All four subtasks use the same recipe (Figure 1): three backbones – `CAMeL-Lab/bert-base-arabic-camelbert-msa`, `aubmindlab/bert-base-arabertv02`, and `aubmindlab/araelectra-base-discriminator` – each fitted independently with a Gated Residual Network head, trained with R-Drop (α=2) and class-weighted cross-entropy, and averaged via stochastic weight averaging over the top-3

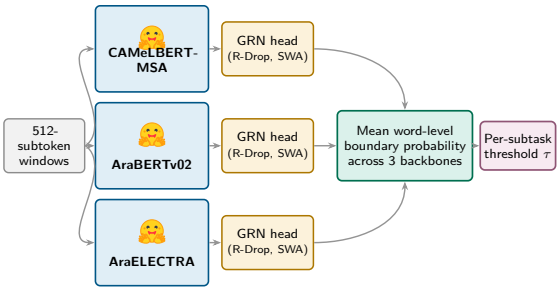

Figure 1: Supervised 3-backbone ensemble (Section 3.1): each backbone is fitted independently with a Gated Residual Network head, trained with R-Drop and stochastic weight averaging; the three backbones' word-level boundary probabilities are averaged and thresholded per subtask.

dev-F_1 checkpoints. Inference uses overlapping 512-subtoken windows (stride 32, mean-logit aggregation); the three backbones' boundary probabilities are averaged and thresholded per subtask via grid search on dev (PA 0.49, NP 0.33, NoPnx-PA 0.49, NoPnx-NP 0.41), replacing an earlier subtask-specific setup (a biaffine head for NoPnx-NP, test-time augmentation for PA, a dual-threshold scheme) that the plain ensemble matches or beats.

3.2 Open-track system for NoPnx-NP

NoPnx-NP is the only subtask where we found a competitive path to using external data. We pseudo-label streamed Arabic Wikipedia articles with our PA-subtask teacher (Section 3.1's CAMeLBERT-MSA+GRN model, run on punctuation-intact text), strip punctuation and diacritics to match NoPnx-NP's format, and transfer any boundary on a stripped token back onto the preceding word (Figure 2). Articles are keyword-bucketed by title/lead text into five coarse genres (literary, political, education, children, general) with a per-bucket quota – coarser than Section 2's 12 genres, since that is a granularity a keyword filter can approximate at Wikipedia scale; we did not audit bucketing accuracy or the teacher's label quality on this out-of-domain text, so some pseudo-label noise should be assumed. We sample 2500 pseudo-labeled documents and combine them with the 174 gold training documents to retrain a 2-backbone version of the recipe above (AraBERTv02 and AraELECTRA, dropping CAMeLBERT-MSA).

We combine two of the three backbones' predictions (AraBERTv02 and AraELECTRA, each thresholded at 0.5, dropping CAMeLBERT-MSA) with our LLM system's (Section 3.3) via a token-level rule: where the two backbones agree, keep

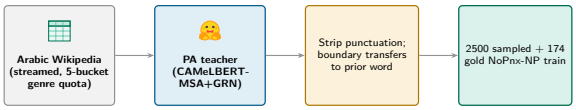

Figure 2: NoPnx-NP open-track data generation (Section 3.2): the PA-subtask teacher (a Hugging Face checkpoint, Section 3.1) labels punctuation-intact Wikipedia text, boundaries survive punctuation stripping via transfer-to-prior-word, and the result is combined with the gold training set.

their agreed label; where they disagree, use the LLM's prediction as tiebreak. This combined system is our open-track entry for NoPnx-NP: it reaches our best dev/test F_1 on this subtask (Table 1), though on the Blind Test set it is edged out by 0.10 points by the real-data-only ensemble+LLM blend (Table 2), which needs no external data and so qualifies for the closed track as well.

3.3 LLM system

An earlier two-stage pipeline – stage 1 classified each document into one or two of 12 genres, stage 2 segmented using only that genre's rules from a single shared guideline (`SEGMENTATION_SKILL.md`), itself synthesized once by cross-validating 8 independent LLM readings of the gold-labeled training set – reached held-out dev F_1 of 88.9 (NoPnx-NP, gemini-3-flash-preview), 85.8 (PA, gemma-4-31b-it), 76.9 (NP, gemma-4-31b-it, single untuned pass), and 72.9 (NoPnx-PA, gemma-4-31b-it, single untuned pass); these are the weaker Gemma model this pipeline was built on, not the current gemini-3.6-flash system, which superseded it with the single-stage prompts in Table 2.

Our currently submitted systems instead use a *single* schema-constrained call per document to `google/gemini-3.6-flash` (Kaggle Model Proxy, plus direct API keys as extra workers for NoPnx-NP), with no separate genre-classification stage – each subtask's prompt encodes genre-specific rules directly. PA and NoPnx-PA use a flat checklist of phenomena (conjunction fusion, reported-speech attribution, hadith isnad chains, poetry/Qur'ānic/Biblical verse-ends, MCQ options, bibliographic blocks), calibrated to the fact that most true boundaries land on punctuation tokens. NoPnx-NP's prompt instead performs a two-level coarse-then-fine pass – first marking discourse-shift blocks, then judging clause-completeness boundaries within each – found by an automated GEPA (Agrawal et al., 2025) search over candidate prompts rather than written by us directly. As before, the model returns anchor word+approximate-position entries, resolved deterministically onto the token sequence via nearest-occurrence, substring-fallback matching (Figure 3).

That resolver required three structural fixes, discovered through genre-stratified error analysis on the punctuation-visible subtasks and unchanged since: gold labels can sit on a trailing punctuation token rather than the anchor word; two visually identical parenthetical patterns (verse citations vs. multiple-choice option markers) resolve in opposite directions; and comma-vs-period surface form is not by itself a reliable boundary-existence signal. Fixing these took the original PA pipeline's 6-document smoke-test F_1 from 7.7 to 86.4 and its held-out dev F_1 from a naive-prompting equivalent of near-zero to 85.8.

Subtask	Track	Dev F_1	Test F_1
PA	Closed & Open	94.77	94.23
NP	Closed & Open	92.96	92.47
NoPnx-PA	Closed & Open	86.34	86.53
NoPnx-NP	Closed	84.00	84.55
NoPnx-NP	Open (+wiki, +LLM)	**85.58**	**84.87**

Table 1: Supervised 3-backbone ensemble, all four subtasks. PA/NP/NoPnx-PA use no external resources, so the same submission qualifies for both tracks; NoPnx-NP's open-track row is the distinct hybrid system of Section 3.2.

4 Experimental Setup

Both systems are evaluated on the same official dev/test splits and, where noted, the official Blind Test set. Supervised hyperparameters: AdamW, learning rate 3×10^{-5}, linear warmup (10% of steps), batch size 8 with gradient accumulation 4, up to 30 epochs with early stopping (patience 4, $\Delta\geq0.001$). LLM hyperparameters: temperature 0, max output tokens 4000, structured JSON output validated against a schema, one API call per document. All F_1 scores are computed at the per-token boundary level using the shared task's own scoring convention. Single-backbone component ablations (head type, R-Drop, SWA) and seed variance are reported in Appendix B.

5 Results

Table 2 reports every officially scored Blind Test set submission with a confirmed generating system, in chronological order per subtask. Three patterns stand out. First, on PA the single-backbone model (94.20, no matching dev/test score measured) trails the 3-backbone ensemble (94.70) by only half a point on the Blind Test set – a modest ensembling

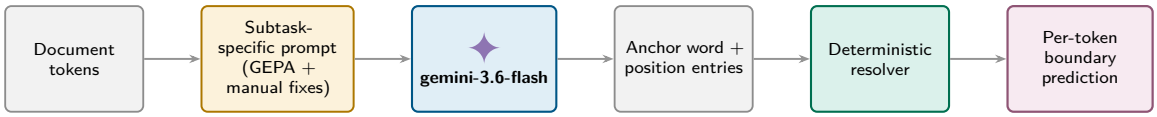

Figure 3: LLM system inference pipeline (Section 3.3), used identically across all four subtasks: a single schema-constrained call per document to `google/gemini-3.6-flash` returns anchor word+position boundary entries, resolved deterministically onto the token sequence.

Subtask	System	Blind F_1	Track
PA	Single-backbone CAMeLBERT-MSA (GRN+R-Drop)	94.20	Closed & Open
PA	LLM, single-stage (GEPA candidate)	85.20	Closed & Open
PA	LLM, single-stage (improved prompt)	90.30	Closed & Open
PA	Supervised ensemble (3-backbone)	**94.70**	Closed & Open
PA	LLM, single-stage (punctuation fix)	89.90	Closed & Open
NP	Single-backbone CAMeLBERT-MSA (baseline)	89.50	Closed & Open
NP	LLM, single-stage (GEPA-distilled prompt)	84.90	Closed & Open
NP	Supervised ensemble (3-backbone)	**91.00**	Closed & Open
NoPnx-PA	Single-backbone CAMeLBERT-MSA (GRN)	87.50	Closed & Open
NoPnx-PA	LLM, seed prompt (gemini-3-flash-preview)	88.40	Closed & Open
NoPnx-PA	LLM, seed prompt (gemini-3.6-flash)	**91.20**	Closed & Open
NoPnx-PA	Supervised ensemble (3-backbone)	89.70	Closed & Open
NoPnx-PA	Ensemble + LLM blend	90.60	Closed & Open
NoPnx-NP	Single model (CAMeLBERT-MSA+GRN+biaffine)	83.00	Closed & Open
NoPnx-NP	LLM, two-stage genre-classify (earlier pipeline)	84.60	Closed & Open
NoPnx-NP	LLM, single-stage flat prompt	85.90	Closed & Open
NoPnx-NP	LLM, hierarchical coarse-to-fine prompt	86.80	Closed & Open
NoPnx-NP	Supervised ensemble (3-backbone, real data only)	85.10	Closed & Open
NoPnx-NP	Ensemble (2-backbone, real data) + LLM blend	**87.40**	Closed & Open
NoPnx-NP	Ensemble (wiki-augmented, genre-filtered) + LLM blend	87.30	Open

Table 2: Every officially scored Blind Test set submission with confirmed provenance, in chronological order (bold = best per subtask). All rows qualify for both tracks except NoPnx-NP's wiki-augmented row (Section 3.2, Open-only, depends on external data). Two further, less certain NoPnx-NP wiki-blend submissions (87.00, 87.10) are omitted.

gain. Second, NoPnx-PA isolates a clean model-upgrade effect: the identical LLM seed prompt scored 88.40 on gemini-3-flash-preview and 91.20 after switching to gemini-3.6-flash, and that unmodified prompt remains our best NoPnx-PA result, ahead of the ensemble (89.70) and our ensemble+LLM blend (90.60) – the only subtask where combining did not help: our two voting backbones (Section 3.2) disagree with each other on just 1.2% of tokens, so the LLM tiebreak rarely fires and correlated backbone errors elsewhere survive into the blend. Third, NoPnx-NP shows the most iteration: from a single model (83.00) through three LLM prompting strategies (84.60–86.80) and a real-data ensemble (85.10), to a real-data ensemble+LLM blend at 87.40, our best result here. Its wiki-augmented counterpart scores highest on dev/test (Table 1) but slightly lower on the Blind Test set (87.30) – echoing NoPnx-PA, where the ensemble (our only tuned dev/test comparison point) is again not the Blind Test set winner. On a controlled, same-checkpoint comparison (Appendix B.1), ensembling beats every individual backbone on every subtask, with the gain growing as structural cues are removed; a document-level bootstrap puts the resulting noise floor at roughly 0.8–1.3 F_1 points, so several of the gaps discussed above are not far outside it.

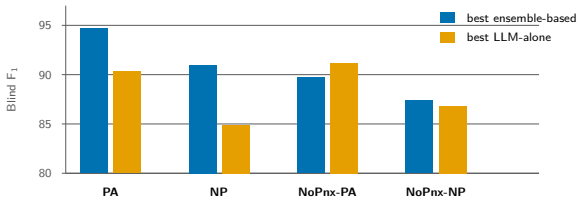

Figure 4: Best Blind F_1 per subtask, ensemble-based vs. LLM-alone systems (Table 2). The ensemble's advantage shrinks and then reverses as punctuation and paragraph cues are removed (PA → NP → NoPnx-PA), where the LLM overtakes it – the clearest single view of this paper's genre/cue-dependence claim (Section 1, Appendix A).

6 Conclusion

As motivated in the Introduction, sentence-boundary judgment on AraSeg 2026 is genre-dependent, and our results show what that costs each modeling paradigm. A supervised ensemble that directly learns boundary statistics from labeled examples is the stronger, more consistent choice on dev/test across all four subtasks (Table 1), and reaches the top Blind Test set score for PA and NP too (Table 2; single-run estimates, std 0.11 F_1 on a 3-seed check, Appendix B). NoPnx-PA is a partial exception: our LLM system's original seed prompt beats both the ensemble and the ensemble+LLM blend on the Blind Test set – the one case where combining did not help, since the LLM only overrides tokens where our two voting backbones disagree (Section 3.2). On NoPnx-NP, stripped of ev-

ery structural cue, the LLM is competitive enough that we combine it with the ensemble for our open-track entry (Section 3.2).

7 Limitations

This paper's Blind Test set comparisons (Table 2) are single-run estimates; our only variance evidence is a 3-seed check on one single-backbone configuration (Appendix B, std 0.11 F_1) and a document-level bootstrap noise floor of roughly 0.8–1.3 F_1 points on the labeled test split (Appendix B.1); several of the gaps we discuss, especially NoPnx-PA's and NoPnx-NP's, are not far outside that floor. The genre-stratified breakdown (Appendix A) uses a smaller, faster LLM (`gemini-3.1-flash-lite-preview`) than the one that produced our official Blind Test set scores (`gemini-3.6-flash`), so its absolute numbers are not directly comparable to Table 2 and only the genre-relative pattern should be read from it. Our GEPA searches (Appendix E) ran on small internal validation splits (30–80 documents, sometimes disjoint from the official dev split) rather than the full 222-document dev set, so their margins are noisy and, for PA and NoPnx-PA, did not transfer into an adopted prompt. NoPnx-NP's open-track system depends on pseudo-labels from a keyword-bucketed Wikipedia sample whose genre-bucketing accuracy and label quality we did not audit. Finally, our LLM system depends on a commercial, closed-weight API whose behavior and availability we do not control, which limits the exact reproducibility of these results going forward.

8 Ethical Considerations

This system performs low-level sentence-boundary segmentation; it does not generate, moderate, or interpret content, and carries minimal potential for misuse. The corpus (Section 2) includes religious genres (Qur'ānic verses, Biblical passages, hadith); our systems treat this text purely as a structural segmentation target and make no claims about religious interpretation or authority. The open-track Wikipedia augmentation (Section 3.2) uses only public, freely licensed text, adding no personal or sensitive data beyond what the shared task's own corpus and Wikipedia already contain. The commercial LLM API used (Section 3.3) was accessed under its provider's standard terms; no human subjects were involved in this work.

A Genre-Stratified Performance

The Introduction motivates this task as genre-dependent but the main results (Table 1, Table 2) report only whole-subtask F_1. This appendix reports a genre-stratified breakdown on a single 80-document, genre-tagged pool shared identically across all four subtasks and both paradigms (the supervised ensemble and the winning LLM prompt), drawn entirely from the 222-document *dev* split so the ensemble's numbers come from each backbone's actual saved checkpoint probabilities rather than retraining anything. Because PA/NoPnx-PA and NP/NoPnx-NP score the exact same documents under the exact same genre tags, each pair remains a minimal pair isolating exactly the effect of removing punctuation and paragraph breaks, just at $4\times$ the sample size of an earlier 20-document pilot. There is no open/closed split: each subtask uses its single winning system per paradigm.

A.1 Winning LLM Prompt, All Four Subtasks

Each subtask uses its winning/deployed LLM prompt (Appendix D: the improved prompt for PA, GEPA candidate 11 for NP, the unmodified seed for NoPnx-PA, the hierarchical coarse-to-fine winner for NoPnx-NP; Appendix E traces how the NP and NoPnx-NP prompts were found).

Caveat – not comparable to Table 2. For throughput, this run used `gemini-3.1-flash-lite-preview` rather than `gemini-3.6-flash`, the model that actually produced Table 2's official Blind Test set scores. The absolute F_1 values below are therefore systematically lower than Table 2 and should not be read as a re-measurement of it; what is meaningful is the genre-relative pattern, macro F_1 per document with a doc under each of its genre tags. PA's quiz score (0.258) looks like an outlier but is not a bug: on several of these documents the model places the boundary on the closing parenthesis of a bare letter option marker (`"(a)"`) rather than on the numeric answer that follows it (`"2007"`) – a genuine `gemini-3.1-flash-lite-preview` misapplication of the quiz rule (Appendix D), confirmed by inspecting its raw output; every referenced token still resolved correctly.

A.2 Supervised Ensemble and Its Individual Backbones, All Four Subtasks (Same 80-Document Pool)

This table reports, for the same 80 documents as Table 3, every individual backbone's genre-stratified F_1 (thresholded at 0.5, matching Table 7's convention) alongside the full ensemble's (mean backbone probability at the subtask's re-tuned threshold: 0.49 PA, 0.33 NP, 0.47 NoPnx-PA, 0.41 NoPnx-NP). All four subtasks now use the genuine 3-backbone ensemble (CAM = CAMeLBERT-MSA, ArB = AraBERTv02, ArE = AraELECTRA): NP/NoPnx-PA/NoPnx-NP's CAMeLBERT-MSA backbone was previously missing (its per-document probabilities were never preserved from the original runs, so this table and Table 7 previously reported a 2-backbone AraBERTv02+AraELECTRA proxy for those three subtasks); it was trained fresh with the identical recipe and is included here and in Table 7.

B Single-Backbone Component Ablations

The submitted systems (Section 3.1) report only the full recipe's score. This appendix reports component-level ablations run during development at the single-backbone level; none of these isolate a component's marginal contribution inside the final 3-backbone ensemble itself.

A 3-seed check of the GRN+R-Drop α=2.0 single-backbone (CAMeLBERT-MSA) configuration gave dev F_1 of 94.24 (base seed), 94.11, and 94.37 – mean 94.24, std 0.11. Swapping only the backbone in this same recipe, AraBERTv02 reaches 94.39 dev F_1 versus CAMeLBERT-MSA's 94.24 (+0.15).

B.1 Per-Backbone vs. Ensemble, All Four Subtasks

Table 2's "single-backbone" rows are not a clean ensembling ablation: each is a different, earlier configuration (different head, different regularization) rather than one backbone from the exact same recipe as the submitted ensemble (Section 5). Table 7 instead isolates ensembling itself: each individual

Genre	n	PA	NP	NoPnx-PA	NoPnx-NP

Table 4: Genre-stratified F_1 of every individual ensemble backbone plus the full 3-backbone ensemble, all four subtasks, same 80 documents as Table 3. CAMeLBERT-MSA is consistently the weakest of the three backbones on every subtask (it is MSA-only pretrained, unlike AraBERTv02/AraELECTRA), most visibly on NoPnx-NP; ensembling still beats every individual backbone in almost every cell despite that. Comparing this table to Table 3: the ensemble outperforms the LLM prompt in nearly every genre/subtask cell, most sharply on PA quiz (0.986 vs. 0.258, see caveat above) and on genres/subtasks where structural cues are weak (e.g. NoPnx-NP hadith, essay); the two paradigms are closest on Qur'ān with punctuation visible (PA, NP), where both are already near-ceiling.

Configuration	Dev F_1	Test F_1
Bare (linear head)	93.26	92.73
+GRN head, weighted CE	94.15	93.56
+GRN+SWA (no R-Drop)	94.09	93.59
+GRN+R-Drop α=0.5	94.14	93.81
+GRN+R-Drop α=1.0	94.26	93.87
+GRN+R-Drop α=2.0 (submitted)	94.24	93.95
+GRN+R-Drop α=3.0	94.25	93.89

Table 5: PA single-backbone (CAMeLBERT-MSA) component ablation; all rows share backbone and data, differing only in the listed component. R-Drop gives a consistent gain over the bare GRN head; SWA alone (no R-Drop) is roughly neutral at this single-backbone level. Note α=1.0 slightly edges out the submitted α=2.0 here (94.26 vs. 94.24 dev) – α=2 was carried forward from earlier tuning and not re-swept after later changes.

Head (NoPnx-NP, single-backbone)	Dev F_1
BiLSTM	79.57
CRF	79.65
GRN (2-layer)	80.62
GRN (1-layer, submitted)	80.88
GRN+MoE+Biaffine (unsupervised)	81.17
GRN+Biaffine+curriculum	81.20
GRN+Biaffine	**81.62**

Table 6: NoPnx-NP single-backbone (CAMeLBERT-MSA+R-Drop α=2) head-type ablation, 212-document dev split. GRN+Biaffine scores highest here, but the submitted 3-backbone GRN ensemble (85.10 dev, real-data-only; Table 1) still exceeds even this best single-backbone head by roughly 3.5 points – consistent with ensembling mattering more than head-architecture choice for this subtask.

backbone's own test-set predictions (thresholded at 0.5, from the exact saved checkpoints behind Section 3.1's recipe) versus the mean-probability ensemble at the subtask's tuned threshold, all on the same 262-document test split, all four subtasks now on the genuine 3-backbone ensemble (CAMeLBERT-MSA's per-token test predictions were originally preserved only for PA; NP/NoPnx-PA/NoPnx-NP's were trained fresh with the identical recipe to fill this gap). These figures are computed independently from this project's saved backbone-level predictions and may differ slightly from Table 1's officially-submitted figures, since checkpoints were retrained more than once during development – the point of this table is the within-table comparison, not an exact reproduction of the submitted numbers.

A document-level bootstrap (2000 resamples,

Subtask	Best single	Ensemble	Gain
PA	94.95	**95.05**	+0.10
NP	93.02	**93.25**	+0.23
NoPnx-PA	88.44	**88.81**	+0.37
NoPnx-NP	85.34	**85.47**	+0.14

Table 7: Best individual backbone vs. 3-backbone ensemble, test F_1, all four subtasks. Ensembling beats every individual backbone on every subtask. NoPnx-NP's gain is smaller with the genuine 3rd backbone included than the 2-backbone proxy previously suggested (+0.14 vs. an earlier +0.33 estimate) – CAMeLBERT-MSA is its weakest backbone by the largest margin of any subtask (Appendix A.2), which caps how much an unweighted average can gain there.

262 test documents) around each subtask's ensemble test F_1 gives 95% confidence half-widths of 0.84 (PA), 1.12 (NP), 1.04 (NoPnx-PA), and 1.28 (NoPnx-NP) points. This is computed on the labeled test split, not the Blind Test set (whose gold labels are not available to us), but gives a concrete noise floor: gaps between systems or subtasks smaller than roughly one point are within the range this bootstrap alone would produce from resampling the same fixed model, before any real difference in behavior.

C Backbone Agreement Analysis (Dev Set)

Table 8 measures token-level agreement between AraBERTv02 and AraELECTRA (the two backbones used in the combination rule of Section 3.2) on each subtask's 222-document dev split, computed directly from each model's saved per-token dev probabilities against gold labels.

As structural cues are progressively removed (PA $\rightarrow$ NP $\rightarrow$ NoPnx-PA $\rightarrow$ NoPnx-NP), the two backbones agree less often, are less reliable when they do agree, and their disagreements concentrate increasingly on true boundary tokens (roughly $9\times$ to $23\times$ the non-boundary disagreement rate, growing with the subtask) – direct, token-level evidence for the cue-dependence claim motivating this paper (Section 1), measured across subtasks rather than across genres specifically. This also substantiates the mechanical explanation in Section 5 for why the LLM tiebreak has limited room to help on NoPnx-PA: the two backbones disagree on only 1.53% of dev tokens, so even a perfect tiebreaker could only revise a small, if disproportionately boundary-heavy, fraction of predictions.

D LLM Prompts

D.1 NoPnx-PA (unmodified seed prompt)

This is the complete, verbatim seed prompt; no GEPA-evolved candidate outperformed it, so it is also our submitted prompt (Section 5).

> **Task.** You are given a document as a flat, ordered list of Arabic words with NO punctuation, but paragraph breaks ARE shown, as literal [PARAGRAPH BREAK] markers in the list. For each word (not the [PARAGRAPH BREAK] markers themselves), decide whether a sentence boundary falls immediately after it (1) or not (0).
>
> **What counts as a sentence boundary.** The gold annotations you are trying to reconstruct were created by first splitting the original punctuated text automatically at punctuation marks, then manually correcting that automatic split: annotators introduced an additional split only when two adjacent spans were actually independent sentences, and merged spans back together when punctuation had incorrectly separated parts of a single sentence. A dependent or incomplete clause is never given its own boundary – only a complete, independent sentence is. Your job is to reconstruct where that manual correction process would have landed, without ever seeing the punctuation itself.
>
> **Paragraph breaks are a clue, not a guarantee.** A [PARAGRAPH BREAK] marker is strong evidence that the word immediately before it ends a sentence, since paragraphs virtually always begin on a sentence boundary. It is not an absolute guarantee, though – apply the same genre-density judgment either way, and do not assume every word right after a [PARAGRAPH BREAK] starts a brand new independent unit if the surrounding content says otherwise.
>
> **Verse and structured-answer overrides.** For Qur'ānic verses, New Testament and Old Testament text, and poetry, the verse is the unit: a sentence boundary falls at the end of every verse, regardless of ordinary clause completeness, and in poetry this same boundary also marks a paragraph break. For question-and-answer material structured like a multiple-choice exam, the question stem is its own unit and every answer option is its own unit, however short.
>
> **Output format.** Return a list of boundary entries, each with the exact word (copied character-for-character) that ends the sentence and its best-guess 1-indexed position (used only to disambiguate repeated words), in increasing order, no duplicates. The last word of the document virtually always ends a sentence.

D.2 NoPnx-NP (GEPA meta-harness winning candidate)

This is the complete, verbatim prompt actually loaded by the Blind Test set inference run (`nopnx_np_hierarchical_coarse_to_fine_winner.md`) that produced the 86.80 Blind Test set result in Table 2; its two-level structure is what

Subtask	Agree rate	Acc. if agree	Disagree rate	Disagree, boundary tok.	Disagree, other tok.
PA	99.56%	99.34%	0.44%	2.48%	0.26%
NP	99.37%	99.05%	0.63%	4.04%	0.33%
NoPnx-PA	98.47%	98.19%	1.53%	6.33%	1.01%
NoPnx-NP	98.18%	97.57%	1.82%	7.62%	1.17%

Table 8: Backbone agreement/disagreement rates and accuracy on the dev split, all four subtasks. The last two columns break the disagreement rate down by whether the gold label at that token is a true boundary or not.

Section 3.3 refers to as the coarse-then-fine pass. Appendix E traces how it was found.

> **Task.** You are given a document as a flat, ordered list of Arabic words with NO punctuation and NO paragraph breaks. For each word, decide whether a sentence boundary falls immediately after it (1) or not (0).
>
> **Procedure: segment top-down, coarse then fine – never judge the whole document in one flat pass.** Judging sentence boundaries over the entire document in one left-to-right pass lets long stretches of text quietly get merged into a single unmarked run, because nothing in the middle "obviously" forces a split when you are holding the whole document's context at once. Avoid this by decomposing the task into two levels.
>
> *Level 1 – coarse discourse blocks.* First, scan the whole document and mark the positions where the discourse itself shifts: a change of topic, a change of speaker, a switch from narration into quoted speech or back, the start of a new anecdote/report/citation, the start of an enumerated list or a Q&A block, or a switch of genre/register. This should produce a small number of chunks, each internally coherent in topic, speaker, and register. Every coarse block boundary is automatically also a final sentence boundary.
>
> *Level 2 – fine judgment within each block.* Take each coarse block one at a time, using ONLY that block's own words as context. Within the block, apply ordinary clause judgment: the gold annotations being reconstructed were created by first splitting the original punctuated text automatically at punctuation marks, then manually correcting that split – a boundary only where two adjacent spans were truly independent sentences. A dependent or incomplete clause never gets its own boundary. If a block still feels too heterogeneous to judge confidently, that is a sign it should have been split further at level 1. Merge the level-2 results across all blocks, in document order, as the final boundary list.
>
> **Verse and structured-answer overrides.** For Qur'ānic verses, Biblical text, and poetry, the verse is the unit: a boundary falls at the end of every verse (each verse is naturally its own coarse block or fine unit), and in poetry this boundary also marks a paragraph break. For multiple-choice-exam-structured material, the question stem is its own coarse block transition and every answer option is its own fine unit within the Q&A block, however short.
>
> **Output format.** Return a list of boundary entries, each with the exact word (copied character-for-character) that ends the sentence and a best-guess 1-indexed position (used only to disambiguate repeated words), in increasing order, no duplicates. The last word of the document virtually always ends a sentence.

E GEPA Search Trajectories

E.1 NoPnx-NP (current system)

The meta-harness search that produced Appendix D's prompt ran on an internal 80-document evaluation subset (distinct from, and smaller than, the official 222-document dev split used everywhere else in this paper). Figure 5 draws the full 2-generation tree; Table 9 gives the same trajectory as exact numbers.

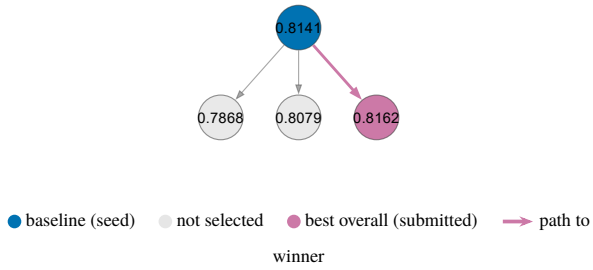

Figure 5: NoPnx-NP GEPA meta-harness tree: baseline (blue) branches into three iteration-2 mutations, two of which regress (gray) and one of which is submitted (purple, path highlighted) – `oversplit_then_merge` (−0.0273), `gap_audit_verification` (−0.0062), `hierarchical_coarse_to_fine` (+0.0022, submitted; full names in Table 9). No per-example Pareto-front data exists for this engine, so unlike the trees below, gray here means simply "not selected," not "off the front."

Iter.	Candidate	Score (Δ)
1	baseline	0.8141 (–)
2	oversplit_then_merge	0.7868 (−0.0273)
2	gap_audit_verification	0.8079 (−0.0062)
2	hierarchical_coarse_to_fine	**0.8162** (+0.0022)

Table 9: Full GEPA meta-harness trajectory for NoPnx-NP. Two of three iteration-2 candidates regressed; the winning margin over baseline is small (+0.0022) on this internal set.

Two of the three iteration-2 mutations *regressed* on this internal set, and the winner's margin over baseline is small. Reading the search's own per-example breakdown, no single candidate dominates:

baseline still wins outright on roughly 32/80 documents, and the direction of error is document-dependent rather than a fixed global bias – candidates that fixed under-splitting on some documents (long, paratactic, hypotactic prose) simultaneously worsened over-splitting on others (short, parallel-clause prose). A planned third iteration, intended to calibrate splitting aggressiveness from each document's own evidence rather than committing to one fixed directional nudge, was never run (search halted after iteration 2; no candidates exist for iteration 3 in the harness's own state log). We report this trajectory in full, including the regressions and the small winning margin, rather than only the winning candidate, since the margin on this 80-document internal set is well within the kind of noise this paper's own Appendix C shows on comparably small samples. Separately, the hierarchical_coarse_to_fine prompt was re-evaluated on a held-out test split disjoint from the search's own 80 documents, where it reached 0.8461 F_1 versus the unmodified baseline's 0.8336 – a gap of similar size to the internal-search margin, which is at least consistent with (though, on one held-out split, not proof against) the win generalizing rather than being an artifact of the search's own evaluation set.

E.2 NP (earlier system, Table 2's "GEPA-distilled prompt" row)

Before the current single-stage, gemini-3.6-flash prompts (Section 3.3), an earlier GEPA search on the two-stage, `gemma-4-31b-it` pipeline (Section 3.3) explored NP prompts with a real, standard GEPA optimizer (reflective mutation with parent-child lineage, not the meta-harness above), on a 30-document internal validation split, and is the origin of Table 2's "GEPA-distilled prompt" row (84.90 on the Blind Test set); it is superseded by the supervised ensemble (91.00) and is reported here purely as a further, real worked example of this project's GEPA usage. Figure 6 draws the full branching tree with node roles taken directly from the GEPA library's own analysis (`gepa.visualization.candidate_tree_dot_from_data`, run against this search's saved optimizer state – not a hand-picked classification), redrawn here in this paper's palette; Table 10 gives the same trajectory, in discovery order, as exact numbers with each candidate's parent and cumulative evaluation-call budget.

Candidates 2, 3, 8, and 11 are all direct children of candidate 1, and their overall scores span nearly the entire observed range (0.4914 to 0.8210) – the same single parent produced both the search's best overall candidate and its lowest-scoring one, which is further evidence (alongside the NoPnx-NP

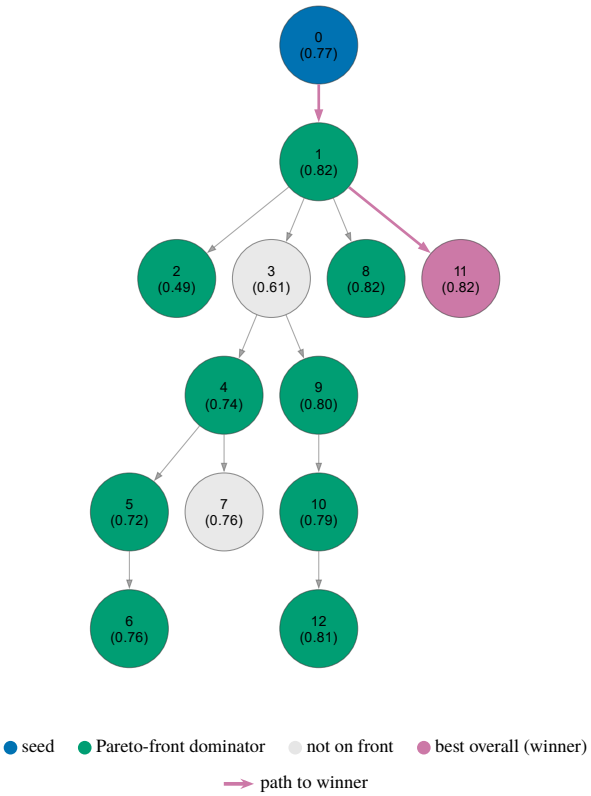

Figure 6: Full GEPA tree for the earlier NP (Gemma) search: 13 candidates, branching to depth 5, roles from the library's own Pareto-front analysis (blue = seed, teal = Pareto-front dominator, gray = not on the front, purple = best overall/winner, path highlighted). Most candidates (teal), including several with a mediocre overall score like candidate 2 (0.4914), are still Pareto-front dominators – each is the single best candidate on at least one validation example, which is exactly why GEPA keeps exploring from them instead of only from the current overall best.

ID	Parent	Score	Calls
0	–	0.7722	0
1	0	0.8184	106
2	1	0.4914	236
3	1	0.6126	296
4	3	0.7449	346
5	4	0.7214	396
6	5	0.7621	446
7	4	0.7631	516
8	1	0.8202	606
9	3	0.7991	676
10	9	0.7935	866
11	1	**0.8210**	976
12	10	0.8100	1086

Table 10: Full GEPA tree for the earlier NP (Gemma) search, in discovery order: candidate ID, its parent candidate, its validation score (30-document internal split), and the cumulative number of LLM evaluation calls spent by the point it was discovered (1086 total). Candidate 11, a child of candidate 1, is the eventual best.

tree above) that a single reflective mutation step's outcome is highly variable and not reliably predictable from its parent's score alone. Yet Figure 6 shows candidate 2 is still a Pareto-front dominator despite that low overall score: GEPA's selection is not purely greedy on the aggregate metric, and a candidate that looks weak on average can still be the sole reason the search keeps a particular failure mode fixed on at least one example.

E.3 PA (Table 2's "GEPA candidate" row)

The same Jul-24 Gemma-reflection GEPA sweep that produced the NP tree above also ran on PA, 17 candidates deep, on its own internal validation split. Candidate 13 (0.8652) is the actual overall best – an earlier script briefly mis-identified candidate 12 (0.7690) as the winner before this was caught and corrected – and it is exactly the candidate behind Table 2's "GEPA candidate" row (85.20 on the Blind Test set), which the separately hand-improved prompt (90.30) beat. Figure 7 draws the full tree, node roles again taken directly from `gepa.visualization`'s own Pareto-front analysis, not a hand classification.

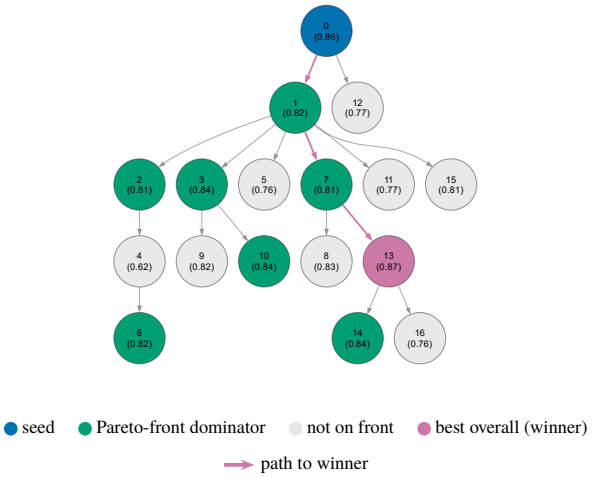

Figure 7: Full GEPA tree for the PA (Gemma) search: 17 candidates (candidate 13, path highlighted). Despite reaching the highest internal score of any PA LLM prompt this project produced, candidate 13 still lost to the manually improved prompt on the Blind Test set (Table 2).

E.4 NoPnx-PA (a separate, later exploration)

Appendix D reports that no GEPA-evolved candidate ever beat the NoPnx-PA seed – that claim comes from an earlier, smaller search (Jul 22) whose only recorded candidate was the seed itself. The same Jul-24 Gemma-reflection sweep as above separately explored NoPnx-PA much further (25 candidates), but on its own internal validation split, not comparable to the Jul-22 run's scale: its seed scored 0.6836 there (vs. 0.9184 on the Jul-22 split) and its best, candidate 12, reached 0.7713 – a real improvement on this run's own terms, but well below the actual deployed seed's score, and never adopted. Figure 8 draws this tree in full since it is real and far more structured than the degenerate one-candidate Jul-22 record, but it is not the search underlying any number in Table 2.

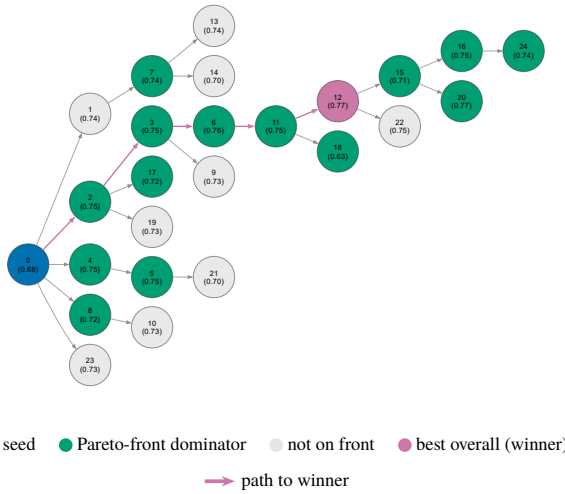

Figure 8: Full GEPA tree for the separate, later NoPnx-PA (Gemma) exploration: 25 candidates, own internal validation scale (see text). Candidate 12 is this run's best; it was tested on the Blind Test set out of curiosity (a genuinely different prompt, worth trying on a stronger model) but no result from it is used anywhere in Table 2.

E.5 Before vs. after GEPA, all four subtasks

Table 11 summarizes seed-vs-best-candidate for the GEPA search actually underlying each subtask's Table 2 entry (NoPnx-PA's row is the real, adopted Jul-22 search, not the larger but unused exploration in Figure 8 above).

F Illustrative Error Patterns

Section 3.3 summarizes three structural fixes found through genre-stratified error analysis. This appendix gives one constructed illustration of each pattern, with Arabic script and its transliteration side by side – these are worked illustrations of the described failure mode, not a verbatim excerpt from one specific document.

Trailing-punctuation attribution. In a sentence ending قال أبو هريرة:... (*...qala Abū Hurayrah:*), the gold boundary falls on the colon-equivalent

Subtask	Seed	Best	Δ	Adopted
PA	0.8628	0.8652	+0.0024	no
NP	0.7722	0.8210	+0.0488	yes
NoPnx-PA	0.9184	0.9184	+0.0000	(seed)
NoPnx-NP	0.8141	0.8162	+0.0021	yes

Table 11: Seed vs. best-candidate internal validation score for each subtask's real, adopted-search GEPA trajectory. Each row's scale is internal to that search (different validation sets/sizes across subtasks, noted in each subsection above) – not comparable across rows, only within. "Adopted" marks whether the best GEPA candidate itself became the deployed prompt: no for PA (a manually improved prompt won instead) and NoPnx-PA (best candidate is the seed – GEPA found no improvement at all), yes for NP and NoPnx-NP. GEPA moved the needle substantially only on NP.

punctuation token itself, not on the preceding word *Hurayrah*. A resolver that always anchors a boundary to the nearest *word* misses this by one token; the fix explicitly allows a punctuation token to be the boundary anchor.

Verse citation vs. MCQ option. *...as stated (2:255) the throne...* is a Qur'ānic āyah citation: the parenthetical is not a boundary. *...Which is the capital? (a) Amman (b) Irbid...* is a multiple-choice option list: each option boundary *is* a real boundary. Both patterns place short parenthetical-adjacent tokens in visually similar positions but resolve in opposite directions (Section 3.3); genre context, not surface form, disambiguates them.

Comma vs. period surface form. A comma-separated list of independent clauses (*...the market closed, the workers left, the street emptied...*) can each be an independent sentence-level unit despite comma punctuation, while some period-adjacent tokens in enumerations or abbreviations are not real sentence boundaries at all – surface punctuation alone under-determines the label, which is why the punctuation-visible subtasks (PA, NoPnx-PA) still need genre-conditioned rules rather than a lookup table from punctuation mark to boundary.

IslamicEval 2026: The Second Shared Task of Capturing LLMs Hallucination in Islamic Content

Abstract

We describe the main findings of the second IslamicEval shared task on hallucination detection in LLM-generated Islam related text (IslamicEval 2026). While the first occurrence of the task in 2025 separately evaluated hallucination detection/correction in quoted Quranic verses and Hadiths alongside a distinct QA retrieval subtask, this year integrates these objectives into four fine-grained subtasks with a much larger provided training set. Given an Islamic question and an LLM response, systems must: 1) detect all cited Quran and Hadith references (including verse numbers and narrators); 2) identify hallucinated citations; 3) correct the hallucinated content; and 4) assess the relevance of every citation to the prompt. Sixteen teams participated in the final phase across the four subtasks, utilizing diverse pipelines that highlight both the challenge of the task and the necessity of mitigation strategies in Islamic AI applications.

1 Introduction

Large Language Models (LLMs) are becoming an important part of Arabic natural language processing applications, with a range of Arabic-focused and multilingual models now being used across tasks such as question answering, retrieval, and content generation (Sengupta et al., 2023; Bari et al., 2024; Fanar Team, 2025). Alongside these advances, hallucination, the generation of text that appears plausible but is factually incorrect, unsupported, or fabricated, remains a key challenge.

This challenge is particularly sensitive in domains where accuracy and authenticity are critical, such as religion. As users increasingly consult LLMs for religious guidance, the risk of generating fabricated or ungrounded Islamic content has become a critical concern (Abdelaal et al., 2026; Elmahjub et al., 2026). Hallucinated citations can lead to misattributed verses, paraphrased text presented as verbatim citations, or entirely fabricated Hadiths, risking misrepresentation of canonical sources and contributing to the spreading of religious misinformation (Fawzi et al., 2026).

Recent benchmarks such as IslamicMMLU (Abdelaal et al., 2026), IslamicLegalBench (Elmahjub et al., 2026), MAWARITH (Bouchekif et al., 2026), and QIAS 2025 (Bouchekif et al., 2025) have expanded the evaluation of LLMs on Islamic content, mainly through factual knowledge and specific reasoning tasks. However, they do not address hallucination in generated Islamic content as a direct evaluation target. Instead, this issue usually appears only indirectly through patterns of factual errors.

IslamicEval 2025 (Mubarak et al., 2025) was the first shared task to make hallucinated citations the central evaluation target. IslamicEval 2026 introduces a few improvements. First, it moves from a single label per quotation to a more granular segment-level evaluation, where each citation is fragmented into its quoted text (*ayah* for Quranic verses or *matn* for the reported prophetic saying), its *isnad* (the chain of transmitters, where a narrator is named), and its claimed source (the collection, chapter, or verse attribution supplied by the model), and each segment receives its own labels. Errors that a single label would conceal, such as an accurately quoted text paired with an incorrect attribution, are now separately evaluable, directly exposing common LLM misattribution patterns. Second, it introduces a relevance subtask to verify whether a cited Quran and/or Hadith is relevant to the question's answer. This subtask was missing last year; we noticed that cited Quran and Hadith can be correctly cited (non-hallucinated) but still irrelevant to the question, which is a different type of relevance-related hallucination. Third, it addresses issues such as variations in attested Hadith wording and the omission of diacritics by providing

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1022–1034

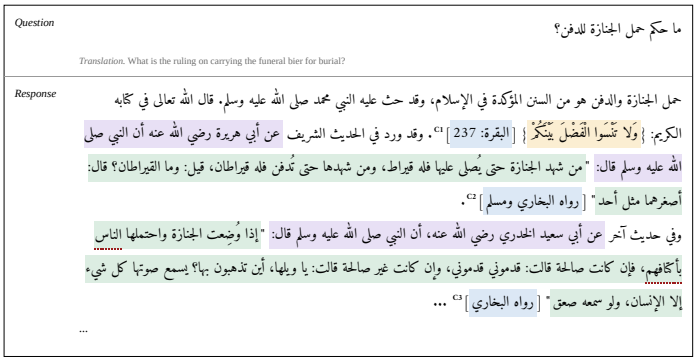
a list of potential corrections rather than a single specific one. Fourth, questions in earlier Arabic Islamic question-answering datasets are usually handwritten (Malhas and Elsayed, 2020) or taken from textbooks (Alnefaie et al., 2023; Bouchekif et al., 2025). These structured sources drift away from natural user queries (Bhatia et al., 2026). Therefore, we built our question pool from real Islamic questions from two interaction logs, namely Fanar and AnsariChat (Fanar Team, 2025; Kadous et al., 2026), thereby providing a realistic sample of what users ask LLMs in practice. Finally, we provide a substantially larger set of training, development, and test data, made possible by employing LLM-assisted annotations validated against expert-annotated gold sets in place of the exhaustive manual annotation used in IslamicEval 2025, and generating a fully annotated set of approximately 6,000 LLM responses across dataset splits, quadrupling the amount of released data compared to IslamicEval 2025.

2 Task Description



IslamicEval 2026 has four subtasks, each evaluated on a separate blind test set to allow teams to participate in any subtask they want. We restricted the teams to using LLM models that are at most 13B parameters.

- **Subtask 1: Span Detection.** Given an LLM-generated response to a user question, participants determine the spans of the claimed fragments of religious texts, and label each by type: *ayah*, Hadith *matn*, *isnad*, or claimed source. Spans are represented by character indexes into the response. Evaluation is based on character-level macro-averaged F1 over the four segment classes.
- **Subtask 2: Hallucination Identification.** For each segment of the gold citations, participants need to categorize it as correct or incorrect. The quoted text (*ayah* or *matn*) is correct only if it reproduces an attested text verbatim, while the *isnad* and claimed source are judged against the quoted text and are N/A when the quoted text is incorrect. Evaluation is based on accuracy per segment type, macro-averaged across types.
- **Subtask 3: Correction.** Given a gold citation span labeled incorrect, recover the canonical text it distorts, or mark the span as uncorrectable if none exists. Correction covers Quranic ayahs and Hadith *matn* within the six canonical collections released with the dataset. A span may have more than one possible correction, and matching any of them is credited.
- **Subtask 4: Answer Relevance.** Given a user question in Arabic, an LLM response to that question, and the correctly extracted Qur'anic and Hadith-matn citation spans from that response, classify each citation using a binary label: **relevant (1)** or **non-relevant (0)**. A citation span is considered **relevant** if it *directly* or *indirectly answers* the question. Citation spans that are merely topically related but *do not answer* the question, as well as citation spans that are entirely *unrelated*, should be classified as **non-relevant**. A citation span may be authentic and accurately quoted yet still be labeled non-relevant if it does not answer the question. The relevance labels are defined as follows.
  - ***Relevant (1)***
    - ***with direct answer***: The citation span *explicitly* answers the question, and its meaning aligns with the question's intent and context, or
    - ***with indirect answer***: This applies in two cases: First: The citation span does not explicitly answer the question, but it *implicitly* provides the requested information, and its meaning aligns with the question's intent and context. Second: The citation span does not directly or implicitly answer the question on its own, but it provides clear textual support for the reasoning in the system's response such that an answer to the question can be inferred.
  - ***Non-relevant (0)***: The citation span does not provide a *direct* or *indirect* answer to the question. If a citation is only topically related but does not actually answer the question or support the answer reasoning in a meaningful way, it must be marked as non-relevant. Topical overlap alone is insufficient.

  We note that *partial support* is permitted; a relevant citation span may provide either a complete answer to the question, or an essential component of the answer. Figure 1 shows an example for all subtasks.

3 Data and Resources

The dataset is built from two sets of real user interactions rather than a curated question bank.

Citation	Segment	Subtask 1 Span Detection	Subtask 2 Hallucination Identification	Subtask 3 Correction	Subtask 4 Answer Relevance
C1 *Ayah citation*	Ayah	127–161	Correct	—	0
	Claimed source	164–175	Correct	—	—
C2 *Hadith citation*	Isnad	203–261	Correct	—	—
	Hadith matn	263–378	Correct	—	1
	Claimed source	381–399	Correct	—	—
C3 *Hadith citation*	Isnad	416–481	N/A	—	—
	Hadith matn	483–657	Incorrect	إِذَا وُضِعَتِ الْجَنَازَةُ وَاحْتَمَلَهَا الرِّجَالُ عَلَى أَعْنَاقِهِمْ ، فَإِنْ كَانَتْ صَالِحَةً قَالَتْ: قَدِّمُونِي ... *one of four accepted attested wordings*	1
	Claimed source	660–672	N/A	—	—

Figure 1: An annotated training-set example (Response R003070, Question Q00405) across the four subtasks. The second Hadith citation is fully correct; the third alters the attested wording, so its *isnad* and claimed source are N/A, and a correction is supplied; the correctly quoted Ayah is judged irrelevant to the question, showing that a correct citation is not necessarily relevant evidence.

Questions from the chat logs of Fanar (Fanar Team, 2025), an Arabic-centric AI platform, form the training and development sets, and questions from AnsariChat (Kadous et al., 2026), an Islamic retrieval-augmented chatbot, form the blind test set. Drawing the test set from a different source ensures no test question appears in the train/dev sets and that systems are evaluated on a question/response distribution not seen during development.

Prompts from both sources were filtered for Islamic relevance, keeping only standalone questions answerable from the Quran and Hadith, and for appropriateness, removing prompts whose framing demeans a group, solicits harm, contains obscene language or personal data. From each filtered pool, 500 questions were sampled, and responses were collected from 12 models: four Arabic-centric, six multilingual, and two frontier models, GPT-5.4 and Gemini-3.1-Pro. All models received the same Arabic prompt that explicitly asks them to support their answers with Quranic ayahs and Hadiths and to name the source of each citation. The generated answers were then cleaned of degenerate repetition, truncation, and heavy code-switching, which would otherwise degrade citation quality through duplicated or truncated spans. After cleaning, 5,674 LLM responses to Fanar questions and 5,629 LLM responses to AnsariChat questions remain. Following citation extraction and release validation, we released 5,190 annotated responses to Fanar questions as the training and development sets, and a sample of 3,620 responses to AnsariChat questions was annotated as the blind test set, a size set by the annotation budget and by the scale of the released development split. Within the test set, 620 responses are reserved for Subtask 1, and the citations of the remaining 3,000 are partitioned among Subtasks 2, 3, and 4 so that the annotation of one subtask cannot leak the labels of another. Annotation runs as an LLM pipeline over the four subtasks in sequence, where each stage annotates the output of the previous one. For each subtask, a sample of the data was annotated by three Islamic-studies experts and used as a gold set to select the frontier model and prompt configuration most aligned with expert annotations, which are subsequently used to annotate the full set. The size of each gold set and its agreement with the automatic labels are reported per subtask in the annotation setup subsections. Table 1 summarises the dataset composition

Subtask & Element	Train	Dev	Test
Subtask 1: Span Detection			
Responses	4,706	484	620
citation-free	583	72	61
Quran citations	8,195	698	1,299
Hadith citations	7,048	588	1,102
Isnad spans	2,634	204	448
Claimed-source spans	14,902	1,238	2,355
Subtask 2: Hallucination Identification (*correct / incorrect*)			
Ayah	4,492 / 3,703	222 / 476	3,539
Matn	2,842 / 4,206	121 / 467	3,076
Isnad	808 / 130	16 / 14	465
Claimed source	6,781 / 1,126	283 / 146	3,295
Subtask 3: Correction (*correctable / not correctable*)			
Ayah	1,677 / 2,026	219 / 257	944
Matn	1,029 / 3,177	108 / 359	1,054
Subtask 4: Answer Relevance (*relevant / not relevant*)			
Ayah	2,953 / 576	76 / 82	432
Matn	2,301 / 401	75 / 49	333

Table 1: Dataset composition across splits and subtasks. For Subtasks 2–4, Train and Dev report slashed label counts formatted as *correct/incorrect* (Subtask 2), *correctable / not correctable* (Subtask 3), and *relevant / not relevant* (Subtask 4). Test reports the total number of unlabelled instances for evaluation. Subtask 2 excludes *isnad* and claimed source spans marked N/A due to incorrect text.

across the training, development, and test splits for all four subtasks.

3.1 Annotation Setup and Guidelines

3.1.1 Subtask 1

To annotate spans, an LLM detects and segments citations, followed by a deterministic matching step that locates each span in the response. Gemini 3.5 Flash (Google DeepMind, 2026b) was selected for this stage because it achieved higher precision and fewer false-positive Hadith detections than GPT-5.5 on a manually annotated validation set. It is prompted to find every intended *ayah* or Hadith in the response, and to return its type, full span, claimed source, and, for Hadith, the *matn* and *isnad* sub-spans. Because the model may return the text slightly altered (e.g., missing diacritics or quotation marks), we locate each fragment in the original response to record its exact start and end positions. A response is discarded whenever any of its fragments cannot be found, guaranteeing that every released span is an exact substring. For the blind test set, responses were annotated independently by Gemini 3.5 Flash and GPT-5.5 (OpenAI, 2026), retaining only spans where the two models agreed on the citation type and boundaries. The automatic annotation was validated against a gold set of 199 responses containing 692 citations (343 Quran and 349 Hadith), with 12 citation-free responses retained to test whether the model correctly abstains when no citation is present. Gold spans were copied verbatim following the boundary guidelines in Appendix A. Against this gold set, the pipeline reached a citation-detection F1 of 98.6% and abstained correctly on all citation-free responses. It segmented every fragment reliably, with span F1 of 99.9% on the *ayah*, 98.6% on the *matn*, 97.4% on the *isnad*, and 99.5% and 98.1% on the Quranic and Hadith claimed source, respectively. The model rarely misses citations, and the residual errors are at the boundary level, such as quotation marks or emphasis markers swept into the span.

3.1.2 Subtask 2

The labels are produced by Gemini 3.1 Pro (Google DeepMind, 2026a), the model selected for this subtask because it achieved the strongest overall agreement with the expert majority labels, which receives each citation through a dedicated Quran or Hadith prompt with its segments as separate fields, so that the quoted text is labelled first and the *isnad* and claimed source are then labelled against it. The labelling rule is strict: the quoted text is correct only if every word matches an attested wording, meaning any documented transmission for Hadith and the canonical verse for Quran, with nothing omitted from the middle; a contiguous partial quotation is accepted, and Quranic diacritics are judged only where the citation supplies them. The authenticity grade of a Hadith does not affect the label, as a weak or forged report quoted exactly is still an existing text, whereas an altered or invented one is not. The decision rules are provided in Appendix B.

The automatic labels were validated against an expert gold set of 350 randomly sampled citations (250 Hadith and 100 Quran), independently annotated by three Islamic-studies experts. Each expert assessed every segment, assigning *correct* or *incorrect* to the quoted text, the *isnad*, and the claimed source. The majority vote across the three experts serves as the gold label. The automatic labels substantially agree with this gold set on Hadith and almost perfectly on Quran, with every segment scored only where the citation supplies it. On Hadith, agreement is substantial on the *matn* ($\kappa = 0.70$, $n = 248$) and the claimed source (0.70, $n = 241$), reflecting the difficulty of judging wording against multiple attested transmissions, and rises to almost perfect on the *isnad* (0.86, $n = 108$). A manual review of the Hadith disagreements shows that

Figure 2: One Hadith is attested in four wordings that are semantically equivalent but differ in wording, with the differences highlighted in red. All four are accepted corrections for a span that distorts this Hadith.

they stem primarily from differing reference texts—where the judge and human experts matched the *matn* to different attested transmissions—or from minor wording variations, rather than cases where a non-existent citation was marked correct. On Quran, where the text is fixed and a quotation either matches the verse or does not, agreement reaches 0.88 on the *ayah* ($n = 99$) and 0.97 on the claimed source ($n = 97$).

3.1.3 Subtask 3

Corrections are produced by GPT-5.4, selected for this stage through validation with expert judgments. The model was prompted to permit a correction only when a contiguous sequence of words from the span appears in a real canonical text after normalization, and to decline spans that share only topic or scattered words with the corpora. Every proposed correction is subsequently grounded against the released corpora by snapping it to the closest text, which fixes the scope of correction to the provided corpora and guards against potential hallucinated corrections. Grounded Hadiths are additionally expanded to retrieve attested variants through word-based Jaccard similarity, so that a participant matching any documented wording is credited. Figure 2 shows one Hadith with four attested variants, all of which are acceptable corrections for the hallucinated span. The corrector was validated on a gold set of 100 incorrect spans (50 Quran and 50 Hadith). Each span was corrected by GPT-5.4 and Gemini 3.1 Pro, and three Islamic-studies experts judged every model's corrections, either accepting or rejecting it and supplying their own, including marking the span uncorrectable. Experts agree reliably on whether a span is recoverable (Fleiss $\kappa = 0.688$), but often propose different valid corrections, so the gold for a span is a set of accepted corrections rather than a single string; a candidate is majority-backed when at least two annotators support it. GPT-5.4 was chosen as the corrector model as it agrees with a majority-backed candidate on 90% of spans, reproduces every correction on which the experts unanimously agree, and its residual errors lean toward the safer failure of declining rather than forcing a correction.

3.1.4 Subtask 4

To establish a reliable and scalable answer relevance annotation pipeline for thousands of question-response-citation triplets, we first conducted a pilot study on a sample of 185 triplets with two Islamic Studies domain experts following structured guidelines with illustrative examples. These guidelines (excluding examples) were then adapted into a zero-shot prompt for three frontier LLMs acting as judges: Gemini 3.5 Flash, GPT-5.4, and Claude Sonnet. To elevate label reliability beyond the moderate agreement observed between human experts (Cohen's $\kappa = 0.497$), we adopted a unanimous agreement protocol across the three models. On the pilot sample, requiring 3-way unanimous LLM agreement raised the overall inter-annotator reliability between experts and models to Fleiss' $\kappa = 0.587$, while agreement among the three LLMs reached $\kappa = 0.617$. Deploying these judges across the Subtask 4 dataset yielded substantial inter-annotator agreement, with Fleiss' κ scores of 0.699 (train), 0.734 (dev), and 0.659 (test). Accordingly, for the published official Subtask 4 dataset, we strictly adopted this full agreement strategy to guarantee maximal label quality and faithfulness.

4 Evaluation Measures

Subtask 1. Character-level macro-averaged F1 is calculated over the four segment classes (*ayah*, *matn*, *isnad*, and claimed source), following IslamicEval 2025 but extended to the segment level: each character of a response is labelled with the class of the span covering it, and F1 is computed per class and macro-averaged. Predictions are matched to the gold by response identifier, and character-level F1 is computed independently for each segment class. Any span predicted where the gold has none counts against precision, so over-detection in citation-free responses is penalised directly.

Subtask 2. Predictions are matched to the gold by response, annotation, and segment identifiers, and scored with accuracy per segment type (*ayah*, *matn*, *isnad*, claimed source). Segments whose gold label is N/A are excluded from scoring, and a

missing prediction for a scored segment counts as incorrect. The official score is the macro-average across all four categories, preventing frequent classes from dominating rare ones.

Subtask 3. Subtask 3 is scored for overall accuracy, and separately for Quran and Hadith. A prediction is counted correct if it exactly matches any of the acceptable corrections for the span, or marks it uncorrectable when the span is baseless. Declining and correcting are scored on the same scale, so over-correcting fabricated spans costs as much as failing to recover real ones. Quran matching is diacritic sensitive apart from default diacritics, while Hadith is diacritic insensitive. Both system answers and gold corrections are normalized before comparison to avoid penalizing superficial orthographic differences, and all gold corrections are grounded in the shared corpora.

Subtask 4. Macro-averaged F1-score is computed using a two-step process to ensure a fair assessment of citation relevance. For each question-response pair, an initial F1-score is calculated over the system relevance labels; then, macro-average is calculated across all questions to compute the final score.

5 Evaluation Setup

We used CodaBench[1] platform to host competitions for all subtasks. To enable local evaluation, we released evaluation scripts, training, and development sets on our GitHub codebase[2]. The maximum allowed number of submissions per team was 100 during the development phase and 30 during the test phase. However, participants were aware that only the last three valid submissions would be considered for the final evaluation. While we made the leaderboard available during the development phase, we kept it hidden during the test phase. Results of the last three runs were shared with participants by the end of the test phase, and they were requested to describe them in their system description papers. The test phase received relatively strong engagement, with 9 teams in Subtask 1 (16 submissions), 8 teams in Subtask 2 (20 submissions), 4 teams in Subtask 3 (10 submissions), and 7 teams in Subtask 4 (18 submissions).

6 Participating Teams and Methods

Table 2 lists the participating teams, their affiliations, and their submitted subtasks; Table 3 presents the official test results across all four subtasks, while Table 6 in Appendix E summarises the methodologies adopted by participating teams.

Subtask 1. All the participating teams treated span detection as a sequence-labelling problem, using fine-tuned Arabic encoders. The majority of the teams chose AraBERT-based models (HIAST, Yaqeen, Bayan_CU, and Qahera), while others used variants of CAMeLBERT (Northwestern 9 and Taqwatech) or AraModernBERT (SanadAI). The most common approach was token classification using standard BIO tagging, although Yaqeen performed character-level labelling. To handle long responses that exceed standard transformer input limits, multiple systems employed overlapping sliding windows (Northwestern 9, Taqwatech, Yaqeen, Bayan_CU, and Qahera). Several teams also applied heuristic post-processing to merge overlapping predictions, reconstruct valid spans, and remove implausible outputs.

Subtask 2. Nearly all participating teams grounded hallucination identification in the canonical corpora, labelling each segment by retrieving and comparing. These retrieval-based systems decoupled text matching from source verification; ayah and matn segments were first matched with canonical sources, after which claimed sources and *isnad* components were validated against the matched texts. For text retrieval, systems combined text normalisation with exact or fuzzy string matching (EIDIANLP, Qahera), sparse TF–IDF search (Taqwatech), or character n-gram retrieval with reranking (Namaa Community). To verify attribution, teams applied explicit heuristic rules over collections and narrators (Taqwatech, Namaa Community, Qahera), entity matching against retrieved references (SanadAI), or trained segment-level classifiers (Yaqeen). Tathabbut built an evidence-fusion pipeline that combines TF-IDF features with SVM and LightGBM classifiers based on text overlap, narrator chains, and citation consistency. Unlike corpus-grounded systems, HIAST framed verification as sequence classification, evaluating each segment directly from its surrounding context with a fine-tuned AraBERT model.

Subtask 3. All four teams treated correction as retrieval over the released corpora rather than gener-

ation, returning verbatim corpus strings so that the required wording and diacritics are preserved. Candidates were retrieved through sparse lexical matching, using character and word n-gram TF–IDF (Yaqeen, Tathabbut, Taqwatech) or fuzzy partial matching (Qahera), and then reranked. Three teams learned the reranking with gradient-boosted trees over lexical alignment features such as coverage, sequence agreement, and score margins (Yaqeen, Tathabbut, Taqwatech), while Qahera combined a bag-of-words score with contiguous-substring coverage. Tathabbut additionally drew on the question, the surrounding response, and the claimed source as supporting evidence, and on the corrections of similar training spans. Every team calibrated separate acceptance thresholds for Quran and Hadith, and three of them made the decision to abstain with a component separate from the one that chose the candidate (Yaqeen, Tathabbut, Taqwatech). Only one team used an LLM, and only for Hadith, where a 4B-parameter model verified retrieved candidates (Qahera).

Subtask 4. Many teams employed small-scale LLMs such as ALLaM-7B, Qwen3-4B, or Gemma-3-4B (AhmedNLP, HaDe, May-X, Qahera). To enhance the models' ability to assess semantic relevance beyond mere topical overlap, participants frequently incorporated Chain-of-Thought (CoT) reasoning (HaDe, May-X, Qahera) or Parameter-Efficient Fine-Tuning (PEFT) via LoRA (AhmedNLP, May-X). Notably, rather than relying on manual prompt crafting, Qahera adopted an iterative propose-evaluate-diagnose search harness to systematically optimize their prompts. Retrieval-augmented architectures spanning both classification and generative setups were also prominent (Bayan, HIAST), demonstrating the value of grounding decisions in external, authenticated corpora. In addition, addressing class imbalance, calibrating decision thresholds, and careful data preprocessing were recurring themes across several systems (AhmedNLP, May-X, Taqwatech).

7 Results and Discussion

7.1 Subtask 1: Span Detection

Bayan_CU secured first place in Subtask 1 with a character-level Macro-F1 score of 97.36%. The team fine-tuned AraBERT as a BIO token classifier and used overlapping windows, span merging, and heuristic filtering to improve the final boundaries. SanadAI placed second with 97.35%, using AraModernBERT, class-weighted training, and additional Quranic and Hadith examples, including manually selected hard negatives from Shamela [3]. HIAST ranked third with 97.25%, using an AraBERT BIO classifier and overlapping windows to process long responses. Most other teams followed a similar encoder-based sequence-labelling approach, using either AraBERT, CAMeLBERT, or AraModernBERT. Only 0.11 percentage points separated the three leading systems, suggesting that post-processing, data preparation, and long-response handling were as important as the choice of encoder. Although Northwestern 9 reported an F1 score of 96.30% on the development set, they received 0% on the official test set due to a submission error on their side.

7.2 Subtask 2: Hallucination Identification

Tathabbut secured first place in Subtask 2 with an accuracy of 94.52%. Its system combined TF–IDF features, SVM and LightGBM classifiers, and rule-based checks to use evidence from canonical texts, narrator information, and citation context. Yaqeen placed second with 91.07%, retrieving candidate texts and using separate classifiers to verify *ayah*, *matn*, claimed-source, and *isnad* segments. Qahera ranked third with 90.58%, using exact and fuzzy matching for quoted texts and explicit checks for their stated sources and narrator information. Taqwatech followed closely with 90.50%, combining Arabic text normalisation, lexical retrieval, character TF–IDF, source checks, and narrator matching. No team used a generative model at inference for Subtask 2; instead, the strongest systems combined retrieval from canonical corpora with classification or rule-based verification.

7.3 Subtask 3: Hallucination Correction

Taqwatech and Tathabbut tied for first on Subtask 3, both reaching 86.29% overall accuracy. Taqwatech used a TF-IDF retriever and ranked candidates with a gradient-boosting model over 30 lexical features, and deciding whether to correct with a separate classifier improved its performance. In addition to TF-IDF retrieval and reranking, Tathabbut used the surrounding context, the original question, and the claimed source as soft signals for ayah correction, together with a memory of training hallucinations to support Hadith correction. Yaqeen placed second, using character n-gram retrieval, a type-aware

(d) Subtask 4

Table 3: Results across the four subtasks, reporting each team's best run; teams are ranked (R) per subtask. Teams marked with (∗) did not submit a system description paper. **Subtask 1**: character-level macro-averaged F1 over the four citation classes (Ayah, Matn, Isnad, CS: claimed source). We exclude the non-citation (neither) class from scoring; therefore, we report no majority baseline, since a trivial all-neither prediction scores 0 and predicting the majority citation class (all-Ayah) reaches only 5% F1. **Subtask 2**: accuracy macro-averaged over the four segment types, with per-segment accuracy; the majority baseline (predicting all segments correct) is **65.62%**. **Subtask 3**: correction accuracy overall and per corpus; the majority baseline (predicting all citations uncorrectable) is **65.77%**. **Subtask 4**: macro-averaged F1; the majority baseline is **71.24%**. Taqwatech and Tathabbut tie for first on Subtask 3. May-X is unranked in Subtask 4; the submission was excluded for exceeding the 13B parameter limit.

classifier for the abstain decision, and reranking applied only to Quran. Qahera placed third, using fuzzy partial matching for retrieval and a Gemma-3-4B model in a verify, select, then re-verify cascade over its Hadith candidates, while its Quran corrections were decided by a single overlap-and-coverage score. No team fine-tuned a model or generated corrections, which leaves both as open directions for future systems on this task.

7.4 Subtask 4: Answer Relevance

The HIAST team officially secured first place in Subtask 4 with a Macro-F1 score of 77.21% (Table 3). They adopted a retrieval-augmented, evidence-grounded framework combining hybrid lexical-semantic retrieval with a fine-tuned AraBERTv02 classifier. Their retrieval pipeline coupled BM25 and E5 dense embeddings indexed via FAISS, fusing the candidate lists using Reciprocal Rank Fusion (RRF).

The second and third ranked teams both leveraged the ALLaM-7B model. The second place, AhmedNLP, achieved a score of 76.79% (Table 3) by fine-tuning ALLaM-7B using LoRA and a response-balanced RankNet loss, deterministically scoring relevance via first-token logit differences between "yes" (*na'am*) and "no" (*la*). Meanwhile, HaDe attained third place with a score of 74.84% using a few-shot prompting setup with ALLaM-7B; notably, their highest test score was achieved without Chain-of-Thought (CoT), slightly outperforming their CoT-augmented baseline.

Although team May-X achieved the highest overall Macro-F1 score of 85.56% (Table 3), their submission was excluded from the official rankings for violating the task constraint prohibiting using

LLMs exceeding 13B parameters. Specifically, they utilized gpt-oss-120B to synthesize rationales for offline reasoning (CoT) distillation into a compact Qwen3-4B student model. In their core architecture, May-X adopted a multi-stage parameter-efficient fine-tuning setup for Qwen3-4B using two specialized LoRA adapters: a domain-specific adapter and a task-specific adapter for answer relevance classification.

8 Conclusion

IslamicEval 2026 builds on IslamicEval 2025 by expanding the evaluation into four subtasks and adopting a more granular approach to evaluating citations, their attribution, their recoverability, and their relevance to the user's query. The benchmark highlights attribution errors involving *isnads* and claimed sources, showing that correctly quoting an *ayah* or Hadith does not necessarily mean that it has been attributed to the correct source or isnad, or is relevant to the question. By separating these different types of failure, we provide a clearer assessment of LLM reliability for developing systems that produce accurate religious answers.

9 Limitations

In IslamicEval 2026, we introduced an LLM-assisted data annotation pipeline to overcome the manual, exhaustive annotation process used in IslamicEval 2025 (Mubarak et al., 2025). As a result, in this edition the released annotated dataset grew substantially. However, we note that although the annotation models in each subtask were validated against manually annotated gold samples, some annotation errors may remain. Moreover, the questions are drawn from two sources of interaction, and 12 models generated the responses explicitly instructed to provide religious evidence. Therefore, the resulting data represent model behaviour when citations are requested and may not generalise to unconstrained responses, other question sources, languages, or model families. In addition, Hadith verification accepts any attested wording but treats a meaning-preserving paraphrase as incorrect; the results therefore measure strict textual fidelity and do not measure acceptability under transmission by meaning (*riwāya bi-l-ma'nā*). While Subtask 2 validated all Hadith variants across different collections, Subtask 3 limited correction to the six canonical collections; we note that some valid, correctable Hadiths attested elsewhere cannot be credited.

10 Ethical Considerations

Given the religious sensitivity of the content of this task, we took care to ensure accuracy and respect. Our annotation, while carried out by Frontier LLMs, followed careful procedures to ensure the highest possible quality, verified by experts as described in the data preparation setup. The dataset is released strictly for research purposes, with the intention of improving the reliability and safety of LLMs in handling religious material. We explicitly caution against any misuse of this resource in contexts that could distort, misrepresent, or disrespect Islamic teachings.

A Subtask 1: Span Annotation Guidelines

In Subtask 1, Gold spans are copied verbatim from the response; wrappers, framing phrases, and punctuation around a segment are excluded from it.

1. **Citation.** Any span framed as Quran or Hadith is annotated, whether or not its content is accurate; framing is signalled by an attribution verb, a quotation wrapper, or a source bracket.
2. **Ayah.** The verse text only, excluding introductory framing (e.g., "قال الله تعالى") and wrappers; the source reference is annotated separately as the claimed source.
3. **Isnad.** The chain of named narrators, from the first narrator term through the transmission verb introducing the saying. An *isnad* is present only when a person is named; a citation that attributes words directly to the Prophet, uses passive narration, or names only a collection has no *isnad*.
4. **Matn.** The reported saying only. A transmission verb occurring within the reported content remains within the *matn*, and in dialogue Hadiths, the entire reported exchange constitutes the *matn*.
5. **Claimed source.** The fullest contiguous attribution phrase, copied verbatim, including any collection name, authenticity grading, and verse or Hadith number.
6. **Special cases.** An Ayah quoted inside a Hadith stays within the *matn* and is not annotated as a separate Quranic citation. Every occurrence is annotated, including repeated quotations of the same text. When the same claimed source is stated more than once for the same citation, the last, fullest occurrence is recorded.

B Subtask 2: Labelling Rules

In Subtask 2, each segment is judged by the decision rules below in Table 4; the *isnad* and claimed source are judged only against a correct quoted text.

Segment	Case	Label
Matn	Quoted exactly, in any documented narration	correct
	Quoted exactly but cut short at a word boundary	correct
	Quoted exactly, though the Hadith is graded weak or forged	correct
	A word or clause added, dropped, or changed; clauses reordered or two Hadiths merged; or no Hadith exists in this wording	incorrect
Ayah	Quoted exactly; diacritics, where given, also correct	correct
	Quoted partially but exactly and contiguously	correct
	Wrong diacritics; a word dropped, changed, or cut off; or not traceable to any verse	incorrect
Isnad	Names the narrator of this Hadith	correct
	Names a different narrator	incorrect
	Quoted text incorrect	N/A
Claimed source	Names the collection containing this Hadith, or the correct sūra (and verse number, if given)	correct
	Names a collection or reference that does not match	incorrect
	Quoted text incorrect	N/A

Table 4: Decision rules for each segment label

Abstract

This paper describes our submission to the IslamicEval 2026 Task 1 (Span Detection) shared task, which aims to identify and classify evidence spans in AI-generated Arabic Islamic answers. We formulate the task as token-level sequence labeling and fine-tune CAMeLBERT-Mix using BIO tagging, overlapping-window inference, and prediction reconciliation to detect four evidence categories: Ayah, matn, isnad, and claimed_source. On the official development set, our approach achieves a Precision of 95.55%, Recall of 97.06%, F1-score of 96.30%, and Token Accuracy of 98.66%. Multi-seed and qualitative analyses demonstrate the robustness of the proposed framework for Arabic evidence span detection.

1 Introduction

Large Language Models (LLMs) have demonstrated remarkable performance in text generation. However, in sensitive domains such as Islamic question answering, they may generate hallucinated or unsupported statements, reducing the reliability of AI-generated responses.

Automatically identifying evidence spans is therefore essential for improving the transparency and trustworthiness of Arabic Islamic question answering systems.This work addresses IslamicEval 2026 Task 1 (Span Detection)(Alharbi et al., 2026), which aims to identify and classify evidence spans in AI-generated Arabic Islamic answers into 4 categories: *Ayah*, *matn*, *isnad*and *claimed_source*.We formulate the task as token-level sequence labeling using BIO tagging and fine-tune CAMeLBERT-Mix with overlapping-window inference and prediction reconciliation to improve span detection in long responses.

The primary challenge is accurate span boundary detection in long Arabic texts. On the official development set, our system achieves an F1-score of 96.30%, demonstrating the effectiveness of the proposed approach.

2 Related Work

Large Language Models (LLMs) have achieved remarkable success in text generation and question answering but may produce hallucinated or unsupported information, motivating research on hallucination detection, including recent shared tasks for Arabic Islamic content (Mubarak et al., 2025).

Pretrained Arabic transformer models such as AraBERT (Antoun et al., 2020), ARBERT, MARBERT (Abdul-Mageed et al., 2021), and CAMeLBERT have achieved strong performance across Arabic NLP tasks. Moreover, (Inoue et al., 2021) showed that pre-training data to fine-tuning data is is more important than corpus size, motivating our use of CAMeLBERT-Mix, which covers Modern Standard, dialectal, and Classical Arabic. Recent span-level methods focus on hallucination localization (Rykov et al., 2025), whereas our work addresses evidence span detection in Arabic Islamic content.

3 System Overview

3.1 Task Formulation

We formulate span detection as a token-level sequence labeling task. Given an Arabic question and its generated answer, the objective is to identify the exact boundaries of evidence spans in the generated response and assign each span to one of four semantic categories: *Ayah*, *matn*, *isnad*, or *claimed_source*.

CAMeLBERT-Mix was selected for its broad coverage of Modern Standard, dialectal, and Classical Arabic.

We employ the BIO tagging scheme, where the `B-` prefix marks the beginning of a span, the `I-` prefix marks subsequent tokens within the same span,

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1035–1039
October 28-29, 2026 ©2026 Association for Computational Linguistics

and the O label represents tokens that do not belong to any annotated span. This produces nine token-level labels: O, B-Ayah, I-Ayah, B-matn, I-matn, B-isnad, I-isnad, B-claimed_source, and I-claimed_source.

3.2 Text Pre-processing and Label Alignment

The generated Arabic responses are tokenized using the fast tokenizer associated with CAMeLBERT-Mix. Character-level annotation offsets are aligned with the corresponding subword tokens using the tokenizer's offset mappings. Special tokens and padding tokens are assigned the value -100, ensuring that they are excluded from both the training loss and evaluation metrics.Responses longer than the model's maximum input length are divided into overlapping chunks. Each chunk contains at most 512 tokens, with a stride of 128 tokens between consecutive chunks. This overlap reduces the likelihood of losing evidence spans located near chunk boundaries. Padding is applied dynamically to the longest sequence in each batch.After inference, predictions from overlapping chunks are mapped back to their original character offsets and reconciled before span extraction. For tokens appearing in multiple overlapping windows, the corresponding prediction scores are aggregated to obtain a single final label. The resulting BIO sequence is then repaired to ensure valid label transitions, where invalid I- tags without a compatible preceding entity are converted into valid span starts, and inconsistent transitions initiate new spans. Finally, the repaired BIO labels are decoded into character-level evidence spans while removing duplicate predictions.

3.3 Overlapping-Window Prediction Reconciliation

Because tokens near chunk boundaries may appear in multiple overlapping windows, the same character range can receive more than one prediction. To reconcile these duplicate predictions, we group token outputs using the response identifier and the token's character-level start and end offsets. The probability vectors produced for identical token offsets across overlapping chunks are averaged, and the label with the highest averaged probability is selected as the final token prediction.The reconciled token predictions are then ordered by their character offsets and decoded into character-level evidence spans. Duplicate spans are removed, and leading or trailing whitespace is excluded from the predicted boundaries. This aggregation procedure prevents tokens appearing in multiple windows from being double-counted and provides a single consistent prediction for each character range.

3.4 Model Architecture

We fine-tune CAMeLBERT-Mix [1], a pretrained Arabic language model trained on a mixture of Modern Standard Arabic, dialectal Arabic, and classical Arabic data (Inoue et al., 2021).The contextual representation produced for each input token is passed to a token-classification layer that generates scores over the nine BIO labels. For an input sequence containing n tokens, the encoder produces contextual representations $\mathbf{H} = (\mathbf{h}_1, \ldots, \mathbf{h}_n)$. A linear classification layer maps each token representation $\mathbf{h}_i$ to a vector of label scores:

$$\mathbf{z}_i = \mathbf{W}\mathbf{h}_i + \mathbf{b}, \tag{1}$$

where $\mathbf{W}$ and $\mathbf{b}$ are trainable parameters. The predicted label for each token is obtained by selecting the label with the highest score. The model is fine-tuned jointly with the newly initialized token-classification layer.

4 Experimental Setup

To assess robustness, we trained the proposed framework using three random seeds (42, 52, and 62). All experiments were conducted on a Tesla T4 GPU (14.56 GB) using PyTorch 2.11 and Hugging Face Transformers. Each run required approximately 10.2 minutes and 3.44 GB of peak GPU memory.

4.1 Dataset Preparation

We use the official training and development data released for the IslamicEval 2026 Span Detection task. Each instance contains an Arabic generated response and character-level annotations identifying the evidence spans and their semantic types. The annotations are converted into BIO labels after tokenization.The original training and development partitions are preserved throughout the experiments. Long responses are represented by multiple overlapping chunks during training and evaluation. No additional external training data

[1] CAMeL-Lab/bert-base-arabic-camelbert-mix

Table 1: Training configuration.

Hyperparameter	Value
Pretrained Model	CAMeLBERT-Mix
Maximum Sequence Length	512
Sliding-window Stride	128
Training Batch Size	8
Evaluation Batch Size	8
Learning Rate	2×10^{-5}
Epochs	3
Weight Decay	0.01
Random Seed	42
Selection Criterion	Development F1

are used.Rather than introducing a novel architecture, we aim to establish a strong and reproducible baseline for IslamicEval 2026 through careful engineering choices tailored to Arabic span detection.The development set contains 484 responses with 2,728 annotated spans across four span types (Ayah, matn, isnad, and claimed_source). The average response length is 1,164.8 characters (median: 934), and 77.7% of the responses require chunking due to the model input length constraint.

4.2 Training Configuration

The system is implemented using PyTorch and the Hugging Face Transformers library. CAMeLBERT-Mix is fine-tuned for three epochs using a learning rate of 2×10^{-5}. The training and evaluation batch sizes are both set to 8, while weight decay is set to 0.01. We use a fixed random seed of 42 for reproducibility.

The development set was used for checkpoint selection, and final performance was evaluated on the test set. The corrected test run achieved an F1-score of 0.9126.

The model is evaluated after every training epoch, and one checkpoint is saved per epoch. The checkpoint achieving the highest development-set F1 score is restored at the end of training. Table 1 summarizes the main hyperparameters.

4.3 Evaluation Metrics

We evaluate the system using token-level precision, recall, F1 score, and accuracy. Tokens assigned the value `-100`, including special and padding tokens, are excluded from evaluation.

Precision, recall, and F1 are computed using micro-averaging over the eight entity-related BIO labels, excluding the `O` label. This prevents the large number of non-entity tokens from dominating the main evaluation scores. Token accuracy is calculated over all valid tokens, including those assigned the `O` label.

Table 2: Token-level performance on the development set.

Class	Precision	Recall	F1	Support
Ayah	0.9821	0.9889	0.9855	10905
matn	0.9679	0.9767	0.9723	11407
isnad	0.8794	0.9008	0.8900	2833
claimed_source	0.9365	0.9714	0.9536	5977
Overall	**0.9555**	**0.9706**	**0.9630**	–

Table 3: Development-set performance across three random seeds.

Metric	Mean	Std.
Precision	0.9583	0.0030
Recall	0.9721	0.0012
F1-score	0.9652	0.0019
Accuracy	0.9873	0.0006

The system was evaluated on the development set using token-level precision, recall, F1 score, and accuracy. Final performance on the official test set was evaluated using the shared-task F1 metric, with the corrected test run achieving an F1 score of 0.9126.

5 Results

Table 2 shows consistently strong performance across all four evidence categories. The model performs best on *Ayah* (F1 = 0.9855), while maintaining F1-scores above 0.89 for all classes, demonstrating strong generalization across different evidence types.

The original Task 1 submission received a score of 0.000 due to a submission error from our side. This result was used to rank our team in the official leaderboard and the shared-task overview paper. After resolving the submission error, the corrected run achieved an F1-score of 0.9126. This corrected result is reported to reflect the performance of our system and was not used for the official ranking.

Table 3 reports the average performance over three random seeds. The low standard deviations, particularly an F1-score of 0.9652 ± 0.0019, confirm the stability and reproducibility of the proposed framework.

5.1 Qualitative Error Analysis

To better understand the behavior of the proposed framework, we manually inspected the predictions on the development set. Table 4 summarizes the distribution of prediction outcomes.

As shown in Table 4, the model correctly

Table 4: Distribution of prediction outcomes on the development set.

Outcome	Count
Exact Match	2477
False Positive	242
Boundary Error	168
Missed Span	67
Type and Boundary Error	11
Type Error	5

Table 5: Representative error examples from the development set.

Error Type	Gold Type	Pred. Type	Span Example
Boundary Error	isnad	isnad	**Gold:** روى البخاري ومسلم عن ابن عباس رضي الله عنهما **Pred.:** ومسلم عن ابن عباس رضي الله عنهما
Type Error	Ayah	claimed_source	**Gold:** سورة آل عمران، الآية ١٣٠ **Pred.:** سورة آل عمران، الآية ١٣٠

predicts both span boundaries and evidence categories in most cases, achieving 2,477 exact matches. Most remaining errors are false positives (242) and boundary errors (168), indicating that span localization is more challenging than evidence type classification. In contrast, only five type errors and eleven combined type-and-boundary errors were observed, demonstrating reliable discrimination among the four evidence categories.

Table 5 presents two representative error cases. The first illustrates a boundary error, where the model predicts the correct evidence category but misses part of the annotated span. The second shows a type error, where the span boundaries are correctly identified but the evidence category is misclassified.

6 Conclusion

This paper presented our submission to the IslamicEval 2026 Task 1 (Span Detection) shared task. We formulated the task as token-level sequence labeling and fine-tuned CAMeLBERT-Mix using BIO tagging, overlapping-window inference, and prediction reconciliation. On the official development set, the proposed system achieved an F1-score of 96.30% and a token accuracy of 98.66%. The corrected test run achieved an F1-score of 0.9126, while the original submission score of 0.000 was retained for the official leaderboard ranking and shared-task overview paper. Qualitative analysis showed that evidence-type confusion is rare, while most remaining errors are related to span boundary localization. Furthermore, multi-seed evaluation confirmed the robustness and reproducibility of the proposed framework. Overall, the proposed approach provides an effective and reproducible baseline for Arabic evidence span detection. Future work will investigate CRF-based decoding, alternative overlap strategies, and improved BIO repair to further enhance span boundary localization.

Abstract

Large Language Models (LLMs) have significantly improved general-purpose question answering but remain prone to hallucinations in fact-sensitive domains such as religion. IslamicEval 2026 addresses these challenges by providing a fine-grained benchmark for evaluating hallucination and relevance in Arabic Islamic citations. This paper presents our approaches to three tasks: Citation Span Detection (Subtask 1), Hallucination Identification (Subtask 2), and Answer Relevance (Subtask 4). Across these tasks, we adopt a task-specific context modeling strategy in which contextual evidence is tailored to the semantic requirements of each citation understanding task. For **Citation Span Detection**, we formulate the problem as BIO-based token classification and fine-tune AraBERT using overlapping sliding-window encoding to process long responses effectively. For **Hallucination Identification**, we introduce a segment-level verification framework that augments each citation with adaptively extracted contextual evidence and citation-type information. For **Answer Relevance**, we combine hybrid lexical-semantic retrieval over authenticated Qur'anic and Hadith corpora with Transformer-based classification, enriching retrieved evidence with citation-specific context such as neighboring Ayat and explicit Surah–verse references. On the official test set, the proposed solutions achieved an F1 of 0.9725, an accuracy of 86.62%, and a macro-F1 of 0.7721 for Subtasks 1, 2, and 4, respectively, demonstrating the effectiveness of the proposed approaches.

1 Introduction

Large Language Models (LLMs) have made significant advances in question answering but remain prone to hallucinations in fact-sensitive domains (El Ganadi et al., 2025). This challenge is particularly critical for religious texts, where both citation authenticity and relevance are essential (Hamed et al., 2025). Even minor alterations to Qur'anic verses or Hadiths, as well as authentic yet irrelevant citations, can lead to misleading responses (Fawzi et al., 2026). Consequently, reliable Islamic question answering requires systems that can accurately identify citation boundaries, verify citation correctness, and assess citation relevance (Mubarak et al., 2025).

The IslamicEval 2026 benchmark (Alharbi et al., 2026) is designed to evaluate hallucination and relevance in Arabic Islamic citations generated by LLMs. It consists of Arabic question–answer pairs containing Qur'anic verses, Hadith texts, isnads, and claimed source references. IslamicEval 2026 evaluates multiple subtasks: Citation Span Detection (Subtask 1), which aims to locate and classify citation spans in responses generated by LLMs; Hallucination Identification (Subtask 2), which focuses on verifying the correctness of the citation; Hallucination Correction (Subtask 3), which focuses on providing the canonical form for citation; and Answer Relevance (Subtask 4), which evaluates whether the evidence cited adequately supports the answer to the given question.

In this paper, we present our approach [1] to Subtasks 1, 2, and 4 of IslamicEval 2026. Our approach is based on a task-specific context modeling strategy that adapts contextual evidence to the semantic requirements of each task. For Citation Span Detection, we formulate the task as BIO-based token classification and fine-tune AraBERT using an overlapping sliding-window mechanism that preserves contextual continuity across long responses. For Hallucination Identification, we propose a citation-centered verification framework that enriches each target citation with adaptive contextual evidence and citation-type information. For Answer Relevance, we introduce an evidence-guided framework

that combines hybrid lexical–semantic retrieval with citation-aware evidence enrichment from authenticated Qur'anic and Hadith corpora.

Our main contributions are threefold: (1) a task-specific context modeling strategy for citation detection, verification, and relevance assessment; (2) a citation-aware hallucination verification framework combining adaptive context expansion and citation-type encoding; and (3) an evidence-guided relevance framework that integrates hybrid retrieval with enriched Islamic evidence for citation relevance assessment.

2 Related Work

The increasing use of large language models (LLMs) in religious applications has raised concerns regarding hallucinations and the reliability of generated Islamic content. To address these challenges, recent studies have focused on identifying, verifying, and correcting religious references in LLM-generated responses (Mubarak et al., 2025; Alharbi et al., 2026). Isnad AI (Elden, 2025) employed a fine-tuned AraBERTv2 model supported by a rule-based synthetic data generation pipeline for religious reference localization. TCE (ElKoumy et al., 2025) investigated retrieval-augmented prompting for citation verification, while BurhanAI (Al Adel et al., 2025) combined synthetic augmentation, diacritic variation, and morphological normalization with a fine-tuned language model to improve the detection of Qur'anic and Hadith references. HUMAIN (Omayrah et al., 2025) formulated span identification as a sequence-to-sequence annotation task and performed verification using a combination of retrieval-based similarity and exact matching.

While prior work highlights the importance of contextual grounding, different citation understanding tasks require different forms of context. We therefore adopt a task-specific context modeling strategy.

3 System Description

In this section, we present the methodologies developed for each of the three benchmark subtasks.

3.1 Citation Span Detection

We formulate Citation Span Detection as a token-level sequence labeling task using AraBERT[2] (Antoun et al., 2020) and the BIO tagging scheme. Each generated response is converted into token-level labels drawn from a label set of nine classes: `O`, `B-AYAH`, `I-AYAH`, `B-MATN`, `I-MATN`, `B-ISNAD`, `I-ISNAD`, `B-CLAIMED_SOURCE`, and `I-CLAIMED_SOURCE`, corresponding to the beginning and continuation of four citation categories: Ayah, Matn, Isnad, and Claimed Source. This formulation enables the model to jointly identify citation boundaries and predict citation types.

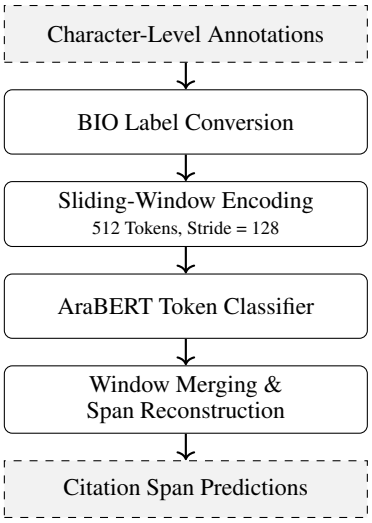

Figure 1: Citation span detection pipeline.

Documents longer than the model's input limit are processed using overlapping 512-token windows with a stride of 128. Character-level citation annotations are mapped to tokens via offset mappings and converted into BIO labels. Each window is treated as an independent training instance while preserving its association with the original document.

We fine-tune AraBERT as a token classification model using the generated BIO labels and optimize it with token-level cross-entropy loss. The overlap between adjacent windows helps preserve contextual information and reduces the likelihood of splitting citation spans across window boundaries.

During inference, the model predicts the BIO labels for each token, which are decoded into citation spans using the corresponding offset mappings. Predictions from overlapping windows are merged at the document level, duplicate spans are removed, and contiguous token sequences sharing the same label are reconstructed into complete citation spans. Finally, the extracted spans are converted into character-level offsets and formatted according to the official evaluation protocol.

3.2 Hallucination Identification

In Subtask 2, citation boundaries are provided by the benchmark, shifting the task from citation localization to factual verification. Rather than classifying the entire generated response, we transform each annotated citation into an independent verification instance by explicitly marking its boundaries and citation type using dedicated special tokens, namely `<Ayah>`, `<Matn>`, `<Isnad>`, and `<ClaimedSource>`, together with their corresponding closing tags.

To provide sufficient evidence while avoiding unnecessarily long inputs, we construct a citation-centered context representation. The sentence containing the target citation is first identified, after which neighboring sentences are incrementally added until a budget of approximately 650 tokens is reached. Context expansion prioritizes sentences following the citation before considering preceding sentences, preserving the natural explanatory flow of the response.

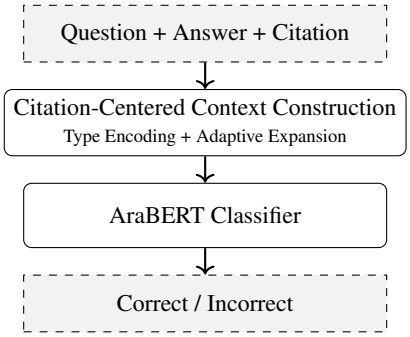

Figure 2: Hallucination identification pipeline.

The resulting input consists of the user question paired with the context-enhanced response containing the highlighted citation. We fine-tune an AraBERT sequence classification model to predict whether the marked citation is *Correct* or *Incorrect*. To avoid data leakage, we use `GroupShuffleSplit` at the response level, ensuring that all citations from a given response remain within the same split. The question and citation-centered context are encoded as paired inputs, with truncation applied only to the context when necessary. To mitigate label imbalance, class weights are incorporated into the cross-entropy loss function. Training further employs mixed-precision optimization and a linear learning-rate scheduler with warm-up, while the checkpoint achieving the highest validation Macro-F1 score is selected as the final model.

3.3 Answer Relevance

Answer Relevance aims to determine whether an authentic Islamic citation adequately addresses the user's question. To reduce reliance on the classifier's parametric knowledge, we adopt a retrieval-augmented, evidence-grounded framework that explicitly verifies each citation against supporting evidence retrieved from trusted Islamic sources.

An *Evidence Builder* first constructs a structured evidence representation for each claim. Given a question, generated answer, and target citation, the system extracts the most relevant supporting sentences from the generated answer using semantic similarity. It then retrieves corroborating evidence from both Qur'anic and Hadith corpora through a hybrid retrieval strategy that combines dense semantic retrieval using `multilingual-e5-large` embeddings (Wang et al., 2024) indexed with FAISS (Douze et al., 2025) and sparse lexical retrieval using BM25. The outputs of both retrieval components are integrated through Reciprocal Rank Fusion (RRF) to improve retrieval robustness. For Qur'anic evidence, the retrieved verse is further enriched with its surrounding context by incorporating neighboring Ayat within a fixed context window, while citation metadata such as Surah names and Ayah numbers are preserved whenever available.

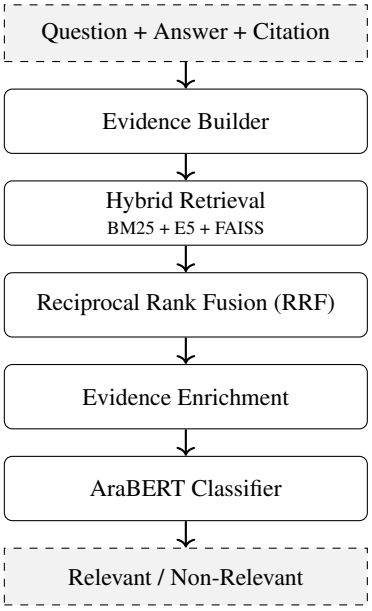

Figure 3: Answer relevance pipeline.

The resulting evidence is organized into a structured input containing four task-specific markers: `[QUESTION]`, `[ANSWER]`, `[CLAIM]`, and `[EVIDENCE]`. The `[EVIDENCE]` section includes rel-

evant supporting sentences from the generated answer together with the retrieved Qur'anic and Hadith evidence. This evidence-aware representation is then processed by a fine-tuned `AraBERTv02` classifier, which jointly models the question, answer, citation, and authenticated evidence to predict whether the citation is *Relevant* or *Non-Relevant*.

