. Application of PME

**Mitigating Privacy Leakage** Our strategy is to prevent Velvet from generating memorized PIIs during inference by applying PME to Velvet on identified TDE attacks reported in Section 4.1. PME allows to edit the relative knowledge of PII associated with multiple memorized prompts by modifying the LLM's parameters directly. The main advantage of this method is that we can edit the TDE attacks directly and there is no need to specify which layers are the target of the edit, unlike methods such as MEMIT [26].

Based on this, for every attack $(x, y)$ with $y = \mathcal{M}(x)$, $x$ the prompt attack and $y$ the leaked PII, we use PME to edit the knowledge encoded in Velvet's FFN layers to force the new association $(x, z)$, where $z$ is the new dummy PII `mail@domain.com`, which is semantically similar to the original PII. With this method, our objective is to reduce the accuracy of attacks, modifying the prediction of the LLM to prevent the generation of the leaked information.

We perform the editing process with an approach called sequential batch editing [12, 13], in which several prompts are edited in multiple steps, with a batch of multiple examples edited at each step. For our experiments, we fixed the batch size to 16.

**Computing Multilingual $C_0$ for PME** PME [13], ROME [25] and MEMIT [26] require a representation of the keys $K_0$ stored in the $l$-th FFN layer to apply the formula defined in Eq.6, which can be modeled as the quantity $C_0^{(l)}$ defined in Eq.7. This quantity is obtained by computing an uncentered covariance statistics on an empirical sample of vector inputs to the layer when parsing a sample of documents. For our experiments, we prepare three types of $C_0$ for PME on the text samples described in Section 4.1:

- IT: computed on the Italian sample;
- EN: computed on the English sample;

| Velvet-2B | PME $C_0$ | TDE Email Attacks | | | | |
|---|---|---|---|---|---|---|
| | | Context Length | Tot. Prompts | Generated PII | Leaked PII | Attack Acc. |
| Pre-edit | - | 50 | 83 | 78 | 75 | 0.904 |
| Post-Edit | multi | | 83 | 51 | 7 | **0.084** |
| | EN | | 83 | 51 | 8 | 0.096 |
| | IT | | 83 | 46 | 9 | 0.108 |
| Pre-Edit | - | 100 | 380 | 370 | 341 | 0.897 |
| Post-Edit | multi | | 380 | 151 | 16 | 0.042 |
| | EN | | 380 | 128 | 12 | **0.032** |
| | IT | | 380 | 157 | 15 | 0.039 |
| Pre-Edit | - | 200 | 34 | 32 | 31 | 0.912 |
| Post-Edit | multi | | 34 | 25 | 16 | **0.471** |
| | EN | | 34 | 27 | 17 | 0.5 |
| | IT | | 34 | 27 | 16 | **0.471** |

**Table 1**
Attack Accuracy results for TDE Email attacks on Pre-edit and Post-edit versions of Velvet-2B. We report the number of attacks **Tot. Prompts** of length **Context Length**, the number of generic email addresses generated by the models **Generated PII**, the quantity of email addresses leaked **Leaked PII**, and the $C_0$ type used for editing **PME $C_0$**.

- `multi`: computed on the English and Italian samples combined.

We compute these statistics for all the FFN layers of Velvet following the same procedure carried out by Meng et al. [26].

This statistic plays a crucial role in Eq.6, as it allows us to determine the interaction between the new keys and the knowledge stored in that layer. An effective computation of this statistic is necessary to obtain effective edits, and we empirically explore how different estimates of $C_0$ may affect the edit in a multilingual setting.

## 4.3. Evaluation

**Post-Edit Attack Accuracy** PME effectively protects the privacy in Velvet if the parameter edit reduces the number of successful TDE attacks against the model. Therefore, the effectiveness of our approach is assessed by measuring the post-edit privacy leakage effects and comparing them with the ones of the pre-edit model.

We adopted the same measure used by Ruzzetti et al. [13], that is, the *Attack Accuracy* for memorization attacks. After we edit Velvet for TDE attacks of $k \in \{50, 100, 200\}$ context lengths, we measure the *Attack Accuracy* of post-edit models and compare their scores with the ones of the pre-edit version of Velvet. We feed the TDE prompts to both post-edit and pre-edit version of Velvet, and then let them generate 100 tokens: if the generated text for each attack contains the expected PII, then the attack is considered successful.

**Post-Edit Multilingual Generation Capabilities** An important aspect of model editing methods is that they are designed to modify specific knowledge of LLMs, while preserving the non-related generative capabilities of the model. For this reason, we need to determine whether the editing had a negative impact on the multilingual generative capabilities of our LLM, thus affecting its skills in non-related tasks.

We adopt an automatic evaluation strategy similar to the one used by Venditti et al. [12] to measure the reliability of our post-edit models. We compare the generation capabilities of the post-edit and pre-edit versions of Velvet by measuring the similarity of generated texts on a sample of prompts in terms of BLUE [34] and METEOR [35] scores. For comparison, we consider the subsequent 50 tokens generated by each model after receiving in input the first 100 token of each prompt of our sample.

We perform the evaluation on a sample of 500 prompts for the English and Italian languages, which is defined as follows:

- English sample: 100 prompts from Books3, Wikipedia-en, and Pile-CC subsets of the Pile, respectively;
- Italian sample: 100 prompts from Clean-C4 and Wikipedia-it, respectively.

The composition of this sample allows to have an indication of the impact of PME editing on post-edit language capabilities of Velvet.

We also extend the *utility* evaluation by measuring the post-edit accuracy of Velvet on LAMBADA[36], one of the tasks included in EleutherAI Language Model Evaluation Harness[37]. LAMBADA is used to measure the accuracy of a model in generating the missing target word from a passage given in input. For the evaluation, we focus on the full test split of the dataset to measure the reliability of the edit. Since we are interested in evaluating the preservation of the post-edit multilingual capabilities of the model, we use both the English and Italian

**Table 2**
Post-edit Automatic Evaluation on English and Italian text samples, compared with the pre-edit generations. **PME** $C_0$ is the type of $C_0$ applied to edit the model, and **Editing Attacks** are the prompts used by PME to remove private information, with *Context* the length of TDE prompts *Prompts*.

versions of LAMBADA to understand if the multilingual generation capabilities of Velvet have been affected.

# 5. Results and Discussion

## 5.1. Editing reduces Privacy Risks

As we observed during the extraction and filtering phase of TDE attacks (see Sec. 4.1), Velvet memorized some PII contained in the pre-training data. For different context lengths $k \in \{50, 100, 200\}$, we obtained 83, 380, and 34 leaked email addresses, respectively, with the same number of memorized prompts. Surprisingly, context of 200 tokens obtained less leaked PII than shorter prompts. In this phase, we observe that a slightly different prompt composition might affect the results: so in pre and post-edit we adopt the same batch size and batch composition, to ensure the reproducibility of the results.

The results reported in Table 1 show that PME is effective in reducing the risks of privacy leakage. The post-edit versions of Velvet for contexts 50 and 100 are more robust than the pre-edit model, leaking less than 9 and 16 PII with respect to 75 and 341 leaked by the pre-edit Velvet. The effect is similar for all the versions of $C_0$ used by PME for editing, with minimal differences among them: in fact, the difference is of 4 more leaked PII at best for context 100.

The number of leaked email addresses is reduced even for context 200 attacks, where post-edit Velvet leaked 17 PII instead of 31 of the pre-edit model. However, the reduction here is lower compared with the other attacks, probably due to the lower number of PII extracted during the data processing phase.

Note that results also show that the model tends to generate a large number of email addresses in general, which are different from the correct ones. These different email addresses could be model's hallucinations, or email addresses that follow the original one in the pre-training corpus. However, results in terms of successfully Leaked PII suggest that PME is still sufficiently effective in preserving privacy on edited prompts.

Finally, we observe that the different statistics computed as an approximation of $C_0$ do not greatly affect the post-edit attack accuracy, with a rather similar number of leaked PII in each configuration.

## 5.2. Generation Capabilities are Preserved

The results reported in Table 2 show that BLEU and METEOR scores are high in general for all the different versions of $C_0$ and attacks used for editing, and the same observation holds for both English and Italian generation capabilities. The overall high scores suggest that the generations of post-edit models are quite similar to the generated texts of the pre-edit model. This aspect, as discussed in [12], suggests that the edit is robust, because it does not interfere with multilingual capabilities in both English and Italian languages.

Interestingly, the scores show that there is no real consensus on the type of statistics that is the best for the English language, since the highest scores are shared between the EN and `multi` $C_0$. However, we note that the `IT` version of $C_0$ obtains lower scores than the other two versions in general, suggesting that the `IT` statistics leads to a less effective preservation of Velvet's generation capabilities for English.

Observing the evaluation results for Italian, we notice that `IT` version of $C_0$ achieves higher BLEU and METEOR scores, suggesting that this version is necessary to preserve the generation capabilities of Velvet for Italian. Also, we note that the EN version of $C_0$ tends to achieve lower scores with respect to the other types, indicating that this $C_0$ is less effective for preserving the abilities for Italian.