4 Evaluation and Results Analysis

All experiments were conducted using the official IslamicEval 2026 datasets and evaluation protocol. To ensure consistency across subtasks, all systems were built on AraBERT v0.2 and fine-tuned using a maximum sequence length of 512 tokens, batch size 8, AdamW optimization, linear learning-rate scheduling, and early stopping. Class-weighted loss was used for Subtask 2 to mitigate class imbalance.

4.1 Citation Span Detection

Our system achieved an **F1-score of 97.25%**, demonstrating that citation boundaries can be effectively modeled through token-level sequence labeling. The strong performance indicates that citation spans in the benchmark exhibit relatively consistent lexical and structural patterns, enabling AraBERT to accurately identify both span boundaries and citation types, even in long responses. By formulating citation span detection as a BIO-based token classification task, the model can predict citation boundaries and categories within a unified framework.

4.2 Hallucination Identification

Table 1 presents the official evaluation results of our system for Subtask 2. The submitted model achieved an **overall accuracy of 86.62%**. Although performance varies across citation categories, the observed differences remain relatively small (3.44 percentage points). Ayah and Matn citations achieve the highest accuracies, likely because they follow more regular linguistic and stylistic patterns. In contrast, Isnad citations comprise the most challenging category, as they often contain long chains of narrators and more diverse lexical structures, making factual verification more difficult.

4.3 Answer Relevance

The system was evaluated using the official Task 4 metric, Macro-F1. Our approach achieved a **Macro-F1 score of 0.7721** on the official test set.

Citation Type	Accuracy (%)
Ayah	87.74
Matn	87.55
Claimed Source	86.89
Isnad	84.30
Overall	**86.62**

Table 1: Official test results for Subtask 2 (Hallucination Identification).

In particular, 165 out of 271 questions (60.9%) achieved a perfect F1 score of 1.0, while 192 questions (70.8%) obtained an F1 score of at least 0.8. These results show that the proposed evidence-grounded framework is effective for relevance assessment, suggesting that hybrid retrieval and citation-aware context provide complementary signals for determining whether a citation adequately supports a generated answer. However, errors were frequently observed when the retrieved evidence was relevant to the question but provided only indirect support for the generated answer. Such cases highlight the challenges of distinguishing semantic relatedness from true evidential relevance.

5 Conclusion

In this paper, we presented our participation in IslamicEval 2026 for Citation Span Detection, Hallucination Identification, and Answer Relevance. Our approaches leverage task-specific context modeling for citation detection, verification, and relevance assessment. The proposed approaches achieved strong performance on the official test set, obtaining an F1 score of 0.9725 for Citation Span Detection, an accuracy of 86.62% for Hallucination Identification, and a Macro-F1 score of 0.7721 for Answer Relevance. These results demonstrate the effectiveness of adapting contextual representations to the semantic requirements of different citation understanding tasks.

Limitations

The proposed approaches were developed and evaluated within the IslamicEval benchmark and may not generalize directly to other domains, languages, or citation styles. Furthermore, while our results demonstrate the effectiveness of the overall framework, a more comprehensive analysis of the contribution of individual components, along with extensive ablation studies, remains necessary. We leave these investigations for future work.

Acknowledgments

We thank the IslamicEval 2026 organizers for the dataset and evaluation infrastructure.

AhmedNLP at IslamicEval 2026: Learning Answer Relevance from Within-Response Citation Preferences

Ahmed Almatrafi
College of Computing and Information Systems
Islamic University of Madinah, Saudi Arabia
almatrfi.ahmed@gmail.com

Abstract

IslamicEval 2026 Subtask 4 asks whether a Qur'anic or Hadith citation is useful for answering an Arabic question, rather than merely related to its topic. We treat this decision as ranking under shared response context. An Arabic instruction prompt is scored by the first answer-token logit difference between *na'am* ("yes") and *la* ("no"). We adapt ALLaM 7B with LoRA and a response-balanced RankNet loss over 1,063 positive–negative pairs drawn from 348 mixed-label responses. Inference uses logits and one calibrated threshold without generation. On Development, the frozen checkpoint obtained 0.87 Question Macro-F1 under question-grouped out-of-fold (OOF) threshold calibration, compared with 0.78 for zero-shot ALLaM. AhmedNLP_AllamR achieved 0.77 on the official test, our best of three runs. The largest Development-to-test drop occurred on all-negative questions, motivating direct supervision for groups containing only non-relevant citations.

1 Introduction

A citation can be authentic yet unhelpful. A Qur'anic verse or Hadith may share the subject of a question without stating a ruling, supplying a necessary premise, or otherwise supporting the answer. IslamicEval 2026 Subtask 4, *Answer Relevance*, makes this distinction explicit: topical similarity alone is insufficient (Alharbi et al., 2026). This extends the IslamicEval line of work on grounded Islamic question answering and hallucination analysis (Mubarak et al., 2025). It also differs from passage-retrieval tasks such as Qur'an QA, where the main problem is finding answer-bearing passages from a collection (Malhas et al., 2023).

Our first systems classified each citation independently. They ranked many examples sensibly, but their final decisions remained sensitive to class imbalance and the score threshold. We then noticed that training rows retain a `Response_ID`: citations extracted from the same generated response share a question and generation context. When one such citation is labeled relevant and another non-relevant, their relation supplies a direct preference: the former should receive a higher score. This observation changed the learning unit from an isolated citation to a within-response pair.

The resulting system combines an Arabic backbone, parameter-efficient adaptation, and a pairwise objective. Its main contribution is not a new loss, but a task-specific alignment between data structure and supervision. The experiments support three observations: (1) response-balanced pair construction provided cleaner supervision than pointwise classification; (2) first-token Arabic label logits allowed deterministic scoring without free generation; and (3) question-grouped threshold calibration exposed both the gain of pairwise training and its blind-test weakness on all-negative questions.

2 Related Work

Our scoring interface follows generative rerankers that interpret label-token logits as relevance scores. MonoT5 generates relevance labels and shows that the target-token choice itself affects ranking quality (Nogueira et al., 2020). FIRST replaces autoregressive list generation with first-token logits and a learning-to-rank loss (Gangi Reddy et al., 2024). We transfer the scoring principle, but use Arabic binary labels and response-local pairs rather than listwise document identifiers.

The supervision objective builds on RankNet's pairwise logistic loss (Burges et al., 2005). We also tested LambdaLoss, which connects pair weighting to ranking metrics (Wang et al., 2018), but it did not outperform response-balanced RankNet under the matched metric. MAIR reports that instruction-tuned retrievers and rerankers remain weak on some long-tail tasks (Sun et al., 2024),

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1045–1049

	Train	Development
Citations	6,231	282
Questions	496	111
Responses	1,652	122
Relevant	5,254	151
Non-relevant	977	131

Table 1: Task 4 data used in our experiments.

while FollowIR finds that existing retrieval models often reduce detailed instructions to basic keywords (Weller et al., 2025). BRIGHT shows a related failure of standard retrieval when relevance requires reasoning beyond surface semantic matching (Su et al., 2025). These results motivated our explicit evidence-usefulness instruction and our direct evaluation of multilingual cross-encoders.

For Arabic, we use ALLaM (Bari et al., 2025). HalluTruthQA, a contemporaneous Arabic preprint, evaluates ALLaM and Falcon-H1 among four models and reports that no single model leads across detection, localization, factual verification, and explanation (Bouchekif et al., 2026). We therefore evaluated Falcon-H1 (Zuo et al., 2025) as a separate backbone. Neither Falcon nor the off-the-shelf reranker branch displaced ALLaM on the official metric.

3 Task and Data

Each row contains an Arabic question, a citation span, its type (Qur'anic *Ayah* or Hadith *matn*), and a generated-response identifier. The output is 1 if the citation answers the question or supplies necessary evidence; otherwise it is 0. The official metric averages positive-class F1 across questions. For an all-negative question, F1 is 1 only if every prediction is negative, and 0 otherwise. We call this *Question Macro-F1*.

Table 1 summarizes the labeled splits. Train is positive-skewed. Within each `Response_ID`, we pair every relevant citation with every non-relevant citation: the Cartesian product (e.g., $2 \times 3 = 6$ pairs). The 348 *mixed-label responses*, containing both labels, yield 1,063 pairs from 1,267 of 6,231 citations. The remaining 1,304 *homogeneous responses* contain only one label. They cannot form pairs but remain in evaluation. With 1–16 pairs per response, unweighted pairs would overrepresent larger groups.

4 System

4.1 Prompt and deterministic score

We use the 7B instruction version of ALLaM, an Arabic–English model from the ALLaM family (Bari et al., 2025).[1] The prompt defines relevance, includes only the question and candidate citation, and ends with the model's native chat template. Early checks showed that asking for Arabic *na'am/la* was more stable than asking for the abstract symbols 1/0. The latter changed both tokenization and the learned conversational interface; the two label formats were therefore not interchangeable. This is consistent with prior evidence that relevance-label tokens are not neutral design choices (Nogueira et al., 2020).

For question q and citation c, z_{yes} and z_{no} are the raw, pre-softmax logits for Arabic *na'am* and *la* at the first answer position:

$$s(q, c) = z_{\text{yes}}(q, c) - z_{\text{no}}(q, c). \tag{1}$$

Following first-token reranking (Gangi Reddy et al., 2024), we use a forward pass without calling `generate()`. Generation defaults such as temperature, top-p, and top-k therefore do not affect these logits; no token is sampled.

4.2 Response-balanced RankNet

Let c^+ and c^- be relevant and non-relevant citations from the same response. We optimize the RankNet logistic preference loss (Burges et al., 2005):

$$\mathcal{L}_{\text{pair}} = \log\big(1 + \exp\big[-(s(q, c^+) - s(q, c^-))\big]\big)\,. \tag{2}$$

If response r produces n_r pairs, each pair receives weight proportional to $1/n_r$. Thus, a response with 16 pairs does not contribute 16 times as much as a response with one pair. This weighting keeps the shared response, rather than the number of citation pairs, as the effective supervision unit.

4.3 Adaptation and decoder

LoRA (Hu et al., 2022) is applied to the query, key, value, and output projections with rank 8, $\alpha = 16$, and dropout 0.05. This exposes 8,388,608 trainable parameters, or 0.12% of the model. We train for 50 optimizer steps with learning rate 2×10^{-5}, pair batch size 2, gradient accumulation 4, and bfloat16 arithmetic. Maximum input length is 1,024 tokens.

[1] Official checkpoint model card.

Figure 1: The same deterministic scorer supports pairwise training and threshold-only inference. Test labels are produced automatically by the frozen global threshold, without generation, sampling, or manual intervention.

System	OOF	Fixed Dev
Qwen 4B + LambdaLoss	0.78	0.78
ALLaM zero-shot	0.78	0.81
ALLaM + pointwise BCE	0.77	0.81
ALLaM + response RankNet	**0.87**	**0.88**

Table 2: Question Macro-F1 on Development. OOF refers to question-grouped threshold calibration.

Post-core branch	OOF F1	Δ
Response RankNet	**0.87**	–
16-feature stacked calibrator	0.86	-0.01
Ayah/matn thresholds	0.85	-0.01
Null-anchor relative score	0.84	-0.03

Table 3: Later branches versus frozen response RankNet. Differences are computed before rounding.

At inference, the frozen adapter scores rows in batches of four. A citation is relevant if $s(q, c) \geq \tau$. We retained one global threshold because response-relative margins, largest-gap rules, type-specific thresholds, and learned calibrators either reduced held-out F1 or produced negligible full-Development gains. The primary submitted run used $\tau = -4.0$.

5 Experiments and Results

5.1 Validation protocol

The adapter was trained once on Train. *Out-of-fold (OOF)* evaluates each question using a threshold chosen without it: we group Development by `question_id` into five folds, calibrate on four, and evaluate the fifth. This is *threshold-calibration OOF*, without model retraining. Fixed Dev applies the median fold threshold to all Development rows. OOF controls threshold selection, but not repeated model and prompt choices on these 111 questions.

5.2 Development comparison

Table 2 reports decision-relevant branches under the same official metric. Increasing capacity was not sufficient: Qwen3 rerankers, available at several scales including 4B and 8B (Zhang et al., 2025), and a Falcon-H1 branch remained below the selected system. Pointwise BCE also failed to improve over ALLaM zero-shot. Response-balanced pairwise adaptation raised frozen-checkpoint OOF F1 from 0.78 to 0.87. The best score observed during training on the full Development set was 0.88; we keep it separate from the more conservative frozen-checkpoint estimate.

We organized the remaining experiments by the hypothesis they tested. LambdaLoss tested metric-aware pair weighting. Qwen 8B and Falcon-H1 tested capacity and backbone alignment. Five multilingual cross-encoders, including mGTE (Zhang et al., 2024), tested transfer from general retrieval. The null anchor tested an explicit "no suitable citation" boundary, while stacked, type-aware, and fusion branches tested post-hoc calibration. None exceeded the selected RankNet checkpoint under a matched held-out protocol. The strongest generic cross-encoder reached 0.60 OOF F1, suggesting that ordinary search relevance did not transfer directly to evidence usefulness. Several branches improved ROC-AUC or full-Development F1 while reducing OOF Question Macro-F1; we rejected them because the official metric determined system selection.

5.3 Decision gates and reliability checks

We used the response RankNet OOF score as a gate for later components. Table 3 lists representative alternatives evaluated after the core checkpoint. The stacked calibrator used 16 score, rank, group-size, and citation-type features with nested tuning. It improved one outer fold but reduced the aggregate score. Separate Ayah and matn thresholds produced a full-Development gain below 10^{-3} while losing 0.01 OOF F1. The null-anchor model created a synthetic "no suitable citation" candidate to incorporate homogeneous groups; its relative score was better than its raw score, but still below the response-pair baseline. These failures support a narrow conclusion: Development was too small to justify extra learned boundaries.

Four folds selected -4.0 and one selected -3.75, with held-out F1 of 0.92, 0.85, 0.92, 0.90, and 0.75 for folds 0–4. The full-Development optimum, -4.0625, gives the same labels as -4.0. We fixed inference batch size at four because bfloat16

Run	τ	Pred. 1/0	Test F1
AllamR	-4.000	510/255	**0.77**
AllamM	-3.875	506/259	0.76
AllamC	-3.750	499/266	0.76

Table 4: Official Question Macro-F1 for the last three valid submissions.

Question type	Dev	Test	Δ
All Negative	0.85	0.60	-0.25
All Positive	0.96	0.86	-0.10
Mixed	0.83	0.72	-0.11

Table 5: Post-hoc F1 by question label composition. Dev uses the best training-time evaluation, not OOF; Test uses the frozen submitted system.

scores changed slightly after adapter reload and with batch composition. The prompt, model, length cap, batch size, score, and threshold jointly specify deployment.

5.4 Official runs and error analysis

The organizers evaluated our final three valid runs on 765 citations from 271 questions. The runs used the same frozen model and differed only in their decision boundary (Table 4). AhmedNLP_AllamR achieved 0.77 and was best among our three runs. We do not infer an overall competition rank from these results.

AllamR lost 0.10 F1 from OOF to test. All-negative questions declined most: 0.25 F1, over twice the other groups (Table 5). On the official test, AllamR produced 442 true positives, 68 false positives, 82 false negatives, and 173 true negatives. The corresponding row-level positive-class F1 was 0.85 and accuracy was 0.80. These values are diagnostic only; the submitted score remains Question Macro-F1. On Development, the selected training-time evaluation produced 23 false positives and 14 false negatives. Error counts were similar for Ayah (12/6) and matn (11/8), so citation type alone did not explain the failures. Table 6 grounds the two recurring patterns in observed errors.

The all-negative decline is consistent with RankNet's supervision gap: it orders mixed-response citations but never directly learns to reject an entire negative group. One false positive changes an all-negative question's F1 from 1 to 0. Repeated selection on 111 Development questions may also contribute; threshold-only OOF does not control it. These are plausible explanations, not proven causes. The three thresholds differ by less than 0.01 test F1, so small boundary changes do not resolve the gap. The null anchor covered homogeneous groups but reduced held-out F1; balanced direct negative-group supervision remains future work.

Question	Citation	G/P
ما حكم بيع الدم	وَلَا تَقْتُلُوا النَّفْسَ الَّتِي حَرَّمَ اللهُ إِلَّا بِالْحَقِّ	0/1
ما هو تعريف الحرام	نَهَى رَسُولُ اللهِ صَلَّى اللهُ عَلَيْهِ وَسَلَّمَ عَنْ كُلِّ ذِي نَابٍ مِنَ السِّبَاعِ ، وَعَنْ كُلِّ ذِي مِخْلَبٍ مِنَ الطَّيْرِ .	1/0

Table 6: Representative Development errors in the original Arabic. The first is a topical false positive; the second is a false negative requiring an additional inference. G/P denotes gold/prediction.

6 Conclusion

AhmedNLP used an Arabic first-token scorer, LoRA, response-balanced RankNet, and one global threshold for IslamicEval 2026 Answer Relevance. It achieved 0.87 frozen-checkpoint OOF F1 and 0.77 official test F1, our best submission. Within-response pairs outperformed larger backbones and extra decoder stages. Future work should combine this relative signal with direct supervision from homogeneous negative responses.

Code availability. Supplementary material includes training code, the Arabic prompt, the selected adapter, scoring, and calibration artifacts.

Limitations

Development has only 111 questions; repeated selection may overstate generalization. OOF holds out questions only for threshold calibration. We used one main seed and do not claim seed robustness. Pairwise supervision excludes homogeneous responses. Post-submission error analysis cannot establish the cause of the generalization gap.

Abstract

Large language models are increasingly used to answer questions about religious texts, yet their fluent responses may contain misquoted, misattributed, or fabricated citations. Detecting such hallucinations requires identifying citation components, verifying their correctness, and recovering the canonical text when a quotation is incorrect. We present Yaqeen's submission to the IslamicEval 2026 shared task, which evaluates these capabilities through three subtasks: detection of Qur'anic verses, Hadith text, chains of narration, and claimed sources; identification of incorrect citation fragments; and correction of erroneous Qur'anic and Hadith quotations. We develop task-specific systems combining AraBERT-based character-level sequence labeling with retrieval-based matching, classification, and reranking. Our systems achieve 96.78% character-level Macro-F1 on Task 1, 91.07% accuracy on Task 2, and 78.02% accuracy on Task 3. The results show that combining contextual Arabic representations with retrieval-based evidence is effective for fine-grained hallucination detection and correction in Arabic Islamic content.

1 Introduction

Large language models (LLMs) are increasingly capable of answering Arabic questions, including those concerning the Qur'an and Hadith (Abdelaal et al., 2026; Brown et al., 2020; Lewis et al., 2020). However, fluent generation does not ensure textual or factual faithfulness (Ji et al., 2023). In religious content, models may alter quotations, combine texts, misattribute passages, or produce nonexistent citations, where textual authenticity is particularly important. Such errors are difficult to detect because hallucinated quotations may remain coherent while differing from the original by only a few characters or words. Moreover, citations may contain independently correct or incorrect components, such as quoted text, narration chains, and claimed sources, making response-level evaluation insufficient. IslamicEval 2026 (Alharbi et al., 2026) addresses this through three tasks: character-level citation span detection, correctness verification, and correction of incorrect Qur'anic and Hadith quotations.

We present Yaqeen, a system covering all three tasks, with three main contributions. First, we develop an offset-preserving AraBERT detector that aggregates logits across overlapping windows and reconstructs character-level citation spans. Second, we introduce evidence-based verification combining canonical similarity, token coverage, sequence agreement, claimed-source rank, and narrator compatibility. Third, we formulate correction as type-specific selective retrieval with calibrated abstention and Qur'an-specific reranking. Yaqeen achieves official test scores of 96.78% Macro F1 for span detection, 91.07% Macro Accuracy for hallucination identification, and 78.02% Macro Accuracy for correction.

2 Task Overview

IslamicEval 2026 decomposes Arabic Islamic citation verification into three tasks: (1) citation span detection, (2) hallucination identification, and (3) hallucination correction. The details of the tasks are discussed below.

Task 1: Given an LLM-generated response, the system assigns each character to one of five classes: `Ayah`, `Hadith matn`, `Isnad`, `claimed source`, or `neither`. Performance is measured by character-level Macro-F1. Task 2: For each citation fragment, the system determines whether it is correct or incorrect. An *Isnad* or claimed source is evaluated only when its corresponding matn is correct; otherwise, it is excluded. Performance is measured by accuracy. Task 3: Given an incorrect Ayah or Hadith matn, the system recovers its corre-

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1050–1054
October 28-29, 2026 ©2026 Association for Computational Linguistics

sponding text from the shared resources, including prescribed writing and diacritics, or returns 'mistake' when no valid correction can be established. Performance is measured by accuracy.

2.1 Dataset

The IslamicEval 2026 dataset contains 4,706 Arabic training responses with 15,826 citation annotations and 32,779 labeled segments, plus 484 validation responses. The shared-task organizers also provided the retrieval resources, comprising 6,236 Qur'anic verses and 24,793 Arabic Hadith matn–isnad records from six major Hadith books.

3 Related Work

Arabic pretrained language models have shown strong performance across Arabic NLP tasks, including sequence labeling and text classification (Antoun et al., 2020; Melhem et al., 2024; Nasr and Ben HajHmida, 2024), motivating our use of AraBERT for span detection. Retrieval-based methods have also been successfully applied to Arabic and Qur'anic question answering, where relevant passages are identified from trusted collections before extracting an answer (Alnefaie et al., 2023). Such grounding is particularly important for religious texts, where minor textual or attribution errors can affect correctness. Following this direction, we ground verification and correction in authoritative Qur'anic and Hadith collections, combining character n-gram retrieval with evidence-based classification. Rather than generating corrections freely, our approach selects them directly from the reference collections to preserve their original wording.

4 Methodology

Our submission consists of three task-specific systems. We use pretrained Arabic language models where contextual understanding is important, and retrieval-based methods for verifying cited texts. The systems are designed independently, but Tasks 2 and 3 share the same general retrieval and matching components.

4.1 Task 1: Span Detection

We use `aubmindlab/bert-base-arabertv02` (Antoun et al., 2020) for five-class sequence labeling. Responses are tokenized into overlapping windows, and each token is assigned the majority character-level label within its offset interval; tokens without valid offsets are ignored. We freeze the embedding and lower Transformer layers and fine-tune the top four layers and classification head for two epochs using AdamW (Loshchilov and Hutter, 2019), with a learning rate of 3×10^{-5} and batch size 8. At inference, logits from overlapping windows are averaged at the character level before selecting the final label. Whitespace omitted during tokenization inherits a non-background label only when both adjacent characters agree. Consecutive characters with the same label are then reconstructed into non-overlapping spans using exclusive end offsets. Finally, we apply validation-selected minimum lengths of four characters for general spans and ten for Ayah and Isnad spans to suppress short spurious detections.

4.2 Task 2: Hallucination Identification

We perform evidence-based verification by retrieving candidate texts and combining textual and citation-level evidence to classify each fragment as correct or incorrect. Inputs are normalized by removing diacritics, Qur'anic recitation marks, tatweel, and punctuation; standardizing alif and hamza variants; and normalizing whitespace. Qur'anic and Hadith candidates are indexed with character n-gram TF–IDF and retrieved by cosine similarity. Qur'anic fragments are matched against the complete verse collection, while Hadith retrieval uses character 3–5-grams.

For the top candidate, we compute retrieval similarity, token coverage, and sequence agreement:

$$\text{coverage}(q, c) = \frac{|T(q) \cap T(c)|}{|T(q)|},$$

where $T(x)$ is the normalized token set. Coverage measures content support, while sequence agreement captures consistency in token order.

For Ayah and matn verification, we train separate histogram gradient-boosting classifiers. Features include retrieval similarity, coverage, sequence agreement, length, and source availability, with Ayah additionally using claimed-verse evidence and matn using narrator and chain evidence. Predictions are considered correct above thresholds of 0.65 for Ayah and 0.70 for matn.

Claimed-source verification combines sparse logistic regression with retrieved citation evidence. Qur'anic chapter names and verse numbers are parsed and checked against retrieval, while Hadith sources are compared with sources associ-

ated with similar matn. Isnad verification similarly combines sparse classification, normalized narrator overlap, and retrieved-matn evidence after removing transmission verbs, honorifics, and generic terms. Because a Hadith may have multiple valid chains, missing narrator overlap alone is not treated as sufficient evidence of an incorrect Isnad.

Finally, following the task dependency structure, Isnad and claimed-source verification is performed only when the associated matn is classified as correct, preventing attribution evidence from compensating for an incorrect quotation.

4.3 Task 3: Hallucination Correction

We formulate Task 3 as retrieval and reranking rather than direct generation. Separate character n-gram TF–IDF retrievers search the Qur'an and Hadith collections, augmented with deduplicated training corrections. For each query, we retain the top candidates and use retrieval scores and their margin to estimate ambiguity.

A type-specific histogram gradient-boosting classifier decides whether to return a correction or abstain, using retrieval scores, score margin, length features, and source-correctness indicators. Acceptance thresholds are 0.50 for Ayah and 0.70 for matn, reflecting the greater variation and incomplete coverage of Hadith texts.

For accepted Ayah predictions, we rerank the top 20 candidates using retrieval rank and score, character and token similarity, word overlap, and length-based features. For matn, validation ablation showed that reranking reduced performance, so the retrieval-and-abstention decision is used directly. Reranking is also skipped when a Qur'anic source has already been resolved from a correct structured citation.

Finally, corrections are copied directly from the retrieved collection rather than generated, preserving the required wording and diacritics.

5 Results

5.1 Baseline Comparison

Table 1 compares our final systems with simple development-set baselines. Task 1 shows the largest gain, with AraBERT-based span detection improving Macro F1 by 21.64 points over lexicon and structural rules. Task 2 improves Macro Accuracy by 7.14 points through retrieval evidence and type-specific classifiers, while Task 3 gains 5.30 points using learned abstention and Ayah reranking. Overall, learned task-specific mechanisms consistently outperform fixed rules and thresholds.

Table 1: Development-set comparison between baseline methods and Yaqeen.

Task	Baseline Method	Metric	Baseline	Yaqeen
Task 1	Lexicon and structural rules	Macro F1	74.18	**95.82**
Task 2	Canonical similarity thresholds	Macro Acc.	85.92	**93.06**
Task 3	Retrieval with fixed thresholds	Macro Acc.	72.64	**77.94**

Table 2: Development and official test-set performance.

Task	Component	Metric	Dev	Test
Task 1	Overall	Macro F1	95.82	96.78
Task 2	Overall	Macro Acc.	93.06	91.07
	Ayah	Acc.	94.70	92.00
	Matn	Acc.	93.37	84.43
	Isnad	Acc.	90.00	92.26
	Claimed source	Acc.	94.17	95.60
Task 3	Overall	Macro Acc.	77.97	78.02
	Ayah	Acc.	75.00	70.44
	Matn	Acc.	80.94	84.82

5.2 Official Test Results

Table 2 reports Yaqeen's development and official test-set performance, including component-level results where available. Task 1 achieves the highest overall performance, improving from 95.82% Macro F1 on the development set to 96.78% on the test set. This suggests that the span-detection model generalizes well beyond the development data. Remaining errors are mainly concentrated around difficult boundaries and short or ambiguous segments, as discussed in Section 6. For Task 2, Macro Accuracy decreases from 93.06% on development data to 91.07% on the test set. This reduction is driven primarily by matn verification, which decreases from 93.37% to 84.43%. In contrast, claimed-source and Isnad verification improve to 95.60% and 92.26%, respectively, while Ayah verification remains relatively stable at 92.00%. The lower matn performance reflects greater textual and transmission variation in Hadith, where surface similarity alone may not establish correctness. Task 3 remains stable overall, achieving 77.97% Macro Accuracy on the development set and 78.02% on the test

set. However, component-level performance differs: Ayah correction decreases from 75.00% to 70.44%, whereas matn correction improves from 80.94% to 84.82%. The higher matn correction score does not necessarily mean that Hadith is easier to correct. Abstention is more prevalent among incorrect matn training instances than Ayah instances (75.53% vs. 54.71%), which favors the higher matn acceptance threshold. Hadith evaluation is also diacritic-insensitive, whereas Qur'anic evaluation preserves more orthographic information. In addition, similar or overlapping verses can make the intended Ayah difficult to identify. The difference therefore likely reflects the data distribution and evaluation setting rather than the intrinsic difficulty of the two text types.

6 Error Analysis

We manually examined 60 validation errors, with 20 examples from each task, to identify recurring failure modes. Task 1 errors mainly involve citation boundaries, Task 2 errors reflect the gap between textual plausibility and contextual correctness, and Task 3 errors arise from ambiguity in recovering the intended source text.

6.1 Task 1: Citation-Boundary Ambiguity

Most Task 1 errors occur at the boundaries between `Isnad`, `matn`, and `claimed source`. The model often identifies the correct citation region but assigns boundary tokens to the wrong component. For example, the gold `Isnad` ends with عن ابن عمر رضي الله عنهما قال:, while the model extends it into كان رسول الله, consequently truncating the `matn`. Reporting verbs such as روى are similarly assigned inconsistently to the source or `Isnad`. Very short `Isnad` spans are also frequently missed. Expressions such as قال: and حديث: provide little contextual evidence and can occur in ordinary prose. These errors indicate difficulty reproducing precise boundaries when adjacent citation components are linguistically continuous.

6.2 Task 2: Plausibility Is Not Correctness

Task 2 errors often arise when textual plausibility is mistaken for contextual correctness. This is particularly evident for `Isnad` and `claimed source` fragments: valid-looking attributions such as رواه مسلم were sometimes accepted despite being incorrect for the associated quotation. Conversely, genuine quotations were rejected when orthographic or transmission variants reduced similarity to the retrieved text. Thus, surface similarity can cause both false acceptance and false rejection. Verification requires establishing the relationship between a citation and its specific source, rather than only determining whether the fragment resembles an authentic Islamic text.

6.3 Task 3: Ambiguous Recovery

Task 3 errors are dominated by conservative abstention and incorrect selection among plausible candidates. Abstention occurs when a corrupted quotation retains too little text for retrieval to reach its confidence threshold. For example, a fragment containing only كلوا من الطيبات shares an anchor with a Qur'anic verse, but the remaining corruption provides insufficient evidence for confident correction. When an incorrect candidate is selected, a short shared phrase can dominate the ranking. For example, الله لا إله إلا هو على كل شيء قدير led to a verse sharing على كل شيء قدير, although the intended source was different. Similarly, a quotation combining material from multiple verses was assigned to the candidate with greater lexical coverage rather than the intended verse. These errors reveal a precision–recall trade-off: stricter acceptance reduces unsupported corrections but increases abstentions. More reliable correction therefore requires ranking evidence across the entire quotation rather than relying on short overlapping phrases.

7 Conclusion

In this work, we presented Yaqeen's submission to IslamicEval 2026. Our systems achieve 96.78% character-level Macro-F1 on Task 1, 91.07% accuracy on Task 2, and 78.02% accuracy on Task 3. The results show that span detection is comparatively robust, while verification and correction are more challenging because correctness depends on the relationship between a citation and its canonical source. Our error analysis highlights citation-boundary ambiguity, Hadith variation, and short overlapping phrases as recurring sources of failure. Future improvements should therefore focus on source-aware retrieval and verification methods that use the full citation context to distinguish plausible but incorrect quotations from authentic ones.

Abstract

This paper presents our participation in IslamicEval 2026 Subtask 4, citation relevance classification for Qur'an and Hadith spans. We propose two independent systems for this task. The first is a generative large language model prompted to produce a structured, step by step relevance judgment. The second is a domain pretrained sentence encoder fine tuned with triplet loss on citation relevance data. Our evaluation compares two generative backends and three encoders pretrained on different Arabic varieties or multilingual data, using macro averaged F1 as the metric. Results show on development set that chain of thought judgment with ALLaM-7B consistently outperforms our embedding similarity ensemble, reaching 0.774 macro F1 against 0.357 for the ensemble, and outperforms an equivalent Fanar-S-1-7B system on seven of eight prompting strategies. Additionally, AraBERT-v02, pretrained on Modern Standard Arabic, obtains the highest development score, ahead of the Classical Arabic pretrained encoder in this citation relevance task. Our best submitted system, ALLaM with few-shot prompting without chain of thought, scores 0.748 macro F1 on the blind test set, narrowly ahead of the same backend with chain of thought added, at 0.744.

1 Introduction

Large language models are increasingly used to answer religious questions by quoting the Qur'an and Hadith literature, including through Arabic centric models such as ALLaM and Fanar. Islamic question answering systems that generate answers from Qur'an and Hadith sources still face a recurring failure mode (Alharbi et al., 2026), in which a system cites a source that is topically adjacent to the question without actually supporting the answer given. IslamicEval 2026 Subtask 4 addresses this directly by asking systems to classify whether a cited Qur'anic verse or Hadith span is genuinely relevant to a given question and its generated answer, rather than merely related by surface topic.

This failure mode is illustrated by a citation that names the same entity a question asks about without stating the relation the question requires (Alharbi et al., 2026). For the question asking who Musa's brother is, Maryam 19:53 states the relationship directly and is labeled relevant, while Taha 20:92 names Harun without stating any relationship to Musa and is labeled non-relevant. Embedding similarity alone is susceptible to this failure, since entity overlap can produce high similarity scores even when the cited text does not answer the question.

In this paper, we develop and compare two independent approaches evaluated on the same development set. The first uses a general-purpose Arabic large language model to produce a prompted relevance judgment, evaluated under direct, few-shot, and chain-of-thought prompting strategies. In the structured reasoning variants, the model is prompted to identify what the question asks, what the citation shows, and how the two relate before returning a final label. The second is a sentence encoder fine tuned specifically for this task with triplet loss, using the released training data together with two auxiliary Arabic resources repurposed for this task. This comparison lets us address the following questions. Does prompted LLM judgment outperform a similarity-based embedding ensemble on this task? Does a Classical Arabic pretrained encoder perform better than other encoder varieties, namely Modern Standard Arabic and multilingual, on citation relevance judgment? Which training data source produces the strongest fine-tuned encoder, and does combining sources improve on the best single source?

The paper is organized as follows. Section 2 reviews related work on Arabic embedding models, retrieval augmented methods, and threshold calibration. Section 3 describes the datasets used. Sec-

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1055–1066
October 28-29, 2026 ©2026 Association for Computational Linguistics

tion 4 describes our two proposed systems. Section 5 describes the experimental setup. Section 6 presents and discusses the results for both systems and for the test set submission. Section 7 concludes with a summary of findings and suggestions for future work, followed by a discussion of limitations.

2 Related Works

Malhas and Elsayed (2020) introduced AyaTEC, a verse based test collection for Arabic Qur'anic question answering, and later proposed CL-AraBERT, an AraBERT variant further pretrained on Classical Arabic text (Malhas and Elsayed, 2022). Their evaluation found this reader outperformed a Modern Standard Arabic baseline on Qur'anic reading comprehension. This finding motivates what we call the variety transfer hypothesis, that the same Classical Arabic advantage holds for citation relevance judgment between Modern Standard Arabic questions and Qur'an and Hadith citations.

Alnefaie et al. (2023) released HAQA and QUQA, Arabic question answer corpora for Hadith and the Qur'an respectively, used here as auxiliary data for training triplets rather than for their original retrieval purpose. Sharaf and Atwell (2012) constructed QurSim, expert labeled Qur'an to Qur'an relatedness pairs derived from Ibn Kathir's tafsir, later used by Alsaleh et al. (2021) to fine tune AraBERT for classifying verse pairs as related or unrelated. We repurpose QurSim for a different task shape, encoding relevance between a question and a citation rather than between two verses directly.

Amin et al. (2025) fine tuned AraModernBERT as a retriever with a curriculum adding HAQA and QUQA, reporting Recall@30 rising from 0.285 to 0.541, though the same technique degraded their reranker's performance. Elrefai et al. (2025) built triplets from HAQA aligned with Sahih al-Bukhari narrations through fuzzy matching, then fine tuned a sentence transformer with triplet loss, the strongest of their three retrieval components.

Lipton et al. (2014) investigated decision threshold selection for F1-based classification and examined how the choice of threshold relates to the optimal F1 score.

Chain of thought prompting, in which a model generates intermediate reasoning steps before a final answer, was established by Wei et al. (2022) as an effective technique for arithmetic, commonsense, and symbolic reasoning tasks. Kojima et al. (2022) showed this benefit extends to a zero-shot setting, without requiring in-context exemplars of the reasoning process itself. Within Islamic NLP specifically, Sibaee et al. (2025) compared direct answer extraction against step by step reasoning for Islamic inheritance law question answering, a different task shape from citation relevance judgment but the same domain and the same direct versus step by step contrast we test here. Our structured chain of thought prompt follows this general zero-shot approach, but its specific structure, characterizing the question and citation independently before judging their relationship under the task's own four-category taxonomy, is designed directly for this task.

Gao et al. (2023) proposed Hypothetical Document Embeddings, in which a language model generates a hypothetical answer passage for a query and an unsupervised encoder embeds this passage as the retrieval query. We adapt this as one query representation condition in our embedding ablation.

3 Datasets

We use the datasets released for IslamicEval 2026 Subtask 4, consisting of a training set, a development set of 282 rows, and a blind test set of 765 rows. Each row pairs a question, a generated answer, and a cited span from either the Qur'an or the Hadith, together with a binary relevance label indicating whether the citation genuinely supports the answer.

For the encoder fine tuning component of our system, we additionally use two auxiliary Arabic resources beyond the released training data. The first is HAQA and QUQA (Alnefaie et al., 2023), Arabic question answer pairs for Hadith and the Qur'an respectively, which we use to mine embedding similarity based hard negatives for triplet construction. The second is QurSim (Sharaf and Atwell, 2012), 7,679 Qur'an to Qur'an verse pairs extracted from Ibn Kathir's tafsir and graded at three relatedness levels (0, 1, and 2), where level 0 marks pairs with no obvious relation and level 1 marks weakly related pairs. We use level 2 pairs as positives and level 0 pairs as negatives, following the binary split in the first dataset of Alsaleh et al. (2021), and exclude level 1 pairs, which Alsaleh et al. (2021) also removed.

4 System Overview

We propose two independent systems for this task, described in the following two subsections.

4.1 Prompted Judgment

For each question and citation pair, we compute an embedding similarity score and a structured chain of thought judgment separately, then combine both into an ensemble prediction. When the embedding score falls between 0.35 and 0.65, an ambiguous middle band, we trust the chain of thought judgment. Outside this band, the two signals are blended, with the embedding score weighted at 0.7 and the chain of thought judgment at 0.3. If the chain of thought output fails to parse as valid structured output, the system falls back to the embedding score alone rather than defaulting to a relevant label. The ensemble result reported in Table 1 uses the raw question condition of Arabic-Triplet-Matryoshka-V2 specifically.

The chain of thought prompt requires the model to state, in order, what the question asks, what fact or relation the citation actually shows, and an explicit category label chosen from direct support, indirect support under two defined cases, or not relevant. This structure directly targets the entity overlap failure mode described in Section 1, rather than asking for a bare relevant or not relevant judgment. We test eight prompt variants against two generative backends, ALLaM-7B (Bari et al., 2025), run locally via Hugging Face inference, and Fanar-S-1-7B (Fanar Team et al., 2025), queried through its hosted API. The eight variants include a direct baseline, three zero-shot chain-of-thought variants with progressively refined relevance and grounding instructions, a few-shot variant, a few-shot variant combined with chain-of-thought, and two structural variants that either hide or sequentially gate the reasoning process before the final label is produced.

For the embedding component of this system, we compare two independently released Arabic sentence embedding models, Arabic-Triplet-Matryoshka-V2 and GATE-AraBert-v1 (Nacar et al., 2025), under three query representation conditions. These are the raw question text, a hypothetical answer generated in the style of Gao et al. (2023), and an averaged representation across several paraphrases of the question.

4.2 Fine-Tuned Encoders

Our second system fine tunes three encoders pretrained on different varieties, CAMeLBERT-CA (Inoue et al., 2021) on Classical Arabic, AraBERT-v02 (Antoun et al., 2020) on Modern Standard Arabic, and XLM-RoBERTa (Conneau et al., 2020) on a multilingual corpus, using triplet loss with the released training data as anchor, positive, and negative examples. This comparison directly tests whether the Classical Arabic pretraining advantage reported by Malhas and Elsayed (2022) for reading comprehension transfers to citation relevance judgment. We build training triplets from three sources. The first is the released labeled training data. The second is hard negatives mined by embedding similarity from HAQA and QUQA. The third is QurSim, repurposed as described in Section 3. We additionally test whether combining the released training data with QurSim into a single larger training set improves on the best individual source alone.

Predictions from this system use a cosine similarity decision threshold applied to the fine-tuned encoder's output. We compare a fixed threshold of 0.5 against a calibrated threshold, selected for each trained configuration by a grid search over 91 values from 0.05 to 0.95 in steps of 0.01, maximizing macro-F1 on the development set, on which the encoders were not fine-tuned. Because we select and report on the same development set, calibrated encoder scores are optimistic estimates (Lipton et al., 2014). The fixed threshold was substantially wrong for most trained configurations, a finding discussed in detail in Section 6.

5 Experimental Setup

All comparisons in this paper use the released 282-row development set, with macro-averaged F1 as the evaluation metric.

6 Results and Discussion

Prompted Judgment. Table 1 reports all eight prompting strategies for both generative backends. Standalone LLM judgment exceeds the combined ensemble score across all eight prompting strategies for both backends. ALLaM-7B outperforms Fanar-S-1-7B on seven of the eight prompting strategies, for example 0.724 against 0.484 under the anti-fabrication CoT variant. Fanar-S-1-7B is stronger on only one strategy, the original CoT variant, with only a minor difference in macro-F1

Configuration	Fanar-S-1-7B Ens.	Fanar-S-1-7B LLM	ALLaM-7B Ens.	ALLaM-7B LLM
Direct	0.336	0.626	0.358	0.686
CoT (orig.)	0.341	0.580	0.302	0.574
CoT (sharp.)	0.350	0.609	0.353	0.717
CoT (anti-fab.)	0.310	0.484	0.361	0.724
few_shot	0.337	0.639	0.363	0.757
few_shot_cot	0.351	0.632	0.357	**0.774**
silent_cot	0.341	0.578	0.358	0.605
gated_cot	0.311	0.490	0.341	0.635

Table 1: Results of prompted judgment with all eight strategies for both backends on the development set, macro F1. Ens. refers to ensemble. The embedding-only score is 0.271, using Arabic-Triplet-Matryoshka-V2 under the raw question condition.

(0.580 compared with 0.574). Inspecting the reasoning trace behind this comparison surfaces a specific, concrete instance of citation hallucination in Fanar-S-1-7B's reasoning, detailed in Appendix C. For the embedding component, reported in Table 2, GATE-AraBert-v1 scores higher than Matryoshka-V2 across all three conditions tested, with differences ranging from 0.001 to 0.010 macro-F1.

Condition	Matryoshka	GATE
Raw question	0.271	0.281
HyDE	0.295	0.296
Paraphrase-averaged	0.292	0.299

Table 2: Embedding similarity ablation, all three query-representation conditions. Macro-F1, development set. Matryoshka refers to Arabic-Triplet-Matryoshka-V2, GATE refers to GATE-AraBert-v1.

Fine-Tuned Encoders. Table 3 reports the complete strategy by variety comparison, after the threshold correction described in Section 4.2. Eight of the nine trained configurations required a threshold near 0.05 or 0.06, not the assumed 0.5, to reach their best performance. Only AraBERT-v02 under QurSim calibrated close to the original default, at 0.54. With threshold calibration applied consistently across all configurations, AraBERT-v02 achieves the highest macro-F1 across all three strategies tested, rather than CAMeLBERT-CA, the Classical Arabic pretrained model that our variety transfer hypothesis expected to perform best. Combining the released training data with QurSim did not improve performance over the stronger individual training strategy for any of the three encoders. For example, AraBERT-v02 achieved a macro-F1 of 0.599 with the combined data, compared with 0.630 when trained on QurSim alone.

Strategy	CA	v02	XLM-R
own_train_data	0.576	0.603	0.595
QurSim	0.618	**0.630**	0.576
Hard negatives	0.601	0.608	0.583
Combined	0.536	0.599	0.568

Table 3: Fine tuned encoders, complete strategy by variety comparison. Calibrated macro-F1, development set. CA refers to CAMeLBERT-CA, v02 refers to AraBERT-v02, XLM-R refers to XLM-RoBERTa. Combined = own_train_data + QurSim.

Submission	Macro F1
ALLaM, few-shot	**0.748**
ALLaM, few-shot+CoT	0.744
ALLaM, Direct	0.698

Table 4: Test set results.

This suggests that, in our experiments, combining the two training sources did not provide an additional benefit over using the stronger source independently.

Selecting an appropriate decision threshold for each configuration, rather than relying on a fixed threshold of 0.5, improved AraBERT-v02 by up to 0.28 macro-F1. This finding highlights the importance of threshold selection when evaluating citation relevance classifiers.

Test Set Results. Table 4 reports test set results for the three best performing configurations on development data. ALLaM with few shot and chain of thought was the highest scoring configuration on development data. On the blind test set, however, it is narrowly outscored by our second strongest development configuration, few-shot prompting without chain of thought.

7 Conclusion

This paper presented our system for IslamicEval 2026 Subtask 4, comparing prompted LLM judgment with fine-tuned encoders for Islamic citation relevance classification. Chain-of-thought prompting with ALLaM-7B achieved our strongest development-set performance at 0.774 macro-F1. Few-shot prompting achieved the highest test-set performance at 0.748 macro-F1, closely followed by few-shot prompting with chain-of-thought at 0.744.

Among the three encoder varieties compared, AraBERT-v02, pretrained on Modern Standard Arabic, achieved the highest development-set

macro-F1, reaching 0.630 when trained on QurSim, compared with 0.618 for the Classical Arabic pretrained CAMeLBERT-CA under the same training strategy.

Future work includes exploring additional triplet construction strategies, integrating Islamic knowledge resources, and evaluating frontier-scale LLMs and additional Arabic LLMs as generative backends.

Limitations

Model selection was constrained to models with 13 billion parameters or fewer, in accordance with the shared task participation requirements. This ruled out including a frontier-scale model as a reference point for comparison.

Acknowledgments

The authors would like to thank the IslamicEval 2026 shared task organizers.

A Complete Results Tables

Table 5's calibrated column reports the same fine tuned encoder values already shown in Table 3, against their uncalibrated counterpart at the fixed 0.5 default.

Enc.	Strat.	Thr.	Uncal.	Cal.	Gain
CA	own_train_data	0.05	0.3629	0.5755	+0.2126
v02	own_train_data	0.05	0.3181	0.6029	**+0.2848**
XLM-R	own_train_data	0.05	0.4601	0.5954	+0.1353
CA	hard	0.05	0.5070	0.6014	+0.0944
v02	hard	0.06	0.4984	0.6077	+0.1093
XLM-R	hard	0.05	0.5394	0.5825	+0.0431
CA	qursim	0.05	0.6117	0.6177	+0.0060
v02	qursim	0.54	0.6267	0.6296	+0.0029
XLM-R	qursim	0.06	0.4749	0.5764	+0.1015

Table 5: Threshold calibration, before and after. Macro-F1 at the fixed, uncalibrated default of 0.5 against macro-F1 at each configuration's own best threshold, development set. All nine trained configurations shown. CA refers to CAMeLBERT-CA, v02 refers to AraBERT-v02, XLM-R refers to XLM-RoBERTa.

B Complete Prompt Text

The English text of all eight prompting strategies described in Section 4.1 is given below. The strategies were run in Arabic against both generative backends; the Arabic originals are available in the project repository.[1] Curly-brace placeholders (question, span_text, span_type, response_context_block, few_shot_block) are filled in programmatically at inference time with the question text, the citation span, its type, and, where the prompt version requires it, the full model response text and a set of few shot demonstrations.

B.1 V0: Zero-shot, Direct

```
You are an expert scholar in Islamic sciences.
Your task is binary classification to find
the relationship between the question and
the citation span. Here is the exact task
definition:
  Given a user question in Arabic, an LLM
response to that question, and the correctly
extracted Qur'anic and Hadith-matn citation
span from that response, classify the citation
span using a binary label: relevant (1) or
non-relevant (0).
  A citation span is considered relevant
if it directly or indirectly answers the
question. Citation spans that are merely
topically related but do not answer the
question, as well as citation spans that
are entirely unrelated, should be classified
as non-relevant. A citation span may be
authentic and accurately quoted yet still
be non-relevant if it does not answer the
question.
  Relevance Label Definitions:
  * Relevant (1):
with direct answer: The citation span
explicitly answers the question, and its
meaning aligns with the question's intent and
context.
with indirect answer: This applies in two
cases:
Case 1: The citation span does not explicitly
answer the question, but it implicitly
```

[1] https://github.com/S-Alowaidi/HaDe_CitationRelevance

```
provides the requested information, and its
meaning aligns with the question's intent and
context.
Case 2: The citation span does not directly
or implicitly answer the question on its own,
but it provides clear textual support for the
reasoning in the system's response such that
an answer to the question can be inferred.
Non-relevant [Not an answer] (0): The citation
span does not provide a direct or indirect
answer to the question. If a citation is
only topically related but does not actually
answer the question or support the answer
reasoning in a meaningful way, it must be
marked as non-relevant. Topical overlap alone
is insufficient.
  Partial support note: A relevant citation
span may provide either a complete answer to
the question, or an important and necessary
part of the answer.
  {response_context_block}
  Reminder: the "relevant" field asks whether
the citation actually answers the question
-- not merely whether it discusses the same
topic.
  Your response must include the "relevant"
field exactly, with a value of true or false
only -- no other value. true means relevant
(1), and false means non-relevant (0). Never
leave this field blank or omit it, even if
uncertain -- choose your closest judgment.
  Return your answer as JSON only, no other
text:
{{"relevant": true or false}}
  Question: {question}
Citation span ({span_type}): {span_text}
```

B.2 V1: Zero-shot CoT, original (unsharpened)

```
You are an expert in Islamic scholarship. Your
task is binary classification to find the
relationship between the question and the
citation span. Follow these steps exactly:
  Step 1 - What does the question ask,
precisely? (one sentence)
Step 2 - What ruling or topic does the quoted
citation (Ayah or Hadith) address, precisely?
(one sentence)
Step 3 - Does the citation from Step 2
directly answer the question from Step 1,
or does it only touch the same general topic
without answering it?
  Important: a citation being authentic and
accurately quoted does not mean it is relevant
-- judge only whether it actually answers the
question.
  VERY IMPORTANT: your response must always
include the "relevant" field exactly, with a
value of true or false ONLY -- no other value
is acceptable (no numbers, no other text,
nothing but exactly true or false). true means
the citation is relevant, and false means it
is not relevant. Never leave this field blank
or omit it, even if uncertain -- choose your
closest judgment.
  Return your answer as JSON only, no other
text:
{{"step1": "...", "step2": "...",
"step3_reasoning": "...", "relevant": true
or false}}
  Question: {question}
Citation ({span_type}): {span_text}
```

B.3 V2: Zero-shot CoT, sharpened (four-category classification)

```
You are an expert in Islamic scholarship. Your
task is binary classification to find the
relationship between the question and the
citation span. Follow these steps exactly:
  Step 1 - What does the question ask,
precisely? (one sentence)
Step 2 - What specific fact, ruling, or
relationship does the citation actually state
-- not merely which people, places, or topics
it mentions? (one sentence)
Step 3 - Classify the relationship between the
citation and the question into exactly one of
the following categories:
  (a) Direct answer: the citation explicitly
answers the question, and its meaning aligns
with the question's intent and context.
(b) Indirect answer - Case 1: the citation
does not explicitly answer the question, but
implicitly provides the requested information
in a way that aligns with the question's
intent and context.
(c) Indirect answer - Case 2: the citation
alone does not answer the question, but
it provides clear textual support for the
reasoning in the system's full response (see
"Response context" below, if provided), such
that an answer can be inferred.
(d) Non-relevant: the citation does not
provide a direct or indirect answer to the
question. If the citation is only topically
related but does not actually answer the
question, or does not support the answer's
reasoning in a meaningful way, it must be
classified here. Topical overlap alone
is insufficient -- merely mentioning the
same person or topic, without meaningfully
supporting an answer or its reasoning, falls
here even if the same entity is mentioned.
  Important note on partial support: a
citation counts as relevant (category a, b,
or c) if it provides either a complete answer,
or an important and necessary part of the
answer -- it does not need to fully answer the
question by itself to count as relevant.
  A citation being authentic and accurately
quoted does not mean it is relevant -- judge
only based on the categories above.
  {response_context_block}
  VERY IMPORTANT: your response must always
include the "relevant" field exactly, with a
value of true or false ONLY -- no other value
is acceptable (no numbers, no other text,
nothing but exactly true or false). true means
the citation is relevant, and false means it
is not relevant. Never leave this field blank
or omit it, even if uncertain -- choose your
closest judgment.
  Return your answer as JSON only, no other
text:
{{"step1": "...", "step2": "...",
"category": "direct" or "indirect_case1"
or "indirect_case2" or "non_relevant",
```

```
"step3_reasoning": "...", "relevant": true
or false}}
  Question: {question}
Citation ({span_type}): {span_text}
```

B.4 V3: Zero-shot CoT, anti-fabrication (mandatory evidence quote + grounding check)

```
You are an expert in Islamic scholarship. Your
ONLY task is to judge whether the citation
below -- not your general knowledge of the
topic -- answers the question.
  Strict and critical warning: you must
not use your own knowledge of the correct
religious ruling for this question. Even
if you know the correct answer from other
sources, judge only based on what the specific
citation below actually says. If the citation
does not specifically address the question's
topic, the answer is non-relevant, regardless
of what you know the actual correct ruling to
be.
  Follow these steps exactly:
  Step 1 - What does the question ask,
precisely? (one sentence)
  Step 2a - Copy, verbatim, the specific
portion of the citation that supports your
understanding of what it says (not what
you think it should say). If no part of the
citation relates to the question's specific
topic at all, write exactly "NONE" -- do not
invent or infer content that is not literally
present in the text. This verbatim quote
is mandatory and will be checked afterward
against the original text.
  Step 2b - Based ONLY on the verbatim quote
in Step 2a (not your general knowledge), what
fact or ruling does the citation actually
state? If Step 2a was "NONE", this step must
also be "NONE".
  Step 3 - Classify the relationship between
the citation (based only on Steps 2a and
2b) and the question into exactly one of the
following categories:
(a) Direct answer: the citation explicitly
answers the question.
(b) Indirect answer - Case 1: the citation
does not explicitly answer, but implicitly
supplies the requested information.
(c) Indirect answer - Case 2: the citation
alone does not answer, but supports the
reasoning in the system's full response (see
below, if provided).
(d) Non-relevant: Step 2a was "NONE", or
the citation provides no genuine support for
answering the specific question.
  Note on partial support: a citation counts
as relevant if it provides a complete answer
or an important and necessary part of one --
this does not apply if Step 2a was "NONE".
  {response_context_block}
  VERY IMPORTANT: your response must always
include the "relevant" field exactly, with a
value of true or false ONLY -- no other value
is acceptable (no numbers, no other text,
nothing but exactly true or false). true means
the citation is relevant, and false means it
is not relevant. Never leave this field blank
or omit it, even if uncertain -- choose your
closest judgment.
  Return your answer as JSON only, no other
text:
{{"step1": "...", "step2_evidence_quote":
"...", "step2": "...", "category": "direct"
or "indirect_case1" or "indirect_case2" or
"non_relevant", "step3_reasoning": "...",
"relevant": true or false}}
  Question: {question}
Citation ({span_type}): {span_text}
```

B.5 few_shot: Few-shot, Direct (training examples, no reasoning scaffold)

```
You are an expert scholar in Islamic sciences.
Your task is binary classification to find
the relationship between the question and
the citation span. Here is the exact task
definition:
  Given a user question in Arabic, an LLM
response, and the correctly extracted Qur'anic
or Hadith-matn citation span from that
response, classify the citation span using
a binary label: relevant (1) or non-relevant
(0).
  A citation span is considered relevant
if it directly or indirectly answers the
question. Citation spans that are merely
topically related but do not answer the
question, as well as citation spans that
are entirely unrelated, should be classified
as non-relevant.
  {few_shot_block}
  {response_context_block}
  Reminder: the "relevant" field asks whether
the citation actually answers the question
-- not merely whether it discusses the same
topic.
  Your response must include the "relevant"
field exactly, with a value of true or false
only. Never leave this field blank or omit
it, even if uncertain -- choose your closest
judgment. Return your answer as JSON only, no
other text:
{{"relevant": true or false}}
  Question: {question}
Citation span ({span_type}): {span_text}
```

B.6 few_shot_cot: Few-shot labels + guided CoT for the new query

```
You are an expert in Islamic scholarship. Your
task is binary classification to find the
relationship between the question and the
citation span. Follow these steps exactly:
  Step 1 - What does the question ask,
precisely? (one sentence)
Step 2 - What specific fact, ruling, or
relationship does the citation actually state
-- not merely which people, places, or topics
it mentions? (one sentence)
Step 3 - Classify the relationship between the
citation and the question into exactly one of
the following categories:
  (a) Direct answer: the citation explicitly
answers the question, and its meaning aligns
with the question's intent and context.
(b) Indirect answer - Case 1: the citation
does not explicitly answer the question, but
```

```
implicitly provides the requested information
in a way that aligns with the question's
intent and context.
(c) Indirect answer - Case 2: the citation
alone does not answer the question, but
it provides clear textual support for the
reasoning in the system's full response (see
"Response context" below, if provided), such
that an answer can be inferred.
(d) Non-relevant: the citation does not
provide a direct or indirect answer to the
question. If the citation is only topically
related but does not actually answer the
question, or does not support the answer's
reasoning in a meaningful way, it must be
classified here. Topical overlap alone
is insufficient -- merely mentioning the
same person or topic, without meaningfully
supporting an answer or its reasoning, falls
here even if the same entity is mentioned.
  Important note on partial support: a
citation counts as relevant (category a, b,
or c) if it provides either a complete answer,
or an important and necessary part of the
answer -- it does not need to fully answer the
question by itself to count as relevant.
  A citation being authentic and accurately
quoted does not mean it is relevant -- judge
only based on the categories above.
  {few_shot_block}
  {response_context_block}
  VERY IMPORTANT: your response must always
include the "relevant" field exactly, with a
value of true or false ONLY -- no other value
is acceptable (no numbers, no other text,
nothing but exactly true or false). true means
the citation is relevant, and false means it
is not relevant. Never leave this field blank
or omit it, even if uncertain -- choose your
closest judgment.
  Return your answer as JSON only, no other
text:
{{"step1": "...", "step2": "...",
"category": "direct" or "indirect_case1"
or "indirect_case2" or "non_relevant",
"step3_reasoning": "...", "relevant": true
or false}}
  Question: {question}
Citation ({span_type}): {span_text}
```

B.7 silent_cot: Silent CoT (reasons internally, exposes only the final label)

```
You are an expert in Islamic scholarship.
Think carefully through the following steps
before answering, but do NOT write these
steps in your response -- reason through them
internally only:
  Step 1 (internal, do not write) - What does
the question ask, precisely?
Step 2 (internal, do not write) - What fact or
ruling does the citation actually state?
Step 3 (internal, do not write) - Does the
citation answer the question directly or
indirectly, or is it merely related to the
same topic without actually answering it?
  {response_context_block}
  Reminder: the "relevant" field asks whether
the citation actually answers the question
-- not merely whether it discusses the same
topic.
  Important note: never leave the "relevant"
field blank or omit it, even if uncertain --
choose your closest judgment.
  After reasoning through these steps
internally, return ONLY the final result
as JSON, with no intermediate steps and no
other text:
{{"relevant": true or false}}
  Question: {question}
Citation ({span_type}): {span_text}
```

B.8 gated_cot: Sequential-gated CoT (direct -> Case 1 -> Case 2 -> topical-overlap, checked in mandatory order)

```
You are acting as a careful human annotator
evaluating Islamic text citations (Ayah or
Hadith) used as supporting evidence in an
answer to a religious question. Your task
is to decide whether a given citation span
is Relevant or Non-relevant to the question,
using the exact criteria below. Base your
decision only on whether the span's content
connects to the question and the answer's
reasoning as defined here, not on outside
theological judgment.
  **Label definitions**
  *Relevant (1)* applies if either holds:
- Direct answer: the span explicitly answers
the question, and its meaning aligns with the
question's intent and context.
- Indirect answer, covering two cases:
- Case 1: the span does not explicitly
answer the question but implicitly conveys
the requested information, aligned with the
question's intent.
- Case 2: the span does not answer the
question on its own, but provides clear
textual support for the reasoning in the
system's answer, such that the answer can be
inferred from the span plus that reasoning.
  *Non-relevant (0)*: the span does not meet
any condition above. This includes spans that
are only topically or thematically related
to the question's subject (shared keywords,
shared general theme) without actually
answering the question or substantively
supporting the reasoning. Topical overlap
alone is never sufficient for relevance.
  **Reasoning steps -- write out your answer
to each step explicitly:**
  Step 1 - Question intent: State precisely
what the question is asking for (the specific
ruling, fact, event, name, condition, or
explanation requested).
Step 2 - Span content: State the literal
meaning and scope of the span_text, in your
own words.
Step 3 - Direct answer check: Does the span,
standing alone, explicitly state the answer
identified in Step 1? Answer yes or no, with
reasoning.
Step 4 - Indirect answer Case 1 check: If Step
3 was no, does the span implicitly convey the
same requested information without stating
it explicitly, while matching the question's
intent? Answer yes or no, with reasoning.
Step 5 - Indirect answer Case 2 check: If
```

```
Steps 3 and 4 were no, examine the reasoning
in the system's answer. Does the span function
as a necessary or clearly supporting piece of
evidence in that reasoning chain, such that
the answer becomes inferable only when the
span and reasoning are combined? Answer yes or
no, with reasoning.
Step 6 - Topical-overlap check: If all prior
checks were no, confirm explicitly whether
the span is merely topically or thematically
related (shared subject matter or vocabulary)
without answering or supporting the answer.
State this even if it seems obvious, to
distinguish a considered non-relevant from
a careless one.
Step 7 - Final label: Based on Steps 3-6,
assign the label. A "yes" at Step 3, 4, or 5
means relevant; otherwise non-relevant.
  {response_context_block}
  VERY IMPORTANT: your response must always
include the "relevant" field exactly, with
a value of true or false only -- true means
relevant, false means non-relevant. Never
leave this field blank or omit it, even if
uncertain -- choose your closest judgment.
  After completing all seven steps, return
your answer as JSON only, including the full
reasoning through every step, with no other
text outside the JSON:
{{"step1_question_intent": "...",
"step2_span_content": "...",
"step3_direct_check": "...",
"step4_indirect_case1_check": "...",
"step5_indirect_case2_check": "...",
"step6_topical_overlap_check": "...",
"relevant": true or false, "justification":
"one to two sentences citing which step/case
applied"}}
  Question: {question}
Citation span ({span_type}): {span_text}
```

C Example Predictions

This appendix reports examples of correct and incorrect predictions from our system, with the question, citation, model reasoning, predicted label, and gold label for each, drawn from the development-set chain of thought log for the ALLaM, few_shot_cot configuration, except for the Fanar-ALLaM comparison example below, which draws on both backends' logs under the same configuration.

Correct prediction. For the question asking whether a Muslim woman may marry a Christian man without restriction, the system correctly labels a verse concerning marriage with polytheists as relevant (predicted and gold labels both relevant). The model's reasoning identifies the verse as directly addressing the question through its reference to marriage with polytheists, leading to a relevant prediction that matches the gold label.

Question: هل يجب السماح لأمرأة مسلمة الزواج من رجل مسيحي دون قيود؟
hal yajib al-samah li-imra'a muslima al-zawaj min rajul masihi duna quyud?

Citation: وَلَا تَنْكِحُوا الْمُشْرِكَاتِ حَتَّىٰ يُؤْمِنَّ ۚ وَلَأَمَةٌ مُؤْمِنَةٌ خَيْرٌ مِنْ مُشْرِكَةٍ وَلَوْ أَعْجَبَتْكُمْ ۗ وَلَا تُنْكِحُوا الْمُشْرِكِينَ حَتَّىٰ يُؤْمِنُوا ۚ وَلَعَبْدٌ مُؤْمِنٌ خَيْرٌ مِنْ مُشْرِكٍ وَلَوْ أَعْجَبَكُمْ ۗ أُولَٰئِكَ يَدْعُونَ إِلَى النَّارِ ۖ وَاللَّهُ يَدْعُو إِلَى الْجَنَّةِ وَالْمَغْفِرَةِ بِإِذْنِهِ ۖ وَيُبَيِّنُ آيَاتِهِ لِلنَّاسِ لَعَلَّهُمْ يَتَذَكَّرُونَ
wa la tankihu al-mushrikati hatta yu'minna, wa la-ama mu'mina khayrun min mushrikatin wa law a'jabatkum, wa la tunkihu al-mushrikina hatta yu'minu, wa la-'abdun mu'minun khayrun min mushrikin wa law a'jabakum, ula'ika yad'una ila al-nar, wallahu yad'u ila al-janna wal-maghfirati bi-idhnihi, wa yubayyinu ayatihi lil-nasi la'allahum yatadhakkarun

Reasoning: النص المقتبس من القرآن الكريم يوضح بشكل صريح حكم الزواج من المشركات والمشركين، مما يجعله إجابة مباشرة على السؤال.
al-nass al-muqtabas min al-qur'an al-karim yuwaddih bi-shakl sarih hukm al-zawaj min al-mushrikat wal-mushrikin, mimma yaj'aluhu ijaba mubashira 'ala al-su'al.

Failure mode: topical relevance mistaken for a direct answer. For the question asking whether the sunnah prayer must be performed after Isha before starting Tarawih, the system is given a general hadith on the virtue of voluntary prayer (not this specific sunnah). Gold labels this non-relevant, but the system predicts relevant, direct. Its own reasoning states the citation "clarifies the general importance of prayer, which is consistent with the question about performing the sunnah after Isha, since it emphasizes the virtue of prayer generally, which includes performing the sunnah after Isha."

Question: هل لازم نصلي السنه بعد صلاه العشاء قبل البدء بصلاه التراويح؟
hal lazim nusalli al-sunna ba'da salat al-'isha' qabla al-bad' bi-salat al-tarawih?

Citation: الصلاة خير موضوع، فمن استطاع أن يستكثر فليستكثر
al-salatu khayru mawdu'in, fa-man istata'a an yastakthira fal-yastakthir

Reasoning: النص المقتبس (الصلاة خير موضوع، فمن استطاع أن يستكثر فليستكثر) يوضح أهمية الصلاة بشكل عام، وهو ما يتوافق مع السؤال الذي يسأل عن أداء السنة بعد صلاة العشاء قبل البدء بصلاة التراويح. النص يقدم إجابة مباشرة على السؤال من خلال التأكيد على فضل الصلاة بشكل عام، مما يشمل أداء السنة بعد العشاء.
al-nass al-muqtabas yuwaddih ahammiyyat al-salat bi-shakl 'amm, wa huwa ma yatawafaq ma'a al-su'al alladhi yas'al 'an ada' al-sunna ba'da salat al-'isha' qabla al-bad' bi-salat al-tarawih. al-nass yuqaddim ijaba mubashira 'ala al-su'al min khilal al-ta'kid 'ala fadl al-salat bi-shakl 'amm, mimma yashmal ada' al-sunna ba'da al-'isha'.

The model treats general topical alignment as sufficient for a direct answer, exactly the failure mode this project's prompt design targets. A second,

structurally identical case occurs for a question asking for the specific zakat nisab threshold: a verse commanding the collection of charity, without stating any threshold amount, is labeled relevant, direct, though gold marks it non-relevant, while several hadith citations that do state the specific nisab amounts are correctly labeled relevant elsewhere in the same log.

> **Question:** ما هو نصاب الزكاة
> *ma huwa nisab al-zakat*
> **Citation:** خُذْ مِنْ أَمْوَالِهِمْ صَدَقَةً تُطَهِّرُهُمْ وَتُزَكِّيهِمْ بِهَا وَصَلِّ عَلَيْهِمْ إِنَّ صَلَاتَكَ سَكَنٌ لَهُمْ
> *khudh min amwalihim sadaqatan tutahhiruhum wa tuzakkihim biha wa salli 'alayhim inna salataka sakanun lahum*
> **Reasoning:** النص المقتبس يحدد النصاب بشكل مباشر وهو مقدار محدد من المال يجب على المسلم دفعه كزكاة إذا وصل ماله إلى هذا المقدار وحال عليه الحول.
> *al-nass al-muqtabas yuhaddid al-nisab bi-shakl mubashir wa huwa miqdar muhaddad min al-mal yajib 'ala al-muslim daf'uhu ka-zakat idha wasala maluhu ila hadha al-miqdar wa hala 'alayhi al-hawl.*

Failure mode: indirect support not recognized. For a question asking whether a person's Islam is valid if they testify the shahada but believe a wali can act in the universe with God's permission, one citation (a hadith on the conditions for accepting someone's Islam) is labeled non-relevant, though gold marks it relevant. The model's own step-three reasoning states the citation "emphasizes that the two testimonies of faith must be sincere to God alone, without associating anyone else with any attribute of divinity... the text does not directly answer the question, but it offers support for the logic of the answer."

> **Question:** هل يصحّ إسلام شخص ينطق بالشهادتين لكنه يعتقد أن أحد الأولياء يتصرف في الكون بإذن من الله؟ ولماذا؟
> *hal yasihh islam shakhsin yantiq bil-shahadatayn lakinnahu ya'taqid anna ahad al-awliya' yatasarraf fi al-kawn bi-idhn min Allah? wa limadha?*
> **Citation:** أمرت أن أقاتل الناس حتى يشهدوا أن لا إله إلا الله وأن محمدًا رسول الله، ويقيموا الصلاة، ويؤتوا الزكاة، فإذا فعلوا ذلك عصموا مني دماءهم وأموالهم إلا بحق الإسلام، وحسابهم على الله
> *umirtu an uqatila al-nasa hatta yashhadu an la ilaha illa Allah wa anna Muhammadan rasul Allah, wa yuqimu al-salata, wa yu'tu al-zakata, fa-idha fa'alu dhalika 'asamu minni dima'ahum wa amwalahum illa bi-haqqi al-islam, wa hisabuhum 'ala Allah*
> **Reasoning:** النص المقتبس لا يجيب بشكل مباشر على السؤال حول صحة إسلام شخص يعتقد أن أحد الأولياء يتصرف في الكون بإذن من الله، ولكنه يوضح شروط الإسلام الأساسية.
> *al-nass al-muqtabas la yujib bi-shakl mubashir 'ala al-su'al hawla sihhat islam shakhsin ya'taqid anna ahad al-awliya' yatasarraf fi al-kawn bi-idhn min Allah, wa lakinnahu yuwaddih shurut al-islam al-asasiyya.*

This is a description of indirect support under the task's own Case 2 definition, stated in the model's own words, yet the final label does not reflect it. Across every citation retrieved for this question in the log, the system predicts non-relevant throughout, a complete miss on a question where gold marks the citation as relevant.

Failure mode: citation hallucination within the reasoning trace. For the question asking whether memorization is better than understanding in learning the Qur'an, Fanar-S-1-7B's chain of thought repeatedly reasons about a specific, well-known hadith on the virtue of learning and teaching the Qur'an, even when the citation actually provided for that row is a different, unrelated verse or hadith. In one representative case, the provided citation is a short verse on proclaiming God's favor, unrelated to memorization or understanding, yet the model's own step two states "the Prophet Muhammad, peace be upon him, encouraged memorizing and understanding the Qur'an, as stated in the noble hadith: 'the best of you is the one who learns the Qur'an and teaches it' (narrated by Bukhari and Muslim)." No such hadith was provided as the citation for this row.

> **Question:** هل الحفظ أفضل من الفهم في تعليم القرآن؟
> *hal al-hifz afdal min al-fahm fi ta'lim al-qur'an?*
> **Citation:** وأما بنعمة ربك فحدث
> *wa amma bi-ni'mati rabbika fahaddith*
> **Reasoning:** النبي محمد صلى الله عليه وسلم شجع على حفظ القرآن وفهمه، كما جاء في الحديث الشريف: 'خيركم من تعلم القرآن وعلمه' (رواه البخاري ومسلم).
> *al-nabi Muhammad salla Allahu 'alayhi wa sallam shajja'a 'ala hifz al-qur'an wa fahmihi, kama ja'a fi al-hadith al-sharif: 'khayrukum man ta'allama al-qur'ana wa 'allamahu' (rawahu al-bukhari wa muslim).*

The model then bases its reasoning on this introduced hadith rather than on the provided citation, concluding that it is a direct answer and predicting it as relevant, while the gold label is non-relevant. This pattern occurs in seven of the citations retrieved for this question, and in six of those seven cases the resulting prediction is incorrect. The same question, evaluated with an identical prompt using ALLaM-7B, shows no instance of this pattern in the same citation set. We checked two possible prompt-level explanations directly. The specific hadith does not appear in the static prompt template and is also absent from the dynamically sampled few-shot demonstrations used for this run, which were drawn with a fixed random seed and were therefore identical across

both backends. These observations show that, in these instances, Fanar-S-1-7B based its reasoning on a hadith that was topically associated with the question but was not present in the citation provided to the model.

A category the normalization logic does not recognize. The chain of thought prompt requires one of four specific category labels. In several rows, the raw category output does not match any of them. For the question asking about the nisab threshold for zakat, the provided citation states the threshold directly (five awaq of silver). The model's reasoning recognizes its relevance to the nisab threshold, although it incorrectly describes the citation as part of a Qur'anic verse.

> **Question:** ما هو نصاب الزكاة
> *ma huwa nisab al-zakat*
> **Citation:** ليس فيما دون خمس أواق صدقة
> *laysa fima duna khamsi awaqin sadaqa*
> **Reasoning:** النص المقتبس يشير إلى جزء من الآية القرآنية التي تحدد النصاب للزكاة، ولكنه لا يقدم معلومات مباشرة حول نصاب الزكاة.
> *al-nass al-muqtabas yushir ila juz'in min al-aya al-qur'aniyya allati tuhaddid al-nisab lil-zakat, wa lakinnahu la yuqaddim ma'lumat mubashira hawla nisab al-zakat.*

The raw category output for this row is the Arabic word for indirect, "غير مباشرة" (*ghayr mubashira*), not one of the four expected English labels, and the normalization logic maps it to unrecognized rather than to any of the four categories. A final relevant label of False is still produced despite this, though gold marks the citation relevant. This is a distinct failure from a parse error: the model did produce a category, just not one the normalization step was built to recognize.

A parse failure, found rather than assumed absent. One row in the log has every chain of thought field (question intent, citation content, reasoning, raw category) recorded as missing, with an explicit parse error flag set, yet the system still returns a relevant prediction, which happens to match gold on this specific row. Despite the parse failure, the model produced the correct label without any reasoning being recorded in the log.

SanadAI at IslamicEval 2026: Detecting Hallucinations in Arabic Islamic Citations through Span Detection and Hybrid Verification

Abir Korched
Independent Researcher, Tunisia
korched.abir@gmail.com

Abstract

We present SanadAI, a modular system for the IslamicEval 2026 shared task on fine-grained hallucination detection and correction in Arabic Islamic content. We participate in Subtasks 1 and 2, which address citation span detection and hallucination detection, respectively. For Subtask 1, we fine-tune AraModernBERT as a BIO sequence tagger to identify Quranic verses (*ayah*), Hadith text (*matn*), transmission chains (*isnad*), and claimed sources. Controlled Quranic and Hadith augmentation, together with Shamela-based hard-negative selection, substantially improves citation span detection over training on competition data alone. For Subtask 2, we use source-specific verification pipelines: Quranic evidence is verified through Arabic normalization and approximate matching, while Hadith evidence is verified using BGE-M3 dense retrieval, FAISS candidate search, lexical reranking, and semantic and entity-level evidence. SanadAI achieves 97.35% Macro-F1 on Subtask 1 and 86.66% official macro-accuracy on Subtask 2 on the hidden test set. Quranic verification is strongest at 96.89%, whereas isnad verification remains the most challenging at 77.42%, reflecting the difficulty of verifying transmission chains when the system relies on narrator compatibility with a retrieved Hadith rather than explicitly modeling narrator order and chain continuity.

1 Introduction

Large language models (LLMs) can generate fluent Arabic responses containing fabricated, altered, or incorrectly attributed Islamic citations. Such errors are particularly difficult to detect when the generated text is linguistically natural but the cited evidence is incorrect. IslamicEval addresses this problem in Arabic Islamic content, with the 2026 edition introducing a fine-grained formulation that distinguishes different citation types (Mubarak et al., 2025; Alharbi et al., 2026).

IslamicEval 2026 defines two subtasks that we address: **Subtask 1, citation span detection**, identifies *ayah*, *matn*, *isnad*, and *claimed source* spans; **Subtask 2, hallucination detection**, determines whether the corresponding evidence is supported by the appropriate reference collection. This naturally separates the problem into two stages: identifying *what and where the evidence is* and determining *whether it is valid*.

We present **SanadAI**, a modular system following this decomposition. For Subtask 1, we fine-tune an Arabic encoder for token-level citation extraction using controlled data augmentation and hard-negative examples. For Subtask 2, we employ source-specific verification pipelines. Quranic citations are matched against the compact, fixed Quranic collection, whereas Hadith verification requires retrieval from a substantially larger collection and additional reasoning over matn, source, and isnad information.

The two official submissions are evaluated independently. We nevertheless describe them in a common pipeline because the resulting decomposition provides a clear separation between citation localization and evidence verification.

Our contributions are:

- a BIO-based citation span detector for *ayah*, *matn*, *isnad*, and *claimed source*;
- controlled Quranic and Hadith augmentation with Shamela-based hard-negative examples;
- a source-aware verification framework combining approximate matching, dense retrieval, lexical similarity, and entity-level evidence;
- release of the code, augmented data, and trained model for reproducibility.[1]

2 Background

IslamicEval 2025 introduced hallucination detection and correction for quoted Quranic and Hadith text, with participating systems exploring retrieval, semantic matching, and LLM-based verification (Mubarak et al., 2025; Al Adel et al., 2025; Omayrah et al., 2025). IslamicEval 2026 extends this setting with a finer-grained formulation that explicitly separates citation span identification from evidence verification (Alharbi et al., 2026).

For fine-grained evidence span detection, transformer encoders are well established for sequence labeling (Devlin et al., 2019), while Arabic-specific pretraining improves performance on Arabic language understanding (Antoun et al., 2020). We use AraModernBERT (Elshehy et al., 2026) for span detection and GLiNER (Zaratiana et al., 2024) to extract entities such as narrators and sources during verification.

Verification requires retrieval over source-specific collections. BGE-M3 provides multilingual dense representations (Chen et al., 2024), while FAISS enables efficient similarity search (Douze et al., 2024). We use these components for Hadith retrieval, where the evidence space is substantially larger and more heterogeneous than the compact, fixed Quranic collection. SanadSet 650K and Shamela provide additional Hadith resources for retrieval and controlled augmentation (Mghari et al., 2022; Belinkov et al., 2016).

3 System

SanadAI consists of two complementary components corresponding to the two shared-task subtasks. Figure 1 summarizes the overall organization. Subtask 1 performs citation localization using AraModernBERT, while Subtask 2 verifies the resulting evidence using source-specific matching and retrieval pipelines. The figure shows the conceptual relationship between the components; the official submissions are evaluated independently.

3.1 Subtask 1: Citation Span Detection

We formulate Subtask 1 as BIO sequence classification over four entity types: *ayah*, *matn*, *isnad*, and *claimed source*. We fine-tune `NAMAA-Space/AraModernBert-Base-V1.0` to predict token-level labels using class-weighted cross-entropy to mitigate the strong class imbalance caused by the dominance of the background class.

To encourage the model to learn recurring citation patterns, we augment the official data with Quranic and Hadith examples and manually selected Shamela-based hard negatives. The augmentation exposes the model to recurring citation structures, including longer *ayah* and *matn* spans, *isnad* preceding *matn*, and *claimed source* spans associated with *ayah* or *matn* citations. The 20 Shamela-based hard negatives were manually selected from classical books to resemble Hadith-style narration while containing neither actual Hadith nor Ayah spans. The selected configuration combines the competition data with 6K synthetic Quranic and 6K synthetic Hadith examples; dataset composition and construction are detailed in Appendix D.

During inference, token probabilities are converted to word-level predictions using a confidence threshold of 0.45. Adjacent fragments are merged, while simple validation and boundary cleaning remove implausibly short predictions and surrounding punctuation. The complete training and inference pipeline is provided in Appendix B.

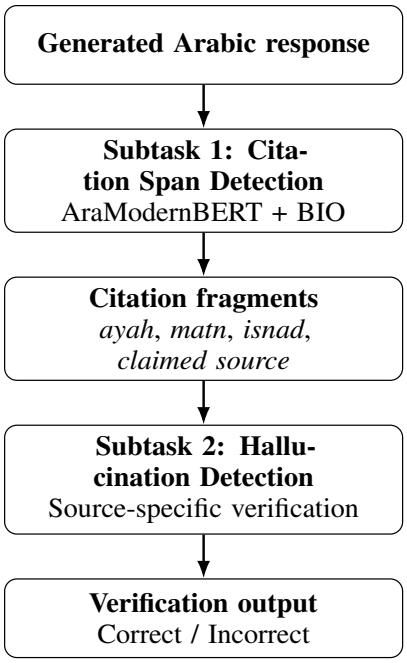

Figure 1: SanadAI overview: citation span detection followed by source-specific evidence verification.

3.2 Subtask 2: Hallucination Detection

We implement Subtask 2 as source-specific evidence verification. Figure 3 summarizes the

`IslamicEval2026-Task1-augmented`; Subtask 2 resources: https://huggingface.co/datasets/AbirKorched9/IslamicEval2026-Task2; model: https://huggingface.co/AbirKorched9/SanadAI-AraModernBERT-IslamicNER

Quranic and Hadith pipelines, which are processed separately because their reference collections and textual structures differ substantially. The complete verification pipelines are provided in Appendix C.

3.2.1 Quranic Verification

For Quranic evidence, generated text and references are normalized to reduce variation in Arabic orthography, diacritics, punctuation, and whitespace. Corpus-wide approximate matching is then performed over the 114 surahs. GLiNER extracts structured source information such as surah and verse identifiers, which is checked against the retrieved reference.

3.2.2 Hadith Verification

For Hadith evidence, the Hadith reference collection provided by the organizers, containing approximately 34K records, is encoded with BGE-M3 and indexed using FAISS. For each generated *matn*, the top-$K = 2048$ candidates are retrieved, followed by RapidFuzz-based lexical selection of the top-1 candidate. The selected candidate is then evaluated using semantic and lexical evidence, while claimed source and isnad verification additionally use GLiNER-based entity matching.

The verification score is generally expressed as

$$S = \alpha S_{\text{sem}} + (1 - \alpha) S_{\text{aux}}, \tag{1}$$

where S_{aux} denotes lexical similarity for Hadith matn verification and entity similarity for metadata verification. Component-specific coefficients and thresholds are selected on the development set; the complete configuration is reported in Appendix A.

4 Results

We evaluate the system using the official IslamicEval scoring procedures. Subtask 1 is evaluated using character-level Macro-F1 over the four citation classes. Subtask 2 uses the official macro-average of per-type accuracies, excluding gold annotations marked *N/A*.

Table 1 summarizes development and hidden-test performance.

4.1 Subtask 1 Results

SanadAI achieves 97.35% Macro-F1 on the hidden test set, compared with 96.61% on development data. The large improvement over training on competition data alone demonstrates the importance of the augmented training set.

Metric / Entity	Dev (%)	Test (%)	Δ
Subtask 1 Macro-F1	96.61	**97.35**	+0.74
Subtask 2 Macro-acc	91.05	**86.66**	-4.39
Ayah	97.42	96.89	-0.53
Matn	94.56	88.56	-6.00
Claimed Source	85.55	83.76	-1.79
Isnad	86.67	77.42	-9.25

Table 1: Official development and hidden-test performance. Δ denotes Test − Dev in percentage points.

Training Configuration	F1 (%)	Δ
Competition data only	81.65	–
+ 2K Quran + 2K Hadith + 20 HNs	95.77	+14.12
+ 6K Quran + 6K Hadith + 20 HNs	**96.41**	**+14.76**
+ 8K Quran + 8K Hadith + 20 HNs	95.78	+14.13
+ Best aug. + post-processing	**96.61**	**+14.96**

Table 2: Subtask 1 data augmentation ablation on the development set. Δ denotes the change in Macro-F1 relative to the competition-only baseline.

Table 2 shows the effect of augmentation size. Training on the competition data alone obtains 81.65% development Macro-F1. Adding 2K + 2K increases this to 95.77%, while 6K + 6K reaches 96.41%. Increasing the augmentation further to 8K + 8K reduces performance to 95.78%, suggesting that additional synthetic data do not necessarily provide further benefit. The final post-processing stage increases the selected configuration to 96.61%.

4.2 Subtask 2 Results

SanadAI achieves 86.66% official macro-accuracy on the hidden test set, compared with 91.05% on development data. As shown in Table 1, Quranic verification is the strongest component at 96.89%, followed by Hadith matn at 88.56%, claimed source at 83.76%, and isnad at 77.42%.

The results highlight increasing difficulty from textual to metadata verification. Quranic verification benefits from a fixed collection and direct matching, whereas Hadith verification must retrieve evidence from a larger, more heterogeneous collection. Our pipeline then verifies metadata against only the top-1 ranked Hadith candidate, which is limiting because the same Hadith may appear with different wording or narrator chains. Thus, top-1 candidate verification can miss valid evidence that would be found among alternative references.

Encoder	Dim.	Dev F1 (%)
BGE-M3	1024	**87.30**
GATE-AraBERT-v1	768	86.08
E5-all-nli-triplet-Matryoshka	384	85.71
Arabic-Triplet-Matryoshka-V2	768	85.46
AraModernBERT-Base-V1.0	768	84.34
GTE-multilingual-base	768	83.74

Table 3: Hadith encoder comparison on the development set.

4.3 Hadith Encoder Comparison

Because Hadith matn verification depends on retrieving a suitable reference, we compare six embedding encoders under the same verification pipeline. As shown in Table 3, BGE-M3 achieves the strongest development performance at 87.30% F1 and is therefore selected for the final system.

5 Discussion

5.1 Retrieval and Verification

As shown in Table 1, verification is easier for Quranic evidence, which is matched against a compact, fixed collection, achieving 96.89% accuracy. Hadith matn verification is more challenging because it requires retrieval from a larger collection.

The current top-1 selection makes retrieval errors irrecoverable and may discard valid variants among other candidates. Expanding the Hadith collection, together with multi-candidate verification or learned reranking, could improve robustness.

5.2 Metadata and Isnad Verification

Claimed-source and isnad verification achieve 83.76% and 77.42%, respectively, below direct textual verification. The current isnad verifier compares extracted narrator entities without modeling their order or chain continuity. Preserving the narrator sequence and comparing positions and adjacent relationships could provide more reliable chain verification.

5.3 Development-to-Test Generalization

Subtask 2 decreases from 91.05% macro-accuracy on development data to 86.66% on the hidden test set, with the largest degradation occurring for isnad verification. This suggests that development-set threshold selection does not fully transfer to unseen examples, particularly for metadata-level verification. More robust calibration or jointly learned verification models could reduce this sensitivity.

6 Conclusion

We presented SanadAI, a lightweight system for IslamicEval 2026 that combines fine-grained citation span detection with source-specific evidence verification. AraModernBERT with controlled augmentation achieves 97.35% Macro-F1 on Subtask 1, while the hybrid Quranic and Hadith pipelines achieve 86.66% official macro-accuracy on Subtask 2. The results show that targeted augmentation substantially improves citation localization, while verification remains limited by retrieval coverage and the structural complexity of Hadith evidence. In particular, isnad verification is constrained by reliance on a single top-ranked candidate and narrator compatibility without explicitly modeling chain order and continuity.

Acknowledgments

We thank the IslamicEval 2026 organizers for providing the benchmark, reference collections, and official evaluation framework. We also acknowledge the NAMAA community for its contributions to Arabic NLP research, resources, and open-source models.

A Complete Experimental Configuration

The complete configuration of the submitted system is summarized in Table 4, including training, retrieval, and verification parameters.

For Hadith matn verification, semantic and lexical similarity are combined as

$$S_{\text{matn}} = \alpha_{\text{matn}} S_{\text{sem}} + (1 - \alpha_{\text{matn}}) S_{\text{lex}}, \quad (2)$$

where S_{sem} is the BGE-M3 similarity and S_{lex} is the normalized lexical similarity.

For claimed-source and isnad verification, semantic similarity is combined with an entity-compatibility score:

$$S_{\text{meta}} = \alpha_{\text{meta}} S_{\text{sem}} + (1 - \alpha_{\text{meta}}) S_{\text{ent}}, \quad (3)$$

where the coefficient α_{meta} is selected separately for claimed-source and isnad verification.

The entity score is computed as

$$S_{\text{ent}} = \frac{1}{|C|} \sum_{c \in C} \max_{t \in T} \text{sim}(c, t), \quad (4)$$

where C is the set of entities extracted from the generated evidence and T is the corresponding set extracted from the reference. The function sim denotes the fuzzy string similarity used by the implementation. If no entities are extracted from the generated evidence, S_{ent} is set to zero.

Each verification component uses a development-selected threshold. An instance is classified as *correct* when its final score is at least the corresponding threshold and as *incorrect* otherwise. For isnad verification, development tuning selected $\alpha_{\text{isnad}} = 0$, so the final score depends entirely on entity compatibility. Thus, the submitted verifier checks narrator compatibility and does not explicitly model narrator order or transmission-chain continuity.

B Subtask 1 Pipeline

Figure 2 shows the training and inference pipeline used for citation span detection.

C Subtask 2 Pipeline

Figure 3 summarizes the source-specific verification pipelines.

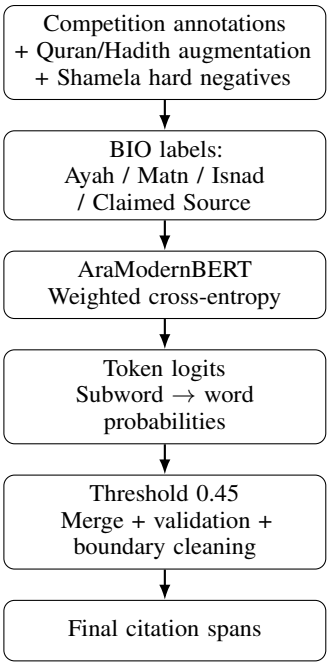

Figure 2: Subtask 1 citation span detection pipeline.

C.1 Quranic Verification

The Quranic reference collection is organized by surah and verse. Generated and reference text are normalized by removing diacritics and annotation marks, normalizing common Arabic character variants, removing tatweel and punctuation artifacts, and collapsing repeated whitespace.

RapidFuzz is then applied corpus-wide over the 114 surahs. For claimed sources, GLiNER extracts surah names, surah numbers, and verse numbers. The extracted metadata are compared with the expected reference, while the corresponding canonical verse is compared with the generated ayah.

C.2 Hadith Matn Verification

The Hadith reference collection contains approximately 34K records. References are encoded using BGE-M3 and indexed with FAISS. For each generated matn, the top 2048 candidates are retrieved. RapidFuzz partial-ratio similarity selects the candidate with the strongest lexical match, after which semantic and lexical scores are combined.

The development-selected configuration uses $\alpha_{\text{matn}} = 0.45$ and a decision threshold of 0.74.

C.3 Hadith Claimed-Source Verification

GLiNER extracts source-related entities from generated and expected source information, including books, scholars, and narrators. Entity similarity is combined with semantic similarity. The selected

Subtask	Component	Configuration
Subtask 1	Encoder	`NAMAA-Space/AraModernBert-Base-V1.0`
	Training objective	Class-weighted cross-entropy
	Epochs	15
	Learning rate	1×10^{-5}
	Maximum sequence length	1024
	Gradient accumulation	16
	Augmentation	6K Quranic + 6K Hadith examples + 20 hard negatives
	Inference	Threshold 0.45; merging and boundary cleaning
Subtask 2: Quran	Matching	RapidFuzz over the 114 surahs
	Source metadata extraction	`NAMAA-Space/gliner_arabic-v2.1` for surah and verse information
	Source verification	Compare extracted metadata with the source of the matched ayah
Subtask 2: Hadith	Encoder	`BAAI/bge-m3`
	Retrieval	FAISS, top-2048 candidates from 34K Hadith records
	Top-1 candidate selection	RapidFuzz partial-ratio
	Matn verification	$\alpha = 0.45$, threshold $= 0.74$
	Source metadata extraction	`NAMAA-Space/gliner_arabic-v2.1` for narrator extraction
	Source verification	$\alpha = 0.45$, threshold $= 0.17$
	Isnad verification	$\alpha = 0.00$, threshold $= 0.70$

Table 4: Configuration of the submitted SanadAI system.

configuration uses $\alpha_{\text{source}} = 0.45$ and a threshold of 0.17.

C.4 Hadith Isnad Verification

GLiNER extracts narrator entities from the generated and reference isnads. The verifier computes narrator compatibility using fuzzy entity similarity and combines this score with semantic similarity. Development optimization selects $\alpha_{\text{isnad}} = 0.00$ and a threshold of 0.70.

The final verifier therefore relies entirely on entity compatibility. It does not explicitly model narrator ordering or chain continuity, and consequently verifies narrator compatibility rather than complete transmission-chain validity.

D Subtask 1 Data Construction

To improve span detection performance, we construct an augmented training dataset by combining the official shared-task training set with synthetic data and targeted hard negatives.

D.1 Quranic Augmentation

We generate 6,000 Quranic examples where each instance contains a single ayah or consecutive ayahs. These are preceded by varied introductory phrases and quotation styles, and paired with a claimed-source statement sampled from multiple templates. We also introduce Arabic and Eastern Arabic numeral variants.

D.2 Hadith Augmentation

We curate 6,000 unique Hadith instances from the SanadSet 650K corpus (Mghari et al., 2022). Each example is constructed from a single Hadith by extracting its *isnad* and *matn*, applying standard Arabic text normalization, and synthesizing claimed-source statements through diverse linguistic templates.

D.3 Shamela Hard Negatives

To expose the span detector to citation-like text that should not be classified as a citation, we include 20 manually selected passages from the Shamela library. These passages exhibit Hadith-like narrative cues but contain neither actual Hadith nor Ayah spans, thereby providing challenging negative examples to reduce citation-span false positives.

D.4 Final Training Dataset

The final training dataset comprises 4,706 official shared-task instances, 6,000 Quranic examples, 6,000 Hadith examples, and 20 Shamela hard negatives, totaling 16,726 instances. The synthetic generation pipelines and reproduction scripts are available online.[2]

[2] https://huggingface.co/datasets/AbirKorched9/IslamicEval2026-Task1-augmented

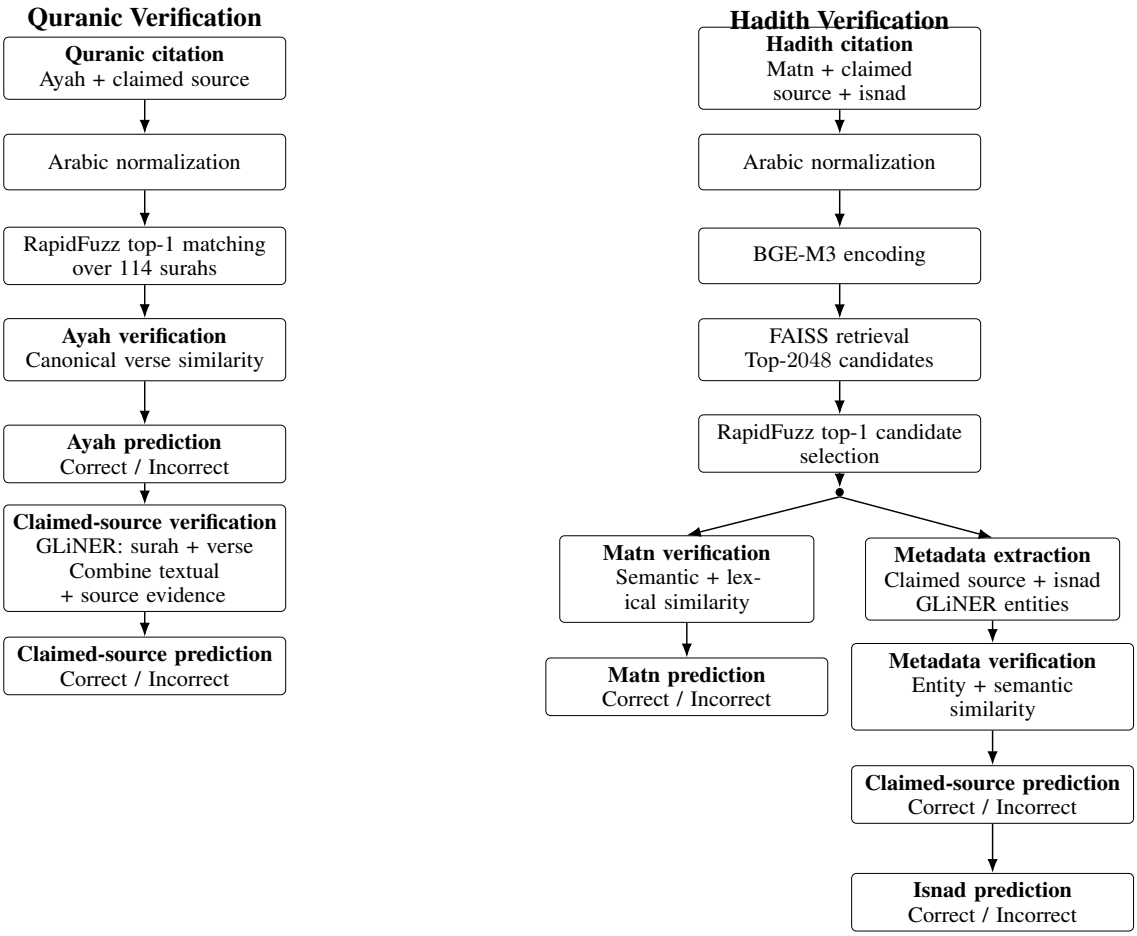

Figure 3: Subtask 2 source-specific verification pipelines. The Quranic pipeline normalizes the citation, retrieves the most similar canonical verse, and independently verifies the Ayah and claimed source. The Hadith pipeline retrieves candidate references using BGE-M3 and FAISS, selects the top candidate using lexical similarity, and verifies the Matn, claimed source, and isnad using semantic, lexical, and entity-level evidence.