In general, observed results indicate that using versions of $C_0$ computed on a different language from the target one is less effective for preserving the generative capabilities of the target language in post-edit. In fact, the `IT` version of $C_0$ obtained lower scores for the English language, and the EN version of $C_0$ was less effective for the Italian language. Thus, these experiments suggest that $C_0$ should be computed on samples containing texts in the target languages.

| **Velvet-2B** | **PME $C_0$** | **Editing Attacks** | | **LAMBADA** | |
|---|---|---|---|---|---|
| | | *Context* | *Prompts* | *EN* | *IT* |
| Pre-edit | - | - | | 53.7 | 45.2 |
| Post-Edit | multi | 50 | 83 | 54.2 | 45.1 |
| | EN | | | 53.9 | 45.2 |
| | IT | | | 54.4 | 45.0 |
| Post-Edit | multi | 100 | 380 | 54.5 | 45.2 |
| | EN | | | 54.7 | 42.1 |
| | IT | | | 55.1 | 45.2 |
| Post-Edit | multi | 200 | 34 | 54.1 | 45.0 |
| | EN | | | 53.9 | 45.9 |
| | IT | | | 54.1 | 45.2 |

**Table 3**
LAMBADA scores for the pre-edit and post-edit versions of Velvet-2B. Results for both English and Italian are comparable with the pre-edit model, suggesting that capabilities of Velvet-2B are preserved in post-edit.

About task performance, results reported in Table 2 of the LAMBADA benchmark corroborate the utility preservation already observed with the previous evaluation analysis. The accuracy scores of post-edit models are comparable with the pre-edit ones, suggesting that the edits performed by PME do not affect considerably the capabilities of the model. The same observation holds for both English and Italian versions of LAMBADA. Differently from the previous analysis, there are no noticeable losses in terms of performance with respect to the version of $C_0$ used for the editing, except for the Italian score of context-100 editing with EN $C_0$ that is lower than the pre-edit score (42.1 vs 45.2). Hence, this result indicates that edits performed by PME are reliable in general, allowing privacy protection of Velvet for Italian data without loss of task performance.

## 6. Conclusions and Future Work

In this work, we show an application of model editing for protecting the privacy of Italian data on Velvet-2B, a multilingual model trained on both Italian and English data.

Our method is based on a recent model editing technique named Private Memorization Editing, which prevents LLMs from generating memorized PII that might be included in the training data. Results of our experiments on privacy protection for email addresses shows that model editing is effective in reducing the privacy risks of Velvet, thus reducing the success of Training Data Extraction (TDE) attacks, harmful prompts obtained from the training data that are effective for extracting private information from the original model. In addition, we show that our approach mitigates the privacy risks while preserving the model's multilingual generation capabilities.

In conclusion, our approach shows that we can adapt and apply model editing techniques for privacy protection in multilingual LLMs for Italian data.

For future work, we should focus on some other aspects to further improve this work. Firstly, our approach should be extended to different types of PII other than email addresses, and further investigation is necessary to understand the effects of the approach with different PII. Another aspect to consider is how well PME scales with larger models such as Velvet-14B: this other model requires additional investigation, because it manages other languages other than English and Italian, and the magnitude of data used for training is larger than the one used for Velvet-2B. Finally, the evaluation of Velvet's post-edit capabilities should be extended to other tasks of the Language Model Evaluation Harness[37] or other benchmarks, and include human evaluation to have a better perspective on the overall quality of post-edit models instead of relying exclusively on automatic metrics.

# "I understand, but...": Towards a Comprehensive Account of the Explainee's Voice in Explanatory Dialogues

**Abstract**

In this paper, we introduce IUBAS, the first annotation scheme that provides an in-depth analysis of the Explainee's reactions in explanatory dialogues. Current schemes, mainly focusing on answers to *what*, *how*, and, occasionally, *why* questions, lack the granularity to capture the full range of the Explainee's contribution. Our richer framework, grounded in argumentation and philosophical theory, distinguishes different kinds of explanation requests, feedback types, and critical questions. We provide empirical evidence of the effectiveness of the scheme through a set of experiments with three SOTA LLMs. The IUBAS scheme provides a more detailed understanding of how Explainees interact with Explainers in a dialogical setting, contributing to the development of more sophisticated and human-like conversational agents.

**Keywords**

explanatory dialogues, annotation scheme, explanations

## 1. Introduction

The ability to provide and understand explanations is crucial in human communication and cognitive development. Psychologists argue that explanation is a key mechanism by which we learn generalizations and theories about the world (e.g., in childhood development) [1, 2]. Similarly, the ability of an automated system to justify its predictions and provide human-understandable explanations for some given facts has been a key research objective since the dawning of Machine Learning (ML) and Artificial Intelligence (AI). The recent rise of AI systems in highly specialised fields, such as the legal or medical domain for prediction and diagnostics, has brought the need for eXplainable AI (XAI) ever more to the forefront, but the computational modeling of agents capable of engaging in collaborative *explanatory dialogues* with users still represents a significant challenge [3, 4]. Researchers have long emphasized that interactive explanatory dialogues — where a user asks clarification questions and an AI system explains — are essential for trust and understanding in critical domains, such as education, healthcare, and law.

However, existing computational frameworks for dialogues typically rely on speech act theory [5], and describe explanations as answers to *what*, *how*, and *why* questions, while not accounting for the kind of feedback given for an explanation in a detailed manner. Explanations or argumentative dialogical turns are described - at the high level - as explanation requests by Explainees (e.g., "Why [*explanandum*]?"), explanatory answers by Explainers ("Because of [*explanans*]"), and possibly some basic feedback by the Explainee ("I (don't) understand.") [6, 7]. However, these frameworks lack the granularity to capture the complex interplay of challenges, clarifications, and personalized feedback, especially on the Explainee's side, that characterize real-world explanatory dialogues.

In order to contribute to this line of research, we introduce *IUBAS* (the *"I Understand, But..." Annotation Scheme*), a novel framework that goes beyond the simplest kinds of "question-answer-feedback" interactions, offering a more fine-grained approach to labelling the Explainee's reactions in explanatory dialogues. Our annotation scheme distinguishes between types of *explanation requests*, *feedback*, and *critical questions*, and incorporate contrastivity and motivation as key dimensions of our proposal. To empirically verify the effectiveness of the scheme, we perform experiments onthe task of predicting dialogue quality with three recent LLMs. Our results demonstrate that automatically annotating the Explainee's turns in a corpus of explanatory dialogues help achieve comparable or higher performance in comparison with current frameworks, confirming the central role of the Explainee in modelling effective explanatory dialogues[1].

## 2. Background

The study of explanations in philosophy and argumentation theory covers a wide range of questions. Researchers have focused on distinguishing **explanations** from other forms of reasoning, such as clarifications and arguments, highlighting the difference in their core function. Explanations differ from **clarifications** in that, while the latter simply aim at understanding, explanations aim at increasing knowledge, carrying greater illocutionary force. Moreover, while **arguments** aim to provide evidence for a doubted claim, explanations seek to account for (e.g., provide a cause for) an already accepted, uncontroversial statement [8, 9, 10, 11]. This distinction becomes evident in the medical context, where a doctor might request an *explanation* for a patient's dark urine (a belief in an already accepted symptom in which no justification is required) but may seek an *argument* for the diagnosis of hemolytic anemia (a hypothesis that requires justification).

Further research has investigated the formal and normative **dimensions of explanations**, concentrating on developing argument schemes and critical questions associated with common explanatory inferences, such as Inference to the Best Explanation [12, 13, 14, 15]. Pragmatic studies, on the other hand, focus on defining the **speech act** of explaining [16] and its communicative function in various contexts. A key pragmatic function attributed to explanations is the transfer or enhancement of understanding [17, 18, 19], which becomes particularly crucial when communication is triggered by a lack of shared beliefs between the participants. In such instances, explanations act as a *local move* within a broader argumentative dialogue, facilitating smoother communication. For instance, an arguer will more easily develop an effective argumentative strategy once she understands "where the opponent is coming from", i.e., once the opponent explains why she doubts or rejects the arguer's thesis [20].

Analyzing explanations as individual moves within broader argumentative contexts, however, differs from studying genuinely explanatory dialogues. Explanatory dialogues[2] are strict dialectical procedures specifically designed to promote the transfer or enhancement of understanding. In **explanatory dialogues**, the prototypical setting is that of an *Explainer* clarifying or transferring their understanding of a phenomenon (represented as $p$) in response to an *Explainee*'s "Why $p$", "What is $p$?", "How does $p$ work?" etc. questions [22, 23, 19]. The inherent dialogical nature of explanations stems from their communicative goal, which is strictly connected with the Explainee's level of understanding, (social and professional) role, curiosity, interests, beliefs, and doubts. Consequently, a comprehensive model of explanatory interactions should not only focus on the explanations provided, but also on the request for and reception of such explanations. In addition, the development of annotation schemes for explanatory dialogues is also crucial for training automatic dialogue systems and evaluating their ability to engage in effective knowledge transfer.

For simplicity, throughout the paper, we will assume the following definitions and notation.

- *Phenomenon* (***p***): event, fact, evidence, effect discussed in the dialogue; its existence is a precondition for explanatory dialogue (e.g., medical condition)
- *Explanandum* (***E***): event, fact, evidence, effect *in that* it requires explanation or understanding (e.g., medical symptom)
- *Explanans* (***H***): event, fact, hypothesis, cause of *E* that provides explanation or understanding (e.g., disease or medical injury)
- *Explainer* (***Er***): who is clarifying or transferring their understanding of *E* through the stating of *H*
- *Explainee* (***Ee***): who is requesting, giving feedback on or challanging an explanation *H* for some given *E*

## 3. Related work

### Models of Explanatory Dialogues

Despite its importance, the field of explanatory dialogues remains relatively understudied compared to that of argumentation in general. Nonetheless, some researchers have studied this phenomenon, contributing to the understanding and modeling of such interactions. Cawsey [22] focuses on human-computer interactions, emphasizing the need for AI systems to respond to user feedback and refine explanations based on their understanding and background knowledge. Cawsey proposes content-related rules for structuring non-interactive explanations and dialogue rules for guiding the interactive process. Moore [23] highlights the role of explanations in facilitating understanding and learning. She proposes four key requirements for interactive explanation systems: naturalness, responsiveness, flexibility, and sensitivity. These requirements emphasize the need for AI systems to engage in natural conversation, adapt to user needs, and be sensitive to contextual factors. Walton [9, 19, 24] present a broader model of explanatory dialogue, characterizing it based on initial situations, collective goals, and rules governing different dialogue stages. Walton [25] distinguishes between explanatory and clarificatory dialogues, noting that clarifications focus on resolving ambiguities in expressions or speech acts while explanations target the understanding of events or facts.

[2] Sometimes also referred to as "explaining dialogues" or "dialogical explanations" [21, 6].

In recent years, Arioua and Croitoru [26] formalized and extended Walton's model, proposing a more flexible protocol that allows for backtracking and dialectical shifts between explanatory and argumentative dialogue. Rohlfing et al. [27] advocated for a social and interactive approach to AI explainability, emphasizing the co-construction of understanding through dialogue. Wachsmuth and Alshomary [6] analyzed human-to-human explanatory dialogues, focusing on linguistic patterns and adaptations based on user proficiency levels and Feldhus et al. [7] revised Wachsmuth and Alshomary [6]'s proposal with an adaptation to a pedagogical setting. More recently, Zaninello and Magnini [28] focused on the co-construction of knowledge in the medical domain, showing that LLMs benefit from a dialogical structure of explanations. Similarly, Fichtel et al. [29] presented a study demonstrating that LLMs can partly engage in co-constructive explanation by fostering user engagement but still struggle to adapt explanations based on user understanding. However, while recognizing the central role of the Explainee, they do not provide a comprehensive framework to model the Explanee's contribution in the co-construction of understanding.

### Annotation Schemes

As mentioned in the previous sections, various models of explanatory dialogues have been proposed, each focusing on different aspects of the interaction. However, within the computational linguistic field, few comprehensive annotation schemes can be found. In the following section, we introduce two of the most prominent annotation schemes: the *5-levels* scheme, proposed by Wachsmuth and Alshomary [6], and the *Rewired* scheme by [7], an extension of the *5-levels* proposal.

**The *5-levels* scheme** [6] annotates each turn of a dialogue according to three different dimensions, resulting in a three-dimensional annotation for each turn where only one tag for dimension is allowed. The dimensions are: the discussed *topic* (T), the *dialogue act* (D), and the *explanation move* (E).

Dimension (T) recognizes that participant might be discussing the main topic (e.g. climate change), a subtopic (e.g., temperature increase), or some (un)related topic (e.g., greenhouse gas emissions). Dimension (D) is based on speech act theory and is derived from the DIT++ Taxonomy of Dialogue Acts[3] [30, 5], providing a coarse account of the type of question asked, whether an answer confirms or disconfirms whay previously asked, and whether a given statement agrees, disagrees or provides more information on a certain concept. The third dimension (E) provides a taxonomy of explanation moves in dialogue, including checking understanding or prior knowledge, giving or requesting explanations, signaling (non-)understanding, providing feedback, assessments, or extra information, and a catch-all for any other moves (see Table **??**).

The *5-levels* scheme was used to annotate the *Wired* [6] and the *ELI5* [21] datasets (see Section 3). In both datasets, annotation is realized at the turn level on the three dimensions (T, D, and E), where a turn corresponds to either the Explainer or the Explainee taking the floor. Each turn can be made of one or more utterances. This scheme provides a high-level categorization of explanatory dialogue acts but, as mentioned, mainly focuses on the Explainer's contribution, as can be seen from Table 11.

**The *Rewired* scheme** [7] is an extension of the *5-levels* scheme that proposes to add a new layer of annotation on top of the three proposed by Wachsmuth and Alshomary [6], drawing from pedagogical studies and teaching practice. The primary difference lies in the introduction of 10 *teaching acts* (T) in the new scheme. This new layer, focused on teaching strategies, such as assessing prior knowledge, proposing lesson steps, engaging in active experience, etc. allows for a more granular analysis of the instructional process, highlighting how teachers manage classroom interactions and instructional delivery.

### Datasets

Despite their importance and relevance, explanatory dialogue data are scarse, as they are difficult to collect and analyze. One of the few available datasets is the *5-levels* "Wired" dataset [6], a corpus of 65 English dialogues from Wired's *5 Levels* video series, where 13 topics are discussed and explained to five explainees of varying expertise, resulting in 65 dialogues for a total of 1550 turns. Other available datasets rely on the crawling of discussions online, such as those in blogs and forums. For instance, the *ELI5-dialogues* corpus contains 399 daily-life explanatory dialogues from the Reddit forum "Explain Like I am Five" (ELI5). We introduce one example dialogue from this dataset in Table 9.

## 4. Accounting for the Explainee's Contribution: The IUBAS Annotation Scheme

As highlighted in Section 3, current dialogue annotation schemes recognize basic explanatory requests, modelled as "what-", "how-", and "why-" questions, which they categorize under "information-seeking" dialogical

[3] https://dit.uvt.nl

functions [5, 19, 6]. Such schemes also acknowledge basic feedback like "signal understanding" or "signal non-understanding" [6]. However, they usually do not recognize complex requests that include contrast classes and motivations, and different kinds of complex feedback that might include, e.g., qualifications, explanatory remarks, or critical questions. Complex requests and feedback are typical in real-world explanatory dialogues. While current accounts underline the dynamic nature of explanatory dialogues, they underestimate the importance of directly considering the Explainee's needs, contextual factors, and the co-construction of understanding, which are, however, vital to fully understand explanatory interactions.

This limited approaches neglect the **contrastive** nature of explanations, where an Explainee might seek to understand why a particular explanandum ($E$) is the case, instead of alternative possibilities ($E^*$) [31, 18]. Furthermore, the **motivations** behind the Explainee's questions are often ignored, neglecting the valuable contextual information that motivates their doubts and inquiries [20], which in turn also has important implications on the Explainer's **reaction** itself. For instance, once the Explainer understands what, exactly, puzzles or confuses the Explainee (where does her explanatory request "come from") the Explainer can provide a more effective, tailor-made, explainee-centered response. She can focus on the aspects of the problem that the Explainee considers most relevant and choose the effective communicative strategy sensitive to the required level of detail, requested type of information, etc.

To improve the current research, we propose to integrate existing accounts with *IUBAS*, a multi-dimensional annotation scheme that captures the diverse nature of Explainees' dialogical contributions and reactions. Our proposed scheme aims to address the limitations of the previous schemes by:

1. Providing a more fine-grained categorization of explanation moves, capturing specific actions within the explanatory process, by applying the annotation at the *utterance* level and allowing one utterance to receive zero or more (E) tags[4].
2. Explicitly considering the Explainee's perspective and their active role in seeking and integrating new information.
3. Empirically demonstrate the effectiveness of modelling the Explainee's role in the dialogue through as set of experiments on dialogue quality prediction.

Table 1 presents a summary of our proposed scheme, which we explain, motivate and exemplify in the next sections. A finer-grained comparison with the *5 levels* scheme can also be found in the Appendix, Table 11.

## 4.1. Explanation Requests

Explanation requests are the dialogical moves that, typically, initiate the explanatory process. They signal the Explainee's need for understanding and provide a target for the Explainer's efforts. We distinguish between different types of requests based on two key criteria: **contrastivity** and **motivation**.

### 4.1.1. Contrastivity: Basic vs. Contrastive Request

**Basic** explanation requests simply refers to (or targets) the *explanandum*, the event or phenomenon requiring explanation (Table 2).

The basic explanatory why-request is recognized in argumentation theory [32, 9, 19, 24, 33, 20], but, for the most part, ignored in contemporary annotation schemes. For instance, although [5] acknowledge that dialogue acts can be used to provide justifications and explanations, they focus on "check questions," "choice questions" and "set questions." Along similar lines, [6] emphasize the importance of "check", "how" and "what" questions.

**Contrastive** explanation requests, on the other hand, explicitly introduce a contrastive class, highlighting the specific aspects of the explanandum that require clarification (Table 3).

This distinction, while prevalent in philosophical literature on explanation [31, 17, 18, 16] is often overlooked in dialogue annotation schemes. Incorporating contrastive requests allows for a more precise representation of the Explainee's information needs, emphasizing the specific aspects of the explanandum that should be understood. Basic and contrastive requests, as exemplified in Tables 2 and 3, introduce questions that (might) require different explanations. So, defining a contrast class sets initial normative boundaries for selecting an adequate *explanans*.

### 4.1.2. Motivation: Pure vs. Motivated Request

**Pure** explanation requests directly inquire about the explanandum (or some aspect of explanandum, if they include contrast class) without further elaboration. In contrast, **motivated explanation requests** introduce further information about the Explainee's cognitive and communicative needs (Table 4). By motivating their requests, Explainees explicitly inform the Explainer what confuses them about the explanandum, or, in other words, what exactly stands in the way of transferring understanding. Such additional information promotes effective communication, and might at times even be necessary for formulating an adequate explanans.