Tathabbut at IslamicEval 2026: Evidence-Grounded Verification and Selective Canonical Correction

Salma Khaled Hegazy
Center for Informatics Science (CIS), School of Information Technology and Computer Science
Nile University, Giza 12588, Egypt
sahegazy@nu.edu.eg

Abstract

Islamic question-answering systems can produce fluent Arabic while altering Qur'anic wording, Hadith text, narrator chains, or source attribution. We present Tathabbut for two IslamicEval 2026 settings: fine-grained verification and canonical correction. For verification, **Canonical-Provenance Evidence Fusion (CPEF)** classifies *Ayah*, *matn*, *isnad*, and claimed-source segments by combining canonical retrieval with collection, narrator, response-level, contradiction, and exact-*matn* provenance evidence. CPEF achieves **0.9452 macro accuracy** on the official Test set. For correction, **Type-Aware Selective Canonical Retrieval (TASCR)** reranks authoritative Qur'anic and Hadith candidates using lexical, memory-based, contextual, and source evidence, and abstains when confidence is insufficient. TASCR achieves **86.29% Test accuracy**. A post-hoc Development diagnostic finds the gold correction for 319/327 (97.55%) recoverable cases in an expanded candidate pool, indicating that candidate discrimination and abstention are larger bottlenecks than retrieval recall. Neither submitted component invokes a generative LLM at inference time.

1 Introduction

Hallucination in religious question answering is not limited to obviously fabricated text. A generated response may preserve the style and broad semantics of an authentic quotation while changing one token, conflating narrations, assigning the wrong collection, or supplying an unsupported narrator chain. These errors call for fine-grained verification against explicit evidence rather than response-level plausibility alone. Related work on factuality has likewise emphasized atomic-fact evaluation (Min et al., 2023), claim-level reference checking (Hu et al., 2024), and multilingual hallucination-span detection (Vazquez et al., 2025; Hikal et al., 2025).

IslamicEval 2025 established a shared-task setting for hallucination in Qur'anic and Hadith content (Mubarak et al., 2025). Participating systems explored exact and normalized matching, fuzzy alignment, character-level retrieval, semantic reranking, and retrieval-augmented verification (Omayrah et al., 2025; Al Adel et al., 2025; ElKoumy et al., 2025). IslamicEval 2026 extends this line of work with fine-grained verification and correction tasks (Alharbi et al., 2026).

We address two complementary decision settings in IslamicEval 2026. Verification asks whether four annotated segment types—*Ayah*, *matn*, *isnad*, and claimed source—are correct or incorrect. Correction instead requires the exact canonical replacement for an erroneous *Ayah* or *matn*, while permitting abstention when a reliable correction cannot be identified. The two settings share evidence sources but require different decisions: verification asks whether the available evidence supports a claim, whereas correction must choose a specific canonical target and determine whether returning it is justified.

The systems share normalization, canonical grounding, source-aware evidence, and group-aware validation, while retaining task-specific decision mechanisms. Our contributions are: (1) CPEF, a relational verification framework combining textual authenticity with source and narrator provenance; (2) TASCR, an abstention-aware correction framework integrating hard-negative reranking, hallucination memory, contextual/source evidence, and type-specific routing; and (3) analysis of official submissions showing the value of treating source metadata as supporting evidence and of using conservative intervention and calibrated abstention.

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1075–1080
October 28-29, 2026 ©2026 Association for Computational Linguistics

2 Tasks, Data, and Shared Processing

Subtask 2. The official score is the unweighted mean of the four segment-level accuracies,

$$\text{MacroAcc} = \frac{1}{4} \sum_{t \in \mathcal{T}} A_t, \tag{1}$$

where $\mathcal{T} = \{\text{Ayah, matn, isnad, source}\}$. Gold `N/A` rows are excluded. The released data contain 24,088 scored Training rows, 1,745 Development rows, and 10,375 Test rows. Test contains 3,539 *Ayah*, 3,076 *matn*, 465 *isnad*, and 3,295 claimed-source instances.

Subtask 3. The correction data contain 7,909 Training, 943 Development, and 1,998 Test instances. Training contains 3,703 *Ayahs* and 4,206 *matns*; Development contains 476 and 467; Test contains 944 and 1,054, respectively. A prediction is either the required canonical text or an abstention decision.

Canonical resources and text handling. Both systems use only the task-provided canonical resources. The Qur'an resource contains 6,236 address records (6,058 unique text strings after exact deduplication in the Subtask 3 pipeline). The Hadith resource contains 34,994 records; 31,811 have populated *matn*, yielding 30,940 unique *matns* after exact deduplication for correction retrieval. We maintain the authoritative canonical string separately from the representation used for search. Search normalization applies Unicode NFKC, removes *tatweel*, diacritics and Qur'anic marks where appropriate, normalizes whitespace and Arabic/Persian digits, strips punctuation/symbols, and folds conservative Arabic orthographic variants. Canonical output is always taken from the preserved resource text rather than reconstructed from its normalized form.

Grouping, cross-fitting, and leakage control. Segments from the same generated response or question can share wording, source strings, and local context. We therefore use group-aware splits whenever learned or memory-based evidence is estimated. The verification pipeline uses five-fold `GroupKFold` by `Response_ID`; the correction pipeline uses question-grouped splits for threshold calibration, hallucination-memory features, and confidence routing. During cross-fitting, each Training segment receives learned evidence only from a model fitted on the remaining response groups, and these out-of-fold predictions become features for later stages. This prevents a fragment from receiving learned or memory evidence derived from a correlated fragment in the same group.

3 Subtask 2: Canonical-Provenance Verification

3.1 Canonical and Collection-Conditioned Evidence

CPEF treats verification as agreement among several evidence sources rather than as four independent text-classification problems. For Qur'an, we index individual verses together with concatenations of up to six adjacent verses from the same surah, enabling partial and multi-verse quotations to retrieve an appropriate canonical span. A source parser normalizes surah aliases and verse numbers, allowing a strong textual match to be rejected when the claimed location is incompatible with the retrieved evidence.

For Hadith, *global retrieval* asks whether a *matn* resembles any canonical narration, whereas *collection-conditioned retrieval* asks whether comparable evidence exists within the claimed collection. Character n-gram TF–IDF with cosine similarity is complemented by fuzzy partial and token-set similarity. Source aliases are normalized, and "agreed upon" is mapped to al-Bukhari and Muslim. A quotation may therefore resemble an authentic narration globally while its specific attribution remains unsupported.

3.2 Type-Specific Verification and Provenance

Ayah and matn. Ayah evidence includes canonical similarity, containment, retrieval margin, and source-location agreement. Matn verification combines global retrieval with collection-conditioned support. The override thresholds are empirical rather than theoretically derived. They were frozen from response-grouped Training audits that prioritized precision over coverage, because a mistaken override can convert a correct decision into an unsupported religious claim. The submitted collection-conditioned rescue requires source confidence ≥ 0.70, no unsupported collection, partial similarity ≥ 0.80, token-set similarity ≥ 0.96, and cosine similarity ≥ 0.50. A response-consistency rule can also rescue a matn that contains at least three normalized words and is strictly shorter, under the rule's normalized representation, than another already-supported matn in the same response;

the pair must reach partial/token-set similarities of at least 0.94/0.92. Here, "short" is defined relative to the supporting matn rather than by a universal Hadith-length cutoff. Grouped Training audits selected 92 and 25 cases for these rules, respectively, with 100% precision in those audits.

Claimed source. Source verification evaluates the relation among the *quotation, canonical candidate, and claimed source*, rather than classifying the source string in isolation. For example, a quotation may retrieve an authentic narration in Muslim while the generated response attributes it to al-Bukhari; in that case, the wording can be authentic-like even though the source relation is unsupported. Qur'anic claims are checked analogously against retrieved verse locations. Hadith source evidence includes global and collection-restricted scores and margins, exact/near-exact matn evidence, number agreement, cross-fitted textual evidence, and relational source–matn memory. Compact learned source models contribute evidence, while conservative routing preserves high-confidence canonical matches and explicit contradictions.

Isnad. The five nearest canonical Hadith matns are retrieved using character-window TF–IDF. Narrator extraction is deliberately conservative rather than based on unrestricted named-entity detection: candidate spans are initiated only by recognized Arabic transmission cues and narration verbs used by the submitted extractor, terminated at reporting, Prophet-reference, or honorific markers, and capped at seven normalized tokens. Simple normalized variants account for common kunyah/name forms and selected shortened *ibn* chains. The resulting features include exact narrator-phrase matches, narrator-token recall, retrieval scores and margins, claimed-book agreement, book-conditioned similarity, and chain/text lengths. A character-level Linear SVM (2–6 grams, $C = 0.5$) supplies out-of-fold lexical evidence, while a 500-tree Random Forest (depth 5, minimum leaf 5, balanced classes) fuses lexical and narrator-provenance features. For claims tied to the six canonical books, the submitted system uses a 0.45 probability threshold; external or empty metadata retain the base decision unless canonical narrator evidence supports an override.

3.3 Directional Contradiction and Provenance Memory

The final system applies asymmetric overrides. Positive rescues require convergent authenticity evidence, whereas negative overrides require localized contradiction evidence. A rare token-insertion rule rejects a near-canonical Hadith only when similarity is high, one-to-three tokens are inserted, no canonical token is deleted, the inserted material is rare, and either a parenthetical gloss or a collection conflict is present. The rule selected seven grouped Training cases, all incorrect. A Qur'anic contradiction rule requires retrieval similarity ≥ 0.90, a parsed source that conflicts with the retrieved verse, and grouped $P(\text{correct}) \leq 0.15$; it selected 24 incorrect Training cases.

The final CPEF component is **exact-matn source-provenance memory**. For each exact normalized matn, the system records positive/negative parent counts, per-book support, and exact source-set counts. An incorrect source prediction is rescued only when every claimed collection has positive support for the same matn, contradictory exact-source evidence is absent, and the support is repeated (the exact source set occurs at least twice, or every claimed collection has at least five positive observations). Across grouped Training folds, the complete memory rule selects 619 cases at 0.9935 precision. This is relational rather than direct label memorization: the decision depends on the consistency of the matn–source association.

4 Subtask 3: Type-Aware Selective Canonical Correction

4.1 Retrieval, Reranking, and Hallucination Memory

TASCR formulates correction as selective ranking over the official inventories. Each inventory is indexed with character `char_wb` 3–5-gram TF–IDF and word 1–2-gram TF–IDF. For Ayahs, up to 20 candidates from each view are retained; for Hadith, up to 10 are retained from each view and then deduplicated. Candidate features include cosine scores and ranks, retriever agreement, score margins, full/partial/token-set fuzzy ratios, token Jaccard and coverage, and length features. A LightGBM reranker is trained with hard retrieved negatives: each available positive is paired with the ten strongest negative candidates rather than with random corpus items. A question-grouped 80/20 split calibrates the candidate-versus-abstention thresh-

old before the reranker is refit on the selected Training pairs.

The **hallucination memory** separately indexes labeled erroneous Training spans with character 3–5-gram TF–IDF. The ten closest hallucinations vote for their known corrections using squared-cosine weights. Features summarize the strongest support, vote share and margin, agreement count, support for abstention, and agreement with the current canonical candidate. Training-time memory features are computed out of fold with five question-grouped folds. When the memory provides sufficiently strong support, it may inject a canonical correction that was absent from the lexical candidate pool.

4.2 Context, Source Evidence, and Selective Routing

Candidate evidence is augmented with character- and word-level similarity to the original question, the local response context, and their concatenation. Source strings are normalized separately, and numerical references, Qur'anic addresses, and aliases of the six Hadith collections are compared with candidate metadata. These source signals remain soft evidence because the generated source itself may be hallucinated.

Development produced two complementary experts: a memory-aware lexical reranker and a context/source-aware reranker. A precursor uses the context/source expert for Ayahs and the memory expert for matns. TASCR adds a second-level Hadith confidence router that evaluates the distinct actions proposed by both experts together with an abstention action. Its 51 global/action-specific features include top and runner-up scores, margins to calibrated thresholds, lexical and memory evidence, context/source support, abstention states, expert agreement, and confidence gaps. The router is a regularized LightGBM model (180 trees, learning rate 0.03, depth 4, seven leaves) assessed with five-fold question-grouped cross-validation. Because routing improves matn correction but slightly reduces Ayah accuracy, the final policy is type-specific: Ayah $\rightarrow$ context/source expert; matn $\rightarrow$ confidence router.

4.3 Diagnostic Candidate Coverage

A post-hoc Development diagnostic expands retrieval across both official inventories and adds source-guided candidates. This diagnostic is not part of the submitted TASCR inference path. Among 327 recoverable Development examples, the gold correction appears in the expanded pool for 319 (97.55%): 216/219 Ayahs and 103/108 matns. Together with 616 Development cases whose correct action is abstention, the candidate-pool oracle is 935/943 (99.15%). The gap between candidate availability and actual accuracy shows that recall alone is insufficient: the system must still distinguish confusable canonical neighbors and determine when abstention is safer.

Subtask 2: official Test accuracy					
Approach	Ayah	Source	Isnad	Matn	Macro
CCMA	.9825	.9590	.9312	.9057	.9446
TECV	.9825	.9590	.9312	.9064	.9448
CPEF	**.9828**	**.9605**	.9312	**.9064**	**.9452**

Table 1: Official Test results for the three submitted Subtask 2 systems.

Subtask 3: official Test accuracy (%)			
Approach	Overall	Ayah	Matn
Type-Routed Hybrid	86.09	**84.53**	87.48
TASCR	**86.29**	**84.53**	**87.86**
Exact-Source Rescue	86.19	84.32	**87.86**

Table 2: Official Test results for the three submitted Subtask 3 systems.

5 Results and Analysis

Subtask 2. CPEF is the strongest submitted verification system. It yields 3,478/3,539 correct Ayahs, 3,165/3,295 claimed sources, 433/465 isnads, and 2,788/3,076 matns. Relative to CCMA, TECV changes four matn decisions and produces a net gain of two correct matns. CPEF then changes six decisions relative to TECV—one Ayah rejection and five source rescues—and all six are beneficial on Test. Although the number of changed decisions is too small to support a significance claim, their outcomes are consistent with the intended high-precision behavior of the final contradiction/provenance layer.

The Development-to-Test gap is strongly type dependent. CPEF moves from 0.9884 Development macro accuracy to 0.9452 on Test. Ayah changes from 0.9928 to 0.9828 and claimed source from 0.9814 to 0.9605, whereas matn falls from 0.9796 to 0.9064 and isnad from 1.0000 to 0.9312. The Development isnad estimate is particularly fragile because it contains only 30 scored chains, compared with 465 at Test time. The remaining matn errors are consistent with partial quotations, re-

ordered clauses, and collection-specific variants, while isnad remains sensitive to narrator aliases, abbreviated chains, and multiple transmission paths.

Subtask 3. TASCR is the strongest submitted correction system, with 1,724/1,998 correct predictions (86.29%). Relative to Type-Routed Hybrid Retrieval, it adds four correct Hadith predictions while preserving Ayah accuracy. The Exact-Source Conservative Rescue run is informative: it improves one Development decision but reduces Test Ayah accuracy from 84.53% to 84.32% while leaving matn accuracy unchanged. This result illustrates that source parseability and specificity are not equivalent to source reliability; a precise citation can itself be hallucinated.

The candidate-coverage diagnostic further separates retrieval from selection. Only eight of 327 recoverable Development cases lack the gold correction in the expanded pool. Nevertheless, TASCR correctly recovers 216/327 recoverable quotations while correctly abstaining on 582/616 gold-abstention cases. This conservative profile reduces false canonical replacements but leaves substantial missed-correction error. Additional Development experiments reinforce the same interpretation: zero-shot multilingual E5 dense fusion reaches 83.78%, and an expanded-retrieval rescue reaches 84.52% but changes 14 abstentions at only 35.7% rescue precision. In this exact-match setting, broader semantic relatedness or additional candidate recall cannot substitute for calibrated candidate discrimination.

Shared lessons. Across both subtasks, canonical evidence is necessary but not sufficient. Source metadata should be treated as evidence that may agree or conflict with the text, not as an infallible key. Hadith requires more conservative handling than Qur'an because its inventory is larger and contains more overlapping and collection-dependent wording. Group-aware estimation is also important because related fragments can leak response/question structure across folds. Finally, the decision mechanism is task-specific: verification benefits from relational contradiction/provenance rules, whereas correction requires calibrated abstention after obtaining a high-recall candidate set.

6 Limitations

Development data were inspected repeatedly during competition development, so progression numbers should be interpreted as model-selection evidence rather than as unbiased generalization estimates. The verification systems are sequential rather than factorial ablations, and the high-precision rule audits do not establish causal component effects. The rule thresholds and evidence combinations were developed for the IslamicEval resources; applying CPEF to other Hadith collections, editions, languages, or hallucination datasets would likely require recalibration rather than direct reuse. Exact-matn provenance memory cannot support unseen matns, and differences in wording, numbering, or edition may separate authentic evidence from the supplied canonical representation. For correction, the 97.55% candidate coverage is a post-hoc diagnostic over an expanded pool rather than part of the submitted inference path. Both systems rely primarily on lexical, contextual, and provenance proxies instead of explicit models of deep semantic entailment or full transmission-history graphs.

7 Ethical Considerations

Religious verification and correction are high-sensitivity applications. A false positive in verification can legitimize unsupported content, while a false correction can replace one hallucination with a different authentic quotation and thereby create a new attribution error. The systems should be viewed as research aids rather than substitutes for qualified Islamic scholarship. Practical use should expose retrieved canonical evidence, source information, and confidence or abstention decisions to human reviewers.

Generative AI tools were used to assist with manuscript organization, drafting, and language editing. The author reviewed the final manuscript and is responsible for the accuracy of the reported methods, experimental results, and citations.

8 Conclusion

Tathabbut unifies IslamicEval 2026 fine-grained verification and canonical correction. CPEF combines canonical, relational, narrator, contradiction, and provenance evidence, achieving 0.9452 Test macro accuracy. TASCR combines hard-negative reranking, hallucination memory, contextual/source evidence, type-aware routing, and explicit abstention, achieving 86.29% Test accuracy. Together, the systems support provenance-aware, conservative use of canonical retrieval.

Bayan_CU at IslamicEval 2026: Fine-Grained Hallucination Span Detection in Arabic Quranic and Hadith Texts

Samah Ghonem
Faculty of Computers and Artificial Intelligence, Cairo University, Egypt
samah.a.ghonem@gmail.com

Abstract

Mitigating factual hallucinations in Large Language Model (LLM) responses is critical, especially when handling sacred Islamic text. This paper presents our system for the IslamicEval 2026 Shared Task-Subtask1 (Span Detection), which requires extracting exact character-level spans and fragment labeling of religious citations in Arabic LLM-generated responses. We frame this as a supervised token-classification task, fine-tuning a monolingual bidirectional encoder (AraBERTv2). To process long sequences, we implement a sliding-window chunking mechanism with an overlapping stride. We reconstruct final character boundaries using a post-processing heuristic that resolves overlapping token predictions. Furthermore, we apply a cascading false-positive filter using cross-type conflict resolution and category-specific minimum length thresholds. Our pipeline yields highly competitive results, achieving a Macro-$F1$ score of 0.9652 on the development set and a peak evaluation score of 0.9736 on the official-task test set.

1 Introduction

Despite the promising capabilities of Large Language Models (LLMs) in Arabic Natural Language Processing (NLP), the language's unique syntactic and semantic characteristics pose formidable computational challenges. These bottlenecks stem from high morphological richness, complex prefix/suffix agglutinations, and orthographic ambiguities arising from the typical omission of short-vowel diacritical marks in daily written text (Alayba, 2025). To resolve these complexities, monolingual Pre-trained Language Models (PLMs) such as AraBERT (Antoun et al., 2020) and MARBERT (Abdul-Mageed et al., 2021) leverage bidirectional Transformer Encoder architectures (Devlin et al., 2019) trained on large-scale Arabic corpora. Consequently, these models have achieved state-of-the-art performance on sequence labeling workloads like Named Entity Recognition (NER) (Antoun et al., 2020).

However, generative LLMs still frequently generate factually inconsistent or unfaithful text, known as hallucinations. This phenomenon is highly prevalent in Arabic; evaluations on the AraHalluEval framework indicate significantly higher hallucination rates in Arabic text generation compared to English across multiple reasoning-based LLMs (Alansari and Luqman, 2025).

Mitigating such distortions is paramount when handling sacred religious (Islamic) texts, where precise quotations from canonical sources—the Holy Qur'an and Prophetic Hadiths—are critical. Fabricating, altering, or misattributing the core text (*matn*) or the chain of transmission (*isnad*) severely degrades user trust. To address this, the **IslamicEval 2025** shared task established a dedicated benchmark for detecting and correcting LLM hallucinations in Islamic text (Mubarak et al., 2025).In this paper, we participate in the **IslamicEval 2026** shared task (Alharbi et al., 2026), addressing **Subtask 1 (Span Detection)**. This task requires extracting exact character-level spans of religious quotations within LLM-generated outputs. To solve this, we propose a lightweight, highly competitive sequence-classification and boundary-reconstruction pipeline powered by a fine-tuned AraBERTv2 encoder. [1]

2 Task Definition

Building upon the foundational benchmarks established in the 2025 shared task (Mubarak et al., 2025), the **IslamicEval 2026 Shared Task** organizers (Alharbi et al., 2026) introduce a finer-grained paradigm for evaluating LLM hallucinations. Rather than merely detecting Quranic verses

[1] Our code and post-processing pipeline are publicly available at https://github.com/Samah-G/Bayan_CU-IslamicEval2026.

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1081–1087
October 28-29, 2026 ©2026 Association for Computational Linguistics

and Prophetic Hadith sayings in religious texts, this framework decomposes citations into their core constituent segments.

Specifically, Quranic quotations are segmented into the *Ayah* (the textual verse) and its associated metadata (the *Surah* name and verse number). Hadith citations are similarly parsed into the *matn* (the core prophetic text), the *isnad* (the chain of transmission/reporters), and the primary source or narrator attribution. Isolating these granular, character-level boundary spans allows for a precise inspection of exactly where factual distortions and fabrications occur, facilitating targeted mitigation of hallucinations in sensitive religious contexts.

3 System Architecture and Methodology

We formulate fine-grained hallucination span detection as a supervised token-classification task using a BIO tagging scheme. Rather than using generative decoder-only models, we fine-tune AraBERTv2 (Antoun et al., 2020)—a stacked bidirectional Transformer encoder (Devlin et al., 2019) designed to capture bidirectional context natively. This architecture is crucial for fine-grained Arabic sequence labeling because it directly handles complex prefix/suffix agglutinations and morphology.

Furthermore, while generative pipelines at IslamicEval 2025 relied on complex, error-prone string-alignment algorithms (such as Needleman-Wunsch) to resolve character offsets from generated text (Omayrah et al., 2025), our token-space approach bypasses these alignment bottlenecks entirely. The complete pipeline is illustrated in Figure 1.

3.1 Preprocessing and Sliding-Window Tokenization

To address class imbalance, we filter the training set by discarding responses that do not contain target spans. Because the average LLM-generated response length is 1,460 characters in the training data set, standard encoding risks context truncation. We resolve this by applying a sliding-window tokenization strategy.

We tokenize input texts using the pre-trained AraBERTv2 tokenizer (Antoun et al., 2020) via the Hugging Face `transformers` library (Wolf et al., 2020) to retrieve token IDs and character offset mappings. Sequences are divided into overlapping chunks of maximum-length $L_{\text{max}} = 512$ tokens. To prevent span boundary truncation, we apply a sliding stride (S). We set $S = 128$ tokens for training and evaluate $S \in \{128, 256, 384\}$ during development and testing phases.

3.2 Sequence Labeling and Model Training

For each chunk, gold-truth character offsets are mapped to a 9-class BIO schema:
$\mathcal{Y} = \{\textbf{O}, \textbf{B/I-claimed source}, \textbf{B/I-Ayah}, \textbf{B/I-matn}, \textbf{B/I-isnad}\}$.
We fine-tune the `bert-base-arabertv2` encoder (~110M parameters) by appending a linear classification head over the token hidden representation to predict the token labels $y_t \in \mathcal{Y}$.

Training is executed for 3 epochs with a learning rate of 3×10^{-5} using a batch size of 16. The complete training configuration and parameter rationales are detailed in Table 5 in Appendix A.

3.3 Span Reconstruction Heuristic

During inference, sequences are processed into unlabeled chunks, yielding token-level predicted tags via

$$\hat{y}_t = \arg\max(\text{logits}_t)$$

. We map $\hat{y}_t$ back to character-level boundaries using a three-step heuristic: (1) **Span Merging:** consecutive tokens of category c starting with B-c followed by I-c are merged into a single span spanning from the start of the B token to the end of the last consecutive I token; (2) **Orphaned Tags:** isolated I-c tags lacking a preceding B-c are treated as single-token spans; and (3) **Negative Space:** all O tags are discarded. A visual example of this token-to-offset reconstruction is detailed in Figure 2 in Appendix B.

3.4 Overlapping Span Merging Heuristic

Because input responses are processed in overlapping sliding-window chunks, predictions from adjacent chunks often produce redundant or partially duplicate spans. To reconstruct a single, cohesive character-level span layout, We group all predicted spans by response ID and sort them chronologically by their starting offset (s). We then iteratively compare consecutive spans of identical segment types—defined as span_1 with boundaries $[s_1, e_1]$ and span_2 with boundaries $[s_2, e_2]$—under a dual-conditional merging framework. Spans are merged if they satisfy at least one of the following:

1) Intersection over Union (IoU) Threshold: The overlap represents a significant fraction of their

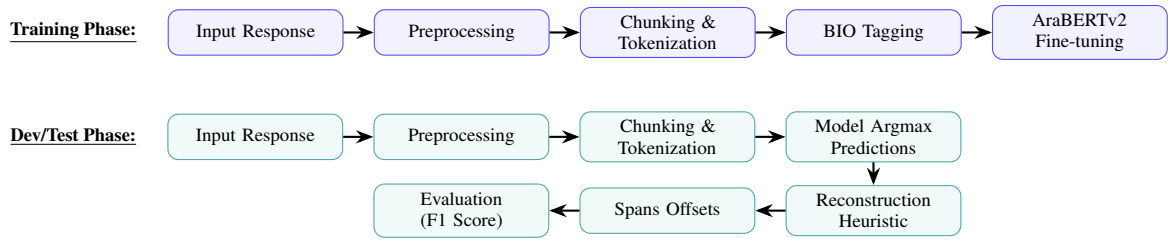

Figure 1: Split-phase system architecture layout showing offline model fine-tuning (top) and online post-processed inference evaluation (bottom).

total combined coverage, defined as:

$$\text{IoU}(span_1, span_2) = \frac{\max(0, \min(e_1, e_2) - \max(s_1, s_2))}{\max(e_1, e_2) - \min(s_1, s_2)} \geq 0.3 \quad (1)$$

2) Boundary Proximity Threshold: To capture short nested spans that would otherwise fail the denominator-heavy IoU check, we merge spans if their start boundaries satisfy:

$$\Delta_{\text{start}} = |s_1 - s_2| \leq 5 \text{ characters} \quad (2)$$

If either condition is met, the spans are merged into a single span with boundaries $[\min(s_1, s_2), \max(e_1, e_2)]$. This merged span replaces both original instances in the queue and is compared against the next span in the sequence. Responses containing no predicted spans are assigned a default `No Annotation` label. Detailed merging calculations are provided in Appendix C.

3.5 False Positive Filtration

To mitigate spurious or hallucinated boundary predictions, we apply a two-step cascading filter:

1. **Cross-Type Conflict Resolution:** Reconstructed spans for a given response are sorted in descending order by character length. If consecutive spans of conflicting segment types overlap (IoU > 0.1), the longer span is preserved and the shorter is discarded.

2. **Minimum Length Constraint:** To eliminate isolated token noise, we enforce a category-specific minimum character-length threshold (T_{len}) and discard spans falling below it:

$$T_{\text{len}} = \begin{cases} 5 & \text{if type} = \texttt{claimed\_source} \\ 10 & \text{if type} \in \{\texttt{isnad}, \texttt{Ayah}\} \\ 15 & \text{if type} = \texttt{matn} \end{cases} \quad (3)$$

3.6 Annotation Grouping

Finally, the remaining filtered spans are grouped into compound annotation units according to the task schema: a Quranic *Ayah* is paired with its corresponding *Claimed Source* under a single annotation ID, while a Hadith *Matn*, *Isnad*, and *Claimed Source* are unified under another unique ID.

3.7 Inference and Test Set Evaluation Pipeline

During evaluation, blind test responses pass through the identical processing chain: (1) **Preprocessing & Sliding-Window Tokenization** using identical parameters ($L_{\max} = 512, S \in \{128, 256, 384\}$); (2) **Model Inference** to predict token-level tags via $\hat{y}_t = \arg\max \text{logits}_t$; and (3) **Post-Processing** to apply span reconstruction, overlap merging, and cascaded filtration. The finalized character-level offsets are then evaluated against the gold annotations using the official character-level macro-averaged F1 score.

4 Experimental Results and Analysis

We evaluate our proposed fine-grained hallucination span detection system across several configurations, training hyperparameters, and post-processing setups. The primary evaluation metric is the character-level macro-averaged F_1 score.

4.1 Development Set Results & Hyperparameter Search

We conduct a systematic grid search on the development set, varying model backbones, learning rates (η), fine-tuning epochs (E), and sliding-window strides (S). All results in Table 1 are reported with post-processing filtration applied.

Hyperparameter Insights: (1) **Learning Rate Sensitivity:** $\eta = 3 \times 10^{-5}$ yields optimal convergence. Slower rates underfit (0.9574), whereas higher rates (5×10^{-5}) destabilize updates (0.9622). (2) **Window Stride:** Expanding S from 128 $\rightarrow$ 384 provides vital overlapping context near chunk

Model Backbone	LR (η)	Ep.	Stride (S)	Dev F_1
Impact of Learning Rate (Fixed $E = 3, S = 384$)				
AraBERTv2-base	2×10^{-5}	3	384	0.9574
AraBERTv2-base	$\mathbf{3 \times 10^{-5}}$	**3**	**384**	**0.9652**
AraBERTv2-base	5×10^{-5}	3	384	0.9622
Impact of Window Stride (Fixed $\eta = 3 \times 10^{-5}, E = 3$)				
AraBERTv2-base	3×10^{-5}	3	128	0.9649
AraBERTv2-base	3×10^{-5}	3	256	0.9647
AraBERTv2-base	$\mathbf{3 \times 10^{-5}}$	**3**	**384**	**0.9652**
Impact of Training Epochs (Fixed $\eta = 3 \times 10^{-5}, S = 384$)				
AraBERTv2-base	$\mathbf{3 \times 10^{-5}}$	**3**	**384**	**0.9652**
AraBERTv2-base	3×10^{-5}	4	384	0.9640
Alternative Pre-trained Encoders				
MarBERT	3×10^{-5}	3	384	0.9645
AraBERT-Large	2×10^{-5}	4	128	0.9609
AraBERT-Large	2×10^{-5}	4	384	0.9606

Table 1: Systematic hyperparameter search and model architecture comparison on the development dataset (with full post-processing filtration applied).

edges, boosting F_1 from 0.9649 to 0.9652 while reducing the incidence of broken character spans. (3) **Epoch Limits:** Fine-tuning for 3 epochs outperforms 4 epochs (0.9640), indicating localized overfitting on repetitive syntactic phrases in the chunked dataset. (4) **Model Backbone:** The monolingual AraBERT-base outperforms both the dialect-aware MarBERT (0.9645) and the over-parameterized (340M) AraBERT-Large (0.9609), highlighting the parameter efficiency of base-sized models on MSA sequence labeling. While larger models tend to overfit on the specialized domain.

4.2 Filtration Ablation Study

Before applying post-processing filters, a confusion matrix analysis of our top development models revealed high false-positive rates caused by spurious, isolated token activations. Enforcing our cascading filtration steps (cross-type conflict resolution and minimum-length thresholds) yielded substantial performance recoveries across configurations: A comprehensive confusion matrix and per-class error breakdown on the development set are provided in Appendix D.

Model Configuration	Raw F_1	Post-Filter F_1
AraBERTv2-base ($E = 4, S = 384$)	0.9634	0.9640
AraBERTv2-base ($E = 3, S = 384$)	0.9649	**0.9652**

Table 2: F_1-score gains after applying filtration

4.3 Official Test Set Evaluation

Our final system configurations were evaluated blind on the official Codabench testing platform across three progressive submissions shown in Table 3: Enabling our cascading filtration pipeline on the same base model in Sub.1 boosted the test F_1 score to **0.9706** ($+0.0015$ gain), validating the noise-suppression heuristic. While the best overall test F_1 score **0.9736** resulted from combining the optimal model parameters, with the post-processing filteration steps.

Sub.	Model Backbone & Config	Post-Filter	Test F_1 Score
1	AraBERTv2-base ($E = 4, S = 384$)	Off	0.9691
2	AraBERTv2-base ($E = 4, S = 384$)	On	0.9706
3	**AraBERTv2-base** ($E = 3, S = 384$)	**On**	**0.9736**

Table 3: Official evaluation results of the test-set submissions on the Codabench platform.

4.4 Key Evaluation Trends

Our blind test results reveal three critical performance dynamics: (1) **Generalizability:** Achieving a peak test F_1 score of **0.9736** (surpassing development results) demonstrates strong out-of-domain generalization without data leakage. (2) **Filtration Impact:** Applying cascading post-processing filters on the 4-epoch model yields a direct $+0.0015$ improvement ($0.9691 \rightarrow 0.9706$), proving our heuristics generalize robustly to unseen test instances. (3) **Epoch Optimization:** Mirroring our development findings, reducing fine-tuning epochs from 4 to 3 increases test F_1 by $+0.0030$ to **0.9736**, establishing our 3-epoch, stride-384, post-filtered configuration as our optimal pipeline.

5 Conclusion

We presented an efficient sequence-labeling pipeline using AraBERT for fine-grained religious hallucination span detection in the IslamicEval 2026 shared task. Our token-classification formulation bypasses the alignment bottlenecks and boundary errors of generative decoder-only architectures. Additionally, our post-processing pipeline—incorporating dual-criteria span merging, cross-type conflict resolution, and length filters—substantially mitigates false positive boundaries. Future work will explore dialect-aware language models and ensemble voting across multi-scale sliding windows to improve boundary robustness.

Limitations

Despite the high macro-averaged F_1 performance of our system, several limitations warrant discussion. First, our pipeline is highly optimized for Modern Standard Arabic (MSA), the primary medium of canonical religious texts. Performance may degrade on informal regional dialects or noisy user-generated content where non-standard spellings of source attributes or colloquial phrases are used. Second, the sliding-window chunking strategy introduces structural dependencies; while the 128-token stride successfully mitigates boundary-severing issues, it increases the total inference overhead. Third, our post-processing filter utilizes static, hardcoded minimum length thresholds for segment types (e.g., a threshold of 15 characters for *matn*). While highly effective for filtering out random token-classification noise on this benchmark, these thresholds are heuristic-based and may over-filter authentic, extremely short quotations or source citations in out-of-domain evaluation contexts.

A Hyperparameter Configurations

This appendix illustrates the Model training hyperparameter settings and selection rationales in Table 5.

B Token-to-Offset Mapping Example

This appendix illustrates the token-to-offset span reconstruction heuristic, mapping predicted token boundaries to localized Arabic text slices. Figure 2 demonstrates how individual token tags (B-, I-, O) are processed to construct the final character-level offsets for a Quranic *Ayah* span.

Segment Type	Total GT	Correct (%)	Missed / FN (%)	Confused / Wrong (%)	Extra / FP
Ayah	698	98.4% (687)	0.9% (6)	0.7% (5)	24
claimed_source	1,238	96.0% (1,188)	3.9% (48)	0.2% (2)	68
isnad	204	87.3% (178)	9.8% (20)	2.9% (6)	34
matn	588	98.3% (578)	1.0% (6)	0.7% (4)	23

Table 4: Per-class error and classification accuracy breakdown relative to ground-truth spans on the development set.

Hyperparameter	Value	Rationale
Max Length (L)	512	Fits long contextual windows
Stride (S)	128	Prevents boundary context truncation
Batch Size	16	Efficient VRAM usage
Epochs	3	Prevents overfitting on chunks
Learning Rate	3×10^{-5}	Optimal for AraBERTv2 fine-tuning

Table 5: Model training hyperparameter settings and selection rationales.

Tokens	قال	تعالى	إن	الله	مع	الصابرين
Tags	O	O	B-Ayah	I-Ayah	I-Ayah	I-Ayah
Offsets	(0, 3)	(4, 9)	(10, 12)	(13, 17)	(18, 20)	(21, 29)
Action	*Discarded*		**Span:** Ayah (10, 29)			

Figure 2: Token-to-offset span reconstruction mapping.

C Span Merging Numerical Examples

This appendix provides concrete examples of the dual-conditional merging framework applied to consecutive predicted segments of identical types during the post-processing phase:

- **Example 1 (No Merge via IoU):** Given $\text{span}_1 = [5, 30]$ and $\text{span}_2 = [20, 50]$, the intersection is $30 - 20 = 10$, and the union is $50 - 5 = 45$.

$$\text{IoU} = \frac{10}{45} \approx 0.22 < 0.3$$

  Because the start boundary delta is $|5 - 20| = 15 > 5$, neither condition is met, and the spans are preserved as separate.

- **Example 2 (Successful Merge via IoU):** Given $\text{span}_1 = [10, 40]$ and $\text{span}_2 = [15, 55]$, the intersection is $40 - 15 = 25$, and the union is $55 - 10 = 45$.

$$\text{IoU} = \frac{25}{45} \approx 0.55 \geq 0.3$$

  This triggers a successful merge, resulting in a single reconstructed span spanning $[10, 55]$.

- **Example 3 (Successful Merge via Proximity):** Given a long reference $\text{span}_1 = [10, 70]$ and a short nested $\text{span}_2 = [15, 25]$, the intersection is $25 - 15 = 10$, and the union is $70 - 10 = 60$.

$$\text{IoU} = \frac{10}{60} \approx 0.167 < 0.3$$

  Although it fails the IoU threshold due to the long union length, the absolute difference between their start offsets is:

$$\Delta_{\text{start}} = |10 - 15| = 5 \leq 5$$

  This satisfies the proximity threshold, successfully merging the segments into a single span spanning $[10, 70]$.

D Detailed Development Error Analysis

In this appendix, we present the detailed error patterns of our fine-tuned AraBERT sequence labeler (3×10^{-5} learning rate, 3 epochs, 384 stride) evaluated on the development set after applying our final cascaded filters.

D.1 Error Classification and Matrix Analysis

Table 6 categorizes the precise types of boundary and classification errors observed across all predicted spans. The model achieves 2,459 exact span matches, while boundary shifting issues (split across minor shifts of 1–5 characters and major shifts of > 5 characters) account for a total of 172 errors. The largest source of performance degradation is hallucinated spans (149 False Positives compared to 258 False Positives without the dual-filteration steps), justifying our cascaded post-processing filtering.

Table 7 provides the token-level confusion matrix among our four primary segment classes: *Ayah*, *claimed_source*, *isnad*, and *matn*, alongside instances that were entirely missed (False Negatives). Table 4 contextualizes these errors as percentages of the total ground-truth (GT) annotations per segment type.

Metric / Error Category	Count
Exact Span Matches	2,459
Missed Spans (FN)	80
Wrong Entity Type	17
Minor Boundary Shift (1–5 chars)	82
Major Boundary Shift (> 5 chars)	90
Hallucinated Spans (FP)	149

Table 6: Detailed development set error classification summary.

	Predicted Category				
Ground Truth	**Ayah**	**claimed_ source**	**isnad**	**matn**	**Missed**
Ayah	687	2	0	3	6
claimed_source	0	1,188	0	2	48
isnad	0	4	178	2	20
matn	2	1	1	578	6

Table 7: Token-level prediction confusion matrix on the development set (Rows: Ground Truth, Columns: Predictions).

D.2 Key Qualitative Observations

Our analysis of the per-class performance reveals several distinct syntactic and structural patterns:

- **High Fidelity on Quranic and Hadith's Matn Spans:** Both *Ayah* and *matn* segments achieve exceptionally high correct-type classification rates of 98.4% and 98.3% respectively. This demonstrates the model's outstanding capability to recognize the highly stylized linguistic structures and traditional opening/closing formulas associated with Quranic verses and canonical Prophetic text.
- **Vulnerability of Isnad Detection:** The *isnad* (chain of transmission) segment presents the lowest correct detection rate (87.3%) and the highest missed rate (9.8%). This is primarily due to the morphological diversity and highly variable length of transmission chains (e.g., lists of sequential narrator names), leading to boundary under-segmentation.
- **Spurious Source Citations:** Out of 149 total hallucinated spans, the *claimed_source* category accounted for the largest fraction (68 instances). The model frequently flagged common reference formatting, Surah names, or general vocabulary as actual quoted sources even when they did not reference a specific span. This empirical finding strongly motivates extra post-processing filters to eliminate isolated, short-length *claimed_source* spans.

Qahera at IslamicEval 2026: Corpus-Grounded Retrieval and Iterative Harness Search with a 4B-Parameter LLM for Islamic Citation Verification

Mohamed Abdelmagid
Team Qahera
mabdelmagid@aucegypt.edu

Hazem Ajlan
Team Qahera
hazemdiaa@aucegypt.edu

Abstract

We describe the Qahera system for the four IslamicEval 2026 subtasks: (1) detecting Qur'an/Hadith citation spans in LLM-generated Islamic answers, (2) judging citation authenticity, (3) correcting inauthentic citations against reference corpora, and (4) judging whether an authentic citation answers the question asked. Under a 13B-parameter open-model constraint, running entirely on free Kaggle GPUs, we combine a lightweight token-classification model with character-level auxiliary features (Subtask 1), corpus-grounded fuzzy retrieval (Subtasks 2–3), and a 4B-parameter instruction-tuned LLM (Gemma-3-4B) used only where retrieval alone cannot discriminate (Subtasks 3–4). Rather than hand-designing LLM prompts once, we develop them through an iterative *propose-evaluate-diagnose* search loop that reads full prediction traces after every candidate and hunts for systematic biases before each change. This surfaces small-model failure modes – a near-universal "reject" bias in isolated yes/no verification, and an "always name something" bias in numbered-list prompts – that would otherwise silently cap performance, and shows that validating candidates on small subsets can be actively misleading. Our final system reaches 0.9716 F1 (Subtask 1), 0.906 accuracy (Subtask 2), 0.773 accuracy (Subtask 3), and 0.673 macro-F1 (Subtask 4) on the official test sets.

1 Introduction

IslamicEval 2026 asks systems to audit Qur'anic and Hadith citations inside answers generated by large language models to real Islamic questions (Alharbi et al., 2026). A generated answer may quote a verse or a Hadith text (*matn*), attribute it to a source (*claimed_source*), and give its chain of narration (*isnad*); any of these can be fabricated, misquoted, or irrelevant to the question. The shared task decomposes this into four subtasks: **Subtask 1** (Span Detection) locates and types each citation segment in the raw response text; **Subtask 2** (Hallucination Identification) labels each Ayah/matn/isnad/claimed_source segment as `correct` or `incorrect`; **Subtask 3** (Correction) supplies the authentic canonical text for incorrect Ayah/matn segments, or the literal string خطأ ("error") when no faithful correction exists; and **Subtask 4** (Answer Relevance) judges whether an authentic citation directly or indirectly answers the question, since topical overlap alone is insufficient.

We operated under a constraint of open models with at most 13B parameters, on free-tier Kaggle GPUs (dual NVIDIA T4). This ruled out proprietary large-LLM judges and shaped our strategy: use cheap, well-understood string-level methods wherever the problem structure allows it, and reserve LLM calls for the sub-decisions where they are needed. For Subtask 4 and the harder half of Subtask 3 (Qur'anic correction), a naive, once-written LLM prompt underperforms a much simpler retrieval baseline, and the gap is explained by specific, reproducible biases of the small judge model rather than prompt wording alone. We therefore developed these components through an iterative search loop (§4) that treats every candidate's full per-example trace as evidence for diagnosing *why* it failed, not just how well it scored.

2 Data and Resources

The training set contains 4,706 model responses (over 15,000 annotated citations); we held out 484 as a question-disjoint dev split for Subtask 1, and used the organizers' `dev_set` files for Subtasks 2–4. Two reference corpora are provided: 6,236 Qur'anic verses and 34,994 Hadith entries from six canonical collections (Bukhari, Muslim, Abu Dawud, Tirmidhi, Nasa'i, Ibn Majah); Subtasks 2 and 3 require every prediction to be grounded in these corpora.

3 System Description

Figure 1 shows the finalized pipeline for each subtask.

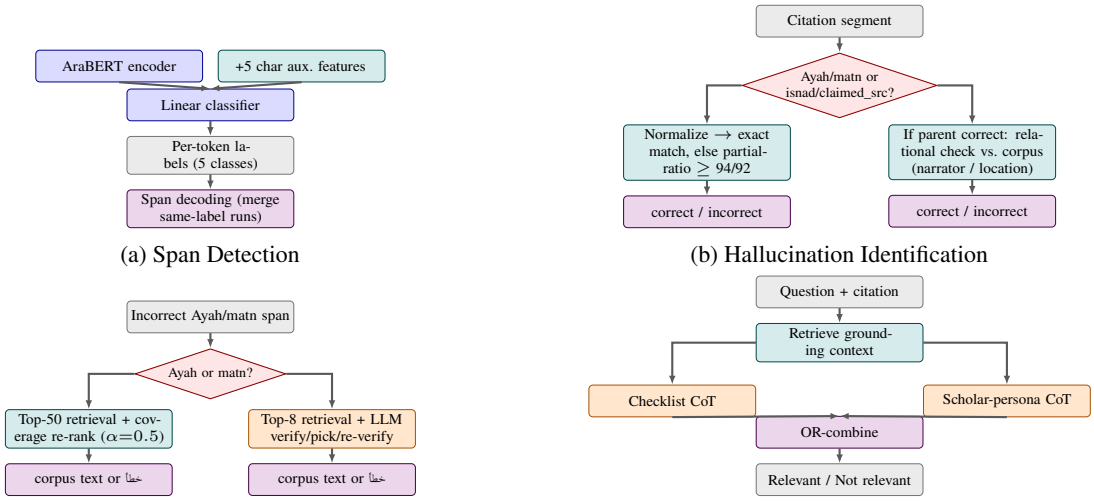
3.1 Subtask 1: Span Detection

We frame span detection as character-level token classification into five labels (`neither`, `Ayah`, `matn`, `isnad`, `claimed_source`), decoded into spans by taking maximal same-label runs (Figure 1a). The backbone is AraBERTv02-base (Antoun et al., 2020); its hidden states are concatenated with a linear projection of five character-level auxiliary features: local tashkeel (diacritic) density, an inside-quotation-marks flag, and three gazetteer hit indicators – 114 surah names, six Hadith-collection names, and common isnad markers such as حدثنا ("he narrated to us"). Class weights compensate for the heavy `neither` majority class, and a 512-token, 128-stride sliding window sums logits across overlaps at inference. Regex post-hoc correction rules for `claimed_source` spans were tested but rejected: they lowered validation F1 (0.968 vs. 0.971).

3.2 Subtask 2: Hallucination Identification

We do not train a classifier for this task; instead we deterministically check each segment against the two provided corpora, labeling it `correct` if located there and `incorrect` otherwise (Figure 1b). Before matching we normalize the Arabic text: strip diacritics and elongation marks, and unify inconsistently written letter shapes (alef/hamza forms, final ة vs. ه, and ى vs. ي).

Ayah and matn. We put all 6,236 Qur'anic verses into one long string and all 34,994 Hadiths into another, and look for a segment's normalized text inside the matching string; an exact hit is `correct`. We deliberately use exact matching – fabricated verses usually look very close to real ones, so a loose fuzzy match would let them through – but exact matching alone is too strict, since a real quotation can have small spelling differences from the canonical text. When the exact match fails, we try one fuzzy step: a partial-match score (`rapidfuzz.partial_ratio`) of at least 94 for Ayah or 92 for matn is still accepted as `correct`. These thresholds work because the two groups sit far apart: real verses that miss the exact match still score 95–100, while altered ones score 60–85. For matn, we first use a word index to narrow candidate Hadiths before running the partial match, given the large corpus.



Isnad. A chain of narration cannot be judged from its own text: correct and incorrect chains often look almost identical (e.g., the same companion, عن أبي هريرة, "on the authority of Abu Hurairah," appears in both). What matters is whether the corpus attributes *this* Hadith text to *this* narrator: we locate the segment's parent matn in the corpus, read the narrator's name from the isnad, and check whether that name co-occurs with the matn there. If so, the isnad is `correct`; if the matn appears only with other narrators, it is `incorrect`. (The isnad dev set is only 30 segments, so this number is noisy.)

Claimed_Source. We again check the claim against the corpus, not in isolation. For a Qur'anic source, we read the surah name and verse number from the claim, look up the real verse there, and compare it with the parent Ayah using a partial-match ratio (threshold 75); a match is `correct`, a valid location with a different verse is `incorrect`. For a Hadith source, we read the claimed collection (e.g., Bukhari) and check whether the parent matn appears there, using one text index per book. Per the subtask's rules, `claimed_source` and `isnad` are scored only when their parent segment is itself correct.

On the development set, this pipeline scores 0.884 macro accuracy: 0.961 for Ayah, 0.942 for matn, 0.733 for isnad, and 0.900 for `claimed_source`. Every label comes from looking something up in the corpus; exact matching catches fabrications, and a small amount of fuzzy tolerance keeps real citations from being rejected over minor spelling differences.

3.3 Subtask 3: Correction

Correction solves two different problems depending on segment type (Figure 1c), treated differently for reasons grounded in evidence, not assumption. For **Ayah**, plain `token_set_ratio` is bag-of-words: a short *generic* shared phrase (e.g. على صراط مستقيم, "on a straight path," a formula recurring across many unrelated verses) can score 100 against a totally unrelated verse, whereas a genuine (possibly truncated) quotation shares most of itself *contiguously* with the true verse. We retrieve a large candidate pool (top-50) and re-rank it by a combined score $\alpha \cdot \text{token\_set\_ratio} + (1-\alpha) \cdot \text{coverage}$, where *coverage* is the longest contiguous substring shared between query and candidate, as a fraction of the query's own length. The top candidate's combined score is thresholded (α=0.5, cutoff 50 – both from a

(a) Span Detection

(b) Hallucination Identification

(c) Correction

(d) Answer Relevance

Figure 1: Finalized pipelines for all four subtasks. Gray = input/output, blue = neural encoder, teal = corpus retrieval, orange = LLM call, violet = decision/merge, red diamond = branching question.

stable plateau in a grid sweep rather than the single best point, to avoid over-fitting); below threshold we emit خطأ. No LLM call is used for Ayah correction: an isolated yes/no verifier showed a near-universal reject bias on genuine paraphrases (§6).

For **matn**, retrieval alone cannot disambiguate near-duplicate Hadiths sharing only generic isnad-adjacent boilerplate (e.g. رسول الله صلى الله عليه وسلم, "the Messenger of Allah, peace be upon him"), so we add a three-stage Gemma-3-4B-it (Gemma Team, Google DeepMind, 2025) pipeline over the top-8 retrieved candidates: (i) an isolated yes/no call asks whether the fuzzy top-1 candidate is genuinely the same Hadith as the (possibly corrupted) span; (ii) if rejected, a second call presents the remaining candidates as a numbered list and asks the model to name the correct one, or 0 for none; and (iii) whatever is named in step (ii) is re-verified with the *same* isolated yes/no framing as step (i) before acceptance. Step (iii) exists because step (ii)'s list-choice framing has a measurable bias toward naming *some* candidate even when none is correct (§6); re-checking with the more reliable isolated framing recovers much of the lost precision. The model never re-generates citation text – only retrieved, corpus-verbatim text is returned – since Qur'anic scoring is diacritic-sensitive and free generation risks subtly wrong diacritics.

3.4 Subtask 4: Answer Relevance

For each citation (Figure 1d), we retrieve its closest corpus match (grounding context only, not a decision signal) and query Gemma-3-4B-it with two independently-worded chain-of-thought prompts: a *checklist* framing walking through the task's direct / indirect-case-1 / indirect-case-2 / topical-overlap-trap distinctions, and a *scholar-persona* framing asking the model to reason as a mufti would about whether the citation is legitimate evidence for this question. The citation is labelled relevant if *either* call says so. An earlier three-way design added a *devil's-advocate* framing (argue the citation is irrelevant, then check if the argument holds); back-testing its stored votes showed it answered relevant on 76% of gold-non-relevant examples regardless of content – it always talked itself into "relevant" – with no discriminative signal beyond the other two, so we dropped it, cutting average LLM calls per example from 3 to roughly 2 at unchanged accuracy.

4 Iterative Harness Search

For Subtasks 3–4, we did not hand-tune a single LLM pipeline, but used an iterative loop – in the spirit of end-to-end harness optimization (Lee et al., 2026), organized around *qualitative* trace diagnosis rather than a purely numeric objective: (1) evaluate the current harness on the full development set and log every example's inputs, calls, and outputs; (2) inspect the wrong-prediction traces for a systematic pattern; (3) propose one concrete, evidence-justified change; (4) re-evaluate, and revert if it does not hold up. Figure 2 summarizes this cycle, which surfaced three findings about small-model failure modes, discussed in §6.

5 Results

Table 1 reports official Codabench test-set scores. All development-set numbers use the organizers'

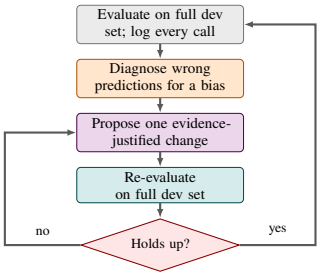


Figure 2: The propose-evaluate-diagnose loop used to develop the Subtask 3–4 harnesses (see §6 for why full-set scoring matters).

Subtask	Metric	Dev	Test
1: Span Detection	F1	0.971	0.972
2: Hallucination ID	Acc.	0.884	0.906
3: Correction	Acc.	0.763	0.773
4: Answer Relevance	Macro-F1	0.706	0.673

Table 1: Official development and test results. Subtask 2's development score is the macro accuracy over the four segment types on the full dev split.

full `dev_set` files, never a subset.

Subtask 2's test breakdown mirrors development: 0.945 Ayah, 0.889 matn, 0.852 isnad, and 0.937 claimed_source, close to dev (0.961 / 0.942 / 0.733 / 0.900) despite the isnad slice's small size. For Subtask 3, Ayah accuracy is 0.715 and matn is 0.824 on test, closely tracking dev (0.710 / 0.816). For Subtask 4, dropping from 0.706 (dev) to 0.673 (test) macro-F1 is a smaller, more typical gap than the subset-vs-full-dev gaps in §6, suggesting the two-vote ensemble is not overfit to dev.

Non-LLM baselines surpassed during development: 0.566 accuracy for Subtask 3 (fixed-cutoff retrieval, no re-ranking or LLM verification) and 0.573 macro-F1 for Subtask 4 (a fine-tuned AraBERT cross-encoder), both on the full dev set.

6 Discussion

The iterative harness search described in §4 surfaced three findings about small-model behavior that we consider more broadly useful than any single prompt:

Small-subset validation is unreliable. A 60-example subset suggested 0.694 Ayah correction accuracy for the retrieval-only baseline; the coverage-rerank policy we eventually adopted looked *worse* on that subset (0.639), arguing against shipping it. On the full 943-row development set the opposite was true: coverage-rerank reached 0.710, a clear improvement over 0.641. We validated every candidate on the full split before trusting it.

Isolated binary verification has a strong reject bias for Qur'anic paraphrase. Adding an LLM yes/no check asking whether a retrieved verse was the one quoted collapsed recall on genuinely correct Ayah matches from 89/219 to 23/219: the raw outputs showed "no" to matches that were, in 66 of 100 inspected cases, an exact substring or extension of the correct verse – precisely what its own prompt permitted. The bias did not respond to more explicit wording, so we removed the LLM check for Ayah entirely.

Numbered-list choice prompts have an "always answer something" bias. Across three iterations, whenever the matn pipeline showed the model a numbered candidate list and asked it to name the correct one or answer 0, it named a concrete (often wrong) candidate roughly three times as often as 0, even when none was genuinely correct. The fix was structural: re-verify whatever the list-choice step names using the isolated single-candidate yes/no framing, which does not exhibit this bias.

Together, these findings share one lesson: a small LLM's failure modes are structural, not random, and can be routed around once diagnosed. This is why LLM-based verification underperformed algorithmic re-ranking for Ayah: the model's judgment carried a stronger bias than the retrieval scorer. It was worth its cost for matn and Subtask 4, where judgment requires weighing semantic content – but even there, the working designs succeed by containing a known bias structurally, not trusting a single call. Under a small-model budget, diagnosing failure beats prompting harder.

Limitations

Our Subtask 3 retrieval index uses only surface fuzzy matching; roughly 7% of genuinely correctable citations in our full-dev audit never appeared among retrieved candidates, a recall ceiling a semantic (embedding-based) index might close. The biases we found are not guaranteed exhaustive; a different held-out split could surface others, and our harness search ran for few iterations (nine for Subtask 3, four for Subtask 4). Finally, all LLM components use a single 4B-parameter model (Gemma-3-4B-it); we cannot say how much of the observed bias is specific to it versus small instruction-tuned LLMs generally.

Abstract

Arabic large language models can generate fluent religious answers but may misquote or misattribute Qur'anic and Hadith evidence. This makes reliable verification important in a domain where the accuracy of the quoted text and its source matters. We describe Taqwatech's systems for Subtasks 1 and 2 of IslamicEval 2026. For Subtask 1, we use CAMeLBERT-Mix with BIO tagging to find Ayah, Hadith *matn*, *isnad*, and claimed-source spans. We then convert the predicted token labels back to the character positions required by the task. For Subtask 2, we use a verification system based on the cited sources that combines Arabic normalization, lexical retrieval, character TF-IDF, Qur'anic verse matching, source checks, and narrator matching. On the official blind test, our systems achieved 0.9683 character-level macro-F1 for Subtask 1 and 0.9050 macro accuracy for Subtask 2. The systems perform well for span detection and Qur'anic verification, while narrator-chain verification remains the main challenge.

1 Introduction

Large language models (LLMs) are widely used for question answering and text generation in Arabic. Although their answers are usually clear and fluent, they may contain information that is incorrect or unsupported. This problem is known as hallucination (Rawte et al., 2023). The problem is particularly important in religious questions, where the accuracy of quotations and their sources is important.

The Qur'an and Hadith are central sources of Islamic knowledge. However, an LLM may change part of a Qur'anic verse, produce an unsupported Hadith, connect a correct quotation to the wrong source, or mention an incorrect narrator. These errors are not always easy to notice because the generated answer may still sound natural. Checking fluency alone is therefore not enough; the quotation must be compared with trusted sources.

IslamicEval 2025 introduced a shared task for detecting and correcting hallucinated Qur'anic and Hadith content in Arabic LLM responses (Mubarak et al., 2025). IslamicEval 2026 extends this work through a more detailed annotation of each citation (Alharbi et al., 2026). A citation may contain an Ayah, a Hadith *matn*, an *isnad*, and a claimed source. This allows each part of a citation to be checked separately.

Taqwatech participated in the first two subtasks. Subtask 1 asks systems to find the exact character positions and types of citation segments. Subtask 2 provides the segments and asks whether each one is correct or incorrect. We use contextual BIO tagging for the first task and source-based verification for the second. On the official blind test, our systems achieved 0.9683 character-level macro-F1 for Subtask 1 and 0.9050 macro accuracy for Subtask 2.

2 Task and Data

Each example contains a user question and an Arabic answer generated by an LLM. An answer can contain no citation, a single citation, or several citations. Each citation is divided into one or more segment types: Ayah, Hadith *matn*, *isnad*, and claimed source.

An Ayah segment contains quoted Qur'anic text. A *matn* contains the main wording of a Hadith. An *isnad* contains narrator information. A claimed source may contain a surah name, verse number, or

Table 1: Statistics of the released data. The final column excludes N/A segments from Subtask 2.

the name of a Hadith collection.

2.1 Subtask 1: Span Detection

In Subtask 1, the system must identify every citation segment in the generated answer. For each segment, the system returns its type and its start and end character positions. Segments belonging to the same citation share an annotation ID. If the answer has no citation, the system returns the required `NoAnnotation` entry.

The official evaluation metric is character-level macro-F1. Every character is assigned to one of five classes: ayah, *matn*, *isnad*, claimed source, or neither. This evaluation measures both the predicted type and the quality of the span boundaries.

2.2 Subtask 2: Hallucination Identification

In Subtask 2, the citation segments and their types are already provided. The system predicts `correct` or `incorrect` for each segment. An ayah is checked against the canonical Qur'an, while a Hadith *matn* is checked against the supplied Hadith records.

Claimed-source and *isnad* segments depend on their main quotations. They are evaluated only when the related Ayah or *matn* is correct. If the main quotation is incorrect, these segments receive the N/A label and are excluded from scoring. Accuracy is calculated for each segment type, and the final score is calculated as the unweighted average of the four accuracy values.

2.3 Dataset and Reference Collections

We used the official training, development, and test files. The training split contains 4,706 responses, 15,826 citations, and 32,779 segments. The development split contains 484 responses, 1,358 citations, and 2,728 segments. After excluding N/A labels, 24,088 training segments and 1,745 development segments are available for Subtask 2.

The organizers also supplied a canonical Qur'an collection and a Hadith collection covering six books. We use these collections as trusted sources for verification. No externally labeled examples are added.

3 Subtask 1 System

3.1 Approaches

We tried two approaches for citation span detection. The first approach treats the task as BIO sequence labeling and fine-tunes CAMeLBERT-Mix, an Arabic pretrained language model (Inoue et al., 2021).. The second approach uses Qwen3-4B (Yang et al., 2025), fine-tuned with QLoRA (Dettmers et al., 2023), to generate a JSON list containing the citation type and its character offsets.

The generative approach could not be evaluated completely so that it could be compared fairly with the sequence-labeling system. We therefore selected CAMeLBERT-Mix for our official submission. This system achieved a character-level macro-F1 score of 0.9683 on the official test set.

3.2 BIO Label Generation

First, we assign a label to each character in the generated answer. The labels include O and beginning/inside labels for each of the four segment types. This results in nine labels in total:

$$\{\text{O}, \text{B/I-Ayah}, \text{B/I-matn}, \text{B/I-isnad}, \text{B/I-source}\}.$$

The CAMeLBERT tokenizer provides an offset mapping between tokens and characters. We use this mapping to transfer the character annotations to token-level BIO labels. Special and padding tokens are ignored during training.

3.3 Model and Training

We fine-tune CAMeLBERT-Mix (Inoue et al., 2021)[1] with a token-classification head. We use this model because the generated answers may combine modern Arabic explanations with classical Qur'anic and Hadith text.

We split the answers into 512-token windows with a stride of 128 tokens. The overlap helps avoid losing citations in long answers before all citations are processed. We use AdamW with a learning rate of 2×10^{-5}, training batch size 8, evaluation batch size 16, and weight decay 0.01. Training is limited to 30 epochs with early stopping after three evaluations without improvement. The random seed is set to 42.

[1] https://huggingface.co/CAMeL-Lab/bert-base-arabic-camelbert-mix

3.4 Span Decoding

During prediction, each token receives a BIO label. We use the stored offset mapping to convert these labels back to character positions. Predictions of the same type are joined when they overlap or touch across two windows.

The task output also requires an annotation ID for each citation. Since the model predicts flat segments, we order them by their starting position and begin a new citation group when the gap from the previous segment is greater than 50 characters. Responses without a predicted citation receive a `NoAnnotation` row.

4 Subtask 2 System

4.1 System Overview

We approach hallucination identification as verification against the provided sources rather than as a general binary classification problem. First, the system normalizes each Arabic fragment, retrieves possible matches from the provided collections, and then applies checks designed for the segment type.

The system consists of several main components:

- Arabic text normalization;
- lexical retrieval for Qur'anic and Hadith text;
- character TF–IDF retrieval for Hadith wording differences;
- memory of known labelled and accepted variants;
- Qur'anic location and Hadith collection checks;
- narrator-chain matching; and
- rules for short, misplaced, or wrongly attributed fragments.

4.2 Arabic Normalization

Arabic text may contain diacritics, tatweel, and different forms of the same letter. These differences can reduce the similarity score even when the text is otherwise the same. We remove diacritics and tatweel, normalize the main alef forms, map alif maqsura to ya, and normalize hamzated waw and ya. We use normalization only for comparison; the original task text and output keys remain unchanged.

4.3 Ayah Verification

The Qur'an index contains individual verses and windows of up to five consecutive verses. These windows are useful when an answer quotes text that crosses a verse boundary.

Candidates are first found using word-based retrieval. They are then compared using character-gram containment, which allows a short quotation to match a longer canonical passage. An Ayah is accepted when the best score reaches 0.970.

The system also checks whether an exact Qur'anic quotation appears at the claimed location. This prevents the system from accepting a correct verse from being accepted when it is linked to a different surah or verse number.

4.4 Hadith Matn Verification

Hadith wording can vary more than Qur'anic text. For this reason, we combine lexical retrieval with character TF–IDF over character grams of length 3 to 7. The lexical matching threshold is 0.840. We may still accept a lower lexical score when its TF–IDF similarity reaches 0.90.

Very short *matn* segments are handled carefully because they may match many unrelated records. A one-token *matn* is rejected. A Qur'anic fragment placed in a Hadith *matn* field is also rejected as an incorrect segment type.

4.5 Claimed-Source Verification

For Qur'anic sources, the system extracts surah names, surah numbers, verse numbers, and verse ranges. It then compares the related Ayah with the canonical text at that exact location.

For Hadith sources, common Arabic names and spelling forms are mapped to the six books included in the task collection. The claimed book is checked against the records retrieved for the related *matn*. A source name alone is not enough; it must agree with the quotation.

4.6 Isnad Verification

We first remove common reporting phrases and honorific expressions from the *isnad*. we use the related *matn* to retrieve possible Hadith records. We then compare the narrator names only with the chain appearing before the Hadith text.

The system accepts the *isnad* when the best narrator-token coverage is at least 0.70. This approach is simple, but it does not handle spelling variations, long chains, or different forms of narrator names well.

Subtask	Metric	Test score
Subtask 1	Character macro-F1	0.9683
Subtask 2	Macro accuracy	0.9050

Table 2: Official blind-test results of the submitted systems.

Segment type	Accuracy (%)
Ayah	97.57
Claimed source	94.93
Matn	91.87
Isnad	77.63
Macro	90.50

Table 3: Subtask 2 accuracy by segment type on the blind test.

5 Results and Analysis

Table 2 reports the official blind-test results. The Subtask 1 system achieved 0.9683 character-level macro-F1. The Subtask 2 system achieved 0.9050 macro accuracy.

The high Subtask 1 score suggests that contextual BIO tagging and offset-based decoding can identify the different citation types with good boundary accuracy. Only the overall test score was provided, so We cannot provide a reliable per-type analysis for this subtask.

Table 3 gives the Subtask 2 results by segment type. Ayah verification achieved the highest accuracy at 97.57%. Claimed-source accuracy was 94.93%, while *matn* accuracy was 91.87%. These results suggest that retrieval from canonical texts works well for quotation and source checking.

The lowest accuracy is 77.63% for *isnad*. Narrator chains are more difficult because names may have different spellings, several narrators may appear in one chain, and the boundary between the chain and the Hadith text is not always clear. This result suggests that future work should use better Arabic name normalization and direct chain alignment.

6 Conclusion

We described Taqwatech's systems for the first two IslamicEval 2026 subtasks. For span detection, CAMeLBERT-Mix was fine-tuned with BIO labels and we converted its token predictions to character offsets. For hallucination identification, we used a source-based system that combined Arabic normalization, lexical retrieval, character TF–IDF, source checks, and narrator matching.

The submitted systems achieved 0.9683 character-level macro-F1 for Subtask 1 and 0.9050 macro accuracy for Subtask 2 on the official blind test. The results are strongest for span detection and Qur'anic verification. Improving the handling of Arabic narrator names and Hadith chains is the main direction for future work.

Limitations

The Qwen span-generation approach could not be evaluated in a directly comparable way and is not presented as a competitive result. The verification thresholds were selected using the released data and may not perform as well on other collections. The Hadith reference data covers six books and cannot confirm every source outside that collection. The *isnad* method uses token overlap and does not explicitly model complete narrator chains or narrator identity. Finally, only the overall Subtask 1 blind-test score is available, so we cannot give a reliable error analysis for each span type.

Ethical Considerations

The system is intended as a verification aid and not as a source of religious rulings. Text matching can find many quotation and source errors, but it cannot determine theological meaning or legal relevance. A false positive could accept fabricated content, while a false negative may reject an authentic wording variant. The predictions should therefore be checked against the retrieved evidence and reviewed by qualified experts when used in practice.

Abstract

Large language models may generate inaccurate Islamic citations when answering religious questions. We present the Namaa Community system for Subtask 2 of IslamicEval 2026, which identifies hallucinations in Qur'anic verses (Ayah), hadith texts (matn), chains of narration (isnad), and claimed sources. We formulate the task as retrieval-grounded verification: citation spans are normalized and matched against the Qur'an and the six major hadith collections using character n-gram retrieval and edit-distance re-ranking. Type-specific verifiers assess Ayah and matn similarity, while claimed sources and isnads are checked against their parent citations. The deterministic pipeline requires no language model or GPU, and every decision is traceable to a canonical record. It achieves a macro accuracy of 0.846 on the development set, 17.9 percentage points above a per-type majority-class baseline, and 0.668 on the official blind test; we trace most of that shortfall to a submission-time configuration error and decompose the remainder by segment type. Our code and submissions are publicly available.[1]

1 Introduction

When large language models answer religious questions they frequently quote scripture—a verse of the Qur'an or a saying of the Prophet (a hadith)—and such quotations are a distinctive locus of hallucination: a model may alter a verse, misattribute a saying, or invent a chain of narrators. Unlike open-domain factuality, the ground truth here is finite and canonical, so faithfulness can be checked exactly. IslamicEval 2026 (Alharbi et al., 2026) formalises this over Arabic responses, continuing the inaugural edition (Mubarak et al., 2025).

Our team entered both subtasks; this paper describes the Subtask 2 system, in which the citation spans are given and the system returns a verdict for each. Every span is one of four types: a quoted verse (Ayah), a hadith body (matn), a chain of narrators (isnad), or a stated attribution (claimed source). Systems are ranked by accuracy computed separately within each type and then macro-averaged over the four (Alharbi et al., 2026), so a rare type weighs exactly as much as a frequent one.

We therefore give each type its own verifier rather than optimising only the two abundant text types: a verse must reproduce its source almost word for word, a hadith body is allowed the variation transmission introduces, and each dependent segment is checked against its parent. Because the evidence is a closed canon, no language model is used to reach a verdict—a transparent match against a named canonical record is cheaper than a neural judgement and, for religious content, easier to defend.

Isnad and claimed source are the two types that depend on a parent text segment, and a verifier that ignores that parent handles both badly. Making them parent-aware raises development macro accuracy from 0.725 to 0.846 (Table 1), since the macro metric gives these two rare types half its weight. The official blind test scores 0.668; we report that figure unchanged, trace most of the shortfall to a submission-time error (Section 4.2), and decompose the remainder by type (Section 4.3).

2 Background

Task setup. For each generated Arabic response, Subtask 2 supplies the citation spans already located by the organisers, together with the type of each. The input is therefore a response paired with a typed span, and the output a binary verdict—correct or incorrect—for every span. Of the four types, Ayah and matn are text segments; isnad and claimed source are structurally dependent, and are scored only when their parent text segment is correct. Otherwise they count as non-applicable and the official

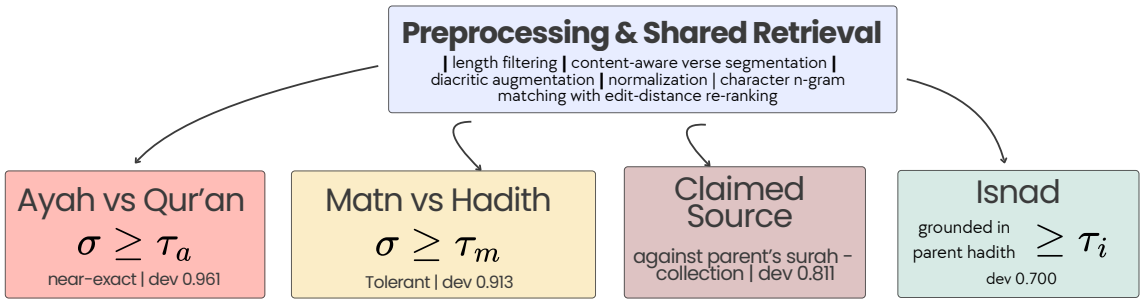

Figure 1: The Namaa Community pipeline. A shared preprocessing and retrieval stage grounds every segment in the canonical corpora; four typed verifiers, one per segment type, produce the verdict. Development accuracy is given beside each verifier (macro 0.846).

scorer drops them.

Data. Verification is grounded against the two corpora the organisers provide, the canonical Qur'an and the six major hadith collections. The Qur'an comprises 6,236 verses and the hadith corpus 34,994 records, of which 31,811 carry a non-empty body; each record also stores its complete narration, chain and body together, which the isnad verifier uses for grounding (Section 3). The development split has 484 responses and 2,728 segments; after non-applicable rows are removed the scored segments number 698 Ayah (222 correct, 476 incorrect), 588 matn (121, 467), 429 claimed source (283, 146) and 30 isnad (16, 14). The text types are predominantly incorrect, the scored attributions predominantly correct, and the isnad is thin yet carries a full quarter of the metric.

Always predicting a type's more frequent label—the *majority-class fallback*, the behaviour any verifier is reduced to without evidence of its own—already reaches macro 0.667, the baseline row of Table 1. Because it is strong on the two skewed text types, the headroom the macro metric leaves lies almost entirely in the structural types. The blind-test split is released with its spans but without labels: 2,173 responses and 10,375 spans (3,539 Ayah, 3,076 matn, 3,295 claimed source, 465 isnad). Its scored supports still depend on the withheld labels, since a dependent segment is scored only when its parent is correct.

Related work. Verifying generated text against evidence is the concern of automated fact verification, from FEVER (Thorne et al., 2018) to reference-free hallucination detectors that score factual precision or self-consistency (Manakul et al., 2023; Min et al., 2023); for Arabic, it has been approached through stance over retrieved evidence (Alhindi et al., 2021). Our setting differs in one respect that shapes the whole design: the claims are exact quotations checked against fixed canonical sources, so verification reduces to grounded matching rather than entailment. The closest precedents are the inaugural IslamicEval systems (Mubarak et al., 2025): TCE (ElKoumy et al., 2025) and HUMAIN (Omayrah et al., 2025) report that Qur'anic quotations must match near word-for-word once diacritics are removed, while hadith bodies require tolerance—an asymmetry we adopt; BurhanAI (Al Adel et al., 2025) verifies through a layered exact-to-semantic index whose cheaper tiers we reuse; and our earlier entry (Emad Eldin, 2025) targeted span detection rather than verification.

3 System Overview

The system runs in two stages (Figure 1). A shared stage grounds each segment in the canonical corpora: it normalises the segment, retrieves candidate records, and scores the best match. A typed stage then applies the verifier belonging to that segment's type, which turns the match into a verdict. Nothing in the pipeline is trained. The only quantities fitted to data are three decision thresholds, and no neural model is evaluated at inference. We submitted a single configuration; the intermediate rows of Table 1 are ablations of it, not alternative submissions.

Preprocessing. Both corpora are prepared identically, so that an undiacritised quotation can align with a vocalised source. Records of extreme length are dropped as a guard on index size. Any remaining text longer than twenty-five sub-word tokens is split into at most two parts at the whitespace nearest its midpoint, so a partially quoted verse can

still match without a word being broken; the token count comes from the AraBERT tokenizer (Antoun et al., 2020), used purely as a length measure (Section 4.1). Every text keeps its vocalised original and gains a diacritic-free copy, and is then expanded into overlapping word windows, so a fragmentary quotation can match a window instead of failing against a whole verse.

A single normaliser is applied to corpus and query alike: it removes diacritics and the elongation mark, unifies the alef, ya, waw-hamza and ta-marbuta variants, and drops non-Arabic characters. Its diacritic ranges are specified by Unicode code point rather than by literal combining marks—a detail that looks cosmetic and is not (Appendix A).

Retrieval. Retrieval supplies candidates; it does not decide any verdict. For each corpus we build a TF-IDF index over word-bounded character n-grams of length three to five (Salton and Buckley, 1988; Pedregosa et al., 2011), since such subword units resist Arabic inflection better than whole words do. A query span is normalised, scored against that index, and the fifteen highest-scoring records are kept as a shortlist.

The shortlist is then re-ranked by two edit-distance measures (Levenshtein, 1966; Bachmann, 2021): a token-set ratio, which compares the texts as sets of words and so ignores word order, and a partial ratio, which aligns the query against the best-matching substring of the candidate. Each candidate takes the higher of the two, and we write $\sigma(x) \in [0, 1]$ for the score of the best candidate for span x. No similarity threshold acts in this stage: every span receives a shortlist, and thresholds enter only in the verifiers below.

Text segments. An Ayah or a matn is judged by comparing σ against a threshold: the verdict is correct when $\sigma(x) \geq \tau_t$ and incorrect otherwise, where $t \in \{a, m\}$ selects the threshold belonging to the type. The two thresholds differ, following the asymmetry noted above. A Qur'anic quotation is expected to reproduce its source almost exactly, so τ_a is set high; a hadith body tolerates the variation that transmission introduces, so τ_m is set lower.

Claimed source. An attribution names a location—a surah and verse number, or a hadith collection—rather than quoting scripture, so searching the corpora for its text is ill-posed. We reuse instead what the parent has already established: for each annotation we retain the record its parent Ayah or matn matched, and ask whether the surah and verse, or the collection, that the attribution names agrees with that record. This verifier applies no similarity threshold, since it compares identifying fields rather than text. It returns incorrect only where it finds a disagreement, and correct otherwise—including where the attribution names nothing it can resolve.

Isnad. An isnad is scored only when its parent matn is correct, and the verifier exploits that precondition: a correct matn has already matched a hadith record, and every record stores its complete narration, chain and body together. The chain to check against is therefore identified by the parent, never retrieved independently. We compute the similarity of the quoted chain to the complete narration of each of the parent's three strongest matches, take the highest, and return correct when it reaches τ_i. This gives the isnad verifier evidence of its own, so it is no longer reduced to the majority-class fallback of Section 2.

4 Experiments

4.1 Experimental Setup

Splits and fitting. The three decision thresholds are the only quantities fitted to data. They are selected on a sample of 1,200 responses from the training split, in two stages. First τ_a and τ_m are swept jointly over a grid and set to the pair that maximises macro accuracy. Then τ_i is swept and set to the value that maximises isnad accuracy, which is the only type it affects. The selected values, $\tau_a = 0.98$, $\tau_m = 0.94$ and $\tau_i = 0.85$, are frozen and applied unchanged to both evaluation splits. The development split is used for ablation and reporting only and never for fitting, so the development figures estimate generalisation rather than fit.

Thresholds and filters. Table 2 in Appendix A collects every threshold, cut-off and filter in the pipeline and marks which are fitted. Only the three verifier decision thresholds are fitted; every other value is fixed in advance. Retrieval applies no similarity threshold at all—it is a candidate generator, cut off by rank ($K = 15$) rather than by score—so a span whose candidates are all poor is not filtered out but passed to its verifier, which judges it incorrect on the low σ. The claimed-source verifier uses no threshold either, since it compares identifying fields rather than text.

Implementation. The pipeline is Python and runs on CPU. Candidate generation uses the scikit-learn TF-IDF vectoriser (Pedregosa et al., 2011) with a word-bounded character-n-gram analyser ($n \in [3, 5]$); re-ranking uses the token-set and partial ratios of RapidFuzz (Bachmann, 2021), normalised to $[0, 1]$. Package versions are pinned in the released environment specification.[2]

How AraBERT is used. AraBERT (Antoun et al., 2020) enters the pipeline at exactly one point, and not as a model: its tokenizer measures the length of a text in sub-word tokens. That measurement drives the two length-based preprocessing rules of Section 3—dropping records of extreme length, and splitting text longer than twenty-five sub-word tokens—and nothing else. No weights are loaded, no embedding is computed, no component is fine-tuned, and AraBERT contributes to no similarity score and no verdict; substituting a whitespace word count would change only how those two rules count. The system runs no neural forward pass at inference, which is why it needs no GPU. The released code does contain an optional AraBERT pair-classifier notebook, but that is exploratory: it is not part of the submitted system and contributes to none of the numbers reported here.

Decoding, post-processing and metric. There is no decoding step: each verdict is a comparison against a fixed threshold or a field-level agreement test, so the system is deterministic once the corpus index is fixed. A verdict is emitted for every segment, including those the scorer discards as non-applicable, so no prediction is ever missing. Every reported figure comes from the organisers' official scorer, which computes accuracy separately within each segment type and macro-averages over the four.

4.2 Results

Table 1 reports the development ablation together with the official blind-test submission. The ablation adds one component at a time. The initial configuration matches the attribution against the corpus as quoted text and leaves the isnad to the majority-class fallback, reaching macro 0.725. Linking the attribution to its parent record instead raises that type from 0.492 to 0.811, and the macro average by 8.0 points. Grounding the isnad in the parent hadith's narration then raises the isnad from 0.533 to 0.700, and the macro by a further 4.2 points, to 0.846, which is 12.2 points above the initial configuration and 17.9 above the fallback baseline. Neither step changes either text type, so the whole improvement is carried by the structural types, which is exactly what the macro metric rewards. Appendix B shows the result is insensitive to the choice of retrieval backend.

Accounting for the development–test gap. The official blind-test macro of 0.668 lies 17.8 points below the development estimate. Two factors contribute, and they differ in how far each can be substantiated.

The first concerns the submission itself: the file scored by the organisers was not generated by the configuration of the last row of Table 1. We record this because it materially qualifies the official figures, while acknowledging that it cannot be confirmed from the released artefacts.

The second is a shift in the test inputs, and unlike the first it is directly measurable without the withheld labels. Applying the final configuration to the released test spans, the proportion it labels *correct* roughly doubles against development: 0.345 to 0.557 for Ayah, 0.241 to 0.440 for matn, and 0.300 to 0.636 for claimed source (Appendix B). Test citations agree with their canonical sources considerably more often than development ones do. Since the thresholds were fitted where citations are predominantly incorrect—on development, 0.318 of scored Ayah and 0.206 of scored matn are correct—they operate at test time at a point they were not calibrated for.

The two factors are complementary rather than alternative, and the claimed source implicates both. Under the shift alone, a verifier that returns correct unless it detects a mismatch should *gain* accuracy on a test set whose citations agree with their sources more often, not fall to 0.340. That the opposite occurred is consistent with the parent linkage having been disrupted in the scored file, though the withheld labels preclude a definitive attribution. We therefore report the official figures unchanged rather than substitute re-scored ones: the gap is not evidence that retrieval-grounded verification fails to transfer, but neither can we settle its cause from what was released.

4.3 Error Analysis

The blind-test profile is uneven rather than uniformly depressed. The Ayah verifier holds at 0.818,

Official blind test					
Submitted system	.818	.622	.340	.895	.668

Table 1: Per-segment-type accuracy and macro average; leading zeros omitted, "c. src" is the claimed source. Upper panel: development, starting from the per-type majority-class fallback, each row then adding one component to the row above. Lower panel: the official score of the submitted file, which did not reflect the last development row's configuration (Section 4.2); its scored per-type supports depend on the withheld labels.

so near-exact Qur'anic matching clearly transfers. The isnad reaches 0.895, above its development value, but we decline to read that as evidence that grounding generalises well: the development estimate rests on thirty scored instances, and while the test split has 465 isnad spans, how many were scored depends on the withheld labels.

The matn falls from 0.913 to 0.622, the decline the input shift of Section 4.2 predicts most directly: one fixed τ_m cannot separate the classes at two operating points. The claimed source is treated there as well.

One property cuts across all four types: the errors are coupled by construction. A single retrieval miss on a parent Ayah or matn propagates to both of its dependent segments, so the structural types can never be more reliable than the text types they hang from—the price of reusing the parent match, paid where the macro metric is most sensitive. Appendix C illustrates both what the structural verifiers buy and one misclassification per type.

5 Conclusion

The Namaa Community system verifies Islamic citations by grounding them in canonical sources rather than by asking a language model to judge them. Every verdict is a comparison against a named canonical record and the pipeline runs on CPU, so the result is auditable in a way a neural judgement is not—for religious content a substantive property, not a convenience. Verifying the two rare structural types against their parent citations, instead of in isolation, carries development macro accuracy from 0.725 to 0.846.

The blind-test score of 0.668 is considerably lower, and we attribute it to a submission error together with a measurable shift in the test inputs (Section 4.2). Both point the same way: thresholds that adapt to the operating point rather than one global τ_m, and an attribution verifier that does not inherit its parent's retrieval errors wholesale.

Limitations

Verification here is lexical. Similarity is character n-gram retrieval refined by edit distance, so a hadith transmitted with different wording but the same meaning falls below τ_m and is judged incorrect. Recognising that kind of paraphrase would need semantic matching, which this pipeline deliberately does not perform, and which would cost the auditability that motivates it.

The thresholds are global and frozen after fitting. Section 4.2 shows test spans agreeing with their sources roughly twice as often as development spans, and one threshold per type cannot serve both operating points; the system neither detects such a shift nor adapts to it.

The two structural verifiers inherit their parent's errors by construction, so a retrieval miss on an Ayah or a matn propagates to its claimed source and its isnad. The claimed-source verifier also returns correct whenever it cannot resolve the reference it is given—when a surah is cited by number rather than by name, for instance—so it under-detects rather than over-detects.

Our isnad evidence is thin: thirty scored development instances, and blind-test labels that were never released, so neither the isnad result nor the corrected configuration can be independently verified (Section 4.3). Coverage is bounded by the two corpora the organisers supply: an attribution to a collection outside the six major books cannot be checked at all. The system is built for Arabic only.

Acknowledgments

We thank the IslamicEval 2026 organisers for the data, the grounding corpora, and the evaluation infrastructure, and the anonymous reviewers for their comments. We also thank Tuwaiq Academy for their support.

A Implementation Details

The retriever indexes character n-grams of length three to five and returns a fifteen-candidate shortlist, which is re-ranked by the higher of a token-set and a partial edit-distance ratio, normalised to $[0, 1]$. The three thresholds, fitted on a 1,200-response training sample, are $\tau_a = 0.98$, $\tau_m = 0.94$ and $\tau_i = 0.85$, and isnad grounding scores the three strongest parent-matn matches. Table 2 lists these values together with every other cut-off in the pipeline, and Table 3 illustrates the preprocessing steps of Section 3; the original text is always retained alongside any derived form.

One implementation detail is invisible on inspection and yet fatal. The normaliser's diacritic ranges must be written numerically, by Unicode code point, and not by typing the Arabic combining marks literally. Literal marks do not render as standalone glyphs, and they can reorder relative to a range delimiter when a file is saved, which silently widens the range to cover the base letters. The normaliser then deletes all Arabic text, and every span fails to match.

Stage	Quantity	Value	Fitted
Preproc.	length filter (chars)	1500	no
Preproc.	split above (tokens)	25	no
Preproc.	window length (words)	5–15	no
Preproc.	window step (words)	3	no
Retrieval	char. n-gram range	3–5	no
Retrieval	shortlist size K	15	no
Retrieval	similarity cut-off	none	—
Ayah	threshold τ_a	0.98	yes
matn	threshold τ_m	0.94	yes
isnad	threshold τ_i	0.85	yes
isnad	parent matches scored	3	no
c. src	threshold	none	—

Table 2: Every threshold, cut-off and filter in the pipeline. Only the three verifier decision thresholds are fitted, on a 1,200-response training sample; all other values are fixed in advance. Retrieval and the claimed-source verifier apply no threshold: retrieval is cut off by rank, and the claimed-source verifier compares identifying fields rather than text.

Transformation	Illustration
Segmentation of over-length verses	a long verse is divided into two parts at the whitespace nearest its midpoint, with no word broken
Diacritic augmentation	the vocalised original is kept and an undiacritised copy added, e.g. الحمد لله رب العالمين alongside its fully marked form
Overlapping windows	a twenty-word body yields windows of five to fifteen words over both the original and normalised forms

Table 3: Preprocessing transformations.

B Component Ablations

Grounding the quoted chain in the parent hadith's complete narration beats the majority-class fallback by nearly seventeen points on development (Table 4). Grounding it in the chain portion alone ties that on development, but is six points weaker on the training sample—and the training sample is the one we selected on, development never having been used for fitting. The similarity itself separates the two classes, averaging 0.84 for correct chains against 0.75 for incorrect ones.

Isnad verifier	Train acc.	Dev acc.
Majority-class fallback	—	0.533
Grounded in chain only	0.663	0.700
Grounded in full narration	0.719	0.700

Table 4: Isnad verification strategies.

Development-to-test input shift. Table 5 reports, for the final configuration, the share of spans of each type that it labels *correct* on development and on the released blind-test spans. The measurement needs no labels, and it shows the two splits presenting the verifiers with materially different inputs.

Segment type	Dev	Test	Spans (dev / test)
Ayah	.345	.557	698 / 3,539
matn	.241	.440	588 / 3,076
isnad	.328	.484	204 / 465
c. src	.300	.636	1,238 / 3,295

Table 5: Share of spans the final configuration labels *correct*, over all spans of each type rather than only the scored ones, on development and on the released blind-test spans. Computed without gold labels; leading zeros omitted.

Table 6 isolates the candidate retriever. Swapping the character n-gram index for word-level TF-IDF or for Okapi BM25, with every other component held fixed, moves macro accuracy by at most 0.005, and BM25 is in fact marginally stronger on both text types. We read this as support for the paper's main claim rather than as a defence of our own choice: candidate retrieval is not the binding constraint here, the typed verifiers are.

Backend	Ayah	matn	c. src	isnad	Macro
char. n-gram (ours)	.961	.913	.811	.700	**.846**
word-level TF-IDF	.961	.912	.823	.667	.841
Okapi BM25	.963	.927	.823	.667	.845

Table 6: Development accuracy with only the retriever swapped; leading zeros omitted. Retriever choice is not what separates configurations; the typed verifiers are.

C Qualitative Examples

Two cases show what the structural verifiers buy. In the first, a hadith body is quoted correctly but attributed to البخاري, while the record it matched belongs to مسلم: the parent-linked verifier catches the collection mismatch and returns incorrect even though the body itself is authentic. In the second, a chain whose similarity to the parent hadith's narration reaches 0.90 clears τ_i, whereas a chain naming transmitters absent from that narration falls below it. Neither distinction is available to a verifier that can only predict the majority class.

Table 7 turns to failures, giving one representative misclassification per segment type with the quoted span, the gold and predicted labels, and the nearest source retrieved. Each illustrates a different limit. The Ayah case differs from its source by one diacritic, which normalisation removes by design, so the verifier cannot see the alteration at all. The matn case quotes only part of a longer record

and falls below τ_m. The isnad case names a single narrator in a span far shorter than the narration it is scored against. The claimed-source case gives the surah numerically rather than by name, so the verifier resolves no surah, detects no mismatch, and returns correct—the default behaviour described in Section 3, here producing the wrong answer.

Type **gold/pred**	**Span / nearest source**
Ayah inc/cor	وَقَالَ رَبُّكُمْ ادْعُونِي أَسْتَجِبْ لَكُمْ وَقَالَ رَبُّكُمُ ادْعُونِي أَسْتَجِبْ لَكُمْ إِنَّ ا...
matn cor/inc	إن الله يرضى لكم ثلاثًا: أن تعبدوه ولا تشركوا به شيئًا... إِنَّ اللَّهَ يَرْضَى لَكُمْ ثَلَاثًا ، وَيَكْرَهُ لَكُمْ...
isnad cor/inc	عن علي رضي الله عنه قال: كُنْتُ رَجُلًا مَذَّاءً ، وَكُنْتُ أَسْتَحْيِي أَنْ أَس...
c. src inc/cor	السورة 3، آية 139 فَإِذَا بَلَغْنَ أَجَلَهُنَّ فَأَمْسِكُوهُنَّ بِمَعْرُو...

Table 7: Development misclassifications, one per type: quoted span (upper) against nearest retrieved source (lower). Labels gold/pred, abbreviated inc/cor; "c. src" is the claimed source.

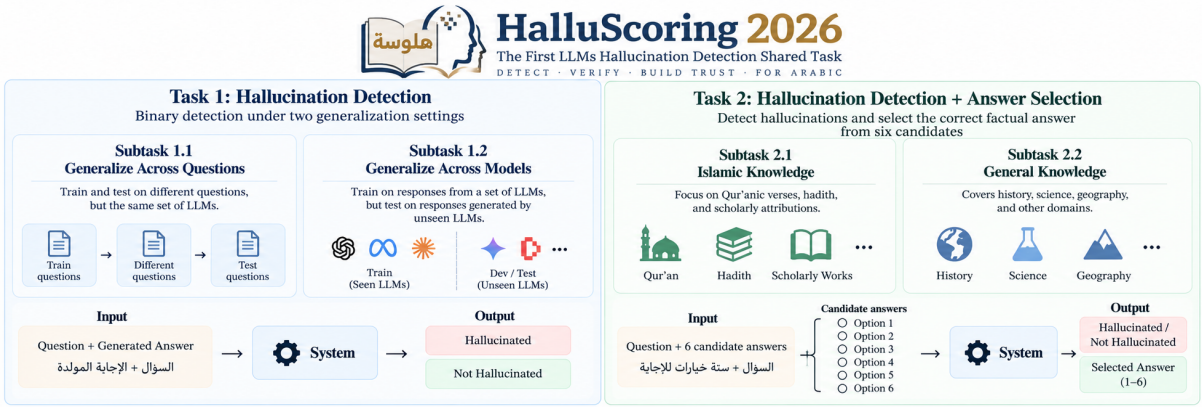

Figure 1: Overview of the *HalluScoring 2026* shared task. Task 1 evaluates binary hallucination detection under two generalization settings: unseen questions (Subtask 1.1) and unseen LLMs (Subtask 1.2). Task 2 extends the evaluation to two stages, first detecting if a generated response is hallucinated and then selecting the correct factual answer from six candidate options, covering Islamic knowledge (Subtask 2.1) and general knowledge (Subtask 2.2).

Abstract

We present *HalluScoring 2026*, a shared task for evaluating hallucination detection and factual verification in Arabic question answering under challenging generalization settings. Its four subtasks are organized into two tasks. Task 1 evaluates binary hallucination detection, considering generalization to unseen questions (Subtask 1.1) and responses generated by unseen LLMs (Subtask 1.2). Task 2 extends the evaluation beyond detection by requiring the systems to additionally identify the correct factual answer from six related candidates, covering Islamic knowledge (Subtask 2.1) and general knowledge (Subtask 2.2). The shared task is based on two Arabic datasets: HalluScore and HalluTruthQA. A total of 13 teams participated in the shared task, ten of which submitted system description papers. The results of Task 1 demonstrate that hallucination detection remains challenging. On the Task 1 test sets, the top-ranked systems achieved AUC-ROC scores of 0.7717 for Subtask 1.1 (REGLAT) and 0.7670 for Subtask 1.2 (NAMAA). Under assisted evaluation, the highest combined detection and answer-selection scores for Subtasks 2.1 and 2.2 were 0.8824 and 0.8565, respectively.

1 Introduction

Large language models (LLMs) are increasingly being used to generate and process Arabic content in a wide range of applications, including question answering (QA), information retrieval, and summarization (Hasanaath et al., 2025; Alzubaidi et al., 2025; Mashabi et al., 2026). Recent Arabic-specific and multilingual LLMs can produce fluent and contextually appropriate Arabic text, supporting their use in both general-purpose and domain-specific applications (Alam et al., 2024; Abdaljalil et al., 2025; Bouchekif et al., 2025). However, fluent responses are not necessarily factually reliable. LLMs may present fabricated, unsupported, or factually incorrect claims as true; we refer to such claims as hallucinations (Maynez et al., 2020; Ji et al., 2023). Such hallucinations may involve entities, dates, numerical values, quotations, source attributions, or supporting explanations (Li et al., 2023; Alansari and Luqman, 2025; Bouchekif et al., 2026).

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1106–1119
October 28-29, 2026 ©2026 Association for Computational Linguistics

Hallucinations may arise from incomplete or noisy training data, limited coverage of domain-specific knowledge, ambiguous prompts, or insufficient contextual grounding. They may also be influenced by LLMs' next-token prediction objective, which optimizes for likely continuations without explicitly verifying the factual correctness of each generated claim (Huang et al., 2025; Alansari and Luqman, 2026b). This challenge is particularly relevant to Arabic, where high-quality, diverse, and domain-specific evaluation resources remain comparatively limited.

The evaluation of hallucinations in Arabic remains underexplored, particularly with respect to generalization beyond the conditions observed during training. A detector that performs well on questions similar to those observed during training may not generalize to new questions (Alansari et al., 2026). Likewise, a system trained on responses generated by a fixed set of LLMs may capture generator-specific characteristics rather than general hallucination signals, potentially limiting its ability to generalize to responses produced by unseen models (Wu et al., 2025). Moreover, correctly detecting a hallucination does not necessarily imply that a system can identify the correct factual information (Bouchekif et al., 2026). These challenges motivate the evaluation of both the robustness of hallucination detection and the ability to identify the correct answer.