Such additional considerations, inspired by the works of [20] and [34] allow us to capture the broader context of

[4] As exemplified in Table 9, we implicitly assume that a tag is expressed at the utterance level and is automatically projected onto the next utterances until a new (E) tag is expressed

| Domain | Type | Subtype | Description | Tag |
|---|---|---|---|---|
| **(R)** | **Basic** | Pure | Why E? | **R01** |
| | | Motivated | Why E, given that M? | **R02** |
| | **Contrastive** | Pure | Why E, instead of E*? | **R03** |
| | | Motivated | Why E, instead of E*, given that M? | **R04** |
| **(F)** | **Positive Basic** | Assert understanding | I understand H. | **F01** |
| | **Positive Complex** | Demonstrate understanding | I understand. So... | **F02** |
| | | Qualified understanding | I understand. But... | **F03** |
| | | **Critical challenge** | I understand. However... [critical question] | **F04** |
| | **Negative Basic** | Assert non-understanding | I don't think H explains E. I rather think H*. | **F05** |
| | **Negative Complex** | Request for clarification | I don't think H explains E. Can you clarify H? | **F06** |
| | | **Critical challenge** | I don't think H... In fact [critical question] | **F07** |
| **(C)** | **Types of Critical Challenges** | | **Description** | **Tag** |
| | Comparative plausibility | | Is H the best available hypothesis? | **C01** |
| | Epistemic distance | | To what extent is H better than the "second-best" alternative hypothesis H*? | **C02** |
| | Generative completeness | | Is the pool of plausible hypotheses complete (big enough)? | **C03** |
| | Non-comparative plausibility | | Is H sufficiently plausible in itself? | **C04** |
| | Causal accuracy | | Does H accurately cause E (does H undergenerate or overgenerate)? | **C05** |
| | Causal responsibility | | Is H a responsible (pragmatically relevant, immediate) cause of E? | **C06** |
| | Explanandum reliability | | Is E reliable and complete (are there false positives or false negatives: undetected symptoms)? | **C07** |
| | Pragmatic considerations | | What are the pragmatic costs or benefits of accepting H (rather than H*)? | **C08** |

**Table 1**
The three IUBAS categories with description and tags, including critical challenge types.

**Table 2**
Basic explanation request.

| Move | Example |
|---|---|
| Explainer: *E.* | Mark has a cough that won't go away. |
| Explainee: *Why E?* | Why does Mark have a cough that won't go away? |

the explanatory request, including the Explainee's background knowledge, assumptions, and potential concerns.

## 4.2. Explainee's Feedback

Once the Explainer offers an explanation, the Explainee typically provides feedback, signaling her understanding or lack thereof. We differentiate between positive and negative feedback, further distinguishing between basic and complex variants.

**Table 3**
Contrastive explanation request.

| Move | Example |
|---|---|
| Explainer: *E.* | Mark has a cough that won't go away. |
| Explainee: *Why E, instead of E*?* | Why does Mark have a cough that won't go away, instead of a temporary cough, or no cough at all? |

### 4.2.1. Polarity: Positive vs. Negative Feedback

**Positive feedback** expresses the Explainee's comprehension of the phenomenon, i.e., offered explanation. **Negative feedback** signals a failure to understand, prompting further elaboration or clarification from the Explainer (Table 5).

**Table 4**
Motivated explanation request.

| Move | Example |
|---|---|
| Explainer: *E.* | Mark has a cough that won't go away. |
| Explainee: _Why E (instead of E*), given that M?_ | Why does Mark have a cough that won't go away, given that he has never smoked cigarettes? |

**Table 5**
Positive and negative feedback.

| Move | Example |
|---|---|
| Explainer: *Because of H.* | Because Mark has cancer. |
| Explainee: *Positive feedback* | I understand why cancer would explain Mark's cough. |
| Explainee: *Negative feedback* | I don't understand why cancer would explain Mark's cough. |

**Table 6**
Complex positive feedback: demonstrating understanding.

| Move | Example |
|---|---|
| Explainee: *I understand. So,...* | I understand. So, (you're saying that) Mark's life is at risk and he should immediately start with chemotherapy... |

### 4.2.2. Complexity: Basic vs. Complex Feedback

**Basic feedback** provides a straightforward assessment of understanding without further elaboration. In contrast, **complex feedback** incorporates additional remarks, questions, or challenges.

### 4.2.3. Types of Complex Positive Feedback

**Complex Positive Feedback** can take several forms:

1. **Demonstration of understanding:** The Explainee may provide additional information or draw inferences to demonstrate their grasp of the explanation (Table 6).
2. **Qualified understanding:** The Explainee may signal partial understanding, acknowledging the need for further clarification on specific aspects of the explanation (Table 7).
3. **Understanding with Critical Challenge:** While understanding the nature of explanation (or conditionally understanding the phenomenon), the Explainee may challenge its plausibility, demanding further justification (Table 8).

**Table 7**
Complex positive feedback: qualified understanding.

| Move | Example |
|---|---|
| Explainee: *I understand, but...* | I understand, but what kind and stage of cancer are we talking about? |

**Table 8**
Complex positive feedback: understanding with critical challenge.

| Move | Example |
|---|---|
| Explainee: *I understand. However, ...* | I understand that lung cancer explains this kind of cough. However, is another diagnosis still possible? Can you still run some more tests?" |

This type of feedback, both positive and negative (see Section 4.2.4) often introduces **critical questions** (see Section 4.3 and Table 7).

### 4.2.4. Types of Complex Negative Feedback

Complex negative can also be analyzed into:

1. **Request for clarification:** The Explainee may point to specific concepts or aspects of the explanation they find unclear.
2. **Critical challenge:** The Explainee may directly challenge the plausibility of the explanation, either categorically rejecting it or requesting further justification.

As seen for their positive counterpart, critical challenges can introduce **critical questions** (Section 4.3).

## 4.3. Explainee's Critical Questions

Critical questions challenge the explanation and its underlying assumptions. They target various aspects of the explanation, testing its plausibility, completeness, and relevance. Inspired by existing literature on Inference to the Best Explanation, argument schemes and critical questions [35, 36, 37, 12, 15], we propose a typology of critical questions tailored to why-explanations. We categorize critical questions according to the *specific aspect of explanation* they target, as summarized in Table 1 and further exemplified in Table 7.

# 5. Comparative annotation

In Table 9, we present a comparative analysis of an example dialogue from the *ELI5* corpus, annotated through the "5-levels" and our "IUBAS" scheme.

IUBAS allows for a finer-grained account of the Explainee's request (e.g. U0, where we can specify that the explanation request is based on an implicit comparison with a complementary group). Also, we can better account for shifts in the explanation move within a turn (e.g. U4-6), as well as combinations of moves within a single turn (e.g. U7). This provides a more precise account of the conversational flow and, crucially, as this example suggests, it seems that providing explanations is not limited to the Explainer's role, and neither does feedback only originate from the Explainee. This observation, once generalised over a broader set of examples, could challenge the traditional view of the Explainer/Explainees roles, a phenomenon which can be analysed in detail through our scheme.

Also, our account of the different types of feedback request (e.g. U7, U8-9) highlight that the Explainee's reaction strongly influences the kind of explanation provided and participates in the co-construction of the explanation process. Finally, IUBAS is organized hierarchically, which makes it possible to navigate its tree-like structure and easily reconstruct the analysis of the explanatory move (Figure 1). Moreover, its structure allows for flexibility in terms of the level of granularity needed for a specific analysis.

## 6. Experiments

We conduct our experiments on the ELI5 dialogue quality assessment task introduced by Alshomary et al. (2024). This corpus consists of explanatory dialogues (399 in total) from the Reddit "Explain Like I'm Five" forum, each labeled with a ground-truth explanation quality score on a 1–5 Likert scale. We integrate the proposed IUBAS scheme into this task by automatically annotating the explainee turns and evaluating its impact on quality prediction.

**IUBAS Annotation with GPT-4.1.** To obtain IUBAS labels for the Explainee's turns, we employed the GPT-4.1[5] model to perform annotation in a zero-shot manner. We targeted only those turns where the *Explainee* explicitly participates in the dialogue, corresponding to the categories **E04** (Request Explanation) and **E07** (Request Feedback) in the original 5-level annotation scheme of Alshomary et al. These are the turns where the Explainee asks a question or provides feedback, i.e., the utterances that reflect the Explainee's reaction and understanding. For each such turn, GPT-4.1 was prompted with the dialogue context and the definition of the IUBAS categories, and it generated a IUBAS tag capturing the turn's properties, choosing among: **R** (type of explanation request, e.g., basic vs. contrastive), **F** (feedback type, e.g., positive vs. negative understanding), and **C** (presence of any critical follow-up or clarification request). This automatic labeling process produced a set of IUBAS annotations for all relevant Explainee turns in the ELI5 corpus, increasing the original labelling by approx. 20%. The resulting enriched dataset contains, for each relevant Explainee utterance, an associated label (R, F, C) indicating the Explainee's needs or feedback in that turn. We manually inspected a sample of the GPT-4.1 annotations to ensure they were coherent with the scheme's guidelines, and overall found the labels to be reasonable, providing a fine-grained view of the Explainee's role in the dialogue.