To address these challenges, we present *HalluScoring 2026*, a shared task on hallucination detection and factual verification in Arabic QA. As shown in Figure 1, the shared task aims to evaluate the robustness of hallucination detection under two complementary generalization settings: Task 1 evaluates binary hallucination detection on unseen questions (Subtask 1.1) and on responses from unseen LLMs to unseen questions (Subtask 1.2). Task 2 requires systems to detect hallucinations and select the correct answer from six candidates. Subtask 2.1 focuses on Islamic knowledge, while Subtask 2.2 covers broader domains, including history, science, and geography. The shared task is based on two carefully annotated Arabic resources, *HalluScore* (Alansari and Luqman, 2026a) and *HalluTruthQA* (Bouchekif et al., 2026; Bekhouche et al., 2026), enabling evaluation across multiple domains and model generators using expert-verified factual information. We also provide a comparative evaluation of participating systems, highlighting methodological approaches, performance trends, and remaining challenges across different evaluation settings.

2 Literature Review

Hallucination in LLMs has motivated several shared tasks aimed at developing standardized evaluation settings for hallucination detection. SemEval-2024 Task 6, *SHROOM* (Mickus et al., 2024), focused on detecting fluent but semantically incorrect outputs in machine translation, paraphrase generation, and definition modeling, considering both model-aware and model-agnostic settings. Its multilingual successor, SemEval-2025 Task 3, *Mu-SHROOM* (Vázquez et al., 2025), extended this work to 14 languages, including Arabic, and evaluated the localization of hallucinated spans in LLM outputs. These shared tasks established standardized settings for evaluating hallucination detection in language and generation tasks.

Arabic research on hallucination has also progressed through both shared tasks and dedicated datasets. The *Halwasa* shared task (Mubarak et al., 2024) addressed hallucination detection in Arabic LLM-generated content, building on a dataset of 10,000 Arabic sentences annotated for factual and linguistic correctness. *IslamicEval 2025* (Mubarak et al., 2025) subsequently targeted hallucinations within the specialized domain of Islamic content, including the detection and correction of hallucinated Qur'anic verses and Hadiths grounded in authoritative sources. Beyond shared tasks, *AraHalluEval* (Alansari and Luqman, 2025) introduced fine-grained hallucination annotations for Arabic generative QA and summarization, distinguishing different factuality and faithfulness errors.

Positioning of HalluScoring 2026. *HalluScoring 2026* extends Arabic hallucination shared tasks by evaluating both the robustness of hallucination detection and the ability to recover correct factual information. Building on *HalluScore* (Alansari and Luqman, 2026a) and *HalluTruthQA* (Bouchekif et al., 2026; Bekhouche et al., 2026), the shared task evaluates generalization to unseen questions and LLMs, as well as joint hallucination detection and correct-answer selection. Moreover, the evaluation covers both Islamic and general-knowledge domains, with the latter spanning areas such as history, science, and geography. Reliable hallucination detection is particularly important in these settings because factually incorrect responses can misrepresent religious teachings, historical events,

scientific facts, or geographical information, potentially misleading users who rely on LLMs as sources of information.

3 HalluScoring 2026

3.1 Task 1: Hallucination Detection

The goal of Task 1 is to detect hallucinations in Arabic QA in diverse domains. Given a question and one or more model-generated responses, the objective is to automatically determine whether each response contains hallucinated content. The questions span multiple domains and topics, exposing models to different types of knowledge and varying levels of factual specificity, which can make generated responses particularly prone to hallucination. To encourage the development of robust detection methods that generalize across different questions and LLMs, the shared task is organized into two complementary subtasks.

Subtask 1.1: Generalize Across Questions In this subtask, participants are required to develop hallucination detection systems that can generalize across different questions. The training and test splits are constructed such that all models appear in both sets, but the questions are disjoint. Each instance consists of a question and a generated response, in which the system must predict whether the response is hallucinated or non-hallucinated.

Subtask 1.2: Generalize Across Models This subtask evaluates the ability of the proposed hallucination detection techniques to generalize across unseen models. The dataset is split such that the training set contains responses generated by one subset of LLMs, while the test set contains responses from different LLMs that are entirely unseen during training. The questions are also partitioned between the training and test sets to evaluate generalization across both models and questions. The goal remains to classify hallucinated versus non-hallucinated outputs. This setting is particularly challenging, as it requires learning model-invariant hallucination signals that transfer across different architectures.

3.2 Task 2: From Hallucination Detection to Truth

The goal of Task 2 is to evaluate whether a system can both detect hallucinations and identify the correct information. Given an Arabic question and a generated answer, the system must first determine whether the answer contains a hallucination. Then, the correct answer must be selected from six candidate options, including a correct answer and five plausible distractors. The candidate options are designed to be close to one another, making it more challenging to distinguish correct from incorrect answers. Task 2 consists of two subtasks.

Subtask 2.1: Islamic Knowledge. This subtask focuses on Islamic knowledge. The questions cover topics such as Prophetic biography, Islamic law, religious concepts, and source-sensitive information, including Qur'anic verses, Hadith, scholarly opinions, and source attributions. This domain is particularly challenging for hallucination detection because a generated answer may provide the correct main answer while still containing incorrect details, such as a verse number, a quotation, an attribution, or a supporting statement.

Subtask 2.2: General Culture. This subtask focuses on general knowledge across a wide range of topics, including history, geography, science, culture, and Islamic knowledge. It evaluates the system's ability to detect factual errors and identify the correct answer across diverse domains. The questions may contain plausible but incorrect information, including errors in dates, entities, locations, events, names, numerical facts, or other factual details, requiring the system to carefully distinguish between accurate and misleading information. Subtask 2.1 focuses on Islamic knowledge, while Subtask 2.2 extends the evaluation to three additional domains: history, science, and geography.

3.3 Task Setup

HalluScoring 2026 was organized by hosting four separate CodaBench competitions, one for each subtask. This separation allowed each task to have its own data format, submission pipeline, and evaluation procedure. The training and development sets for all tasks were released in 16th May 2026. For Task 1, the training and development data were provided in `Excel` format, whereas for Task 2, they were provided in `JSON` format. Appendix B illustrates some samples given to the participants.

Participants used these released splits to develop and validate their systems before submission. To preserve the integrity of the final evaluation, we did not publicly release the test sets to participants. Instead, we provided a Jupyter Notebook template that specified the required procedures for model loading, inference, and output. Participants were asked to implement their systems using this template and submit the completed notebook to the

organizers. The organizers executed the submitted notebooks on the hidden test sets.

3.4 Shared Task Restrictions

To ensure a fair and controlled evaluation setting, we provided clear restrictions on participating systems via the CodaBench platform. All submissions were required to be based on a fine-tuned generative language model whose base model is open-source or openly available for research use. We restricted submitted models to a maximum of 13 billion parameters to maintain comparable computational settings between participants. During evaluation, participants were not allowed to use retrieval-augmented generation (RAG), external search tools, or other retrieval-based systems. This restriction was introduced to ensure that performance primarily reflects the capabilities of the submitted model rather than its access to external information during inference. However, participants were allowed to use external datasets for model fine-tuning and were requested to disclose any external datasets. These constraints were designed to provide a standardized evaluation setting while still allowing teams flexibility in model selection, training data, and fine-tuning strategies.

4 Datasets and Evaluation Metrics

4.1 HalluScore Dataset

The *HalluScore* (Alansari and Luqman, 2026a) dataset is proposed for the evaluation, detection, and mitigation of Arabic hallucination in LLMs. It is a structured Arabic QA benchmark comprising 827 carefully curated QA pairs across multiple domains, including health, science, finance, religion, and geography. The dataset is constructed through a rigorous pipeline involving quality assurance, filtering for clarity and factual validity, and model-driven selection to retain questions that consistently trigger hallucinations. For each question, responses were generated by 17 Arabic, multilingual, and reasoning LLMs and manually annotated as either hallucinated or non-hallucinated, resulting in a total of 14,059 annotated QA-response instances. For the shared task, only the information required for the corresponding prediction tasks was provided to participants, while the additional annotations and metadata available in the original *HalluScore* benchmark were not included as prediction targets. The test sets and their corresponding labels were kept hidden from participants and were used exclusively by the organizers for the final evaluation. The annotation guidelines are provided in Appendix A.1.

4.2 HalluTruthQA Dataset

HalluTruthQA (Bekhouche et al., 2026) contains 4,000 Arabic question–answering instances covering four domains: Islamic knowledge, history, science, and geography. The corpus is balanced, with 1,000 instances per domain. Each instance includes a question, a model-generated answer, an expert-verified reference answer, a binary hallucination label, and six candidate answers consisting of one correct answer and five plausible distractors. The candidate answers were manually constructed to be semantically related and stylistically similar, reducing the possibility of identifying the correct answer through superficial cues. The model-generated answers were produced using `QCRI/Fanar-1-9B-Instruct` (Team et al., 2025) with a maximum of 1,024 new tokens, a temperature of 0.0, top-p set to 1.0, and a batch size of 4, using `bfloat16` precision.[1]

Beyond the HalluScoring task's objectives of binary hallucination detection and correct-option selection, the original HalluTruthQA corpus provides richer fine-grained annotations. In particular, hallucinated responses include character-level erroneous spans and human-written explanations describing why each span is incorrect. This supports error localization, explanation, and fine-grained analysis beyond the official shared-task objectives. The annotation guidelines are provided in Appendix A.2.

4.3 Data Splits

The numbers of LLMs, questions, and instances in the train, development, and test sets are reported in Table 1. Subtask 1.1 and 1.2 combine *HalluScore* and *HalluTruthQA* to increase the number and diversity of instances available for training and evaluation. Subtask 2.1 uses the Islamic-knowledge subset of *HalluTruthQA*, whereas Subtask 2.2 uses the full mixed-domain dataset, covering Islamic knowledge, history, science, and geography.

4.4 Evaluation Metrics

For Task 1, we evaluate the submitted hallucination detection systems using two widely adopted metrics: area under the receiver operating characteristic curve (AUC-ROC) and macro F1-score,

[1] Experiments were run on an NVIDIA RTX 5880 Ada GPU with 48 GB of memory.

Subtask	Dataset	# LLMs			# Questions			# Instances		
		Train	Dev.	Test	Train	Dev.	Test	Train	Dev.	Test
Subtask 1.1 Across Questions	HalluScore HalluTruthQA	5	5	5	2,221	900	206	4,705	1,300	1,030
Subtask 1.2 Across Models	HalluScore HalluTruthQA	5	2	2	2,221	100	206	4,705	200	412
Subtask 2.1 Islamic Knowledge	HalluTruthQA	1	1	1	400	400	200	400	400	200
Subtask 2.2 General Culture	HalluTruthQA	1	1	1	1,600	800	1,600	1,600	800	1,600

Table 1: Dataset statistics for the four subtasks of HalluScoring 2026. For the HalluScore dataset, train set responses are generated by five models: GPT-o3, ALLaM, DeepSeek-V3, Fanar, and Claude Sonnet, whereas for HalluTruthQA, the responses are generated by Fanar.

allowing a robust assessment of performance, particularly in the presence of class imbalance.

For Task 2, evaluation is performed in two steps. First, hallucination detection is evaluated using the macro F1-score, $F1_{\text{macro}}$. Second, the system selects the correct option among six candidates (A–F). An instance is counted as correct for answer selection only if both the hallucination label and the selected option are correct; otherwise, it receives a score of zero.

Let N_{both} denote the number of instances with correct hallucination detection and option selection, and N the total number of test instances. The answer-selection accuracy is $\text{AnswerAcc} = \frac{N_{\text{both}}}{N}$. The final score gives equal weight to hallucination detection and answer selection:

$$\text{Score}_{\text{Task2}} = 0.5\, F1_{\text{macro}} + 0.5\, \text{AnswerAcc}.$$

We consider two evaluation settings, *blind* and *assisted*, which differ in the information available during the hallucination detection stage. In the *blind* setting, the system receives only the question and the generated answer when predicting whether the response is hallucinated. In the *assisted* setting, the six candidate answers, which consist of one correct option and five plausible distractors, are additionally provided during this prediction. In both settings, the candidate answers are available for the subsequent answer-selection stage.

5 Shared Task Teams & Results

In total, *HalluScoring 2026* received submissions from **13 teams**, of which **10 teams** submitted system description papers. Of the participating teams, **5** participated exclusively in Task 1, **6** exclusively in Task 2, and **2** participated in both tasks.

5.1 Selected Participating Teams

Table 2 provides an overview of the systems submitted for each subtask and summarizes the approaches adopted by the participating teams. In this section, we discuss some selected participating teams in more detail to highlight their methodological approaches in the different subtasks.

Anhnamxtanh proposed counterfactual cross-check recognition (C3R), based on a QLoRA-adapted ALLaM-7B model. C3R uses two complementary roles: a TRUTH role that identifies the factually correct option and a MATCH role that selects the option best matching the response. A response is classified as non-hallucinated when the two roles agree and hallucinated otherwise. The approach also employs counterfactual training examples, option-order permutations, and constrained likelihood scoring to improve robustness.

AyahVerse fine-tuned CamelBERT for binary hallucination detection using the final-layer [CLS] representation, while post-submission experiments explored intermediate-layer representations and domain-category embeddings to improve generalization. For *Task 2.1* and *Task 2.2*, they adopted a separate detection-and-verification pipeline, using CamelBERT for hallucination detection and a QLoRA-tuned AceGPT-v2-8B-Chat to select the correct answer by directly comparing the logits of the six candidate options.

Hashtag AI proposed a QLoRA-adapted Gemma 4 12B system for hallucination detection and answer selection. Their approach uses a knowledge-graph retrieval system as an offline teacher to identify difficult facts and construct contrastive training examples, which are then distilled into the model during fine-tuning. The submitted system uses neither retrieval nor external knowledge at inference

Team	Subtask	Description
Anhnamxtanh (Nguyen and Takahashi, 2026)	All	QLoRA-adapted ALLaM-7B with counterfactual cross-check recognition (C3R), using complementary TRUTH and MATCH roles, counterfactual training, option permutations, and constrained likelihood scoring.
AyahVerse (Rashid, 2026)	1.1, 1.2, 2.2	CAMeLBERT-based hallucination detection for Tasks 1.1–1.2 and a detection–verification pipeline combining CAMeLBERT with QLoRA-tuned AceGPT-v2-8B-Chat for Tasks 2.1–2.2.
DzairVerse (Chenini and Belhadef, 2026)	2.1	QLoRA-tuned Fanar-1-9B-Instruct with a leak-free two-stage pipeline: blind hallucination detection followed by candidate-based answer selection using separate prompts.
Hashtag AI (Chaudhuri et al., 2026)	2.1, 2.2	QLoRA-adapted Gemma 4 12B with offline knowledge-graph teacher distillation and contrastive training examples, followed by hallucination detection and candidate answer selection.
HelsinkiTeam (Bounab et al., 2026)	2.2	LoRA-adapted ALLaM-7B-Instruct trained with approximately $30K$ augmented domain-specific and synthetic examples for joint hallucination detection and answer selection.
ShadowDz (Kraimia and Eutamene, 2026)	2.1	LoRA-tuned Fanar-1-9B-Instruct using blind hallucination detection followed by a separate candidate-selection stage conditioned on the predicted hallucination label.
NAMAA (Albalhy et al., 2026)	1.1, 1.2	CAMeLBERT cross-encoder for reference-free hallucination detection, with additional experiments on knowledge distillation, contrastive learning, ensembling, calibration, and uncertainty estimation.
REGLAT (Ashraf et al., 2026)	1.1, 1.2	Soft-voting ensemble of MARBERTv2, CAMeLBERT-Mix, and ARBERT classifiers trained with Focal Loss on question–answer pairs.
Scalar_NITK (R and Madasamy, 2026)	1.1, 1.2	Teacher–student knowledge-distillation framework combining an encoder ensemble and external linguistic features into a QLoRA-tuned Qwen2.5-3B-Instruct student.
Vescera (Sellam et al., 2026)	2.2	LoRA-adapted ALLaM-7B with privileged-information distillation, hidden-representation alignment, prompt paraphrasing, and option permutation for blind inference.

Table 2: Overview of the approaches adopted by teams that submitted system description papers to HalluScoring 2026.

time. The system first predicts the hallucination label and then uses a second prompt with the six candidate answers to select the correct option.

NAMAA proposed a CAMeLBERT cross-encoder that jointly encodes the question and generated answer and uses the hallucinated-class softmax probability as the prediction score. The team also investigated reference-aware modeling, knowledge distillation, LoRA-InfoNCE contrastive learning, model ensembling, temperature scaling, and MC-Dropout uncertainty estimation to analyze cross-question and distributional generalization, calibration, and selective prediction.

REGLAT proposed an ensemble of three Arabic pretrained encoders: MARBERTv2, CAMeLBERT-Mix, and ARBERT. Each model was independently fine-tuned as a binary classifier using the question and generated answer as input, with Focal Loss to emphasize difficult examples. The final system combines the three models' hallucination probabilities through unweighted soft voting, with each encoder contributing equally to the final prediction.

5.2 Results and Discussion

In this section, we present and discuss results for all subtasks. Appendix C provides the baseline results, while Appendix D presents a detailed methodological analysis of the submitted systems.

5.2.1 Track 1 Results

subtask 1.1 Table 3 presents the results for subtask 1.1, where systems are evaluated on their ability to generalize to unseen questions. *REGLAT* achieved the best overall performance according to the primary ranking metric, obtaining a test AUC-ROC of 77.17. It was followed closely by the *AR-BERT baseline* (76.39), *AyahVerse* (76.30), and *NAMAA* (75.96), indicating a relatively narrow performance gap among the highest-ranked systems. In contrast, the remaining submissions achieved test AUC-ROC scores ranging from 74.61 to 59.03.

A notable observation is the substantial discrepancy between development and test performance. For example, *REGLAT* decreased from 94.13 AUC-ROC on the development set to 77.17 on the test set, while *Sense* decreased from 94.16 to 74.61. A similar pattern is observed for the baselines, including *CAMeLBERT*, which decreased from 92.20

		Development		Test	
Rank	**Team**	**AUC-ROC**	**F1-Macro**	**AUC-ROC**	**F1-Macro**
1	REGLAT	94.13	**87.04**	**77.17**	**65.76**
2	Baseline_ARBERT	92.05	85.07	76.39	62.54
3	AyahVerse	92.17	86.01	76.30	64.01
4	NAMAA	92.63	85.95	75.96	64.44
5	Baseline_MARBERT	91.44	83.75	74.66	62.48
6	Sense	**94.16**	86.95	74.61	62.43
7	Baseline_CAMeLBERT	92.20	85.67	74.59	65.70
8	Baseline_mBERT	91.14	83.57	70.14	60.84
9	Anhnamxtanh	79.42	73.32	66.01	59.41
10	Scalar_NITK	81.48	78.35	64.92	62.98
11	RaghadAlrasheed	80.74	70.45	59.03	50.36

Table 3: Results for subtask 1.1 (Generalize Across Questions) on the development and test sets. Baseline systems are shown in blue.

		Development		Test	
Rank	**Team**	**AUC-ROC**	**F1-Macro**	**AUC-ROC**	**F1-Macro**
1	NAMAA	75.80	66.11	**76.70**	66.34
2	REGLAT	79.21	69.34	74.50	65.07
3	Baseline_MARBERT	79.64	69.34	73.92	65.24
4	AyahVerse	74.92	63.24	72.99	61.35
5	Baseline_ARBERT	79.27	68.53	72.08	62.81
6	Sense	**83.25**	**71.52**	71.96	48.34
7	Baseline_CAMeLBERT	76.09	66.77	70.08	62.00
8	Baseline_mBERT	73.65	62.38	68.70	59.26
9	Scalar_NITK	60.86	64.38	67.97	**67.21**
10	Anhnamxtanh	64.64	59.48	62.29	58.49
11	RaghadAlrasheed	51.66	50.96	49.07	43.05

Table 4: Results for subtask 1.2 (Generalize Across Models) on the development and test sets.

to 74.59. Importantly, this decline should be interpreted in light of the different dataset compositions of the two splits. The development set combines instances from both *HalluTruthQA* and *HalluScore*, whereas the test set consists exclusively of *HalluScore*. Unlike conventional QA collections, *HalluScore* is specifically constructed around hallucination-prone questions designed to elicit unsupported or unreliable responses from LLMs. Consequently, the test set represents a more challenging distribution in which systems must distinguish hallucinations among questions intentionally designed to expose model weaknesses. The development–test gap therefore reflects not only generalization to unseen questions, but also robustness to a shift toward a more challenging hallucination-oriented question distribution. These findings suggest that models achieving high performance on the mixed development distribution may rely on patterns that transfer less effectively to systematically hallucination-prone questions.

Subtask 1.2 evaluates a different form of robustness: whether a hallucination detector can generalize to answers generated by unseen LLMs. As shown in Table 4, *NAMAA* achieved the highest test AUC-ROC of 76.70, outperforming *REGLAT* (74.50) and the strongest baseline, *MARBERT* (73.92). *NAMAA* therefore improved on the best baseline by 2.78 AUC-ROC points, representing a clearer improvement on the provided baselines than observed in subtask 1.1. *AyahVerse* also remained competitive, achieving 72.99 AUC-ROC, while *Sense* obtained 71.96 despite achieving the strongest development performance on AUC-ROC (83.25). The results of subtask 1.2 again reveal a pronounced development–test discrepancy. *Sense* provides the clearest example: despite ranking first on both development metrics, its test AUC-ROC dropped by 11.29 points to 71.96. *REGLAT* similarly decreased from 79.21 to 74.50, while the *MARBERT* baseline decreased from 79.64 to 73.92. In contrast, *NAMAA* showed an unusual degree of robustness, with its AUC-ROC increasing slightly from 75.80 on development to 76.70 on test. This suggests that *NAMAA* learned representations or decision criteria that transferred more effectively

across model-generated outputs. More broadly, the variation across systems indicates that hallucination detectors can be sensitive to the characteristics of the LLMs used to generate their training data, reinforcing the importance of explicitly evaluating cross-model transfer rather than assuming that a detector trained on one set of generators will generalize to unseen ones.

5.2.2 Track 2 Results

Table 5 reports the official results for Task 2. As described in Appendix C, the systems are evaluated under two settings: with access to the candidate options (**assisted**) and without access to them (**blind**). Overall, most systems perform better in the assisted setting. In this setting, the model receives not only the question and generated answer, but also six candidate answers consisting of one correct option and five closely related plausible distractors. These candidates provide additional factual alternatives that may lead the model to revise its hallucination judgment, particularly when the generated response is plausible but contains a specific factual error. In contrast, the blind setting requires hallucination classification based solely on the question and the generated answer. Excluding the baseline, the mean assisted score is approximately 5.99% higher than the mean blind score in Subtask 2.1 and 15.12% higher in Subtask 2.2.

For **subtask 2.1** *(Islamic Knowledge)*, *Anhnamxtanh* achieved the best performance in both settings, scoring 0.8824 under assisted evaluation and 0.8593 under blind evaluation. The system uses a QLoRA-adapted *ALLaM-7B* model with a cross-check verification strategy. The narrow gap of 0.0231 indicates that its performance remains stable without candidate information during hallucination detection. *Hashtag AI* reached 0.8124 in the assisted setting and a slightly higher 0.8262 in the blind setting, making it the only system for which candidate access did not improve the score. Its *Gemma 4 12B* model was trained with contrastive examples derived from an offline knowledge-based teacher, which may contribute to its strong blind performance. *DzairVerse* also showed relatively stable results, with scores of 0.7881 and 0.7582, respectively. Its *Fanar-1-9B-Instruct* system explicitly separates hallucination detection from answer selection, which is consistent with the limited degradation observed in the blind setting.

For **subtask 2.2** *(General Culture)*, *Anhnamxtanh* again ranked first, obtaining 0.8565 in the assisted setting and 0.8348 in the blind setting. The small gap of 0.0217 follows the same pattern as in subtask 2.1 and indicates stable performance across both evaluation settings and domains. In contrast, the remaining systems show larger assisted–blind gaps. *AyahVerse* obtained 0.7762 and 0.6331, respectively. The latter combines *CamelBERT* for hallucination detection with *AceGPT-v2-8B-Chat* for answer selection. *Vescera*, based on *ALLaM-7B* with privileged-information distillation, obtained 0.7224 in the assisted setting and 0.6256 in the blind setting. These larger gaps indicate that candidate information provides a stronger signal for these systems during factual verification.

Overall, the two settings capture complementary aspects of factual verification. Assisted evaluation measures the benefit of candidate information, while blind evaluation provides a stricter assessment of hallucination detection. The results show that candidate answers improve detection, though some systems remain stable without them, highlighting the challenge of jointly detecting hallucinations and recovering correct factual information.

6 Conclusion

We presented *HalluScoring 2026*, a shared task for evaluating hallucination detection and factual verification in Arabic QA across unseen questions, unseen LLMs, and different knowledge domains. The results demonstrate that generalization remains challenging, with several systems showing substantial performance drops under distribution shifts,

while Task 2 further highlights the distinction between detecting hallucinations and identifying the correct factual information. Overall, the findings emphasize the need for Arabic hallucination detection systems that are robust across questions and model generators and that can move beyond detection toward reliable factual verification.

Limitations & Ethical Considerations

HalluScoring 2026 has several limitations. The shared task focuses on Arabic QA and therefore does not directly assess whether the observed findings generalize to other languages or generation tasks. Moreover, the datasets cover a finite set of domains, questions, and LLM-generated responses, and performance may vary for unseen domains, model families, or future LLMs. The shared-task restrictions excluded retrieval-augmented generation and external search during inference. In Task 2, systems nevertheless received candidate answers during answer selection in both settings and during hallucination detection in the assisted setting.

From an ethical perspective, hallucination detection systems should not be interpreted as guaranteeing the factual correctness of LLM-generated content. This is particularly important in sensitive domains, including the religious content represented in the Islamic knowledge subtask, where incorrect quotations, attributions, or interpretations may have significant consequences. We therefore encourage the use of such systems as supporting tools rather than replacements for appropriate human or domain-expert verification.

Appendix

A Annotation Guidelines

A.1 HalluScoring Annotation Guidelines

The LLM responses were manually annotated by two annotators following a predefined hallucination annotation protocol. The annotation distinguished hallucinations from general errors. For instance, an unsupported or fabricated real-world claim presented as factual was considered a hallucination, whereas an incorrect response accompanied by uncertainty, hesitation, or an explicit indication of insufficient knowledge (e.g., "I don't know") was treated as an error rather than a hallucination. The annotations were performed against the verified ground-truth answers and supporting evidence provided in *HalluScore*. Inter-annotator agreement (IAA) was measured using Cohen's κ separately for each evaluated LLM's responses. The agreement was consistently high, ranging from $\kappa = 0.9400$ to $\kappa = 0.9768$ across the 17 models, corresponding to almost perfect agreement and demonstrating the high reliability of the human annotations.

A.2 HalluTruthQA Annotation Guidelines

The annotation process was conducted in two stages. First, four domain experts, one for each domain, verified the questions and reference answers and constructed and validated the candidate answers and corresponding answer keys. In a second stage, two trained research assistants independently reviewed the questions, reference answers, candidate options, and answer keys. Any unclear or disputed instance was returned to the corresponding domain expert for final adjudication, providing an additional quality-control step before the final dataset release. Inter-annotator agreement was high across all annotation dimensions, with Cohen's κ values of 0.92 for the binary hallucination label, 0.86 for macro-level hallucination types, and 0.80 for micro-level hallucination types.

A response was labeled as *hallucinated* if it contained at least one factually incorrect, fabricated, unsupported, misleading, or contextually inconsistent claim. Annotators evaluated the complete generated response rather than considering only its main conclusion. Therefore, an answer could be labeled as hallucinated even when its main conclusion was correct, but its supporting evidence, numerical value, date, quotation, citation,

Field	Value
Question	في أي سنة تخرج نزار قباني من جامعة القاهرة؟ *Gloss:* In which year did Nizār Qabbānī graduate from Cairo University?
Gold Answer	تخرج من جامعة دمشق عام ١٩٤٥ *Gloss:* He graduated from the University of Damascus.
Generator model	`Allam`
Generated Answer	في عام ١٩٤٥. *Gloss:* In the year 1945.
Label	**1** (hallucinated)

Table 6: Representative annotated data sample provided to participants in Track 1 (subtasks 1.1 and 1.2). Systems receive the question, the gold answer, the generator model, and the generated answer, and must predict the binary hallucination Label (1 = hallucinated, 0 = not hallucinated).

or source attribution was incorrect. A response was considered *non-hallucinated* when all factual claims relevant to the question were correct and adequately supported.

B Data Samples

To illustrate the data released to participants, Tables 6 and 7 present representative annotated examples from Track 1 and Track 2, respectively. Each Arabic field is shown together with an English gloss. The Track 1 sample follows the question–answer format used in subtasks 1.1 and 1.2, where systems predict a binary hallucination label for a generated answer. The Track 2 sample follows the format used in subtasks 2.1 and 2.2, which additionally provides a set of candidate answers with an answer key and, for hallucinated responses, span-level annotations with explanations.

C Baseline Models

Task 1. We provided the participants with baseline results established using four pretrained language models: CAMeLBERT, ARBERT, MARBERT, and multilingual BERT (mBERT). Each model was fine-tuned on the training split and evaluated on the development set and the held-out test set. Moreover, we released the corresponding baseline code as a starter toolkit to facilitate system development and provide participants with a reproducible implementation for data loading, model fine-tuning, inference, and submission generation.

For both subtasks 1.1 and 1.2, the question and generated answer were jointly provided to the classifier as a sentence pair, following the input format `[CLS] question [SEP] model_answer [SEP]`. The input sequences were truncated to a maximum length of 512 tokens. All baseline models were fine-tuned using a batch size of 16, a learning rate of 2×10^{-5}, a linear warmup ratio of 0.1, and a weight decay of 0.01. Training was performed for up to 5 epochs, with early stopping if the development AUC-ROC did not improve for 3 consecutive epochs. For each model, the checkpoint achieving the highest development AUC-ROC was retained for evaluation on the test set.

Among the four baseline systems, as shown in Table 3, ARBERT achieved the highest test AUC-ROC of 76.39, followed by MARBERT at 74.66, CAMeLBERT at 74.59, and mBERT at 70.14 in subtask 1.1. On the other hand, MARBERT served as the strongest baseline for Task 1.2 according to both evaluation metrics. The reduction in performance relative to the development results also highlights the difficulty of generalizing hallucination detectors to outputs produced by unseen language models.

Task 2. We use the same model and generation configuration as those used to produce the `generated_answer` field (see Section 4.2), but with a different prompt and a reduced maximum generation length from 1,024 to 256 new tokens.

Baseline prediction follows a two-stage process. In the first stage, the model predicts whether the generated answer is hallucinated or not. In the *blind setting*, the model receives only the question and the generated answer. In the *assisted setting*, the six candidate answers are also provided during hallucination detection.

This baseline evaluates Fanar's ability to detect errors in its own generated answers and the benefit of providing candidate answers for self-verification.

D Methodological Analysis

D.1 Task 1 Systems

Table 8 summarizes the main methodological choices adopted by participating teams in subtasks 1.1 and 1.2. A clear trend is the dominance of **encoder-based architectures**, which are provided in the starter toolkit. Five of the six teams employed encoder models, while decoder-based

Field	Value
Question	ماذا يطلق على اليوم العاشر من ذي الحجة؟ *Gloss:* What is the tenth day of Dhū al-Ḥijja called?
Gold Answer	يوم النحر *Gloss:* The Day of Sacrifice (*Yawm al-Naḥr*).
Options	A: اليوم العاشر من ذي الحجة يطلق عليه يوم عرفة. B: اليوم العاشر من ذي الحجة يطلق عليه يوم التروية. C: اليوم العاشر من ذي الحجة يطلق عليه يوم الجمعة. D: اليوم العاشر من ذي الحجة يطلق عليه يوم الفطر. E: اليوم العاشر من ذي الحجة يطلق عليه يوم النحر. F: اليوم العاشر من ذي الحجة يطلق عليه يوم عاشوراء.
Answer	**E**
Generator model	`QCRI/Fanar-1-9B-Instruct`
Generated Answer	يوم عرفة *Gloss:* The Day of Ārafa.
Label	**hallucination**
Hallucination annotations	span `[0, 8]`: يوم عرفة — وردت معلومة غير دقيقة؛ والصواب: يوم النحر. *Gloss:* The span "the Day of Ārafa" is inaccurate; the correct answer is "the Day of Sacrifice".

Table 7: Representative annotated data sample provided to participants in Track 2 (subtasks 2.1 and 2.2). Each instance provides a set of candidate answers (Options) with an Answer key, and, when the response is hallucinated, span-level Hallucination annotations with explanations.

	Subtask		Model Family		Approach

REGLAT	✓	✓	✓		✓				
Scalar_NITK	✓	✓	✓	✓	✓		✓	✓	✓
Sense	✓	✓	✓		✓				

Table 8: Overview of the approaches adopted by participating teams in Tasks 1.1 and 1.2. A checkmark indicates that the corresponding component was used in the submitted system. Distill.: knowledge distillation; Ext. Feat.: external features; PEFT: parameter-efficient fine-tuning.

models were used only by *RaghadAlrasheed* and *Scalar_NITK*. This preference is consistent with the discriminative nature of Task 1, where systems classify whether a given question–answer pair contains hallucinated information rather than generate new text. Moreover, all teams participated in both subtasks, allowing the same general modeling strategies to be evaluated under both question-level and cross-model generalization settings.

Another recurring strategy was **model ensembling**. *REGLAT*, *Sense*, and *Scalar_NITK* combined predictions from multiple models, suggesting that participants explored model diversity as a means of improving robustness. Notably, *REGLAT*, which achieved the highest test AUC-ROC in subtask 1.1, used an encoder-based ensemble, while *Sense* also adopted an encoder ensemble and obtained the strongest development AUC-ROC in both subtasks 1.1 and 1.2. Nevertheless, ensembling did not consistently guarantee stronger test generalization: *NAMAA*, which achieved the highest test AUC-ROC in subtask 1.2, relied on an

Hashtag AI	✓	✓		✓	✓	✓		✓	✓	✓	
HelsinkiTeam		✓		✓	✓				✓		
ShadowDz	✓			✓	✓	✓					
Vescera		✓		✓	✓	✓		✓	✓		✓

Table 9: Overview of the approaches adopted by participating teams in Tasks 2.1 and 2.2. A checkmark indicates that the corresponding component was used in the submitted system. PEFT: parameter-efficient fine-tuning; Distill.: knowledge distillation; Data Aug.: data augmentation; Priv. Info.: privileged information.

encoder-based approach without an ensemble. This suggests that effective cross-model generalization may depend more strongly on the learned representations and training strategy than on combining multiple classifiers alone.

More specialized techniques were less commonly explored. *RaghadAlrasheed* employed a decoder-based architecture together with knowledge distillation and parameter-efficient fine-tuning (PEFT), whereas *Scalar_NITK* adopted the most heterogeneous methodology, combining encoder- and decoder-based models with ensembling, distillation, external features, and PEFT. Despite their greater methodological complexity, these systems did not outperform the simpler encoder-based approaches on the primary test metric. Overall, the submitted systems indicate that **pretrained encoder representations, optionally combined through ensembling, remain a strong paradigm for Arabic hallucination detection**. At the same time, the limited use of reference-based information, contrastive learning, and other explicit factuality-oriented mechanisms reveals opportunities for future work, particularly for improving robustness to the distribution shifts and unseen model outputs considered in subtasks 1.1 and 1.2.

D.2 Task 2 Systems

Table 9 summarizes the main methodological choices adopted by participating teams in subtasks 2.1 and 2.2. In contrast to Task 1, **decoder-based architectures dominated Task 2**, reflecting the more complex nature of the task, which requires systems not only to detect hallucinated responses but also to identify the correct factual answer. All participating teams employed decoder-based models, with *AyahVerse* additionally incorporating an encoder-based component. Parameter-efficient fine-tuning (PEFT) was also widely adopted across the submitted systems, indicating a preference for adapting pretrained language models to the task without requiring full-model fine-tuning.

Several teams employed **multi-stage or verification-oriented strategies**. *AyahVerse*, *DzairVerse*, *Hashtag AI*, *ShadowDz*, and *Vescera* used two-stage approaches, separating different components of the prediction process rather than treating the task as a single classification decision. Cross-checking mechanisms were used by *Anhnamxtanh*, *DzairVerse*, *ShadowDz*, and *Vescera*, reflecting an effort to explicitly verify intermediate or final predictions. Other strategies were less common. *Hashtag AI* used knowledge distillation, while *Anhnamxtanh* employed counterfactual supervision and cross-role agreement. Moreover, *Hashtag AI* and *Vescera* adopted data augmentation. Retrieval was used by *Hashtag AI* and *HelsinkiTeam*, providing additional information that could support factual verification and correct-answer identification. *Vescera* additionally incorporated privileged information, making it the only submitted system to explore this strategy.

The methodological diversity observed in Task 2 highlights the additional challenges introduced by factual verification compared with binary hallucination detection. The submitted systems demonstrate that no single methodological component characterizes all high-performing approaches. Overall, Task 2 encouraged greater use of **generative models, staged reasoning, and explicit factual verification mechanisms** than Task 1, reflecting the need to move beyond identifying whether a response is hallucinated toward determining what the correct factual information should be.

Hashtag AI at HalluScoring-2026: Distilling Knowledge-Graph Retrieval into Gemma 4 for Arabic Hallucination Detection*

Abstract

We describe our submission to HalluScoring 2026 for Arabic hallucination detection in general-culture and Islamic-knowledge question answering. Our system adapts the instruction-tuned 12B-parameter Gemma 4 model with QLoRA. Its central idea is to use the Hashtag AI knowledge-graph retrieval system only during offline data construction: we query facts related to development-set failures, create contrastive training examples, and distill them into the model parameters. The submitted model is closed-book and uses no retrieval, search, or external knowledge at evaluation time. On organizer-provided test annotations, it obtains 73.59 macro-F_1 on the 400-example Islamic set and 77.56 on the 1,600-example mixed-domain set; answer-option accuracies are 75.25% and 81.13%. Analysis shows strong science performance but lower recall for subtle hallucinations in history, geography, and Islamic knowledge.

1 Introduction

Hallucination detection is especially consequential for Arabic question answering because a fluent response can conceal a factual error, and errors in Islamic content may concern sensitive religious claims. HalluScoring 2026 (Alansari et al., 2026) evaluates systems on general-culture and Islamic-knowledge data using Arabic question–answer pairs. We participate in both Tasks 2.1 and 2.2.

Our approach is deliberately compact: we adapt a sub-13B instruction model rather than relying on a larger proprietary model at inference. We fine-tune Gemma 4 12B IT with quantized low-rank adaptation (QLoRA; Dettmers et al. 2023), constrain the output to a small JSON schema, and use deterministic decoding. Knowledge-graph retrieval serves as an offline teacher for difficult facts, not as an evaluation-time component.

Knowledge graphs represent entities and their relations in a structured form that supports querying and reasoning (Hogan et al., 2021). Retrieval-augmented generation (RAG) complements a model's parametric memory with retrieved non-parametric evidence (Lewis et al., 2020); more recent work extends this idea to question answering over textual graphs (He et al., 2024). Unlike these inference-time retrieval systems, our submitted detector performs no retrieval at evaluation. We use knowledge-graph evidence only to construct additional supervision, then distill that supervision into the model weights.

Our main contributions are: (i) a rule-compliant method for distilling knowledge-graph evidence into a closed-book detector; (ii) a reproducible parameter-efficient Gemma 4 system; and (iii) a domain-level analysis of correct and failed cases.

2 Task and Data

Each instance contains an Arabic question, a generated answer, and a binary label: `hallucination` or `no_hallucination`. Task 2 instances additionally provide six candidate answers (A–F), and the submission format requires both a predicted label and a selected option. The shared-task benchmark is HalluTruthQA (Bouchekif et al., 2026); the Track 2 resource is its HalluTruthQA-4K corpus (Bekhouche et al., 2026), comprising 4,000 expert-curated instances across Islamic knowledge, history, science, and geography. The organizers supplied 400 Islamic-knowledge test examples for Subtask 2.1 and 1,600 examples for Subtask 2.2; the latter comprises four 400-instance groups in the delivered file. To prevent leakage, inference files retained only the ID, question, generated answer, and options; all labels, reference answers, and annotations were removed before prediction and used

*We thank Agastya Patel of SavvyWise for helpful discussions.

October 28-29, 2026 ©2026 Association for Computational Linguistics

only for post-hoc local evaluation.

For supervised adaptation we use the 4,705 labeled instances distributed in the official Track 1 starter kit, which is associated with the HalluScore Arabic hallucination benchmark (Alansari and Luqman, 2026). A fixed seeded split produces 4,215 training and 490 validation examples (89.6/10.4%). The training portion contains 2,214 hallucination and 2,001 non-hallucination examples; the validation portion contains 259 and 231, respectively. We keep the official development sets (1,300 examples for Task 1.1 and 200 for Task 1.2) disjoint from training and use them only for model comparison.

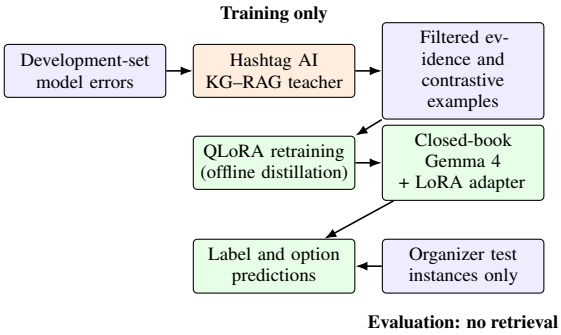

Figure 1: Knowledge-graph evidence is used only to construct and distill offline supervision. The submitted model receives no KG, retrieved evidence, search results, or external API access at evaluation time.

3 System Description

3.1 Detection Model

The backbone is `google/gemma-4-12B-it`, selected to satisfy the task's model-size constraint. We express each example as a chat instruction containing the question and generated answer. The system instruction requests exactly one JSON object and no explanation. Its single `predicted_label` field contains either `hallucination` or `no_hallucination`. Only assistant tokens contribute to the causal language-modeling loss.

We use LoRA (Hu et al., 2022) on the attention projections (`q`, `k`, `v`, and `o`) and MLP projections (`gate`, `up`, and `down`). The rank is 16, scaling factor 32, and dropout 0.05. The frozen backbone is loaded in 4-bit NF4 with double quantization and bfloat16 computation. We train for three epochs with a maximum length of 2,048 tokens, batch size 1, 16-step gradient accumulation, learning rate 2×10^{-4}, cosine scheduling, 3% warm-up, and paged 8-bit AdamW. This setup follows the memory-efficient QLoRA recipe while limiting learned parameters to the adapter.

3.2 Offline Knowledge-Graph Distillation

The shared-task rules permit external data for fine-tuning but prohibit RAG, search, knowledge bases, and external information during evaluation. We therefore separate knowledge acquisition from inference. This design is motivated by RAG's use of retrieved evidence (Lewis et al., 2020) and by graph-based retrieval for knowledge-intensive question answering (He et al., 2024), but moves retrieval entirely to offline supervision construction. After evaluating the first QLoRA model, we collect questions from its remaining errors, focusing on history and geography. During data preparation only, we submit these questions to the knowledge-graph-based reasoning and RAG system developed by Hashtag AI (Hashtag AI, 2026). Retrieved answers are canonicalized into short references, manually filtered, and converted into both faithful answers and hard hallucinations through controlled perturbations of dates, quantities, entities, locations, and unsupported details.

Figure 1 summarizes the separation between the offline teacher pipeline and evaluation-time inference.

The final augmentation is grounded in 9 answered hard questions and contains 100 examples (55 hallucinated and 45 non-hallucinated). We repeat this focused set ten times and mix it with 4,215 official training examples, yielding 5,215 training rows; the 490-example official validation split remains unchanged. This resembles a student reviewing externally explained mistakes before a closed-book examination: the knowledge graph teaches the model during training, but neither retrieved passages nor the KG system are available to the submitted model.

At evaluation time the artifact consists only of the frozen Gemma 4 backbone and learned LoRA weights. Prompts contain only organizer-permitted instance fields. No API call, retrieval index, external search, or knowledge-base lookup occurs, satisfying the competition's closed-book constraint.

3.3 Inference and Option Selection

Inference is greedy and deterministic. A parser first reads the requested JSON key and normalizes common surface variants. If parsing fails, the detector conservatively emits `hallucination`. For Task 2,

Model	Training data	Evaluation split (n)	Acc.	Macro-F_1	Option Acc.
Gemma 4 12B	None (zero-shot)	General dev (1,300)	91.31	91.20	–
Gemma 3 12B SFT	Official (4,215)	General dev (1,300)	88.69	88.43	–
Gemma 4 12B QLoRA	Official (4,215)	General dev (1,300)	**95.62**	**95.53**	–
Gemma 4 KG-QLoRA	Official + KG (5,215 rows)	General dev (1,300)	95.15	95.06	–
Gemma 4 QLoRA	Official (4,215)	Islamic dev (200)	97.00	96.76	–
Gemma 4 KG-QLoRA	Official + KG (5,215 rows)	Islamic dev (200)	**97.50**	**97.31**	–
KG-QLoRA final	Official + KG (5,215 rows)	Test 2.1 (400)	76.25	73.59	75.25
KG-QLoRA final	Official + KG (5,215 rows)	Test 2.2 (1,600)	79.31	77.56	81.13

Table 1: Training data and evaluation results (percent). *Official* denotes the 4,215-example training split; *Official + KG* adds 1,000 repeated rows drawn from 100 manually filtered KG-derived examples. Accuracy and macro-F_1 evaluate hallucination detection; option accuracy evaluates A–F answer selection and therefore applies only to Task 2.

a second prompt receives the question, generated answer, candidate options, and predicted detection label, and emits a single option letter. A malformed option response falls back to the candidate with the highest normalized character-sequence similarity to the generated answer. This fallback is intended only to guarantee a valid submission schema.

The released notebook loads the adapter, runs both stages, and creates the prediction, metadata, and submission files. Code, prompts, and configurations are available at `https://github.com/Anugithub2019/Koran`.

4 Results

We report accuracy and macro-F_1, with macro-F_1 giving equal weight to both labels. Table 1 summarizes completed runs. Plain QLoRA strongly improves over the prompt-only backbone. KG-guided retraining produces a mixed result: relative to plain QLoRA it improves Task 1.2 accuracy from 97.00% to 97.50%, but decreases Task 1.1 from 95.62% to 95.15%. We use the KG-guided model for both Task 2 test submissions. Local test evaluation uses organizer-provided annotations; official Codabench scores were not yet available at writing time.

On Test 2.1, the detector produces 216 true negatives, 24 false positives, 71 false negatives, and 89 true positives. On Test 2.2, the corresponding counts are 858, 59, 272, and 411. Hallucination precision is high (78.76% and 87.45%), but recall is only 55.63% and 60.18%, respectively. Thus, the main error is accepting a plausible but hallucinated answer.

5 Results Analysis

Correct cases. The detector is strongest when the generated answer directly conflicts with a stable fact, such as a wrong date, named entity, location, or scientific definition. Science is the clearest success case on Test 2.2: label accuracy is 93.75%, macro-F_1 is 93.64, option accuracy is 93.00%, and hallucination recall is 90.45%. Across the complete test sets, non-hallucination recall is 90.00% (Task 2.1) and 93.57% (Task 2.2), showing that faithful answers and paraphrases are usually accepted.

Failure cases. Errors are strongly domain-dependent. Geography reaches 71.50% accuracy and only 53.62% hallucination recall. The 55-instance history subset identified by the `historic2` prefix is hardest: accuracy is 50.91%, macro-F_1 is 41.56, and only 3 of 30 hallucinations are detected. The remaining 345 history cases fare better (79.71% accuracy), but hallucination recall remains 43.52%. Islamic knowledge obtains 76.25% accuracy and 55.63% hallucination recall.

Inspection reveals four recurring patterns. First, topically plausible answers naming a neighboring entity, date, location, or religious source are often accepted. Second, the model accepts broadly defensible alternatives when the reference expects one specific formulation. Third, underspecified questions encourage reasonable caveats that nevertheless disagree with the short reference. Fourth, partially correct answers combine a true core claim with an unsupported detail, making the hallucination subtle. Option selection is less affected than binary detection on geography and the small history subset, suggesting that the model often identifies the best reference answer even when it fails to label the generated answer as hallucinated. Output-format fallbacks were needed for 13/400 labels and 14/400 options in Task 2.1, and 55/1,600 labels and 42/1,600 options in Task 2.2.

The precision–recall imbalance clarifies the aggregate scores. Relative to non-hallucinated answers, hallucinated answers are more heterogeneous: an error may alter one entity, append one unsupported clause, or exploit ambiguity in the question. The detector's high hallucination precision but moderate recall therefore indicates conservative positive predictions rather than indiscriminate over-flagging. The gap between binary-label and option accuracy further shows that ranking a supplied reference among six candidates is easier than deciding whether a free-form answer contains any unsupported claim. Future augmentation should consequently emphasize minimally edited, partially correct negatives and ambiguous cases rather than only obvious factual substitutions.

6 Limitations and Conclusion

Our test scores are local calculations from the annotations supplied with the corpus and must be replaced or confirmed by official Codabench results. The small `historic2` subset makes its topic estimate uncertain, and its distinct ID prefix may indicate a distribution shift. Parser fallbacks can also conflate generation-format errors with classification errors. The model is closed-book and may reproduce knowledge gaps or biases from its backbone. Finally, religious claims warrant expert verification; a binary classifier should not be treated as an authority on Islamic knowledge.

We presented a compact Gemma 4 QLoRA system that converts knowledge-graph retrieval into offline supervision and remains fully closed-book at evaluation time. The KG-guided augmentation improves the smaller Islamic development split but does not uniformly improve every domain, motivating broader and more diverse knowledge distillation. Test analysis identifies semantic near-misses, underspecification, partial correctness, and annotation granularity as the main remaining challenges.

A Related Work

Arabic hallucination benchmarks. HalluScoring builds on recent efforts to evaluate factuality in Arabic question answering. HalluScore studies Arabic hallucination detection across general and Islamic knowledge (Alansari and Luqman, 2026), while HalluTruthQA introduces fine-grained detection, localization, and explanation annotations (Bouchekif et al., 2026). HalluTruthQA-4K further documents the corpus construction and expert annotation process used for truth verification (Bekhouche et al., 2026). Our work differs from benchmark construction: we focus on a constrained shared-task system and analyze how a compact, closed-book detector behaves across domains.

Parameter-efficient adaptation. LoRA learns low-rank updates while keeping the pretrained backbone frozen (Hu et al., 2022); QLoRA combines this idea with quantized backbone weights to reduce fine-tuning memory (Dettmers et al., 2023).

We apply QLoRA to an instruction-tuned Gemma 4 model and supervise a constrained JSON classification output. This makes the final artifact reproducible and deployable without a retrieval service.

Retrieval and knowledge distillation. RAG supplements parametric knowledge with retrieved evidence at generation time (Lewis et al., 2020), and graph-based retrievers extend retrieval to structured or textual graphs (Hogan et al., 2021; He et al., 2024). Our use of retrieval is deliberately different: a KG–RAG system acts only as an offline teacher for constructing additional training examples. At evaluation time the student receives only the organizer-provided fields. The contribution is therefore best viewed as retrieval-to-parameter distillation under a closed-book evaluation constraint, rather than an inference-time RAG system.

B Additional System and Data Details

Table 2 makes the supervision mixture explicit. The KG-derived set contains 100 unique examples grounded in nine answered hard questions. We repeat this focused set ten times so that rare, difficult patterns have non-negligible weight during the second training stage. Repetition changes the number of training rows but not the number of unique KG-derived examples.

Source	Unique	Rows used	Hall./Non-hall.
Official training split	4,215	4,215	2,214/2,001
KG-derived augmentation	100	1,000	55/45 unique
Final training mixture	4,315	5,215	–
Official validation split	490	490	259/231

Table 2: Supervision used by the final KG-QLoRA model. *Hall.* abbreviates hallucination. The validation split is never included in training.

Fine-tuning objective. For a target linear layer ℓ, let $W_\ell \in \mathbb{R}^{d_{\text{out}} \times d_{\text{in}}}$ be its frozen pretrained weight. QLoRA stores the backbone in 4-bit form; $Q_4(W_\ell)$ denotes the corresponding dequantized weight used in the forward pass. It learns only a rank-r update,

$$W_\ell^{\text{eff}} = Q_4(W_\ell) + \frac{\alpha}{r} B_\ell A_\ell.$$

The factors have dimensions $A_\ell \in \mathbb{R}^{r \times d_{\text{in}}}$ and $B_\ell \in \mathbb{R}^{d_{\text{out}} \times r}$. Here $r = 16$ and $\alpha = 32$. If y_{it} is the target token at position t in example i, the trainable adapter parameters $\theta = \{A_\ell, B_\ell\}_\ell$ minimize masked causal cross-entropy,

$$\mathcal{L}(\theta) = -\sum_i \sum_t m_{it} \log p_\theta(y_{it} \mid x_i, y_{i,<t}),$$

where $m_{it} = 1$ only for assistant-response tokens. Thus, the question, generated answer, and instruction provide context, while loss is applied only to the target JSON output. The quantized Gemma backbone remains frozen throughout training.

Knowledge graph and its role. A knowledge graph can be represented as a directed labeled multigraph $G = (V, E)$, where nodes V denote entities or concepts and an edge $(u, r, v) \in E$ records a relation r, for example a person–place, event–date, or work–author fact. For a development error with question q, the offline teacher retrieves a relevant subgraph $G_q \subseteq G$ and verbalizes its relations as evidence z_q. We manually filter z_q, form a faithful answer, and construct hard hallucinations by perturbing a relation endpoint, date, quantity, location, or unsupported clause.

This structure helps in two ways. First, explicit relations disambiguate neighboring entities that a language model may otherwise conflate. Second, the same verified fact can generate controlled contrastive pairs that differ in only one factual relation, directly targeting the detector's failure modes. Training transfers this supervision into the LoRA parameters; neither G_q nor z_q is available at evaluation. The mixed development result in Table 1 also limits the claim: the focused graph-derived set improves Islamic development performance but is too small and narrow to guarantee gains in every domain.

The detector and option selector are run sequentially. The first prompt maps the question–answer pair to one of two labels; the second maps the same instance and six supplied options to a letter. Greedy decoding removes sampling variance. Parsing first targets the requested JSON key, then normalizes surface variants; only malformed generations invoke the conservative label or similarity-based option fallback described in Section 3.3.

C Additional Qualitative Analysis

Table 3 gives stylized examples of the recurring behaviors observed during manual inspection. They abstract the semantic pattern rather than reproduce corpus items verbatim, so they should not be interpreted as additional scored instances.

The domain results suggest that augmentation coverage matters as much as model capacity. Science questions often contain crisp definitional or numerical conflicts, whereas history, geography, and Islamic knowledge more often require resolv-

Pattern	Typical outcome	Diagnostic interpretation
Neighboring entity	False negative	A related ruler, scholar, city, or source remains topically plausible.
Wrong date/quantity	Mixed	Salient contradictions are detected; small numeric changes are less reliable.
Partial correctness	False negative	One unsupported clause is masked by an otherwise true answer.
Reference granularity	False positive/disputed	A defensible answer may be broader than the expected formulation.
Faithful paraphrase	Correct negative	High non-hallucination recall shows tolerance of rewording.
Option/label disagreement	Correct option, wrong label	Candidate ranking is easier than free-form factuality detection.

Table 3: Representative qualitative patterns abstracted from manual error inspection.

ing closely related entities, chains of transmission, locations, or competing formulations. The especially low recall on the small `historic2` subset should be treated cautiously because its sample size is only 55 and its identifier suggests a possible distribution shift. Nevertheless, the repeated failure on partially correct answers points to a concrete next step: generate minimal-pair examples in which exactly one clause, entity, date, or attribution is perturbed while the remainder of the answer is preserved.

Vescera at HalluScoring 2026: Privileged-Information Distillation with Contrastive Representation Alignment for Arabic Hallucination Detection

Abstract

HalluScoring 2026 Subtask 2.2 (Hallucination Detection & Find the Truth) requires systems to judge whether an Arabic generated answer is hallucinated and to select the correct one among six candidates, without access to the reference answer that would make both judgments trivial. We treat that withheld reference as privileged information: a teacher is fine-tuned with it in the prompt, then never deployed, and its advantage is transferred to a blind student through two channels knowledge distillation over the teacher's output distribution, and a contrastive privileged-information (CPI) term that aligns the student's hidden representation with the teacher's gold-conditioned one. Our fine-tuned ALLaM-7B attains 84.62 combined score (Comb) on the official test set and 83.47 on the dev set.

1 Introduction

A fluent but factually wrong answer to an Arabic question is not a cosmetic failure but a trust-breaking one. **HalluScoring 2026 Subtask 2.2 (Hallucination Detection & Find the Truth)** poses hallucination detection and answer selection as one joint problem: given a question, a candidate answer, and six options, a system predicts a faithfulness label and the correct letter, scored by a weighted combination of label F1 and option accuracy. We adopt the task formulation and the HalluTruthQA-4K resource of HalluScoring 2026 Track 2 (Alansari et al., 2026; Bekhouche et al., 2026), which pairs each Arabic question with a model-generated response, a gold answer $a^\star$ (the verified, human-checked correct answer against which faithfulness is judged), and five distractors. Whether $a^\star$ is visible is what separates an easy version of this task from a hard one: exposing the gold answer at inference would turn both faithfulness judgment and option selection into near-trivial string matching, which is why the evaluation protocol withholds it. The task's difficulty is therefore not a matter of scaling or prompting a blind model harder, but of transferring what $a^\star$ would contribute into a model that never sees it at test time. This framing places the task in the learning-using-privileged-information setting (Vapnik and Vashist, 2009; Vapnik and Izmailov, 2015), which Lopez-Paz et al. (Lopez-Paz et al., 2016) unify with knowledge distillation (Hinton et al., 2015) as a transfer channel: soft teacher outputs carry exactly the information a privileged feature would otherwise supply. Most hallucination-mitigation systems instead keep a reference or a judge inside the inference loop (Manakul and Gales, 2023), which relaxes the blind constraint architecturally or pays repeated inference cost. Concurrent systems on this shared task (Ziani, 2026; Bekhouche et al., 2025; Swaileh et al., 2026; Bouchekif et al., 2025) report a similar detection-selection gap while keeping comparable machinery active at inference. We take the opposite position: keep the test-time system minimal, and confine every use of the gold answer $a^\star$ to training. Our system is a single low-rank adapter (Hu et al., 2021) over a frozen 7B Arabic instruction model (Bari et al., 2024), decoded greedily in two passes, with no reference-consuming module and no search. Privileged information enters only during training, through three mechanisms: detection and selection share one adapter, so option evidence regularizes the faithfulness decision; a teacher fine-tuned with $a^\star$ in its prompt supplies soft targets that expose calibrated uncertainty a one-bit label and a single letter cannot; and a privileged alignment term pulls the student's last-token representation toward a cached embedding of $a^\star$, so the gold answer shapes the representation space without ever entering a prompt. We further expand the 1,599 official training examples to 19,188 sequences through prompt paraphrasing and option permutation an augmentation that preserves blindness by construction. Our fine-tuned ALLaM-7B

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1126–1130
October 28-29, 2026 ©2026 Association for Computational Linguistics

reaches 84.62 Comb on the official test set and 83.47 on dev, closing part of the blind-versus-gold gap with no change to the test-time architecture. Our contributions:

- We cast blind Arabic hallucination scoring as privileged-information transfer from a gold-answer-conditioned teacher.
- We combine gold-answer distillation with a contrastive privileged-information (CPI) term and blindness-preserving augmentation all training-time only, with inference unchanged.

2 Proposed Method

We propose a privileged-information distillation pipeline for Arabic hallucination scoring. A reference answer is available in training data and turns the problem into a comparison, but it is withheld at test time, leaving the model to judge a fluent answer on prior knowledge alone. Our method closes that gap by letting a teacher read the reference, then transferring its advantage into a student that never does, through three components: a privileged teacher fine-tuned with the reference in its prompt, which supplies targets richer than the one-bit label and single letter the annotations provide; knowledge distillation, which moves the teacher's output uncertainty to the blind student; and a contrastive privileged-information (CPI) term that additionally aligns their hidden representations, so the transfer is not confined to the final layer. Prompt and option-order augmentation, with teacher caches keyed to every augmented row, keeps this supervision dense rather than restricted to canonical phrasing. All three act only during training: inference is a single adapted model making two blind JSON calls, exactly as the competition protocol requires. Figure 1 contrasts the resulting objective with plain distillation. Each instance is a tuple $e = (q, \hat{y}, \mathcal{O}, y^{\text{lab}}, y^{\text{opt}}, a^{\star})$: an Arabic question q, a generated answer $\hat{y}$ to be judged, six candidates $\mathcal{O} = \{A, \ldots, F\}$, a hallucination label, the correct letter, and a reference answer $a^{\star}$. We decode two independent JSON views detection, $(q, \hat{y}) \rightarrow \{\texttt{predicted\_label}\}$, and option selection, $(q, \hat{y}, \mathcal{O}) \rightarrow \{\texttt{selected\_option}\}$ because the official score weights them separately, $\text{Comb} = 0.4\,\text{F1}_{\text{macro}} + 0.6\,\text{Acc}$; a single joint decode would let detection errors corrupt the more heavily weighted option accuracy. Detecting a hallucination is easy when $a^{\star}$ is visible and hard when it is not, yet the evaluation forbids showing it. We

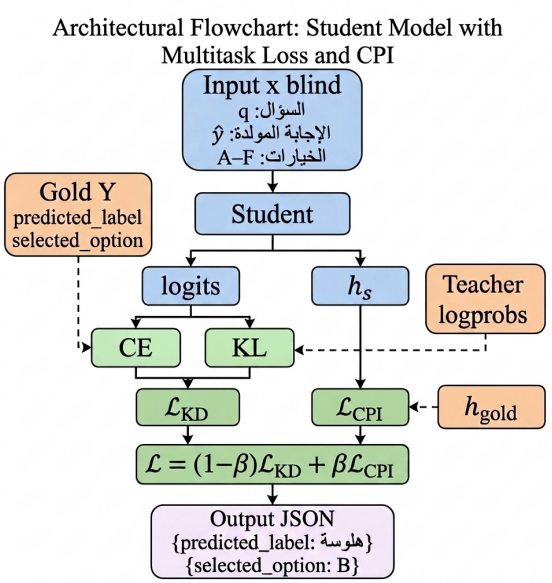

Figure 1: Overview of the Student training pipeline with Multitask Knowledge Distillation ($\mathcal{L}_{\text{KD}}$) and Contrastive Privileged Information Alignment ($\mathcal{L}_{\text{CPI}}$) for Arabic hallucination detection.

treat $a^{\star}$ as *privileged information*: available during training, absent at inference. We fine-tune a LoRA teacher $\mathcal{T}$ with cross-entropy on prompts that append the reference block containing $a^{\star}$, and never deploy it. One frozen forward pass records everything we need the top-K token log-probabilities $p_{\mathcal{T}}$ over the supervised span and the last-layer hidden state h_{gold} at the final supervised token so the teacher is paid for once and never re-run. The blind student $\mathcal{S}$ is initialized from $\mathcal{T}$: the two models share the output format and differ only in what the prompt reveals, so training starts from a policy that already emits valid JSON. Hard labels alone are a poor teacher here, since y^{lab} is one bit and y^{opt} one letter, both silent about *how close* a wrong option was. The teacher's soft distribution carries that information, so we distil it,

$$\mathcal{L}_{\text{KD}} = \alpha\, T^2\, \text{KL}\Big(p_{\mathcal{T}}^{(K)} \,\Big\|\, p_{\mathcal{S}}\Big) + (1-\alpha)\, \mathcal{L}_{\text{CE}}(Y, p_{\mathcal{S}}), \tag{1}$$

keeping cross-entropy on the gold JSON Y so the student stays anchored to the correct answer when the teacher is itself uncertain. Eq. 1 still supervises only the output layer, but the teacher's advantage lives earlier reading $a^{\star}$ changes how it *represents* the question, not merely which token it emits. We recover that with a contrastive term that pulls the blind representation toward the privileged one,

$$\mathcal{L}_{\text{CPI}} = 1 - \cos\big(h_{\text{student}}, h_{\text{gold}}\big), \tag{2}$$

evaluated at the same token position, and combine the two:

$$\mathcal{L} = (1 - \beta)\,\mathcal{L}_{\text{KD}} + \beta\,\mathcal{L}_{\text{CPI}}. \tag{3}$$

The terms are complementary rather than redundant Eq. 1 constrains *what the model says*, Eq. 2 constrains *what it encodes* before saying it so we keep β small (0.1): CPI is a regularizer on the hidden state, and a larger weight would trade away the token-level accuracy Comb actually measures.

3 Data and Experimental Setup

We evaluate on HalluScoring Subtask 2.2: 1,599 train, 800 dev, and 1,600 official test instances across four domains, with labels skewed roughly 59/41 toward *no_hallucination*. Augmentation expands the 3.2k-row training set to 19,188 rows through three prompt paraphrases $\times$ three option-order permutations. We compare ALLaM-7B, Qwen2.5-7B, and Falcon3-7B on augmented data. All models are trained with LoRA adapters for 5 epochs on augmented data , using fixed hyperparameters, with greedy JSON decoding throughout.

4 Results

We evaluate under the official protocol: two greedy JSON calls with no gold answer in the prompt, and $\mathrm{Comb} = 0.4\,\mathrm{F1}_{\text{macro}} + 0.6\,\mathrm{Acc}$. *Base* denotes unaugmented SFT on 3,198 rows; *Ours* denotes the full method (augmentation, distillation, and CPI). Table 1 reports both configurations for each backbone on the dev set and on the official test set; Table 2 isolates the contribution of each individual component on our submitted backbone.

Our submitted system, **ALLaM-7B**, improves over its own baseline on both splits: relative to Base, Ours yields a $+1.42$ Comb improvement on dev (82.05 to 83.47) and a $+1.46$ improvement on the official test set (83.16 to 84.62), with official performance exceeding dev the only backbone for which this holds. **Qwen2.5-7B** and **Falcon3-7B** exhibit a markedly different pattern: both show a modest dev-set gain over Base ($+0.23$ Comb for Qwen, $+0.22$ for Falcon), but this gain reverses on the official set, where Ours underperforms Base by 0.68 Comb for Qwen and by 1.83 Comb for Falcon the latter more than double the magnitude of the dev-set gain it is meant to reflect. This asymmetry indicates that the improvements from augmentation and distillation transfer reliably for the Arabic-native backbone but not uniformly across backbones.

Backbone	Method	Split	Joint	M-F1	Opt	Comb
ALLaM-7B	Base	Dev	71.12	82.12	82.00	82.05
		Official	72.69	82.36	83.69	83.16
	Ours	Dev	72.75	82.11	84.38	**83.47**
		Official	74.25	82.27	86.19	**84.62**
Qwen2.5-7B	Base	Dev	73.50	82.79	83.50	83.22
		Official	69.56	78.90	82.94	**81.32**
	Ours	Dev	74.88	84.13	83.00	**83.45**
		Official	69.31	77.85	82.50	80.64
Falcon3-7B	Base	Dev	62.12	79.04	72.50	75.12
		Official	61.94	76.63	74.62	**75.43**
	Ours	Dev	62.62	78.67	73.12	**75.34**
		Official	60.25	74.39	73.06	73.60

Table 1: Base versus Ours (full method) on the dev set and the official test set, across three backbones. ALLaM-7B is our submitted system. Bold marks the better Comb within each backbone–split pair.

Table 2 isolates the contribution of each training-time component on our submitted backbone. On dev, the terms combine additively: Base CE attains 82.05 Comb, augmentation raises this to 82.89, distillation improves it further to 83.35, and CPI contributes a final $+0.12$ to reach 83.47. CPI's benefit also holds in the absence of distillation on dev, where Aug CE+CPI attains 83.35 Comb, a $+0.46$ improvement over Aug CE alone; this effect does not, however, carry over to the official set, where Aug CE+CPI (84.01) falls 0.04 Comb *below* Aug CE alone (84.05), a sign reversal relative to dev. CPI's contribution on top of distillation is the one effect that retains its sign across both splits ($+0.12$ on dev, $+0.65$ on official), and the resulting configuration, Aug KD+CPI (**Ours**), remains the strongest overall at 84.62 Comb. We conclude that CPI constitutes a reliable addition on top of distillation but not a substitute for it: its apparent benefit over cross-entropy alone appears to be a dev-set artifact that does not generalize. Across configurations, gains concentrate almost entirely in option accuracy, while Macro-F1 remains within a narrow 81-83 range throughout consistent with the hypothesis that the withheld gold answer $a^\star$ primarily disambiguates *which* option is correct, rather than *whether* the given answer is faithful.

5 Discussion

Two results anchor our analysis: CPI's contribution is well-characterized on ALLaM-7B, and the backbone ranking in Table 1 is consistent with each

Config	Joint	M-F1	Opt	Comb
Base CE (Dev)	71.12	82.12	82.00	82.05
Base CE (Off.)	72.69	82.36	83.69	83.16
Base KD (Dev)	70.38	81.07	81.25	81.18
Base KD (Off.)	72.00	82.02	83.38	82.83
Aug CE (Dev)	72.88	82.16	83.38	82.89
Aug CE (Off.)	73.88	82.35	85.19	84.05
Aug KD (Dev)	72.62	82.55	83.88	83.35
Aug KD (Off.)	73.38	82.04	85.25	83.97
Aug CE+CPI (Dev)	73.50	82.76	83.75	83.35
Aug CE+CPI (Off.)	73.81	82.15	85.25	84.01
Ours (Dev)	72.75	82.11	84.38	83.47
Ours (Official)	**74.25**	**82.27**	**86.19**	**84.62**

Table 2: Ablation on our submitted system (ALLaM-7B): dev vs. official test.

model's documented Arabic-language pretraining. CPI (Eq. 2) pulls the student's blind hidden state toward a frozen, gold-conditioned reference, constraining the representation a decision is read *from* rather than the output distribution itself as $\mathcal{L}_{\text{KD}}$ does. Table 2 supports this distinction directly: CPI's gain on top of distillation is the only term that retains its sign across both splits ($+0.12$ dev, $+0.65$ official), while distillation alone does not Aug KD trails Aug CE on official (83.97 vs. 84.05), reversing its dev-set lead. The gain is concentrated almost entirely in option accuracy ($+0.50$ dev, $+0.94$ official), with Macro-F1 nearly unmoved. This is consistent with where the two objectives act: detecting a hallucination is often resolvable from surface-level inconsistency, while selecting the correct option among six candidates requires encoding *which* one is correct information a representation-level signal is better positioned to carry than an output-level one. The per-backbone ranking in Table 1 matches each model's documented Arabic pretraining depth. ALLaM-7B has a dedicated 1.2-trillion-token Arabic/English pretraining stage (Bari et al., 2024). Qwen2.5-7B includes Arabic as one of roughly 30 supported languages, with no stage specific to it (Qwen et al., 2025). Falcon3-7B, the backbone we evaluate, had no native Arabic tokenizer or embedding support at all: TII's own release notes for a subsequent Arabic-adapted variant confirm the base checkpoint required extending the vocabulary with 32,000 Arabic-specific tokens to add Arabic support after the fact (TII Team, 2025). This ordering ALLaM, then Qwen, then Falcon matches the Comb ranking in Table 1, and offers a plausible account for why the same recipe yields a stronger model on ALLaM. It does not explain the dev-to-official reversal visible for Qwen2.5-7B and Falcon3-7B in the same table: corpus composition is a property of the backbone alone, while the reversal is a difference in generalization between splits, and we lack the per-backbone ablation needed to attribute it to a specific component.

6 Conclusion

We presented a privileged-information distillation pipeline for Arabic hallucination scoring: a teacher reads the reference answer and never deploys it, transferring its advantage to a blind student through output-level distillation and a contrastive term aligning hidden representations. Our fine-tuned ALLaM-7B reaches 84.62 Comb on the official test set and 83.47 on the dev set. CPI improves every backbone we tested, on both splits, by concentrating its gain in answer selection rather than detection evidence that aligning representations, not just output distributions, recovers the teacher's advantage reliably.

AyahVerse at HalluScoring-2026: Category-Aware Arabic Hallucination Detection with Multi-Layer Representations

Ibad-ur-Rehman Rashid
Department of Computer Science, Government Postgraduate College Mansehra, Pakistan
ibad.rashid.research@gmail.com

Abstract

We present our submission to HalluScoring 2026, an ArabicNLP shared task on hallucination detection and answer recovery in Arabic LLM outputs. For Track 1, our submitted baseline fine-tunes CAMeLBERT for binary hallucination detection, achieving 0.921 and 0.763 AUC-ROC on the development and test sets of Task 1.1, and 0.749 and 0.729 on Task 1.2, respectively. We further conduct post-submission ablations with intermediate-layer supervision and category embeddings to study their effect on generalization. The combined model achieves 0.929 AUC-ROC on Task 1.1 and 0.777 on Task 1.2 development sets. For Track 2, we separate hallucination detection from answer selection, using CAMeLBERT for detection and a decoder-based, QLoRA-tuned AceGPT-v2-8B-Chat for option selection. The system achieves combined scores of 0.784 on Task 2.1 and 0.829 on Task 2.2 on the validation sets, improving substantially over the corresponding zero-shot baselines.

1 Introduction

Arabic LLMs increasingly answer knowledge-intensive questions in Islamic scripture, history, science, and geography domains. Fluent but factually incorrect answers can pose a credibility risk, particularly in sensitive domains. HalluScoring 2026 (Alansari et al., 2026) evaluates this problem through two tracks: Track 1 detects whether a generated answer is hallucinated, while Track 2 additionally requires recovery of the verified answer from six candidate options.

We use CAMeLBERT (Inoue et al., 2021) for hallucination detection and AceGPT-v2-8B-Chat (Huang et al., 2024) for option selection. For Track 1, we fine-tune CAMeLBERT with intermediate-layer supervision and domain-category embeddings, evaluating their effects under in-domain and out-of-domain settings. For Track 2, we use the detector with options as input and pair it with a QLoRA-tuned AceGPT-v2-8B-Chat that selects candidate options through logit comparison. We participate in Leaderboard B (assisted detection), where the detector has access to the candidate options.

We made three contributions. First, we ran ablations over four training configurations: (1) a CAMeLBERT detector baseline, (2) the baseline with intermediate-layer supervision, (3) the baseline with category-aware representations, and (4) the baseline with both components for Arabic hallucination detection. Second, we analyze these components across Subtasks 1.1 and 1.2, which evaluate different generalization settings. Third, for Track 2 assisted detection, we retrain CAMeLBERT for hallucination detection and fine-tune AceGPT-v2-8B-Chat model with QLoRA (Dettmers et al., 2023) for option selection using logit-based scoring of candidate options. For Track 1 our system ranked second in Task 1.1, and third in Task 1.2. For Track 2 our system ranked third on both subtasks according to combined-score evaluation, while the leaderboard only mentions subtask 2.2 scores for our team. Code is available on GitHub[1]

2 Background

2.1 Task Setup

The HalluScoring 2026 shared task evaluates hallucination detection and factuality in Arabic LLM-generated answers (Alansari and Luqman, 2026). It comprises two tracks. Track 1 evaluates binary hallucination detection, while Track 2 combines hallucination detection with answer verification.

2.2 Data

Track 1: Hallucination Detection. Given an Arabic question and an LLM-generated answer,

Subtask	Train	Dev	Test
1.1	4,705	1,300 (Seen)	1,030 (Seen)
1.2	4,705	200 (Unseen)	412 (Unseen)

Table 1: Track 1 dataset statistics.

Subtask	Domain	Train	Dev	Test
2.1	Islamic Knowledge	400	200	400
2.2	General Culture	1,600	800	1,600

Table 2: Track 2 dataset statistics.

the system predicts whether the answer is hallucinated. Subtask 1.1 evaluates generalization to unseen questions from seen models, whereas Subtask 1.2 evaluates generalization to answers generated by unseen models. The dataset sizes are summarized in Table 1.

Track 2: Detection-to-Truth. Track 2 combines hallucination detection with six-way answer selection. Each instance contains a question, generated answer, gold answer, and six candidate options. This track has two leaderboards: Blind Detection and Assisted Detection. We participate in Assisted Detection, where the detector has access to the candidate options.[2]

Subtask 2.1 focuses on Islamic knowledge, while Subtask 2.2 covers general culture and knowledge domains.

2.3 Related Work

Recent Arabic work has increasingly shifted toward fine-grained hallucination detection and analysis. General factuality research shows that fluent LLM outputs may still contain unsupported or incorrect information (Wang et al., 2024; Li et al., 2023). HalluScore (Alansari and Luqman, 2026) extends hallucination evaluation to Arabic knowledge-intensive and culturally grounded questions, while HalluTruthQA provides fine-grained factual annotations (Bouchekif et al., 2026) with 2,400 expert-curated Arabic QA instances containing verified answers, hallucination labels, erroneous spans, explanations, and hierarchical error types. HalluTruthQA-4K (Bekhouche et al., 2026) further extends this setting to 4,000 instances with verified answers and five plausible distractors, supporting both hallucination detection and factual verification. AlGhamdi et al. (2026) propose a knowledge-graph based diagnostic framework that analyzes hallucinations and question misalignment in Arabic Qur'anic machine reading comprehension through triple-level comparison of passage, question, and answer representations. These benchmarks motivate evaluating not only whether Arabic LLM outputs are incorrect, but also how factual errors can be detected and corrected.

Beyond detection, recovering the correct answer once a hallucination is identified requires efficient model adaptation. Parameter-efficient methods such as LoRA (Hu et al., 2021) and QLoRA (Dettmers et al., 2023) enable adaptation of large language models without full fine-tuning. HalluScoring 2026 (Alansari et al., 2026) brings these evaluation settings together through a shared task covering hallucination detection, generalization across models, and answer selection. Our contribution analyzes multi-layer representations and category embeddings for Arabic hallucination detection, and uses a decoder-based QLoRA-fine-tuned model for constrained answer recovery from the provided options. Together, these components address both the identification of hallucinated responses and the recovery of supported answers in a unified Arabic evaluation setting.

3 System Overview

3.1 Track 1: Category-Aware Multi-Layer Detection

1. Baseline configuration. We use CAMeLBERT (CAMeL-Lab/bert-base-arabic-camelbert-mix) with the default single-layer configuration. The submitted baseline uses the final-layer `[CLS]` representation h_{12}, which is passed to a binary classification head, with an auxiliary classification loss applied to the same layer. We then extend this baseline with intermediate-layer supervision and category embedding in post-submission ablation experiments.

2. Intermediate-layer supervision. We extract and concatenate the `[CLS]` representations h_4, h_8, and h_{12} from layers 4, 8, and 12 for classification, each layer supervised independently through its own auxiliary loss.

3. Category embedding. Each example is associated with a category indicated by its identifier. We extract the category prefix, e.g., `islamicHallucination_574` $\rightarrow$ `islamic`, and

[2] We report both 0.6/0.4 and 0.5/0.5 combined-score formulations in Table 5; the official leaderboard scores are marked separately.

Task	Split	Total	Valid	Default	Isl. / Hist. / Sci. / Geo.			
1.1	Train	4,705	1,600	3,105	400	400	400	400
1.1	Dev	1,300	776	524	176	200	200	200
1.1	Test	1,030	-	-	-	-	-	-
1.2	Train	4,705	1,600	3,105	400	400	400	400
1.2	Dev	200	0	200	0	0	0	0
1.2	Test	412	-	-	-	-	-	-

Table 3: Category Prefix Table. Valid examples contain a specific domain prefix, while Default examples have no recognizable prefix and fall back to index 0.

map it to a category index which is represented using a learned 32-dimensional embedding.

Category index assignment

`islamicHallucination`→ 1,
`historicHallucination`→ 2,
`ScienceHallucination`→ 3,
`geographyHallucination`→ 4

For identifiers containing only a numeric ID or an unrecognized prefix, category index 0 is used as the shared default category embedding. The category information is derived from the sample identifier rather than from the question or generated answer. The category embedding is concatenated with h_{12} when used alone, or with $[h_4; h_8; h_{12}]$ when combined with multi-layer supervision, with auxiliary losses applied at each selected layer.

4. Full Model: The full model combines multi-layer supervision and category embeddings, providing the final classifier with both multi-layer representations and explicit category information as shown in Figure 2.

3.2 Track 2: Decoder-based Answer Recovery

Track 2 combines hallucination detection with multiple-choice answer selection. We evaluate a zero-shot baseline and a separate-training pipeline that combines an encoder-based detector with a decoder-based option selector, as shown in Figure 1.

Zero-shot baseline. The zero-shot baseline combines pretrained CAMeLBERT detection with untuned AceGPT option scoring.

Separate training. Our system trains the detection and option-selection components separately. CAMeLBERT serves as the encoder-based detector, while the decoder-based AceGPT model is fine-tuned for option selection.

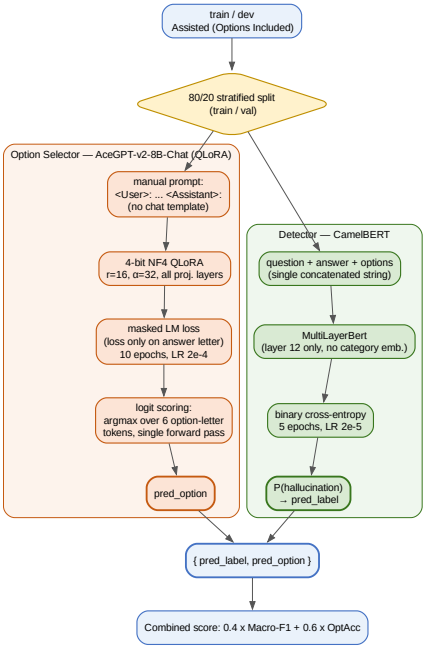

Figure 1: Track 2 system: detection and truth recovery.

Detection. We use the CAMeLBERT detector for the first stage. Because the assisted-detection setting exposes the candidate options to the system, the options are included in the detector input as:

السؤال : {question} الإجابة : {generated_answer} الخيارات: A: {option_A} B: {option_B} C: {option_C} D: {option_D} E: {option_E} F: {option_F}

Option selection. We fine-tune the decoder-based AceGPT-v2-8B-Chat with QLoRA for option selection. At inference time, candidate options are scored from their token logits using a single forward pass. We compare the logits assigned to the six candidate option tokens at the final prediction position and select the option with the highest score. This formulation avoids autoregressive generation and parsing failures while allowing the candidates to be scored efficiently in batches.

4 Experimental Setup

Track 1 training. We fine-tune CAMeLBERT for up to five epochs using a batch size of 16 and a learning rate of 2×10^{-5}. We use 10% warmup, a weight decay of 0.01, and FP16 training. Early stopping with a patience of three epochs is used. Inputs are formatted as `[CLS] question [SEP]`

`model_answer [SEP]` and truncated to a maximum length of 512 tokens.

The baseline training objective is

$$\mathcal{L} = \mathcal{L}_{\text{final}} + \alpha \mathcal{L}_{12}, \qquad \alpha = 0.3,$$

where $\mathcal{L}_{\text{final}}$ is the final classification loss produced by the final classifier, and $\mathcal{L}_{12}$ is the auxiliary classification loss produced by a separate classification head operating on h_{12}.

For intermediate-layer supervision, the objective is

$$\mathcal{L} = \mathcal{L}_{\text{final}} + \alpha \sum_{l \in \{4,8,12\}} \mathcal{L}_l, \qquad \alpha = 0.3,$$

where $\mathcal{L}_{\text{final}}$ is the cross-entropy loss from the classifier operating on the concatenated representation $[h_4; h_8; h_{12}]$, and $\mathcal{L}_l$ is the auxiliary loss produced by a separate classification head attached to layer l.

The auxiliary head is used only during training in both cases.

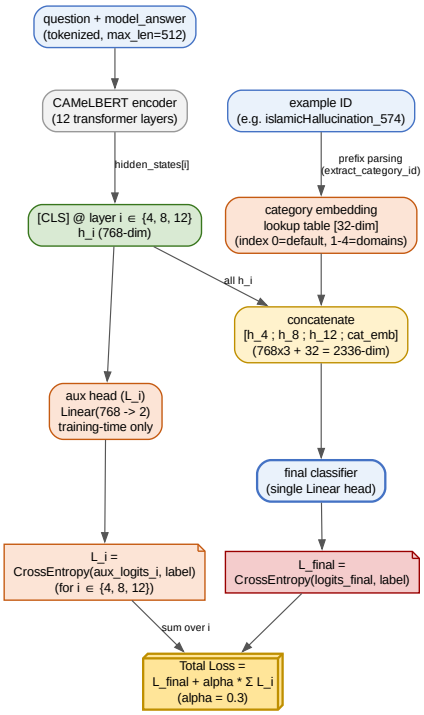

Figure 2: Full model: layer supervision + category embedding.

Track 2 detection. We use the CAMeLBERT pretrained (CAMeL-Lab/bert-base-arabic-camelbert-mix) checkpoint without task-specific fine-tuning as a baseline for assisted detection, where the candidate options are included in the input. For the fine-tuned CAMeLBERT, we use the same training hyperparameters as the Track 1 baseline.

Track 2 option selection. For option selection, we fine-tune AceGPT-v2-8B-Chat with QLoRA using 4-bit NF4 quantization, rank-16 adapters, and a learning rate of 2×10^{-4}.

As AceGPT does not provide a native chat template, we construct the instruction format manually. We also concatenate token IDs directly to avoid BPE boundary inconsistencies. Left padding and explicit position IDs are used to maintain RoPE alignment, while left-side truncation preserves the answer-label tokens required for option scoring.

For both Track 2 components, the training data is split 80/20 into training and internal validation sets, respectively, while the official development set remains unseen during training and model selection.

5 Results

Official versus post-submission results. Our official shared-task submission used the baseline CAMeLBERT configuration described in Section 3. The enhanced configurations were evaluated after submission on the development sets and were not submitted to the shared-task leaderboard.

The full model performs best overall on Task 1.1, while on Task 1.2, category embedding gives the highest AUC-ROC and the full model gives the highest Macro-F1, as shown in Table 4. For Track 2, the fine-tuned pipeline substantially outperforms the zero-shot baseline on both subtasks. Official test-set results are reported separately and marked in Table 5.

6 Analysis

Ablation Analysis The ablation results show that the contribution of each component depends on the evaluation setting. In Task 1.1, the individual components produce little change relative to the baseline, while their combination gives the strongest overall performance. In Task 1.2, category embedding provides the largest individual AUC-ROC improvement on the development set, from 0.749 to 0.782. Since all examples in this development set use the default category embedding, this improvement may reflect the large number of

Config	AUC-ROC	Macro-F1	AUC-PR
Task 1.1 (in-domain)			
Baseline (Dev. Set) †	0.921	0.860	0.935
Baseline (Test) †	0.763	0.640	0.918
+ layer supervision (Dev.)	0.921	0.854	0.940
+ category embedding (Dev.)	0.920	0.853	0.937
+ both (full model) (Dev.)	**0.929**	**0.867**	**0.948**
Task 1.2 (out-of-domain)			
Baseline (Dev. Set) †	0.749	0.632	0.844
Baseline (Test) †	0.729	0.613	0.908
+ layer supervision (Dev.)	0.768	0.658	0.857
+ category embedding (Dev.)	**0.782**	0.669	**0.868**
+ both (full model) (Dev.)	0.777	**0.703**	0.852

Table 4: Ablation results with full training data and dev-set evaluation. † denotes official shared-task leaderboard results.

Task	Approach	Comb. (0.6/0.4)	Comb. (0.5/0.5)	Det. AUC	Det. Acc.	Opt. Acc.	Macro-F1
2.1	Zero-shot (No Training) (Dev. Set)	0.578	0.611	0.815	0.841	0.445	0.778
	Fine-tuned Models (Dev. Set)	**0.784**	**0.791**	**0.960**	**0.855**	**0.755**	**0.828**
	Fine-tuned Models (Test Set)	**0.772**	**0.767**	**0.814**	**0.747**	**0.795**	**0.739**
2.2	Zero-shot (No Training) (Dev. Set)	0.649	0.650	0.745	0.655	0.646	0.654
	Fine-tuned Models (Dev. Set)	**0.829**	**0.828**	**0.917**	**0.831**	**0.835**	**0.821**
	Fine-tuned Models (Test Set)	**0.785**	**0.776**†	**0.848**	**0.766**	**0.819**	**0.734**

Table 5: Task 2 results for the validation and test sets under assisted detection. † denotes official shared-task leaderboard results.

training examples assigned to the default category (3,105) rather than domain-specific category information. The full model similarly achieves the highest Macro-F1 on this development set, from 0.632 to 0.703. Since the full model also incorporates the category embedding, this gain is subject to the same caveat.

In-Domain vs. Out-of-Domain Generalization. The difference between the two settings is more noticeable under out-of-domain evaluation. While the individual components have a minor effect on Task 1.1, both provide larger improvements on Task 1.2, particularly category embedding. However, the category-embedding improvement is measured on a development set where all examples use the shared default category embedding (see Table 3 for split-level coverage). Therefore, this improvement should not be interpreted as evidence of domain-specific category information improving generalization to unseen generators.

Decoder-Based Option Selection The fine-tuned option selector performs substantially better than zero-shot scoring, reaching 0.755 and 0.835 option accuracy on Tasks 2.1 and 2.2, respectively. This improvement is obtained with 4-bit NF4 QLoRA and direct comparison of candidate-token logits, avoiding free-form generation and output parsing.

Qualitative examples of model disagreements and representative errors are provided in Appendix A, while the study's limitations are discussed in Limitations section.

7 Conclusion

Separately, post-submission ablations show that the combined configuration achieves the strongest development-set performance on Task 1.1, reaching 0.929 AUC-ROC, while achieving 0.777 on Task 1.2. Our Track 2 system decouples detection from option selection, using a QLoRA-tuned decoder-based AceGPT model for option scoring, and achieves combined validation scores of 0.784 on Task 2.1 and 0.829 on Task 2.2. Future work includes Arabic-specific preprocessing, threshold calibration, and joint training of the detection and option-selection components.

Limitations

Our study has several limitations. First, the enhanced Track 1 configurations were evaluated only on development sets after submission, so their improvements have not been confirmed on a held-out test set. Second, we use a single run per configuration and do not report statistical significance. For Task 1.2, the category-embedding ablation is measured on a development set where all examples use the default category embedding, so its improvement may not reflect domain-specific category information, and more plausibly reflects the default embedding's own contribution as the most heavily-trained category vector (3,105 of 4,705 training examples). Evaluating the contribution of domain-specific category embeddings would require per-category ablation results on evaluation examples with identifiable category prefixes. Prefix coverage on the official Task 1.1/1.2 test sets could not be computed for this paper, as the underlying test IDs were not released to participants. Finally, Track 2 uses separate training for detection and option selection; joint training was not explored.

A Error Analysis

The examples in Table 6 show three recurring patterns. First, intermediate-layer supervision can correct cases where the others miss a factually valid but concise answer, as in 51-M1. Second, category information can help with domain-specific cases, such as Sci-948 and Isl-92, where category embedding preserves the baseline's correct prediction, while layer supervision and the full model both fail on the same examples. Third, some fluent but incorrect responses remain difficult for all configurations, as illustrated by 51-M2. The examples also show that the enhanced configurations can correct specific factual errors, including incorrect scientific answers and erroneous citations, although the gains are not consistent across all cases.

Question | Arabic | Translation							
ID	**Generated Answer**	**True Label**	**Base**	**+Layer**	**+Cat.**	**Full**	**Note**
Question: ا نوع الأسلوب في جملة 'إياك والكذب *(What is the type of style in the sentence "Beware of lying"?)*							
51-M1	تحذير. ("Warning.")	Not hallucinated	✗	✓	✗	✗	Only layer supervision fixes it.
Question: ا نوع الأسلوب في جملة 'إياك والكذب *(What is the type of style in the sentence "Beware of lying"?)*							
51-M2	أسلوب إنشائي (نهي). (Rhetorical style (prohibition))	Hallucinated	✗	✗	✗	✗	The response is fluent but incorrect, and none of the configurations identifies the error.
Question: من الملقب بالملقب بشيخ تراجمة العصر العباسي *(Who is known as the "Sheikh of Translators" of the Abbasid era?)*							
79-M1	الملقب بشيخ تراجمة العصر العباسي هو حنين بن إسحاق (The person known as the "Sheikh of the Abbasid-era translators" is Hunayn bin Ishaq.)	Not hallucinated	✓	✓	✓	✓	All configurations got it right, question is very similar to answer.
Question: من الملقب بالملقب بشيخ تراجمة العصر العباسي *(Who is known as the "Sheikh of Translators" of the Abbasid era?)*							
79-M2	حنين بن إسحاق (Hunayn bin Ishaq)	Not hallucinated	✗	✗	✗	✗	All got wrong.
Question: A ماهي صفات الشخص الذي يحمل فصيلة الدم *(What are the characteristics of a person with blood type A?)*							
56-M2	فصيلة الدم A شائعة ولا ترتبط علميًا بصفات شخصية محددة؛... (Blood type A is common and is not scientifically linked to specific personality traits;...)	Not hallucinated	✗	✓	✗	✗	Only layer supervision fixes it.
Question: ما هو العنصر الأكثر وفرة في القشرة الأرضية *(What is the most abundant element in the Earth's crust?)*							
Sci 948	الأكسجين (Oxygen)	Not hallucinated	✓	✗	✓	✗	Baseline and Category both retain the correct prediction.
Question: ؟ من هم القوم الذين خرجوا من ديارهم وهم ألوف حذر الموت *(Who were the people who left their homes numbering...)*							
Isl 92	ي إسرائيل، كما ورد في القرآن الكريم في سورة البقرة، الآية 249 (Children of Israel, as stated in the Holy Quran in Surah Al-Baqarah, Verse 249...)	Hallucinated (Wrong Ayah citation and generation)	✓	✗	✓	✗	Baseline and Category both retain the correct prediction.

Table 6: Qualitative examples from Task 1.1 and 1.2 showing how the baseline and three enhanced configurations (layer supervision, category embedding, full model) disagree on individual predictions. ✓ = matches the true label, ✗ = does not.

NAMAA Community at HalluScoring-2026: Beyond Predictive Performance: Reliability and Generalization in Arabic Hallucination Detection

Abstract

Reliable Arabic hallucination detection requires not only strong ranking performance but also robustness to distribution shift, calibrated probabilities, and useful uncertainty for selective prediction. We present the NAMAA Community's submission to HalluScoring 2026 Task 1.1 and a set of post-submission diagnostic experiments. The scored, template-compliant system is a CAMeLBERT cross-encoder over the question and generated answer; it achieves 0.7596 ROC-AUC on the hidden test set, ranking third among seven teams. We compare this template-defined input path with reference-aware answer-pair models that use the gold answer. A CAMeLBERT input-framing ablation raises the unseen-question ROC-AUC from 0.8713 to 0.9272, while similar gains appear across ARBERT and MARBERTv2. Reference-free distillation recovers only a small portion of this advantage, whereas LoRA-InfoNCE substantially improves direct cosine discrimination. On a separately trained CAMeLBERT reliability replicate, temperature scaling reduces expected calibration error from 0.0993 to 0.0562, and MC-Dropout variance reduces retained-set error from 14.08% to 8.35% when the 30% most uncertain cases are deferred. These results motivate reporting distributional generalization, calibration, and selective risk alongside ROC-AUC. Code and checkpoints for the scored submission are publicly available. [1]

1 Introduction

Arabic hallucination detectors are commonly compared by ROC-AUC, but deployment also depends on generalization to unseen questions, calibrated probabilities, and the ability to defer uncertain cases. Large language models can produce fluent Arabic answers that are unsupported or factually incorrect, while dedicated Arabic hallucination resources remain limited relative to English. Recent benchmarks and shared tasks have begun to narrow this gap (Ji et al., 2023; Alansari and Luqman, 2026; Mubarak et al., 2025).

HalluScoring 2026 Task 1.1 evaluates hallucination detection on questions unseen during training(Alansari and Luqman, 2026). Each released instance contains a question, a gold reference answer, and an LLM-generated answer. However, the protected inference cell in the organizer-provided submission template encodes only the question and generated answer. Our scored, template-compliant CAMeLBERT system follows this template-defined, reference-free path. We separately investigate reference-aware answer-pair models using the gold answer but treat them exclusively as development-set diagnostics.

A single leaderboard ROC-AUC does not capture all relevant behavior. Performance may change when questions or generator/topic distributions differ from those observed during training; probabilities may be poorly calibrated; and uncertainty estimates may or may not identify cases that should be deferred. We therefore use the shared task as the basis for a broader analysis and our contributions are threefold:

- We report a template-compliant CAMeLBERT cross-encoder that achieves a 0.7596 hidden-test ROC-AUC, ranking third among seven teams, and distinguish this scored result from all development-only follow-up analyses.
- We compare template-defined question-answer framing with reference-aware answer-pair framing on unseen questions and held-out generator/topic evaluations and examine reference-free transfer through

knowledge distillation and LoRA-InfoNCE representation learning.

- We study calibration and selective prediction using temperature scaling, MC-Dropout, risk-coverage analysis, and model fusion and characterize the high-confidence errors that remain after calibration.

2 Related Work

Hallucination detection has been studied through response-level factuality benchmarks, supervised classifiers, retrieval-based verification, entailment-based consistency models, and LLM-based judges (Li et al., 2023; Ji et al., 2023). Although much of this research has focused on English, recent work has begun to develop resources for Arabic hallucination evaluation. HalluScore provides the Arabic question-answering benchmark underlying HalluScoring-2026, with verified reference answers and human-annotated hallucination labels (Alansari and Luqman, 2026). IslamicEval 2025 further introduced hallucination detection and correction tasks for sensitive Arabic religious content (Mubarak et al., 2025).

Our encoder-based experiments build on Arabic pretrained language models, including ARBERT and MARBERT (Abdul-Mageed et al., 2021), AraBERT (Antoun et al., 2020), and CAMeL-BERT (Inoue et al., 2021). These models provide strong Arabic representations, but their robustness under changes in questions, generator families, and available reference information remains an important empirical question.