**Quality Prediction Task Setup.** Using the automatically annotated corpus, we replicate the dialogue quality prediction setup of Alshomary et al. (2024) to evaluate how the additional IUBAS metadata influences performance. The goal of the task is to predict the human-assigned quality score of a dialogue given the dialogue transcript (with or without annotations). We compare four input conditions:

- **No Annotation:** Each dialogue is given to the model as plain text, with no turn-level labels (baseline condition).
- **Original ELI5 Labels:** Each turn in the dialogue is followed by the original annotation tags for explanation move, dialogue act, and topic.
- **IUBAS Labels:** Each explainee turn is prefixed with its IUBAS labels (R, F, C values) as metadata, while explainer turns remain unlabeled.
- **Combined (ELI5 + IUBAS):** Both the original ELI5 turn labels and the IUBAS labels for Explainee turns are included.

We format the prompt for each dialogue by inserting the turn-level metadata (if any) immediately after each utterance, between square brakets, with a concise description of the tag itself (for example `(F01) Positive Basic Feedback - Assert understanding`). After presenting the entire dialogue, we append a final instruction asking the model to *"Rate the overall explanation quality on a 1–5 scale."* The model then outputs a single rating.

We evaluate three instruction-tuned LLMs: **Llama-3.1-8B-Instruct** [38], **Gemma-3-4b-it**[6], and **Qwen2.5-14B-Instruct-1M** [39]. We use HuggingFace's lm_eval harness [40] in the multiple choice mode, asking the model to choose between a number from 1 to 5, indicating the dialogue quality. We report RMSE and MAE against human ratings of each model's prediction, and assess significance using a paired t-test.

| | ELI5-only | 1.40 | 1.01 | <1e-21 |
| | IUBAS-only | **1.38** | **0.99** | <1e-12 |
| | IUBAS-only (C) | 1.44 | 1.06 | <1e-26 |
| | IUBAS-only (F) | 1.44 | 1.05 | <1e-17 |
| | IUBAS-only (R) | 1.43 | 1.04 | <1e-21 |
| | ELI5 + IUBAS | 1.38 | 1.01 | <1e-4 |
| Qwen | No annotation | 1.61 | 1.16 | <1e-28 |
| | ELI5-only | 1.41 | 1.01 | <1e-14 |
| | IUBAS-only | 1.46 | 1.04 | <1e-20 |
| | IUBAS-only (C) | 1.48 | 1.05 | <1e-21 |
| | IUBAS-only (F) | 1.47 | 1.05 | <1e-19 |
| | IUBAS-only (R) | 1.50 | 1.08 | <1e-24 |
| | ELI5 + IUBAS | **1.40** | **1.02** | <1e-17 |

**Table 10**
Prediction error (RMSE and MAE) and paired t-test p-values for each model and annotation strategy. Lower is better. Bold = best per model across both measures.

### 6.1. Results and Analysis

Table 10 summarizes performance. Across all models, incorporating IUBAS annotations improves predictive accuracy over the unannotated baseline. Notably, the *IUBAS-only* condition consistently outperforms the *ELI5-only* setup for LLaMA and Gemma models (e.g., RMSE 1.36 vs. 1.42 for LLaMA). The best overall performance is typically achieved by the *combined* condition (ELI5+IUBAS), confirming the complementarity of the two annotation types.

Ablation experiments on IUBAS dimensions show that the *F-only* and *C-only* variants perform nearly as well as the full IUBAS scheme, while *R-only* annotations provide slightly smaller gains. The strongest single dimension was *F-only* for Gemma, while *C-only* was best for LLaMA. All annotation-enhanced variants significantly outperform the no-label baseline ($p < 0.05$).

## 7. Conclusion

In this paper, we introduced IUBAS, a framework that contributes to a richer understanding of the Explainee's role within explanatory dialogues. We incorporate contrastivity and motivation alongside a categorization of feedback and critical questions, providing a more comprehensive account for analyzing and modeling such interactions. By adopting this scheme, we can move towards developing more sophisticated conversational AI systems capable of engaging in truly human-like explanatory dialogues, ultimately enhancing communication effectiveness and fostering deeper understanding.

# Appendix

## Limitations

While the manual annotation of a full dataset falls outside the scope of our current proposal, we believe that future work should involve testing the agreement between the automated annotation and human-annotation. Additionally, the proposed typology could be expanded to account for the different kinds of explanations and reasoning patterns on the Explainer's side, too.

## Ethical Considerations

This research focuses on analyzing explanatory dialogue, and it is crucial to acknowledge the potential ethical implications of applying such schemes to real-world situations, especially in sensitive domains like healthcare or by covering topics such as ethnicity, physical ability, gender and sexual orientation (as in the case of the reported example in Table 9). Careful consideration should also be given to data privacy, informed consent, and potential biases in the annotation process.

**Table 11**
The IUBAS scheme (green) represented as an extension of the *explanatory move* (E) dimension of the *5-levels* scheme (blue).

| [E] tag | Value | Description |
|---|---|---|
| **1** | Test understanding | Checking whether the listener understood the explanation. |
| **2** | Test prior knowledge | Checking the listener's prior knowledge of the topic. |
| **3** | Provide explanation | Explaining a concept or topic to the listener. |
| **4** | Request explanation | Requesting an explanation from the listener. |
|  | **Contrastivity** | ***Is a contrastive class introduced?*** |
| **4.1** | **Basic** | Directly inquiring about $E$, the event or phenomenon requiring explanation. |
| **4.2** | **Contrastive** | Introducing a contrastive class, high-lighting specific aspects of $E$. |
|  | **Motivation** | ***Is additional information provided?*** |
| **4.1.1 (R01)** | Basic - **Pure** | Why $E$? |
| **4.1.2 (R02)** | Basic - **Motivated** | Why $E$, given that $M$? |
| **4.2.1 (R03)** | Contrastive - **Pure** | Why $E$, instead of $E^*$? |
| **4.2.2 (R04)** | Contrastive - **Motivated** | Why $E$, instead of $E^*$, given that $M$? |
| **5** | Signal understanding | Informing the listener that their last utterance was understood. |
| **6** | Signal non-understanding. | Informing the listener that the utterance was not understood. |
| **7** | Provide feedback | Responding qualitatively to an utterance by correcting errors or similar. |
|  | **Polarity** | ***Does the feedback confirm or disconfirm* H?** |
|  | **Complexity** | ***Is the feedback simple or complex?*** |
| **7.1** | **Positive feedback** | Agreeing with $H$. |
| **7.1.1 (F01)** | Positive - **Basic** | Agreeing with $H$ without further elaboration. |
| **7.1.2** | Positive - **Complex** | Agreeing with $H$ with further elaboration. |
| **7.1.2.1 (F02)** | Positive - Complex - **DU** | **Demonstrative understanding**: I understand. So... |
| **7.1.2.2 (F03)** | Positive - Complex - **QU** | **Qualified understanding**: I understand. But... |
| **7.1.2.3 (F04)** | Positive - Complex - **CC** | **Critical challenge**: I understand. However... [*critical question*] (see Table 7) |
| **7.2** | **Negative feedback** | Disagreeing with $H$. |
| **7.2.1 (F05)** | Negative - **Basic** | Disagreeing with $H$ without further elaboration. |
| **7.2.2** | Negative - **Complex** | Disagreeing with $H$ with further elaboration. |
| **7.2.2.1** | Negative - Complex - **P** | **Pure**: I don't think $H$ explains $E$. I rather think $H^*$. |
| **7.2.2.2 (F06)** | Negative - Complex - **CR** | **Clarification request**: I don't think $H$ explains $E$. Can you clarify $h \in H$? |
| **7.2.2.3 (F07)** | Negative - Complex - **CC** | **Critical challenge**: I don't think $H$... In fact [*critical question*] (see Table 7) |
| **8** | Provide assessment | Assessing the listener by rephrasing their utterance or giving a hint |
| **9** | Provide extra info | Giving additional information to foster a complete understanding |
| **10** | Other | Making any other explanation move |