Predictive reliability is distinct from ranking performance. MC Dropout estimates predictive variation through repeated stochastic forward passes (Gal and Ghahramani, 2016), while temperature scaling provides post-hoc probability calibration (Guo et al., 2017). Selective classification evaluates the risk-coverage trade-off obtained when uncertain predictions are deferred (Geifman and El-Yaniv, 2017). For reference-free transfer, we examine knowledge distillation (Hinton et al., 2015) and parameter-efficient representation learning through LoRA (Hu et al., 2022) combined with an InfoNCE-style contrastive objective (Gao et al., 2021).

3 Task & Experimental Setup

The released training and development files contain 4,705 and 1,300 instances, respectively; the development set covers 900 unique questions. The hidden test contains 1,030 instances over 206 questions. Training/development rows include a question Q, the gold answer A_{gold}, a generated answer A_{gen}, and a binary gold annotation $y \in \{0, 1\}$. This annotation provides supervision only: systems submit a continuous hallucination score $s = p(y = 1 \mid Q, A_{gen}) \in [0, 1]$. The official inference path is reference-free.

Track	Inference input	Evaluation role
Official CAMeL-BERT	$Q + A_{gen}$	Hidden-test submission
Reference-aware	$A_{gold} + A_{gen}$	Reference-access diagnostic
Distillation	$Q + A_{gen}$	Teacher–student transfer
LoRA–InfoNCE	$Q + A_{gen}$	Gold-free representation test
Uncertainty	$Q + A_{gen}$	Calibration and selective risk

Table 1: Experimental tracks are not a single common leaderboard

$$x_{QA} = [Q; A_{gen}], \tag{1}$$

whereas our diagnostic consistency experiments use

$$x_{NLI} = [A_{gold}; A_{gen}]. \tag{2}$$

Because x_{NLI} contains privileged information, NLI results are never reported as alternative official scores.

For internal comparisons, we use full development AUC, **Clean AUC** on questions not observed in training, and **reference-aware held-out generator** on answers produced by held-out generator families where available. Results from different tracks are interpreted within their own protocols: the official system, reference-aware experiments, representation-learning experiments, and uncertainty studies do not all share the same inference information or evaluation subset.

We additionally report ROC-AUC on a held-out generator/topic split containing $n = 200$ instances from 2 held-out generators. Because generator identity and topic are structurally coupled in this split, this evaluation measures joint generator/topic shift rather than an isolated generator effect. The split is grouped by question to prevent question overlap across partitions.

4 System Overview

Official cross-encoder. The officially scored submission is a reference-free sequence-classification pipeline: the question and generated answer are paired as $[Q; A_{gen}]$, encoded with CAMeL-Lab/bert-base-arabic-camelbert-mix, and mapped to the hallucinated-class softmax probability used as the submitted continuous score. No prompted generative LLM or gold answer is used on the official inference path. We apply no additional Arabic-specific normalization before tokenization; the released question and generated-answer strings are passed directly to the pretrained model tokenizer. Training uses AdamW, learning rate 2×10^{-5}, batch size 16, five epochs, warmup ratio 0.1, weight decay 0.01, maximum sequence length 512, and seed 42.

Reference-aware models. We recast detection as consistency between A_{gold} and A_{gen} and fine-tune CAMeLBERT, ARBERT, MARBERTv2, and multilingual variants. Soft-vote ensembles average hallucination probabilities. The strongest internal NLI ensemble reaches 0.9519 clean AUC, but it was not evaluated on the final hidden test. This ensemble includes sawb-arabert-large, a checkpoint previously trained on 2,904 external Arabic hallucination examples; the officially scored CAMeLBERT submission does not use this resource. Appendix B.1 reports the full ensemble progression.

Reference-free transfer and representation learning. A MARBERTv2 student is trained from an NLI teacher with

$$\mathcal{L}_{KD} = (1-\alpha)\mathcal{L}_{CE} + \alpha T^2 D_{KL}(p_t^T \| p_s^T), \quad (3)$$

where $T = 2$ and $\alpha = 0.3$ (Hinton et al., 2015). A separate LoRA-InfoNCE experiment freezes CamelBERT-MSA, adds LoRA adapters ($r = 16$, $\alpha = 32$) and a $768 \to 768 \to 128$ projection head, and trains in-batch contrastive pairs. The task-specific component contains 1,278,848 trainable parameters (about 4.89 MB).

Uncertainty. The single-model reliability study uses a separately trained CAMeLBERT replicate with the same reference-free architecture and $Q + A_{\text{gen}}$ input framing as the scored submission. This replica is distinct from the official checkpoint. We perform 30 MC dropout passes, apply temperature scaling, and evaluate uncertainty based on selective prediction. A separate dynamic-fusion study combines CAMeLBERT, AraBERT, and XLM-R using per-instance MC-Dropout uncertainty. Fusion hyperparameters are selected from out-of-fold training predictions, with the development set reserved for final evaluation.

5 Results & Analysis

5.1 Reference access and generalization

Table 2 compares the reference-free and reference-aware variants across evaluation settings. Only the scored CAMeLBERT system was evaluated on the hidden test (n=1,030), achieving 0.7596 ROC-AUC; E01–E06 are development diagnostics. Using the gold answer consistently improves performance for both ARBERT and MARBERTv2.

System	Full dev ($n = 1{,}300$)	Clean dev ($n = 800$)	Held-out ($n = 200$)
Reference-free ($Q + A_{gen}$)			
CAMeLBERT (scored)	.9263	.8713	–
CAMeLBERT QA (E03)	.9015	.8618	.7513
ARBERT QA (E02)	.9084	.8732	.7889
MARBERTv2 QA (E01)	.9016	.8751	.7589
MARBERTv2 KD (E06)	.9004	.8799	.7637
Reference-aware ($A_{gold} + A_{gen}$)			
ARBERT NLI (E04)	.9651	.9355	.9489
MARBERTv2 NLI (E05)	.9595	.9342	.9470
Δ ARBERT	+.0567	+.0623	+.1600
Δ MARBERTv2	+.0579	+.0591	+.1881

Table 2: ROC-AUC by evaluation split. Clean dev contains the 800 development rows whose questions do not appear in training; the held-out split contains 200 examples and measures joint generator/topic shift.

5.2 Controlled ablations, alternatives, & stability

Rather than pooling heterogeneous experiments into one ranking, Table 3 summarizes controlled within-track ablations and comparisons that answer three narrower questions: whether teacher knowledge transfers without the reference, whether contrastive training makes similarity directly useful, and whether conclusions are sensitive to fine-tuning variation. These comparisons are interpreted only within their respective protocols.

Diagnostic	Controlled comparison / result
Distillation transfer	MARBERTv2 QA → KD: +.0048 Clean AUC and +0.0048 reference-aware held-out generator.
Contrastive geometry	Cosine Dev AUC: frozen .6527; BCE 0.5318; InfoNCE **0.8746**. With RF heads: 0.9215/0.9163/0.9178
Seed stability	Reference-aware MARBERTv2: single 0.9032 Dev AUC; 3-seed probability ensemble **0.9172**.

Table 3: Targeted diagnostics for reference-free transfer, representation quality, and training stability. Values are interpreted only within each row's protocol.

Distillation recovers only a small fraction of the reference-aware advantage. InfoNCE is most useful as evidence that the embedding geometry itself becomes informative, not as a universal improvement once supervised nonlinear heads are added. The seed study separately shows that single-run development scores can vary enough to warrant stability reporting.

5.3 Calibration & Selective Prediction

The uncertainty experiments highlight the distinction between ranking performance and decision reliability. In the three-model reference-free fusion study, entropy-based dynamic weighting achieves a development ROC-AUC of 0.93236, essentially matching the best fixed weighted ensemble (0.93212) and the logistic-regression meta-learner (0.93184). The fixed weights (CAMeLBERT/AraBERT/XLM-R = 0.40/0.25/0.35) are selected from out-of-fold training predictions rather than the development set. Thus, uncertainty provides little additional ranking benefit in this setting. Table 9 in Appendix B.3 reports the corresponding bootstrap intervals.

The benefit of uncertainty is more apparent for the separately trained CAMeLBERT reliability replicate. On the 1,300-instance development set, the replicate achieves 0.9155 ROC-AUC and 0.8592 accuracy, compared with 0.9263 ROC-AUC for the official CAMeLBERT system. Table 4 summarizes the resulting reliability metrics. Temperature scaling improves probability calibration, while MC-Dropout variance achieves the lowest area under the risk-coverage curve among the evaluated selection signals. Appendix C presents the complete calibration and risk-coverage analyses.

Reliability measure	Before	After / selected
ECE ↓	0.0993	**0.0562**
NLL ↓	0.5401	**0.4027**
Brier ↓	0.1227	**0.1148**
Retained-set error ↓	14.08% (100% cov.)	**8.35%** (70% cov.)

Table 4: Core reliability results for the separately trained reference-free CAMeLBERT reliability replicate on development data.

6 Error Analysis

At threshold 0.5, the CAMeLBERT reliability replicate correctly classifies 1,117 of 1,300 development examples (accuracy 0.8592; Macro-F1 0.8568), with 473 TN, 644 TP, 74 FP, and 109 FN (Appendix C). The larger false-negative count shows that some hallucinated answers remain undetected.

Calibration does not eliminate confidently wrong predictions: among 987 predictions with calibrated confidence $\geq$ 0.90, 91 are wrong (9.22%): 64 FN and 27 FP. The gold answer is used only for post-hoc inspection and is never provided to CAMeLBERT at inference. These examples show why uncertainty supports triage but cannot replace factual verification of individual cases.

Error		Arabic example
False negative	**Q:**	من مؤسس علم التاريخ عند العرب؟
	Generated:	ابن هشام
	Gold:	اليعقوبي
		$p(\text{hall}) = .0154$; conf. $= .9846$
False positive	**Q:**	ما أكثر عنصر في القشرة الأرضية؟
	Generated:	الأكسجين
	Gold:	الأكسجين
		$p(\text{hall}) = .9480$; conf. $= .9480$

Table 5: Two verified high-confidence errors made by the CAMeLBERT reliability replicate.

7 Limitations

Several limitations should be considered when interpreting these results. Most analyses are evaluated only on the development data, limiting conclusions about generalization to the hidden test set. Reference-aware models require gold answers unavailable in the official setting, and calibration is evaluated in-sample.

8 Conclusion

In this study, we provide a broader study of generalization and predictive reliability for

Arabic hallucination detection. Our template-compliant reference-free CAMeLBERT cross-encoder achieved 0.7596 ROC-AUC on the hidden test set, ranking third among seven teams. Development-set analyses showed that reference-aware answer-pair framing substantially improves discrimination, while uncertainty estimation improves calibration and selective prediction without increasing ROC-AUC. Future work should evaluate these methods under independent calibration data and more controlled distribution shifts.

Appendix

A Reproducibility and Implementation Details

This section collects the input templates and core settings needed to reproduce the main comparisons. The official submission is an encoder classifier rather than a prompted generative LLM, so there is no generation prompt or decoding configuration for the official inference path.

For the clean-development diagnostic used in the official-system experiment log, 800 development rows are retained because their questions do not occur among the 2,221 unique training questions; roughly 500 of the 1,300 development rows correspond to overlapping questions. This split is used as a generalization diagnostic rather than as an alternative official score. For the official CAMeLBERT run, the released Arabic strings are not subjected to an additional normalization stage. The question and generated answer are tokenized as a paired input with a maximum length of 512.

Setting	Input template
Official / reference-free	[CLS] question [SEP] model_answer [SEP] [CLS] gold_answer [SEP]
Reference-aware diagnostic	model_answer [SEP]

Table 6: Cross-encoder input templates. The official submission never uses the gold answer at inference.

Experiment	Key configuration
Official CAMeLBERT	$Q + A_{gen}$; max 512; 5 epochs; batch 16; seed 42.
ARBERT QA (E02)	$Q + A_{gen}$; max 256; 2 epochs; batch 16; seed 42.
ARBERT NLI (E04)	$A_{gold} + A_{gen}$; max 256; 4 epochs; batch 16; seed 42.
MARBERTv2 QA (E01)	$Q + A_{gen}$; max 256; 2 epochs; batch 16; seed 42.
MARBERTv2 NLI (E05)	$A_{gold} + A_{gen}$; max 256; 3 epochs; batch 16; seed 42.
MARBERTv2 KD (E06)	$Q + A_{gen}$; max 256; 2 epochs; $T = 2$, $\alpha = .3$.
CAMeLBERT uncertainty	$Q + A_{gen}$; max 512; 5 epochs; batch 16; seed 42; 30 MC-Dropout passes.

Table 7: Core training configurations. E01–E06 use learning rate 2×10^{-5}, weight decay .01, and 10% warmup.

LoRA-InfoNCE freezes CamelBERT-MSA and trains LoRA adapters ($r = 16$, scaling 32) plus a $768 \rightarrow 768 \rightarrow 128$ projection head, for 1,278,848 trainable task-specific parameters. The CAMeLBERT uncertainty study uses the same reference-free model and input framing as the official architecture, 30 MC-Dropout passes, 15 ECE bins, a 0.90 high-confidence threshold, a 0.5 classification threshold, and a temperature of 1.6203 fitted on the same 1,300-example development set used for calibration evaluation.

B Additional Diagnostic Results

These supporting results are grouped by protocol and should not be read as a common leaderboard.

B.1 Reference-aware ensemble progression

Variant	Models	Clean
S23	CAMeLBERT + MARBERTv2	.9373
S24v	S23 + ARBERT	.9478
S25v	S24v + mBERT	.9497
S25v2	CAMeLBERT + ARBERT + mBERT + sawb-arabert-large	**.9519**

Table 8: Reference-aware ensemble progression. Values are diagnostic Clean AUC, not hidden-test scores.

S23 was scored on the CodaBench development leaderboard; later variants were internal only. S25v2 includes sawb-arabert-large, previously trained on 2,904 labeled examples from a prior Arabic hallucination project. This external resource is not part of the official CAMeLBERT submission.

B.2 Additional official-system ablations and negative results

Holding CAMeLBERT fixed while changing the input framing from reference-free QA (S01) to reference-aware NLI (S02) raises Clean AUC from 0.8713 to 0.9272 (+0.0559), reinforcing the effect of direct reference access. Two discarded runs provide additional negative evidence: a zero-shot LaBSE cosine-similarity baseline (S22) reaches 0.6212 Clean AUC and 0.6768 full-development AUC, while focal loss on the sawb-arabert-large NLI model (S30) reaches 0.8886 Clean AUC and exhibits unstable epoch-level AUC. Neither run was used in the official submission.

B.3 Reference-free fusion

Fusion method	Dev AUC	Bootstrap 95% CI
Fixed weighted	.93212	[.91804, .94469]
Entropy dynamic	**.93236**	[.91809, .94487]
Logistic stacking	.93184	[.91749, .94465]

Table 9: Three-model reference-free fusion. Fixed weights were selected on out-of-fold training predictions (CAMeLBERT/AraBERT/XLM-R = 0.40/0.25/0.35).

C Reliability and Error Analysis

The reliability analysis uses the separately trained reference-free CAMeLBERT reliability replicate,

distinct from the official checkpoint. The figures and tables below follow the same sequence as the main discussion: calibration, selective prediction, then threshold-level classification errors.

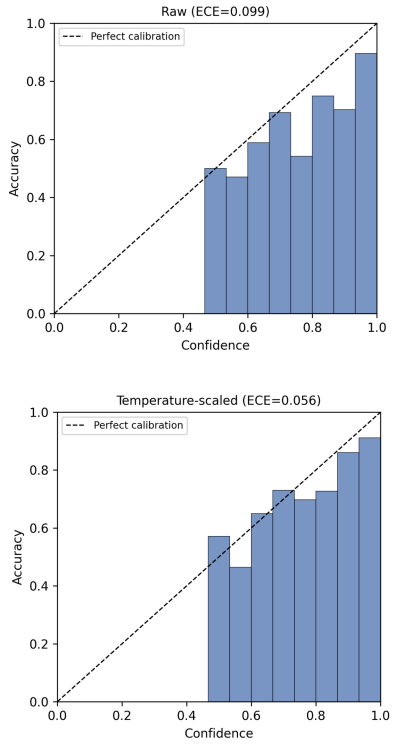

Figure 1: CAMeLBERT reliability diagrams before and after temperature scaling.

Estimate	ECE	NLL	Brier
Raw	.0993	.5401	.1227
Temp.-scaled	**.0562**	**.4027**	**.1148**
MC-Dropout mean	.0829	.4659	.1171

Table 10: CAMeLBERT calibration diagnostics; lower is better.

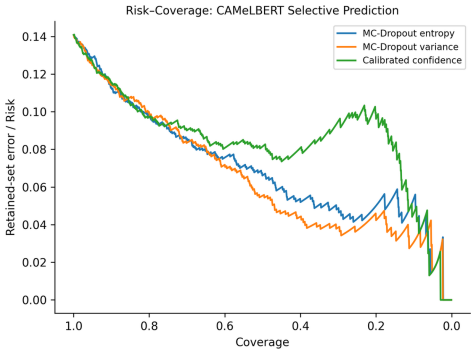

Figure 2: Selective risk–coverage for CAMeLBERT. Lower retained-set risk is better as uncertain cases are deferred.

Signal	AURC	R@90	R@70	R@50
MC-Dropout variance	**.0655**	.1145	**.0835**	**.0554**
MC-Dropout entropy	.0704	**.1128**	.0857	.0662
Calibrated confidence	.0852	.1154	.0901	.0815

Table 11: CAMeLBERT selective-prediction diagnostics. R@k is retained-set error at k% coverage; lower is better.

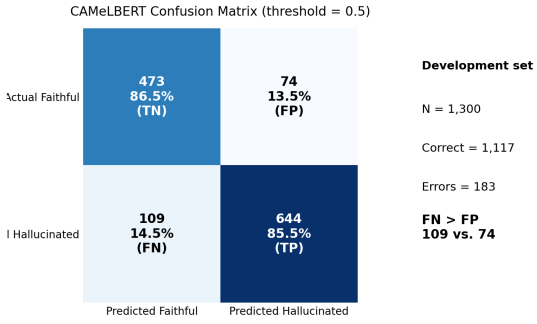

Figure 3: CAMeLBERT development confusion matrix at threshold 0.5: 473 TN, 74 FP, 109 FN, and 644 TP. False negatives are more frequent than false positives at this operating point.

D Dataset Structure

The task uses a binary gold annotation, while systems output a continuous hallucination score in $[0, 1]$. Topic tags in the dataset-structure figure below are inferred from training identifiers and are not official annotations. Topic and generator are structurally paired in the released split, so the displayed rates are descriptive rather than independent topic or generator effects.

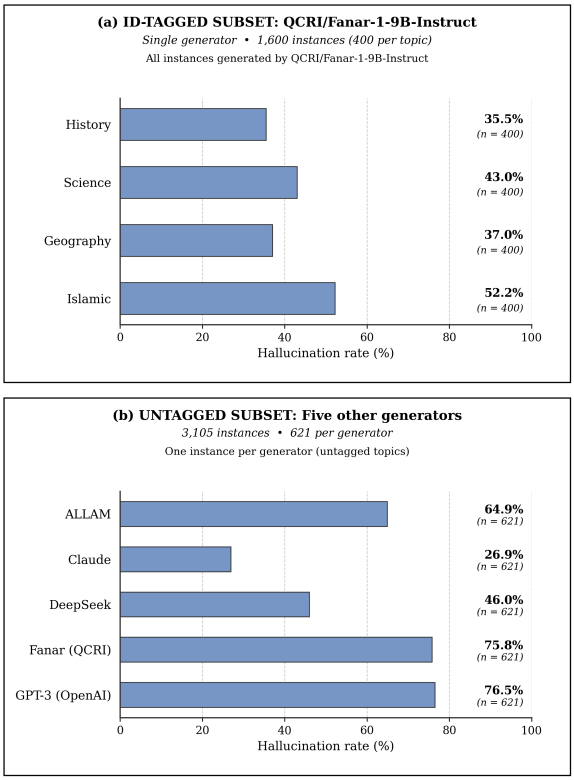

Figure 4: Training-set structure and observed hallucination rates. Top: the ID-tagged subset contains four inferred topic tags generated by QCRI/Fanar-1-9B-Instruct. Bottom: the untagged subset contains 621 instances from each of five other generators.

REGLAT at HalluScoring-2026: A Multistage Approach for Arabic Hallucination Detection

Abstract

This paper presents a multistage ensemble-based approach developed for the HalluScoring-2026 shared task on Arabic hallucination detection. The proposed system combines three Arabic pretrained language encoders: MARBERTv2, CAMeLBERT, and ARBERT. The diverse linguistic representations captured by these models enable the ensemble to improve the robustness and discriminative capability of hallucination detection compared to the individual encoders. On the development set, the ensemble achieved an AUC-ROC of 0.9413, Macro-F1 of 0.8704, and an AUC-PR of 0.9610, outperforming the individual models. On the official test set, the system achieved an AUC-ROC of 0.7717, Macro-F1 of 0.6576, and an AUC-PR of 0.9181. These results secured the highest overall ranking among all submitted systems, placing our system first in the HalluScoring-2026 shared task. Further analysis reveals substantial variation in detection performance across generator models and linguistic phenomena, with subtle factual deviations, dialectal and culturally specific expressions, and unusually long responses posing particular challenges. Overall, the findings demonstrate the effectiveness of combining distinct Arabic-specific pretrained encoders for robust Arabic hallucination detection.

1 Introduction

Large language models (LLMs) have achieved strong performance in question answering and text generation, but they can still produce fluent responses containing fabricated, unsupported, or factually inconsistent information, commonly known as hallucinations (Huang et al., 2025). Reliable hallucination detection is an essential task for trustworthy AI, particularly for low-resource languages such as Arabic. Compared with English, Arabic hallucination detection remains relatively underexplored due to limited benchmarks and standardized evaluation settings (Mubarak et al., 2024; Alansari and Luqman, 2025). Arabic presents additional challenges because of its rich morphology, lexical variation, and substantial differences between Modern Standard Arabic, regional dialects and domain-specific texts (Diab and Habash, 2014; Labib et al., 2026; Sobhy et al., 2025; Ehab et al., 2026). These characteristics can make subtle factual and semantic inconsistencies more difficult to identify, highlighting the need for Arabic-focused hallucination detection methods (Mubarak et al., 2024; Alansari and Luqman, 2025). The HalluScoring-2026 shared task addresses this gap by providing a standardized framework for detecting hallucinated responses in Arabic question answering.

In this work, we present a multistage ensemble approach that combines various Arabic pretrained language encoders for hallucination detection. The proposed system exploits diverse representations from multiple Arabic models through probability-level ensembling and is evaluated under the official HalluScoring setting. Our results demonstrate the effectiveness of Arabic-specific ensemble modeling for reliable hallucination detection in Arabic QA.

2 Background

The HalluScoring-2026 shared task (Alansari et al., 2026) focuses on detecting hallucinated content in Arabic responses generated by large language models (LLMs). We participate in **Task 1.1: Generalization Across Questions**, which formulates hallucination detection as a binary classification problem. Each instance contains an Arabic question q, a verified gold answer a_g, and a model-generated answer a_m. The system predicts a binary label $y \in \{0, 1\}$, where 0 denotes a non-hallucinated response and 1 denotes a hallucinated

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1146–1153
October 28-29, 2026 ©2026 Association for Computational Linguistics

response. A response is non-hallucinated when it is factually consistent with the gold answer, including acceptable paraphrases or omitted details that introduce no false information. Conversely, a response is hallucinated when it contains fabricated or incorrect information, contradicts the reference, or introduces false information into an otherwise correct answer (Alansari and Luqman, 2026).

An example from the dataset illustrates the task. For the question في أي سنة تخرج نزار قباني من جامعة القاهرة, the gold answer is تخرج من جامعة دمشق, whereas the answer generated by Allam is في عام ٥٤٩١. The response is labeled 1 (hallucinated) because it provides a plausible answer that is inconsistent with the reference. This illustrates how hallucinated responses can remain linguistically fluent and plausible despite containing factual inconsistencies.

Task 1.1 specifically evaluates **generalization across questions**. Evaluation questions are completely disjoint from those in the training data, while the same generator-model architectures are represented across the splits (Alansari and Luqman, 2026). The task, therefore assesses whether systems learn transferable signals of factual consistency rather than question-specific patterns.

The HalluScoring dataset consists of Arabic question-answer instances covering diverse domains, including Islamic studies, history, geography, science, literature, and general knowledge. Each instance contains an identifier, question, gold answer, generator model, generated response, and binary hallucination label, with labels withheld for the official test set (Alansari and Luqman, 2026). In the dataset version used in our experiments, responses originate from six LLMs: Claude-Sonnet, Allam, DeepSeek-V3, Fanar, GPT-o3, and QCRI/Fanar-1-9B-Instruct. Across the combined labeled training and development data, hallucinated examples account for 53.72% of the instances. The proportion is 52.56% in the training set and 57.92% in the development set. Further details on the dataset splits are provided in Section A. Hallucination detection is important for LLM reliability because generated responses can be fluent while containing fabricated, unsupported, or factually inconsistent information (Huang et al., 2025). Despite increasing attention to hallucination detection, Arabic remains comparatively underexplored. Mubarak et al. (2024) introduced *Halwasa*, an Arabic-focused resource for analyzing hallucinations in LLM-generated text, while Alansari and Luqman (2025) proposed *AraHalluEval*, a fine-grained framework for evaluating hallucinations in Arabic generative question answering and summarization. These studies highlight the need for robust Arabic-specific hallucination detection methods. Our work addresses this need under the HalluScoring-2026 Task 1.1 setting by combining three Arabic-specific encoders—MARBERTv2, CAMeLBERT, and ARBERT—through probability-level ensembling. These models capture distinct representations of Modern Standard and dialectal Arabic (Abdul-Mageed et al., 2021; Inoue et al., 2021). By integrating their predictions, our approach aims to improve hallucination detection robustness across unseen questions and heterogeneous LLM-generated responses.

3 System Overview

Our proposed framework combines three Arabic pretrained Transformer encoders such as MARBERTv2, CAMeLBERT, and ARBERT to provide robust hallucination detection across diverse Arabic questions and LLM-generated responses. As illustrated in Figure 1, the framework follows two stages: *independent model optimization* followed by *probability-level ensemble inference*. This design preserves the specialized representations learned by each encoder while exploiting their predictions in the final decision.

In the first stage, MARBERTv2, CAMeLBERT, and ARBERT are independently fine-tuned as binary classifiers, with the best checkpoint for each model selected according to development AUC-ROC. Rather than classifying the generated response in isolation, each model jointly encodes the question Q and generated answer A_m as:

$$[\text{CLS}]; Q; [\text{SEP}]; A_m; [\text{SEP}], \quad (1)$$

allowing the classifier to assess the generated response in the context of its corresponding question. In the second stage, the three selected checkpoints independently predict hallucination probabilities for the same input. Their logits are converted to probabilities using softmax, and the hallucinated-class probabilities from MARBERTv2, CAMeLBERT, and ARBERT, denoted by $p_M(x)$, $p_C(x)$, and $p_A(x)$, respectively,

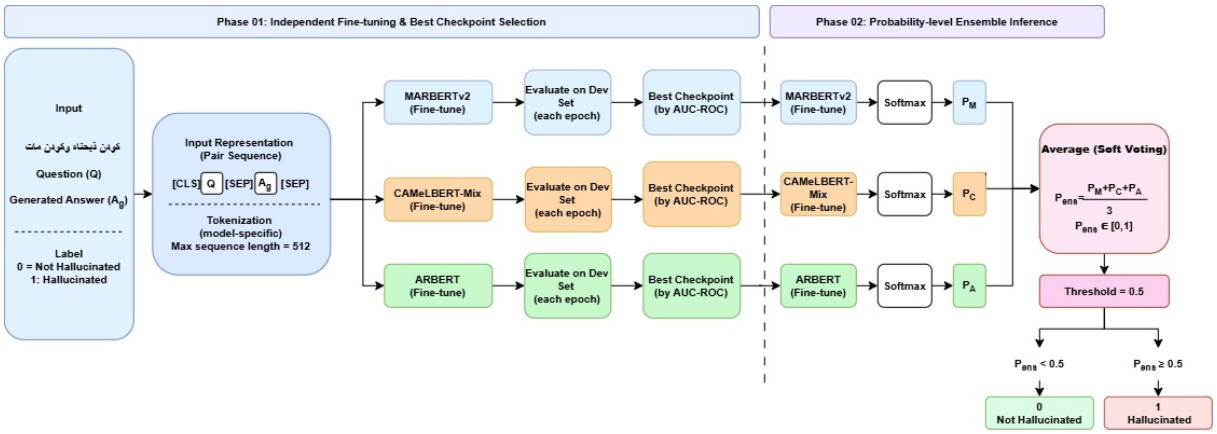

Figure 1: Overview of the proposed ensemble framework for Arabic hallucination detection.

are combined through unweighted soft voting:

$$p_{\text{ens}}(x) = \frac{p_M(x) + p_C(x) + p_A(x)}{3}. \quad (2)$$

Unlike hard voting, which discards prediction confidence by combining discrete labels, our framework directly integrates the probability estimates of the three encoders. Each model contributes equally, avoiding additional weighting parameters or ensemble-specific tuning. The final label is determined using a threshold of 0.5:

$$\hat{y}(x) = \begin{cases} 1, & p_{\text{ens}}(x) \geq 0.5, \\ 0, & p_{\text{ens}}(x) < 0.5, \end{cases} \quad (3)$$

where 1 and 0 denote hallucinated and non-hallucinated responses, respectively. We evaluate four configurations: MARBERTv2 (S1), CAMeLBERT (S2), ARBERT (S3), and the proposed ensemble (S4). S1–S3 represent the independently optimized classifiers, while S4 is the final submitted system. Importantly, the framework uses no additional task-specific labeled data beyond that provided by the shared-task organizers; external resources are limited to the three pretrained Arabic encoders and their tokenizers.

4 Experimental Setup

Our experiments are conducted on the HalluScoring-2026 Subtask 1.1 dataset (Alansari and Luqman, 2026), statistics and other details of the dataset have been reported in Appendix A. The task is formulated as a binary classification problem in which the objective is to determine whether a model-generated answer constitutes a hallucination (Label = 1) or not (Label = 0). For each instance, the classifier receives only the Arabic question and its corresponding model-generated answer as input. The verified gold answer provided in the dataset is not supplied to the model during training or inference; it is used only as part of the dataset annotation and reference framework for determining the ground-truth hallucination label.

4.1 Preprocessing and Hyperparameter Details

4.1.1 Preprocessing

We adopted a minimal preprocessing strategy to preserve the original linguistic and stylistic characteristics of the Arabic text. The HalluScoring dataset was provided with each generated answer already paired with its corresponding question; therefore, no additional question–answer construction or pairing was performed. The provided question–answer pairs were retained without aggressive normalization or linguistic transformations and were directly processed using the model-specific tokenizers available through the Hugging Face Transformers library. Specifically, CAMeLBERT[1] uses a vocabulary of 30,000 tokens, while MARBERTv2[2] and ARBERT[3] each use vocabularies of 100,000 tokens. For all three models, the maximum input sequence length was set to 256 tokens, with sequences exceeding this limit truncated during tokenization. This minimal preprocessing setup was intentionally maintained to preserve potentially informative lexical and stylistic cues relevant to hallucination detection.

4.1.2 Hyperparameter Configuration

All three BERT-based models were fine-tuned using the same hyperparameter configuration to ensure a consistent comparison. Appendix B summarizes the training setup. Focal Loss (Lin et al., 2017) with $\gamma = 2.0$ was employed primarily to emphasize difficult and ambiguous examples. In preliminary development experiments, Focal Loss slightly improved ensemble AUC-ROC compared with standard cross-entropy (0.9413 vs. 0.9397), and was therefore retained in the final configuration. Final predictions are obtained using the unweighted soft-voting ensemble described in Section 3, with a decision threshold of 0.5. During development, we additionally evaluated Qwen2.5-1.5B-Instruct with LoRA as an exploratory baseline, and a detailed description of this baseline is given in Appendix C.

Experiments were conducted on Google Colab using an NVIDIA Tesla T4 GPU (15.6 GB VRAM). The implementation uses PyTorch (Paszke et al., 2019) and Hugging Face Transformers (Wolf et al., 2020), with a fixed random seed of 42 for reproducibility.

4.2 Task Evaluation Metrics Summary

Following the HalluScoring-2026 evaluation protocol, AUC-ROC is used as the primary ranking metric, while Macro-F1 provides a class-balanced evaluation. We additionally report AUC-PR and per-class precision, recall, and F1-score. We assess pairwise differences between model predictions on the development set using McNemar's test at a significance level of $\alpha = 0.05$. Class 0 represents *Not Hallucinated*, while class 1 represents *Hallucinated*.

5 Results

In this section, we present and interpret the experimental results of our Arabic hallucination detection system, discussing findings alongside the results rather than as a separate block.

We report the performance of the four system configurations: MARBERTv2, CAMeLBERT, ARBERT, and their soft-voting ensemble together with an exploratory LoRA-tuned Qwen2.5-1.5B-Instruct development baseline on the HalluScoring-2026 Subtask 1 dataset, using AUC-ROC as the primary metric alongside Macro-F1 and AUC-PR. We then compare the individual configurations and examine the factors behind their relative performance, including the ensemble's gains from diversity, variance reduction, and calibration. We next examine how detection difficulty varies across the six generator models represented in the data, before turning to a detailed error analysis of misclassification patterns, probability distributions, and linguistic factors.

5.1 Comparative Performance Across System Configurations

Table 1 compares the performance of the three Arabic-specific encoders, the proposed soft-voting ensemble, and the exploratory Qwen2.5-1.5B-Instruct baseline. The three Arabic-specific encoders achieve comparable development performance, with AUC-ROC scores above 0.92, while the proposed ensemble (S4) obtains the strongest development results. Based on this performance, the ensemble was selected as the final system for official shared-task submission and subsequently **ranked first** on the HalluScoring-2026 test set. The LoRA-adapted Qwen2.5-1.5B-Instruct model was evaluated only as an exploratory development baseline using the provided training and development splits and was not included in the final shared-task submission. Its lower development performance compared with the Arabic-specific encoders and their ensemble further supported the selection of the ensemble as the submitted system.

Table 1: Performance comparison of individual models and the ensemble configuration.

Configuration	Model	AUC-ROC	Macro-F1	AUC-PR
S0	Qwen2.5-1.5 + LoRA	0.9121	0.8244	0.9337
S1	MARBERTv2	0.9258	0.8551	0.9495
S2	CAMeLBERT	0.9274	0.8649	0.9434
S3	ARBERT	0.9268	0.8629	0.9453
S4	**Ensemble-Dev**	**0.9413**	**0.8704**	**0.9610**
S4	**Ensemble-Test**	**0.7717**	**0.6576**	**0.9181**

To determine whether the observed performance differences between the evaluated classifiers were statistically significant, we conducted pairwise McNemar tests on the development-set predictions using a significance level of $\alpha = 0.05$. Here, n_{01} denotes the number of instances for which the first model in the comparison was incorrectly classified while the second model was correctly classified, whereas n_{10} denotes the number of instances for which the first model was correct and the second was incorrect. The complete pairwise statistical comparison and discussion is given in Appendix F.

5.2 Model and Generator-Specific Performance Analysis

To examine whether the difficulty of hallucination detection varies across generator models, we analyze MARBERTv2 performance on responses from the six generators. As shown in Table E, performance varies substantially, with AUC-ROC ranging from 0.8707 to 0.9928. MARBERTv2 performs best on Claude-Sonnet responses (AUC-ROC = 0.9928; Macro-F1 = 0.9599), while QCRI/Fanar-1-9B-Instruct is the most challenging generator (AUC-ROC = 0.8707; Macro-F1 = 0.7884). The remaining generators achieve AUC-ROC scores between 0.9674 and 0.9784. The generator-specific class distributions also vary considerably, indicating that the observed performance differences may reflect both generator-specific response characteristics and differences in class balance and sample size. Overall, the results highlight substantial generator-dependent variation that may be obscured by aggregate performance metrics. Appendix D summarizes the predicted hallucination probabilities in detail.

6 Conclusion

This paper presented REGLAT, an ensemble of MARBERTv2, CAMeLBERT, and ARBERT for Arabic hallucination detection in HalluScoring-2026. The ensemble achieved an AUC-ROC of 0.9413, Macro-F1 of 0.8704, and AUC-PR of 0.9610 on the development set and ranked **first** in the official shared-task evaluation. Our analysis further showed that detection difficulty varies across generator models and linguistic characteristics, particularly for subtle factual errors, dialectal expressions, and extreme response lengths. These findings demonstrate the value of combining three Arabic-specific encoders for robust hallucination detection. Future work will explore dialect-aware modeling and improved detection of subtle factual inconsistencies.

7 limitations

To better understand the limitations of the proposed system, we analyzed misclassified development instances and predicted probability distributions. False positives often involve factually correct responses with uncommon information, elaborate paraphrases, or non-standard linguistic forms. Dialectal and culturally specific expressions also present challenges; for example, instances 507 and 508 contain the colloquial expression كودن ذبحناه وكودن مات. False negatives typically occur when otherwise plausible responses contain subtle factual errors, such as incorrect dates, numerical values, or attributions, or when incorrect information is embedded within an otherwise correct answer. Some errors may also reflect differences in reference-answer specificity. For example, one development instance asked ما الحدث الذي يُعد نهاية رمزية للحرب الباردة؟. The gold answer was قمة مالطا (١٩٨٩), whereas the generated response stated سقوط جدار برلين عام ١٩٨٩ يعتبر حدثًا رمزيًا لنهاية الحرب الباردة. هذا الحدث أدى إلى إعادة توحيد ألمانيا وساهم بشكل كبير في انهيار الاتحاد السوفيتي وتفككه لاحقاً، مما وضع حداً رسمياً للتوترات والصراع بين القوى العظمى خلال تلك الفترة. Although the generated response mentions the historically correct year 1989, it identifies the fall of the Berlin Wall rather than the Malta Summit as the reference event and was therefore labeled as hallucinated. The model nevertheless assigned a hallucination probability of only 0.0003, illustrating the difficulty of detecting subtle event-level factual mismatches in otherwise fluent and plausible responses.

The analysis further reveals systematic effects related to linguistic variation and response characteristics. Questions containing Gulf or Egyptian Arabic expressions produce higher error rates for MARBERTv2 and ARBERT, whereas CAMeLBERT is more robust on these cases. Mid-length responses (approximately 30–50 words) are classified more accurately than very short (< 10 words) or very long (> 80 words) responses, while responses containing explicit uncertainty markers are more frequently classified as hallucinated. These observations suggest that the models rely on both semantic information and linguistic or stylistic cues, including dialect, response length, and expressions of uncertainty.

Appendices

A Data Split Usage

The dataset is organized into two predefined splits: a training set comprising 4,705 samples and a development set containing 1,300 samples. The training set was used for model fine-tuning, while the development set was employed for model evaluation and selection. The detailed class distribution and statistics of both splits are summarized in Table 2. The dataset exhibits a relatively balanced class distribution, with a slightly higher proportion of Hallucinated instances. No separate labeled test set was provided; therefore, the development set was used to evaluate and compare the proposed models while the test set was kept blind.

Split	Total	Halluc.	Not Halluc.
Train	4,705	2,473 (52.56%)	2,232 (47.44%)
Dev	1,300	753 (57.92%)	547 (42.08%)
Total	**6,005**	**3,226 (53.72%)**	**2,779 (46.28%)**

Table 2: Class distribution across the training and development sets.

B Unified hyperparameter configuration used for all BERT-based models

Hyperparameter	Value
Batch Size	16
Learning Rate	2×10^{-5}
Max Epochs	5
Early Stopping Patience	3
Max Sequence Length	256
Optimizer	AdamW
Scheduler	Cosine with Warmup
Warmup Ratio	0.1
Weight Decay	0.01
Loss Function	Focal Loss ($\gamma = 2.0$)
Mixed Precision	FP16
Random Seed	42

C Exploratory Qwen2.5 Baseline

Qwen2.5-1.5B-Instruct with LoRA has been impleented to assess whether parameter-efficient adaptation of a generative LLM could provide competitive performance on the task. This experiment was conducted only on the provided training and development splits and was not part of the final submitted system. The model was trained for three epochs with a maximum sequence length of 384, learning rate of 1×10^{-4}, training batch size of 1, evaluation batch size of 4, and 16 gradient accumulation steps. LoRA was configured with rank $r = 32$, $\alpha = 64$, and dropout of 0.05, with a warmup ratio of 0.1, weight decay of 0.01, and random seed of 42.

D Predicted Hallucination Probabilities

Table 3 summarizes the predicted hallucination probabilities. The individual encoders produce mean probabilities between 0.5138 and 0.5214 and cover nearly the full probability range. The ensemble has a slightly lower standard deviation (0.3812) than the individual models (0.3821–0.3895), indicating a modest smoothing effect from probability averaging. Overall, the most difficult cases involve subtle factual deviations, dialectal and culturally specific expressions, extreme response lengths, and differences in reference-answer specificity.

Table 3: Probability distribution characteristics of the individual models and ensemble.

Model	Min Probability	Max Probability	Mean	Std Dev
CAMeLBERT	0.0001	0.9999	0.5214	0.3821
MARBERTv2	0.0016	0.9972	0.5138	0.3895
ARBERT	0.0015	0.9982	0.5182	0.3858
Ensemble	0.0023	0.9989	0.5178	0.3812

E Per-generator class distribution and MARBERTv2 performance on the development set

Generator	N	Halluc.	Not Halluc.	AUC-ROC	Macro-F1	AUC-PR
Claude-Sonnet	100	47 (47%)	53 (53%)	0.9928	0.9599	0.9930
Allam	100	78 (78%)	22 (22%)	0.9784	0.8645	0.9937
DeepSeek-V3	100	67 (67%)	33 (33%)	0.9769	0.9430	0.9906
Fanar	100	85 (85%)	15 (15%)	0.9710	0.9169	0.9946
GPT-o3	100	92 (92%)	8 (8%)	0.9674	0.8464	0.9971
QCRI/Fanar-1-9B-Instruct	800	384 (48%)	416 (52%)	0.8707	0.7884	0.8719
Overall	**1,300**	**753 (57.92%)**	**547 (42.08%)**	**0.9258**	**0.8551**	**0.9495**

F Pairwise McNemar Test

Table 4 reports results of the pairwise McNemar test on the development set. The McNemar analysis shows that the ensemble differs significantly from MARBERTv2 ($\chi^2 = 7.446$, $p = 0.0064$). In contrast, the differences between the ensemble and CAMeLBERT ($p = 0.1307$) and between the ensemble and ARBERT ($p = 0.0637$) are not statistically significant at the 0.05 level. Pairwise differences among the individual encoders are also non-significant. These results indicate that although the ensemble achieves the strongest overall development metrics, its improvement is statistically clear relative to MARBERTv2, while the gains over CAMeLBERT and ARBERT are more modest.

Table 4: Pairwise McNemar test results on the development set.

Model Comparison	n_{01}	n_{10}	χ^2	p-value
MARBERTv2 vs. Ensemble	44	21	7.446	0.0064
MARBERTv2 vs. CAMeLBERT	66	57	0.520	0.4707
MARBERTv2 vs. ARBERT	64	56	0.408	0.5228
Ensemble vs. CAMeLBERT	30	44	2.284	0.1307
Ensemble vs. ARBERT	21	36	3.439	0.0637
CAMeLBERT vs. ARBERT	65	66	0.000	1.0000

A noticeable performance gap is observed between the development and official test sets. The proposed ensemble decreases from an AUC-ROC of 0.9413 and Macro-F1 of 0.8704 on the development set to 0.7717 and 0.6576, respectively, on the hidden test set. Importantly,

this degradation was not unique to REGLAT. The official leaderboard shows that all participating systems experienced a decrease in AUC-ROC from development to test evaluation, with drops ranging from approximately 13.4 to 21.7 percentage points. This consistent pattern suggests that the hidden test set represented a substantially more challenging generalization setting for participating systems. Despite this shift, REGLAT achieved the highest official test AUC-ROC and secured first place in the shared task, indicating comparatively strong generalization under the more difficult hidden-test conditions.

Anhnamxtanh at HalluScoring-2026: Counterfactual Cross-Checking for Hallucination Detection and Answer Verification in Islamic Knowledge

Nguyen Tu Nam and Hiroki Takahashi
The University of Electro-Communications, Tokyo, Japan
g2340024@gl.cc.uec.ac.jp, rocky@inf.uec.ac.jp

Abstract

Hallucination detection in Arabic Islamic question answering is challenging because fluent answers may misstate a verse, narration, ruling, attribution, or historical fact. The task jointly requires detecting hallucination and recovering the factually correct option. We introduce C3R, a Counterfactual Cross-Check Recognition framework that couples these outputs through two role-conditioned predictions from one Arabic-centric language model: a truth role selects the factual option, while a match role selects the candidate that best matches the generated response. Training uses targeted counterfactual responses, hard distractors, option-order permutations, and completion-only supervision; no cross-view consistency loss is used. At inference, C3R scores valid structured completions, maps option probabilities from permuted presentations back to semantic identities, averages them, and derives the hallucination label from argmax agreement between the two roles. The cross-check is therefore applied only at inference. With a QLoRA-adapted ALLaM-7B backbone, C3R ranks first on the official test leaderboard with a final score of 0.8824, comprising 0.8673 macro-F1 and 0.8975 option accuracy. These results show that structured cross-role agreement can support strong performance in knowledge-sensitive hallucination detection and answer verification.

1 Introduction

Large language models (LLMs) often produce fluent but unsupported content, commonly described as hallucination (Ji et al., 2023; Huang et al., 2025). This is especially consequential in Arabic Islamic question answering, where a minor error in a name, verse, attribution, ruling, or date can create misinformation. Arabic resources document this problem (Mubarak et al., 2024), yet surface fluency remains weak evidence of factuality. A response may remain topical and grammatical while changing a verse number, legal condition, or chain of attribution. The setting therefore requires fine-grained distinctions among closely related religious and historical statements.

We study the Islamic-knowledge track of the HalluScoring 2026 shared task (Alansari et al., 2026), which requires both a hallucination label and the factually correct answer among six options. These outputs are structurally linked through the candidate that best represents the generated response: agreement with the factual option supports a non-hallucination decision, whereas disagreement supports hallucination. Treating them as independent classification problems discards this consistency constraint. Free-form generation requires mapping unconstrained text back to the fixed label set, while multiple-choice predictions can change under option reordering (Pezeshkpour and Hruschka, 2024; Wei et al., 2024).

To address these issues, we propose C3R, a Counterfactual Cross-Check Recognition framework. A shared model learns a truth role that selects the factual option while treating the generated response as untrusted, and a match role that selects the option expressing that response. Training combines gold-response and hard-negative counterfactuals with option permutations. Inference scores only valid completions, averages probabilities after mapping permuted labels back to their semantic identities, and declares the response non-hallucinated when the two roles select the same option. Here, cross-check denotes this inference-time agreement, not a cyclic training loss.

2 Related Work

Hallucination detection and factuality. Hallucination research covers detection and factual verification for open-ended outputs (Ji et al., 2023; Huang et al., 2025). HaluEval frames response-level discrimination (Li et al., 2023),

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1154–1159
October 28-29, 2026 ©2026 Association for Computational Linguistics

while FActScore decomposes outputs into atomic claims for evidence-based verification (Min et al., 2023). Evidence-free approaches instead use sampled disagreement, semantic perturbations, cross-model checks, or generated verification questions (Manakul et al., 2023; Zhang et al., 2023; Dhuliawala et al., 2024). These methods generally operate over free-form outputs and may require repeated generation or auxiliary verification. C3R obtains two role-conditioned distributions from one model over a fixed candidate set and derives the label directly from their agreement.

Arabic factuality and language models. Arabic hallucination detection remains comparatively underexplored. Halwasa provides 10,000 Arabic LLM-generated sentences annotated for factual and linguistic errors (Mubarak et al., 2024), and later work evaluates prompted recognition of Arabic hallucinations (Sibaee et al., 2024). HalluTruthQA extends response-level detection to error localization, explanation, and factual verification (Bouchekif et al., 2026), while HalluTruthQA-4K emphasizes expert construction and detailed error annotation (Bekhouche et al., 2026). C3R focuses on the shared-task Islamic setting and couples response-level detection with candidate selection, rather than span localization or explanation generation.

Robustness. Robust prediction can aggregate alternative views, as in self-consistency over reasoning paths (Wang et al., 2022). Multiple-choice models are also sensitive to option order, labels, and token choices (Pezeshkpour and Hruschka, 2024; Wei et al., 2024; Zhou et al., 2024). C3R treats option order as a nuisance variable: training remaps supervision under shuffling, while inference averages aligned option probabilities across deterministic presentations.

3 Counterfactual Cross-Check Recognition

3.1 Problem Formulation and Recognition Roles

Figure 1 summarizes the C3R training and inference pipelines. Each instance is $x = (q, g, \mathcal{O})$, where q is an Arabic question, g is a generated answer, and $\mathcal{O} = \{(k_j, o_j)\}_{j=1}^{K}$ is the candidate set. Here $K = 6$ and $k_j \in \{\mathrm{A}, \ldots, \mathrm{F}\}$. Let $a^\star$ be the factually correct option and let $m^\star = m(g, \mathcal{O})$ be the option that best matches g. C3R uses one model with two prompts: the TRUTH role treats g as untrusted and targets $a^\star$, whereas the MATCH role targets $m^\star$ without judging whether g is correct. For original examples, $m^\star$ is assigned by combining Arabic-normalized character similarity and token Jaccard overlap with weights 0.6 and 0.4; the counterfactual examples below have exact match targets.

Both roles target the constrained JSON completion $c(k) =$ `{"selected_option": "`k`"}` and differ only in their instruction and target option. Prompt tokens are masked, and standard autoregressive cross-entropy is applied only to completion tokens in the augmented training set. No cross-view consistency loss is used.

3.2 Counterfactual and Permutation Augmentation

For each labeled instance, C3R creates four variants: (i) the original TRUTH example targeting $a^\star$; (ii) the original MATCH example targeting $m^\star$; (iii) a positive match example with $g \leftarrow o_{a^\star}$ and target $a^\star$; and (iv) a negative match example with $g \leftarrow o_h$ and target h. The hard negative h is the incorrect option most similar to the gold option under the same Arabic-normalized similarity measure. These interventions change the response while keeping the question, candidates, and factual answer fixed.

Each variant is rendered in the original order and one seeded permutation ($R_{\text{train}} = 2$). Option symbols and targets are remapped together, preserving semantic identity and yielding eight supervised sequences per instance.

3.3 Constrained Likelihood Recognition

At inference, C3R scores rather than generates. For each role r, semantic option k, and presentation permutation π, it computes the length-normalized likelihood of the corresponding valid completion:

$$s_{r,k}^{(\pi)} = \frac{1}{|c(\pi(k))|} \sum_{t=1}^{|c(\pi(k))|} \log p_\theta(c_t(\pi(k)) \mid P_r(x^\pi), c_{<t}(\pi(k))) . \tag{1}$$

The scores are converted to option probabilities using a temperature-scaled softmax. After mapping display symbols back to semantic option identities, C3R averages the distributions over R_{test} deterministic presentations:

$$\bar{p}_{r,k} = \frac{1}{R_{\text{test}}} \sum_{\pi \in \Pi} p_{r,k}^{(\pi)} . \tag{2}$$

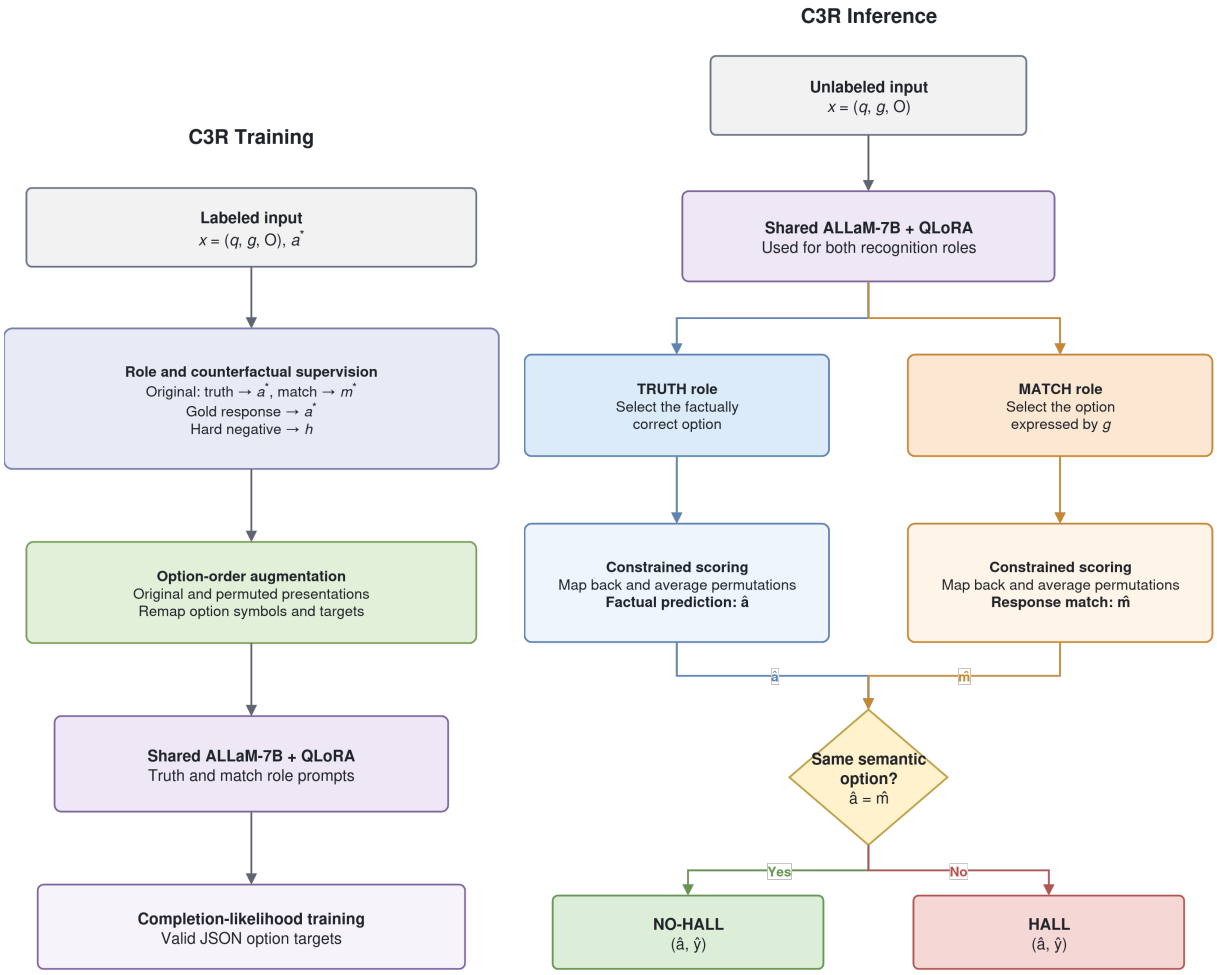

Figure 1: Separate C3R pipelines for counterfactual training (left) and cross-role inference (right).

Enumerating all candidates guarantees an in-set prediction and avoids parsing free-form output.

3.4 Cross-Role Agreement Decision

The two roles produce the factual prediction $\hat{a} = \arg\max_k \bar{p}_{\text{truth},k}$ and response-match prediction $\hat{m} = \arg\max_k \bar{p}_{\text{match},k}$. C3R declares the response non-hallucinated exactly when they identify the same semantic option:

$$\hat{y} = \begin{cases} \text{NO-HALL}, & \hat{a} = \hat{m}, \\ \text{HALL}, & \text{otherwise.} \end{cases} \tag{3}$$

Thus, cross-role agreement is used only as the inference decision rule in Eq. 3.

4 Experiments

4.1 Dataset and Task

We follow the Islamic-knowledge data release and task definition provided by the HalluScoring 2026 shared task (Alansari et al., 2026). The release contains 400 labeled training instances, 200 labeled development instances, and 400 test instances. Each instance consists of an Arabic question, an LLM-generated answer, and six closely related candidate answers indexed from A to F. Training and development instances additionally provide a binary hallucination label and the factually correct option; the corresponding test targets are hidden.

We use the 400 official training instances for adaptation and the 200-instance development set for the analyses reported below. In accordance with the shared-task rules, we use only the official data and no external resources. With one hard negative and two option presentations, the four role-specific variants in Section 3.2 produce 3,200 supervised completion sequences. The official test instances are kept separate and evaluated only through external evaluation.

4.2 Evaluation Metrics

The official score averages two output metrics: macro-F1 for hallucination labels and exact accu-

racy for factual-option predictions over A–F:

$$\text{FinalScore} = 0.5\,\text{MacroF1} + 0.5\,\text{OptionAcc}. \quad (4)$$

Macro-F1 balances the `no_hallucination` and `hallucination` classes, while option accuracy requires an exact match to the gold option. The gold option represents the generated answer for non-hallucinated instances and the corrected factual answer otherwise.

4.3 Implementation Details

C3R uses ALLaM-7B as its backbone (Bari et al., 2025). We adapt the model with QLoRA (Hu et al., 2022; Dettmers et al., 2023) for three epochs using learning rate 10^{-4}, per-device batch size 1, gradient accumulation over 16 steps, and maximum sequence length 2,048. The frozen backbone uses 4-bit NF4 double quantization. LoRA adapters with rank 32, scaling 64, and dropout 0.05 are applied to the query, key, value, output, gate, up, and down projections. At inference, C3R uses three deterministic option presentations, temperature $\tau = 0.1$, and the parameter-free argmax agreement rule. The checkpoint and inference configuration are fixed before development evaluation; no test-time threshold fitting or output repair is applied.

5 Results

Table 1 reports performance on the development and official test sets; C3R ranks first on the shared-task leaderboard. Relative to development, macro-F1 falls by 9.46%, whereas option accuracy falls by 4.25%, suggesting that factual recognition transfers more robustly than the cross-role decision.

Error analysis. Errors concentrate on responses that are only partially represented by the candidate set. Although cases without an exact response option constitute 55.5% of the test set, they account for 81.6% of label errors and 73.2% of option errors. The most difficult responses contain an additional qualifier or multiple claims that no single candidate captures. Three failure patterns emerge:

Split	Final	Macro-F1	Option
Dev.	0.9510	0.9619	0.9400
Test	0.8824	0.8673	0.8975

Table 1: C3R results with the ALLaM-7B backbone. "Final" is defined in Eq. 4.

the truth view can select an incorrect option even when cross-view disagreement yields the correct hallucination label; the match view can ignore an erroneous detail and produce accidental agreement; or both views can select the same semantically close distractor. Table 2 illustrates these failure modes.

ID	Outcome	Error case	Diagnosis
181	Label correct	A quotation by Zechariah is attributed to Moses.	T predicts the incorrect Moses option, while M selects a different option. Their disagreement correctly detects hallucination, but truth recovery fails.
268	Option correct	A valid definition of Sunnah divorce adds "one or two" pronouncements.	Both views select the gold one-pronouncement option, missing the added error.
240	Both wrong	Physical purification is confused with spiritual purification.	Both views select the same topically close but incorrect definition.

Table 2: Representative test errors. T and M denote the truth and match views.

6 Conclusion

We presented C3R, a structured recognition framework that jointly recovers the factual answer and detects hallucination through agreement between truth and response-matching roles. Counterfactual supervision, option permutations, and constrained likelihood scoring enable a QLoRA-adapted ALLaM-7B model to achieve a final score of 0.8824 and rank first on the official HalluScoring 2026 test leaderboard. The remaining errors mainly involve responses whose qualifiers or multiple claims are not fully captured by any single candidate, indicating that finer-grained response matching is a promising direction for future work.

Abstract

Large language models (LLMs) produce fluent but factually incorrect outputs which become significant when such models are applied to local languages, such as Arabic, because of the language's complex morphology, dialectal richness, and the insufficient material available for training and evaluation. The competition HalluScoring-2026 Track 1 aims to address these problems and consists of two tasks that demand hallucination detection in Arabic question-answering settings. To solve this issue, we transfer the knowledge of a powerful reference-based teacher that is a stacked ensemble of five fine-tuned encoder classifiers with dynamic lexical, embedding, and entailment characteristics onto a fine-tuned, open-weight generative student model whose input is restricted to exactly the fields available at test time.

1 Introduction

Although large language models (LLMs) are deployed for Arabic Q&A-type tasks, determining when an LLM's answer is fictitious or hallucinated remains challenging, as there are fewer tools for detecting hallucinations in Arabic than in English. The HalluScoring-2026 shared task (Alansari et al., 2026) addresses this directly: Track 1 (Tasks 1.1 and 1.2) poses hallucination detection as binary classification, where Task 1.1 evaluates generalization to unseen questions generated by the same set of LLMs, whereas Task 1.2 evaluates cross-model generalization by testing on hallucinations produced by previously unseen LLMs.

Our main system strategy is a two-stage teacher-student pipeline. First, we train a reference-based teacher, which is an ensemble of five fine-tuned encoder classifiers combined via a stacked meta-model with lexical, embedding-similarity, and natural language inference (NLI) features computed against the gold reference answer. Second, because the released test set omits the gold reference entirely (only the question and generated answer are provided), we distill the teacher's judgments into a fine-tuned generative student model whose input is restricted to exactly the fields the test set actually provides. Hence, the submitted system never depends on information it will not have at the time of evaluation.

2 Background

Task setup: Tasks 1.1 and 1.2 take as input a tuple (question, gold answer, generator model, generated answer) and require a binary hallucination label plus a continuous $P(\text{hallucinated}) \in [0, 1]$ as output. For example, consider the question *"What is thermal expansion?"* The gold answer states that it is *"an increase in the dimensions of a material as a result of an increase in its temperature."* In contrast, the generated answer states that thermal expansion is *"a decrease in the dimensions of a material when its temperature increases due to the contraction of molecules."* Because the generated answer directly contradicts the gold answer, its correct label is 1 (hallucinated). Critically, the released test set provides only the question and the generated answer with no gold reference and no label, which we treat as a hard constraint on any submitted system's inference-time inputs.

Dataset: The HalluScore dataset (Alansari and Luqman, 2026), used in Track1 of the HalluScoring 2026 shared task, consists of Arabic question–answer instances paired with LLM-generated responses annotated with binary hallucination labels. Both tasks 1.1 and 1.2 take place in a shared hallucination detection environment; however, they have different aims with respect to generalization. The training dataset consists of 4,705 samples with 2,221 questions. Task 1.2's dev dataset consists of samples generated by two hidden models. Therefore, task 1.2 represents a stricter probe of a de-

tector's performance in perceiving hallucination signals that do not depend on the generators rather than on the effects produced by the models present during training. The dataset distribution is as seen in the Table 1

Tracks: We participated in Track 1, submitting to both Task 1.1 and Task 1.2, using a single underlying system architecture (§3) trained separately per task on each task's respective data split.

Related work. Hallucination in machine-generated text is well-studied broadly (Saxena and Bhattacharyya, 2024), which categorizes hallucinations as intrinsic, extrinsic, factual, or faithfulness errors, but Arabic-specific evidence suggests the problem is both more severe and less studied: Sibaee et al. (2024) find that Arabic's morphological complexity compounds hallucination detection difficulty, and Mubarak et al. (2024) show empirically that roughly a quarter of ChatGPT/GPT-4-generated Arabic sentences in their Halwasa dataset are factually incorrect, underscoring the need for detection methods built for Arabic specifically, rather than transferred from English tooling.

The dominant approach to this problem is reference-based: comparing a candidate answer against a trusted reference via NLI-style entailment checking, lexical overlap, and embedding similarity (R, 2025). However, Kang et al. (2024)'s multilingual comparison shows this approach's central weakness for our setting: NLI-based metrics perform well for sentence-level hallucinations in high-resource languages but degrade on atomic facts and lower-resource languages where the regime Arabic falls into. More fundamentally, every reference-based method in this line of work assumes a trusted reference is available at evaluation time, an assumption that HalluScoring-2026's test set does not satisfy. We address this gap directly: rather than abandoning the strength of reference-based detection, we retain it during training and transfer its judgments through the knowledge distillation framework Hinton et al. (2015) into a student that operates without a reference at inference time.

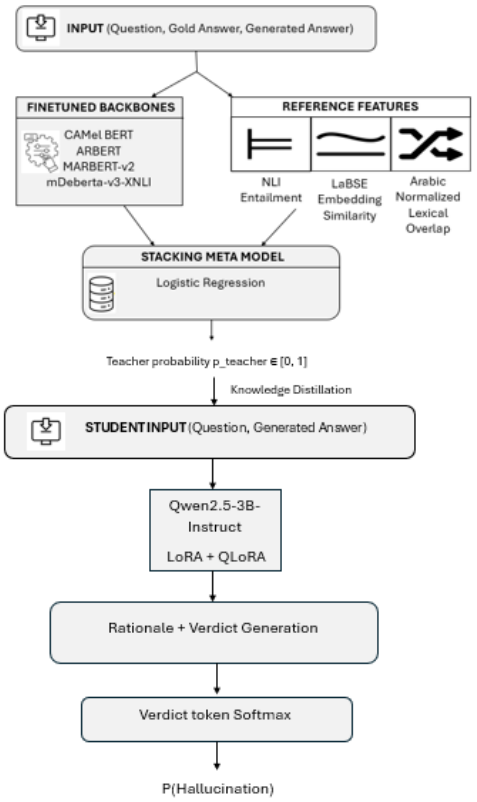

Figure 1: Overview of the Student-Teacher Model.

3 System Overview

3.1 Reference-Based Teacher Ensemble

We fine-tune five encoder classifiers on (question, gold answer, generated answer) triples: CAMeL-BERT (Inoue et al., 2022), ARBERT and MARBERTv2 (Abdul-Mageed et al., 2021), multilingual BERT, and an mDeBERTa-v3 NLI model. Out-of-fold (5-fold) predictions on the training split provide leakage-free inputs to a stacking stage. Along with these five backbone probabilities, we compute reference-based engineered features per instance such as NLI entailment/contradiction scores, LaBSE embedding cosine similarity, lexical (Jaccard) overlap, and named-entity/numeric mismatch indicators between the gold and generated answers. A logistic regression meta-classifier combines all of these signals and is validated with repeated stratified cross-validation. This teacher requires the gold reference answer and is therefore never itself submitted for test-set prediction. The overview of this student-teacher ensemble is as shown in the Figure 1.

Algorithm 1 Teacher-to-student distillation

Require: Training set $\mathcal{D} = \{(q_i, g_i, a_i, y_i)\}_{i=1}^{N}$; teacher T; features F_i; student S_θ; KL weight λ

$\mathcal{D}' \leftarrow \emptyset$
for each $(q_i, g_i, a_i, y_i) \in \mathcal{D}$ **do**
  $p_i \leftarrow T(q_i, g_i, a_i, F_i)$
  $\hat{y}_i \leftarrow 1[p_i \geq 0.5]$
  $r_i \leftarrow \textsc{Rationale}(g_i, a_i, F_i, \hat{y}_i)$
  $t_i \leftarrow r_i \,\|\, \textsc{Verdict}(\hat{y}_i)$
  $x_i \leftarrow \textsc{Prompt}(q_i, a_i)$
  $\mathcal{D}' \leftarrow \mathcal{D}' \cup \{(x_i, t_i, p_i)\}$
end for
for each minibatch $\{(x_i, t_i, p_i)\}_{i=1}^{B} \subset \mathcal{D}'$ **do**
  $s_i \leftarrow \textsc{Softmax}(S_\theta(x_i))$ over HALLUC. and NOT HALLUC.
  $\mathcal{L}_{\text{SFT}} \leftarrow \frac{1}{B}\sum_i \textsc{CrossEntropy}(S_\theta, x_i, t_i)$
  $\mathcal{L}_{\text{KD}} \leftarrow \frac{1}{B}\sum_i D_{\text{KL}}((p_i, 1-p_i) \,\|\, s_i)$
  $\mathcal{L} \leftarrow \mathcal{L}_{\text{SFT}} + \lambda \mathcal{L}_{\text{KD}}$
  Update θ using $\nabla_\theta \mathcal{L}$
end for

3.2 Distillation into a Reference-Free Student

The main challenge is to transfer the teacher's discriminative signal without transferring its dependence on the gold reference. For each training instance, we obtain the teacher's calibrated probability p_{teacher} and construct a supervised fine-tuning example whose *input* contains only the question and generated answer, and whose *target* is a short rationale stating the correct fact directly (e.g., "the correct answer is Canberra; the generated answer states something different") followed by a verdict token, rather than a rationale that references "the gold answer" as a field the student will not have.

We fine-tune Qwen2.5-3B-Instruct, an open-weight decoder under the shared task's 13B-parameter limit, using LoRA (Hu et al., 2025) with 4-bit quantization (QLoRA; Dettmers et al., 2023). The training loss combines a standard supervised fine-tuning term $\mathcal{L}_{\text{SFT}}$ with an auxiliary knowledge-distillation term $\mathcal{L}_{\text{KD}}$: a KL-divergence between the teacher's Bernoulli verdict distribution $(p_{\text{teacher}}, 1-p_{\text{teacher}})$ and the student's own predicted distribution over the "Hallucinated" vs. "Not Hallucinated" token at the position immediately following the prompt,

$$\mathcal{L} = \mathcal{L}_{\text{SFT}} + \lambda \cdot \mathcal{L}_{\text{KD}} \tag{1}$$

following the general distillation framework of Hinton et al. (2015), with λ controlling the weight of the calibration term relative to the standard fine-tuning loss. Algorithm 1 shows the full teacher-to-student distillation procedure.

During inference, the student model has access only to the question and the output answer. For each instance, we obtain its score, which is the softmax over just the two verdict tokens in the first position, allowing us to compute the AUC-ROC continuously. Additionally, we decode the full rationale for qualitative evaluation. No NLI or embedding or entity matching computations are performed at inference, and only the fine-tuned generative model is run.

Table 2: Official leaderboard results (%) for our submitted teacher and student systems on Tasks 1.1 and 1.2.

Task	System	Split	AUC-ROC	F1-M	AUC-PR
1.1	Teacher	Dev	97.91	94.66	98.57
1.1	Student	Dev	81.48	78.35	82.73
1.1	Student	Test	64.92	62.98	86.97
1.2	Teacher	Dev	99.58	96.28	99.75
1.2	Student	Dev	60.86	64.38	68.63
1.2	Student	Test	67.97	67.21	86.37

We submit a single system configuration to both Task 1.1 and Task 1.2, trained separately on each task's training/development split, with identical architecture.

4 Experimental Setup

Data splits. Backbones and the stacker are trained on each task's training split with out-of-fold predictions used for stacking. The student is fine-tuned on distillation data derived from the training split only.

Hyperparameters. The proposed model with full input encoding (question + gold answer + generated answer), default training epochs per backbone, and 5-fold out-of-fold prediction generation for stacking. Stacker uses a logistic regression meta-classifier, 5-fold $\times$ 5-repeat stratified cross-validation, and SMOTE oversampling enabled for Task 1.2 (smaller, more imbalanced dev split) but not for Task 1.1. The student model is a Qwen2.5-3B-Instruct base model, LoRA rank R=16, α=32, dropout 0.05, targeting all attention and MLP projection matrices (`q_proj`, `k_proj`, `v_proj`, `o_proj`, `gate_proj`, `up_proj`, `down_proj`), learning rate 2e-4, effective batch size 16 (per-device batch size 4 $\times$ gradient accumulation 4), 3 epochs, KL weight λ=0.5, max sequence length 768, 4-bit (QLoRA) quantization with non-reentrant gradient checkpointing, and single-GPU training.

5 Results

Quantitative findings. Table 2 reports our official leaderboard results. A striking pattern emerges across the two tasks: Task 1.1 AUC-ROC *drops* from 81.48 (dev) to 64.92 (test), a 16.6-point fall, while Task 1.2 AUC-ROC *rises* from 60.86 (dev) to 67.97 (test), a 7.1-point gain, the opposite direction. Since both tasks share the same training data and system configuration, this asymmetry is attributable to the composition of each task's unseen-generator dev/test splits rather than to the model itself. Task 1.2's dev split is small (200 instances, two anonymized generators) and imbalanced, so its dev AUC-ROC is a noisier estimate of true generalization than Task 1.1's; it is plausible that Task 1.2's particular dev-set generator pairing happened to be unusually difficult relative to its test-set pairing, while Task 1.1's dev pairing happened to be unusually easy relative to its test pairing. For the student, AUC-PR ranges from 68.63 to 86.97 across the reported development and test splits, suggesting the system retains strong precision-orientated ranking quality even where AUC-ROC fluctuates.

6 Conclusion and Future Work

We have developed a teacher-student architecture for the HalluScoring 2026 Tasks 1.1 and 1.2 that converts a powerful ensemble classifier that uses references into a generative model that does not rely on references. This demonstrates that task-defined reliability at the development/test scale splits input tasks and is as large a factor in overall performance as the gap between reference-based and reference-free architectures, since cross-model evaluation is sensitive to which unseen generators are included in the split. Nevertheless, the main limitation of the solution is that the student's knowledge (which has 3 billion parameters) cannot surpass the knowledge of the references used during distillation. Future research will focus on employing larger student backbones, removing the KL term, and conducting error analyses on official testing, with other pairs of generators held aside during the experiment.

Abstract

The rapid advancement of large language models (LLMs) has enabled powerful AI applications, yet hallucinations remain a major challenge to their reliability. As part of Track 2 of the HalluScoring 2026 shared task at ArabicNLP 2026, we present a system for detecting hallucinated answers and selecting the correct answer from six closely related candidates. We adapt the Arabic–English ALLaM-7B-Instruct model using Low-Rank Adaptation (LoRA) with domain-specific supervision from Qur'anic text, Hadith, Islamic law and inheritance, Islamic history, and general knowledge. The system jointly performs hallucination detection and answer selection, achieving 88.9% accuracy and 88.6% macro-F1 for hallucination detection, and 91.1% answer selection accuracy on the 800-instance development set. Error analysis identifies geography and structured-output parsing as the main remaining weaknesses.

1 Introduction

Over the last decade, natural language processing (NLP) has advanced rapidly with the emergence of Transformer-based large language models (LLMs) (Vaswani et al., 2017; Bounab et al., 2025). Arabic has received increasing attention due to the growing demand for robust language technologies and its unique linguistic characteristics (Bekhouche et al., 2025). Despite their ability to generate fluent Arabic text, multilingual and Arabic-specific LLMs remain susceptible to hallucinations, including unsupported names, dates, quotations, and factual claims. Such errors are particularly consequential in religious and legal contexts, where minor lexical changes can alter the meaning of a Qur'anic verse, Hadith, or inheritance ruling. Detection is further complicated by Arabic's rich morphology, spelling variations, and culturally specific knowledge.

HalluScoring 2026 addresses these challenges through a benchmark for hallucination detection, factuality verification, and trustworthy Arabic question answering (Alansari et al., 2026). Track 2 requires systems to determine whether a generated answer is hallucinated and select the correct answer from six closely related candidates. It comprises Task 2.1 on Islamic knowledge and Task 2.2 covering geography, science, history, and Islamic knowledge.

These tasks highlight the broader need for trustworthy LLMs, particularly in high-stakes applications where plausible but incorrect information can have serious consequences. Motivated by this need, this work makes the following contributions:

- A domain-adaptive training strategy that combines canonical Islamic material, controlled corruptions, inheritance reasoning, and broad synthetic factuality examples.
- A unified framework for jointly performing hallucination detection, candidate answer selection, and explanation generation.
- A reproducible evaluation on the HalluScoring 2026 development set, including domain-level and structured error analyses.

2 Related Work

Hallucinations remain a major challenge to the reliability of large language models (LLMs), motivating research on their characterization, detection, and mitigation. They are commonly categorized by factuality and faithfulness, or as intrinsic and extrinsic errors (Kumar, 2025; Cleti and Jano, 2024; Mohammadabadi et al., 2025; Pesaranghader and Li, 2026). Detection approaches include uncertainty and internal-state analysis (Hou et al., 2025; Aisin and Shamardina, 2025; Wang et al., 2025a), self-consistency and multi-agent reasoning (Friel and Sanyal, 2023; Sun et al., 2025), and external fact verification (Wang et al., 2025b; Su et al., 2025). Multilingual and domain-specific studies further

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1165–1170
October 28-29, 2026 ©2026 Association for Computational Linguistics

show that hallucination behavior varies across languages and applications (Islam et al., 2025; Joshi, 2025; Spracklen et al., 2025).

Arabic hallucination resources remain relatively limited. HalluScore (Alansari and Luqman, 2026) provides 827 curated Arabic questions with evidence, explanations, and human annotations of responses from 17 LLMs. HalluScoring extends this setting by jointly evaluating hallucination detection and selection among closely related candidate answers. MAWARITH (Bouchekif et al., 2026b) provides structured Arabic inheritance cases and intermediate legal decisions, which we use for domain-adaptive supervision while targeting the distinct task of factual hallucination detection and answer selection.

For efficient adaptation, LoRA (Hu et al., 2022) introduces trainable low-rank updates while keeping pretrained model weights frozen, reducing the cost of full fine-tuning. We apply LoRA to ALLaM-7B with a domain-adaptive Arabic corpus containing authentic and synthetic hallucination examples, formulating hallucination detection and answer selection as a unified instruction-following generation task for HalluScoring 2026.

3 Task Definition

Participants must jointly determine whether a generated answer is hallucinated and select the correct answer from six candidates. Each instance consists of a question q, generated answer g, optional reference r, and candidates $O = \{o_A, \ldots, o_F\}$. The system predicts a hallucination label $y \in \{\text{HALLUCINATION}, \text{NO-HALLUCINATION}\}$ and the correct candidate $z \in \{A, \ldots, F\}$. It additionally generates a justification and identifies erroneous spans for hallucinated answers, although only the label and candidate selection are used for quantitative evaluation.

Since these tasks are related but distinct, a correct candidate may be selected even when the hallucination label is incorrect, and vice versa. We therefore report label accuracy, macro-F1, candidate selection accuracy, and strict joint accuracy, which requires both predictions to be correct.

4 Benchmark & Domain-Adaptive Data

We evaluate our approach on **HalluTruthQA-4K**, the official Subtask 2.2 dataset of HalluScoring 2026, comprising 4,000 expert-annotated Arabic instances equally distributed across Islamic knowledge, history, science, and geography. Each instance contains a binary hallucination label and six candidate answers with one verified correct option, while hallucinated instances additionally include erroneous spans and human-written explanations. The official split contains 1,600 training, 800 development, and 1,600 held-out test instances (Bouchekif et al., 2026c; Bekhouche et al., 2026).

We further enrich the training data with approximately 30,000 domain-specific examples after filtering and deduplication, extending coverage of Islamic knowledge and fine-grained factual corruptions. As some source groups overlap after balancing, the component counts reported below do not represent unique examples.

- **Controlled hallucinations:** We generated 16,000 negative examples using localized corruptions, including character or word replacement, deletion, sentence modification, and changes to Surah names or verse numbers, exposing the model to subtle factual inconsistencies.
- **Canonical religious texts:** We include 8,000 Qur'anic and 4,000 Hadith examples, pairing authentic content with carefully constructed corrupted alternatives.
- **Inheritance and Islamic law:** We use 4,000 examples derived from MAWARITH (Bouchekif et al., 2026b), introduced for the QIAS 2026 shared task (Bouchekif et al., 2026a). ALLaM-generated answers were compared with annotated references, and discrepancies were converted into supervised hallucination examples.
- **Broader synthetic coverage:** We generated 17,000 candidate examples covering Fiqh, Islamic history, the biography of the Prophet Muhammad, and related topics.

For each question in the adaptation corpus, we generated both a factually supported answer and an intentionally hallucinated alternative. After format validation and quality filtering, the retained examples were incorporated into training. This diverse mixture exposes the model to both fine-grained textual corruptions and higher-level knowledge contradictions, while the inclusion of both positive and negative examples helps reduce bias toward classifying domain-specific statements as hallucinated.

5 System Description

5.1 Base model & Parameter-Efficient Fine-Tuning

The proposed system uses ALLaM-7B-Instruct-preview[1], an Arabic–English autoregressive Transformer (Bari et al., 2025) with 7B parameters, 32 decoder layers, a 4,096-dimensional hidden size, 32 attention heads, a 64K-token vocabulary, and a 4,096-token context length. Its bilingual pretraining and Arabic instruction tuning make it well suited for Arabic factuality verification.

We freeze the base model and apply LoRA to the attention and feed-forward projections using $r = 32$, $\alpha = 64$, dropout of 0.05, and no bias. This adds approximately 80M trainable parameters (1.1% of the model). Table 1 summarizes the fine-tuning configuration.

Hyperparameter	Value
Epochs	3
Per-device batch size	1
Gradient accumulation	16
Effective batch size	16
Learning rate	2×10^{-5}
Weight decay	0.01
Warm-up ratio	0.03
Scheduler	Cosine
Maximum sequence length	4,096
Precision	BF16
Gradient checkpointing	Enabled
Distributed optimization	DeepSpeed
Training objective	Completion-only LM loss
LoRA rank / alpha	32 / 64

Table 1: LoRA Fine-Tuning Configuration.

Completion-only loss masks the system and user tokens in each training sequence, so the loss is computed only over the target assistant response. This encourages schema compliance while preventing the model from learning to reproduce the input prompt.

5.2 Inference Pipeline

After fine-tuning, we load the frozen ALLaM checkpoint in BF16 on a single GPU and attach the PEFT adapter. The model is prompted through its chat template with an Arabic system message defining three tasks: hallucination detection, correct-option selection, and erroneous-span identification. The user message contains the question, generated answer, available gold reference, and six options (A–F). The model returns a JSON object with `predicted_label`, `predicted_answer`, `selected_option`, `justification`, and `hallucinations`.

Inference uses greedy decoding (`do_sample=False`) with a maximum of 384 generated tokens and processes one instance at a time. During post-processing, we extract the first JSON object, normalize the predicted label, and retrieve the selected option from `selected_option`, `predicted_answer`, or `pred_option`, in that order. Empty `span_start` or `span_end` values are replaced with `null` before JSON decoding, as these offsets are not required for evaluation.

6 Development Results & Error Analysis

6.1 Results

We evaluate on the 800-instance Task 2.2 development set, generated by `QCRI/Fanar-1-9B-Instruct`, with 200 instances each from Islamic knowledge, history, science, and geography. The set contains 359 hallucinated and 441 non-hallucinated answers.

All metrics include format failures; parsing exceptions are assigned HALLUCINATION with an empty answer option. Macro-F1 is the unweighted mean of both class F1 scores. Table 2 reports these local development results, which are not official test-set scores.

Metric	Score (%)
Hallucination-label accuracy	88.9
Label macro-F1	88.6
Correct-option accuracy	91.1
Strict joint accuracy	84.0
Valid structured outputs	96.5

Table 2: Results on the 800-instance Task 2.2 development set.

Table 2 shows that candidate selection is more accurate than binary hallucination detection. The label confusion matrix comprises 291 true positives, 420 true negatives, 21 false positives, and 68 false negatives. For the hallucination class, the model achieves a precision of 93.3%, a recall of 81.1%, and an F1 score of 86.7%. These results indicate that the model is conservative: hallucination predictions are usually correct, but some subtle or fine-grained hallucinations remain undetected.

[1] `humain-ai/ALLaM-7B-Instruct-preview`

To better understand the model's behavior across knowledge areas, we further analyze the development results by domain. Table 3 reports the label and answer-option accuracies for each of the four Task 2.2 domains.

Domain	Label acc.	Option acc.
Islamic knowledge	93.0	95.5
History	90.5	88.5
Science	93.0	99.0
Geography	79.0	81.5

Table 3: Development accuracy (%) by domain; each row contains 200 instances.

The results show clear domain differences. Geography is the most challenging, with the lowest label and option accuracies, while science achieves the highest option accuracy (99.0%). History is the only domain where label accuracy exceeds option accuracy, suggesting greater difficulty distinguishing among similar candidate answers.

6.2 Error Analysis

We qualitatively examine the main failure modes, focusing on subtle lexical differences, historical ambiguity, structured generation failures, and reference-based evaluation.

Small lexical substitutions. Difficult false negatives often involve a single incorrect name or character within an otherwise correct answer. For example, the model may produce the Tunisian *al-Qayrawan* instead of the Moroccan university *al-Qarawiyyin*, where high semantic similarity can obscure the localized factual error.

Ambiguous historical attribution. Some questions allow multiple interpretations. Muhammad ibn Tumart may be regarded as the spiritual founder of the Almohad movement, whereas Abd al-Mu'min established and expanded the ruling state. A single gold answer may therefore penalize otherwise defensible responses.

Structured generation failures. Twenty-eight of 800 outputs (3.5%) caused parsing exceptions, commonly due to missing character-offset values. Replacing these with `null` resolves some cases, while constrained decoding could further reduce such failures.

Reference leakage and realism. The development prompt includes reference answers when available, making the setting closer to reference-based verification than closed-book detection. The results therefore should not be interpreted as reference-free factual recall; an ablation without references is needed to assess this capability.

7 Conclusion

Large language models have advanced Arabic question answering, yet hallucinations remain a critical challenge. We presented a LoRA-adapted ALLaM-7B system for HalluScoring 2026, jointly addressing hallucination detection and answer selection through domain-adaptive supervision from authentic and synthetic Arabic data. The system achieved strong local development performance, particularly in Islamic knowledge and science, while geography, historical ambiguity, lexical substitutions, and structured output failures remain key challenges.

Future work will explore reference-free evaluation, constrained decoding, authoritative knowledge retrieval, cross-model validation, and systematic ablations of the training data to improve the robustness and reliability of Arabic hallucination detection.

Ethical Considerations

Religious texts and Islamic inheritance law are sensitive domains. This system is intended for benchmark research and error detection, not for issuing fatwas or determining legal shares. Synthetic corruptions should remain clearly separated from canonical sources to prevent their misuse as authentic material. Deployment should involve qualified Arabic-speaking domain experts and clearly communicate model uncertainty and supporting evidence to users.

Acknowledgments

This research was conducted within the LifeFact-Future (LFF) consortium[2], involving the University of Turku, the University of Helsinki, and Finnish life science and technology companies. We acknowledge Business Finland (Funding decision No. 6755/31/2023, LFF-HY 2024–2026) for supporting trustworthy AI and minimizing hallucinations in pharmaceutical applications. We also thank the HalluScoring 2026 organizers for preparing the shared task and benchmark dataset.

DzairVerse at HalluScoring-2026: Leak-Free QLoRA Fine-Tuning for Arabic Hallucination Detection and Truth Selection

Abdelmalek Chenini **Hacene Belhadef**
University of Constantine 2, Algeria
abdelmalek.chenini@univ-constantine2.dz
hacene.belhadef@univ-constantine2.dz

Abstract

Large language models answer fluently but not always truthfully, and catching a wrong answer is hardest in knowledge-sensitive domains such as Islamic question answering, where a confident but fabricated citation of Qur'an, Hadith, or jurisprudence is easy to produce and costly to miss. We study this through our participation in the HalluScoring 2026 shared task, Task 2 (Islamic Knowledge) (Alansari et al., 2026): given a question, a baseline-generated answer, and six candidate options, a system must decide whether the answer is hallucinated and then select the correct option. Our system is a single QLoRA adapter fine-tuned on Fanar-1-9B to reproduce the organizers' two-step inference, under a strictly leak-free setup, where no answer information beyond the question and generated answer enters the detection prompt, following our hypothesis that answer exposure inflates detection scores through leakage rather than judgment. On the official leaderboard our submission placed **second** of five teams, scoring 0.7582 on the blind track we targeted and 0.7881 on the assisted track. Controlled follow-up experiments support it: showing the options during detection is worth $+0.047$ Macro-F1 on both splits, and detection ability comes entirely from supervision, the frozen generator accepting its own output on all 400 test items. A 1,200-item probe, however, corrects our own initial diagnosis. The model is not blind to clean falsehoods, catching 80.5% of them; it is biased toward rejection, wrongly flagging 32.5% of verified-correct answers, and that single bias is the central limitation of the approach.

1 Introduction

Islamic question answering rewards precision and punishes plausible invention: Qur'anic references, Hadith and jurisprudence are easy to fabricate fluently and costly to get wrong. HalluScoring 2026 Task 2 (Alansari et al., 2026) turns this into a unified Arabic problem, built on the HalluTruthQA benchmark (Bouchekif et al., 2026b; Bekhouche et al., 2026) and motivated by the broader difficulty of detecting hallucination in generated text (Ji et al., 2023). Each instance gives a question, an answer from QCRI/Fanar-1-9B-Instruct and six close options (A–F); a system labels the answer, then selects the correct option, scored jointly as

$$\text{Final} = 0.5 \times \text{Macro-F1}_{\text{label}} + 0.5 \times \text{Acc}_{\text{option}}, \quad (1)$$

with the coupling rule that a wrong label makes the option wrong too. Two leaderboards are run: **A (Blind)**, where options are hidden during detection, and **B (Assisted)**, where they are visible; we targeted the harder Leaderboard A. Beyond the system we contribute the controlled experiments our original submission lacked: a leakage test, a frozen-model baseline, a large reliability probe, and evidence that the headroom left in this task lies entirely in detection.[1]

2 Background and Related Work

Data. The official Islamic splits contain 400 training, 200 development and 400 test examples in Modern Standard Arabic. Label priors differ sharply: 52.2% hallucination in training, 66.0% in development and 40.0% in test; as Section 4.4 shows, this inversion explains most of the development-to-test drop. One regularity shaped our design: in 97.5% of training and development items the generated answer copies an option verbatim, in all 259 `no_hallucination` items the copied option is the gold one, and no hallucinated item ever copies it ($0/326$). Selection is thus trivial whenever the label is trusted. This is a property of the splits we measured, not of the task: under the same matcher the test set copies an option in only 55.8% of items.

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1171–1175
October 28-29, 2026 ©2026 Association for Computational Linguistics

Related work. Our approach sits at the intersection of parameter-efficient fine-tuning (Hu et al., 2022; Dettmers et al., 2023) and Arabic pretrained language models (Antoun et al., 2020; Inoue et al., 2021), now routinely fine-tuned for Arabic classification (Djemmal and Belhadef, 2025). Evaluating LLMs on Islamic knowledge is an emerging line of work: Bouchekif et al. (2025) assess LLMs on Islamic legal reasoning through inheritance law and find fluent Arabic generation coexisting with unreliable rule application, and Bouchekif et al. (2026a) formalise this into MAWARITH, a dataset and benchmark for legal inheritance reasoning. Both show that surface fluency is a poor proxy for correctness here, the gap our probe (Section 4.6) measures. The base model, Fanar-1-9B-Instruct (Fanar Team, 2025), is Arabic-centric and built on Gemma-2 (Gemma Team, 2024), the same family that produced the dataset's answers, which makes self-evaluation bias a first-order concern.

3 System

Leakage hypothesis. Letting the model see information about the answer it must judge makes detection look easy: given a reference answer, or even the options, a fine-tuned model can learn to *compare* rather than to *judge*. We therefore adopted one rule: nothing beyond the question and the generated answer ever enters a detection prompt, and the gold answer is never read. A development variant placing the reference answer in the prompt reached ≈ 0.94 but would score ≈ 0.55 under the real protocol, which never supplies it. Section 4.3 tests the milder form, option exposure.

Model. Our submission is a single QLoRA adapter (Dettmers et al., 2023) on Fanar-1-9B-Instruct, fine-tuned to imitate the organizers' two-step inference. Each instance becomes two supervised samples using the official prompts verbatim: a blind detection sample (question + answer → `{"predicted_label": ...}`, no options) and a selection sample (question + answer + options → `{"selected_option": ...}`), with completion-only loss. Algorithm 1 is the inference it reproduces. A heterogeneous leak-free pipeline (AraBERTv02 with a 4-bit LLM judge and a selector ensemble) reached only 0.772 on development and is inadmissible under the single-model rule.

Algorithm 1 Two-step leak-free inference

Require: question q, generated answer a, options O
$\ell \leftarrow \textsc{Gen}(\textsc{DetectPrompt}(q, a))$ ▷ no options shown
$label \leftarrow \textsc{Parse}(\ell)$
$s \leftarrow \textsc{Gen}(\textsc{SelectPrompt}(q, a, O))$
$opt \leftarrow \textsc{Parse}(s)$; **if** $opt \notin \{A..F\}$ **then** $opt \leftarrow A$
return $(label, opt)$

Config	Ma-F1	Lbl Acc	Opt Acc	**Comb.**
A (r16, 3ep, 2e-4)	0.808	0.830	0.810	**0.809**
C (r16, 2ep, 2e-4)	0.783	0.795	0.800	0.792
B (r32, 3ep, 1e-4)	0.795	0.805	0.780	0.787
D (r32, rsLoRA)	0.398	0.660	0.175	0.286

Table 1: QLoRA sweep on development. All runs use `paged_adamw_8bit` except C (`adamw_torch`). The four differ in more than one factor each, so single-factor effects are not identified.

Setup. Configurations are trained on the 400 training examples and scored on the 200 development examples with the organizers' verbatim harness and Eq. (1); the submitted adapter retrains the winner on all 600. Table 1 reports the four we compared (Saadi and Belhadef, 2019). Configuration A is used throughout: 4-bit NF4 QLoRA, LoRA r=16, α=32, dropout 0.05 on all attention and MLP projections, `paged_adamw_8bit`, learning rate 2e−4 cosine, warmup 0.05, 3 epochs, effective batch 16, sequence length 2048, seed 42 and `attn_implementation="eager"` (Gemma-2 softcapping), on one Kaggle T4. Figure 1 tells the same story from the optimisation side: A, B and C descend smoothly below 10^{-2}, while the rsLoRA variant D (Kalajdzievski, 2023) never leaves its ≈ 0.11 plateau and spikes at step 40, a divergence visible long before it shows in the score. Because the four differ in more than one factor each, this grid selects a configuration but does not identify single-factor effects, and we make no such claim. We build on `transformers` and `peft`; the post-hoc experiments run on two T4s in ≈5.8 GPU-hours.

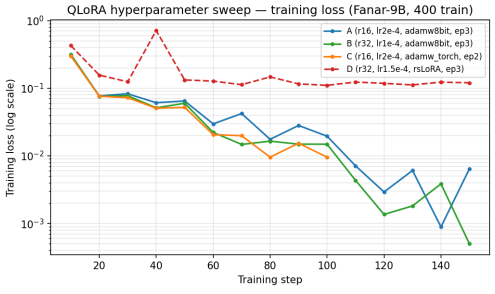

Figure 1: Training loss for the four sweep configurations (log scale).

4 Results and Analysis

4.1 Official result

The organizers placed us **second of five** on both tracks (Table 2), at 0.7582 blind and 0.7881 assisted. The two tracks order teams differently, though: every team except the leader gains +0.03 to +0.09 from seeing the options, whereas Anupamhashtag alone scores *higher* blind, which is independent evidence for the effect measured in Section 4.3.

4.2 A frozen baseline, and self-evaluation bias

Table 3 reports frozen Fanar-1-9B under byte-identical prompts and no adapter, scored generatively (what the harness does) and by constrained log-probability comparison of the two label strings, which cannot fail to parse. The two agree, so formatting is not the story. The story is that the frozen model is *degenerate*: it answers `no_hallucination` on 400/400 test items, giving Macro-F1 0.386 against a majority-plus-random floor of 0.289. Fine-tuning adds +0.357. This also quantifies the self-evaluation bias our design invites: asked to audit its own output, the generator never once flags it, so detection ability is created by supervision, not inherited.

4.3 Leak-free versus leaky detection

We trained two adapters from scratch in the same session, on the same 400 examples, with the same seed, configuration and library versions, differing *only* in whether the options appear in the detection prompt. Showing them raises detection Macro-F1 from 0.811 to 0.858 on development (+0.047) and from 0.754 to 0.800 on test (+0.046). The effect replicates at almost the same magnitude on both splits: a model given the options learns to compare against them rather than judge the answer on its own terms. Two qualifications. The gain is confined to detection, since option accuracy *falls* slightly (−0.005 dev, −0.028 test) and combined improves by only +0.021 and +0.009. And it is learned rather than intrinsic: frozen Fanar given the same leaky prompt moves +0.051 on test but −0.023 on development. The retrained leak-free arm reaches 0.811 against 0.808 in our original sweep, reproducing the pipeline to within 0.003 on a different software stack.

4.4 Test-set diagnostics

Figure 2 gives the test confusion matrix with option accuracy in each cell. Per class the system scores P 0.656 / R 0.775 / F1 0.711 on `hallucination` (n=160) and P 0.832 / R 0.729 / F1 0.777 on `no_hallucination` (n=240): it *over-flags*, predicting `hallucination` 189 times against 160 true positives. The coupling rule punishes this twice, because in the 65 false-positive cells a wrongly rejected answer is pushed off the copy-matching path and option accuracy collapses from 0.989 (true negatives, n=175) to 0.585. Selection is right 87.3% of the time when detection is right (n=299) and 62.4% when it is not (n=101): detection errors, not selection errors, are what cost us. The prior inversion explains this. The model was selected on a split that is 66.0% hallucination and evaluated on one that is 40.0%, and a threshold calibrated to the former must over-predict the positive class on the latter; Macro-F1 duly falls from 0.808 to 0.743 while option accuracy is unchanged at 0.810.

Validity and consistency. Because option accuracy could be inflated by a default, we logged every parse: the label was unparseable in 0/400 items and the option in 2/400 (0.5%), so the reported 0.810 is not an artefact of the fallback-to-A rule. The adapter does not enforce consistency be-

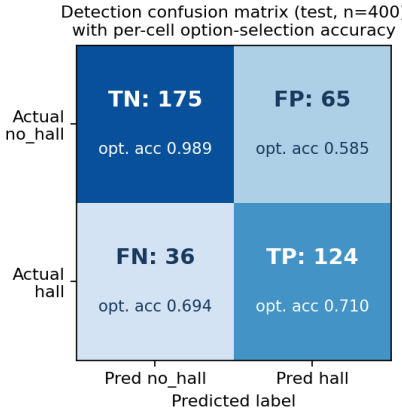

Figure 2: Test detection confusion matrix (n=400), with option-selection accuracy in each cell.

tween its steps: it predicts `no_hallucination` yet selects an option other than the copied answer in $8/135$ cases (5.9%), and predicts `hallucination` yet selects the copied answer in $30/88$ (34.1%).

4.5 Structural rules do not pay

The copy-match regularity suggests three rules: (R1) when predicting `no_hallucination`, take the copied option; (R2) when predicting `hallucination`, never take it; (R0) an answer copying no option is a hallucination. On train and development all three are exceptionless; on test all three *lose*. R1 costs 0.015 option accuracy to buy 0.003 coupled accuracy, R2 costs 0.075 (all 30 options it changes go from right to wrong), and R0 costs 0.057 Macro-F1. Each is conditioned on the *predicted* label, which is wrong for a quarter of items: R2 fires mostly on false positives, where the copied option was in fact gold, so forbidding it destroys a correct selection. With oracle detection and R1 the combined score would be 0.934: essentially all remaining headroom is in detection, none in post-processing.

4.6 What the detector actually learned

Our original analysis concluded, from ten hand-written items, that the model misses plainly false but fluent assertions. A larger probe reverses that. For each of the 400 test questions we build a *true* assertion (the gold option), a *false* one (a distractor that is neither gold nor the copied answer), and the organizers' verified free-text answer, then run blind detection on all $1{,}200$. The model labels the false assertions correctly 80.5% of the time (it is *not* blind to plain lies), but accepts only 65.5% of true assertions and 67.5% of verified-correct answers (balanced Macro-F1 0.729). The verified-answer

Outcome	Item
Missed	"What was the Battle of al-Furqān?" invents a battle (*ghazwat al-Furqān*) dated Friday 17 Ramaḍān 3 AH, passed as authentic.
Wrongly flagged	"Which grandfather raised the Prophet?" answered *'Abd al-Muṭṭalib*, correct but labelled a hallucination; selection then also failed.
Caught	A fabricated Qur'anic attribution rejected correctly, but the wrong option then selected: the coupling penalty in miniature.

Table 4: Representative test items. Arabic originals are released with the per-item error analysis.

arm is most telling: that text is free-flowing prose rather than an option string, unlike anything seen in training, yet a third of it is rejected. The failure mode is thus a bias toward rejection rather than blindness to falsehood, the same bias visible in the test precision of 0.656 and in the 65 false positives that halve option accuracy. Table 4 illustrates all three outcomes on real test items.

4.7 Reproducibility of the reported score

Our own run of the submitted adapter scored 0.777 against the organizers' 0.7582. We can bound what that gap is not: the prompts are byte-identical to those released with the adapter, and 16-bit rather than 4-bit gives 0.787, *further* from the official figure, so neither prompt wording nor quantisation explains it. What it shows is instability: identical weights and prompts differing only in precision disagree on 4.3% of labels and 8% of option choices. We treat a two-point spread as run-to-run variation and take the organizers' number as authoritative.

5 Conclusion

Our leak-free QLoRA system placed second of five teams (0.7582 blind, 0.7881 assisted). The controlled experiments reported here support the leakage hypothesis that motivated it, since option exposure buys $+0.047$ detection Macro-F1 on both splits, and show that detection ability is created by supervision rather than inherited: the frozen generator never flags its own output. They also correct our initial reading of the failure mode. The detector is not blind to fluent falsehoods, catching four in five, but is biased toward rejection, flagging roughly a third of verified-correct answers; that single bias explains the precision of 0.656, the collapse of option accuracy on false positives, and most of the development-to-test drop once the inverted prior is accounted for. Because every struc-

tural shortcut is conditioned on that unreliable label, none helps, and with oracle detection the combined score would be 0.934. The way forward is better-calibrated detection (prior-aware thresholding, training data with stylistically clean factual errors, knowledge-grounded verification) rather than better post-processing.

Limitations

Trained on 600 examples and specialised to this harness, the system is not a general Islamic QA or fact-checking model. The probe of Section 4.6 is built from option strings, stylistically in-distribution for training, though its verified-answer arm is not and points the same way. Our configuration grid does not identify single-factor effects, and the copy-match regularity holds on training and development but not on test, which we did not explain.

Acknowledgments

We thank the HalluScoring 2026 organizers for the task, data and harness, and the QCRI Fanar team for the base model.

Abstract

Large language models used for question answering can produce fluent but factually incorrect answers, a problem that is acute in knowledge-sensitive domains such as Islamic religious knowledge. We describe our system for the HalluScoring 2026 shared task (Islamic Knowledge track), which requires jointly detecting hallucinated answers and selecting the correct option among six candidates. We fine-tune Fanar-1-9B-Instruct with LoRA and decompose inference into two independently-prompted steps, judging hallucination before revealing the candidate options, to prevent a textual-similarity shortcut where one option is a near-verbatim restatement of the generated answer. Our system scores 0.7149 (Assisted) and 0.6222 (Blind) on the official hidden test set, ranking 5th of 5 reported teams; a controlled comparison shows this shortcut-resistant design costs roughly 10 points against a single-pass variant on a held-out development subsample (0.7625 vs. 0.8639 Combined Score). We release our code and model to support further work on this trade-off.

1 Introduction

Large Language Models (LLMs) have demonstrated strong capabilities in answering questions across diverse domains, yet they remain prone to hallucination, generating fluent and confident text that is factually incorrect, unsupported, or misleading (Ji et al., 2023). This issue is particularly critical in knowledge-sensitive domains such as Islamic religious knowledge, where factual errors involving Qur'anic references, Hadith attributions, or jurisprudential rulings can have significant real-world consequences. This work addresses hallucination detection and correction for **Modern Standard Arabic** questions in the Islamic knowledge domain.

The HalluScoring 2026 shared task (Alansari et al., 2026), built upon the HalluTruthQA benchmark (Bouchekif et al., 2026b; Bekhouche et al., 2026), frames this problem as a unified two-step task: given a question, an LLM-generated answer, and six candidate options, participating systems must (1) determine whether the generated answer contains hallucinated information, and (2) select the factually correct option among the six candidates. This paper describes our system, submitted by team ShadowDZ, for the Islamic Knowledge track of this shared task.[1]

Our main strategy is to fine-tune an open-source generative language model, Fanar-1-9B-Instruct (Team et al., 2025), using Low-Rank Adaptation (LoRA) (Hu et al., 2021). Rather than using a single combined prompt, we split inference into two independent, sequentially-prompted steps, so the model cannot infer the hallucination label from textual similarity to the candidate options instead of genuine factual verification. The full rationale is given in Section 3.

On the official hidden test set, our system achieves an Assisted Score of 0.7149 and a Blind Score of 0.6222, ranking 5th among five reported teams on the Islamic Knowledge track. The main challenge we encountered was a measurable trade-off between this stricter, shortcut-resistant inference design and raw leaderboard performance: on a genuinely held-out development subset, our two-step architecture scored 0.7625, noticeably lower than a single-pass variant we also developed (0.8639), which we hypothesize benefits from the aforementioned textual-similarity shortcut.

2 Background

Task setup. Each instance provides a question, an answer generated by a baseline LLM, and six candidate answers labeled A–F. For example, given the question من أول من بدأ بجمع القرآن الكريم من الخلفاء الراشدين؟

[1] Code available at https://github.com/KraimiaFaiz/halluscoring-2026-islamic.

October 28-29, 2026 ©2026 Association for Computational Linguistics

(*Which of the Rightly-Guided Caliphs first undertook the compilation of the Qur'an?*) and a generated answer naming Abū Bakr, systems must output a binary hallucination label (`hallucination` / `no_hallucination`) and select the option (A–F) that best answers the question. By construction, this coincides with the generated answer when it is labeled `no_hallucination`, and with the correct factual answer otherwise.

Dataset. We use the Islamic Knowledge subset of HalluTruthQA-4K (Bekhouche et al., 2026), the official dataset for Track 2 of HalluScoring 2026, itself an extension of the original HalluTruthQA benchmark (Bouchekif et al., 2026b). All questions and answers are in Modern Standard Arabic, covering Qur'anic interpretation, Hadith, Islamic jurisprudence (fiqh), and Islamic history. The Islamic Knowledge track provides 400 training, 200 development, and 400 test instances (1,000 total); gold labels and answers are released for the training and development splits only.

Track. We participate in a single track: Islamic Knowledge (Task 2.1).

Related work. Hallucination in LLM-generated text has been studied extensively in English (Ji et al., 2023). Work on Arabic remains comparatively limited, motivating benchmarks such as HalluTruthQA (Bouchekif et al., 2026b; Bekhouche et al., 2026) and related work on configuring deep architectures for Arabic (Saadi and Belhadef, 2018, 2020). Among concurrent submissions to the same track, Ziani (2026) fine-tune `google/gemma-4-12B-it` with deterministic decoding, normalizing raw generations to extract the label and option. Unlike this and other single-pass formulations, we investigate whether withholding candidate options during hallucination judgment reduces a model's reliance on textual-similarity shortcuts, a question not explicitly addressed in concurrent work on this task. Additional related work is discussed in Appendix A.

3 System Overview

Base model and fine-tuning. We fine-tune Fanar-1-9B-Instruct (Team et al., 2025) (Fanar Prime, 8.7B parameters, continually pretrained from Gemma-2 9B on Arabic, English, and code data) with LoRA (Hu et al., 2021) (rank r=16, α=32, dropout 0.05), applied to all attention and MLP projection matrices (`q_proj`, `k_proj`, `v_proj`, `o_proj`, `gate_proj`, `up_proj`, `down_proj`). The base model is loaded in 4-bit NF4 quantization during training. Training uses a per-device batch size of 1 with gradient accumulation over 16 steps (effective batch size 16), a learning rate of 2×10^{-4} with cosine decay, and 2 epochs.

Two-stage training. We fine-tune in two stages: *Stage A* trains on `train` only, re-initializing LoRA weights for *Stage B*, which trains on `train+dev` combined and produces the official submission checkpoint (data splits detailed in Section 4). Because Stage B sees all released labels, its performance on `dev` reflects memorization rather than generalization; we rely on Stage A for an unbiased estimate (Section 5).

Two-step inference (main design decision). Rather than presenting the six candidate options alongside the generated answer in a single prompt, we decompose inference into two sequential, independently-prompted steps, illustrated in Figure 1 and summarized in Algorithm 1. This addresses the following task challenge: because one candidate option is always a near-verbatim restatement of the generated answer, exposing all options during hallucination judgment allows a model to infer the label via textual similarity rather than independent verification of the answer's factual content.

Algorithm 1 Two-step inference

Require: question q, generated answer a, options $\{o_A, \ldots, o_F\}$

$v \leftarrow \textsc{Generate}(\texttt{prompt}_1(q, a))$ ▷ Step 1: no options shown

$\hat{y} \leftarrow \textsc{ParseLabel}(v) \in \{\texttt{hallucination}, \texttt{no\_hallucination}\}$

$g \leftarrow \textsc{Generate}(\texttt{prompt}_2(q, a, \hat{y}, \{o_A, \ldots, o_F\}))$ ▷ Step 2: informed by $\hat{y}$

$\hat{o} \leftarrow \textsc{ParseOption}(g) \in \{A, \ldots, F\}$

return $(\hat{y}, \hat{o})$

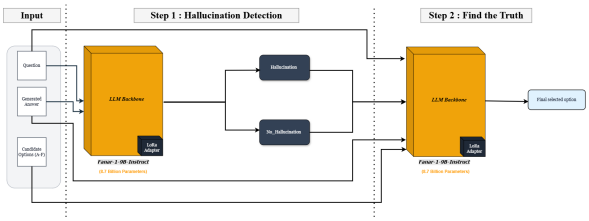

Figure 1: Two-step inference architecture.

Concrete example. A full worked example is given in Appendix B.

Decoding and parsing. Both steps use greedy decoding (full parameters in Appendix D). During Stage B training, the ground-truth label is used as $\hat{y}$ in Step 2's prompt (teacher forcing); at inference, the model's own Step 1 prediction is used, so an incorrect Step 1 verdict can propagate to Step 2.

Single-pass configuration (comparison system). For comparison (Section 5), we additionally train a single-pass configuration with the same base model, LoRA configuration, and training procedure, but where hallucination judgment and option selection are produced in one generation from a single prompt containing the question, generated answer, and all six options simultaneously. Because one option is always a near-verbatim restatement of the generated answer, this setup lets the model infer the hallucination label by matching the generated answer's wording against the options directly, rather than verifying its factual content. This textual match is not a valid signal of factual correctness, since a fluently-worded hallucination could still surface a similar option, which our two-step design is intended to avoid.

4 Experimental Setup

Data splits. The track provides 400 `train`, 200 `dev`, and 400 `test` instances. Stage A is evaluated on a random 30-instance `dev` subsample (seed 42) held out from training. Stage B trains on `train+dev` (600 instances) and is evaluated on the hidden `test` split; a further 20-instance `dev` subsample serves as a post-training sanity check only (not a generalization estimate).

Preprocessing. Each training instance is converted into two supervised examples, one per inference step (Section 3): a Step 1 example (prompt without options, target is the analysis and hallucination label) and a Step 2 example (prompt with the gold label and all six options, target is the analysis and correct letter). Prompts are formatted with the base model's chat template and truncated to 1536 tokens. Loss is computed only on the completion following the prompt, using a completion-only data collator that masks the prompt tokens.

Hyperparameters. We fine-tune with LoRA (r=16, α=32) under 4-bit NF4 quantization for 2 epochs (learning rate 2×10^{-4}, effective batch size 16); inference uses greedy decoding. The complete configuration, sufficient for replication, is listed in Appendix D.

Software. We use Hugging Face `transformers` (4.44–4.50), `peft` (0.11–0.14), `trl` (0.11–0.13), `accelerate` ($\geq$0.31), `bitsandbytes` ($\geq$0.43), and `datasets` ($\geq$2.19)[2], together with PyTorch and scikit-learn for evaluation. No additional external datasets, retrieval systems, or proprietary APIs are used.

Evaluation metrics. Following the shared task's official formula, systems are scored with a Combined Score $= 0.5\times$ Macro F1-Score (`hallucination/no_hallucination`, macro-averaged) $+ 0.5\times$ Option Accuracy (exact match on the selected letter). The leaderboard reports this as the *Assisted Score*, alongside a complementary *Blind Score* discussed in Section 5.

5 Results

5.1 Official results

Table 1 shows the official leaderboard for the Islamic Knowledge track, on the hidden `test` split (400 instances), released after submission. Our two-step system ranks 5th out of 5 reported teams, with an Assisted Score of 0.7149 and a Blind Score of 0.6222.

Team	Assisted	Blind
Anupamhashtag	0.8124	0.8262
CH-A-Malek	0.7881	0.7582
IslamicAI	0.7313	0.6541
Yazid_Bounab	0.7199	0.6661
ShadowDZ (ours)	**0.7149**	**0.6222**

Table 1: Official test-set leaderboard, Islamic Knowledge track.

Based on the organizers' evaluation script, we hypothesize that Blind Score reflects hallucination-detection quality in isolation, while Assisted Score reflects the combined task; we could not confirm this with the organizers before submission. A separate, non-comparable Development-phase score is reported in Appendix C for completeness.

5.2 Design decision impact (post-submission analysis)

To quantify the cost of our two-step design, we compare it against the single-pass configuration described in Section 3, both trained identically on `train` only (Stage A) and evaluated on the same held-out subsample of 30 `dev` instances never seen

[2] URLs: github.com/huggingface/transformers, github.com/huggingface/peft, github.com/huggingface/trl, github.com/huggingface/accelerate, github.com/bitsandbytes-foundation/bitsandbytes, github.com/huggingface/datasets

during training. This comparison was conducted after official submission and is not part of the leaderboard evaluation.

Config.	Macro F1	Opt. Acc	Combined
Single-pass	0.8611	0.8667	0.8639
Two-step (ours)	0.7917	0.7333	0.7625

Table 2: Held-out dev subsample (30 instances, Stage A, never used for training either configuration).

The single-pass configuration scores roughly 10 points higher on this held-out split. We attribute this gap to the textual-similarity shortcut described in Section 1: with all options visible during hallucination judgment, the single-pass model can align the generated answer against the options directly, whereas our two-step model must judge hallucination from the question and generated answer alone, a strictly harder sub-problem. We note this same single-pass configuration was never submitted for official test-set evaluation, so this comparison is necessarily confined to the held-out dev subsample.

5.3 Error analysis

On this held-out subsample, the single-pass configuration's confusion matrix is as follows: for the `hallucination` class (support 14), precision 1.00 and recall 0.71; for `no_hallucination` (support 16), precision 0.80 and recall 1.00. All errors are false negatives on `hallucination` instances that the model reclassifies as `no_hallucination`. This is consistent with the shortcut hypothesis, since a model matching the generated answer to a superficially similar option would default to `no_hallucination`.

All three option-selection errors in this run share the same gold answer, option C, while the model instead predicted E, B, and F, respectively (e.g., for instance `islamicHallucination_747`, gold `C`, predicted `E`). In each case, the model's justification states the generated answer is مطابقة تمامًا للمعلومة الصحيحة (*exactly matching the correct information*), indicating the model defaulted to endorsing the generated answer rather than identifying the specific factual error. This is precisely the shortcut behavior our two-step design targets. We do not have an equivalent per-instance error breakdown for the two-step configuration, as its evaluation logs retained only aggregate metrics.

6 Conclusion

Summary. We presented a two-step inference pipeline for the HalluScoring 2026 Islamic Knowledge track, fine-tuning Fanar-1-9B-Instruct with LoRA to judge hallucination and select the correct answer as two independently-prompted steps, rather than a single combined prompt. This design is specifically intended to prevent reliance on a textual-similarity shortcut available when candidate options are shown alongside the generated answer during hallucination judgment. Our system scored 0.7149 (Assisted) and 0.6222 (Blind) on the official hidden test set, ranking 5th of 5 reported teams. On a genuinely held-out development subsample, our two-step configuration scored 0.7625, compared to 0.8639 for an otherwise identical single-pass configuration, quantifying the cost of removing this shortcut.

Limitations. The controlled comparison in Table 2 isolates the design choice but is confined to a small held-out subsample (30 instances), a single base model, and a single seed. Our architecture also introduces an error-propagation risk absent by construction in single-pass systems, since an incorrect Step 1 verdict can mislead Step 2's judgment, and compute constraints limited us to 2 epochs without a systematic hyperparameter search. Finally, we only evaluate on the Islamic Knowledge track; generalization to the General Culture track or other languages remains untested.

Future work. Promising directions include mitigating Step 1-to-Step 2 error propagation, for example through conditioning Step 2 on a confidence estimate or joint training of the two steps, and running a systematic hyperparameter search across seeds. We also plan to extend the design to the General Culture track and other base models, and to explore reinforcement-learning-based training (Ouamane and Belhadef, 2022) to directly optimize the Combined Score.

Acknowledgments

We thank Hacene Belhadef for helpful discussions and advice, and the HalluScoring 2026 organizing team for maintaining the shared task and evaluation infrastructure.

A Additional Related Work

A separate line of work evaluates LLMs directly on Islamic legal reasoning, closely related to the factual correctness problem addressed here. Bouchekif et al. (2025) benchmark seven LLMs on 1,000 multiple-choice questions covering Islamic inheritance law (*'ilm al-mawārīth*), reporting a wide performance gap: models such as o3 and Gemini 2.5 exceed 90% accuracy, while others, including Fanar, the base model used in this work, score below 50%.

Bouchekif et al. (2026a) introduce MAWARITH, a larger benchmark of 12,500 Arabic inheritance cases annotated with step-by-step reasoning traces, enabling fine-grained evaluation of intermediate legal reasoning rather than final-answer accuracy alone. This structured, multi-stage evaluation style is conceptually related to our own two-step decomposition (Section 3), and suggests inheritance law as a promising domain for extending this work.

B Worked Example

Consider again the example from Section 2: the question "من أول من بدأ بجمع القرآن الكريم من الخلفاء الراشدين؟" with a generated answer naming Abū Bakr. In Step 1, the model receives only the question and this generated answer (no options) and outputs `no_hallucination`, since Abū Bakr was historically the first to compile the Qur'an into a single *muṣḥaf*. In Step 2, the model receives the question, the generated answer, the verdict $\hat{y} =$ `no_hallucination`, and the six options, one of which (option E) restates "Abū Bakr al-Ṣiddīq", and selects $\hat{o} =$ `E`, matching the generated

answer as expected under the task's decision rule (Section 2).

C Development-Phase Leaderboard

Separately from the final test-phase ranking reported in Section 5, an earlier Development-phase leaderboard scored predictions on the released dev split. Our single-pass system, trained with dev included in its training data (Stage B), scored 0.9177 there, ranking 2nd. We report this only for completeness: since dev labels were seen during training, this score reflects memorization rather than generalization, and is not comparable to the held-out results in Table 2 or the official test results in Table 1.

D Full Hyperparameter Configuration

Table 3 lists the complete configuration used for both training stages (Stage A and Stage B use identical hyperparameters, differing only in training data) and for inference, sufficient for replication.

Component	**Value**

Abstract

We present KnowledgeGraphEval 2026, the first Arabic shared task dedicated to knowledge graph (KG) construction from text. The task focuses on extracting named entities and semantic relations from Arabic text to build structured, machine-readable knowledge representations. It includes two subtasks: (*i*) **AdaptNER**, which evaluates cross-domain named entity recognition (NER), and (*ii*) **Relation Extraction (RE)**, which predicts semantic relations between predefined entity pairs. For AdaptNER, we release the MSA subset of *Konooz*, an Arabic NER benchmark annotated with 21 entity types across 10 domains. For RE, we release *Wojood*^{Relations}, an Arabic RE dataset annotated with 40 relation types. At test time, 14 teams participated, of which 13 submitted system description papers; and one RE paper was subsequently rejected. The best systems achieve micro-F1 scores of 75.96% and 94.06% on AdaptNER and RE, respectively. Results show that cross-domain NER remains challenging, while RE systems continue to face difficulties with rare and semantically confusable relations. We release the datasets, baselines, and evaluation tools for reproducible research in Arabic information extraction and KG construction.

1 Introduction

Knowledge graphs (KGs) have become a fundamental component of modern AI and NLP systems. A KG represents knowledge as entities and the semantic relations between them in a structured, machine-readable form. This representation supports a wide range of downstream applications, including question answering (Shaheen and Ezzeldin, 2014), semantic search (Guha et al., 2003), information extraction and retrieval (Jiang et al., 2016), word sense disambiguation (Jarrar et al., 2023b; Al-Hajj and Jarrar, 2021), language understanding (Khalilia et al., 2024), interoperability (Jarrar et al., 2011), and cybersecurity (Tikhomirov et al., 2020). More recently, KGs have become integral to Retrieval-Augmented Generation (RAG) systems for Large Language Models (LLMs), where structured knowledge grounds and constrains model outputs (Zhu et al., 2025).

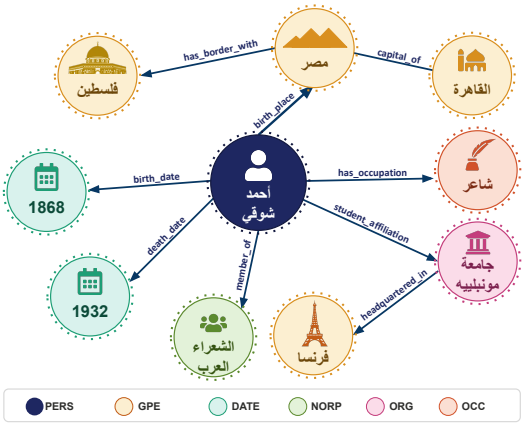

Figure 1: An example of a Knowledge Graph illustrating extracted entities and their relations.

Constructing KGs from text requires identifying both the entities and the semantic relations that connect them. This process primarily involves two tasks: (*i*) *Named Entity Recognition* (NER), which identifies entity mentions and assigns them predefined types such as `PERS`, `ORG`, and `LOC`; and (*ii*) *Relation Extraction* (RE), which identifies the semantic relations between these entities. For example, in Figure 1, الشاعر is recognized as `OCC` and أحمد شوقي as `PERS`, with `has_occupation` identifying the relation between them.

Both tasks present substantial challenges for Arabic. For NER, existing systems and datasets are predominantly focused on narrow domains, particularly news. Their performance can degrade under shifts in domains, dialects, and writing styles due to changes in entity distributions and vocabulary (Hamad et al., 2025). Arabic RE is similarly under-resourced, with limited availability of large-

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1182–1194
October 28-29, 2026 ©2026 Association for Computational Linguistics

scale datasets covering diverse and fine-grained relation types. This resource gap hinders the development of robust Arabic KG construction systems and leaves end-to-end extraction from diverse, multi-domain text comparatively underexplored.

To address this gap, we introduce **KnowledgeGraphEval** 2026, the first ArabicNLP shared task dedicated to knowledge graph construction. The shared task focuses on extracting entities and semantic relations from Arabic text to build structured knowledge representations. It comprises two subtasks: (*i*) **Cross-Domain Named Entity Recognition (AdaptNER)**, which evaluates domain-adaptive NER, and (*ii*) **Relation Extraction (RE)**, which identifies semantic relations between predefined entity pairs. For AdaptNER, we release ***Konooz***, a new Arabic NER benchmark covering 21 entity types across 10 domains (Hamad et al., 2025). For RE, we release ***Wojood***^{Relations}, an Arabic dataset annotated with 40 relation types (Aljabari et al., 2025b).

Teams were invited to explore recent modeling strategies, including pretrained language models, large language models, parameter-efficient fine-tuning, retrieval-augmented methods, and ensemble-based approaches. A total of 44 unique teams registered for the shared task. Of these, eight teams submitted models for evaluation on AdaptNER, while nine teams submitted models for evaluation on RE.

2 Related Work

2.1 Domain Adaptation in NER

Most Arabic NER corpora are in-domain, focusing primarily on MSA, including *ANERCorp* (Benajiba et al., 2007), *OntoNotes* 5.0 (Weischedel et al., 2013), and *Wojood* (Jarrar et al., 2022), along with its extensions *Wojood*$_{Fine}$ (Liqreina et al., 2023; Jarrar et al., 2023a) and *Wojood*^{Gaza} (Jarrar et al., 2024). As a result, out-of-domain benchmarks for Arabic NER remain limited, hindering systematic evaluation of cross-domain generalization. *Konooz* addresses this gap by providing a benchmark spanning domains and dialects distinct from the *Wojood* training distribution (Hamad et al., 2025).

Domain adaptation for NER has been extensively investigated with pretrained language models, including approaches based on self-training, knowledge distillation, adversarial training, and adaptive pre-training (Zhou et al., 2023; Ge et al., 2023; Han and Eisenstein, 2019). For Arabic, however, existing studies have primarily examined MSA-to-dialect adaptation and have considered relatively small entity-type inventories Khalifa et al. (2021); Mekki et al. (2022). Thus, the combination of MSA domain shift and broader entity-type coverage remains underexplored, which we address by introducing AdaptNER based on *Konooz*.

2.2 Relation Extraction

Arabic relation extraction remains substantially under-resourced, with existing datasets offering limited coverage in terms of domains, relation types, and annotation scale (Doddington et al., 2004; Seganti et al., 2021; Huguet Cabot et al., 2023). This scarcity has constrained the systematic development and evaluation of Arabic RE systems. Consequently, prior work has largely relied on cross-lingual transfer (Lan et al., 2020) or task-specific approaches, including evidence-augmented methods (Rakan Al Mraikhat et al., 2024), and joint neural extraction frameworks (El Khbir et al., 2022; Osman et al., 2023). Differences in datasets, relation inventories, and evaluation settings further limit direct comparison across studies (Aljabari et al., 2024).

Wojood^{Relations} (Aljabari et al., 2025b) addresses this resource gap by providing a large-scale, manually annotated Arabic RE corpus with fine-grained relation types and formally defined ontology constraints. Building on *Wojood*^{Relations}, we establish the RE subtask to provide a unified evaluation setting and enable systematic comparison of different approaches on a common benchmark.

2.3 Shared Tasks in Knowledge Graphs

Several previous shared tasks have supported progress in KG construction and enrichment. The Open Knowledge Extraction (OKE) challenges evaluated entity recognition, linking, typing, and knowledge-base enrichment from text (Nuzzolese et al., 2015, 2016). SemTab focuses on semantic annotation and linking of tabular data to KGs (Jiménez-Ruiz et al., 2020), while the OAEI KG track evaluates instance- and schema-level alignment between KGs (Hertling and Paulheim, 2020). WikiKG90M, introduced within the OGB Large-Scale Challenge, benchmarks large-scale KG completion through link prediction (Hu et al., 2021).

For Arabic, previous shared tasks have mainly focused on individual extraction components. WojoodNER 2023 and 2024 introduced benchmarks for flat, nested, and fine-grained Arabic NER (Jar-

rar et al., 2023a, 2024). KnowledgeGraphEval 2026 extends this direction toward KG construction by combining cross-domain NER with fine-grained semantic relation extraction.

3 Shared Task Overview

3.1 Subtask 1: AdaptNER Cross-Domain Named Entity Recognition

NER is a fundamental NLP task that identifies and classifies named entities in text into predefined categories (see Figure 2). This subtask targets cross-domain adaptation for Arabic NER. Participants develop NER systems trained on *Wojood* and evaluated on the MSA subset of the existing *Konooz* benchmark, which spans ten unseen target domains, to measure how well NER models generalize across Arabic domains. Systems must be trained using only the training and development splits of the *Wojood* NER corpus as the source domain.

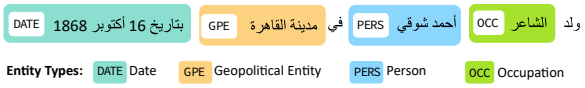

Figure 2: Example of NER annotation.

Participants are encouraged to go beyond standard supervised fine-tuning and apply domain adaptation methods such as self-training, adversarial training, or feature alignment to improve robustness and reduce the performance gap between source and target domains. Submissions will be ranked by their aggregate NER performance (Micro-F1) across the ten target domains.

3.2 Subtask 2: Relation Extraction

Relation extraction is central to knowledge graph construction, as it identifies the semantic connections that form edges between entities (see Figure 3). Building on this role, Subtask 2 focuses on extracting such relations from Arabic text. Each input sentence is provided with a single subject–object entity pair, specified by their entity spans. Participants must predict the semantic relation between the pair from a predefined set of relation types, or assign *no_relation* when no predefined relation holds between the entities.

Figure 3: Example of sentence-level relation extraction annotation.

3.3 Restrictions

This section outlines the guidelines for participating in KnowledgeGraphEval 2026. These rules have been put in place to ensure fairness and transparency for all participants.

Modeling. For Subtask 1 (AdaptNER), participants are only allowed to use encoder-based models fine-tuned on *Wojood*, using *Konooz* solely for evaluation. Training on *Konooz* is not permitted. For Subtask 2 (RE), participants may also use LLMs for fine-tuning or in-context learning, in addition to encoder-based models fine-tuned on $Wojood^{Relations}$.

External data. In both subtasks, participants may use external data or resources for additional training or as information sources during inference. Any use of external data must be explicitly reported in the system description paper, including how they were used.

4 Subtask 1: Cross-Domain Named Entity Recognition (AdaptNER)

4.1 Dataset

For Subtask 1, we use *Konooz* (Hamad et al., 2025), the first Arabic NER benchmark corpus spanning ten domains and 16 dialects, including Modern Standard Arabic (MSA). The MSA portion contains approximately 8K tokens per domain. For the shared task, we released an MSA subset referred to as " *Konooz*-MSA ", covering all ten domains, with 5K tokens per domain, comprising 50K tokens in total. The ten MSA domains are Politics, Economics, Finance, History, Law, Science, Health, Agriculture, Art, and Sport. All domains were held out exclusively for evaluation. Table 1 presents the number of sentences available in each domain for participant evaluation.

Participants were also provided with the training and development splits of *Wojood* as labeled source-domain data, comprising approximately 448K tokens and 72K entity mentions across 21 entity types. These splits were the only labeled data permitted for training the models.

We selected a subset of the *Konooz*-MSA test set as a development set -*Konooz*-dev- to support participants in evaluating their models during target-domain adaptation and model tuning, while keeping its gold annotations hidden. For the final evaluation, participants' systems were evaluated on the full *Konooz*-MSA test set, which included the "*Konooz*-dev" subset.

Domain	Sentences	Domain	Sentences
Agriculture	176	History	130
Art	130	Law	129
Economics	132	Politics	128
Finance	237	Science	149
Health	281	Sport	153
Total		**1,645**	

Table 1: Number of sentences per domain in the *Konooz*-MSA test set.

Format The released data follows a column-based BIO format: each line contains a token followed by 21 BIO-tag columns, one per entity type (`CARDINAL`, `CURR`, `DATE`, `EVENT`, `FAC`, `GPE`, `LANGUAGE`, `LAW`, `LOC`, `MONEY`, `NORP`, `OCC`, `ORDINAL`, `ORG`, `PERCENT`, `PERS`, `PRODUCT`, `QUANTITY`, `TIME`, `UNIT`, `WEBSITE`). Sentences are separated by a blank line, and the ten domains are concatenated into a single file in alphabetical order (Table 1).

4.2 Baselines

As a baseline for this subtask, we provide a single no-adaptation baseline, in which an AraBERT (Antoun et al., 2020) model is trained exclusively on *Wojood* and evaluated directly on *Konooz*-MSA without applying any domain adaptation technique. This baseline reflects the performance of a NER model when deployed on unseen target domains without adaptation. The implementation is publicly available on GitHub[1].

4.3 System Descriptions

Table 2 summarizes the techniques employed by the participating teams in Subtask 1. According to the shared task rules, participants were not allowed to use the unlabeled *Konooz*-MSA data for training. However, some participants leveraged the unlabeled data for pre-training. Therefore, we divided the subtask into two tracks. In Track 1, participants followed the shared task rules and did not use *Konooz*-MSA data during training. In Track 2, participants used the unlabeled *Konooz*-MSA data for pre-training. In both tracks, final evaluation is conducted on unlabeled *Konooz*-MSA test data.

NAMAA(Fathallah et al., 2026) NAMAA combines three complementary models for nested NER: two BIO taggers, using ARBERTv2 (Abdul-Mageed et al., 2021) and XLM-R-large (Conneau et al., 2020) encoders with learned mixtures of their top four hidden layers and 21 per-type constrained CRF decoders, plus a third model pairing ARBERTv2 with GlobalPointer to predict typed spans directly for explicit boundary modeling. An entity is retained only when at least two models agree exactly on span and type, yielding a conservative, high-precision ensemble.

Wasl (Abdo and Adam, 2026) Wasl fine-tunes AraBERTv02 with 21 independent per-type BIO heads over a shared encoder, matching the 21-column format directly. Each head trains with a compound loss (cross-entropy, Dice, Tversky, Focal) plus a variance penalty to keep frequent types from dominating rare ones. To handle domain-shift variance, Wasl ensembles three seeds via span-level majority vote — chosen over mean-probability or union combination, since seed disagreement on the blind set proved systematic rather than random, favoring a precision-preserving vote.

PTUK-NLP (Duridi et al., 2026) PTUK-NLP follows strict zero-shot transfer, pairing ArBERT with a nested tagger of 21 independent BIO heads. Label imbalance is addressed by oversampling sentences with rare entity types and replacing eligible non-nested mentions with same-type mentions from a Wojood-derived gazetteer, preserving token alignment and annotations. At inference, lightweight rules extend fragmented website spans and recognize unseen Latin-script currency codes. *Konooz*-MSA text is never used—for pretraining, fine-tuning, model selection, or hyperparameter optimization—making this a simple, data-centric alternative to target-aware adaptation.

McMasterNLP (Serour et al., 2026) McMasterNLP builds a heterogeneous mixture of token- and span-level experts: token classifiers on AraBERTv2, CAMeLBERT-Mix, and MARBERTv2, plus an AraBERTv2 span classifier, trained on data augmented by replacing entity mentions with same-type mentions from other sentences. A fifth AraBERTv2 expert, adapted via masked-language-model pretraining on unlabeled

NAMAA	✓	✓		✓				✓	✓	✓						Two BIO-CRF taggers (ARBERTv2, XLM-R) plus an ARBERTv2 GP classifier, combined via ≥2/3 exact-span voting for a high-precision.
Wasl	✓						✓			✓						AraBERTv02 with 21 independent per-type BIO heads, trained with a compound loss (CE + Dice + Tversky + Focal plus a variance penalty). Three random seeds are then combined by span-level majority vote
McMasterNLP	✓		✓		✓	✓	✓			✓	✓				✓	Token- and span-level ensemble (AraBERTv2, CAMeLBERT, MARBERTv2) with a Konooz-adapted tie-breaker; Qwen3-14B adjudicates unresolved spans.
PTUK-NLP	✓	✓					✓								✓	Strict zero-shot ArBERT nested tagger (21 heads); oversampling and gazetteer-based mention replacement address label imbalance, with inference-time rules for WEBSITE spans and currency codes.
ArmyForNER		✓					✓			✓	✓	✓				ARBERTv2, adapted via MLM pretraining on *Konooz*; a multi-seed ensemble generates self-training pseudo-labels, combined via soft voting.
AdaptLinker	✓						✓					✓	✓	✓		AraBERT is adapted via GRL domain classification and confidence-gated pseudo-labels, with final weights from SWA over the last four checkpoints.
YafaNER	✓						✓			✓	✓	✓			✓	AraBERTv2 with TAPT on *Konooz*; three teachers generate filtered soft labels, distilled into students combined via entity-specific F1 weights.
ANLP_UniSo	✓		✓						✓	✓	✓	✓				MARBERT + GP, adapted via DAPT and self-training on Konooz, then stacked with AraBERT using entity-specific decoding thresholds.

Table 2: Overview of Subtask 1 (AdaptNER) systems: backbone family, classification, and domain adaptation.

Konooz-MSA text, breaks ties during voting. Spans supported by multiple encoder families are retained; unresolved candidates go to Qwen3-14B for constrained multiple-choice adjudication, which cannot alter already accepted predictions.

ArmyForNER (Syulistyo et al., 2026) A multi-stage ARBERTv2 pipeline: the encoder is first adapted to the target domains via masked-language-model pretraining on unlabeled *Konooz*-MSA sentences, then fine-tuned on Wojood with 21 parallel BIO heads, allowing overlapping entity types to be predicted independently. An ensemble trained with varied adaptation settings and seeds generates pseudo-labels for *Konooz*-MSA, which are combined with Wojood for self-training; three resulting models are then combined via token-level soft voting.

AdaptLinker (Ho and Thin, 2026) AdaptLinker uses a shared AraBERT encoder with 21 independent BIO heads for nested NER. Training begins with supervised fine-tuning on Wojood, then continues with joint source-target adaptation on labeled Wojood and unlabeled *Konooz*-MSA sentences: a gradient-reversal domain classifier encourages domain-invariant representations, while a frozen teacher generates confidence-thresholded target-domain pseudo-labels. Final parameters come from stochastic weight averaging over the last four adaptation checkpoints.

YafaNER (Hamed et al., 2026) YafaNER builds an AraBERTv2 multi-head BIO system combining several adaptation techniques: task-adaptive pretraining on unlabeled *Konooz*-MSA text, then three R-Drop-regularized teacher models fine-tuned on Wojood (one with strong augmentation for diversity). Teachers generate soft labels for *Konooz*, filtered by confidence and entropy thresholds; three student models then train jointly on gold Wojood annotations and these filtered soft labels, with predictions combined via entity-specific weights from per-type validation F1 scores.

ANLP_UniSo (Bergaoui et al., 2026) Pairs MARBERT with a GlobalPointer decoder (Rotary Position Embeddings) to predict spans directly, capturing overlapping and nested entities without flattening. MARBERT undergoes continued MLM pretraining on unlabeled *Konooz*, then fine-tunes on Wojood; a pseudo-labeling stage then uses this model to label *Konooz*, merged with Wojood for self-training. A second AraBERT-based model is combined with MARBERT's via stacking, and entity-specific decoding thresholds are tuned to balance per-category precision and recall.

4.4 Evaluation

For Subtask 1, participants submit their predictions through the official Codabench competition page.[2] The submission consists of one `.txt` file containing predictions for all ten domains. The file follows the CoNLL format: each line contains a token followed by its IOB2 tag (Sang and Veenstra, 1999), separated by a space, with sentences separated by

[2] https://www.codabench.org/competitions/17349/

blank lines. Predictions for the ten domains must be concatenated in the domain order specified on Codabench. Evaluation uses strict entity-level matching: a predicted entity is correct only if both its span boundaries and entity type match the gold annotation. The primary metric is micro-averaged F1 across all 21 entity types and ten domains.

4.5 Results and Discussion

Table 3 presents the official results of AdaptNER. In track 1, NAMAA achieved the highest F1 of 75.96, followed by Wasl and PTUK-NLP. All described systems exceeded the unadapted AraBERTv02 baseline, with absolute improvements ranging from 6.0 to 12.0 points. In track 2, some participants utilized the provided unlabeled "*Konooz*-dev" for target-domain adaptation using adversarial training, while others used the blind *Konooz*-MSAtest data during training.

Rank	Team	Precision	Recall	Micro-F1	Macro-F1
Track 1					
1	NAMAA	**83.83**	69.44	**75.96**	**66.00**
2	Wasl	80.60	69.82	74.83	63.16
3	McMasterNLP	75.00	**74.00**	74.38	65.00
4	PTUK-NLP	71.84	66.59	69.11	60.70
Track 2					
1	ArmyForNER	82.11	68.77	74.85	65.20
2	AdaptLinker	75.48	71.21	73.29	63.37

4	ANLP-UniSo	81.43	63.04	71.06	61.01
–	Baseline	63.87	62.30	63.00	44.00

Table 3: Official results for Subtask 1 (AdaptNER) (%).

A common theme across the participating systems is ensembling pretrained language models, either by combining different Arabic or multilingual encoders, including AraBERT, ARBERT, MARBERT, CAMeLBERT, and XLM-R, or by combining multiple instances of the same model trained with different random seeds. NAMAA (75.96) ensembles three pretrained Arabic language models, while Wasl (74.83) ensembles a single pretrained model across multiple seeds. Their results indicate that model diversity, either across architectures or random initializations, can provide strong performance for cross-domain adaptation without incorporating *Konooz*-MSAduring training.

Other systems employ continued pretraining through Domain-Adaptive Pretraining (DAPT) or Task-Adaptive Pretraining (TAPT). McMasterNLP (74.99) ensembles four pretrained models, including one adapted through TAPT on unlabeled *Konooz* data. ArmyForNER (74.85), YafaNER (71.33), and ANLP_UniSo (71.06) similarly employ DAPT or TAPT, combined with methods such as pseudo-labeling, knowledge distillation, or adversarial alignment. Notably, McMasterNLP, despite using *Konooz* during training through TAPT, achieves a score comparable to the aforementioned systems that did not use *Konooz* during training. This suggests that incorporating the target-domain data available to the team did not yield a clear performance advantage in this setting.

Self-training provides mixed results across the submissions. YafaNER combines adaptation with pseudo-labeling but achieves lower performance than the top-ranked systems, while AdaptLinker (73.29) combines self-training with adversarial alignment using the *Konooz*-dev development data. These results suggest that pseudo-labeling does not consistently improve cross-domain NER performance, potentially because errors in pseudo-labels can propagate during adaptation.

Data augmentation provides another approach to improving adaptation. PTUK-NLP (74.85) augments only the *Wojood* training data using two strategies — oversampling and a Wojood-derived gazetteer — to increase the number of rare entity type instances. Its performance is comparable to the other high-performing systems and substantially exceeds the baseline (+6%), suggesting that improving the representation of underrepresented entity types can benefit cross-domain NER.

Overall, the results indicate that more elaborate adaptation pipelines do not necessarily translate into higher performance. Adaptation quality appears to depend less on pipeline complexity. The strongest systems instead consistently incorporate ensemble-based strategies, either by ensembling multiple models or multiple seeds of a single model. The precision–recall patterns further suggest that these ensemble strategies favor precision, although this is accompanied by lower recall. Thus, ensemble diversity appears to be a promising component for Arabic cross-domain NER.

5 Subtask 2: Relation Extraction (RE)

5.1 Dataset

For Subtask 2, we use *Wojood*^{Relations} (Aljabari et al., 2025b), an Arabic relation extraction (RE) corpus built on the Wojood NER corpus, which contains $33K$ sentences and $550K$ tokens (Jarrar et al., 2022). *Wojood*^{Relations} contains approximately $14K$ annotated relation triples spanning 40 relation types, including organizational, geograph-

ical, and familial relations. The corpus follows a multi-relation setting in which a sentence may contain multiple entity pairs associated with distinct relations.

For the KnowledgeGraphEval 2026 shared task, we cast RE as a *relation classification* problem. Given an Arabic sentence and a target subject–object entity pair occurring in that sentence, the task is to predict the relation holding between the two entities. Each annotated relation triple in *Wojood*^{Relations} is therefore converted into an individual classification instance, while retaining the complete sentence as contextual input. Consequently, a sentence containing multiple annotated relations contributes multiple instances, each corresponding to a different target entity pair. For example, the relation between قبة الصخرة and مدينة القدس in the sentence below is represented as a single classification instance with the label `located_in`.

sentence_id: 100009219
triple_id: 8311
sentence: تقع قبة الصخرة في مدينة القدس، وقد شُيدت في عهد الخليفة عبد الملك بن مروان عام ٦٩١م.
subject: قبة الصخرة
object: مدينة القدس
relation: located_in

We further introduce negative instances to explicitly model the absence of a relation. Specifically, for entity pairs occurring in the same sentence but not associated with an annotated relation, we assign the `no_relation` label. This label is included in the training and validation data to expose systems to the distinction between related and unrelated entity pairs. The resulting classification space therefore comprises 41 labels: the 40 annotated relation types and `no_relation`. The test set, however, contains only instances corresponding to annotated relations and does not include `no_relation` instances. Accordingly, `no_relation` is excluded from the official evaluation.

The final dataset contains approximately $24K$ relation-classification instances across the training, validation, and test splits. The training set is provided with gold relation labels, while the validation and test sets are provided without gold labels and remain blind to participants. Table 4 summarizes the split statistics.

Split	Train	Validation	Test
# Instances	17,381	2,074	4,386

Table 4: *Wojood*^{Relations} split statistics for KnowledgeGraphEval 2026.

5.2 Baselines

We use the NLI-based relation extraction (NLI-RE) system introduced with the *Wojood*^{Relations} corpus as the baseline. The approach formulates relation classification as binary natural language inference: given a sentence and a predefined subject–object entity pair, each candidate relation is converted into a hypothesis using a relation-specific template, with the sentence serving as the premise. A BERT-based NLI classifier then predicts whether the candidate relation is entailed. The implementation is publicly available on GitHub.[3]

5.3 System Descriptions

Table 5 provides an overview of the approaches adopted by the participating systems. We describe these approaches below.

U4RASD (Abbas et al., 2026) U4RASD first identifies and types entity occurrences using a NeoAraBERT-based TypePredictor, then uses WojoodOntology (Aljabari et al., 2025a) domain and range constraints to determine the valid candidate relations for each entity pair. Within this pipeline, the team evaluates two approaches: encoder-based EntityPair models with typed entity markers and separate relation-existence and relation-classification heads, and QLoRA-adapted LLMs, including Yehia and Qwen3.5, formulated as either multiple-choice or sequence-classification models. The best-performing system, Yehia-RE, achieves 94.06% Micro-F1 on the official test set.

NAMAA (Fathallah et al., 2026) Three decoder-only LLMs are fine-tuned with LoRA, each receiving the Arabic sentence, ordered subject and object mentions, and the complete relation-label inventory. Rather than relying on free-form generation, inference is constrained to the 41 valid labels by scoring each candidate relation using its mean teacher-forced token log-likelihood. Predictions from the three models are combined via majority voting, with Qwen3.5-4B breaking ties when all three models disagree.

[3] https://github.com/SinaLab/ArabicNLI-RE

Team	Backbone				Ensembling				Constraints			Method Summary
	AraBERT	XLM-R	ARBERTv2	LLM	CV	Multi-model	Vote/Avg	None	Ont. (soft)	Ont. (hard)	Imb.-aware	
U4RASD				✓				✓		✓	✓	Yehia-7B fine-tuned with QLoRA as a row-specific Arabic multiple-choice task over the full vocabulary.
NAMAA				✓		✓	✓					Three LoRA-tuned causal LLMs scored by length-normalized log-likelihood over 41 labels, combined by majority vote.
ArmyForRE	✓	✓	✓			✓	✓			✓	✓	Seven encoders (focal loss) combined by soft voting; incompatible relations masked by ontology constraints.
Wasl	✓				✓		✓		✓			Typed markers on AraBERTv02 (5-fold CV, logit-averaged) over 41 relations, with a soft ontology-based type-constraint penalty at decoding.
McMasterNLP	✓				✓		✓		✓			Five-fold AraBERT ensemble for 41-way classification, reranked by a five-fold NLI model, with schema penalties.
ISNAD	✓							✓			✓	AraBERTv2 fine-tuned end-to-end with entity markers; class imbalance addressed via moderated weighted sampling.
YafaRE			✓					✓				ArBERTv2 fine-tuned as a relation classifier, then adapted via transductive self-training on pseudo-labeled test inputs.

Table 5: Overview of Subtask 2 (Relation Extraction) systems: Design choices adopted by participating systems.

ArmyForRE (Shoumi et al., 2026) ArmyForRE formulates RE as a 41-way classification task using typed entity markers and pretrained language encoders to represent subject–object pairs. Focal loss addresses class imbalance. At inference, ontology-based domain and range constraints mask incompatible relations. The final system is a seven-model soft ensemble comprising four independently seeded XLM-RoBERTa-large models and three Arabic BERT-based models, with predictions aggregated through soft voting.

Wasl (Abdo and Adam, 2026) Wasl uses a pretrained encoder with typed punctuation-based entity markers and a two-layer feed-forward classifier over the concatenated subject and object start-marker representations. The model is trained as a 41-way classifier. The final system ensembles five models trained with sentence-grouped 5-fold cross-validation, with a soft ontology-based type-constraint penalty applied during decoding.

McMasterNLP (Serour et al., 2026) McMasterNLP uses an AraBERT-based relation classifier with explicit subject and object markers, trained with sentence-grouped 5-fold cross-validation and auxiliary objectives for entity-type prediction, together with embedding-level FGM adversarial training. The classifier produces relation scores, after which candidate relations are verbalized as Arabic hypotheses and reranked using a five-fold AraBERT-based NLI ensemble. Final predictions combine the classifier and NLI probabilities with a soft entity-type schema penalty.

ISNAD (Hassaneen et al., 2026) Fine-tunes AraBERTv2 with cross-entropy loss for multi-class relation classification, using entity markers inserted around the subject and object spans. Class imbalance is addressed through moderated sampling that increases the probability of underrepresented relations without excessive rebalancing.

YafaRE (Melhem et al., 2026) YafaRE fine-tunes ArBERTv2 for relation classification and applies transductive self-training by pseudo-labeling the unlabeled test inputs to adapt the model to the test distribution, improving Micro-F1 from 70.20% to 91.92%. The team also explores two- and three-model ensembles with soft weighted voting, but neither outperforms the self-training approach.

5.4 Evaluation

For RE, participants submit a single `.txt` file through Codabench[4], containing one tab-separated `triple_id predicted_relation` entry per line. The number and order of entries must exactly match those of the released test file.

Each system predicts one of 41 labels for every entity pair: the 40 predefined relation types and *no_relation*. The *no_relation* label is derived from entity pairs for which no relation annotation is present, rather than being independently annotated as a relation type. Therefore, its frequency and prediction performance are not directly comparable to those of the 40 annotated relation types. Following the evaluation protocol adopted in relation classification benchmarks (Fan, 2023; Hendrickx et al., 2010; Zhou et al., 2020), instances with *no_relation* as the gold label are excluded from evaluation. Accordingly, F1 is computed only

[4] https://www.codabench.org/competitions/17338/

over instances whose gold label corresponds to one of the 40 predefined relation types.

5.5 Results and Discussion

Table 6 reports the official Relation Extraction results, ranked by micro-F1. Seven teams submitted valid runs. The table also includes the official baseline, based on NLI AraBERTv02 fine-tuned on the released training split.

Rank	Team	Precision	Recall	Micro-F1
1	U4RASD	95.55	**92.61**	**94.06**
2	NAMAA	96.80	90.38	93.48
3	ArmyForRE	94.78	91.91	93.32
4	Wasl	**97.16**	89.69	93.28
—	*Baseline*	—	—	93.09
5	McMasterNLP	96.56	89.60	92.95
6	ISNAD	92.74	92.36	92.55
7	YafaRE	96.19	88.01	91.92

Table 6: Official Relation Extraction results (%).

Among the submitted systems, the two LLM-based approaches, U4RASD and NAMAA, rank first and second with Micro-F1 scores of 94.06 and 93.48, respectively, followed by the two encoder-based ensemble systems, ArmyForRE (93.32) and Wasl (93.28); all four outperform the organizer baseline (93.09), while McMasterNLP (92.95), ISNAD (92.55), and YafaRE (91.92) fall below it.

Ontology-based constraints. Among the *LLM-based systems*, U4RASD (94.06) outperforms NAMAA (93.48). A notable methodological difference is that U4RASD incorporates hard ontology-based constraints to restrict candidate relations, whereas NAMAA does not use ontology constraints. This difference suggests that ontology-based constraints may contribute to U4RASD's stronger performance, although other differences between the two systems prevent their effect from being isolated. A similar pattern is observed among the *encoder-based* systems: ArmyForRE (93.32), Wasl (93.28), and McMasterNLP (92.95) all outperform ISNAD (92.55) and YafaRE (91.92). Among the top three, ArmyForRE applies hard ontology-based constraints, while Wasl and McMasterNLP incorporate a soft ontology-based type-constraint penalty during decoding; ISNAD and YafaRE use neither. The consistent association between ontology-based constraints — whether hard or soft — and higher performance within both model families suggests that such constraints may provide useful structural information for RE. However, this remains an observational finding, as the systems also differ in their architectures, training procedures, and other inference strategies.

Encoder- vs. LLM-based approaches: performance and computational considerations. Two of the four top-performing systems, ArmyForRE and Wasl, are encoder-based, while U4RASD's best submission (Yehia-RE) and NAMAA are LLM-based. NAMAA fine-tunes and ensembles three LoRA-adapted causal LLMs, whereas ArmyForRE and Wasl rely on much smaller BERT-scale encoders. Despite this difference in scale, the encoder-based systems remain competitive: ArmyForRE's seven-model soft ensemble (four XLM-RoBERTa-large seeds and three Arabic BERT-based models) trails NAMAA's three-model LLM ensemble by only 0.16 points, and Wasl's five-model encoder ensemble is 0.78 points behind U4RASD's best system. These results indicate that encoder-based ensembling, combined with ontology-based constraints, remains a competitive and computationally lighter alternative to LLM-based approaches.

Long-tail and semantically confusable relations remain challenging. Several systems employ imbalance-aware strategies, including focal loss (ArmyForRE) and frequency-based sampling (U4RASD, ISNAD), yet rare relations remain difficult to classify. Beyond class imbalance, Wasl's error analysis identifies persistent confusions between semantically close relations sharing the same argument-type signature, such as *birth_place* vs. *lives_in* and *capital_of* vs. *geopolitical_division*, which cannot be distinguished through ontology constraints alone. U4RASD similarly identifies difficulty with rare and semantically adjacent relations as a limitation.

6 Conclusion

KnowledgeGraphEval introduced a shared benchmark for Arabic Knowledge Graph construction through two subtasks: cross-domain NER (Adapt-NER) and Relation Extraction (RE). The results highlight persistent challenges in domain adaptation for Arabic NER, while RE, despite competitive results, still faces open challenges in disambiguating long-tail and semantically confusable relations. Future editions should address these limitations in both evaluation design and modeling.

Limitations

The study has two main limitations. First, the datasets used in the shared task are primarily representative of Modern Standard Arabic (MSA) and provide limited coverage of dialectal variation. Consequently, the findings may not fully reflect RE and NER performance across the broader spectrum of Arabic varieties.

Second, Subtask 2 (RE) formulates each instance around a single subject–object entity pair within a sentence. When a sentence contains multiple entity pairs or relations, each pair is treated as a separate classification instance. This formulation isolates individual relations and does not evaluate the joint identification and classification of multiple relations within a sentence. Future shared-task editions could consider a formulation that evaluates all candidate entity pairs within each sentence jointly.

Acknowledgments

We thank all participating teams for their valuable contributions to the KnowledgeGraphEval shared task and for advancing research on Arabic knowledge graph construction and information extraction. We also thank the organizers of the ArabicNLP 2026 conference and the broader Arabic NLP community for their continued support. Mustafa Jarrar acknowledges that this work was partially supported by internal research grants from the College of Humanities and Social Sciences at Hamad Bin Khalifa University.

Abstract

This paper presents the submission of team **AdaptLinker** to the AdaptNER shared task (Subtask 1: Cross-Domain Named Entity Recognition) at KnowledgeGraphEval 2026. To address nested entities and domain shift across 10 unseen target domains, we propose a multi-head token classification framework built on the AraBERT backbone. Our approach integrates: (1) 21 parallel linear classifiers to predict overlapping named entities; (2) a Domain Adversarial Neural Network (DANN) using a Gradient Reversal Layer (GRL) to align feature spaces; (3) confidence-gated pseudo-labeling on unlabeled target text; and (4) Stochastic Weight Averaging (SWA). Our final system achieved a Precision of 75.48%, Recall of 71.21%, a Micro F1 of 73.29%, and a Macro F1 of 63.37% on the official blinded test set, outperforming the shared-task baseline (0.7329 vs. 0.622 Micro F1) and ranking 6th out of all participating teams. Our code is publicly released on GitHub.[1]

1 Introduction

Named Entity Recognition (NER) is essential for Information Extraction and Knowledge Graph Construction. Although supervised models perform well in-domain, performance often degrades markedly on unseen target domains. The AdaptNER shared task (Subtask 1: Cross-Domain Named Entity Recognition) at KnowledgeGraphEval 2026 (Aljabari et al., 2026) (benchmarked alongside WojoodRelations (Aljabari et al., 2025b)) evaluates models on 10 unseen *Konooz* domains (Hamad et al., 2025) (Agriculture, Art, Economics, Finance, Health, History, Law, Politics, Science, Sport) after training on Wojood (Jarrar et al., 2022).

Arabic NER is uniquely challenging due to rich morphology, absence of capitalization, and frequent nested entities where standard flat sequence taggers collapse overlapping mentions. Team **AdaptLinker** addresses these challenges using AraBERT (Antoun et al., 2020) equipped with 21 parallel classification heads, enabling concurrent label predictions per token. To bridge the domain gap, we perform unsupervised adaptation on unlabeled target texts using domain adversarial alignment with a Gradient Reversal Layer (GRL) (Ganin et al., 2016) combined with confidence-gated pseudo-labeling (Lee, 2013; Xie et al., 2020), followed by Stochastic Weight Averaging (SWA) (Izmailov et al., 2018) to seek wider local optima.

2 Dataset Analysis & Task Formulation

2.1 Dataset Splits & Annotation Scheme

Our supervised source data is the Wojood corpus (Jarrar et al., 2022), annotated with 21 entity categories from WojoodOntology (Aljabari et al., 2025a) spanning general classes (`PERS`, `ORG`, `GPE`) and domain-specific types (`LAW`, `WEBSITE`, `CURR`). Entity nesting is common in Wojood; for example, a geopolitical entity فلسطين (Palestine, `GPE`) is literally contained within an organization mention بنك فلسطين (Bank of Palestine, `ORG`).

Wojood adopts a multi-column CoNLL format where each token receives space-separated BIO tags representing active labels (e.g., فلسطين `I-ORG B-GPE`). Standard flat classification networks collapse overlapping labels and miss nested mentions. Our multi-head architecture preserves this structure by isolating predictions into 21 independent channels. The Wojood training corpus exhibits an extreme long-tailed label distribution: frequent categories such as `GPE` (2,156 validation mentions) and `ORG` (1,882 mentions) dominate, whereas minority classes like `PRODUCT` (8 mentions) and `QUANTITY` (3 mentions) provide sparse

October 28-29, 2026 ©2026 Association for Computational Linguistics

supervision.

The target domain is represented by the *Konooz* corpus (Hamad et al., 2025), which spans 10 specialized domains. To prevent data leakage, splits are strictly isolated: supervised pre-training uses the official Wojood training set; in-domain validation is tracked on the Wojood validation set; Phase 2 adaptation strictly uses the unlabeled *Konooz* development set across the 10 domains; and the blinded *Konooz* test set (1,645 sentences) was held out exclusively for final competition evaluation.

2.2 Task Formulation

Given token representations $H \in \mathbb{R}^{L\times 768}$ from the AraBERT backbone, we define 21 parallel linear classifiers, one for each entity type:

$$\hat{y}_t^{(c)} = \text{Softmax}(W^{(c)} h_t + b^{(c)}) \quad (1)$$

where $W^{(c)} \in \mathbb{R}^{3\times 768}$ and $b^{(c)} \in \mathbb{R}^3$ parameterize the classifier for category c, and $\hat{y}_t^{(c)} \in [0,1]^3$ is the predicted BIO distribution $\{B, I, O\}$ for token t and entity type c. By predicting each entity channel independently, the model represents tokens belonging to multiple entity types simultaneously.

Because each entity head outputs a single BIO tag per token, this formulation supports arbitrary overlapping mentions across different entity types, but cannot natively represent concentric spans sharing the identical entity label (e.g., an `ORG` strictly nested inside another `ORG`). In Wojood, such same-type nested mentions do not occur in the annotation schema, making the 21-head factorization well-suited to the task.

3 System Methodology

Our pipeline operates in two sequential phases: supervised source pre-training (Phase 1) and unsupervised target adaptation (Phase 2), followed by SWA checkpoint aggregation.

3.1 Phase 1: Supervised Pre-training

In Phase 1, the network is trained on the labeled Wojood training set by minimizing the summed multi-head cross-entropy loss:

$$\mathcal{L}_{\text{ner\_src}} = \sum_{c=1}^{21} \mathcal{L}_{\text{CE}}(\hat{y}^{(c)}, y^{(c)}) \quad (2)$$

Subword alignment assigns the gold token BIO labels to the first subword piece of each word, while setting subsequent subwords to `ignore_index=-100`. This standard masking ensures that loss computation is evaluated exactly once per word token, preventing multi-subword tokens from exerting disproportionate gradient weight.

3.2 Phase 2: Unsupervised Domain Adaptation

In Phase 2, the model adapts to *Konooz* using labeled source batches (Wojood training set) and unlabeled target batches (*Konooz* development set).

Domain Adversarial Alignment We align the latent feature distributions of the source and target domains via a domain classifier operating on the pooled `[CLS]` representation. The domain head is a two-layer MLP: $\text{Linear}(768, 256) \rightarrow \text{ReLU} \rightarrow \text{Dropout}(0.2) \rightarrow \text{Linear}(256, 2)$ (Srivastava et al., 2014). A Gradient Reversal Layer (GRL) (Ganin et al., 2016) is inserted between the backbone and the domain classifier. In the forward pass, GRL acts as an identity operator; in the backward pass, it multiplies incoming gradients by $-\lambda$, encouraging the encoder to learn domain-invariant representations: $\lambda = 2/(1 + e^{-10\cdot p}) - 1$, where $p = \text{step}/\text{total\_steps}$. The domain classification loss is $\mathcal{L}_{\text{domain}} = \mathcal{L}_{\text{CE}}(\hat{d}, d)$, where $d \in \{0, 1\}$ denotes source vs. target domain. The binary source-vs-target discriminator provides a domain-adversarial objective for reducing aggregate source-target representation discrepancy (Ganin et al., 2016) without requiring fine-grained domain partitions or target labels.

Confidence-Gated Pseudo-Labeling To transfer task knowledge to the target domain, we employ a one-shot teacher-student framework with a fixed teacher. At the start of Phase 2, a frozen copy of the best Phase 1 checkpoint is instantiated as the teacher model θ_{teach}, while the student model θ_{stud} is initialized from the same Phase 1 weights (with its bottom 6 transformer layers frozen). For target sentences, the teacher generates predictions with gradients disabled. We apply token-level confidence gating independently to each token t and entity type c:

$$\mathcal{L}_{\text{st\_tgt}} = \sum_{c=1}^{21} \frac{1}{|S_c|} \sum_{t\in S_c} \mathcal{L}_{\text{CE}}(\hat{y}_{t,\text{stud}}^{(c)}, y_{t,\text{pseudo}}^{(c)}) \quad (3)$$

where $S_c = \{t \mid \max_k \hat{y}_{t,\text{teach}}^{(c)}(k) > \tau\}$ is the subset of tokens whose maximum teacher probability for class c exceeds the threshold $\tau = 0.90$, and

$y^{(c)}_{t,\text{pseudo}}$ is the corresponding predicted tag. Filtering at the token $\times$ entity-type level ensures that only highly confident predictions provide pseudo-supervision, while ambiguous tokens are excluded without discarding entire sentences. The teacher remains frozen throughout Phase 2 to prevent confirmation bias drift.

The student model and domain classifier are jointly optimized by minimizing $\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{ner\_src}} + 0.8\mathcal{L}_{\text{st\_tgt}} + 0.3\mathcal{L}_{\text{domain}}$. The self-training weight (0.8) down-weights pseudo-labeled gradients relative to ground-truth Wojood labels to curb noise propagation, while the conservative domain weight (0.3) avoids distorting token representations (Ganin et al., 2016; Yadav and Bethard, 2018).

3.3 Stochastic Weight Averaging (SWA)

Following adaptation, we average parameter weights across the final $M = 4$ adaptation checkpoints:

$$\theta_{\text{SWA}} = \frac{1}{M} \sum_{m=1}^{M} \theta_m \tag{4}$$

Because AraBERT uses Layer Normalization rather than Batch Normalization, uniform weight averaging does not require recomputing running statistics. SWA is motivated as a regularizer to encourage convergence toward flatter loss basins that can favor generalization (Izmailov et al., 2018).

4 Experimental Setup

Experiments were implemented in PyTorch using Hugging Face transformers on Kaggle Cloud (2$\times$ NVIDIA Tesla T4 GPUs, 30GB RAM, random seed 42).

Preprocessing & Backbone: Sequences are tokenized via AraBERT's WordPiece tokenizer (`bert-base-arabertv02`) with maximum length 512 and first-subword alignment.

Phase 1 (Supervised): Trained using AdamW (Loshchilov and Hutter, 2017) (learning rate 2×10^{-5} (Devlin et al., 2019), ExponentialLR $\gamma = 0.95$, batch size 8, dropout 0.1 (Srivastava et al., 2014)) for up to 50 epochs. Early stopping (patience 5) on Wojood validation Micro F1 terminated training at Epoch 7 (8 epochs total).

Phase 2 (Adaptation): Trained for 5 epochs on the combined Wojood training set and unlabeled *Konooz* development set (batch size 4, weight decay 0.01 (Krogh and Hertz, 1991), learning rate 2×10^{-5} (Howard and Ruder, 2018; Sun et al., 2019)). The bottom 6 layers of AraBERT (embeddings + layers 0–5) are frozen following transfer learning findings that lower transformer layers capture general linguistic features (Kovaleva et al., 2019; Lee et al., 2020), while layers 6–11 and classification heads adapt. SWA is applied across the last 4 checkpoints. Hyperparameters ($\tau = 0.90$, loss weights 0.8 and 0.3, 6 frozen layers, 5 epochs, SWA over 4 checkpoints) were selected during development to balance target adaptation against source retention, drawing on transfer learning conventions for BERT backbones (Kovaleva et al., 2019; Howard and Ruder, 2018).

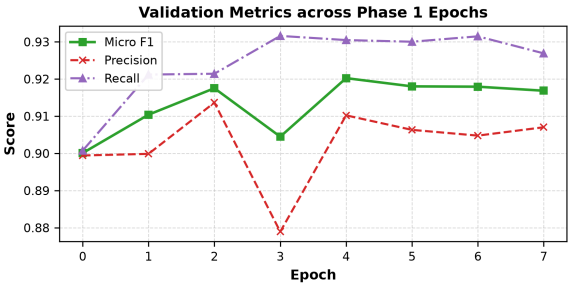

Figure 1: Validation Micro F1, Precision, and Recall metrics over Phase 1 (supervised training) epochs on the Wojood validation set (Seed 42).

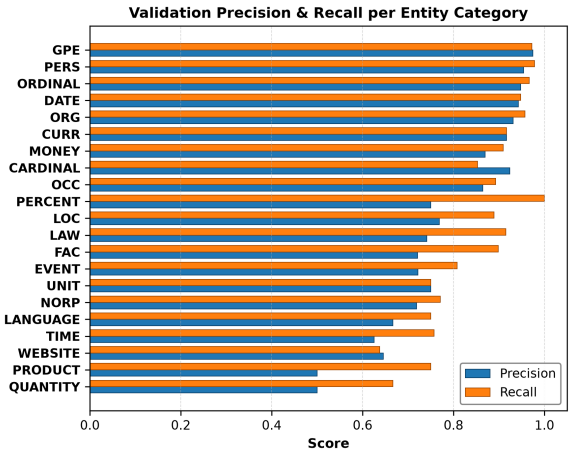

Figure 2: Per-category validation Precision and Recall on the Wojood validation set (evaluated on the post-adaptation SWA model).

5 Results & Discussion

5.1 In-Domain Validation Performance

Figure 1 tracks Phase 1 training. Validation loss reaches its minimum at Epoch 2 (0.0874, F1: 0.9175), whereas validation Micro F1 peaks at Epoch 4 (0.9202, Precision: 91.02%, Recall: 93.05%). This illustrates that validation loss can

System (Evaluation Split)	Precision	Recall	Micro F1
AdaptLinker (Wojood Val)	0.9089	0.9330	0.9208
Shared Baseline (*Konooz* Test)	0.6300	0.4400	0.6220
AdaptLinker (*Konooz* Test)	**0.7548**	**0.7121**	**0.7329**

Table 1: System performance on Wojood validation and official *Konooz* test sets alongside the baseline. AdaptLinker Macro F1: 0.8151 (val), 0.6337 (test).

decouple from entity F1 under 'O'-class dominance, supporting validation Micro F1 as the early-stopping metric.

Phase 2 adaptation initialized from this Epoch 4 model; at adaptation epoch 0, the model achieved 0.9211 Micro F1 on the Wojood validation set. Averaging the final 4 checkpoints via SWA yielded the final model θ_{SWA}, scoring 0.9208 Micro F1 (0.9089 Precision, 0.9330 Recall, 0.8151 Macro F1) on the Wojood validation set (Table 1).

Figure 2 details class-wise Precision and Recall for θ_{SWA}. The system achieves high performance on dominant categories such as `GPE` (0.9735 F1) and `PERS` (0.9658 F1), but exhibits lower scores on rare classes like `PRODUCT` (0.6000 F1) and `QUANTITY` (0.5714 F1), consistent with their sparse representation in the data.

5.2 Official Test Evaluation

Table 1 reports official competition results on the blinded test set (1,645 sentences across 10 *Konooz* domains). The final SWA model achieved an official Micro F1 of 0.7329 (0.7548 Precision, 0.7121 Recall, 0.6337 Macro F1), placing 6th, compared with 0.622 Micro F1 (0.63 Precision, 0.44 Recall) for the baseline.

The 18.79% drop in Micro F1 illustrates cross-domain difficulty. Higher Precision (75.48%) than Recall (71.21%) may reflect more conservative predictions out-of-domain. We hypothesize that while adversarial alignment and pseudo-labeling capture shared structural features, pronounced lexical and syntactic shifts disproportionately suppress recall on domain-specific entities. Moreover, the Micro F1 (0.7329) vs. Macro F1 (0.6337) gap is consistent with the long-tailed class distribution: frequent categories transfer more reliably, whereas rare categories exhibit lower scores, lowering the unweighted macro average.

6 Error Analysis

Out-of-Vocabulary Subword Fragmentation: In technical domains (Health, Science, Law), specialized Arabic terminology is infrequent in AraBERT's vocabulary. The tokenizer fractures these terms into multiple subwords; we hypothesize this weakens span representations, contributing to missed entities and lower recall (71.21%).

Boundary Ambiguity in Nested Mentions: Because the 21 classification heads operate independently without transition decoding constraints, overlapping predictions can exhibit boundary inconsistencies where one head detects a span but an overlapping head misses or truncates it.

Minority-Class Pseudo-Label Sparsity: We hypothesize that a fixed threshold ($\tau = 0.90$) disadvantages low-support categories (e.g., `PRODUCT` with 8 validation instances, `QUANTITY` with 3). Because the teacher rarely predicts rare entities with high confidence, the student receives negligible pseudo-supervision for minority classes on target text.

7 Limitations

Domain Shift Sensitivity: Unsupervised alignment using GRL and pseudo-labeling cannot fully bridge pronounced lexical shifts in technical domains like Law and Medicine.

Pseudo-Label Noise: Confident but erroneous teacher predictions introduce noisy supervision, which can propagate confirmation bias to the student model.

Structural Representation Constraint: Factorizing the label space into 21 independent heads cannot represent concentric nested mentions of the identical entity type, though this constraint matches Wojood's annotation schema.

Computational Footprint: Dual forward passes (source and target batches) and maintaining a separate teacher model increase memory requirements during adaptation.

8 Conclusion & Future Work

We presented AdaptLinker, a multi-head AraBERT framework for cross-domain Arabic nested NER combining domain adversarial training, pseudo-labeling, and SWA. AdaptLinker achieved an official Micro F1 of 0.7329 on the out-of-domain *Konooz* test set (vs. 0.622 for the baseline), placing 6th. Future work includes character encoders (CANINE), multi-domain objectives, and component ablations.

Abstract

Arabic knowledge graph construction is a challenging problem due to the linguistic complexity of Arabic and the need for robust generalization across domains. This paper presents our systems for the KnowledgeGraphEval 2026 shared task on Arabic knowledge graph construction and domain adaptation, covering two subtasks: AdaptNER for cross-domain named entity recognition and relation extraction (RE). For AdaptNER, we employ an entity-span ensemble combining two BIO sequence taggers with constrained conditional random field (CRF) decoding and a GlobalPointer span classifier. Our system achieved a micro-F1 score of 75.96%, ranking first in the official evaluation. For relation extraction, we use a majority-vote ensemble of three LoRA-fine-tuned causal language models. This approach achieved a micro-F1 score of 93.48%, ranking second. These results demonstrate the effectiveness of model ensembling and complementary prediction strategies for Arabic named-entity recognition and relation extraction.

1 Introduction

Knowledge graphs (KGs) structure entities and their semantic relations, which is beneficial for applications like information retrieval and question answering. The construction of KGs from Arabic texts still suffers from the language diversity and the scarcity of annotated data. KnowledgeGraphEval 2026 covers this with two subtasks: Named Entity Recognition (NER) and Relation Extraction (RE) (Aljabari et al., 2026).

The first subtask, **AdaptNER**, evaluates cross-domain generalization for Arabic NER. Systems are trained using *Wojood*, which contains approximately 550K tokens annotated with 21 entity types and nested entities (Jarrar et al., 2022; Aljabari et al., 2025a), and evaluated on ten unseen domains from *Konooz* (Hamad et al., 2025). This setup measures how well NER models handle domain shift, an important challenge since previous evaluations have reported substantial performance degradation on unseen Arabic domains.

The second subtask, **Relation Extraction**, requires predicting the semantic relation between predefined entity pairs or assigning *no-relation* when no valid relation exists (Aljabari et al., 2026). The task is based on $\text{Wojood}^{\text{Relations}}$, which contains approximately 15K annotated relation triples across 40 relation types (Aljabari et al., 2025b). Accurate relation extraction is essential for transforming detected entities into structured knowledge graph connections.

The two subtasks pose complementary challenges: AdaptNER requires accurate entity boundaries and cross-domain generalization, while RE requires distinguishing fine-grained and ambiguous relations. We address both using ensemble-based approaches that combine complementary models for entity and relation prediction.

Our main contributions are:

- For **AdaptNER**, we propose an entity-span ensemble that combines two BIO sequence taggers with constrained CRF decoding and a GlobalPointer span classifier. The system achieves a **micro-F1 score of 75.96%** and ranks **first** in the official evaluation.
- For **Relation Extraction**, we develop a majority-vote ensemble of three LoRA-fine-tuned causal language models. The system achieves a **micro-F1 score of 93.48%** and ranks **second** in the official evaluation.

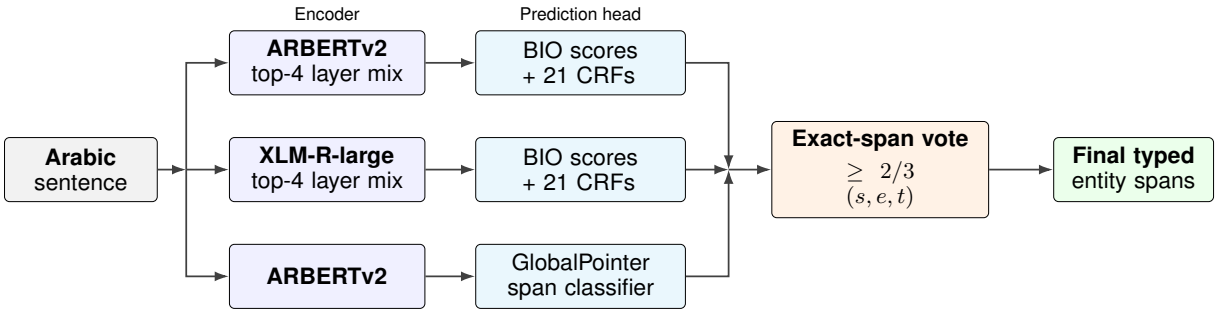

Figure 1: Subtask 1 pipeline combining two BIO-CRF models and a GlobalPointer span model using exact entity-span majority voting.

et al., 2020), and cross-domain data augmentation (Chen et al., 2021). Ensemble approaches combine predictions from multiple pretrained encoders: Schneider et al. (2022) use token-level soft voting over transformer taggers for complex NER, improving over individual models on two of the three evaluated tracks. Span-based methods provide another formulation of entity recognition; GlobalPointer directly scores typed candidate spans and supports nested entities (Su et al., 2022). For Arabic, Konooz evaluates NER across multiple domains and dialects and documents substantial performance degradation on unseen domains (Hamad et al., 2025).

Subtask 2: Relation Extraction. Entity-centered representations support supervised RE (Baldini Soares et al., 2019), while AREEj incorporates relational evidence for Arabic extraction (Al Mraikhat et al., 2024). For causal LLM-based RE, Efeoglu and Paschke (2025) fine-tune Llama2 and Mistral using LoRA and also integrate the adapted models into retrieval-augmented generation. LoRA learns low-rank weight updates while freezing pretrained parameters, reducing the number of trainable parameters (Hu et al., 2021). Heterogeneous LLM ensembling also appears in ZeroSemble, which uses weighted majority voting for entity-type resolution in a zero-shot document IE pipeline before entity-constrained RE (Pham Hoang Le et al., 2025).

3 Methodology

3.1 Subtask 1: Cross-Domain Named Entity Recognition

As shown in Figure 1, our AdaptNER system consists of three complementary models: two BIO sequence taggers with constrained CRFs and a GlobalPointer span classifier. Their predictions are combined using exact entity-span majority voting.

3.1.1 Encoder Models

We use ARBERTv2 as an Arabic-specific encoder and XLM-RoBERTa-large as a multilingual encoder (Abdul-Mageed et al., 2021; Conneau et al., 2020). To exploit information from different representation levels, we learn a weighted mixture of the top four Transformer layers:

$$h_i = \sum_{k=1}^{4} \mathrm{softmax}(\mathbf{a})_k h_i^{(k)}, \tag{1}$$

where $\mathbf{a}$ contains trainable mixture weights, h_i refers to the ith token hidden state and k refers to the layer number. The resulting representation is projected into BIO scores for each of the 21 entity types.

3.1.2 BIO-Constrained CRF

For each encoder, 21 independent linear-chain CRFs are trained, one for each entity type. Hard BIO constraints prevent invalid sequences, such as an `I` tag starting a sequence or directly following an `O` tag. Training combines the CRF negative log-likelihood with a weighted token-level cross-entropy loss:

$$\mathcal{L} = \mathcal{L}_{\mathrm{CRF}} + 0.1\,\mathcal{L}_{\mathrm{CE}}. \tag{2}$$

Using ARBERTv2 and XLM-RoBERTa-large provides model diversity while preserving the same structured prediction architecture.

3.1.3 GlobalPointer

The third model uses ARBERTv2 with GlobalPointer (Su et al., 2022), formulating NER as typed span classification. For an entity type t and a candidate span (s, e), the span score is

$$S(t, s, e) = \frac{q_{s,t}^{\top} k_{e,t}}{\sqrt{d}}, \tag{3}$$

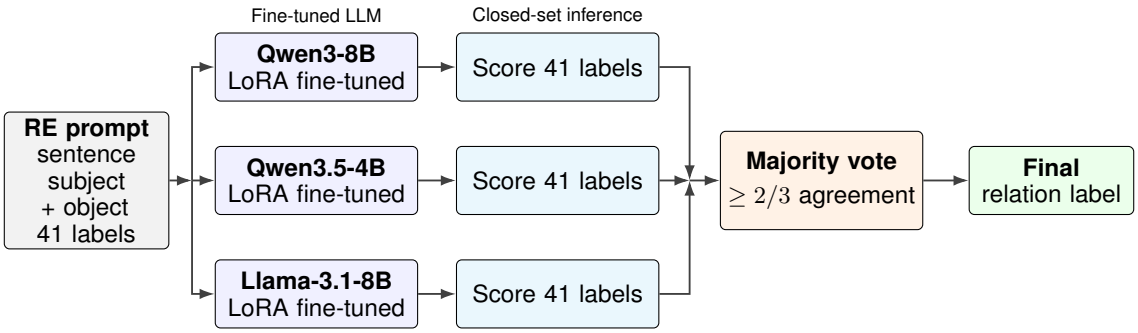

Figure 2: Subtask 2 pipeline combining three LoRA-fine-tuned causal LLMs with constrained label scoring and majority voting.

where $q_{s,t}$ and $k_{e,t}$ are learned type-specific representations of the start and end positions, respectively, and d is their representation dimension. The dot product measures the compatibility of s and e as the boundaries of an entity of type t, while the factor $\sqrt{d}$ stabilizes the score magnitude. Thus, a higher $S(t, s, e)$ indicates greater confidence that the span corresponds to entity type t.

The maximum span length is a hyperparameter set to 64 words, based on the assumption that longer named entities are rare. At inference, spans whose scores exceed the decoding threshold are retained. If more than 256 candidates remain for an entity type, only the top 256 are considered. Weighted interval scheduling is then applied to select the highest-scoring non-overlapping spans for each entity type.

3.1.4 Exact Entity-Span Ensemble

The three models are combined using exact entity-level majority voting. Each model prediction is converted into a set of typed spans of the form $(\text{start}, \text{end}, \text{entity type})$, and votes are counted for each unique span. A candidate is retained when at least two of the three models predict exactly the same start and end boundaries and entity type. This span-level voting directly matches the official exact-span evaluation criterion and avoids inconsistencies that may arise from combining predictions at the token level.

3.2 Subtask 2: Relation Extraction

As shown in Figure 2, our relation extraction system uses supervised fine-tuning followed by closed-set relation label scoring. We fine-tune Qwen3-8B, Qwen3.5-4B[1], and Llama-3.1-8B-Instruct using Low-Rank Adaptation (LoRA) (Hu et al., 2021). Each prompt contains the Arabic sentence, ordered subject and object mentions, and the complete relation-label inventory, while the target contains only the correct relation label.

3.2.1 LLM Fine-Tuning and Ensemble

Rather than using free-form generation, inference is constrained to the 41 valid relation labels. Each candidate relation r is scored using its mean teacher-forced token log-likelihood:

$$\frac{1}{|r|}\sum_{j=1}^{|r|}\log p(r_j \mid x, r_{<j}), \tag{4}$$

where r_j is the j-th token of the candidate relation label and x denotes the input prompt. Averaging over the label length reduces bias toward labels represented by fewer tokens. The highest-scoring label is selected for each model. The predictions from the three LLMs are then combined by majority voting with a deterministic tie-breaker, with Qwen3.5-4B used as the tie-breaker when all predictions differ, as it is the model with best standalone performance.

4 Experiments

4.1 Datasets

For **Subtask 1**, we train on the Wojood NER corpus, which contains approximately 550K Arabic tokens annotated with 21 entity types, including nested entities (Jarrar et al., 2022). Evaluation is performed on ten unseen domains from Konooz, making the task a direct test of cross-domain generalization (Hamad et al., 2025).

For **Subtask 2**, we use the Relation Extraction dataset derived from $\text{Wojood}^{\text{Relations}}$, which contains approximately 15K annotated relation triples across 40 semantic relation types (Aljabari et al., 2025b). Including `no_relation`, the final prediction space contains 41 labels.

[1]Official model identifier: `Qwen/Qwen3.5-4B`.

Model	Acc.	Recall	Precision	Micro-F1
Shared-task baseline	–	63.87	62.30	63.00
ARBERTv2 + CRF	99.55	70.08	80.69	75.01
XLM-R-large + CRF	99.55	71.12	79.41	75.04
ARBERTv2 + GlobalPointer	99.48	66.17	84.02	74.03
Exact-Span Ensemble	99.53	69.44	83.83	**75.96**

Table 1: Official AdaptNER test results. Precision, recall, and F1 are entity-level micro-averages under exact span-and-type matching. Scores are reported as percentages; – denotes an unreported baseline metric.

4.2 Training Setup

For AdaptNER, models use a maximum input length of 512, dropout of 0.1, batch size of 32, BF16 precision, and train for up to 15 epochs with early stopping patience of 5. The encoder learning rate is 2×10^{-5}, with 10^{-4} for task heads and 10^{-3} for CRFs; we use 0.01 weight decay, 10% warmup, and a linear scheduler.

For Relation Extraction, the three causal LLMs are fine-tuned with LoRA using rank 16, scaling factor 32, dropout 0.05, and a learning rate of 2×10^{-4}. Training uses BF16 precision for three epochs, with sentence-level grouping between training and validation splits.

4.3 Results

4.3.1 Subtask 1: AdaptNER

Table 1 compares the shared-task baseline, the two CRF systems, the GlobalPointer model, and their exact-span ensemble. The ensemble achieved a **micro-F1 score of 75.96%**, exceeding the baseline F1 of 63.00% by 13.00 percentage points and ranking **first** in the official evaluation.

4.3.2 Subtask 2: Relation Extraction

Table 2 compares the shared-task BERT (ArBERTv2) and LLM (gpt-4o) baselines with the three fine-tuned LLMs and their majority-vote ensemble. The ensemble achieved a **micro-F1 score of 93.48%**, exceeding the baseline F1 scores of 88.61% and 85.78% by 4.87 and 7.70 percentage points, respectively, and ranking **second** in the official evaluation.

4.4 Analysis & Limitations

For AdaptNER, exact-span voting enhances micro-F1 from 75.04 to 75.96, a gain of 0.96 points. Ensemble precision rises from 79.41 to 83.83, while recall drops from 71.12 to 69.44, indicating a conservative approach that may filter out valid entities. In Relation Extraction, majority voting boosts the micro-F1 score from 92.77 to 93.48, reflecting a gain of 0.71 points, along with improved precision (96.20 to 96.80) and recall (89.58 to 90.38). However, both ensemble methods increase inference costs and do not resolve shared errors, with limitations on error localization.

Model	Recall	Precision	Micro-F1
Shared-task baseline	–	–	93.09
Qwen3-8B	89.35	95.59	92.36
Qwen3.5-4B	89.58	96.20	92.77
Llama-3.1-8B-Instruct	89.03	96.21	92.48
Majority-Vote Ensemble	90.38	96.80	**93.48**

Table 2: Results for Subtask 2 (Relation Extraction). Scores are reported as percentages.

5 Conclusion

This paper presented our systems for the KnowledgeGraphEval 2026 shared task on cross-domain Arabic NER and relation extraction. For AdaptNER, an ensemble of two BIO-CRF models and a GlobalPointer classifier achieved **75.96%** micro-F1 and ranked **first**. For Relation Extraction, a majority-vote ensemble of three fine-tuned causal LLMs achieved **93.48%** micro-F1 and ranked **second**. Overall, the results highlight the effectiveness of complementary model ensembles for Arabic entity and relation extraction.

Abstract

This paper presents the PTUK-NLP submission to KnowledgeGraphEval 2026 Subtask 1 (AdaptNER), evaluating cross-domain and cross-dialect nested Arabic NER: models trained on Wojood are evaluated zero-shot on *Konooz*, spanning ten unseen domains and sixteen Arabic dialects. Our system fine-tunes ArBERT with targeted augmentation for rare entity types and lightweight inference-time post-processing, using *Konooz* strictly for evaluation, never for training or adaptation. The submitted system achieves 91.07% micro-F1 and 83.11% macro-F1 on Wojood, and 71.84% precision, 66.59% recall, 69.11% micro-F1, and 60.70% macro-F1 on the official *Konooz* blind test – fourth on the final leaderboard, 6.11 points above the organizers' baseline. A post-submission ensemble of ArBERT and AraBERTv2 does not improve over the best single model. Overall, targeted data-centric modifications provide useful gains for rare entity types while a standard MSA-pretrained encoder remains competitive under substantial domain and dialect shift.

1 Introduction

Named Entity Recognition (NER) is a fundamental component of information extraction and knowledge graph construction (Kejriwal, 2019). Although recent Arabic NER systems achieve strong performance on established benchmarks, their performance can degrade substantially when evaluated across domains and dialects. This challenge is particularly pronounced for nested NER, where entity spans may overlap, and for dialectal Arabic, which exhibits substantial lexical, morphological, and orthographic variation.

KnowledgeGraphEval 2026 (Aljabari et al., 2026), organized by Birzeit University's SinaLab, addresses these challenges through AdaptNER (Aljabari et al., 2026), a shared task on cross-domain and cross-dialect nested Arabic NER. Systems are trained exclusively on the Wojood corpus, which contains Modern Standard Arabic (MSA) together with Palestinian and Lebanese dialectal text (Jarrar et al., 2022), and are evaluated on the *Konooz* benchmark, which covers ten previously unseen domains and sixteen Arabic dialects (Hamad et al., 2025). This setting therefore evaluates transfer beyond both the domains and dialectal varieties represented in the training corpus.

Our study investigates three practical questions. First, can an MSA-pretrained encoder provide competitive transfer performance without dialect-specific pretraining or target-domain adaptation? Second, can targeted data augmentation improve recognition of severely under-represented entity types? Third, does combining complementary pretrained encoders provide additional robustness under domain and dialect shift?

Rather than introducing a new NER architecture, we build on the official SinaLab ArabicNER framework (Khalilia) and examine several practical modifications. We adopt ArBERT as the encoder, introduce a span-preserving augmentation strategy during training, and apply two lightweight post-processing rules at inference time. Checkpoint selection is aligned with the task evaluation metric by using validation micro-F1 rather than validation loss.

The submitted system achieves 91.07% micro-F1 on Wojood and 69.11% micro-F1 on the official *Konooz* blind test. We additionally analyze the effect of augmentation and a post-submission encoder ensemble: augmentation gains concentrate in rare entity categories, while the ensemble shows no benefit over the best individual encoder.

2 Background

2.1 Task and datasets

The AdaptNER shared task (Aljabari et al., 2026) is based on the Wojood and *Konooz* datasets, which

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1205–1211
October 28-29, 2026 ©2026 Association for Computational Linguistics

share a nested annotation schema containing 21 entity types. Wojood (Jarrar et al., 2022) contains approximately 550K annotated tokens spanning Modern Standard Arabic and two dialectal Arabic corpora: the Palestinian *Curras* corpus and the Lebanese *Baladi* corpus.

Unlike conventional flat NER, Wojood allows entities to overlap, represented via parallel BIO tag layers (Section 3).

We use the official Wojood split, consisting of 23,125 training sentences, 3,304 validation sentences, and 6,606 test sentences, corresponding to approximately 391K, 57.6K, and 113.7K tokens, respectively. Approximately 4.4% of tokens are assigned to multiple nested labels.

The target benchmark, *Konooz*, contains text from ten previously unseen domains covering sixteen Arabic dialects (Hamad et al., 2025). Since AdaptNER evaluates cross-domain and cross-dialect transfer, models are trained using Wojood and applied to *Konooz* without target-domain supervision. Predictions must preserve the released tokenization and follow the fixed 21-column nested BIO output format.

2.2 Related work

Early experiments on Wojood reported an F1 score of 88.4% using AraBERTv2 (Jarrar et al., 2022). Subsequent Wojood shared-task systems explored more sophisticated approaches, including bi-encoder span representations (Hussein et al., 2023) and nearest-neighbor-enhanced decoding (Abdou and Mahmoud, 2024). Previous evaluations have also shown that AraBERT-family models can perform strongly on Wojood despite being pretrained primarily on MSA, motivating the use of an MSA-oriented encoder in the present cross-domain setting. Beyond NER, the Wojood ecosystem has been extended to event-argument extraction (Aljabari et al., 2024) and relation extraction (Aljabari et al., 2025), reflecting its broader role as a foundation for Arabic information extraction.

More generally, cross-domain NER has been studied using domain-adaptive pretraining, shared-parameter architectures, and adaptation layers. Liu et al. (2021), for example, demonstrated the effectiveness of continued pretraining on unlabeled target-domain data for cross-domain NER. Such approaches, however, are not applicable to the strict zero-shot setting considered here because the AdaptNER protocol restricts training to the labeled Wojood data and does not permit target-domain adaptation.

Our work therefore focuses on relatively lightweight interventions that remain compatible with the shared-task constraints: encoder selection, targeted augmentation of rare entity types, and inference-time rules that preserve the released tokenization and nested output structure.

3 System

Our system extends the official SinaLab ArabicNER framework with a different encoder, targeted training-time augmentation, and task-specific inference-time post-processing. The underlying nested NER architecture remains unchanged. Figure 1 summarizes the end-to-end pipeline.

3.1 Model architecture

We adopt the `BertNestedTagger` architecture provided by the official SinaLab ArabicNER framework (Khalilia). The architecture consists of a shared BERT encoder followed by 21 independent token-classification heads, one for each entity type.

For every subword token, the shared encoder produces a contextualized representation that is passed to all 21 classification heads. Each head predicts a three-way B/I/O distribution for its corresponding entity type. Because the heads operate independently, multiple entity types can be assigned to the same token, allowing overlapping entity spans to be represented naturally without modifying the input representation or tokenization.

3.2 Encoder comparison and checkpoint selection

We use ArBERT (UBC-NLP/ARBERT) (Abdul-Mageed et al., 2021) as the main encoder. For comparison, we also train AraBERTv2 (aubmindlab/bert-base-arabertv2) (Antoun et al., 2020) under the same general experimental configuration.

The two encoders achieve similar performance on the Wojood validation set, while ArBERT provides stronger performance in our cross-domain development experiments on *Konooz*. The official submission uses ArBERT. To avoid conflating model selection with the analysis of individual target-domain behaviors, the *Konooz* development results are reported separately from the source-domain checkpoint-selection criterion.

During training, checkpoints are selected according to validation micro-F1 rather than validation

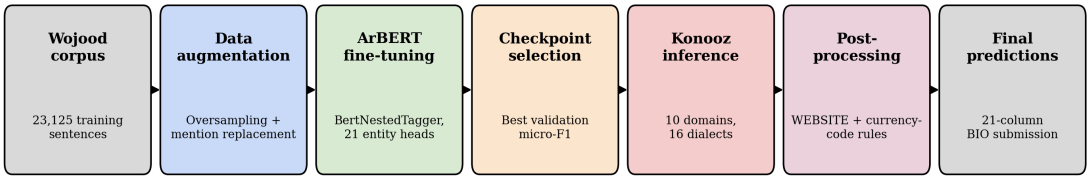

Figure 1: End-to-end system pipeline, from Wojood training data through augmentation, fine-tuning, checkpoint selection, *Konooz* inference, and post-processing to the final submission.

loss. This aligns checkpoint selection with the span-level metric used for evaluation: validation loss may plateau or increase even when F1 continues to improve. Selecting according to the evaluation metric therefore provides a more direct criterion for choosing the final checkpoint.

3.3 Targeted data augmentation

Entity-type imbalance is substantial in Wojood, with several entity categories having very few training examples. We therefore apply two complementary augmentation procedures during training only.

First, sentences containing at least one mention of an entity type with fewer than 1,000 corpus-wide occurrences are oversampled by a factor of two. This criterion identifies 12 of the 21 entity types.

Second, flat entity mentions are replaced with same-type mentions drawn from a type-specific gazetteer constructed from the training set. Each gazetteer contains surface-form token sequences extracted from flat entity mentions of the corresponding type. Replacement is performed while preserving the number of tokens and the corresponding BIO labels. Nested entity mentions are excluded from replacement to avoid altering overlapping structures.

The two procedures increase the training set from 23,125 to 29,035 sentences. For example, the number of MONEY mentions increases from 172 to 373 and UNIT mentions from 46 to 106. Neither the validation nor test data is augmented.

The detailed augmentation parameters are provided in Appendix A.1, while the gazetteer construction procedure is described in Appendix A.2.

3.4 Inference-time post-processing

We apply two lightweight post-processing rules after model inference.

The first addresses WEBSITE entities. Because web addresses can be fragmented across several tokens, the procedure extends an existing WEBSITE prediction across adjacent URL-related tokens when appropriate.

The second addresses Latin-script ISO 4217 currency codes, such as USD, EUR, and JPY, which are absent from the training data. When one of the predefined currency codes is predicted as O, it is assigned a B-CURR label.

Both procedures are conservative: they supplement or extend existing predictions and do not overwrite non-O model predictions. The complete rules are given in Appendix A.3 and A.4.