**Figure 1:** The hierarchical structure our IUBAS annotation scheme.

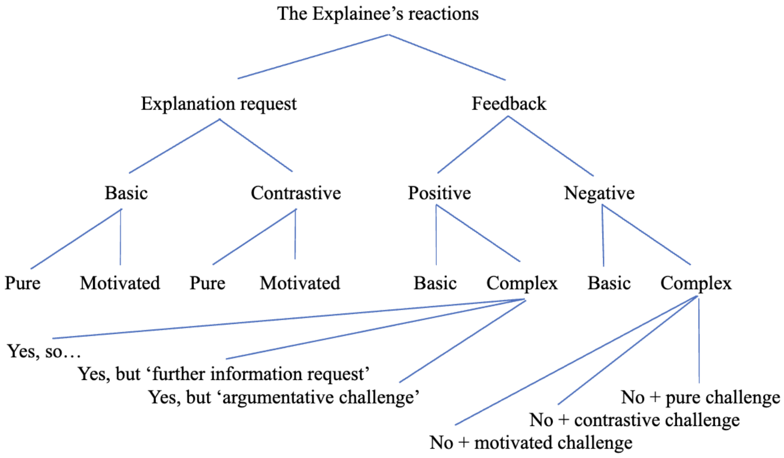

**Table 12**
Typology of critical questions for the Complex Negative Feedback's Critical challenges.

| Tag | Question Type | Description (question) | Example |
|---|---|---|---|
| **C01** | **Comparative plausibility** | *Is H the best available hypothesis?* | Is 'lung cancer' the best explanation of Mark's symptoms among available explanations? |
| **C02** | **Epistemic distance** | *To what extent is H better than the "second-best" alternative hypothesis H*?* | If 'lung cancer' is the best hypothesis, is it significantly or only slightly better than the most plausible alternative hypothesis (e.g., asthma)? |
| **C03** | **Generative completeness** | *Is the pool of plausible hypotheses complete (big enough)?* | Did doctors overlook some promising hypotheses, to begin with (e.g., sinusitis)? |
| **C04** | **Non-comparative plausibility** | *Is H sufficiently plausible in itself?* | Even if 'lung cancer' is the best available explanation, is it likely? |
| **C05** | **Causal accuracy** | *Does H accurately cause E (does H undergenerate or overgenerate)?* | Does 'lung cancer' cause Mark's condition? Perhaps this diagnosis does not explain all the symptoms, or entails symptoms that were not detected. |
| **C06** | **Causal responsibility** | *Is H a responsible (pragmatically relevant, immediate) cause of E?* | Is 'lung cancer' the cause we are looking for? Perhaps we are dealing with multiple causes: the patient coughs because of lung cancer, but also because of contracting COVID-19. |
| **C07** | **Explanandum reliability** | *Is E reliable and complete (are there false positives or false negatives: undetected symptoms)?* | *Is cough the only symptom that needs to be explained?* Is it a real symptom (or is the patient faking it)? |
| **C08** | **Pragmatic considerations** | *What are the pragmatic costs or benefits of accepting H (rather than H*)?* | What is the cost of being mistaken if one proceeds as if the patient has cancer, or as if she has asthma? |

## Declaration on Generative AI

During the preparation of this work, the author(s) used ChatGPT (OpenAI) in order to: Paraphrase and reword, Improve writing style, and Grammar and spelling check. After using these tool(s)/service(s), the author(s) reviewed and edited the content as needed and take(s) full responsibility for the publication's content.

# PharmaER.IT: an Italian Dataset for Entity Recognition in the Pharmaceutical Domain

Andrea Zugarini[1,†], Leonardo Rigutini[1,*,†]

[1] *expert.ai, Siena (Italy)*

## Abstract

Despite significant advances in Natural Language Processing, applying state-of-the-art models to real-world business remains challenging. A key obstacle is the mismatch between widely used academic benchmarks and the noisy, imbalanced data often encountered in domains such as finance, law, and medicine, especially in non-English languages, where resources are typically scarce. To address this gap, we introduce *PharmaER.IT*, a new dataset for entity recognition in the pharmaceutical and medical domain for the Italian language. *PharmaER.IT* is constructed from drug information leaflets obtained from the Agenzia Italiana del Farmaco, and annotated using either semi-automatic or fully automatic methods. The dataset comprises two complementary corpora: (1) the GOLD corpus, consisting of 57 leaflets annotated via a committee-based algorithm followed by expert manual validation, yielding 16833 high-quality entity mentions; and (2) the SILVER corpus, containing 2138 leaflets annotated solely through the automatic pipeline, without any human curation. We establish reference performance evaluating a range of token classification models and several LLMs under zero-shot conditions.

## Keywords

NER, Pharmaceutical NER, Dataset, LLM

## 1. Introduction

Named Entity Recognition (NER) is a crucial task in Natural Language Processing (NLP), and arguably among the most demanded in industrial applications. While recent advances in transformer-based models [1] and Large Language Models (LLMs) [2, 3, 4, 5] have significantly improved entity extraction performance on standard benchmarks, their application to real-world business and professional contexts remains difficult. A primary challenge is the discrepancy between academic datasets and the often noisy, domain-specific texts encountered in real-world practice. This challenge is further exacerbated in specialized domains such as finance, law, and medicine. When dealing with languages other than English, annotated resources are even scarcer or non-existent.

In the medical and pharmaceutical domain, accurate entity recognition is critical for applications ranging from drug safety monitoring to automated clinical documentation. However, the Italian language remains underrepresented in the landscape of medical NER resources, limiting the development and evaluation of robust systems for local healthcare and regulatory contexts. Existing datasets are either too small, lack sufficient domain specificity, or are unavailable for public use due to privacy or licensing restrictions.

In this article we present *PharmaER.IT*, a novel dataset for NER in the pharmaceutical field for the Italian language. The dataset is derived from Riassunti delle Caratteristiche del Prodotto (RCPs), the official drug information leaflets, made publicly available by the Agenzia Italiana del Farmaco (AIFA).

*PharmaER.IT* is composed of two complementary corpora: a curated GOLD corpus, consisting of 57 RCPs annotated using a committee-based approach and refined through expert manual validation, and a SILVER corpus, comprising 2138 RCPs automatically annotated without human intervention.

This dual-corpus structure enables both evaluation and large-scale experimentation, facilitating the development of high-quality models as well as scalable weakly supervised approaches. To establish baseline performance, we evaluate a range of token classification models and several LLMs under diverse zero-shot settings.

## 2. Related work

CoNLL-2003 [6], was one of the first NER datasets and it is still a reference corpus for NER. It was constituted of news articles annotated with four entity types: person (PER), organization (ORG), location (LOC) and miscellaneous (MISC). Recently, numerous NER datasets have been released, many of which have been constructed using semi-automatic or fully automated annotation methods [7, 8, 2, 9], significantly expanding the entity tag-set. For instance, In Pile-NER [2], annotations were distilled from ChatGPT, resulting in about 45 thousands examples in English and more than 13 thousands distinct entity

```

types. Even so, these resources do not target documents from vertical domains, such as finance or health. Other works proposed domain-specific NER corpora, such as in the financial [10, 11] and healthcare [12, 13] domains. However, these datasets are in English and mainly consist of well-curated, isolated sentences. In contrast, our work focuses on technical descriptions of pharmaceutical drugs.

**Italian NER Datasets.** The availability of NER data sets in Italian is extremely limited, particularly outside the traditional general-purpose domains and entity labels set [14]. Indeed, most NER datasets focus on news and social media contents [15, 16, 17, 18, 19].

Recently, it was introduced Multinerd [20], a multilingual dataset, covering Italian and a set of 15 distinct entity types. Among them, *Disease* and *Biological Entity* classes were included. However, examples originated from Wikipedia and Wikinews sentences, which are typically educational and encyclopedic. In *PharmaER.IT* instead, we collected drug leaflets, which present an highly technical and specialized lexicon. As an alternative strategy, [21] proposed to translate existing healthcare English datasets for NER, in Italian. Nonetheless, automatic translation may introduce errors or segmentation issues, especially on such a vertical domain.

## 3. Data Collection

In order to create a highly pharmaceutical-oriented dataset in Italian, we collected documents from the AIFA website.

### Target documents

The AIFA is the official government institution that regulates the distribution of drugs in Italy[1]. The agency maintains the list of drugs authorized for sale in Italy, the list of pharmaceutical companies producing them and all the documentation made available by the manufacturer for each drug, including the drug leaflet. The leaflet is the short information document that accompanies the drug in the package and is divided into two types:

- Foglietto Illustrativo (FI) - the Package Leaflet. This is a document aimed at patients, with a simplified structure and language.
- Riassunto delle Caratteristiche del Prodotto (RCP). RCPs are documents for healthcare professionals, with a slightly more complex structure and more technical language and content. RCPs are approved documents, part of the marketing authorization for a drug, and intended primarily for healthcare professionals, adopting a medical-scientific terminology. In particular, RCPs contain detailed information on how to use the medicine, for example: therapeutic indications (what the medicine treats), dosage and method of administration, contraindications, special warnings, mechanism of action, side effects.

Given the strong technical content, we chose to use RCPs to build our data set. We choose to use only RCPs and ignore the FI since (1) the contents of the FIs are a subset of the contents of the second, and (2) the RCPs contain technical information relating to pharmacological properties and therapeutic indications that provide information of diagnostic-prescriptive value.

### Data download

For each drug authorized for sale in Italy, AIFA assigns the unique AIC (Authorization for Placing on the Market) identification code[2] consisting of 9 digits in which the the 3 most significant on the left identify the type of packaging (capsules or syrup, mg, etc.), while the remaining 6 on the right (eventually padded with zeros) uniquely identify the drug (it is also referred as AIC6). Similarly, also for the companies producing the authorized drugs, AIFA assigns an unique three-digit code called SIS.

The open-data section of the AIFA website[3] contains several databases, including the list of drugs approved and distributed in Italy. This list can be downloaded as a csv file[4] and itemizes the AIC codes of the authorized class A and class H drugs, together with a series of auxiliary information. In addition, the AIFA website also provides an API endpoint to download all available documentation for authorized drugs. The API allows to download a drug RCP by specifying the SIS and the AIC6 codes and the type of document required (RCP) in the request URL, according to the scheme reported in URL 1.

[1] https://www.aifa.gov.it/

[2] In collaboration with the European Medicines Agency (EMA), if the drug is intended for multiple European countries

[3] https://www.aifa.gov.it/open-data

[4] https://www.aifa.gov.it/web/guest/liste-dei-farmaci

Using the drug list and the download API, we collected 8634 RCP files in PDF format relating to class A and class H drugs, which were then converted to raw text files using a PDF-to-text conversion tool. Figure 1 shows an excerpt from the first page of a downloaded RCP.

## 4. Data annotation

For data labeling, we followed a semi-automatic procedure which included a human in the loop. Specifically, we first exploited a "committee" approach based on the use of two different automatic annotation models. Secondly, the annotated documents were reviewed by humans, with particular attention to the cases of discordant annotations returned by the two automatic annotators.

### Tag-set

In designing the tag-set, we identified three families of data points: *Chemicals* , *Condition* and *Organism*. In this way, for each family it is possible to define a subset of related entity types. In the first version of the data, only *Condition* has more than an entity type, but we intend to extend the groups in the future. The resulting tag-set is reported in Table 1.

### Automatic Pre-annotation

In the first step of annotation, documents are automatically labeled using a committee approach. The idea is to employ a limited group of automatic annotators, usually consisting of different algorithms and models, to generate multiple annotations for a single file. The acceptability of each annotation is subsequently assessed by examining the levels of concordance and discordance among these automatic annotators. We selected two approaches that were considered very different so that the concordance cases would provide a higher degree of reliability: (a) a neural annotator based on the use of a generative LLM and (b) a symbolic pre-annotator based on the use of an NLP Platform.

**LLM-based pre-annotator.** This automatic annotator was based on the use of a generative LLM. In particular, using a prompt specifically designed and developed for this task (Prompt 1), for each data-point type, this annotator model asks to the LLM to identify all the entities present within the text (provided as input) belonging to the target data-point. When the length of the content exceeds the input size of the LLM, the content of the drug information leaflet is divided into smaller chunks respecting the sentence grammar. We chose to use LLama 3.1 70B[5], a state-of-the-art, open source generative language model released by Meta that has reported excellent performance on several NLP tasks.
Given the generative nature of the LLM (as opposed to the word-classifying nature of the task), the result consists of a list of the identified entities without the position in which they were found (the start-end pairs). To obtain the final set of occurrences, a post-processing procedure performs the placement of the entities in the text using a string-matching search approach.

**Rule-based pre-annotator.** This annotator was based on the use of deep linguistic analysis. In particular, we used a NLP platform that, thanks to integrated linguistic resources (knowledge graph, semantic disambiguator and linguistic rules), allowed us to identify the occurrences of entities within the RCPs. For this task we used the proprietary NLP Platform of expert.ai[6] which consists in an integrated environment for deep language understanding and provides a complete natural language workflow with end-to-end support for annotation, labeling, model training, testing and workflow orchestration. To increase the recognition performances, the selected NLP Platform has been specialized by integrating knowledge and linguistic rules for the medical and pharmaceutical domains.
Given the lower generalization capacity typical of expert system approaches, for the entities identified by the rule-based annotator but missed by the LLM-based annotator, an additional verification step was included. In particular, for such cases of discordance, a further query was performed to an LLM in which confirmation of the extraction performed by the linguistic annotator is requested. The used prompt is reported in Prompt 2. For this additional step, we used the OpenAI GPT APIs[7], and

**Table 1**
The tag-set defined in *PharmaER.IT*.

| Tag Family | Tag Name | Description |
|---|---|---|
| *Chemicals* | *DRUGS* | A synthetic or natural substance with beneficial effects in treating diseases, including product names and drug types. |
| *Condition* | *DISEASES* | Any pathological state or alteration of the body or one of its organs, including malformations, mental disorders, and injuries. |
| | *SYMPTOMS* | A morbid event indicating the presence of a disease. |
| *Organism* | *ANATOMICAL_PARTS* | All human body parts anatomically described, including organs, limbs, and anatomical structures. |

**Prompt 1**
The prompt used for the LLM-based pre-annotator.