3.5 Training setting

***Konooz* usage.** We state explicitly, as requested by the organizers: no *Konooz* data of any kind – development or blind test – is used for training or for any form of target-domain adaptation at any point in this work. Training uses Wojood exclusively. *Konooz* development is used only for two purposes prior to the blind submission: reporting development-set metrics (Section 4) and the encoder comparison in Section 3 (choosing ArBERT over AraBERTv2), both permitted uses of the released development split. The *Konooz* blind test is used exclusively for the single official evaluation reported here. This is consistent with the final leaderboard, on which our system is confirmed by the organizers to be among the four submissions that used *Konooz* strictly for evaluation.

We tokenize input using ArBERT's WordPiece tokenizer with a maximum sequence length of 512 subword tokens; during *Konooz* inference, the released placeholder annotation columns are discarded while the original tokenization is preserved. Models are fine-tuned for up to 30 epochs using AdamW with a learning rate of 5×10^{-5} and a batch size of 16, with early stopping (patience of five epochs) based on validation micro-F1; all encoder parameters are updated during fine-tuning.

Experiments are implemented using PyTorch,

HuggingFace Transformers, Accelerate, and seqeval, and are conducted on a single NVIDIA T4 GPU. Unless otherwise stated, results are entity-level micro-F1 and macro-F1 calculated using seqeval in accordance with the official evaluation procedure.

4 Experimental Results

We first evaluate the system on the in-distribution Wojood test set. We then report results on the *Konooz* development set and the official blind test. Finally, we analyze the contribution of the augmentation strategy and a post-submission encoder ensemble.

4.1 Wojood

Model	Mi-F1	Ma-F1
AraBERTv2 baseline (Jarrar et al., 2022)	88.40	–
ArBERT reported (Hamad et al., 2025)	91.73	–
Ours (submitted checkpoint)	**91.07**	**83.11**

Table 1: Wojood nested NER test results.

Our submitted model achieves 91.07% micro-F1 and 83.11% macro-F1 on the Wojood test set. This improves over the original AraBERTv2 baseline by 2.67 micro-F1 points and approaches the strongest previously reported result shown in Table 1.

Performance is particularly strong for frequent entity categories. GPE, ORG, PERS, and DATE each achieve F1 values above 90%. WEBSITE remains the most difficult category, with an F1 of 43.32%. The fragmented structure of web addresses contributes to partial span predictions, motivating the WEBSITE-specific post-processing rule described above.

Because several entity types have very small test support, individual per-type scores should be interpreted cautiously. The complete per-type results are reported in Appendix A.

4.2 Augmentation ablation

To evaluate the contribution of our augmentation strategy, we train three additional ArBERT models under the same protocol: one on the original 23,125-sentence Wojood training set without any augmentation, one with oversampling applied alone, and one with mention replacement applied alone, isolating each component's individual effect alongside the full, submitted combination.

The full decomposition reveals that *neither component alone reproduces the gain of the combination*. Oversampling alone yields a small overall improvement (+0.19 micro-F1, +0.14 macro-F1) but is inconsistent per type, hurting PRODUCT, UNIT, and MONEY relative to no augmentation. Mention replacement alone is, if anything, worse overall (Ma-F1 77.26, *below* the no-augmentation baseline of 80.31): it helps PRODUCT, MONEY, and CURR, but collapses UNIT entirely to 0% F1 (0 of 11 test instances correctly tagged) – while this collapse is on very low support and could partly reflect chance, at minimum it shows mention replacement alone can destabilize a rare type's representation, plausibly because replacing a large share of the already-scarce UNIT mentions with gazetteer substitutes, without oversampling to reinforce them, reduces the model's exposure to reliable UNIT examples rather than increasing it. Only when both components are combined does every one of the five targeted types improve, most strikingly PRODUCT (48.48% to 78.79%) and UNIT's full recovery to 90.00%.

Type	No aug.	+Over.	+Repl.	Both
Mi-F1	90.82	91.01	90.76	**91.07**
Ma-F1	80.31	80.45	77.26	**83.11**
PRODUCT	48.48	46.51	60.00	**78.79**
UNIT	80.00	66.67	0.00	**90.00**
QUANTITY	63.16	63.64	66.67	**70.00**
MONEY	78.87	74.67	82.86	**84.51**
CURR	88.10	91.76	90.00	**92.31**

Table 2: Wojood test results decomposing the augmentation strategy into oversampling alone, mention replacement alone, and both combined ("Both" is our full, submitted configuration).

This pattern is best read as a positive interaction between the two components rather than either one driving the gain: oversampling appears to supply the repeated exposure that keeps replacement's added lexical diversity from destabilizing the rarest types, while replacement supplies diversity that oversampling alone lacks. Neither substitutes for the other; the two together compound into most of the reported +2.80 macro-F1 improvement. As with the combined result, we recommend interpreting individual per-type changes cautiously given the very small test support of these categories (e.g. PRODUCT has only 19 test instances, UNIT and QUANTITY have 11 and 9).

4.3 *Konooz* development

On the *Konooz* development set, the system obtains 70.52% micro-F1 and 55.29% macro-F1. The development set contains only 100 sentences, so these values should be regarded as a relatively noisy indicator of cross-domain performance.

Metric	Value
Precision	72.93
Recall	68.26
Micro-F1	**70.52**
Macro-F1	**55.29**

Table 3: *Konooz* development results across all ten domains.

Compared with the Wojood test results, performance decreases substantially under the combined domain and dialect shift. Precision is higher than recall, suggesting that the model behaves conservatively under distribution shift: it is more likely to miss unfamiliar entities than to introduce large numbers of false positives. This interpretation is consistent with the model producing 410 predicted spans compared with 438 reference spans.

The difference between source-domain and target-domain performance illustrates the difficulty of transferring nested NER models beyond the domains and dialectal varieties represented during training.

4.4 *Konooz* official test

The submitted system achieves 71.84% precision, 66.59% recall, 69.11% micro-F1, and 60.70% macro-F1 on the official *Konooz* blind test, per the shared task's final results.

Rank	Team	P	R	Mi-F1
1	NAMAA	83.83	69.44	75.96
2	Wasl	80.60	69.82	74.83
3	McMasterNLP	75.00	74.00	74.38
4	**PTUK-NLP (ours)**	**71.84**	**66.59**	**69.11**
5	ArmyForNER	82.11	68.77	74.85
6	AdaptLinker	75.48	71.21	73.29
7	YafaNER	73.25	69.52	71.33
8	ANLP-UniSo	81.43	63.04	71.06
–	Baseline	63.87	62.30	63.00

Table 4: Final official AdaptNER leaderboard. Ranks 1–4 used *Konooz* strictly for evaluation, like ours; ranks 5–8 used Konooz data during training or adaptation.

Our system ranks fourth on the final official leaderboard, among the four rule-compliant systems (Section 3). Its 69.11% micro-F1 exceeds the organizers' 63.00% baseline by 6.11 percentage points; macro-F1 is 60.70% versus 44.00%.

The blind test result is close to the *Konooz* development micro-F1 (70.52%), while macro-F1 rises from 55.29% to 60.70%; since the test set is much larger than the 100-sentence development set, it gives a more stable estimate of cross-domain performance. We also regenerated predictions from the saved checkpoint and obtained identical scores, confirming reproducibility.

4.5 Post-submission encoder ensemble

As a post-submission analysis (not part of the official submission), we test whether combining ArBERT and AraBERTv2 predictions via per-entity-type specialist voting improves cross-domain performance.

System	Mi-F1	Ma-F1
AraBERTv2 alone	67.96	47.11
Specialist ensemble	70.04	55.14
ArBERT alone	**70.52**	**55.29**

Table 5: Post-submission comparison on the *Konooz* development set.

The specialist ensemble achieves 70.04% micro-F1, slightly below ArBERT alone's 70.52%; this 0.48-point gap is small given the development set's size and should not be read as strong evidence that ensembling is generally ineffective. Encoder complementarity on source-domain data does not necessarily translate cross-domain: AraBERTv2 is competitive with ArBERT on several Wojood categories, but these advantages do not consistently transfer to *Konooz*.

5 Conclusion

This paper presented the PTUK-NLP system for KnowledgeGraphEval 2026 Subtask 1 (AdaptNER), evaluating nested Arabic NER under cross-domain and cross-dialect transfer. Rather than a new architecture, our contribution is empirical: whether a standard MSA-pretrained encoder with targeted augmentation and lightweight post-processing can perform competitively on previously unseen *Konooz* domains and dialects. The submitted ArBERT system achieves 91.07% micro-F1 and 83.11% macro-F1 on Wojood and 69.11% micro-F1 and 60.70% macro-F1 on the official *Konooz* blind test, outperforming the organizers' baseline by 6.11 micro-F1 points.

Neither augmentation component alone reproduces the full effect – only their combination delivers the macro-F1 gain – and the tested encoder ensemble does not improve upon ArBERT alone (Section 4). The 91.07-to-69.11 micro-F1 drop from Wojood to *Konooz* is the paper's clearest signal: cross-dialect and cross-domain shift remain substantially harder for Arabic NER than in-distribution performance suggests, and closing that gap will likely require target-domain-aware methods beyond this system's current constraints.

6 Limitations

This study has several limitations. First, the *Konooz* development set contains only 100 sentences, making development-set comparisons potentially noisy; we therefore place greater emphasis on the official blind-test result. Second, models were trained using a limited number of runs with no seed-variance analysis, so small differences – and in particular the individual-component ablation results in Section 4.2, which rest on single runs each – should not be read as statistically established; the apparent interaction effect between oversampling and mention replacement could partly reflect training variance rather than a stable property of the two techniques. Third, some entity-level results rest on very small test supports (PRODUCT, UNIT, and QUANTITY have only 19, 11, and 9 test instances, respectively), most notably UNIT's collapse to 0% F1 under mention replacement alone, and should be interpreted cautiously. Fourth, the post-processing rules are hand-designed for the released task representation, their effectiveness outside this setting is unknown, and we do not separately quantify each rule's contribution. Finally, the study is strictly zero-shot and does not investigate domain-adaptive pretraining or other unlabeled target-domain adaptation, which fall outside the task's constraints.

A Additional Implementation Details

A.1 Augmentation parameters

The rare-type threshold is 1,000 mentions. The resulting targeted entity types are CURR, FAC, LANGUAGE, LAW, LOC, MONEY, PERCENT,

PRODUCT, QUANTITY, TIME, UNIT, and WEBSITE.

The oversampling factor is $2\times$. Mention replacement is applied to 15% of the original training sentences.

All augmentation is performed only on the training set. Validation and test instances are not modified.

A.2 Gazetteer construction

For each entity type, we scan every training sentence and collect the surface-form token sequence of every flat, non-nested mention of that type.

Occurrences are appended to a type-specific list and are not deduplicated. Consequently, if a surface form occurs k times in the training corpus, it appears k times in the corresponding list.

When replacing a mention, a candidate is sampled uniformly from the list using `random.choice`, excluding entries identical to the mention being replaced. Because repeated surface forms occur multiple times in the list, this procedure samples surface forms in proportion to their frequency in the training data rather than uniformly over unique surface forms.

Nested mentions are never added to the gazetteers and are never selected as replacements.

A.3 WEBSITE post-processing

The WEBSITE procedure operates on the model's per-token predictions in two passes.

In the forward pass, tokens are scanned from left to right. Whenever a token is already tagged B-WEBSITE or I-WEBSITE, the procedure extends the prediction to immediately following tokens when those tokens: (1) are not already tagged; (2) match one of the predefined URL-fragment patterns; and (3) occur within the maximum extension length of 15 tokens.

The backward pass scans from right to left and applies the analogous procedure.

The extension patterns include bare punctuation (`/`, `.`, `:`, `-`, `_`), URL/domain keywords such as `http`, `https`, `www`, `com`, `org`, `net`, `io`, `edu`, and `gov`, and bare Latin alphanumeric tokens of length 1–20 characters.

The procedure only extends an existing WEBSITE prediction. If the model predicts no WEBSITE token anywhere in a span, the rule does not introduce an entirely new WEBSITE entity.

A.4 Currency-code post-processing

The currency procedure scans all tokens once.

If a token exactly matches one of the predefined ISO 4217 currency codes and the model predicts O for that token, the prediction is changed to B-CURR.

No multi-token currency spans are constructed. Tokens already assigned a non-O label are never overwritten.

The closed list contains the following 33 codes: USD, EUR, JPY, GBP, CNY, CHF, CAD, AUD, NZD, SAR, AED, QAR, KWD, BHD, OMR, JOD, EGP, ILS, TRY, RUB, INR, PKR, SEK, NOK, DKK, SGD, HKD, KRW, THB, MYR, IDR, ZAR, BRL, MXN.

Abstract

Relation extraction (RE) is a fundamental component of knowledge graph construction, question answering, and text summarization. Although recent RE models achieve strong overall performance through the fine-tuning of pretrained language models, their aggregate performance can obscure substantial disparities across relation types, particularly under long-tailed distributions. This issue remains largely unexplored for Arabic RE. In this work, we investigate the effectiveness of class-balancing strategies for long-tail relation extraction in Arabic by fine-tuning AraBERT with entity markers on Wojood^{Relations}. Our system, submitted to the KnowledgeGraphEval 2026 shared task, achieves a Micro-F1 score of 92.73 on the official test set. Further analysis shows that errors are disproportionately concentrated among low-frequency and semantically overlapping relation types, indicating that imbalance-handling strategies developed primarily for English benchmarks do not fully address the challenges posed by the long-tailed relation distribution in Arabic.

keywords Arabic Relation Extraction, Knowledge Graphs, Wojood^{Relations}, Arabic NLP, Class Imbalance

1 Introduction

Relation Extraction (RE) is a core building block of automatic knowledge graph construction, but Arabic RE remains difficult given the language's rich morphology and the limited availability of annotated resources. Recent RE systems, built on fine-tuned pretrained language models, report strong headline yet a single aggregate metric can conceal how unevenly a model actually performs: relation types with few training examples are frequently misclassified even when overall accuracy looks high. This disparity, driven by the long-tailed distribution typical of relation extraction datasets, has received little attention in Arabic RE specifically. Existing Arabic systems, such as AREEj(Rakan Al Mraikhat et al., 2024),fine-tune pretrained models on datasets like Wojood^{Relations}(Aljabari et al., 2025b) without addressing this imbalance directly, leaving performance on minority relations largely unmeasured and unimproved.

We adopt entity markers technique for Arabic RE in our submission to the KnowledgeGraphEval 2026 shared task (Aljabari et al., 2026).

Our paper presents an empirical study of entity marking and imbalance-aware training for long-tail relation extraction in Arabic:(1) We adapt an established entity-marker representation in the sentence to represent the subject and object entities to provide the model with clearer information about the target relation. (2) We mitigate the severe class imbalance using a **WeightedRandomSampler**, applied only during training without manually modifying the original dataset. (3) We briefly summarize the system's performance across relation types and discuss the main sources of classification errors and limitations. To encourage reproducibility, full code and configuration are available on our GitHub public repository.[1]

2 Background

Arabic RE is challenging because of the linguistic variability of Arabic and the limited availability of large-scale annotated corpus. The Wojood^{Relations} corpus (Aljabari et al., 2025b) provides a large-scale resource for Arabic RE, that is built on Wojood (Jarrar et al., 2022) a nested Arabic Named Entity corpus and recognition using BERT. The Wojood^{Relations} contains 41 relation types and exhibits a highly imbalanced distribution. The task of RE is based on NER as found in *Konooz* (Hamad et al., 2025) and in *WojoodOntology* (Aljabari et al.,

2025a). Recent works in Arabic for RE tasks such as efforts in (Diaz-Garcia and Lopez, 2025) which give a comprehensive study on RE techniques. Authors in (Mashabi et al., 2026) and (Fields et al., 2024) introduce a recent survey of Large Language Models for Arabic Language and its dialects. In (Wang et al., 2023), authors conclude and discuss the research issues of domain RE.

3 Class-Balanced Relation Extraction

Our submitted system treats this task as a multi-class classification task. The system predicts one relation from a fixed set of different relation types based on a given sentence and a target pair of entities [subject, object]. The main architecture of the system consists of three main components: adding entities marks before and after subject and object in the sentence, an AraBERTV02-based classifier and imbalance-aware training using the idea of weighted sampling. The system pipeline can be summarized as Figure 1.

3.1 Data Description

We use the *Wojood*^{Relations} (Aljabari et al., 2025b) dataset, a single Arabic RE dataset constructed from *Wojood* (Jarrar et al., 2022). The dataset contains annotated semantic relations between entity pairs that cover different relation types and topics. Each sample contains a sentence, a target subject and object, and their corresponding relation label.

3.1.1 Training and validation Dataset

Thee organizers provided us with training dataset containing 17,381 instances with 41 labels. This dataset is distinguished from the original Wojood^{Relations} corpus, which has a different corpus size and split. It exhibits a high level of imbalance. The *no_relation* class contains 8,092 instances, *Location.located_in* contains 4329 instances, whereas several relation types contain fewer than 10 instances. For example, *Family.has_relative* has 2 instances, *Productivity.manufacturer_of* has 3 instances, *Organization.employs, Organization.employs, GPE.has_area and Productivity.builder_of* has 4 instances each, the complete distribution is provided in Appendix B.

In our experiments, to ensure same distribution split in the training and validation dataset for fine-tuning, We divide the provided training dataset using a stratified split with a fixed random seed and the ratio of 60 % for training (10,428 samples) and 40 % for validation (6,953 samples).

3.1.2 Testing Dataset

The test dataset provided by the shared task organization is used only for generating the submitted predictions for final evaluation without the *no_relation* label. It does not contain the target label. The model predicts the relation category from a closed set of provided relations.

3.2 Evaluation metrics

We evaluate our system by using *Micro-F1* (3) score as main evaluation metric as required in the shared task because the dataset has high imbalance among classes. Micro-F1 aggregates all the measurements' performances of all relations taking into consideration their percentage in the dataset. We also calculate accuracy, precision (1), and recall (2) for each relation to help in analyzing the behavior on the system on different relation types.

$$P = \frac{\text{TP}}{\text{TP} + \text{FP}} \tag{1}$$

$$R = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{2}$$

$$F1 - score = \frac{2PR}{P + R} \tag{3}$$

3.3 Methodology

Our submitted system is designed to treat RE as a direct multi-class classification task. Given a sentence that contains a pair of entities, the finetuned model predicts the relation between the target pair from a specified set of relation types. The architecture of the system consists of three components that are applied in sequence: (1) Adding entities marks around the subject and object in the sentence to make the model give more attention to them in the sentence during training. (2) finetuning the AraBERTv02 model with a cross-entropy loss. (3) Handling imbalance via a weighted sampler.

Our model is trained using cross-entropy loss not through binary entailment decisions in NLI-based shared task pipeline. It predicts the relation in just a single classification step.

3.4 Entity-Aware Input Representation

Entity markers are an established technique in relation extraction. We adapt this technique in our experiments, by identifying the target subject and

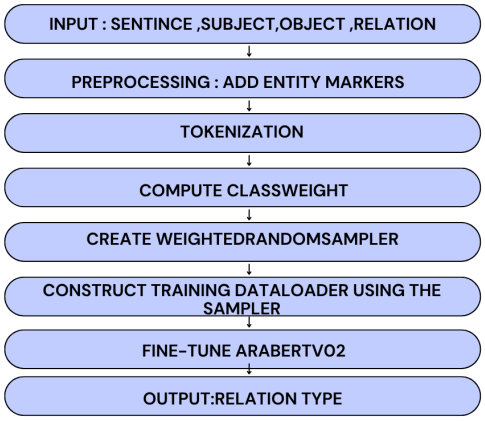

Figure 1: Overview of the submitted system

object in the sentence, providing explicit information about which entities the relation must be predicted, like below:

```
... <SUBJ> subject1 </SUBJ> ...
<OBJ> object2 </OBJ> ...
```

The marked sentence is then passed through the tokenizer of AraBERTv02. To ensure a fixed input size, sequences exceeding the maximum sequence length are truncated to a max length of 256, while shorter sequences are padded. We choose this methodology for padding and truncation as 95% of tokenized sentences after adding entity marks and applying tokenization contain below 249 tokens per sentence.

3.5 Handling Class Imbalance

One of the challenges in Wojood^{Relations} is the highly imbalanced distribution of relation classes. To solve this problem without manually modifying the dataset, we use a **WeightedRandomSampler** from `torch.utils.data` library during training. For each relation type, we calculate class weight based on the frequency of this class in the dataset using the **compute_class_weight** from `sklearn.utils.class_weight` library. The sampler then integrated into the **DataLoader** from `torch.utils.data` and is used only for constructing training batches. The evaluation is performed on the original dataset distribution. This approach increases the attendance of minority relations classes during finetuning.

3.6 AraBERTv02 Relation Classifier

We finetune different Arabic language models, but the best performance comes from the model **aubmindlab/bert-base-arabertv02** (Antoun et al., 2020) from HuggingFace library. AraBERTv02 is a BERT-based model pretrained specifically for Arabic language text and provides contextual representations for Arabic NLP tasks.

The hidden representation of the `[CLS]` tokens are used as the sentence-level representation and are passed through a linear classification layer that maps it to the 41 relation classes. The AraBERTv02 encoder and the classification layer are fine-tuned during training. The model assigns a probability score to each relation class, and the relation with the highest probability score is chosen as the prediction.

Parameter	Value
Optimizer	AdamW
Learning rate	2×10^{-5}
Train & validation batch size	32
Maximum epochs	30
Weight decay	0.01
Maximum sequence length	256
Random seed	42
Early stopping patience	5
Early stopping threshold	0.001
Model selection	Best validation F1
Sampling	WeightedRandomSampler
Sampling replacement	True

Table 1: Training configuration of the submitted system.

4 Experimental Setup

4.1 Training Configuration

Table 1 introduces the hyperparameters used for the configuration of the training process. To prevent overfitting, We evaluate the model performance at the end of each epoch using **F1_score** rather than accuracy because of the imbalance in the dataset and use early stopping technique. We save the checkpoint values after each epoch. The checkpoint with the best validation F1-score is automatically restored at the end of training.

4.2 Implementation Details

All the experiments were run on Google Colab environment (`https://colab.research.google.com/`) using **T4 GPU**. The system is implemented using PyTorch (`https://pytorch.org/`) and the HuggingFace Transformers library (`https://huggingface.co/`).We also use pandas (`https://pandas.pydata.org/`) , NumPy (`https://numpy.org/`) ,and scikit-learn (`https://scikit-learn.org/stable/`) libraries.

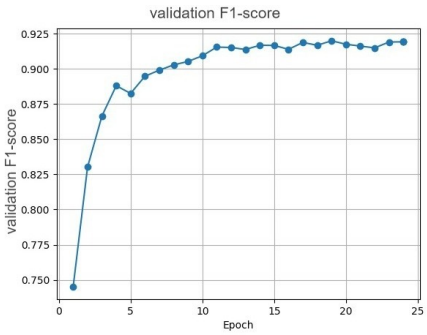

Figure 2: validation F1-score during training

System	Micro-F1 (%)
BERT baseline	88.61
LLM baseline	85.78
our system (AraBERTv02 + Markers + Sampler)	**92.73%**

Table 2: Official KnowledgeGraphEval 2026 test results.

5 Results

5.1 Official Shared Task Results

Our final submitted system achieved a Micro-F1 score of **91.92%** on validation dataset during development after 24 epochs as shown in Figure 2. The system achieved **92.73%** on the official KnowledgeGraphEval 2026 test dataset, with the predictions submitted under the name Wateen_Team. The test dataset does not contain *no_relation* class. To be sure about choosing *no_relation* label, we set probability score threshold for the output from predictions if this label is *no_relation*, the prediction is replaced with the relation label having the second-highest probability. Table 2 introduces the performance of our submitted system in comparison with the available systems reported for the shared task.

5.2 Development Experiments

To investigate the effect of the different components of our system, We performed different design choices on the training dataset during development experiments. These experiments Were conducted during system development but were not used in the official shared task submission. Based on these experiments, in our submitted system we design an architecture that combines the AraBERTv02 with entity-aware input representation and WeightedRandomSampler.

5.3 Error Analysis

Despite the strong overall performance of the submitted system 91.92% as micro f1-score , the system achieves only 74.01% macro f1-score.This gap between micro-F1 and macro-F1 shows the difficulty of predicting low-frequency relations. The imbalance in the dataset contributes in difficulty of predicting low-frequency relations. Some errors happen when the same subject-object pair is showen in different relation types across different contexts. This contextual variation makes relation prediction more challenging, particularly for semantically similar relation types. one another reason, the confusion between the semantics of the relations and the inability of the system to discover the relation and predict *no_relation*. Although weighted sampling technique increases the exposure of minority classes, the model struggle to learn reliable representation from these few examples. Figure 3 shows examples of errors from the validation dataset.

Sentence	True Relation	Predicted Relation
مقابلة مع**محمد حرب** عليان حول **قرية القالونجة المدمرة** ، محافظة عزة .	Location.lives_in	no_relation
إذ عزا **العراق الكويت** في 2 أغسطس 1990 ، ووجد الرئيس اليمني آنذاك علي عبد الله صالح نفسه في وضع لا يحسد عليه ، ,	Business.has_conflict_with	Location.has_border_with
كما ذكر بتضامن **المغربي**مع البحرين في كل القضايا التي تهم هذا البلد الشقيق ، تنفيذا للتعليمات السامية لجلالة**الملك محمد السادس**. ,	Location.lives_in	Administration.president_of

Figure 3: Representative relation classification errors.

6 Conclusion

We present our system for the Relation Extraction — KnowledgeGraphEval 2026 shared task on $Wojood^{Relations}$, presents Arabic RE as a multi-class classification task. The system combines **aubmindlab/bert-base-arabertv02** a pretrained Arabic language model with adding entity markers and a `WeightedRandomSampler` to mitigate the effects of high class imbalance. The final system achieved a Micro-F1 score of **91.92%** on validation dataset and **92.73%** on the official KnowledgeGraphEval 2026 hidden test dataset. We suggest for Future work focusing on increasing the representation of minority relation types and developing context-aware approaches to better distinguish context-dependent and relations semantically similar.

7 Acknowledgments

The authors thank the Relation Extraction — KnowledgeGraphEval 2026 organizers for providing the dataset and sessions for instructions.

Abstract

We describe Team Wasl's systems for the KnowledgeGraphEval 2026 shared task at ArabicNLP 2026, which decomposes Arabic knowledge-graph construction into two evaluated stages: nested NER under domain shift and relation extraction between given mentions. For Subtask 1 (AdaptNER), we train a multi-head BIO tagger (one three-way O/B/I head per entity type over a shared pretrained Arabic encoder) on Wojood and combine three random seeds by span-level majority vote. For Subtask 2, forced-choice classification over the 40 Wojood^{Relations} relation types, we fine-tune a typed-marker classifier with type-constraint decoding, ensembling five grouped folds by logit averaging. Our submissions scored 0.7483 micro-F1 on AdaptNER's blind Konooz slice (ten unseen domains), 4th of the eight officially ranked teams and 11.8 points above the official baseline, and 0.9571 micro-F1 on relation extraction with the no-relation class masked at decoding, 2nd at the results release; re-scored by the organizers over all 41 classes, the same ensemble reaches 0.9328, 4th in the organizers' final ranking. We analyze where the 18.6-point domain-shift tax on NER falls: chiefly on recall. We further show that type-constraint decoding and ensembling are partially redundant (+0.9 points on a single RE model, +0.1 on the ensemble) and that the surviving errors share an argument-type signature that no type constraint can separate.

1 Introduction

Knowledge-graph construction from Arabic text requires two capabilities in sequence: finding the entities and typing the relations between them. The KnowledgeGraphEval 2026 shared task (Aljabari et al., 2026) decomposes this pipeline into two subtasks. **AdaptNER** asks for nested named-entity recognition over 21 entity types, trained on the Wojood corpus and evaluated blind on Konooz, ten domains unseen in training. **Relation Extraction** asks for forced-choice classification of a given entity-mention pair into one of 40 relation types from Wojood^{Relations}. We entered both subtasks as Team Wasl and finished 4th and 2nd of the eight officially ranked teams at the results release (§6.1 reports the organizers' later re-scoring of Subtask 2).

Our approach favors disciplined engineering of well-understood components over novel architecture: (1) a faithful reimplementation of the multi-head nested-BIO recipe for AdaptNER; (2) type-constraint decoding for RE, which penalizes relation logits inadmissible for the pair's argument types; (3) ensembling matched to each task's variance source, random seeds with span-level voting for NER and grouped 5-fold logit averaging for RE; and (4) a leakage-free protocol, under which Konooz never touches training, validation, or model selection.

2 Related Work

Our systems assemble published components of the Wojood ecosystem rather than new architecture. Wojood supplies the 21-type nested Arabic NER corpus and the multi-task BIO reference tagger (Jarrar et al., 2022), extended by two WojoodNER shared tasks (Jarrar et al., 2023, 2024), whose 2024 out-of-domain Open Track is AdaptNER's direct precursor. Wojood^{Relations} adds 40 relation types over the same entity scheme (Aljabari et al., 2025b), Wojood^{Hadath} extends the annotation layer to event arguments (Aljabari et al., 2024), *WojoodOntology* places the entity and relation types in an ontology aligned with Schema.org and Wikidata (Aljabari et al., 2025a), and Konooz, the corpus behind the blind test, measures 12–20 F1 points of cross-domain degradation for Arabic NER models (Hamad et al., 2025). From the wider literature we adopt the multi-head per-type BIO formulation with the unified imbalance-aware

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1219–1226

loss of El Mahdaouy et al. (2023), typed punctuation entity markers for relation classification (Zhou and Chen, 2022), and AraBERTv02 (Antoun et al., 2020), the encoder of the organizers' official baselines for both subtasks.

3 Task and Data

Subtask 1: AdaptNER. Training data is Wojood with its standard train/validation split. The blind test set is a slice of Konooz released without labels: 50,175 tokens of MSA across its ten domains. The full corpus also spans sixteen dialects, which the task excludes, so the shift studied here is domain shift within MSA, not dialect shift. Systems submit one IOB2-tagged file and are scored by nested span micro-F1. Task rules prohibit using any part of Konooz, including its public development portion, for training, validation, or model selection.

Subtask 2: Relation Extraction. Wojood^{Relations} provides sentences with a marked subject and object mention; the system outputs exactly one of 40 positive relation types per instance. The task page states that the test set contains no negative pairs, under which micro-F1 equals precision, recall, and accuracy; the official protocol, clarified after the results, scores the full 41-class output, so a `no_relation` prediction counts as a miss (§6.1). The distributed training material contains 17,381 labeled records; the blind test set has 4,386 pairs. Both systems train only on the distributed task data (the Subtask 2 reporting requirement), and all predictions are automatic.

4 System Overview

4.1 AdaptNER

Tagger. We fine-tune `aubmindlab/bert-base-arabertv02` with 21 independent per-type O/B/I heads (a single 21×3-wide linear layer over the shared encoder states), which emit the 21-column submission format directly. Following El Mahdaouy et al. (2023), we train each head with $0.4\,\text{CE}+0.2\,\text{Dice}+0.2\,\text{Tversky}(\alpha{=}0.5)+0.2\,\text{Focal}(\gamma{=}2)$, and the total loss adds a variance penalty across per-head losses to stop frequent types from dominating rare ones; its weight, 5.0, is the value El Mahdaouy et al. fix without tuning, and we did not tune it either (sensitivity: Appendix H). We label only the first sub-token of each word and split over-long sentences at word boundaries within the 512-token budget. Decoding applies standard IOB2 rules with a single repair (an orphan `I-x` starts a new span).

Seed ensemble. The submitted ensemble trains three seeds (13, 42, 77) on train+validation, with a fixed 29-epoch schedule, the train-only model's validation peak; folding validation into training forfeits early stopping. We combine the seeds in three ways: **mean-prob** (argmax of the seed-averaged softmax), **union** (any span predicted by $\geq$1 seed, a recall lever), and **majority vote** ($\geq$2 seeds, a precision lever); overlap resolution: Appendix C.

4.2 Relation Extraction

Classifier. We pair the same encoder with typed punctuation entity markers in the style of Zhou and Chen (2022): the subject mention is wrapped as `@ * type * mention @` and the object as `# ^ type ^ mention #`, so the argument types enter as plain text with no new vocabulary; a two-layer feed-forward head over the concatenated start-marker states classifies into 41 classes (40 relations + `no_relation`). We train on the full 41-way problem. Our official submission set the `no_relation` logit to $-\infty$ at decoding, following the task page's statement that the test set holds no negatives; at the organizers' request after the results we resubmitted the same ensemble with the mask removed (§6.1).

Argument typing at test time. The blind test provides mentions but not the entity types the markers and constraints need. We join each record's sentence id to Wojood's gold sentences (entity annotations only, never relation labels) and match the mention string to a gold entity surface, falling back to a corpus-wide mention→type lexicon and finally to UNK, which disables that instance's constraints rather than guessing (coverage: Appendix C).

Constraint decoding. We build a table of inadmissible relations per (subject type, object type) pair from the task's relation type specification unioned with every type pair observed in training, since gold annotations occasionally violate the specification. At decode we subtract a fixed constant from each inadmissible relation's logit, a soft penalty rather than a hard mask; a sweep over penalties 0–4 on development data selected 3.0.

Fold ensemble. The final system averages the raw test logits of five models trained on grouped

Task	System	Mi-F1	P	R	Ma-F1
NER	v1 single s13	0.7385	0.7874	0.6953	0.6249
NER	v2 vote ens.	**0.7483**	0.8060	0.6982	0.6316
RE	v1 single+p3	0.9519	—	—	—
RE	v2 5-fold+p3	**0.9571**	—	—	—
RE	v2 unmasked†	0.9328	0.9716	0.8969	—

Table 1: Official blind-test results. RE is scored forced-choice single-label, so P and R equal micro-F1 for the masked rows; no macro-F1 is published. †the same ensemble decoded without the `no_relation` mask, scored by the organizers over all 41 classes after the results release (§6.1).

5-fold splits, grouped by sentence id because sentences average 2.75 triples and row-level splits would leak; each fold early-stops on its own held-out fold. The pooled out-of-fold (OOF) predictions re-validate the penalty choice on all 17,381 records.

5 Experimental Setup

All experiments ran on a single NVIDIA T4 (free Kaggle tier) with deterministic seeds; no reported system cost more than $\approx$4 GPU-hours in aggregate. Appendix A lists the hyperparameters; code is available at `https://github.com/Salah-Sal/kgeval2026-team-rabt`.

Validation protocol. AdaptNER model selection used only the Wojood validation split (early stopping on span micro-F1); we scored the Wojood test split once per finished system as an in-domain reference; Konooz never entered any loop. For RE, we made development decisions on a single grouped held-out split (15,207 train / 2,174 dev), replaced for the final system by grouped 5-fold cross-validation.

We used two submission slots per track: v1 single models and v2 ensembles (Table 5).

6 Results

6.1 Official test results

Among the eight officially ranked teams we finished **4th** on AdaptNER, +0.12 micro / +0.19 macro over the no-adaptation AraBERTv02 baseline (0.63 / 0.44), and **2nd** on relation extraction at the results release (0.9571, behind 0.9603; +0.026 over the organizers' baseline retrained on the released split, 0.9309). After the release the organizers re-scored Subtask 2 over all 41 classes, and the same ensemble, decoded without the `no_relation` mask, scores 0.9328 (P 0.9716, R 0.8969; 4th of the seven ranked teams in the organizers' final table): the scorer counts each of the 337 `no_relation` predictions as a miss, and 264 of them had been correct under the mask. Ensembling improved both tracks on the blind test (Table 1): +0.98 micro-F1 for AdaptNER and +0.52 for RE under the masked protocol, where the pooled-OOF estimate anticipated the blind score to within 0.3 points.

6.2 Development results and analysis

Ensembling where the variance is. In domain, majority vote is the strongest seed combination: +0.6 over the ensemble's own seed-13 member (train+val, 0.9268; Table 3), the reference for all in-domain ensemble deltas; the union, the intended recall lever, buys +0.9 recall for -2.0 precision. On the blind set the three seeds largely agree (the union holds only 8% more spans than the largest single seed), so the recall deficit under shift is *systematic*: entities no seed finds. We therefore submitted the precision-preserving vote, and the blind result bore the reading out: +1.9 precision, +0.3 recall over the submitted single model (v1).

The domain-shift tax falls on recall. The submitted single model (v1: train only, early-stopped seed 13) drops 18.6 points from its in-domain Wojood test score (0.9240) to blind Konooz (0.7385), a domain shift within MSA, and the drop falls chiefly on recall (-23.6 points, vs. -13.0 precision), reversing the in-domain P–R profile (Table 3). Two anchors put 0.7385 in context: 10.9 points above the official no-adaptation baseline, and at the top of the 12–20-point degradation band Konooz itself measures (Hamad et al., 2025).

Constraint decoding and ensembling are partially redundant. The type-constraint penalty is worth +0.92 points on the single model but only +0.08 pooled-OOF on top of the 5-fold ensemble (Table 4): most type-inadmissible errors are single-model flukes that logit averaging already removes. The penalty's remaining value concentrates in macro-F1 (+1.0 point OOF), i.e., in rare relations, which is why we selected the penalty on macro-F1 rather than on the official micro-F1: micro-F1 peaks at 4.0, by 0.0001, and the whole sweep spans 0.0008 (Table 6). The recipe: ensemble first, then constrain.

6.3 Error analysis

RE: the surviving errors share type signatures. We reran one fold model of the submitted ensemble on its held-out fold (3,476 records), leaving 74 misclassified positives, and their structure explains why the constraint penalty saturates: the residual confusions hold between relations with the *same* argument-type signature, which no type constraint can separate by construction. Two of the largest clusters are PERS–GPE `lives_in` vs. `president_of` (11) and GPE–GPE `capital_of` vs. `geopolitical_division` (7). Two patterns recur. First, a pull toward the type pair's majority relation even against an explicit lexical cue: in برنامج القدس الفلسطينية عاصمتنا ("the program 'Palestinian Jerusalem, Our Capital' "), gold `capital_of` is predicted as `geopolitical_division`, which outnumbers it 59-to-1 in training. Second, genuine overlap between readings: for رئيسة وزراء بريطانيا العظمى، مارغريت تاتشر ("the Prime Minister of Great Britain, Margaret Thatcher"), the model outputs `president_of`, the closest leadership relation the inventory offers, while gold encodes `lives_in`; the confusion runs both ways (6 vs. 5 cases), unlike the one-way majority pull above. On the blind test the penalty flips only 6 of 4,386 ensemble predictions.

NER: metonymy, attachment, and register. On Wojood test (0.9240), errors partition into four mutually exclusive categories (Appendix C). Exact-boundary type confusions number only 138, and 60% of them are ORG↔GPE metonymy: in أنتجت بولندا بنشاط البنادق الهجومية ("Poland actively produced assault rifles"), بولندا is gold-annotated ORG as a state actor but predicted GPE, its default type. Same-type boundary errors (510) concentrate on trailing locatives and appositions, e.g. gold نافورة تابيثا ("the Tabitha Fountain") predicted with في يافا ("in Jaffa") attached. Outright misses (591) and spurious spans (876) both skew toward NORP, ORG, and EVENT, and misses reach into colloquial-register occupations such as شاويش ("sergeant").

Blind-set behavior. Without blind gold, we can characterize out-of-domain errors only behaviorally. Seed unanimity over predicted spans orders the ten domains by distance from the training register: spans predicted by a single seed account for 13–15% of all predicted spans in Finance and Economics, the registers closest to Wojood's news-heavy composition, but 28% in Science and Sport (Table 7).

6.4 Post-submission loss ablation

After the submission close we ablated the unified loss (Appendix H; no run touched Konooz or a scored submission). The result is negative: plain cross-entropy slightly outperforms the submitted recipe in domain (Table 8; single-seed runs), and partial mixtures collapse rare types. The variance penalty functions as a guard against the instability the other loss terms introduce (+12.4 macro over the penalty-free mixture), not as a lever over CE.

7 Conclusion

Disciplined engineering of published components produced 4th of 8 on nested NER under domain shift and 2nd of 8 on relation extraction at the results release, 4th of 7 after the organizers' 41-class re-score: one Arabic encoder, two task-shaped heads, ensembling matched to each task's variance, and a leakage-free protocol. The clearest finding is negative space: the domain-shift tax falls on recall and is shared across seeds, so closing it requires target-domain adaptation, not better combination of Wojood-only models (design alternatives: Appendix G).

8 Limitations

The per-type BIO-head architecture cannot represent nesting of two same-type entities; Konooz happens to contain none, so this costs nothing here, but the architecture is not a general nested-NER solution. We used no external data, augmentation, or domain-adaptive pretraining, so our numbers are a floor for this architecture family; each task also relies on a single encoder family. With no labeled out-of-domain validation permitted, the choice among ensemble variants rested on in-domain scores and the seed-agreement analysis alone, and the rejected variants remain unmeasured on the blind set. Development metrics use our own scorer implementations, reconciled against submission rehearsals but not the official evaluation code; only Codabench numbers are authoritative. RE argument typing at test time is a heuristic join against Wojood gold entities; 96 subject and 91 object sides could not be typed and ran with untyped markers and constraints disabled. No result carries a confidence interval or significance test. Seed variance on the blind set is unmea-

sured, since each seed was submitted only inside the ensemble, so the +0.98 ensemble gain there is a single-seed comparison; in domain, the three seeds span 0.20 points (Table 3).

Acknowledgments

We thank the KnowledgeGraphEval organizers for the task, data, and prompt rulings on protocol questions. All experiments ran on free Kaggle T4 compute.

Config	**Eval**	**Mi-F1**	**Ma-F1**
Single, no constraints	held-out	0.9378	0.656
+ penalty 3.0	held-out	0.9470	0.705
5-fold ens., no constr.	pooled OOF	0.9592	0.638
+ penalty 3.0	pooled OOF	0.95995	0.648

Table 4: RE development results (micro-F1, macro-F1), positives only. Per-fold best validation micro-F1 spans 0.9518–0.9670 (mean 0.9590).

C Prediction Statistics

- RE marker placement: when a mention string occurs more than once in its sentence (5.9% of instances), we mark the disjoint occurrence pair with minimal distance; when the object is embedded inside the subject mention (≈20%), markers are nested so both stay in context.

- AdaptNER seed combination: for union and vote, same-type overlaps resolve greedily by (votes, length, position).

- AdaptNER blind test: the v1 single model predicts 5,780 spans over 50,175 tokens (density 11.5%, close to Wojood's), all 21 types emitted, 201 BIO-sequence repairs during decoding; the submitted vote ensemble predicts 5,670 spans (Table 7). Health yields the fewest predictions in both (228).

- RE blind test: the ensemble changed 97/4,386 predictions (2.2%) vs. the single model, concentrated in the `located_in`/`subsidiary` and `president_of`/`lives_in` confusion clusters, the same affiliation/location clusters that dominate development-set confusion matrices. 34/40 relation types appear in the ensemble output; `located_in` alone accounts for 46%.

- RE test-time typing: the sentence-id join located the source sentence for 4,360/4,386 records (99.4%); with the lexicon fallback, 4,290 subjects (97.8%) and 4,295 objects (97.9%) received a type; the remaining 96 subjects and 91 objects were typed as unknown, disabling their constraints rather than guessing.

- NER error taxonomy (§6.3): each errant gold span is paired with at most one errant predicted span, by precedence: exact boundaries with a different type (confusion), then same type with overlapping boundaries (boundary). Unpaired gold spans count as misses, unpaired predicted spans as spurious, so the four categories are mutually exclusive by construction.

D Submission Manifest

Track	System	Date	Score
AdaptNER	v1 single s13	Jul 22	0.7385
AdaptNER	v2 3-seed vote	Jul 24	0.7483

Science	423
Sport	841
Total	5,670

Table 7: Predicted span counts of the submitted vote ensemble on the blind Konooz test slice, per domain (no gold available pre-deadline).

G Design Alternatives Considered

The design phase rejected the following on published evidence rather than taste: LLM in-context NER (published Arabic results of 0.29–0.74 F1), MRC-style per-type querying (21× inference cost), grid decoders whose extra expressiveness the submission format cannot carry, LLM-only RE (the task's GPT-4o RAG baseline trails its supervised one (Aljabari et al., 2025b)), negative downsampling (reported to cost ≈10 F1 in comparable settings), and hard constraint masking (gold annotations occasionally violate the type specification, so constraints must stay soft). Our design notes projected ≈0.73 micro-F1 for zero-shot Wojood→Konooz transfer; the submitted single model scored 0.7385. The adaptation levers designed but not built by the deadline (continued pretraining on the unlabeled test tokens, guarded self-training, domain-targeted augmentation) were projected to be worth a further 3–8 points and are the obvious next step.

H Post-Submission Loss Ablation and Penalty-Weight Sweep

Run August 3, after the July 29 submission close, on the AdaptNER baseline configuration (Wojood-only, seed 13); no ablation run touched Konooz, the leaderboard, or any submitted system. Adding Dice to CE collapses PRODUCT to 0 F1; the full mixture without the variance penalty additionally zeroes UNIT and QUANTITY; the variance penalty rescues all three. Whether E1's slight in-domain edge holds under domain shift is untestable without Konooz gold. A sweep of the penalty weight (P1, P2, P10; run September 4 after the reviews, same setup) shows macro-F1 rising monotonically from 0 to 5.0 and falling back at 10.0, while micro-F1 varies by at most 0.1 points from 0 to 5.0 and drops 0.4 at 10.0; on this single seed the untuned 5.0 is the best of the five weights on macro-F1 and no worse than any other on micro-F1.

	Loss	Val	Test
E1	CE only	.9227 / .8334	.9267 / .8489
E2	+Dice	.9233 / .7777	.9258 / .7674
E3	+Tversky	.9224 / .7780	.9263 / .7863
E4	+Focal (full mix)	.9202 / .7201	.9240 / .7226
P1	full + pen. 1.0‡	.9198 / .7326	.9239 / .7265
P2	full + pen. 2.0‡	.9207 / .7532	.9239 / .7608
E5	full + pen. 5.0†	.9208 / .8324	.9240 / .8462
P10	full + pen. 10.0‡	.9166 / .7711	.9203 / .7941

Table 8: Post-submission loss ablation (run August 3, after the July 29 close) and penalty-weight sweep (run September 4); never part of a scored submission. Wojood val/test span micro-F1 / macro-F1, seed 13, baseline configuration. Mixture weights over (CE, Dice, Tversky, Focal): E2 (.5,.5,0,0), E3 (.4,.3,.3,0), E4/E5/P* (.4,.2,.2,.2); variance-penalty weight as listed, none in E1–E4. †E5 is the submitted recipe. ‡sweep rows, ordered with E4 and E5 along the weight axis.

McMasterNLP at KnowledgeGraphEval-2026: Heterogeneous Expert Systems for Arabic Knowledge Graph Construction

Abstract

Automated knowledge graph (KG) construction involves two core components: nested named entity recognition (NER) and relation extraction (RE). In this work, we address cross-domain nested NER alongside RE. We integrate domain adaptation methods within a mixture-of-experts ensemble system for nested NER from Arabic text, evaluated in a cross-domain setting. The system combines multiple Arabic pretrained encoders for token- and span-level classification with domain data augmentation, and integrates their predictions using a vote-based ensemble routing with a complementary XLM-R expert. For RE, we employ an adversarially trained relation classifier backed by auxiliary entity types, NLI reranking, and structural schema rules, treating `no_relation` as a standard relation label. We additionally study a positive-relation setting that excludes `no_relation` from both training and inference. Our NER system reaches 0.7438 micro F1 on the hidden test set. For RE, the positive-relation setting achieves 0.9608 micro F1, while the `no_relation`-aware system achieves 0.9295.

1 Introduction

Knowledge Graphs (KG) benefit myriad knowledge-aware systems such as search engines and dialogue systems that require accurate natural language understanding and complex reasoning (Ji et al., 2022). A KG contains entities as nodes and semantic relations between them as edges, forming a structured graph representation of knowledge (Hogan et al., 2021). Given increasing volumes of unstructured textual data, natural language processing methods for extracting entities and their relations support automated KG construction (Yan et al., 2018). However, there is limited research on methods for Arabic (Aljabari et al., 2026).

To bridge this gap, we address two tasks within the Arabic KG Construction and Domain Adaptation shared task (Aljabari et al., 2026): (1) nested named entity recognition (NER) spanning 21 semantic types from the WOJOOD schema (Jarrar et al., 2022) under a cross-domain setup, and (2) relation extraction (RE) following the WOJOODRELATIONS schema (Aljabari et al., 2025b).

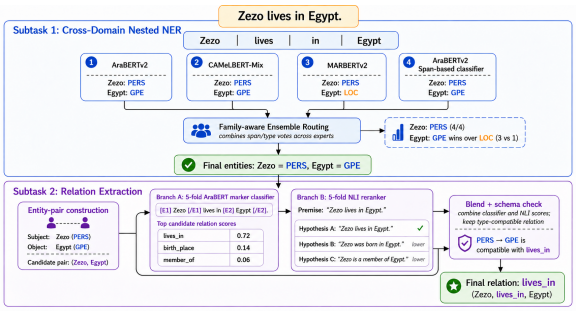

Figure 1: System inference.

Our system (Fig. 1) integrates data augmentation for developing an ensemble of heterogeneous NER experts across three pretrained Arabic encoders, whose outputs route through a trained XLM-R model providing additional candidate spans under a conservative rule. RE follows in a multistage pipeline consisting of a relation-existence classifier, followed for positive pairs by an adversarial- and auxiliary-trained relation classifier, a natural language inference (NLI)-based class ranker, and a relation-type validator. Our code is published at github.com/McMasterNLP/ArabicKG-2026.

2 Background

Domain adaptation addresses the challenge in which models suffer performance degradation on target domains that differ in vocabulary, style, or genre from the data seen in training (Han and Eisenstein, 2019; Gururangan et al., 2020), known to emerge in entity recognition (Lin and Lu, 2018; Jia et al., 2019) and relation extraction Bassignana and Plank (2022). Adaptation techniques can be applied at the data-level, such as controlled data augmentation and entity swaps that generate new

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1227–1237
October 28-29, 2026 ©2026 Association for Computational Linguistics

training examples (Hu et al., 2023), and in training procedures, such as TAPT and DAPT that continue self-supervised masked language modeling (MLM) pretraining before downstream finetuning (Han and Eisenstein, 2019; Gururangan et al., 2020).

Toward *Arabic KG construction*, Jarrar et al. (2022) introduced the large multidialect Arabic nested NER corpus WOJOOD with 21 entity types and established multi-task flat-and-nested baseline architectures. Extensions included WOJOOD$_{fine}$ with finer-grained subtypes Liqreina et al. (2023), *WojoodOntology* which unifies external schemas (Aljabari et al., 2025a), and WOJOOD^{Relations} containing entity relation labels (Aljabari et al., 2025b). Hamad et al. (2025) introduced the multidialect NER dataset KONOOZ, containing several domains that are absent in WOJOOD. Their cross-domain evaluation of Arabic NER models revealed an F1-score performance degradation of up to 38% when transferring models trained on formal source data to unseen target domains. Motivated by these cross-domain challenges, we investigate several strategies within our Arabic knowledge graph construction pipeline for improving transfer to unseen domains, including encoder diversification, targeted data augmentation, span-based modeling, and ensemble routing.

3 System Overview

We propose a system that integrates several domain adaptation techniques for an Arabic KG construction pipeline (see Fig. 1). Given a raw Arabic input sentence, the system processes the data through two primary modules. First, a cross-domain NER ensemble detects and categorizes nested entities through three stages: (1) expert construction, (2) symmetric ensemble routing, (3) complementary candidate addition using XLM-R. Second, a multi-stage Relation Extraction (RE) pipeline first determines whether an entity pair expresses a relation or `no_relation`, then classifies positive pairs using the positive-relation pipeline.

3.1 Nested NER Expert Development

We develop four base experts for nested NER: three token-level models based on AraBERTv2, CAMeLBERT-Mix, and MARBERTv2 (Antoun et al., 2020; Inoue et al., 2021; Abdul-Mageed et al., 2021), and an AraBERTv2 span-based model following the span-classification approach of Elkhbir et al. (2023). We additionally train XLM-R base as a complementary token-level expert. The token-level models use BIO $\times$ entity-type labeling, while the span-level model predicts complete entity spans using boundary embeddings and span-width features. The Arabic encoder experts are trained on WOJOOD, with entity-swap augmentation applied to the primary token-level experts. The augmentation replaces selected isolated entities with WOJOOD entities of the same type while preserving the corresponding labels. For 10% of eligible training samples, isolated entity spans are swapped with spans of the same type from other samples–details and statistics in Table 2 and §B.

No KONOOZ sentences or labels are used for NER pretraining, supervised training, checkpoint selection, threshold calibration, or ensemble selection.

3.2 NER Ensembling Routing

Given an input sentence, the four primary experts independently produce NER predictions. We combine these predictions using a symmetric exact-span voting procedure.[1]

Candidate spans must receive at least two exact votes from the four base experts. Predicted spans of the same entity type that overlap in the text are grouped into components, and only candidates with the highest base-expert vote count are retained. When multiple candidates are tied, ties are resolved deterministically by preferring the shorter span, followed by earlier start position, and earlier end position. The selected spans form the ensemble baseline B.

XLM-R is used as a complementary expert after the primary ensemble has been fixed. We first construct the corresponding five-expert candidate set and identify XLM-R-supported spans that are introduced by the additional expert evidence. Only candidates that do not overlap an already accepted primary-ensemble span are added. Thus, XLM-R can add supported predictions but cannot replace or modify spans already selected by the four-expert ensemble.

3.3 Semantic Relation Extraction

Our RE system contains two stages. First, a relation-existence model determines whether an entity pair expresses a relation or `no_relation`. For pairs predicted as relations, an AraBERTv0.2-based relation classifier (RE-CLF) ranks the 40

[1] See §C for other ensemble approaches explored.

positive relation classes, the top five candidates are reranked by an NLI model, and a soft entity-schema penalty is applied to the resulting scores.

The entity types of relation arguments constrain the likelihood and validity of relation types–"*person* is *president of organization*" is valid, "*percent* is *president of website*" isn't. Thus, we train the RE-CLF in a multitask setup with auxiliary heads that learn to classify the subject and object entity types[2], all jointly optimized on a weighted objective: $L_{\text{total}} = L_{\text{relation}} + 0.15 \times (L_{\text{subject}} + L_{\text{object}})$, yielding entity-type-aware representations useful for relation classification. We perform adversarial training, using fast gradient method (FGM), wherein after a forward pass on an input, another forward pass is performed on a new adversarial input created by perturbing the input embeddings toward the gradient (Goodfellow et al., 2015; Miyato et al., 2017).

To model `no_relation`, we train a separate AraBERTv0.2 model on all 17,367 cleaned source instances with a binary relation-existence head and a 40-way positive-relation head, together with the auxiliary subject and object entity-type heads. The existence loss is computed over all training instances, while the 40-way relation loss is computed only for positive instances. FGM adversarial training and the auxiliary subject and object entity-type objectives are retained. At inference, the relation-existence probabilities from the five folds are averaged and a fixed threshold of 0.5 is applied. Pairs below the threshold are assigned `no_relation`; the remaining pairs are passed to the positive-relation pipeline described above.

Inspired by Aljabari et al. (2025b), we add a module that reranks RE-CLF relation candidates with NLI model to resolve ambiguity between semantically similar relations (e.g., `birth_place` & `lives_in`). Treating the original text as a premise, hypotheses are constructed by slotting a (subject, object, relation) into natural language templates[3], as in "{subject} was born in {object}". For the NLI model, AraBERTv0.2 is finetuned on constructed (premise, hypothesis) pairs from the training data, with *entailment* labels on hypotheses with ground truth relations, and *contradiction* labels on samples created by swapping semantically similar (not same) entities or relations. At inference time, we run the NLI model for the top-5 relation types, and rerank them by entailment likelihood.

The third module derives final scores S for a candidate r. S_1 aggregates RE-CLF and NLI probabilities as $S_1(r) = 0.55 \cdot P_{RE}(r) + 0.45 \cdot P_{NLI}(r)$. The r is checked against a schema[4] of compatible relation- and argument-entity types $\mathcal{C}$. Invalid types can result from NER errors, so rather than eliminating such candidates, S_2 integrates a penalty:

$$S_2(r) = \begin{cases} S_1(r), & r \in \mathcal{C}, \\ S_1(r)\exp(-\lambda), & r \notin \mathcal{C}, \end{cases} \quad \lambda = 2.0$$

Method	F1	Pr	Re
Four-expert ensemble + XLM-R	**0.7438**	**0.75**	**0.7378**

Method	OOF F1	Blind test
Positive-relation pipeline	0.9715	0.9608
`no_relation`-aware system	0.9242	0.9295

Table 1: NER results on the official KONOOZ test set (top) and RE results (bottom). For RE, the positive-relation OOF result is evaluated over positive relation instances, while the `no_relation`-aware OOF result uses the complete sentence-grouped OOF data, including negative pairs.

4 Experimental Setup

The final NER evaluation measures precision, recall, and micro F1 across ten unseen target domains on a hidden test set from the KONOOZ corpus, to assess cross-domain generalization. For an out-of-domain development benchmark, we experiment on CV-18 (Saidi et al., 2026), an external public Arabic NER dataset annotated with the same scheme. RE systems are developed and evaluated on the formal train/test splits of WOJOOD^{Relations}, which contains 40 positive relation labels together with `no_relation`, with micro F1 as the primary performance metric. We report both the positive-relation pipeline and a `no_relation`-aware configuration. The latter uses a source-trained relation-existence model with a fixed decision threshold of 0.5, without using hidden-test predictions to select or adjust the threshold.[5]

All token-level NER models and AraBERT-based RE models are optimized using AdamW. All hyperparameters and training configs are in §B.

[2]Entity labels obtained from our NER system (see §D.3).

[3]We use template structures from SinaLab (2025)

5 Results and Discussion

Table 1 summarizes the NER and RE results from the competition. Our final NER system, developed without KONOOZ pretraining or adaptation, achieved a micro F1 of 0.7438 on the hidden KONOOZ test set, with 0.7500 precision and 0.7378 recall.

For RE, the positive-relation pipeline combining auxiliary NER learning, FGM adversarial training, NLI reranking, and schema constraints achieved 0.9608 micro F1 on the blind test, with no exact-match overrides applied. Adding explicit `no_relation` handling through the source-trained relation-existence model with a fixed 0.5 threshold resulted in 0.9295 micro F1. We discuss both settings below.

5.1 NER Analysis

Further metrics on both the auxiliary CV-18 benchmark and KONOOZ test set are in §C, including additional systems explored in development.

Auxiliary Out-of-Domain Evaluation. We computed Spearman rank correlation between micro F1 performances of 14 systems evaluated on both CV-18 and the KONOOZ hidden test set. System ranking across the two datasets show a moderate positive correlation (Spearman $\rho = 0.6535$, $p = 0.011$, $N = 14$). This shows that while CV-18 performance is not a perfect proxy for KONOOZ performance, it provides a practical out-of-domain benchmark for system development. Therefore, we base our system design decisions on CV-18 performance rather than performance gains on the in-domain development set.

Expert Complementarity. We analyze exact-span agreement among AraBERT (A), CAMeLBERT (C), MARBERTv2 (M), and the AraBERT span-based model (S) on CV-18, to determine whether ensemble reliability depends only on the number of supporting experts or also on the architectural diversity of those experts. On CV-18 development data, candidate reliability increases strongly with agreement among the four primary experts. Predictions supported by all four experts achieve 95.1% precision, compared with 84.0% for three-expert agreement, 59.7% for two-expert agreement, and 32.4% for single-expert predictions. This supports requiring agreement from at least two experts in the primary ensemble. This supports the use of architecturally complementary experts, with the span-based model providing particularly useful boundary information.

Routing and Complementary XLM-R Predictions. Using the clean source-only experts, the symmetric four-expert ensemble achieved 0.7780 micro F1 on the frozen CV-18 test set. We then evaluated XLM-R as a complementary expert. The addition policy was selected using CV-18 development data and does not allow XLM-R to modify spans already accepted by the four-expert ensemble. Adding the resulting non-overlapping XLM-R-supported candidates increased CV-18 test micro F1 to 0.7843. Applying the same frozen procedure to the hidden KONOOZ test set produced 0.7438 micro F1, with 0.7500 precision and 0.7378 recall.

Boundary Errors. NER errors frequently involve boundary ambiguity. NeRValuate analysis (Batista and Upson, 2026) of an earlier ensemble configuration on CV-18 identifies 124 boundary-only errors and 26 errors involving both boundary and entity type, meaning that 150 of 215 aligned mismatches (69.8%) involve incorrect entity boundaries. These include cases where predictions include only part of a multi-token entity, fragment one entity into multiple spans, or incorrectly merge adjacent entities. For example, in an expression corresponding to "an hour ago", AraBERT predicts only "hour" as TIME, while another expert recovers the complete gold span. Conversely, an expert can incorrectly merge two adjacent PERS entities into a single span. These cases motivate our use of complementary expert evidence for boundary decisions.

5.2 RE Analysis

Semantic Resolution. We initially submitted an RE-CLF AraBERT baseline which reached 0.9535 micro F1 on the blind test set. On development data, we observed its errors often involved confusion between semantically similar relations such as `birth_place` & `lives_in`; quantitatively, the highest-likelihood class matched the ground truth in 96.59% of cases, while it was among the top five in 99.61%, which were typically semantically similar. This motivated NLI reranking.

Dependency Between Pipeline Stages. Introducing FGM and auxiliary NER learning changed the primary classifier's error distribution, reducing the NLI reranker performance trained on the original classifier's errors. Retraining the reranker on hard

[4] Schema derived from training data–see §D.6.

[5] Detailed dataset statistics and split breakdowns are provided in Table 3; see §E for evaluation of negative relations.

negatives from the updated classifier improved the combined system, suggesting downstream components may need to be retrained when upstream changes substantially alter their error distributions.

Schema constraints provide targeted corrections but remain imperfect: on OOF predictions, they changed 51 of 9,289 decisions, correcting 31 errors while introducing 16 new ones, supporting their use as soft rather than hard constraints.

Handling `no_relation`. To explicitly model negative entity pairs, we use the relation-existence head of the two-head AraBERT model to gate the positive-relation pipeline. Using the fixed 0.5 threshold, the relation-existence decision achieves 0.9510 recall for relation instances and 0.9308 recall for `no_relation` in sentence-grouped five-fold OOF evaluation, corresponding to 0.9409 balanced accuracy. When combined with the positive-relation pipeline, the system achieves 0.9242 positive-class micro F1 over the complete OOF set and 0.9300 full 41-class accuracy. The corresponding blind-test result is 0.9295 micro F1. The threshold is fixed from the source-side setup and is not adjusted using hidden-test predictions.

6 Conclusion

We addressed cross-domain Arabic knowledge graph construction across the unseen domains of the KONOOZ corpus. For nested NER, combining token-level models from different encoder families with an AraBERT span-based expert provided complementary evidence under domain shift. Symmetric routing over four source-trained experts followed by complementary XLM-R additions achieved 0.7438 micro F1 on the hidden KONOOZ test set without KONOOZ pretraining or adaptation. For RE, the positive-relation pipeline without exact-match overrides achieved 0.9608 micro F1 on the blind test. When extended with explicit `no_relation` prediction with a fixed 0.5 threshold, the system achieved 0.9295 micro F1. Overall, the results demonstrate the value of combining complementary model architectures with conservative ensemble decisions for cross-domain Arabic KG construction.

Limitations

NER development also partly relies on CV-18, which does not fully represent the linguistic and domain variation of the hidden KONOOZ data, as reflected by the moderate correlation between their system rankings. Finally, annotation inconsistencies in the WOJOOD nested data introduce training and evaluation noise and limited the reliable use of automatically generated augmentation examples.

Acknowledgments

We are grateful for the shared task organizers for making this work and that of other teams' possible. We also thank Mahdi Astaraki and Hongyi Zhang for their support and feedback in early phases of the development of this work. B Training and Reproducibility Details

B.1 Token-Level NER Training

The token-level NER experts use the ArabicNER nested tagging pipeline with 21 BIO classification heads. AraBERTv2, CAMeLBERT-Mix, and MARBERTv2 are fine-tuned on the clean WOJOOD nested training data. AdamW is used for optimization, and corrected runs use validation micro F1 for checkpoint selection.

B.2 Entity-Swap Augmentation

We applied entity-swap augmentation to 10% of the 13,408 eligible WOJOOD training sentences. With seed 42, 1,341 sentences were selected and one isolated entity span was replaced in each sentence by another entity of the same type drawn from the WOJOOD training data, while preserving the corresponding labels.

The augmentation is restricted to DATE, GPE, ORG, and PERS entities. Replacement candidates match the entity type and token length; for multi-token GPE and ORG entities, replacements additionally preserve the entity head token. The augmented examples are appended to the original 23,125-sentence training set, producing 24,466 sentences and 415,056 tokens.

The final entity-swap experts are obtained by continuing from their selected clean-WOJOOD checkpoints for one epoch using learning rate 5×10^{-6}, batch size 8, and seed 42. Development and test splits remain unchanged.

B.3 AraBERT Span Classifier

To provide architectural diversity beyond BIO token classification, we train an AraBERTv2 multi-label span classifier following Elkhbir et al. (2023). First-subtoken encoder representations are contextualized using a single-layer bidirectional LSTM. Each candidate span is represented using its start and end states together with a learned 64-dimensional span-width embedding. The resulting span representation is passed through a two-layer feed-forward projection before independent classification over the 21 entity types.

The model enumerates spans up to 15 tokens and is trained using weighted binary cross-entropy, with negative span–label pairs downweighted by a factor of 0.02. The encoder uses learning rate 1×10^{-5}, while the BiLSTM, span-width representation, projection layers, and classifier use learning rate 1×10^{-4}. Training uses batch size 4, seed 42, 5% warmup, and gradient clipping at 1.0. The final expert uses the continued epoch-8 checkpoint. Entity-specific decision thresholds are calibrated during development before final inference.

B.4 XLM-R Complementary Expert

The complementary XLM-R model is fine-tuned on the clean WOJOOD nested training data using XLM-R-base. The model uses the same 21-head BIO formulation as the token-level Arabic encoders.

Checkpoints are saved after every supervised epoch, and checkpoint 2 is selected using CV-18 development performance.XLM-R does not participate in the primary four-expert vote. It is introduced after the primary ensemble has been fixed and is used only to provide additional non-overlapping candidate spans under the complementary addition procedure described in Section 3.2.

Setting	Value
Encoder	XLM-R-base
Learning rate	2×10^{-5}
Batch size	8
Maximum epochs	20
Patience	4
Maximum length	512
Dropout	0.1
Gradient clip	1.0
Seed	42
Optimizer	AdamW

Table 4: Training configuration for the complementary XLM-R expert.

Method	Micro F1	Macro F1	Weighted F1	Pr	Re	Acc.

C NER System Experiments

C.1 Ensembles

Our final NER system combines four primary experts based on AraBERTv2, CAMeLBERT-Mix, MARBERTv2, and an AraBERTv2 span-based classifier. Their predictions are first combined using symmetric exact-span voting. XLM-R is then used as a complementary expert to add supported predictions that do not overlap spans already accepted by the four-expert ensemble.

The Symmetric Four-Expert Ensemble combines predictions from AraBERTv2, CAMeLBERT-Mix, MARBERTv2, and the AraBERTv2 span-based model. A candidate span requires at least two exact expert votes. For overlapping predictions of the same entity type, candidates with the highest expert support are retained; remaining ties are resolved by preferring the shorter span, followed by the earlier span.

Complementary XLM-R Expert XLM-R is trained independently on WOJOOD and does not participate in the primary four-expert vote. After the primary ensemble predictions are fixed, XLM-R is used to identify additional supported candidate spans. Only additions that do not overlap an already accepted primary-ensemble span are retained. Thus, XLM-R can add predictions but cannot replace predictions already selected by the four-expert ensemble. All NER experts in this configuration are developed without KONOOZ pretraining or adaptation. Model and routing decisions are made using WOJOOD and the auxiliary CV-18 development benchmark. Table 5 reports the performance of the final NER system on the official KONOOZ hidden test set. Table 6 reports the contribution of the ensemble components on CV-18, which is used as the auxiliary out-of-domain benchmark during development.

C.2 Expert Support Patterns

Table 7 reports the reliability of exact-span predictions according to the number of primary experts supporting them. Agreement among multiple experts is substantially more reliable than single-expert predictions, supporting the use of a minimum two-expert agreement in the primary ensemble.

Supporting experts	Precision
4 of 4	0.9509
3 of 4	0.8398
2 of 4	0.5971
1 of 4	0.3241

Table 7: Exact-span precision on CV-18 development data according to the number of supporting primary experts.

C.3 Auxiliary Target-Adaptation Experiment

Our main NER result assumes that unlabeled target-domain text is not available before model development, consistent with the cross-domain setting of the shared task. In practice, however, some applications may provide access to unlabeled target-domain text before inference. We therefore also investigated target-adaptive pretraining as an auxiliary setting. A target-adapted configuration reached 0.7499 micro F1 on KONOOZ, compared with 0.7438 for the final system reported above. We retain the non-adapted system as our main result because it does not assume prior access to the target corpus, while the auxiliary result shows the potential benefit of unlabeled target-domain data when such access is available.

D Relation Extraction Training and Development Analysis

D.1 Training Hyperparameters

The relation classifier and NLI reranker both use AraBERTv0.2. Table 8 summarizes their main training configurations.

Setting	RE classifier	NLI reranker
Encoder	AraBERTv0.2	AraBERTv0.2
Learning rate	2×10^{-5}	2×10^{-5}
Batch size	16	8 groups
Maximum epochs	5	4
Patience	2	2
Maximum length	384	384
Weight decay	0.01	0.01
Warmup ratio	0.10	0.10
Seed	42	42

Table 8: Main training hyperparameters for Subtask 2.

Five sentence-grouped folds are trained independently. Sentence grouping ensures that entity pairs originating from the same sentence are not split across training and validation folds. At inference, the probabilities produced by the five fold-specific classifiers are averaged.

The `no_relation`-aware model uses the same sentence-grouped five-fold structure. At inference, the five fold-specific relation-existence probabilities are averaged before applying the fixed 0.5 decision threshold.

D.2 Marker-Based Relation Classifier

The positive-relation classifier is a 40-way AraBERTv0.2 classifier over the positive relation labels. We first preprocess the sentences by inserting `[SUBJ]` and `[OBJ]` token markers around the entities in the target subject-object pairs (Baldini Soares et al., 2019), as in "`[SUBJ] Zezo [/SUBJ] lives in [OBJ] Egypt [/OBJ]`".

This marker-based AraBERT classifier provides the base positive-relation probabilities used by the NLI reranker and schema adjustment. Explicit `no_relation` prediction is handled by the relation-existence component described in Section E.

D.3 Entity Type Training Labels

We obtain entity type labels for the RE dataset using our NER system; it identified entity labels for both relation arguments in 86.07% of training instances. We account for the missing labels during training by masking out the auxiliary losses so that only the relation loss contributes.

D.4 Fast Gradient Method Adversarial Training

We additionally apply Fast Gradient Method (FGM) adversarial training to improve the robustness of the AraBERT relation classifier. FGM is applied to the model's input embedding parameters during training; it does not modify the Arabic sentence or generate new textual training examples.

Given the gradient g of the clean training loss with respect to an embedding parameter θ, the adversarial perturbation is

$$r_{\text{adv}} = \epsilon \frac{g}{\|g\|_2},$$

and the perturbed parameter becomes

$$\theta_{\text{adv}} = \theta + r_{\text{adv}}.$$

We use $\epsilon = 1.0$. For each training batch, gradients are first computed on the original input. The embedding parameters are then perturbed in the gradient direction and an additional adversarial forward and backward pass is performed. The perturbation is removed before the optimizer update. The adversarial loss is weighted by $\lambda_{\text{adv}} = 1.0$:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{multi}} + \lambda_{\text{adv}} \mathcal{L}_{\text{adv}}.$$

This training procedure encourages the encoder to remain stable under small embedding-space perturbations. Adding FGM increases mean OOF F1 from 0.9612 to 0.9643, and combining it with the auxiliary entity-type objective further increases F1 to 0.9659.

D.5 NLI Reranker

For each candidate relation, a fixed relation-specific template is used to construct a natural-language hypothesis containing the subject and object. The original sentence acts as the premise, and the NLI model estimates whether the sentence supports the candidate relation. This formulation allows the reranker to compare the meanings of semantically similar relation labels directly against the source sentence.

During training, each NLI group contains one positive relation hypothesis and five hard-negative hypotheses selected from competing relation predictions. The NLI objective combines binary entailment classification with a ranking loss weighted by 0.50.

We retain the five-fold development structure for the NLI stage, producing five fold-specific

rerankers. At inference, each of the relation classifier's top five candidate relations is scored by all five rerankers and their scores are averaged. The averaged NLI scores are converted to probabilities using temperature 0.75.

$$p_{\text{blend}}(r) = 0.55\, p_{\text{RE}}(r) + 0.45\, p_{\text{NLI}}(r).$$

The schema adjustment described below is applied only after this semantic score blending.

D.6 Entity-Schema Audit and Soft Penalty

The entity types produced by Subtask 1 provide an additional source of evidence about which relations are plausible for a subject–object pair. Because NER predictions can themselves be incorrect, we do not use entity types as hard constraints. Instead, we first audit relation–type compatibility on the training data and then use the resulting schema as a soft adjustment.

For each positive relation with known subject and object types, we compare the observed ordered entity-type pair with the proposed subject–object type configuration for that relation. Training instances are categorized as matching the expected direction, matching the reverse direction, or matching neither direction. A relation is retained as schema-active only when it has at least five auditable training examples and at least 80% type compatibility.

This audit produces 30 active relation types. It also identifies relation-specific inconsistencies in the training data. In particular, the operational direction of `GPE.has_population` is reversed to reflect the observed `CARDINALITY`→`GPE` pattern. The relations `Administration.leader_of`, `GPE.capital_of`, and `GPE.has_currency` are excluded from the active schema because their observed subject–object type patterns are not sufficiently consistent.

At inference, the schema adjustment defined in §3.3 is used only when reliable entity types are available for both the subject and object.

Incompatible candidates are not removed from consideration. This is important because an incorrect NER prediction should not be able to eliminate a relation that is strongly supported by the sentence. The final schema is applicable to 3,806 of the 4,386 blind-test instances, where sufficiently reliable subject and object types are available.

D.7 Component Ablation

Table 9 shows the progressive development of the positive-relation component using sentence-grouped five-fold out-of-fold evaluation over the positive relation instances. We report the blind-test submission progression separately in Table 10, since not every development configuration was submitted to the shared-task server.

Method	Mean OOF F1
AraBERT + markers	0.9612
+ FGM	0.9643
+ auxiliary NER heads	0.9659
+ retrained NLI blend	0.9701
+ schema penalty	**0.9715**

Table 9: Progressive development of the positive-relation component using sentence-grouped five-fold out-of-fold evaluation over positive relation instances.

RE configuration	Blind-test F1
AraBERT marker ensemble	0.9535
+ NLI reranking	0.9580
+ schema penalty	0.9583
FGM + NER-aux + retrained NLI + schema	**0.9608**
+ `no_relation` prediction ($\tau = 0.5$)	0.9295

Table 10: Subtask 2 blind-test results. The first four configurations classify among the positive relation labels. The final configuration additionally predicts `no_relation` using the source-trained relation-existence model with a fixed 0.5 threshold.

D.8 Reranker Adaptation

The initial NLI reranker was developed using errors produced by the earlier AraBERT relation classifier. After FGM adversarial training and auxiliary entity-type supervision were introduced, the primary classifier produced a different distribution of mistakes. In particular, the identities and rankings of the hard negative relations changed.

We therefore rebuilt the NLI training data using hard negatives produced by the updated FGM + NER-auxiliary classifier and retrained all five NLI rerankers. The resulting NLI training set contains 65,023 binary premise–hypothesis instances constructed from 9,289 positive RE rows, including 18,578 entailment and 46,445 non-entailment examples.

With the retrained reranker, the final blend uses weights of 0.55 for the AraBERT relation classifier and 0.45 for NLI, with temperature 0.75. This configuration reaches 0.9701 mean OOF F1 before

the schema-level adjustment. Applying the audited schema increases the positive-relation OOF score to 0.9715 and changes 29 blind-test predictions.

E Negative Relations in Subtask 2

The task permits either one of the 40 positive relation labels or `no_relation` for an entity pair. After removing 14 contradictory negative instances, the cleaned source training data contains 17,367 instances, including 9,289 positive relations and 8,078 `no_relation` instances.

To model this distinction explicitly, we train an AraBERTv0.2 model with a shared encoder and two classification heads. A binary relation-existence head predicts whether the entity pair expresses a relation, while a 40-way relation head predicts the positive relation class. The relation-existence loss is computed over all training instances, whereas the 40-way relation loss is computed only for positive instances. FGM adversarial training and the auxiliary subject and object entity-type objectives are retained.

At inference, the relation-existence probabilities from the five fold-specific models are averaged. A fixed threshold of 0.5 is applied to the resulting relation probability. Instances below this threshold are assigned `no_relation`. For the remaining instances, the positive relation is produced by the FGM + auxiliary-NER classifier, NLI reranking, and soft schema adjustment described in Section 3.3. No hidden-test predictions are used to select or adjust the relation-existence threshold.

System	Rel. Re	no_relation Re	Bal. Acc.	Positive F1	41-class Acc.
no_relation-aware RE ($\tau = 0.5$)	0.9510	0.9308	0.9409	0.9242	0.9300

Table 11: Sentence-grouped five-fold OOF evaluation of the `no_relation`-aware RE system over the complete 17,367-instance source data. Relation and `no_relation` recall and balanced accuracy evaluate the relation-existence decision; positive F1 and 41-class accuracy evaluate the resulting RE predictions.

The source OOF results show that the relation-existence model retains high recall for both positive relations and `no_relation`. When combined with the positive-relation pipeline, the corresponding blind-test configuration achieves 0.9295 micro F1. The positive-relation experiment, which excludes `no_relation` from training and inference, achieves 0.9608 micro F1 on the same blind test.

YafaRE at KnowledgeGraphEval 2026: A Relation Extraction ArBERTv2-based Approach for Arabic Knowledge Graph Construction

Anas Melhem[1], Osama Hamed[1,2,*], Noora Shawareb[1]

Abstract

Relation extraction (RE) identifies semantic relations between entities, converting unstructured text into structured facts for downstream applications such as knowledge graph construction. Arabic RE remains challenging due to rich morphology, complex syntax, dialectal variation, and the scarcity of high-quality annotated resources. We present Yafa's Team submission (ranked 7th) to Subtask 2 of the KnowledgeGraphEval 2026 Shared Task, which frames Arabic RE as multiclass classification over 40 relation types from the *Wojood*^{Relations} dataset. We propose an ArBERTv2-based entity-marker classifier that fuses global sentence context ($[CLS]$) with entity-specific representations (h_e1, h_e2) into a joint representation for relation prediction. Building on this baseline, we exploit a self-training step that pseudo-labels the released test inputs at a softmax confidence threshold of 0.95 and retrains on them, obtaining Micro-F1 of 91.92%. We further conduct a systematic analysis of cross-backbone ensembling with MARBERTv2 and AraBERTv2, finding that ensembling does not outperform the single model. Our results highlight self-training as a simple yet effective strategy for improving Arabic RE robustness.

1 Introduction

Relation extraction (RE) identifies semantic relations between entities in text. It is a fundamental information extraction task because it turns unstructured sentences into structured facts that can be reused by downstream NLP systems. These facts are especially useful for constructing and enriching knowledge graphs, where entities and relations are organized into machine-readable representations (Aljabari et al., 2025b,a). Arabic NLP remains challenging because Arabic exhibits rich morphology, complex syntax and semantics, and wide variation across writing styles and dialects (Hamed, 2019). Consequently, Arabic RE also suffers from a scarcity of high-quality annotated resources.(Aljabari et al., 2025b). Existing Arabic resources often cover only narrow relation sets or appear as small Arabic portions within multilingual corpora, which restricts robust model development and evaluation (Aljabari et al., 2025b,a). These challenges motivate the need for robust Arabic RE systems that can better support knowledge graph construction in realistic settings.

This paper presents Yafa's Team submission (ranked 7th on the leaderboard) to Subtask 2 of the KnowledgeGraphEval 2026 Shared Task (Aljabari et al., 2026) for Arabic RE, focusing on extracting semantic relations between entities in Arabic text. The shared task frames relation extraction as a multiclass classification problem: given a sentence and a pair of entities, the objective is to identify the semantic relation that holds between them. This task is based on *Wojood*^{Relations}, a large-scale Arabic dataset annotated with 40 predefined relation types covering diverse semantic categories (Aljabari et al., 2025b). To address this task, we develop an ArBERTv2-based entity-marker classifier for Arabic relation extraction. Subject and object entities are explicitly marked within each sentence using [E1]...[/E1] and [E2]...[/E2] tokens, and the model builds a joint representation by concatenating the global sentence representation ([CLS]) with the entity-specific hidden states (h_e1, h_e2), which is then passed to a classification layer over the 40 relation types. This raises the micro-F1 score from 0.702 to 0.9192. Overall, this paper makes three contributions:

1. We present an ArBERTv2-based relation extraction model with an entity-marker architecture that classifies each entity pair from a concatenation of the [CLS] token representation (global sentence context) and the hidden representations of the two marked entities (h_e1,

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1238–1243
October 28-29, 2026 ©2026 Association for Computational Linguistics

h_e2).

2. We introduce a semi-supervised transductive self-training step that pseudo-labels the released test inputs (softmax ≥ 0.95) and retrains on them.

3. We provide a systematic analysis of cross-backbone ensembling (MARBERTv2 and AraBERTv2), showing that it does not outperform the single transductive model.

The paper is organized as follows: Section 2 presents prior and recent research on Arabic RE. Section 3 provides an overview of the datasets used. Sections 4 and 5 describe the proposed systems and experimental setup. Section 6 presents and discusses our experimental results. Finally, Section 7 concludes the paper and suggests directions for future work.

2 Background

In recent years, language models have driven substantial progress in RE, enabling systems to move beyond surface-level lexical patterns and capture deeper contextual and semantic relationships between entities. At the sentence level, one common approach marks the subject and object spans with entity markers or special tokens, then classifies the relation from the encoder's contextualized representations. DialogRE (Yu et al., 2020) applies this to dialogue text, marking subject and object boundaries with special tokens. Yan et al. (2022) compare the pipeline and joint approaches to Entity and Relation Extraction and find that the best joint models beat the best pipelines.

SRED-FM and RED-FM (Huguet Cabot et al., 2023) are companion multilingual relation extraction datasets built from Wikipedia using the cRocoDiLe tool and mBART to normalize relation types across 18 languages. SRED-FM is the larger, automatically generated set, with 40 million relations total; its Arabic subset holds 2.9 million relations across 393 of the dataset's 400 relation types. RED-FM is smaller and manually revised, used for evaluation. Both feed mREBEL (Huguet Cabot et al., 2023), a sequence-to-sequence RE model trained on SRED-FM that became the state-of-the-art baseline for later Arabic RE work.

Rakan Al Mraikhat et al. (2024) build on this with AREEj, which augments the Arabic subset of SRED-FM with evidence annotations. Text spans justifying a predicted relation are included. A relation and its evidence are also predicted together. Since SRED-FM has no evidence labels, the authors generate them with ChatGPT-4 using chain-of-thought prompting (Wei et al., 2022), fine-tune an mBART-based model (ArBartEv) on those, then use ArBartEv to annotate all 2.9 million Arabic relations. AREEj beats mREBEL despite far fewer relations (2.9 million versus 40 million): 0.72 F1 on extraction against 0.69, and 0.78 versus 0.71 on classification. It catches 72 relations mREBEL misses; mREBEL catches 47 it misses. Evidence raises recall substantially at a small cost to precision, which the authors attribute to evidence grounding predictions in the text.

This mirrors a broader pattern: using an LLM to bootstrap silver labels for a smaller task-specific model, rather than fine-tuning the LLM directly. Wadhwa et al. (2023) find chain-of-thought prompting consistently helps GPT-3 and Flan-T5 on RE.

3 Dataset

This section presents an overview of the *Wojood*^{Relations} dataset (Aljabari et al., 2025b), released by the shared task organizers for Subtask 2, and reports descriptive statistics on its structure and label distribution.

3.1 *Wojood*^{Relations} Corpus

Wojood^{Relations} is a large-scale Arabic dataset for semantic relation extraction that extends the original Wojood named entity recognition (NER) corpus (Jarrar et al., 2022) with annotated semantic relations between entities. Each instance is represented as a ternary tuple (subject, relation, object), drawn from 40 relation types spanning diverse semantic categories, such as `Location.located_in`, `PartOf.geopolitical_division`, and `Personal.has_occupation`, along with a `no_relation` label for entity pairs that co-occur in a sentence without holding any of the predefined relations.

This dataset consists of 19,455 observations, 17,381 of which are used for training and 2,074 for validation. The training set is dominated by the `no_relation` label and exhibits a highly unbalanced distribution across the 40 relation categories, with the top 15 categories (including `no_relation`) accounting for approximately 98% of the training data. To keep our internal validation stable and reduce noise from extremely rare classes,

we restricted our development-set analysis to these 15 categories; the official evaluation, in contrast, is performed over all 40 relation types. Figure 1 illustrates the relation distribution.

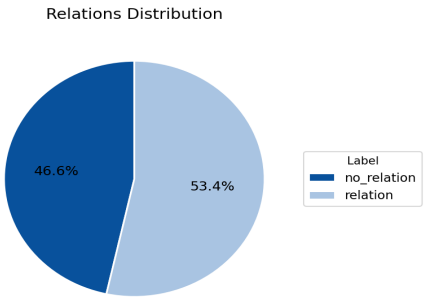

Figure 1: Distribution of relations in the training set.

4 System Description

This section describes the system developed for Subtask 2 of the Arabic RE Shared Task. The code and released resources are available at https://github.com/ohamed/Arabic-RE.

4.1 Model Architecture

We adopt an entity-marker architecture for relation classification. Given a sentence containing a subject and an object entity, the two entity spans are first delimited in the raw text using special marker tokens, [E1]...[/E1] for the subject and [E2]...[/E2] for the object, before the sentence is passed through the ArBERTv2 encoder. This markup allows the encoder to condition its contextual representations on the identity and position of each entity within the sentence, rather than relying on separately encoding entity mentions outside their sentential context.

From the encoder's output, we extract three vectors: the hidden state at the [CLS] token, which summarizes the sentence as a whole, and the hidden states at the [E1] and [E2] marker positions, denoted h_e1 and h_e2, which capture entity-specific contextual information for the subject and object, respectively. These three 768-dimensional vectors are concatenated into a single 2304-dimensional pair representation, $\mathrm{concat}([\mathrm{CLS}], h_{e1}, h_{e2})$, that jointly encodes global sentence semantics and the two entities to be related.

This representation is passed through a classification head consisting of a linear projection down to 768 dimensions, a $tanh$ non-linearity, a dropout layer for regularization, and a final linear layer projecting to 40 output units, one per relation type (including no_relation): $\mathrm{Linear}(2304 \rightarrow 768) \rightarrow \mathrm{Tanh} \rightarrow \mathrm{Dropout} \rightarrow \mathrm{Linear}(768 \rightarrow 40)$. A softmax over these 40 logits yields the predicted relation distribution for the entity pair.

We further extend our method using semi-supervised transductive self-training. First, we use the best inductive model, which was trained on the official training set, to generate pseudo-labels for the released unlabeled test instances. We retain only the high-confidence predictions (softmax $\geq$ 0.95), resulting in 3,758 pseudo-labeled instances out of 4,386 candidate pairs. Then, the model is retrained on the original training set, which is augmented with these pseudo-labeled instances. This approach achieves 91.92% Micro-F1 official test. Figure 2 in Appendix A illustrates the full architecture.

4.2 Cross-backbone Ensemble

We further investigate cross-backbone ensemble methods that combine ArBERTv2 with MARBERTv2 (Abdul-Mageed et al., 2021) and AraBERTv2 (Antoun et al.). Specifically, we test: (i) two-model probability averaging (ArBERTv2 + MARBERTv2), reaching 91.64%; (ii) three-model averaging (ArBERTv2 + MARBERTv2 + AraBERTv2), reaching 91.69%; (iii) a confidence-gated selective merge that overrides ArBERTv2 only where it is unconfident and the two auxiliary models strongly agree, which does not exceed the base model; and (iv) soft low-weight averaging (weights 0.85/0.08/0.07), reaching 91.72%. None of these variants exceeds the single transductive ArBERTv2 model (91.92%), since the auxiliary backbones are individually weaker on this data and ArBERTv2 and MARBERTv2 already agree on 94.3% of test pairs; on the remaining disagreements, neither auxiliary model is reliably more correct, so averaging lowers rather than raises the overall score.

5 Experimental Setup

All experiments are conducted on the Google Colab platform, for both training and inference. Table 2 in Appendix A outlines the main hyperparameters used for fine-tuning the ArBERTv2 model.

6 Results

This section presents our experimental results, ranked by Micro-F1. Table 1 compares our method against the BERT baseline (ArBERTv2).

Our method obtains 91.92% Micro-F1, compared to 88.61% for the baseline. This improvement is driven primarily by precision: our model reaches 96.19%, substantially higher than the baseline, while recall (88.01%) remains close to, and marginally below, the baseline's 88.65%. This indicates that self-training makes the model more accurate in the relations it predicts, reducing false positives, rather than increasing the number of true relations it successfully identifies.

Model	Prec. (%)	Rec. (%)	Micro F1 (%)
Baseline (ArBERTv2)	–	–	93.09
LLM baseline (gpt-4o)	89.25	83.66	85.78
ArBERTv2-T	**96.19**	88.01	91.92

Table 1: A Performance comparison of used models.

6.1 Error Analysis

The results in Table 1 mean that the false-positive rate among predicted relations is about 3.81%. Also, the number of false negatives is roughly 3.4 times the number of false positives. To better understand the remaining errors after transductive self-training, we analyze the predictions of our final ArBERTv2 model on the development set, grouping the observed errors into three categories.

Confusion with `no_relation`. Given the severe class imbalance in the training data (Section 3), a substantial share of errors involve the `no_relation` label. These errors occur in two directions: cases where the gold label is `no_relation` but the model predicts a specific relation type (false positives), and cases where a true relation is missed and predicted as `no_relation` (false negatives). This pattern is consistent with our precision/recall results (Section 6). The model achieves high precision, indicating that its specific relation predictions are generally reliable, while the lower recall indicates that some true relations remain unidentified.

Confusion between semantically adjacent relations. The remaining errors include confusions between relations that are semantically close. Such confusions arise when different relation types share similar lexical or contextual cues. For example, relations describing different types of affiliation, location, or organizational relationships may require distinctions that are not explicit in the local context. These cases suggest that the model can have difficulty distinguishing fine-grained semantic relations when their surface contexts are similar.

7 Conclusion

In conclusion, this paper presents the ARBERTv2 transductive (ARBERTv2-T), a robust Arabic relation extraction approach based on the ArBERTv2 model, which improves the performance of Arabic RE systems. Our team, dubbed Yafa's Team (YafaRE is ranked 7th), achieved a micro-F1 score of 91.92% on the WojoodRelations benchmark. This score outperforms the LLM baseline and is comparable to the ArBERTv2 baseline model. The results demonstrate the effectiveness of our semi-supervised transductive self-training approach, which leverages pseudo-labeled data to improve the model's generalization capabilities. The experiment also explores the use of cross-backbone ensemble methods. However, these methods do not outperform the single transductive ArBERTv2 model due to its strong individual performance and high prediction agreement. The study provides a reliable and fine-grained Arabic RE model that generalizes well across domains and relation types, addressing the limitations of existing models. Future work will examine the feasibility of using other Arabic pretrained language models or small LLMs for this task.

A Additional Experimental Details

This appendix is meant to provide further details that are essential for understanding our system description paper. This include, among others, the ArBERTv2 entity-marker architecture, (Figure 2), the hyperparameters used for fine-tuning ArBERTv2 (Table 2), and the limitation of this sStudy .

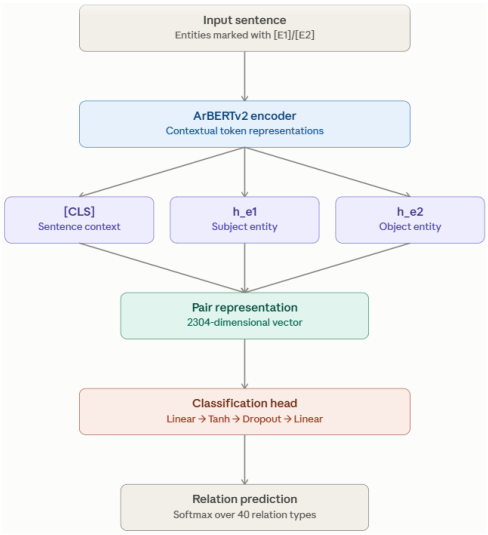

Figure 2: The ArBERTv2 entity-marker architecture used for the relation classification subtask.

Hyperparameter	**Value**
Learning rate (LR	2×10^{-5}
Weight decay	0.01
Batch size (train/eval)	16
Maximum sequence length	160
Number of epochs	4
Linear scheduler warmup	10%
Optimizer	AdamW
Pseudo-label confidence	0.95

Table 2: Main hyperparameters used for fine-tuning ArBERTv2.

Study Limitations One limitation of this work is that the WojoodRelations test set was unlabeled during system development. Therefore, direct error analysis on the target-domain predictions was not possible. Our final system relies on transductive self-training using the released test inputs. This improves robustness under distribution shift, but it also ties the model to the specific test set, rather than yielding a fully inductive model. Additionally, the experiments were conducted using ArBERTv2-based models. While we explored MARBERTv2 and AraBERTv2 in our ensembling analysis, we did not evaluate other Arabic pretrained language models.

YafaNER at KnowledgeGraphEval 2026: AraBERTv2-based Approach to Cross-Domain Adaptation for Arabic NER

Abstract

Cross-domain Arabic Named Entity Recognition (NER) remains challenging because models trained on one domain can lose performance when applied to unseen domains with different vocabulary, writing styles, and entity distributions. This paper addresses this challenge, and presents Yafa's Team submission (ranked 7th) to Subtask 1 of the KnowledgeGraphEval 2026 Shared Task. Our system leverages an AraBERTv2-based model for nested Arabic NER to approach it. The proposed approach combines task-adaptive (TAPT) pretraining on unlabeled Konooz data, R-Drop fine-tuning on Wojood, strong data augmentation, teacher-student knowledge distillation, span-level confidence and entropy filtering, and an entity-specific confidence-aware weighted-logit ensemble. Three teacher models generate soft labels for Konooz, and three distilled student models are combined in the final ensemble to produce the final predictions. Wojood contains approximately 448K tokens and 72K entity mentions across 21 entity types, while Konooz contains data from 10 domains for cross-domain evaluation. The final system achieves a Micro F1 of 71.33% on the official Konooz test set, improving over the non-adapted AraBERTv02 baseline of 61.00% by 10.33 points. The results show that combining domain adaptation, filtered knowledge transfer, and entity-specific ensembling can improve cross-domain Arabic NER performance.

1 Introduction

Named Entity Recognition (NER) is a fundamental information extraction task that identifies mentions of people, organizations, locations, dates, and other semantic classes in text. NER plays a vital role in many applications, such as word sense disambiguation (Jarrar et al., 2023), knowledge graph construction, and relation extraction (Jarrar et al., 2022; Aljabari et al., 2025b). Arabic NER remains particularly challenging due to rich morphology and complex orthographic variations. Domain shift across domains and dialects adds a further layer of difficulty: a model trained on a specific domain often suffers significant degradation when applied to another (Hamad et al., 2025a). Moreover, annotated resources remain limited and often differ in tagsets and coverage (Hamed, 2019; Ali et al., 2020). These challenges are especially pronounced in cross-domain NER, where models trained on one domain often suffer substantial performance degradation when applied to unseen domains, reflecting differences in entity definitions, boundaries, and lexical context (Hamad et al., 2025a; Aljabari et al., 2025a). This makes robust domain-adaptive Arabic NER a necessary step toward reliable knowledge extraction across heterogeneous text sources.

This paper outlines the Yafa's Team (YafaNER is ranked 7th on the leaderboard) submission to Subtask 1 of the KnowledgeGraphEval 2026 Shared Task (Aljabari et al., 2026) at the Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026). Where we tackle the cross-domain adaptation for Arabic NER. This shared task focuses on recognizing and classifying named entities in Arabic text while evaluating the ability of systems to generalize across unseen domains. It is based on the AdaptNER benchmark, where models are trained on one or more source domains and evaluated on different target domains to measure cross-domain robustness.

This paper makes the following three contributions. First, we present an enhanced AraBERTv2-based system for cross-domain, nested Arabic named entity recognition. This system integrates task-adaptive pretraining (TAPT), R-Drop fine-tuning, entity-preserving strong data augmentation, teacher-student knowledge distillation, and ensemble learning. Second, we propose a span-level confidence and entropy filtering strategy to select reliable teacher-predicted entity spans from the unlabeled Konooz corpus prior to knowledge distil-

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1244–1249
October 28-29, 2026 ©2026 Association for Computational Linguistics

lation. This reduces the impact of noisy supervision during student training. Third, we develop an entity-specific, confidence-aware weighted logits ensemble. The ensemble weights are derived from per-entity validation F1 scores using a temperature-controlled softmax function. This enables each entity type to benefit from the model that performs best for that entity type. Our final system achieved a Micro F1 score of 71.33% on the official Konooz test set.

The paper is organized as follows: Section 2 presents prior and recent research on Arabic AdaptNER. Section 3 provides an overview of the datasets used. Sections 4 and 5 describe the proposed systems and experimental setup. Section 6 presents and discusses our experimental results. Finally, Section 7 concludes the paper and suggests ideas for future work.