```
You are an expert in the field of pharmacology.

### INSTRUCTIONS

You are provided with a portion of a drug leaflet in Italian.
Your task is to identify and extract relevant entities regarding:

{TAG NAME with description}

Report the terms and expressions in singular form.
Branches of medicine such as ’pulmonology’, ’traumatology’, etc. are NOT diseases.
Return the result in a structured JSON.
Be sure to include only the terms ’explicitly’ mentioned in the leaflet.
Exclude any interpretation or inference outside the text provided.
Report the terms as they are mentioned in the text, DO NOT make any changes or normalizations.

### TEXT

{Drug leaflet content}
```

in particular the “gpt-4o-mini” model.

## Human Review

The output of the automatic pre-annotation phase consists of duplicate versions of the same RCP, each with labels inserted by the two different automatic annotators. To produce the single and final annotated version, a subsequent review phase was necessary in which, for each document, the outputs of the two models were analyzed in order to be accepted or rejected, and in which any tags missed during the pre-annotation phase could also be inserted. In particular, a merged version of each RCP was then created, reporting the outputs of the two annotators, also highlighting the cases of agreement (both models had identified the occurrence of an entity) and disagreement (only one of the two models had hypothesized the occurrence of an entity). These “merged” documents were then distributed to human experts to examine the annotations inserted by the pre-annotation phase (accepting or rejecting them) and with the possibility of adding new ones.

For this human validation phase, we employed a panel of five human reviewers and assigned each of them a set of RCPs randomly drawn from the total. To subsequently measure the degree of consistency of the final annotation outputs, we designed the assignment so that part of them were blindly shared between two reviewers. In this way, we obtained a total of $57$ RCPs selected for human review, $6$ of which were randomly and hiddenly assigned to two reviewers. This step has been performed using the annotating support of the expert.ai natural language platform[6].

**Review guidelines.** To improve the consistency of the final annotations, a document containing guidelines was drafted and provided to the reviewers. In this document, a set of indications on how to consider ambiguous cases were specified, mainly based on the context in which they appear.

## Annotation quality assessment

To estimate the quality of the final annotation outputs, we exploited the set of $6$ RCPs reviewed by a pair of human experts. In particular, by indicating with $L_1(RCP_i)$ and $L_2(RCP_i)$ the two sets of annotations resulting from the review phase of reviewer *rev*$_1$ and *rev*$_2$ respectively

**Prompt 2**

The prompt used for the LLM-based validation step for the linguistic-based pre-annotator.

```
You are an expert in the field of pharmacology.

Check if the word {WORD} provided in the following text could be a {TAG NAME}

Text: {TEXT}

Answer only with YES or NO.
No preamble or anything else.
```

on the same $RCP_i$ document, we calculated several standard indices[8]:

(a) Joint Probability of Agreement, which measures the chance of having a match between the annotations resulting from the two reviewers: $\mathit{JPA} = \frac{\#(L_1 \cap L_2)}{\#(L_1 \cup L_2)}$.

(b) Conditional Probability of Agreement of $\mathit{rev}_k$, which measures the naive probability that annotations resulting from the reviewer $k$ have a match with the annotations resulting from the other reviewer: $\mathit{CPA} = \frac{\#(L_1 \cap L_2)}{\#(L_k)}$, $k \in \{1, 2\}$.

(c) Coverage of $\mathit{rev}_k$, which measures the probability that a randomly selected annotation in $RCP_i$ comes from the reviewer $k$: $\mathit{Cov} = \frac{\#(L_k)}{\#(L_1 \cup L_2)}$, $k \in \{1, 2\}$.

(d) Cohen's kappa ($\kappa$), which extends the Joint Probability of Agreement taking into account that agreement may occur by chance [22]: $\kappa = \frac{p_o - p_e}{1 - p_e}$ where $p_o = \mathit{JPA}$ is the observed agreement, $p_e = \frac{\#(L_1) \times \#(L_2)}{N^2}$ estimates the probability of a random agreement and $N = \#(L_1 \cup L_2)$ is the total number of annotations.

The values were evaluated for each $RCP_i$, and then averaged over all RCPs (micro-average), separately for each data point.

**Table 2**

The quality assessment results of the output of the annotation and validation process.

| Data point | *JPA* | *CPA* | *Cov* | $\kappa$ |
|---|---|---|---|---|
| *DRUGS* | 0.85 | 0.91 | 0.91 | 0.90 |
| *DISEASES* | 0.98 | 0.84 | 0.86 | 0.83 |
| *SYMPTOMS* | 0.74 | 0.86 | 0.87 | 0.84 |
| *ANATOMICAL_PARTS* | 0.68 | 0.84 | 0.84 | 0.76 |
| **Average** | **0.81** | **0.86** | **0.87** | **0.83** |

The results are reported in the Table 2 and the values of Cohen's kappa ($\kappa$) show a substantial agreement in the resulting annotated data [23].

## 5. The *PharmaER.IT* dataset

The resulting *PharmaER.IT* dataset consists of the two corpora: the GOLD corpus and the SILVER corpus. We made it publicly available and free-to-download from HuggingFace[9].

### The GOLD corpus

The GOLD corpus consists of the 57 labeled RCPs which were annotated by the semi-automatic procedure described in Section 4. It is composed by a total of 16833 occurrences of entities identified by automatic pre-annotators and then reviewed by humans. We then established a predefined split for training, validation and testing, randomly selecting 37, 10 and 10 RCPs respectively. The resulting distribution of occurrences of the data points is reported in Table 3.

**Table 3**

Distribution of annotated entities in the GOLD corpus.

| Data point | Train | Validation | Test | Total |
|---|---|---|---|---|
| *DRUGS* | 5911 | 716 | 1222 | 7849 |
| *DISEASES* | 3344 | 477 | 614 | 4435 |
| *SYMPTOMS* | 2582 | 363 | 480 | 3425 |
| *ANATOMICAL_PARTS* | 817 | 121 | 186 | 1124 |
| **Total** | 12654 | 1677 | 2502 | 16833 |

### The SILVER corpus

To build the SILVER corpus we sampled 2138 leaflets from the remaining 8567 documents. These RCPs were pre-annotated with algorithm in Section 4, without any revision from human annotators. The resulting documents were added to the *PharmaER.IT* dataset as a SILVER corpus. Table 4 shows the distribution of

[8] https://en.wikipedia.org/wiki/Inter-rater_reliability

[9] https://huggingface.co/datasets/expertai/PharmaER.IT

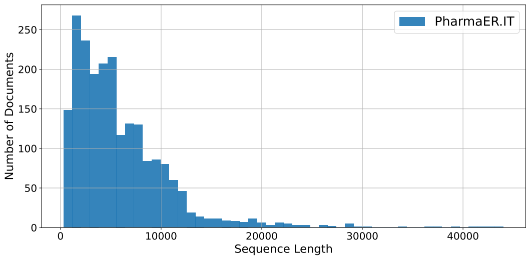

**Figure 2:** Sequence length distribution (in words) of *PharmaER.IT* documents in SILVER partition.

annotations within SILVER.

**Table 4**
Distribution of annotated entities in the SILVER corpus.

| Data point | Total |
|---|---|
| *DRUGS* | 385210 |
| *DISEASES* | 245240 |
| *SYMPTOMS* | 80763 |
| *ANATOMICAL_PARTS* | 70587 |
| **Total** | 781800 |

## 6. Experiments

NER has been traditionally tackled as a token classification problem, with models fine-tuned on the downstream task. With the emergence of LLMs, alternative approaches to NER based on prompting in zero-shot or few-shot settings have gained popularity. Therefore, we established a set of baselines on *PharmaER.IT* using both strategies and a wide range of models.

### Experimental setup

**Models.** We evaluated several state-of-the-art transformer-based architectures for token classification that are widely adopted: bert [24], roberta [25] and xlm-roberta [26]. We studied them on different sizes and pre-trained versions specialized for Italian[10] or multilingual.

Concerning LLMs, we considered several backbones ranging from 7B to 24B parameters, i.e. in the small-medium size tier. We paid particular attention to models that were either pre-trained or further adapted for the Italian language, or that explicitly included Italian in their pre-training corpora. In particular, we assessed on *PharmaER.IT* Llama-3.1-8B, LLaMAntino-3-8B [27], Minerva-7B [28], Velvet-14B[11], Salamandra-7B [29], EuroLLM-9B [30] and Mistral-Small-3.1-24B[12]. We tested two different prompts. A simple one where the LLMs is asked to generate a structured JSON with the entity types as keys and the entities extracted as values. In the second prompt, a definition and some annotation guidelines are specified for each class. In this second evaluation, we also considered SLIMER-IT-8B [5], a fine-tuned version of LLaMAntino for zero-shot NER that follows the approach of [31]. Differently from the rest, SLIMER-IT-8B extracts one entity type at a time, thus each context is repeated 4 times.

**Document Chunking.** *PharmaER.IT* documents are characterized by their considerable length and dense presence of annotated entities, which poses specific challenges for NER models based on transformer architectures with fixed-length input windows. As shown in Figure 2, many documents exceed the standard maximum token limit (e.g., 512 tokens). Documents' size is also problematic for LLMs, which – despite supporting longer contexts – still face practical limits, especially when there are hundreds of entities per document. Therefore, documents are split in chunks. For encoders, we tokenize documents with their respective tokenizer. We set a maximum length of 512 and a window stride of 64. Conversely, for LLMs text is split in passages of sentences having at most 768 characters.

**Training.** Encoder models were fine-tuned on the train/validation/test split reported in Table 3. To augment the training data, we also added the Silver corpus in the train set, and we evaluated its impact on the performance. We kept in all the experiments the learning rate fixed to $5 \cdot 10^{-5}$, 8 epochs and early stopping with patience 3. Batch size was set to 16 in all the experiments without silver data, and 128 otherwise. Unlike encoder-based models, LLMs were used without fine-tuning, relying solely on zero-shot prompts for entity extraction.

**Metrics.** All the models were evaluated on the test set measuring the F1 score. However, due to the different chunking and the non-positional nature of generative models, LLMs and token classifiers were evaluated independently. We adopted the standard micro-F1 score (simply denoted as F1) for token classification models on their positional predictions. In LLMs instead, evaluation occurs at document-level. First, we collect in each passage all the unique text spans extracted per-class by the LLM, then we measure the F1 score against all the

**Table 5**
Results of state-of-the-art encoders fine-tuned for token classification on *PharmaER.IT*.

| Model | Use Silver | Precision | Recall | F1 | Δ (F1) |
|---|---|---|---|---|---|
| roberta | True | 77.32 | **75.96** | 76.64 | **+7.44** |
| | False | 66.86 | 71.71 | 69.20 | |
| roberta-large | True | **79.10** | 75.45 | **77.23** | **+5.57** |
| | False | 71.42 | 71.91 | 71.66 | |
| xlm-roberta | True | 78.01 | **76.12** | 77.05 | **+8.33** |
| | False | 66.16 | 71.49 | 68.72 | |
| xlm-roberta-large | True | 78.06 | 74.92 | 76.46 | **+4.25** |
| | False | 70.25 | 74.28 | 72.21 | |
| bert-multilingual-cased | True | 77.07 | 74.85 | 75.94 | **+9.64** |
| | False | 64.60 | 68.10 | 66.30 | |
| bert-italian-cased | True | 76.80 | 75.05 | 75.91 | **+7.12** |
| | False | 65.37 | 72.57 | 68.79 | |

unique target entities of the document, following the UniNER [2] implementation[13]. Please note that these two F1 scores are computed on fundamentally different values, and therefore they are not comparable.

### Results

**Token Classification.** From Table 5, we can observe that F1 score varies from about 66 to 72 across all models when fine-tuned on the training set without silver corpus. Roberta architectures yield the best scores, in particular xlm-roberta-large that achieves the best result (in the no silver setting).

**Impact of Silver Partition.** The results, shown in Table 5, clearly demonstrate that augmenting the training set with pre-annotated (silver) documents significantly enhances model performance. All evaluated models benefit from this data augmentation, with improvements reaching up to 9.64 F1 points. Notably, smaller models gain the most from the additional data, effectively narrowing the performance gap between base and large architectures. As a result, the base versions of RoBERTa and XLM-RoBERTa emerge as the best and second-best performing models, respectively.

**Off-the-shelf LLMs.** Zero-shot entity extraction of pharmaceutical entities is a challenging task in such an unfamiliar domain. Albeit Mistral-small and LLama-based models achieve relevant scores, other LLMs like, Salamandra, Minerva and Velvet-14B, were not able to follow the provided instructions. Therefore, we reported in Table 6 the F1 scores of only the models that were able to extract entities.

**Table 6**
Zero-shot extraction with simple prompt.

| Model | Precision | Recall | F1 |
|---|---|---|---|
| Llama-3.1-8B | 38.90 | 38.47 | 38.69 |
| LLaMAntino-3-8B | 40.20 | 55.36 | 46.58 |
| EuroLLM-9B | 43.13 | 16.65 | 24.02 |
| Mistral-Small-3.1-24B | **43.61** | **61.90** | **51.17** |

**LLMs with Definition and Guidelines.** When the prompt is enriched with entity type definition and annotation guidelines, all the LLMs generally improve their scores, with the exception of LlaMAntino, which registers a small flexion. In particular, all the models extracted some entities. This suggests that with appropriate prompt design there is room for improving these baselines. Results are presented in Table 7.

**Table 7**
LLMs with definition and guidelines.

| Model | Precision | Recall | F1 |
|---|---|---|---|
| Minerva-7B | 9.69 | 3.08 | 4.68 |
| salamandra-7b | 13.84 | 11.59 | 12.62 |
| Llama-3.1-8B | 35.24 | **57.09** | 43.58 |
| LLaMAntino-3-8B | 34.39 | 54.99 | 42.31 |
| SLIMER-IT-8B | 54.60 | 32.18 | 40.50 |
| EuroLLM-9B | 25.20 | 38.72 | 30.53 |
| Velvet-14B | **58.33** | 4.32 | 8.04 |
| Mistral-Small-3.1-24B | 53.63 | 56.47 | **55.02** |

## 7. Conclusions and future works

In this work, we presented *PharmaER.IT*, an Entity Recognition dataset for the pharmaceutical domain in Italian language. *PharmaER.IT* was created from AIFA drug information leaflets. It includes two corpora: a curated

[13] https://github.com/universal-ner

GOLD corpus 57 of created semi-automatically, and the SILVER corpus, consisting of 2138 annotated RCPs without human intervention.

To establish comprehensive baselines, we assessed a selection of different NER models, both based on token-classification models and zero-shot extraction with LLMs. The resulting *PharmaER.IT* dataset has been released in HuggingFace[14].

In the future, we intend to extend *PharmaER.IT* in two directions. On one side, we plan to increase the amount of manually labeled data and to extend the labels set with more domain-specific tags. On the other hand, we aim to introduce relations between entities in order to extend the dataset to Relational Extraction.

## Declaration on Generative AI

During the preparation of this work, the author(s) used ChatGPT (OpenAI) in order to: Paraphrase and reword, Improve writing style, and Grammar and spelling check. After using these tool(s)/service(s), the author(s) reviewed and edited the content as needed and take(s) full responsibility for the publication's content.