2 Related Work

Arabic NER has progressed from rule-based and feature-engineered systems to neural sequence models and transformer encoders. Early Arabic systems relied on handcrafted lexical, morphological, and gazetteer features (Shaalan and Raza, 2007; Benajiba et al., 2007; Abdul-Hamid and Darwish, 2010; Abdallah et al., 2012; Mohit et al., 2012). BiLSTM-CRF and related neural models improved robustness by learning distributed representations directly from data (Lample et al., 2016; Khalifa and Shaalan, 2019). The shift to pretrained transformers further advanced Arabic NER, with AraBERT, ARBERT, and MARBERT providing stronger contextual representations and better handling of morphology and orthographic variation (Antoun et al., 2020; Abdul-Mageed et al., 2021).

Arabic corpora often differ substantially in entity inventories and boundary conventions. *Wojood* highlights this issue by showing that entity definitions vary even within Arabic, across datasets such as ANERCorp, AQMAR, and OntoNotes, making direct transfer unreliable (Jarrar et al., 2022; Aljabari et al., 2025a). These divergences are especially harmful in cross-domain settings, where models trained under one genre or annotation guideline must generalize to unseen domains with different vocabulary, style, and entity distributions.

Wojood demonstrated that a single corpus can cover MSA and dialectal Arabic across multiple domains while supporting nested annotations and a richer tagset than prior Arabic resources (Jarrar et al., 2022). $Wojood_{fine}$ extends this scheme with finer-grained subtypes, while $Wojood^{Gaza}$ and *Konooz* further broaden domain and dialect coverage (Liqreina et al., 2023; Jarrar et al., 2024; Hamad et al., 2025a).

Cross-domain Arabic NER therefore remains an open problem at the intersection of representation learning and dataset harmonization. This gap motivates **KnowledgeGraphEval 2026 Shared Task Subtask 1 (AdaptNER)**, which requires systems that do not merely memorize a single corpus but generalize reliably across heterogeneous Arabic domains.

3 Datasets and Stats

This work relied on two main Arabic datasets, *Wojood* (Jarrar et al., 2022) and *Konooz* (Hamad et al., 2025b), as well as an augmented version of the training data generated using Strong Data Augmentation; each dataset was used at a different stage of the proposed system.

3.1 Wojood

Wojood is a corpus for Arabic nested NER. It contains approximately 448K tokens and 72K entity mentions annotated with 21 entity types. Wojood is the official labeled dataset used in AdaptNER subtask competition to train and evaluate models *for nested named entity recognition*. The dataset consists of three main files, which are corresponding to the training, validation, and test sets. Each line in the Wojood files contains a token followed by one or more BIO tags, depending on the number of overlapping entities associated with that token.

3.2 Augmented Wojood Training Set

Since the original training data was limited compared to the diversity of domains present in the test data, an augmented version of the Wojood training set was created using Strong Data Augmentation.

The augmented data retains the same Wojood data format and the same tagging scheme (Nested BIO) to ensure compatibility with the model. Thus, new new sentence versions were generated using various data augmentation techniques while maintaining tag consistency as much as possible. Specifically, for approximately 30% of the training sentences, one of three entity-preserving operations: O-only word dropout, O-only word masking, or O-only adjacent word swap was randomly applied to O-tagged tokens , while entity-bearing tokens (B-/I- tags) were left unchanged.

3.3 Konooz

Konooz is the official test set for the competition. It is an unlabeled dataset used to evaluate the models' ability to generalize to new domains (cross-domain generalization). The dataset consists of 10 files, each representing a different domain. As for the Konooz files, each line contains a token followed by 21 columns representing entity types, all of which have a value of **O** because this is an unlabeled dataset.

Overall, the following note applies to the three datasets: Each pair of sentences within the three datasets is separated by a blank line. This format defines sentence boundaries during training and evaluation.

4 System Description

We used AraBERTv2-based models to label the tokens found in the development and test sets, known respectively, as "dev-konooz" and "blinded-test-data". Here, we provide a brief description of the base models, followed by a detailed description of the variant models used for submission on Codabench. Code and released resources are available at `https://github.com/ohamed/Arabic-NER`.

4.1 AraBERT and AraBERTv2

AraBERT (Antoun et al., 2020) is an Arabic-specific, pretrained transformer model that extends the Google's BERT architecture. It was pre-trained on corpora of Arabic news articles comprising tens of millions of sentences.

AraBERTv2 is the updated version of AraBERT model presented by Antoun et al. (2020) *AraBERTv2 is an advanced, transformer-based pre-trained language model built specifically for the Arabic language*. AraBERTv2 was trained on a massive 77GB dataset (200 million Arabic sentences or 8.6 billion words) of Arabic text.

4.2 AraBERTv2 Ensemble

Our proposed system is based on AraBERTv2 and uses the BertNestedTagger architecture to identify nested named entities in Arabic text. The model performs token-level classification with parallel BIO classification heads, which allow multiple entity labels to be assigned to the same token, thereby supporting nested entity recognition. It combines TAPT, R-Drop regularization, teacher-student knowledge distillation, span-level confidence, and entropy filtering. Our system was developed as follows:

First, TAPT was performed on the unlabeled Konooz corpus using only its raw, unlabeled text via masked language modeling. No gold labels were used at any stage prior to the final prediction. Then, the resulting model was fine-tuned on the Wojood dataset using R-Drop. Three teacher models were trained with random seeds 1, 42, and 2026. Strong data augmentation was applied to the third teacher model to increase prediction diversity. These three teacher models were then combined using a weighted logits ensemble to generate soft labels for the unlabeled Konooz corpus. The teacher-predicted entity spans were then filtered using span-level confidence and entropy thresholds to retain only the most reliable entity spans.

Next, three student models were trained using teacher-student knowledge distillation. Each student model learned jointly from the manually annotated Wojood dataset and the filtered Konooz teacher outputs through soft supervision.

The final system is an ensemble of the three distilled student models. During inference, their predictions are combined using an entity-specific, confidence-aware weighted logit ensemble. The ensemble weights are derived from per-entity validation F1 scores using a temperature-controlled softmax function. A temperature of 0.03 produced the best validation performance and was thus employed in the final submission. Figure 1 shows the general sequence of stages followed to label Konooz files using our proposed AraBERTv2-based ensemble system.

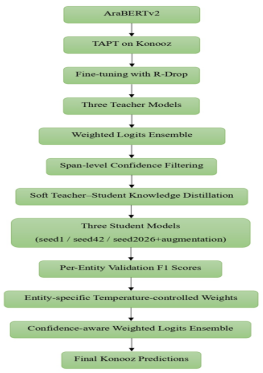

Figure 1: The development of AraBERTv2 ensemble.

5 Experimental Setup

This system does not use prompting, retrieval, or external knowledge sources. It relies exclusively

on AraBERTv2, the Wojood dataset, and the unlabeled Konooz corpus. All phases of the project were carried out using the Google Colab platform. The NER models were trained using AdamW with a learning rate of 1×10^{-5}, a batch size of 8, a maximum sequence length of 512, and a dropout rate of 0.1. R-Drop used $\alpha = 1.0$, while knowledge distillation used a temperature of $T = 2.0$ and a weight of 0.5. These values were empirically selected based on preliminary experimentation with the validation set.

5.1 Preprocessing

Before implementing the proposed training stages, a series of data preprocessing steps were performed to prepare the datasets for the requirements of each stage. These steps fall into four categories: (i) preparing Konooz for task-adaptive pretraining; (ii) tokenization and sequence preparation; (iii) preparing Konooz for NER prediction; and (iv) creating the augmented Wojood training set.

5.2 Final System Configuration

As shown in Figure 1, we conducted our experiments iteratively until we reached the final system configuration. The final system is an AraBERTv2 ensemble (AraBERTv2-E), which is an entity-specific, confidence-aware weighted logits ensemble. The adopted hyperparameter values are listed in Table 2 in Appendix A.1, along with the rationale behind key choices (e.g., the ensemble temperature).

6 Results

Table 2 presents the performance of the final AraBERTv2 ensemble (AraBERTv2-E) on the official Konooz test set compared with the baseline model. AraBERTv2-E improves the Micro F1 from 0.61 to 0.7133, an improvement of 10.33 percentage points. The final system obtains a Weighted F1 of 0.7069 and a Macro F1 of 0.6091. The difference between the Macro and Weighted F1 scores shows that performance is not uniform across entity types.

Model	Micro F1	Macro F1	Weighted F1	Precision	Recall
BERT w/o adaptation (AraBERTv02)	0.61	–	–	–	–
AraBERTv2-E w adaptation	**0.7133**	0.6091	0.7069	0.7325	0.6952

Table 1: Performance comparison of the evaluated models.

Table 3 in Appendix A.2 shows how each system component contributes to the Dev-Konooz and official Konooz test sets.

6.1 Error Analysis

An error analysis of the models forming AraBERTv2-E, based on the labeled Wojood test set, reveals difficulties in distinguishing some contextual expressions from named entities. For example, in "اجتماع نابلس", the gold annotation labels only "نابلس" as GPE, while all three models forming the final ensemble incorrectly identify "اجتماع نابلس" as an EVENT. Another difficulty appears in nested entity recognition. In "انتخابات المجلس الإسلامي الأعلى", the gold annotation contains an EVENT spanning the full expression and an ORG nested within it. One of the student models identifies the inner ORG but misses the enclosing EVENT, while another correctly identifies both entities. These examples show that contextual ambiguity and overlapping entity structures remain challenging for the models used in the final system.

6.2 Limitations

One limitation of this work is that the Konooz test set was unlabeled during system development, so direct error analysis on the target-domain predictions was not possible. In addition, the experiments were conducted using AraBERTv2-based models, and other Arabic pretrained language models were not evaluated.

7 Conclusion

This paper presented our approach for the KnowledgeGraphEval 2026 Shared Task, Subtask 1 on cross-domain Arabic NER. Our AraBERTv2-based system combines task-adaptive pretraining, R-Drop fine-tuning, strong data augmentation, teacher-student knowledge distillation with span-level confidence and entropy filtering, and an entity-specific confidence-aware weighted logits ensemble. It achieved a Micro F1 score of 71.33% on the official Konooz test set. Future work will investigate other Arabic pretrained language models, small LLMs, improved confidence estimation and knowledge transfer methods, and more effective use of unlabeled data for cross-domain adaptation.

A Additional Experimental Details

A.1 Hyperparameter Configuration

Table 2 lists the main hyperparameters of the final ensemble system.

The per-entity ensemble weights were derived from the Wojood validation F1 score. The single

Parameter	Value
Input Models	3 Student Models
Ensemble Level	Logits
Weighting Strategy	Entity-Specific Weights
Weight Source	Per-Entity Validation F1
Weight Normalization	Softmax
Temperature (T)	0.03
Output	Final Prediction Files

Table 2: Main hyperparameters used for AraBERTv2-E.

ensemble-temperature value was selected by comparing four candidates (0.03/0.05/0.07/0.10) via the official Konooz leaderboard, with the score spread (0.7128–0.7133) indicating low sensitivity to this choice.

A.2 Incremental Ablation Results

To isolate the contribution of each component, we report in Table 3 incremental results on Dev-Konooz used for comparative evaluation during system development, alongside results on the official Konooz test set used for the shared-task submission. Results obtained on the two evaluation sets are not directly comparable.

Stage	Evaluation Set	Micro F1	Δ F1
Baseline	Dev- Konooz	0.6272	—
TAPT	Dev- Konooz	0.6870	+0.0598
TAPT + R-Drop	Dev- Konooz	0.6961	+0.0091

Abstract

The ANLP team submitted a system to Subtask 1 (Named Entity Recognition) of KnowledgeGraphEval 2026 (Aljabari et al., 2026), which focuses on nested NER in Arabic and evaluates cross-domain and cross-dialect generalization from the Wojood corpus to the multi-domain KONOOZ(Hamad et al., 2025) benchmark. The system is a combination of an Efficient GlobalPointer decoder with rotary position embeddings and a MARBERT backbone. To reduce the domain gap, we first perform domain-adaptive pretraining (DAPT) on unlabeled KONOOZ text, then apply a pseudo-labeling self-training stage. We train a second model based on AraBERT and combine it with the first model using a stacking ensemble to improve prediction diversity. As for the Wojood test set, the best ensemble achieves a micro F1 of 0.9288, increasing to 0.9292 when entity-type-specific decision thresholds are used, compared with 0.9211 for the single Phase-1 MARBERT model (before self-training). On the official blind KONOOZ test set, however, the submitted system obtains a micro F1 of 0.7106 (macro F1 = 0.6101, weighted F1 = 0.7013, P = 0.8143, R = 0.6304, accuracy = 0.9948). The lower recall suggests that the decoding threshold chosen based on the Wojood validation data was too strict for the domain-shifted KONOOZ data. The system analyzes this difference and proposes a threshold-recalibration strategy to improve the performance under the target-domain distribution. The implementation of the proposed system is publicly available in the accompanying Colab notebook.[1]

1 Introduction

KnowledgeGraphEval 2026 is the first shared task dedicated to Arabic knowledge graph construction, with two subtasks covering named entity recognition (Subtask 1) and relation extraction (Subtask 2). The team participated in Subtask 1, which focuses on nested named entity recognition. In this subtask, models are trained on the Wojood corpus (Jarrar et al., 2022) and evaluated on KONOOZ, a held-out benchmark covering ten domains: Agriculture, Art, Economics, Finance, Health, History, Law, Politics, Science, and Sport, and sixteen Arabic dialects. None of these domains and dialects are in-distribution with respect to Wojood.

The main challenge in this task is transferring a nested NER model across different domains and dialects. Although models trained on Wojood perform well on in-domain data, differences in vocabulary, writing style, and dialectal variation make generalization to KONOOZ substantially more difficult. This motivates the use of domain adaptation techniques.

To address this challenge, three complementary strategies are adopted. Domain-adaptive pretraining is first performed on unlabeled KONOOZ text, followed by self-training with pseudo-labeled KONOOZ examples. Finally, MARBERT and AraBERT are combined using a stacking ensemble to improve robustness under domain shift.

On the Wojood test set, the proposed ensemble improves the entity-level micro F1 score from 0.9211 to 0.9288. The official submission achieved a micro F1 score of 0.7106 on the KONOOZ blind test set. A post-submission analysis suggests that the lower recall is largely due to a conservative decoding threshold under domain shift. This analysis is discussed in Section 5.

2 Background

Task and data. Subtask 1 uses Wojood's nested-NER annotation scheme, which covers 21 entity types (e.g., PERS, ORG, GPE, DATE, QUANTITY), with about 22.5% of entities nested inside another entity (Jarrar et al., 2022). Training and validation data are the standard Wojood nested splits;

October 28-29, 2026 ©2026 Association for Computational Linguistics

the blind evaluation data is drawn from KONOOZ, which follows the same 21-type annotation guidelines but spans ten topical domains and sixteen dialects, none seen during Wojood training. The official submission format requires one file with 21 fixed-order BIO columns per token (one column per entity type, since nested tagging allows a token to be `B-/I-` in more than one column simultaneously), with all ten domains concatenated in a fixed alphabetical order.

Related work. Previous work has approached nested NER using either layered sequence tagging models or span-based methods that avoid the flat-BIO assumption altogether. The second choice was adopted: the (Efficient) GlobalPointer formulation of Su et al. (2022) scores every candidate span independently per entity type using a biaffine-style product of query/key projections, which supports arbitrarily overlapping spans without additional decoding machinery. For the Arabic backbone, MARBERT (Abdul-Mageed et al., 2021) is used, a BERT-style model trained on Arabic dialectal Twitter data, and AraBERT (Antoun et al., 2020), trained primarily on Modern Standard Arabic, a complementary backbone with stronger coverage of Modern Standard Arabic.

3 System Overview

Figure 1 summarizes the pipeline, which consists of four stages.

Span-scoring model Both backbones use an Efficient GlobalPointer head (Su et al., 2022). Token representations are projected into query and key vectors with an inner dimension of 64 and rotary position embeddings. Each span (i, j) is scored independently for the 21 entity types using the query and key representations, with a small type-specific bias. Since each type is scored over the full $\mathrm{seq_len} \times \mathrm{seq_len}$ grid, the model can handle nested and overlapping entities directly. Training uses GlobalPointer's multilabel categorical cross-entropy loss. Since standard focal loss is not directly compatible with this objective, class imbalance is handled using other strategies.

Domain-adaptive pretraining (DAPT) Before any labeled training, we continue masked-language-model pretraining of the MARBERT backbone on the separate unlabeled KONOOZ domain-adaptation data available during development. The blind KONOOZ evaluation files are not used during DAPT or pseudo-label self-training and are accessed only during final inference. The goal is to adapt the backbone's vocabulary and phrasing to the target domains before the NER objective is introduced, under the hypothesis that this makes entity boundaries easier to detect once Phase 1/2 training begins.

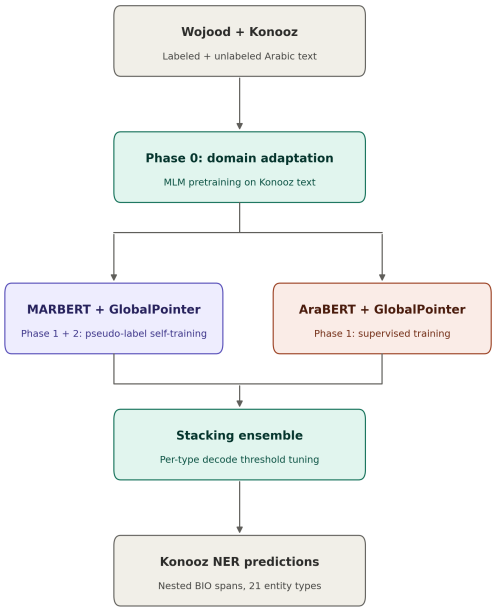

Figure 1: System architecture: domain-adaptive pretraining on separate unlabeled KONOOZ development data, followed by parallel MARBERT and AraBERT training (the former continuing into pseudo-label self-training), combined via a stacking ensemble.

Phase 1: Supervised training on Wojood. The DAPT-adapted MARBERT backbone is fine-tuned on labeled Wojood nested-NER data. To manage the large class imbalance between high-support types (e.g., GPE, DATE, ORG, each with thousands of training instances) and low-support types (e.g., PRODUCT, UNIT, QUANTITY, each with fewer than 20), two complementary, loss-compatible strategies are used: a `WeightedRandomSampler` that oversamples sentences containing rare types, and per-type loss weighting inside the GlobalPointer objective. In parallel, an independently initialized AraBERT model is trained on the same Wojood data (Phase 1 only, no DAPT or self-training), to provide a second, architecturally diverse model for ensembling. We limit DAPT and self-training to MARBERT to reduce the computational cost and keep the di-

versity between the ensemble members. The same adaptation to AraBERT can make its predictions closer to MARBERT, thus reducing the benefits of ensemble stacking.

Phase 2: Pseudo-labeling self-training on KONOOZ. The Phase-1 MARBERT model is used to pseudo-label the separate unlabeled KONOOZ domain-adaptation data. The resulting pseudo-labeled examples are then combined with the original Wojood training data for Phase-2 fine-tuning. Since KONOOZ has no gold labels, no local F1 can be computed at this stage, the system uses qualitative spot-checks and the Wojood held-out validation F1 to detect degradation. (The blind KONOOZ test set is not used in this stage.)

Ensembling. The Phase-2 adapted MARBERT model and the Phase-1 AraBERT model are combined in word-index space (so the two backbones' differing subword tokenizations do not need to be aligned), using three strategies: union voting, intersection voting, and stacking. For stacking, a logistic regression meta-model is trained on candidate spans from the Wojood validation set. The input features are the raw span logits from both backbones. If a backbone does not predict a candidate span, a large negative score is assigned to it. The resulting ensemble is then evaluated on the held-out Wojood test set. Also separate decision thresholds are investigated for each entity type, as the preliminary analysis showed that numeric and measurement entities, as well as PRODUCT, require different precision–recall trade-offs than other entity types.

4 Experimental Setup

Data splits and preprocessing. We use the standard Wojood nested train/validation/test splits (6,606 sentences in test). Entity types are discovered automatically from the training data's tag vocabulary, yielding 21 types, matching KONOOZ's fixed column order. Sequences are tokenized with each backbone's own tokenizer, sub-word aligned via `is_split_into_words`, and truncated/padded to a maximum length of 128 tokens.

Model configuration. Backbones:`UBC-NLP/MARBERT`(Abdul-Mageed et al., 2021) (primary) and `aubmindlab/bert-base-arabertv02` (Antoun et al., 2020) (ensemble partner). The GlobalPointer inner dimension was selected by comparing 32 and 64 in preliminary experiments. The 64-dimensional setting achieved better validation F1 and was retained, while broader tuning was limited by computational constraints.with rotary position embeddings enabled. During domain-adaptive pre-training, the model is trained for four epochs with a learning rate of 5×10^{-5}, a batch size of 16, and a masking probability of 0.15.Phase 1 (supervised): 5 epochs, learning rate 2×10^{-5}, per-step batch size 5 with gradient accumulation over 4 steps (effective batch size 32). Phase 2 (self-training): 3 epochs at half the Phase-1 learning rate (1×10^{-5}). Inference/evaluation batch size: 16. Mixed-precision (FP16) training is used whenever a GPU is available. All experiments use a fixed random seed (42).

Threshold	P	R	F1
-2.0	0.8490	0.9467	0.8952
-1.0	0.8847	0.9346	0.9090
0.0	0.9129	0.9216	0.9173
$+0.5$	0.9238	0.9132	0.9184
$+1.0$	0.9358	0.9032	**0.9192**

Table 1: Decode-threshold sweep on Wojood validation data (MARBERT, Phase 1). $+1.0$ is selected as the global threshold.

Decoding threshold selection. The GlobalPointer decision threshold that maximizes entity-level F1 is selected by evaluating several candidate thresholds on Wojood validation data (Table 1), yielding a global threshold of $+1.0$. Per-type thresholds are additionally selected by maximizing each type's own validation F1 independently.

Tools and libraries. All models are implemented in PyTorch using the Hugging Face `transformers` and `accelerate` libraries. The stacking classifier is implemented with `scikit-learn`'s `LogisticRegression`, while `joblib` is used to save trained models

Post-processing. Predictions are written directly in the required 21-column, fixed-domain-order BIO format. Since GlobalPointer predicts entity spans directly, no additional BIO-flattening or conflict-resolution step is required before generating the final 21-column submission files.

5 Results

Official result. On the KONOOZ blind-test leaderboard (Subtask 1), the submitted ANLP system achieved a micro F1 of **0.7106** (macro F1 = 0.6101, weighted F1 = 0.7013, precision = 0.8143,

Method	Micro F1
Task baseline (AraBERTv2, no domain adaptation)	0.6300
ANLP (official submission)	**0.7106**

Table 2: Official results on the KnowledgeGraphEval 2026 blind KONOOZtest set.

Method	P	R	F1
MARBERT (Phase 2, self-trained)	0.9395	0.9074	0.9232
AraBERT alone	0.9375	0.9056	0.9213
Vote (union)	0.9146	0.9342	0.9243
Vote (intersect)	0.8886	0.9360	0.9117
Stacking	0.9451	0.9131	**0.9288**
Stacking, per-type	0.9362	0.9222	**0.9292**

Table 3: Held-out Wojood test results (gold labels, not the official KONOOZ score). Stacking gives the best overall F1; per-type decision thresholds give a marginal further gain.

recall = 0.6304, token-level accuracy = 0.9948). Table 2 compares our official submission with the shared-task baseline. Since KONOOZ does not provide gold labels, these are the only official evaluation results. Self-training improves MARBERT's in-domain F1 from 0.9211 to 0.9232 on Wojood. However, its impact on KONOOZ cannot be directly measured because the blind test set has no public gold annotations.

Table 3 shows that stacking always outperforms both models when these thresholds are tuned on the same test set, we report this experiment's micro F1 from 0.9232 to 0.9288. Applying per-type decision thresholds further improves the stacking ensemble. When tuned on the same test set, this experiment is reported separately as a post-submission analysis. These complementary strengths explain why stacking the two models yields better overall performance.

Per-type error analysis. Comparing MARBERT and AraBERT per entity type on the Wojood test shows systematic, complementary weaknesses: AraBERT is clearly stronger (F1 gain > 0.02) on CARDINAL, TIME, MONEY, WEBSITE, and PRODUCT, while MARBERT is clearly stronger on QUANTITY, LANGUAGE, CURR, and LOC. Both models struggle most on the lowest-support types: PRODUCT (support 19, F1 0.59–0.64), QUANTITY (support 9, F1 0.58–0.78), and WEBSITE (support 106–116, F1 0.59–0.63), consistent with the severe class imbalance in Wojood's training distribution. This complementarity is the primary motivation and benefit of ensembling the two backbones rather than relying on either alone.

5.1 Discussion and Error Analysis

One possible reason for the high precision and low recall pattern (P=0.8143, R=0.6304) on the official KONOOZ evaluation is that the decoding threshold chosen on Wojood is conservative when applied to the target domain. Because KONOOZhas a large domain shift, even correct entity spans may have a lower prediction confidence, which leads to fewer accepted predictions.

Since KONOOZ does not provide gold labels, this hypothesis cannot be directly verified. Instead, the density of predicted entities across different decoding thresholds is compared with the corresponding density observed on Wojood. Although indirect, this analysis suggests that lowering the decoding threshold may recover additional true positives without substantially reducing precision.

Based on this analysis, we plan to investigate two modifications in future work: (1) recalibrating the decoding threshold for the target domain and (2) reducing the pseudo-label confidence threshold during self-training. Both changes aim to improve recall under domain shift while maintaining high precision.

6 Limitations

This study has several limitations. The lack of gold annotations for the blind KONOOZ test set makes it difficult to measure the individual effects of DAPT and self-training on the target domain. The gain from 0.9211 to 0.9232 after self-training is therefore limited to the Wojood test set. Likewise, the per-type threshold analysis was only validated on Wojood.

Class imbalance remains another issue, particularly for low-support types such as PRODUCT and QUANTITY. Augmentation was tested but reduced overall performance, so it was not retained. Sequence truncation may also affect recall, although its impact on KONOOZ could not be measured without access to the gold annotations.

Finally, the gap between Wojood (0.9292) and KONOOZ (0.7106) shows that cross-domain and cross-dialect generalization remains challenging. Computational limits also prevented broader hyperparameter tuning and experiments with adapting both MARBERT and AraBERT.

7 Conclusion

This paper presents ANLP's system for Subtask 1 of KnowledgeGraphEval 2026. The system uses GlobalPointer for nested NER and combines MARBERT and AraBERT through domain-adaptive pretraining, pseudo-label self-training, and stacking. On the held-out Wojood test set, the ensemble achieved a micro F1 of 0.9288, increasing to 0.9292 with entity-specific decision thresholds.

The official KONOOZ result was lower, with a micro F1 of 0.7106, precision of 0.8143, and recall of 0.6304. This gap shows the difficulty of applying the system across domains. Our post-submission analysis suggests that the threshold selected on Wojood may be too conservative for KONOOZ, leading to fewer predicted entities and potentially lower recall. However, this cannot be verified directly because KONOOZ does not provide gold labels.

Future work will focus on better threshold calibration under domain shift and on using entity-specific thresholds for pseudo-label generation. We will also investigate data augmentation for less represented types, including PRODUCT, QUANTITY, and WEBSITE. Finally, we will study whether adapting both MARBERT and AraBERT can improve target-domain performance while preserving the model diversity needed for effective ensembling.

Acknowledgments

We thank the KnowledgeGraphEval 2026 organizing committee for the shared task, data, and evaluation infrastructure.

A Per-type Validation Thresholds

Table 4 lists the best decode threshold and validation F1 found independently for each entity type (MARBERT, Wojood validation set), used as candidates for the per-type stacking cutoffs reported in Section 5.

Threshold	Entity types	F1 range
−2.0	PERCENT, UNIT, QUANTITY	0.5714–1.0000
−1.5	CURR	0.8400
−0.5	ORDINAL, MONEY	0.8636–0.9469
0.0	GPE, CARDINAL, LAW, LOC, LANGUAGE	0.8457–0.9664
0.5	PERS, ORG, WEBSITE, PRODUCT	0.5906–0.9547

Abstract

In this paper, we present a relation extraction system developed for Subtask 2 of KnowledgeGraphEval 2026. The system fine-tunes a single ARBERTv2 encoder on inputs with typed entity markers that expose entity boundaries and types, also classifies each entity pair from the encoder's classification token (`[CLS]`) state concatenated with the states at the subject and object start markers. It is trained over the full 41-label space, including *no-relation*, with focal loss, class-balanced sampling, label smoothing, and *no-relation* down-weighting to counter severe class imbalance. Our submission ranked third of seven teams with a micro-F1 of 0.9332, 0.23 points above the official baseline, which fine-tunes the same encoder. We also report an analysis of seed-dependent behaviour on fine-grained geopolitical relations from our earlier development experiments and discuss the limitations of our evaluation.

1 Introduction

Knowledge graphs underpin semantic search, question answering, recommendation, and Retrieval-Augmented Generation (RAG) pipelines built on large language models (Hogan et al., 2021; Peng et al., 2024). Their structured (subject, relation, object) representation offers a clear advantage over plain text for downstream reasoning and retrieval.

Relation Extraction (RE), identifying and classifying semantic relations between entities, is therefore a crucial step in constructing knowledge graphs from text. An inaccurate RE stage propagates directly into an incomplete or erroneous knowledge graph, degrading downstream applications such as question answering and GraphRAG (Zhong et al., 2023; Zhao et al., 2024).

Arabic RE research still lags well behind Arabic NER: most prior work has focused on entity recognition, leaving large-scale RE resources scarce (Aljabari et al., 2025b). Arabic's rich morphology, semantic ambiguity, and flexible word order add further difficulty to extracting relations accurately.

Aljabari et al. (2025b) recently introduced WojoodRelations, currently the largest Arabic RE dataset, built on top of the Wojood corpus with fine-grained annotations across 40 semantic relation types, each instance structured as a (subject, relation, object) triple. Its release opens new possibilities for Arabic RE research.

KnowledgeGraphEval 2026 Subtask 2 adopts WojoodRelations directly (Aljabari et al., 2026): gold entity spans are provided, so systems classify the relation between each entity pair into one of 40 types or assign *no-relation* when no connection exists, evaluated by micro-F1.

In this paper, we present our Relation Extraction system for Subtask 2. Our system frames RE as sentence-level classification over typed entity markers and fine-tunes a single ARBERTv2 encoder over all 41 labels with imbalance-aware objectives. Our official submission achieved a micro-F1 of 0.9332, placing third in Subtask 2. Because the official baseline fine-tunes the same encoder, the 0.23-point difference reflects our input representation and training choices taken together. The top of the leaderboard is tightly clustered (Table 2), so we present our results as a competitive, reproducible configuration rather than as evidence that any single component is decisive. Our contributions are:

- Typed entity markers combined with entity-start pooling as an input representation for Arabic RE.
- A training setup over the full label space that keeps *no-relation* predictable while countering class imbalance (focal loss, class-balanced sampling, label smoothing, *no-relation* down-weighting), with a complete hyperparameter specification.
- An analysis, from earlier development runs, of how random seeds change the behaviour

Table 1: Official Subtask 2 baselines on the held-out test split (Aljabari et al., 2026): a fine-tuned ArBERTv2 classifier (Abdul-Mageed et al., 2021) and a few-shot GPT-4o (OpenAI, 2023) RAG pipeline. The corpus covers 40 relation types across 17,381 train / 2,074 validation / 4,386 test instances.

of XLM-RoBERTa-large on closely related geopolitical relations (§5.2).

2 Background

The KnowledgeGraphEval 2026 shared task decomposes Arabic knowledge graph construction into cross-domain named entity recognition (Subtask 1: AdaptNER) and relation extraction between identified entities (Subtask 2) (Aljabari et al., 2026).

For Subtask 2, models are trained and evaluated on the WojoodRelations corpus, which extends the Wojood NER corpus (Jarrar et al., 2022) with annotated semantic relations between entities (Aljabari et al., 2025b). Each of the 40 fine-grained relation types is represented as a structured (subject, relation, object) triple. The released data comprises 17,381 training instances, 2,074 validation instances, and a held-out test set of 4,386 instances, with the official evaluation reported as micro-F_1 on the test split.

Task challenges are: (i) *Fine-grained relation classification,* distinguishing among 40 closely related categories, or correctly predicting *no-relation*, requires deep contextual and syntactic understanding of Arabic constructions. (ii) *Interaction with nested entities,* systems must reason over relations between overlapping or nested entities, such as a geopolitical entity nested inside an organization (e.g., "Cairo" inside "Cairo University"). (iii) *Evaluation rigorm* under the official scoring, a single boundary or classification error penalizes both precision and recall simultaneously, which explains the gap between the fine-tuned and few-shot baselines in Table 1.

3 System Overview

3.1 Task Formulation

Given a sentence s and an entity pair $(\mathbf{e}_{\text{subj}}, \mathbf{e}_{\text{obj}})$ with their named entity types, we predict a label $r \in \mathcal{R}$, where $\mathcal{R}$ contains the 40 relation types plus *no-relation* ($|\mathcal{R}| = 41$). The system can therefore decline to assert a relation whenever none of the 40 types holds. The prediction is conditioned on both the textual context and the entity types via typed markers.

3.2 Typed Entity Markers

Following Zhou and Chen (2022), we insert typed entity boundary markers directly into the input text. For a subject entity of type $\texttt{T}_\texttt{s}$ and object entity of type $\texttt{T}_\texttt{o}$, we wrap each entity span with special tokens:

$$\texttt{[SUBJ-T}_\texttt{s}\texttt{]}\ \textit{entity}\ \texttt{[/SUBJ-T}_\texttt{s}\texttt{]}$$

$$\texttt{[OBJ-T}_\texttt{o}\texttt{]}\ \textit{entity}\ \texttt{[/OBJ-T}_\texttt{o}\texttt{]}$$

This produces 60 typed special tokens (subject/object $\times$ 15 types $\times$ open/close) and four generic fallback markers, for 64 markers in total. They are added to the tokenizer vocabulary, and the encoder embedding matrix is resized; the new embeddings are initialized from a normal distribution matching the mean and covariance of the existing embeddings. The markers identify entity boundaries and expose entity types directly in the input sequence.

3.3 Model Architecture

We encode the marked sentence with ARBERTv2 (Abdul-Mageed et al., 2021) (`UBC-NLP/ARBERTv2`, 163M parameters). For the classification representation, we use `cls_entity_start` pooling. We extract the hidden states at the subject-start marker $\mathbf{h}_{\text{ss}}$ and object-start marker $\mathbf{h}_{\text{os}}$, and concatenate them with $\mathbf{h}_{\text{cls}}$, the final hidden state of the classification token `[CLS]` that BERT-style encoders prepend to every input as an aggregate representation of the whole sequence:

$$\mathbf{r} = [\mathbf{h}_{\text{cls}}\ ;\ \mathbf{h}_{\text{ss}}\ ;\ \mathbf{h}_{\text{os}}] \in \mathbb{R}^{3H}$$

This $3H$-dimensional vector is passed through dropout (0.1) and a linear classifier that produces logits over the 41 labels.

3.4 Training

Handling of *no-relation*. The training set contains 17,381 entity pairs, of which 8,092 (46.6%) are labeled *no-relation*. We keep all of them and treat *no-relation* as a 41st class. The task asks systems to predict *no-relation* whenever none of the

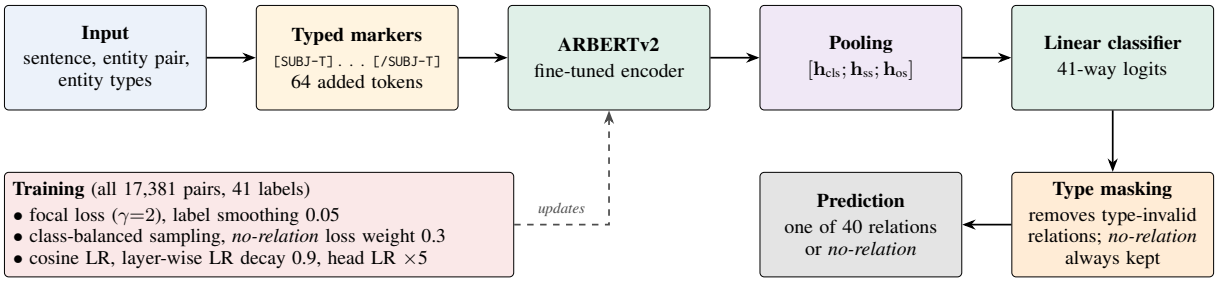

Figure 1: Our RE pipeline. Typed entity markers are inserted around the subject and object, the sentence is encoded by a single fine-tuned ARBERTv2 encoder, and the state of the classification token (`[CLS]`) is concatenated with the states at the subject and object start markers and classified into 41 labels (40 relations plus *no-relation*). Training (bottom left) uses all pairs, including *no-relation*, with imbalance-aware objectives. At inference, ontology-based type masking removes relations whose domain or range is incompatible with the entity types; *no-relation* is never masked.

40 relations holds, and a model that cannot output this label would produce a false positive for every unrelated pair. Training on negative pairs also lets the classifier learn to separate relations from the absence of a relation, not only from one another. Because *no-relation* is by far the largest class, we down-weight its contribution to the loss by a factor of 0.3.

Class-balanced sampling. The 40 relation types are also highly skewed. We draw training batches with a weighted random sampler whose weights are inverse class frequencies, so that each label is sampled with approximately equal probability in every epoch.

Focal loss and label smoothing. We replace standard cross-entropy with focal loss (Lin et al., 2017):

$$\mathcal{L}_{\text{focal}} = -(1 - p_t)^{\gamma} \log p_t$$

with $\gamma = 2.0$, where p_t is the predicted probability of the gold label. The $(1 - p_t)^{\gamma}$ factor down-weights easy, well-classified examples and focuses training on hard instances, which is intended to benefit rare relation types. We additionally apply label smoothing ($\epsilon = 0.05$) to reduce over-confident predictions.

Optimization. We train for 10 epochs with AdamW, a base learning rate of 2×10^{-5}, a batch size of 16 with 2 gradient-accumulation steps (effective batch size 32), and a cosine learning-rate schedule. We apply layer-wise learning-rate decay of 0.9 (each encoder layer receives 0.9 times the learning rate of the layer above it) and give the classification head five times the base learning rate. Training uses mixed precision (fp16). All hyperparameters are listed in Appendix A.

Model selection. We hold out 10% of the 17,381 training pairs as an internal dev set (15,643 train / 1,738 dev, random seed 42) and keep the checkpoint with the highest internal-dev micro-F1 over all 41 labels. Because every pair receives exactly one label, this score equals accuracy, and it is not necessarily computed the same way as the official score.

3.5 Inference-Time Type Constraints

The domain (allowed subject type) and range (allowed object type) of each relation are taken from WojoodOntology (Aljabari et al., 2025a), which formalizes the 40 WojoodRelations relation types (Aljabari et al., 2025b) as OWL object properties with domain–range constraints. For example, *capital_of* requires a GPE subject and a GPE object. At inference time we apply hard constraint masking: the logit of every relation whose domain or range is violated by the given entity types is set to $-\infty$ before the softmax. *No-relation* has no domain or range restriction and is never masked. If either entity type is unknown, no constraints are applied.

4 Experimental Setup

Data. We train on all 17,381 annotated entity pairs of WojoodRelations (Aljabari et al., 2025b), including the 8,092 *no-relation* pairs, across 41 labels. The official test set contains 4,386 pairs spanning 2,673 sentences.

Hardware. The submitted model was trained on a single NVIDIA T4 GPU (16 GB) on Google Colab; one epoch takes about four minutes. Earlier development runs (§5.2) used an NVIDIA RTX 3070 Ti (8 GB).

Implementation. Our system is implemented in

Rank	Team	Micro-F1
1	RabEt	0.9406
2	NAMAA	0.9348
3	**ArmyForRE (ours)**	**0.9332**
4	Wasl	0.9328
–	Baseline (ArBERTv2)	0.9309
5	McMasterNLP	0.9295
6	ISNAD	0.9255
7	YafaRE	0.9192

Table 2: Final official results for KnowledgeGraphEval 2026 Subtask 2 (held-out test set), as announced by the organizers.

System	Evaluation	Score
ArBERTv2 baseline	Official test	0.9309
Ours (submitted)	**Official test**	**0.9332**
Ours (submitted)	Internal dev	0.9462
Variant: no *nr* weight, 6 ep.	Internal dev	0.9419

5 Results and Analysis

5.1 Main Results

Table 2 shows the final official Subtask 2 ranking. Our submission ranked third with a micro-F1 of 0.9332, 0.23 points above the ArBERTv2 baseline, 0.74 points behind the first-ranked system, and 0.04 points ahead of the fourth-ranked system. Given these small margins and the absence of significance testing, the ranking among the top systems should be interpreted with caution.

Table 3 places the official score next to the internal-dev scores. The submitted model reached its best internal-dev score of 0.9462 at epoch 6 of 10; the score rose from 0.8806 after the first epoch and stayed between 0.9452 and 0.9462 for the remaining epochs. We also trained one unsubmitted variant without *no-relation* down-weighting and with a shorter, 6-epoch schedule, which reached 0.9419. Since this variant changes two settings at once and each configuration was run with a single seed, the 0.43-point difference is not evidence for either setting in isolation.

The internal-dev score is 1.3 points above the official score. The internal dev set is a random sample of the training pool that shares its distribution and was used for checkpoint selection, so it is an optimistic estimate.

5.2 Earlier Development Runs

Before settling on the submitted model, we built a 40-label system that removed *no-relation* from training and masked it at inference. It combined four XLM-RoBERTa-large (Conneau et al., 2020) runs (seeds 42–45, trained with Adafactor (Shazeer and Stern, 2018), a cosine schedule, and gradient checkpointing), two ARBERTv2 runs, and one AraBERTv0.2-large (Antoun et al., 2020) run in a soft-voting ensemble. We replaced it with the single 41-label model because a system that can never output *no-relation* does not solve the task as defined. The 40-label system is not the submitted model; we report two observations from it because they concern model behaviour rather than the final score.

Seed variance. On a 928-pair internal dev set of positive pairs only, XLM-R-large reached 0.9440 (seed 42) and 0.9655, 0.9666, and 0.9666 (seeds 43–45), a spread of over 2 points under an otherwise fixed configuration. These scores measure discrimination among the 40 relations only and are not comparable to the scores in Table 3.

Capital-of collapse. Seeds 43–45 predicted only 0–15 *capital_of* instances on the test set, compared to 24–25 for seed 42 and for the BERT models. On the internal dev set, these seeds absorbed *capital_of* into the closely related *geopolitical_division* class, a seed-specific collapse between neighbouring classes that share identical entity types (GPE→GPE). In the ensemble, the BERT models partially offset this tendency, bringing the *capital_of* count to 15–17. Since test labels are not available to us, we cannot verify which count is closer to the gold distribution; the analysis shows that models disagree systematically on this class, not which one is correct. We did not repeat this analysis for the submitted single model.

5.3 Error Analysis

Inspection of confusion matrices from our development runs points to two recurring error patterns. We describe them qualitatively, because the underlying counts were not preserved with the submitted model.

Geopolitical confusion. *capital_of* and *geopolitical_division* are confused in both directions. The two relations share identical entity types

(GPE→GPE), so type information cannot separate them, and they often appear in similar syntactic contexts ("X is the capital of Y" vs. "X is a region of Y"). This is the same pair affected by the seed-specific collapse in §5.2.

Affiliation confusion. *employee_of*, *member_of*, and *leader_of* are frequently confused with each other, particularly when the subject is a person and the organization context is ambiguous (e.g., a politician who is both a member of a party and an employee of a government body).

5.4 Missing Ablations

We did not run controlled ablations of the individual components (typed versus untyped markers, focal loss versus cross-entropy, with versus without class-balanced sampling, *no-relation* down-weighting, or type masking), and each configuration was trained with a single seed. Consequently, we cannot attribute the 0.23-point gain over the baseline to any single component, and the component-level claims in this paper are design motivations rather than measured effects. We likewise report micro-F1 only; since focal loss and class-balanced sampling target rare relations, macro-F1 and per-relation scores would be the appropriate evidence for their effect.

6 Limitations

Our system has several limitations. First, the submitted system is a single model trained with a single seed, and our development runs showed seed spreads of over 2 points for XLM-R-large; the official score may therefore partly reflect a favourable seed, and the 0.04-point margin over the fourth-ranked team is well within such variation. Second, we provide no controlled ablations, macro-F1, per-relation results, or significance tests. Third, *no-relation* down-weighting and class-balanced sampling both reduce the influence of the largest class, which may bias the model against *no-relation* where unrelated pairs dominate, such as open extraction over all entity pairs in a document; we did not tune this trade-off or calibrate a *no-relation* threshold. Fourth, our checkpoint-selection metric (41-label accuracy on internal dev) is not necessarily the official metric. Fifth, the seed and *capital_of* analyses come from earlier 40-label models and may not transfer to the submitted model. Finally, type-constraint masking depends on the entity types supplied with each pair; incorrect types would exclude the correct relation.

7 Conclusion

We presented ArmyForRE, an Arabic RE system that fine-tunes a single ARBERTv2 encoder with typed entity markers, entity-start pooling, and imbalance-aware training over the full 41-label space, including *no-relation*. The system achieved 0.9332 micro-F1 on the official test set, placing third in KnowledgeGraphEval 2026 Subtask 2 and 0.23 points above a baseline that fine-tunes the same encoder. Earlier development runs showed that XLM-RoBERTa-large behaves differently across random seeds, notably on *capital_of* versus *geopolitical_division*. Future work includes controlled ablations, multi-seed evaluation, per-relation and macro-F1 analysis, and calibrating the *no-relation* decision for settings with many unrelated pairs.

Abstract

This paper details our submission to KnowledgeGraphEval 2026 Subtask 2 on directed Arabic relation extraction. We explored encoder-based and large language model approaches for predicting one of 40 relations or *no_relation* from an Arabic sentence and a subject–object pair. Our encoder systems use typed entity markers and separate relation-existence and relation-classification heads, while our LLM systems fine-tune Yehia and Qwen3.5 with QLoRA and ontology-constrained prediction. Our best system, an ensemble of Yehia-RE, Qwen-RE, and TypedPair, achieved a micro-F1 score of 94.06 and ranked **1st** in Subtask 2. Yehia-RE (full-vocabulary) achieved 92.98, while the best encoder and Qwen-RE achieved 92.69 and 91.94 respectively. Our results highlight the importance of constrained prediction and complementary modeling approaches for Arabic relation extraction.

1 Introduction

Relation Extraction (RE) is an information extraction task that aims to identify semantic relations between entities mentioned in text. In directed RE, the relation is predicted from a designated subject to a designated object. Arabic RE remains challenging when relations are semantically similar, entity mentions occur multiple times in the same sentence, or entity-type information is needed to determine which relations are valid.

In this paper, we present our submission to KnowledgeGraphEval 2026 Subtask 2 on directed Arabic relation extraction. Given an Arabic sentence and a subject–object pair, the task is to predict one of 40 positive relations or *no_relation* when no valid relation is expressed (Aljabari et al., 2026). The task data are also highly imbalanced, making accurate positive-relation prediction and *no_relation* handling particularly important.

We investigate two system families. The first, TypedPair, uses Arabic encoder models with typed directional entity markers and separate heads for relation existence and positive-relation classification. The second uses Yehia (Navid-AI, 2025) and Qwen3.5 (Qwen Team, 2026), adapted with QLoRA (Dettmers et al., 2023), resulting in our Yehia-RE and Qwen-RE systems. Yehia-RE formulates relation prediction as a constrained Arabic one-token multiple-choice task, while Qwen-RE is evaluated using both causal-LM prediction and sequence classification. All systems share entity-occurrence resolution, entity-type prediction, and ontology-based relation filtering.

Our main contributions are: (1) the TypedPair encoder family; (2) ontology-constrained Yehia-RE and Qwen-RE systems; and (3) a shared pipeline for occurrence resolution, entity typing, and relation filtering. Our best ensemble achieved a micro-F_1 score of 94.06 and ranked **1st** in Subtask 2. The strongest individual Yehia-RE, TypedPair, and Qwen-RE systems achieved 92.98, 92.69, and 91.94, respectively. The trained models and released resources are available at `https://huggingface.co/U4RASD`.

2 Background

The task data are derived from Wojood^{Relations} (Aljabari et al., 2025b), while WojoodOntology provides relation definitions and domain–range constraints over entity types (Aljabari et al., 2025a). Konooz (Hamad et al., 2025) is used in the shared task's NER subtask; our submission addresses only Subtask 2 on relation extraction.

Prior relation-extraction work has explored marker-based encoder models, including entity markers (Baldini Soares et al., 2019), PL-Marker (Ye et al., 2022), and typed entity markers (Zhou and Chen, 2022). For Arabic RE, Wojood^{Relations} introduces NLI-RE, which formulates candidate

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1261–1280
October 28-29, 2026 ©2026 Association for Computational Linguistics

relations as natural-language-inference hypotheses and filters them according to compatible entity types (Aljabari et al., 2025b).

Generative approaches have also modeled RE through sequence generation and prompting. AREEj augments Arabic relation extraction with textual evidence supervision (Rakan Al Mraikhat et al., 2024), while GPT-RE and related work explore in-context and instruction-based relation prediction (Wan et al., 2023; Wadhwa et al., 2023; Zhang et al., 2023). Our work investigates both encoder-based and constrained LLM-based approaches under the same ontology-aware Arabic RE setting.

3 System Overview

Figure 1 summarizes the shared full pipeline and the two model families. The following subsections summarize the components that distinguish the submitted systems.

3.1 Shared Pipeline

The input provides the subject and object strings, but repeated occurrences may require resolving which mentions should be evaluated, and entity types are not directly provided to the relation models. We therefore locate all exact subject and object occurrences and construct the possible directed occurrence pairs. Each occurrence is then assigned an entity type using our TypePredictor, and the predicted types are used both in the typed entity markers and to restrict the candidate relations according to WojoodOntology. When multiple occurrence pairs are possible, the system applies a row-level decision strategy to select or combine their predictions. TypePredictor and candidate-pair handling are detailed in Appendices B and C.

3.2 Encoder-Based Systems

The TypedPair family inserts typed directional markers around the selected subject and object occurrences. It combines the sentence-start state, the two opening-marker states, simple pair interactions, and a 42-dimensional subject–object type vector. A multilayer perceptron feeds two heads: a binary head predicts whether a positive relation exists, and a 40-way head selects the positive relation. Negative rows supervise only the existence head, avoiding an arbitrary positive-class target. At inference, the positive head is masked by the predicted type pair and is consulted only when the existence score passes a validation-selected threshold.

We evaluate NeoAraBERT (Abou Chakra et al., 2026), AraBERTv02 (Antoun et al., 2020), ARBERTv2 (Elmadany et al., 2023), AraBERTv02-Large (Antoun et al., 2020), and AraModernBERT (Elshehy et al., 2026) backbones, together with various row-level candidate-pair decision strategies. The exact representation, loss, threshold selection, tensor dimensions, and candidate algorithms are provided in Appendix D.

3.3 LLM-Based Systems

3.3.1 Yehia-RE

We fine-tune Yehia with QLoRA and formulate each relation decision as a row-specific Arabic multiple-choice problem. The marked sentence, predicted entity types, and only the ontology-compatible positive relations are shown in the prompt, followed by *no_relation*. Each displayed option is mapped to an existing Arabic one-token code, and the model returns the code alone.

We evaluate two Yehia-RE training variants. The full-vocabulary variant optimizes the gold code against the complete model vocabulary and, at inference, compares only the displayed option codes. The row-local variant instead normalizes the training objective only over the option codes displayed for the current example. Full objectives and candidate-pair aggregation are detailed in Appendix E.

3.3.2 Qwen-RE

We fine-tune Qwen3.5-4B and Qwen3.5-9B with QLoRA using prompts containing the marked Arabic sentence, entity strings and types, and concise meanings for the ontology-compatible labels. We denote the causal-LM variants as Qwen-RE-4B and Qwen-RE-9B, and the 9B sequence-classification variant as Qwen-RE-9B-Cls. The markers identify the entity occurrences in the sentence and make the subject–object direction explicit. The causal-LM systems are trained to produce the relation label. At inference, we either generate the label or append each compatible label and score it using its mean token log-probability. Because the output label set is fixed, we additionally fine-tune Qwen3.5-9B with a trainable 41-way sequence-classification head. This classifier receives a shorter prompt and directly predicts a relation class, with ontology-incompatible classes masked during both training and inference, avoiding textual generation and parsing failures.

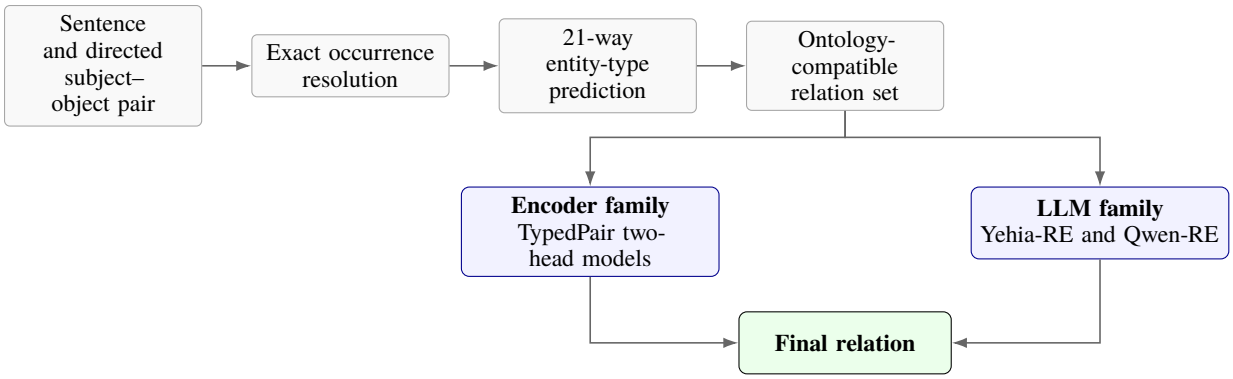

Figure 1: Shared relation-extraction pipeline and the two model families.

The Qwen prompt structures, a paired causal-LM/classifier example, complete-label scoring, class-imbalance interventions, and training configuration appear in Appendix F. We also tested manual disambiguation rules and GEPA prompt evolution (Agrawal et al., 2026); these exploratory interventions did not replace the selected submitted configurations and are documented separately in Appendix G.

4 Experimental Setup

4.1 Data and Preprocessing

The labeled training data were enriched with occurrence-specific character spans and entity types. We first aligned relation mentions with the Wojood flat and nested NER annotations (Jarrar et al., 2022); unresolved mentions were then matched against predictions from the Wojood NER model. Two authors manually resolved the remaining 240 training rows that could not be enriched automatically, retaining the original relation labels. This enrichment was used only for training; blind-test rows were processed entirely by the full inference pipeline. Conflict filtering, ontology compatibility filtering, and deduplication reduced 17,381 raw relation rows to 15,686 training instances; the development artifact contains 1,687 rows, while the official blind evaluation input contains 2,074 rows. The development artifact contains both positive relations and *no_relation* examples, whereas the official blind evaluation input contains only positive-relation rows; the resulting difference in class distribution means development and blind micro-F_1 scores are not directly comparable. Complete processing details are given in Appendix A.

The processed training distribution is strongly imbalanced: *no_relation* has 6,677 examples, followed by `Location.located_in` with 4,269 and `PartOf.geopolitical_division` with 1,684. Encoder models use cross-entropy objectives, Yehia-RE uses frequency-based sampling, the Qwen-RE causal-LM experiments use clipped inverse-frequency weighting, and the Qwen-RE classifier uses square-root inverse-frequency sampling. Selected relation-frequency statistics are reported in Appendix A, while model-specific sampling and weighting details are reported in Appendices D, E, and F.

4.2 Training, Decoding, and Selection

A cross-system summary of the principal training and selection configurations is provided in Table 21 in Appendix I. TypePredictor and TypedPair encoders are fully fine-tuned. Yehia and Qwen use 4-bit NF4 QLoRA with frozen base weights. Marker handling after tokenization follows the procedure described in Appendix C. Relation-extraction checkpoints are selected using the 1,687-row development artifact and then frozen before official inference. Fixed runner settings are reported separately in the corresponding system appendices. TypePredictor is selected independently using its entity-typing validation split.

Efficiency. AraBERTv02-Large TypedPair required approximately 43 minutes on a single NVIDIA A40, while Yehia-RE required approximately 3.32 hours on a single NVIDIA L40S. Qwen-RE-9B required approximately 12 hours on a single NVIDIA RTX PRO 4500. Since these measurements were obtained on different GPUs, they should not be treated as a controlled efficiency comparison, but they illustrate the substantially higher training cost of the LLM-based systems relative to the encoder-based model.

Official evaluation uses micro-F_1. Depending on the configuration, the row-level deci-

sion uses either majority voting, top-existence/top-confidence selection, max-positive selection, or nearest-candidate selection. Detailed definitions and deterministic tie-breaking are provided in Appendices C, D, E, and F.

5 Results

Table 1 summarizes representative official submissions. All values are full-pipeline scores on the blind set; post-submission prompt analyses are reported separately in Appendix G. The shared task permitted up to 30 official submissions per team; we used 22.

5.1 Encoder Results

Across the official blind submissions, AraModernBERT achieved the strongest encoder result at 92.69, compared with 91.96 for ARBERTv2 and 92.20–92.29 for the two reported AraBERTv02-Large aggregation strategies. NeoAraBERT with majority + logit-sum obtained 88.33. A component ablation on AraModernBERT (Appendix D.6) shows that the complete configuration with both typed text markers and the directional type vector achieved the strongest performance among the tested variants. The complete encoder and aggregation results are reported in Appendix D.5.

5.2 LLM Results

Yehia-RE (full-vocabulary) achieved 92.98, while the row-local variant reached 92.84 with max-positive aggregation. Its constrained one-token formulation eliminates free-form label formatting errors by casting relation prediction as a row-specific Arabic multiple-choice task. Our best system, a three-system majority ensemble of Yehia-RE, Qwen-RE, and TypedPair, achieved 94.06 and ranked **1st** in Subtask 2. Detailed Yehia-RE formulations, candidate aggregation, and official results are provided in Appendix E.

On the official blind evaluation, Qwen-RE-4B and Qwen-RE-9B obtained 91.53 and 91.76, respectively, while Qwen-RE-9B-Cls obtained 91.94. These blind-set differences are reported descriptively rather than as controlled ablations. Complete official Qwen results are reported in Appendix F.8.

5.3 Error Analysis

The main failure modes reflect interactions among pipeline components. A type error can change the typed markers and remove the correct relation from the compatible set. Repeated surface forms can associate the prediction with the wrong textual evidence. Semantically close relations, especially generic location versus headquarters or administrative division, are difficult under a highly skewed label distribution. Finally, causal-generation systems may understand the relation but emit an invalid or partial canonical label. Additional qualitative error analysis is provided in Appendix H, while the exploratory disambiguation experiments are reported in Appendix G.

6 Conclusion

We presented two complementary system families for KnowledgeGraphEval 2026 Arabic relation extraction. The encoder family combines typed directional markers with a two-head relation objective, while the LLM family constrains Yehia-RE and Qwen-RE to ontology-compatible decisions. Our best system, an ensemble of Yehia-RE, Qwen-RE, and TypedPair, achieved an official micro-F_1 score of 94.06 and ranked **1st** in Subtask 2. Yehia-RE (full-vocabulary) achieved 92.98, while the strongest encoder and Qwen-RE systems reached 92.69 and 91.94, respectively. The results highlight the importance of constrained prediction, entity-type compatibility, candidate resolution, and complementary modeling approaches. Future work will propagate type uncertainty, jointly score occurrence and relation hypotheses, and study confidence-weighted ensembles.

Limitations

The reported training-level results are based on a single random seed. Consequently, small differences between model configurations should be interpreted cautiously, as we cannot quantify variation across training runs. The systems also depend on hard entity-type predictions and exact-match occurrence recovery, and they remain challenging for rare or semantically adjacent relations. Because the TypePredictor dataset uses a mention-level split, sentence-level overlap with relation-extraction inputs is possible. Although TypePredictor never uses relation labels, such overlap may affect the entity-type predictions used for typed markers and ontology filtering.

System	Training/decoder	Row-level decision	Official F_1
TypedPair–NeoAraBERT	Two-head encoder	Majority + logit-sum	88.33
TypedPair–ARBERTv2	Two-head encoder	Majority + logit-sum	91.96
TypedPair–AraBERTv02-Large	Two-head encoder	Top existence	92.29
TypedPair–AraModernBERT	Two-head encoder	Majority + logit-sum	**92.69**
Yehia-RE (row-local)	Row-local CE	Max positive	92.84
Yehia-RE (full-vocabulary)	Full-vocabulary CE	Max positive	**92.98**
Qwen-RE-4B	Causal-LM label generation	Nearest candidate	91.53
Qwen-RE-9B	Causal-LM label generation	Nearest candidate	91.76
Qwen-RE-9B-Cls	Sequence classification	Nearest candidate	**91.94**
Team ensemble	Yehia-RE (full-vocabulary) + Qwen-RE-9B-Cls + TypedPair–AraModernBERT	Majority vote; Yehia-RE tie-break	**94.06**

Table 1: Summary of representative official KnowledgeGraphEval 2026 Subtask 2 submissions. Bold values mark the strongest configuration within each model family.

A Data Processing and Artifacts

A.1 Source Resources and Processed Schema

The shared-task data are derived from Wojood^{Relations}, which extends Wojood with 40 directed relation types (Aljabari et al., 2025b). Wojood supplies nested entity annotations over 21 types (Jarrar et al., 2022), while WojoodOntology supplies relation definitions and directed domain–range constraints (Aljabari et al., 2025a).

We retained the original sentence, subject, object, and relation fields unchanged and added occurrence-specific character offsets, token offsets, and entity types. These additions support typed marker insertion, span validation, and ontology compatibility checks.

A.2 Verified Raw and Enriched Example

Table 2 shows a verified row from the original Wojood^{Relations} training file. The row illustrates the task input before our span and type enrichment.

The corresponding processed row retains all original fields and adds the resolved occurrence information shown in Table 3. This example is particularly useful because the object occurs inside the subject span, illustrating a nested mention case.

A.3 Artifacts and Processing Stages

The blind input contained no gold relation labels. It was used only to produce official predictions; we did not manually inspect, infer, or reconstruct its hidden labels.

A.4 Span and Entity-Type Recovery

Training relation rows provide entity surface forms but not the occurrence-specific spans and types required by our systems. We first align mentions with Wojood flat and nested NER annotations (Jarrar et al., 2022), preferring exact span matches and allowing compatible containment matches when necessary. Unresolved mentions are then matched against predictions from the Wojood NER model. After these automatic steps, two authors manually resolved the spans and entity types of the remaining 240 training rows, while retaining their original relation labels.

No manual span or type annotation is used for the blind set; its occurrences and entity types are determined entirely by the inference pipeline described in Appendix C.

A.5 Span Validation

For every processed row, we verified that the character slice identified by the subject offsets reproduced the subject string and that the object slice reproduced the object string. Rows with mismatched offsets were rejected rather than silently accepted. The final processed training and development artifacts reported zero slice errors.

This check is important because selecting the wrong repeated occurrence can associate a relation label with unrelated textual evidence. At blind inference, the systems resolve possible occurrence pairs as described in Appendix C.

A.6 Conflict Removal and Deduplication

We first removed groups containing contradictory annotations for the same resolved sentence and entity pair, reducing 17,381 raw rows to 17,208 non-conflicting rows. We then removed exact duplicates sharing the sentence, subject, object, and relation label. Together with the ontology-compatibility filtering described below, these preprocessing steps produced 15,686 final training instances.

A.7 Ontology Compatibility and Operational Mapping

For each positive training instance, we checked the resolved subject and object types against the directed domain–range constraints defined by WojoodOntology (Aljabari et al., 2025a). Because the task is directional, compatibility is evaluated specifically for the ordered pair (τ_s, τ_o). Training rows whose subject–object type pair was not a valid domain–range combination for the labeled relation were removed during preprocessing. This prevents the models from being trained on relation instances that are incompatible with the ontology under the resolved entity types.

We made one systematic modification to the operational compatibility map based on a highly frequent pattern observed in the labeled training data. In the original WojoodOntology constraints, the domain and range of `Location.located_in` are more restricted. However, the relation data repeatedly contain labeled `Location.located_in` examples involving ORG, FAC, LOC, and GPE entities in both subject and object positions. We therefore expanded the operational domain–range set for this relation to

$$\begin{aligned} r &= \texttt{Location.located\_in}, \\ \text{Domain}(r) &= \{\text{ORG}, \text{FAC}, \text{LOC}, \text{GPE}\}, \\ \text{Range}(r) &= \{\text{ORG}, \text{FAC}, \text{LOC}, \text{GPE}\}. \end{aligned}$$

This modification was motivated by the recurring annotation pattern in the provided relation data and was applied consistently during preprocessing and ontology-based candidate filtering. It is an implementation-level adaptation used by our system; it does not alter the published WojoodOntol-

`Location.headquartered_in`	172

Table 5: Selected frequent and difficult relations in the processed training artifact.

ogy itself or the relation labels provided by the shared task.

A.8 Relation and Entity-Type Distributions

The subject side is dominated by organizations, persons, and geopolitical entities, while the object side is dominated by geopolitical entities, organizations, occupations, and locations. Frequent directed type pairs therefore include organization–place, place–place, organization–organization, person–place, and person–occupation.

B TypePredictor

B.1 Dataset Construction

The TypePrediction collection was curated from the Wojood and WojoodFine NER resources (Jarrar et al., 2022; Liqreina et al., 2023). Each example contains an Arabic sentence, one exact mention occurrence, and its entity type. TypePredictor is trained only on entity-type labels and never uses relation labels. Relation-extraction rows were excluded from this curation. Exact duplicate mentions were collapsed, and same-span examples with conflicting labels were removed.

The resulting collection contains 125,996 examples over 21 types: 100,796 for training, 12,600 for validation, and 12,600 for testing. The split is a shuffled, stratified, mention-level 80/10/10 split. It was produced using two stratified `train_test_split` operations with `random_state=42`. The same sentence may occur in multiple splits with different entity spans. Because the split is mention-level, sentence-level overlap with relation-extraction inputs, including the blind evaluation input, is possible. Such overlap may affect the entity-type predictions subsequently used for typed markers and ontology filtering, but it does not expose relation labels to TypePredictor. Validation and test examples are therefore additionally categorized as `seen_sentence_new_entity` or `unseen_sentence`.

GPE	ORG	DATE	PERS	NORP	ORDINAL	OCC	EVENT

LANGUAGE	PERCENT	PRODUCT	QUANTITY	UNIT			
332	312	190	106	106			

Table 6: TypePrediction mention counts over all splits.

B.2 Verified Example

Table 7 gives a verified TypePrediction training row. Unlike the relation artifacts, the TypePrediction files do not physically store the marked model input. The marked input is constructed at loading time from the sentence and stored character offsets.

Training rows store `entity`, `type`, `sentence`, `start_token`, `end_token`, `start_char`, `end_char`, `raw_types`, `sources`, and `id`; validation and test rows additionally store `evaluation_category`. The marked input itself is not stored.

For the example in Table 7, the generated input contains the fragment

كما تدير [ENT] المنظمة [/ENT] مركزاً للإصابات البالغة في مديرية الحوبان، وهو يعالج جرحى الحرب والمرضى الذين يحتاجون إلى الرعاية الطبية.

The model input is generated as

$$x' = x_{<s}\ \texttt{[ENT]}\ x_{s:e}\ \texttt{[/ENT]}\ x_{>e},$$

possibly within a selected context window. The tokens `[ENT]` and `[/ENT]` were explicitly added to the tokenizer as special tokens with IDs 65,000 and 65,001, respectively, and the encoder embedding matrix was resized to a vocabulary size of 65,002.

B.3 Architecture and Training

The TypePredictor consists of `U4RASD/NeoAraBERT` and a single classification layer. Let $H \in \mathbb{R}^{L\times 768}$ be the final hidden states and let $\mathbf{h}_{\text{cls}} = H_0$. The classifier computes

$$\begin{aligned}\mathbf{z}^{\text{type}} &= W_t\,\text{Dropout}_{0.1}(\mathbf{h}_{\text{cls}}) + \mathbf{b}_t,\\ \mathbf{z}^{\text{type}} &\in \mathbb{R}^{21}.\end{aligned} \tag{1}$$

The $768 \to 21$ head contains 16,149 parameters. Training minimizes unweighted multiclass cross-entropy and inference returns the highest-scoring type.

B.4 Detailed Evaluation

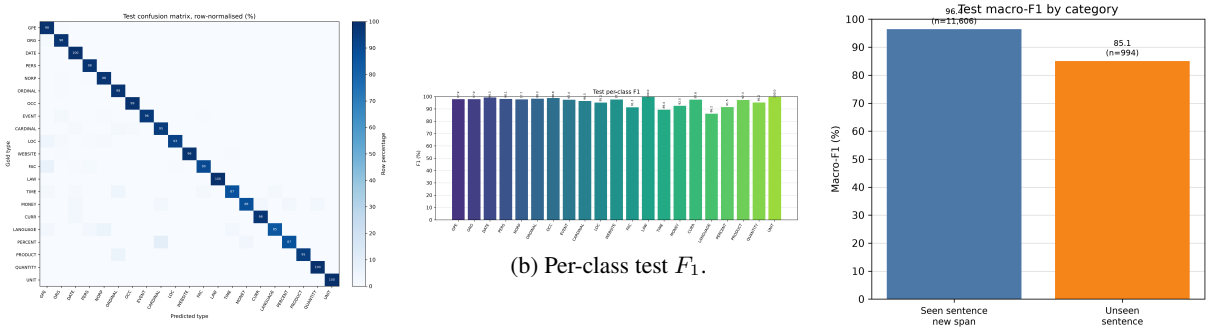
We further evaluate the TypePredictor using aggregate performance metrics, sentence-level generalization categories, per-type performance, and diagnostic visualizations. Overall validation and test performance is reported in Table 9, while Table 10 separates performance between seen sentences with new entity spans and entirely unseen sentences. Table 11 provides the detailed per-type precision, recall, and F_1 scores on the test split. Finally, Figure 2 presents the normalized confusion matrix, per-class F_1 scores, and performance across sentence categories.

C Shared Inference Pipeline

C.1 Marker Insertion and Overlap Handling

Markers are inserted from character spans rather than through global surface replacement. Insertions are ordered to keep nested, overlapping, adjacent, and equal-span cases deterministic. After tokenization, the system verifies that the required opening and closing marker IDs remain present. When necessary, the sentence is cropped around the outer entity boundaries.

C.2 Ontology Filtering



For a predicted directed type pair (τ_s, τ_o), the operational WojoodOntology map returns the compatible positive relations. *no_relation* remains available for every pair. Incompatible encoder and classifier logits are masked, while generative prompts display or score only compatible labels.

C.3 Candidate-Pair Handling

The model families use different strategies when several occurrence pairs are possible; there is no single nearest-distance rule shared by all released runners. TypedPair can score all candidate pairs and aggregate their predictions as described in Appendix D. Yehia-RE also scores candidate pairs and applies the row-level aggregation rules described in Appendix E.

Loss	Unweighted cross-entropy
Selection metric	Validation macro-F_1

Table 8: TypePredictor training configuration.

For Qwen-RE configurations using the nearest-candidate heuristic, let the subject span be $[s_s, s_e)$ and the object span be $[o_s, o_e)$. Candidate pairs are sorted lexicographically by

1. character gap

$$d_{\text{gap}} = \max(0, \max(s_s, o_s) - \min(s_e, o_e)) ;$$

2. twice the absolute distance between span centers,

$$d_{\text{center}} = |s_s + s_e - o_s - o_e|;$$

3. ascending subject start offset s_s; and

4. ascending object start offset o_s.

The first candidate under this ordering is selected. Overlapping and nested mentions therefore receive a character gap of zero, and the final two offsets make ties deterministic.

D TypedPair Encoder Systems

D.1 Typed Directional Input

For subject and object types τ_s and τ_o, the sentence receives typed opening and closing markers such as `[SUBJ_PERS]` and `[OBJ_ORG]`. Across 21 entity types, this introduces 84 marker strings. We additionally construct the directional type vector

$$\mathbf{t}_{s,o} = [\text{onehot}(\tau_s); \text{onehot}(\tau_o)] \in \mathbb{R}^{42}, \quad (2)$$

where the first 21 coordinates always represent the subject and the final 21 represent the object.

D.2 Pair Representation and Two-Head Objective

Let $H \in \mathbb{R}^{L \times d}$ be the encoder output, and let $\mathbf{h}_c$, $\mathbf{h}_s$, and $\mathbf{h}_o$ denote the sequence-start, subject-opening, and object-opening states. The directed

Table 11: Per-type TypePredictor results on the 12,600-row test split.

pair representation is

$$\mathbf{u}_{s,o} = [\mathbf{h}_c; \mathbf{h}_s; \mathbf{h}_o; |\mathbf{h}_s - \mathbf{h}_o|; \mathbf{h}_s \odot \mathbf{h}_o; \mathbf{t}_{s,o}]. \quad (3)$$

Its dimensionality is $5d + 42$. A shared MLP applies $(5d + 42) \to 1024 \to 512$ using LayerNorm, GELU, and dropout.

The existence head returns $\mathbf{z}^e \in \mathbb{R}^2$, while the positive-relation head returns $\mathbf{z}^+ \in \mathbb{R}^{40}$. For relation label y, define $a = \mathbf{1}[y \neq \textit{no\_relation}]$. Training minimizes

$$\mathcal{L}_{\text{EP}} = \text{CE}(\mathbf{z}^e, a) + a\ \text{CE}(\mathbf{z}^+, y^+). \quad (4)$$

Thus, every row supervises relation existence, whereas negative rows do not assign an arbitrary target to the positive-relation head.

D.3 Row-Level Candidate Strategies

For occurrence-pair candidate c, let

$$\begin{aligned} p_c &= P_c(\text{relation exists}), \\ q_c(r) &= P_c(r \mid \text{relation exists}). \end{aligned} \quad (5)$$

after ontology-incompatible positive relations have been masked. The released pipeline contains several deterministic alternatives for combining predictions across occurrence pairs.

Majority + logit-sum. Let $P = \{c : p_c \geq \tau\}$ among N candidates. The row is treated as positive only when

$$|P| \geq \lceil 0.5N \rceil .$$

For a positive row, masked positive-relation logits are summed over the passing candidates and the relation with the largest aggregate score is selected.

Top existence. First select

$$c^* = \arg\max_c p_c.$$

If $p_{c^*} < \tau$, the row is assigned *no_relation*. Otherwise, the output is

$$\arg\max_r q_{c^*}(r).$$

Max joint. Among candidates that pass the existence threshold, select

$$(c^*, r^*) = \arg\max_{c,r} p_c q_c(r). \quad (6)$$

If no candidate passes the threshold, the result is *no_relation*.

Soft joint pooling. Positive evidence for relation r is pooled as

$$S(r) = \sum_{c: p_c \geq \tau} p_c q_c(r), \quad (7)$$

and the relation with the largest pooled score is returned when a positive decision is made. Ties are resolved deterministically using decision score, existence probability, candidate order, and relation index.

Operation	Base	Large

AraBERTv02-Large, soft pool	92.20
AraBERTv02-Large, top existence	92.29
AraModernBERT	**92.69**

Table 13: Official TypedPair results.

D.4 Dimensions and Training

For $d = 768$, the MLP and heads add 4,525,610 parameters; for $d = 1024$, they add 5,836,330. The no-interactions variant uses $[\mathbf{h}_c; \mathbf{h}_s; \mathbf{h}_o; \mathbf{t}_{s,o}]$ and adds 2,952,746 parameters.

Training uses four epochs, maximum length 512, physical batch size 4, gradient accumulation 4, encoder learning rate 10^{-5}, new-layer learning rate 5×10^{-5}, weight decay 0.01, 10% warm-up, FP16, and MLP dropout 0.1. Evaluation occurs every 250 optimizer steps. For the released AraModernBERT model, the existence threshold selected on labeled validation data is 0.01, with positive micro-F_1 used for threshold selection.

D.5 Extended Official Results

Table 13 summarizes the official scores across encoder configurations, with AraModernBERT obtaining the highest reported F_1 score of 92.69.

D.6 AraModernBERT Component Ablation

AraModernBERT achieved the strongest encoder result and was therefore used to compare configurations with and without typed text markers and the directional type vector. Table 14 reports the corresponding official full-pipeline ablation submissions.

The complete configuration obtains the strongest result among these four submissions. The ablation artifacts share the intended four-epoch training setup, batch sizes, learning rates, weight decay, warm-up, MLP dimensions, dropout, and TypePredictor dependency.

Typed markers	Type vector	Official F_1
No	No	90.65
No	Yes	90.75
Yes	No	89.94
Yes	Yes	**92.69**

Table 14: AraModernBERT component ablation on the blind evaluation.

E Yehia-RE

E.1 Row-Specific Arabic Multiple Choice

Early Yehia variants generated full Arabic relation phrases and were vulnerable to explanatory text, punctuation, and harmless lexical variation. Yehia-RE instead reformulates each instance as a row-specific Arabic multiple-choice problem.

For each ontology-compatible relation, the option shown to the model is an Arabic natural-language template (`template_ar`), rather than the canonical relation identifier. Our Arabic relation templates were inspired by the relation-aware templates used in the Wojood^{Relations}/SinaTools implementation (Aljabari et al., 2025b).[1] Thus, labels such as `Affiliation.employee_of` are used internally to construct and evaluate the example, while the model sees the corresponding Arabic formulation, such as الأول يعمل لدى الثاني. The canonical relation names are not presented as answer options.

Each displayed Arabic option is assigned a verified one-token Arabic code. The available codes are أ، ب، ج، د، ه، و، ز، ح، ط، ي. The codes are row-local addresses rather than global relation-class IDs, and *no_relation* is represented by its own Arabic option لا توجد علاقة. The largest ontology-compatible candidate set contains nine positive relations, for the directed type pair PERS→ORG. Including *no_relation*, a row therefore contains at most ten options, matching the ten available Arabic answer codes.

E.2 Full-Vocabulary and Row-Local Objectives

In both variants, all prompt and padding tokens are masked from the training loss so that exactly one assistant code token is supervised.

For the full-vocabulary variant, let g be the gold code and $\mathcal{V}$ the complete model vocabulary. The

[1] https://github.com/SinaLab/sinatools

objective is

$$\mathcal{L}_{\text{FV}} = -\log \frac{\exp z_g}{\sum_{v \in \mathcal{V}} \exp z_v}. \tag{8}$$

At inference, only the codes corresponding to options displayed in the current row are compared.

The row-local variant instead normalizes directly over the displayed code set C_i:

$$\mathcal{L}_{\text{RL}} = -\log \frac{\exp z_g}{\sum_{c \in C_i} \exp z_c}. \tag{9}$$

E.3 Prompt Template

The Yehia-RE system message is:

أنت مصنّف علاقات. حدّد العلاقة الموجّهة من الكيان [الأول] إلى الكيان [الثاني].
اختر علاقة واحدة من القائمة تناسب معنى الجملة ونوعي الكيانين.
إن لم تنطبق أي علاقة فاختر «لا توجد علاقة».
أجب برمز الخيار فقط: حرف عربي واحد دون رقم أو شرح.

The row-specific user message follows this structure:

الجملة:
{marked_sentence}

نوع الأول: {first_type_ar}
نوع الثاني: {second_type_ar}

الخيارات:
أ) {option 1}
ب) {option 2}
...
{last} ({code لا توجد علاقة})

رمز الإجابة:

The assistant message contains exactly one displayed code.

E.4 Complete Training Example

The following is a fully instantiated training example from the released record `train_1831`. The canonical relation identifiers are used only internally to construct and evaluate the example; the actual prompt presents the corresponding Arabic `template_ar` options.

System message.

أنت مصنّف علاقات. حدّد العلاقة الموجّهة من الكيان [الأول] إلى الكيان [الثاني].
اختر علاقة واحدة من القائمة تناسب معنى الجملة ونوعي الكيانين.
إن لم تنطبق أي علاقة فاختر «لا توجد علاقة».
أجب برمز الخيار فقط: حرف عربي واحد دون رقم أو شرح.

User message.

الجملة:
``نجدّد نداءاتنا للسلطات التركية المعنية لتسهيل العبور العاجل للإمدادات الأساسية والموظفين إلى شمال غرب سوريا للسماح بتوسيع نطاق استجابتنا الإنسانية والطبية في المنطقة." [الأول] كريستيان ريندرز [/الأول]، منسّق أنشطة [الثاني] أطباء بلا حدود [/الثاني] في شمال غرب سوريا.

نوع الأول: شخص
نوع الثاني: منظمة

الخيارات:
أ) الأول قائد للثاني
ب) الأول مؤسس للثاني
ج) الأول رئيس للثاني
د) الأول مدير للثاني
ه) الأول عضو في الثاني
و) الأول طالب لدى الثاني
ز) الأول يعمل لدى الثاني
ح) الأول منافس للثاني
ط) الأول مالك للثاني
ي) لا توجد علاقة

رمز الإجابة:

Assistant target.

ز

The target code ز maps internally to `Affiliation.employee_of`. The canonical relation identifier is not shown to the model as an answer option; instead, the model sees its Arabic `template_ar`, الأول يعمل لدى الثاني. Only the single assistant code token contributes to the training loss.

E.5 Deterministic Transformation

For each training row, the builder validates spans and types, inserts [الأول] and [الثاني] with overlap-safe ordering, maps types to Arabic names, retrieves compatible relations, renders their Arabic `template_ar` formulations, deterministically shuffles positive options with seed 42, appends *no_relation*, assigns one-token codes, maps the gold relation to its code, and builds the chat messages.

The corresponding audit checks marker occurrence, option uniqueness, domain/range compatibility, code-token alignment, reversibility, maximum sequence length, and absence of canonical relation-identifier leakage from the answer.

E.6 QLoRA Configuration

Yehia-RE uses rank-stabilized LoRA (RS-LoRA) (Kalajdzievski, 2023). The all-linear audit finds 225 supported linear/head modules: seven internal projections in each of 32 transformer layers plus the language-model head. PEFT wraps the 224 internal modules and leaves `lm_head` frozen. Only the 448 LoRA matrices receive gradients.

E.7 One-Token Masking Audit

For each labeled row, the system message, user message, chat-template boundary, trailing template tokens, and padding positions receive label -100. Exactly one assistant code token contributes to the loss. A row is rejected if the prompt/full-conversation boundary differs, the answer code is not one token, or the sequence exceeds 1,024 tokens.

E.8 Candidate-Pair Aggregation

For occurrence-pair candidate c, let $\pi_c(k)$ denote the normalized probability of displayed option code k. Let k_c^* be the winning code, r_c its relation, and define

$$u_c = \pi_c(k_c^*)$$

as the candidate confidence. We also define the score margin

$$m_c = \ell_c^{(1)} - \ell_c^{(2)},$$

where $\ell_c^{(1)}$ and $\ell_c^{(2)}$ are the largest and second-largest option log-probabilities.

The released runner implements the following row-level strategies.

Top confidence. Select from all occurrence-pair candidates according to the lexicographic key

$$(u_c, m_c, -c),$$

where c is the deterministic candidate index. The winning candidate's relation, including *no_relation* when applicable, is returned.

Max positive. Discard candidates whose predicted relation is *no_relation*. If no positive candidate remains, return *no_relation*. Otherwise, select the remaining candidate using the same lexicographic ordering

$$(u_c, m_c, -c)$$

and return its predicted positive relation.

Majority vote. Let N be the total number of candidate occurrence pairs and let $\rho = 0.5$. Positive voting is allowed only when at least

$$\lceil \rho N \rceil$$

candidates predict a positive relation; otherwise the row is assigned *no_relation*. Positive candidates vote by predicted relation. A relation-count tie is broken by, in order:

1. the sum of normalized probability support for the tied relation over all candidates;
2. the largest winning-candidate margin for that relation; and
3. canonical relation order.

E.9 vLLM Inference

The released blind-test runner uses BF16 bitsandbytes loading, one GPU, `tensor_parallel_size=1`, maximum length 1,024, prefix caching, temperature 0, top-$p = 1$, one generated token, and an allowed-token list equal to the codes displayed in the current row. Requests are batched up to 512 prompts.

E.10 Representative Official Results

Table 16 summarizes the official results of the two Yehia-RE training variants.

Category	Setting	Value	Notes
Base	Model	`Navid-AI/Yehia-7B-preview`	pinned revision
Base	Revision	`b9dda4715eafee7e8090d2c83cfe078d75f4ebb8`	
Runtime	Quantization	4-bit NF4 + double quant.	BF16 compute
Runtime	Maximum length	1,024	gradient checkpointing
LoRA	Target	eligible internal linear layers	RS-LoRA
LoRA	r/α/dropout	16 / 32 / 0.05	39,976,960 trainable
Training	Batch/accumulation	4 / 4	effective batch 16
Training	Epochs/steps	3 / 2,943	best step 2,750
Training	LR / warm-up	5×10^{-5} / 5%	cosine, zero decay
Training	Optimizer	`paged_adamw_8bit`	clipping 1.0
Sampling	Row weight	$n_c^{-0.25}$	replacement
Evaluation	Frequency	250 steps	full development set
Seed	Data and model	42	one reported seed

F Qwen-RE

F.1 Causal-LM Prompt Template

The Qwen-RE causal-LM prompt is constructed separately for each directed subject–object pair. It contains a system message defining the relation extraction task and required output format, followed by a user message containing the marked Arabic sentence, the subject and object strings and their predicted entity types, and only the relations compatible with the directed type pair under the operational ontology. Each compatible relation is presented with its label, Arabic template, direction note, and concise meaning. The generic prompt structure is shown below, where braced expressions denote row-specific values.

System message

You are an Arabic relation extraction system.

Given one Arabic sentence with a marked subject and object, return exactly one relation label.

You must always choose one label from the allowed label set.

Use the Arabic relation templates and direction notes as ontology definitions.

Prefer a positive relation label whenever the sentence provides plausible evidence for one.

Use *no_relation* only as a last resort when none of the allowed positive relations is supported.

Do not copy explanations, templates, or direction notes.

Return only the exact label text and nothing else.

User message

Classify the relation from the marked SUBJECT to the marked OBJECT.

The sentence uses `[SUBJ/...]`[`/SUBJ/...]` and `[OBJ/...]`[`/OBJ/...]` markers.

Use the Arabic ontology template beside each allowed label to understand its meaning.

Follow each direction note strictly because relation direction changes the label.

Choose exactly one label from the provided label set.

Prefer choosing the best-supported positive relation.

Use *no_relation* only when none of the allowed positive relations fits the marked sentence.

Task rules

1. Read the Arabic sentence and identify the relation between the marked subject and object.

2. Choose exactly one relation label.

3. Prefer the best-supported positive relation instead of defaulting to *no_relation*.

4. Use *no_relation* only when none of the allowed positive relations fits the marked sentence.

5. Use the Arabic templates and direction notes as label definitions, not as text to copy.

6. Return only the label text with no explanation.

Allowed labels and ontology meanings for this subject–object type pair

Direction: classify the relation from SUBJECT to OBJECT.

`{RelationLabel}`: Arabic template: SUBJECT OBJECT template} {relation

Direction: {relation-specific direction note}

Meaning: {concise relation meaning}

The preceding relation block is repeated for every ontology-compatible positive relation.

no_relation: Arabic template: لا توجد علاقة صالحة بين SUBJECT و OBJECT في هذه الجملة

Direction: use only when no allowed positive relation is supported by the marked sentence.

Meaning: no allowed positive relation is supported between the marked SUBJECT and OBJECT in the required direction.

Subject: {subject}

Object: {object}

Subject type: `{subject type}`

Object type: `{object type}`

Sentence:

and SUBJECT typed the containing {sentence markers} OBJECT

Answer:

During supervised fine-tuning, the assistant response following this prompt contains only the gold relation label. At inference, no gold label is provided: the constructed prompt ends at `Answer:`, after which the causal language model predicts the relation label. Because the candidate inventory is derived from the predicted directed entity-type pair, the allowed label set can differ from one input row to another.

F.2 Verified Causal-LM Training Example

The following example instantiates the prompt in Appendix F.1 using the verified training row `triple_id=3830` from Table 2.

Subject: بلدية قلقيلية

Object: قلقيلية

Subject type: `ORG`

Object type: `GPE`

Allowed relations:

`Business.has_conflict_with`: SUBJECT لديه نزاع مع OBJECT

`Location.headquartered_in`: SUBJECT يقع مقره الرئيسي في OBJECT

`Location.located_in`: SUBJECT يقع في OBJECT

`Location.nearby`: SUBJECT يقع بالقرب من OBJECT

no_relation: لا توجد علاقة صالحة بين SUBJECT و OBJECT في هذه الجملة

Sentence:

بلدية `[SUBJ/ORG]` قلقيلية `[OBJ/GPE]` قائمقام الى : `[/SUBJ/ORG]` `[/OBJ/GPE]` طولكرم / مدير منطقة قلقيلية : قرارات مجلس محلي قلقيلية : بتاريخ (2 / 1 / 1964) .

Assistant target: `Location.located_in`

During inference, the same row-specific prompt content is used without the assistant target, and the model predicts one of the allowed labels.

F.3 Generation and Complete-Label Scoring

Free-form generation can produce explanations, punctuation, partial labels, or an incompatible continuation. We therefore evaluate complete-label scoring. Let $\mathcal{C}(x)$ denote the ontology-compatible candidate set, including *no_relation*. For candidate label $c = (y_1, \ldots, y_{T_c})$, its score is the mean token log-probability

$$s(c \mid x) = \frac{1}{T_c} \sum_{i=1}^{T_c} \log p_\theta(y_i \mid x, y_{<i}). \tag{10}$$

The selected label is

$$\widehat{c} = \arg\max_{c \in \mathcal{C}(x)} s(c \mid x). \tag{11}$$

For analysis, scores can be normalized over the compatible set:

$$P(c \mid x, \mathcal{C}) = \frac{\exp s(c \mid x)}{\sum_{c' \in \mathcal{C}(x)} \exp s(c' \mid x)}. \tag{12}$$

This normalization does not change the highest-scoring label, although its value depends on the size and composition of the candidate set.

F.4 Sequence-Classifier Prompt and Objective

Qwen-RE-9B-Cls receives the same marked sentence and entity metadata but uses a shorter instruction because the model learns a fixed 41-way classification head.

A rendering for the same verified example is:

You are an expert Arabic relation extraction encoder.

Determine the semantic relation from the marked SUBJECT to the marked OBJECT. Respect relation direction and use *no_relation* only when no positive relation is stated or clearly implied. The classification head selects the final class; do not generate an answer.

Arabic sentence:

بلدية `[SUBJ/ORG]` قلقيلية `[OBJ/GPE]` قائمقام الى : `[/SUBJ/ORG]` `[/OBJ/GPE]` طولكرم / مدير منطقة قلقيلية : قرارات مجلس محلي قلقيلية : بتاريخ (2 / 1 / 1964) .

SUBJECT: بلدية قلقيلية

SUBJECT type: `ORG`

OBJECT: قلقيلية

OBJECT type: `GPE`

Property	Causal LM	Classifier
Output	Generated/scored label	One score per class
Objective	Token prediction	Multiclass CE
Inference	Generation/scoring	Masked argmax
Parsing	Required	Not required
Ontology	Prompt/candidate set	Direct logit mask

Table 17: Qwen-RE causal-LM and classifier formulations.

For input x_i, let $\mathcal{C}_i$ be the compatible relation classes, including *no_relation*. The classifier produces $\mathbf{z} \in \mathbb{R}^{41}$. Ontology-incompatible logits are masked before cross-entropy, so the effective training objective is

$$\mathcal{L}_{\text{CLS}} = -\log \frac{\exp z_{r^*}}{\sum_{r' \in \mathcal{C}_i} \exp z_{r'}}. \tag{13}$$

Rows whose gold relation is incompatible with the supplied entity types are rejected, and the same compatibility mask is used for evaluation and final prediction.

F.5 Class-Imbalance Interventions

For weighted causal-LM training, raw inverse-frequency weights are

$$w_r^{\text{raw}} = \frac{1}{n_r}. \tag{14}$$

They are normalized to mean one and clipped:

$$w_r = \min\left(5.0, \max\left(0.25, \frac{w_r^{\text{raw}}}{\frac{1}{|\mathcal{R}|}\sum_{r'} w_{r'}^{\text{raw}}}\right)\right). \tag{15}$$

Qwen-RE-9B-Cls instead uses a weighted random sampler with

$$q_r \propto (1/n_r)^{0.5}.$$

F.6 QLoRA Fine-Tuning

Qwen3.5-4B and Qwen3.5-9B are adapted with QLoRA (Dettmers et al., 2023). The frozen backbone is loaded in 4-bit NF4 with double quantization and BF16 computation. LoRA adapters target `q_proj`, `k_proj`, `v_proj`, `o_proj`, `gate_proj`, `up_proj`, and `down_proj`.

The sequence-classification run uses train/evaluation batch sizes 4/4, gradient accumulation 4, and maximum sequence length 1,280; the recorded causal-LM evaluation configuration uses batch size 1. The classifier's recorded LoRA rank and scaling are $r = 32$ and $\alpha = 64$.

Hyperparameter	Value
Training epochs	8
Learning rate	2×10^{-4}
Scheduler / warm-up	Cosine / 0.03
Weight decay	0.0
LoRA r/α/dropout	32 / 64 / 0.05
Quantization	4-bit NF4
Double quantization	Yes
Compute dtype	bfloat16
Optimizer	Paged AdamW 8-bit
Gradient checkpointing	Yes
Evaluation interval	1,000 steps
Seed	42

Table 18: Core Qwen-RE QLoRA settings recorded by the released configurations.

Checkpoint	Positive F_1	Acc./micro-F_1
Base prompt	0.5641	0.4707
Step 1,000	0.5035	0.6129
Step 2,000	**0.7155**	**0.6977**
Step 2,943	0.7099	0.6941

Table 19: Archived Qwen-RE-9B development results.

F.7 Validation and Checkpoint Selection

Causal-LM checkpoints are evaluated on the 1,687 development examples using generation-based inference. Outputs are mapped to the relation inventory, with ontology-incompatible predictions mapped to *no_relation*, and checkpoints are selected by development micro-F_1.

The best confirmed development micro-F_1 is 0.6846 for Qwen-RE-4B and 0.6977 for Qwen-RE-9B. Table 19 shows the archived trajectory for the inspected 9B run. Since this is single-label classification, accuracy equals all-class micro-F_1; positive-only F_1 is reported separately.

Step 2,000 correctly predicts 1,177 of 1,687 examples. Because the archive does not reliably map checkpoint steps to epochs, we report steps directly. These development results are not directly comparable with the official blind scores because they use a different split and evaluation pipeline.

F.8 Extended Results

The official scores differ by 0.18 points between Qwen-RE-9B and Qwen-RE-9B-Cls.

G Qwen Exploratory Prompt Optimization

G.1 Disambiguation Rules

We manually wrote decision rules for semantically close relations using the definitions in WojoodOn-

Qwen-RE system	Official F_1
Qwen-RE-4B	91.53
Qwen-RE-9B	91.76
Qwen-RE-9B-Cls	91.94

Table 20: Official Qwen-RE results.

tology (Aljabari et al., 2025a). A representative fragment is:

> **Allowed labels and Arabic meanings:**
>
> `Location.located_in`: ordinary physical or geographic containment.
>
> `Location.headquartered_in`: OBJECT is the headquarters or principal institutional location of SUBJECT.
>
> `PartOf.geopolitical_division`: SUBJECT is an administrative or geographic division of OBJECT.
>
> **Decision rule:** Prefer the more specific headquarters, administrative-division, capital, border, or proximity relation when its evidence is present; otherwise use ordinary containment.

These rules were diagnostically useful but did not eliminate confusion. In particular, headquarters examples could still be predicted as `Location.located_in`, while longer supportive and contrastive rules reduced validation performance for the selected Qwen configuration.

G.2 GEPA Prompt Evolution

We explored GEPA, a reflective prompt-evolution method that revises prompts using model errors and validation performance (Agrawal et al., 2026). The experiment used a stratified subset of 506 training examples and 196 validation examples.

For each candidate prompt, prediction errors were summarized with the gold and predicted labels, model output, compatible labels, relation meanings, and disambiguation guidance. The reflective editor `openai/gpt-5.5` used this feedback to propose revised prompts, which were evaluated on the validation subset and selected using GEPA's Pareto-based procedure.

The best stored GEPA prompt obtained positive $F_1 = 0.6011$ and accuracy 0.5408 on the 196-example validation subset. Because the corresponding pre-GEPA score on the same subset was not recorded, we do not claim a measured improvement over the initial prompt. This experiment was exploratory and did not replace the official system.

H Additional Error Analysis

H.1 Entity-Type Errors

A hard type error can simultaneously alter the typed text markers, the 42-dimensional subject–object type vector, and the ontology-compatible relation inventory. Type prediction is therefore consequential even though TypePredictor achieves high aggregate accuracy, particularly for lower-support types and unseen-sentence mentions.

H.2 Repeated Mentions

When a surface form occurs multiple times, the system must associate the provided subject and object strings with the textual occurrences that express the relation. Nearest-candidate selection can choose an incorrect occurrence, while score-all inference increases computation and introduces competing span hypotheses. Joint occurrence and relation scoring is a natural direction for future work.

H.3 Semantically Close Relations

A recurring difficulty is distinguishing generic and specific geographic relations, particularly `Location.located_in`, `Location.headquartered_in`, and `PartOf.geopolitical_division`.
The much larger training support for `Location.located_in` can favor the generic relation when the sentence contains evidence for a more specific alternative.

H.4 Causal Generation Errors

Causal generation adds a separate failure mode: a model can assign useful semantic probability mass to the correct relation while still generating extra prose, punctuation, an alias, or only part of a canonical label. This motivated complete-label scoring in Qwen-RE and the direct 41-way classification formulation in Qwen-RE-9B-Cls.

I Reproducibility

I.1 Released Resources

The current public inventory includes:

- `U4RASD/TypePredictor`;
- `U4RASD/DRU-RE-TypedPair-TwoHead`;
- TypedPair checkpoints for AraModernBERT, AraBERTv02, ARBERTv2, AraBERTv02-Large, and NeoAraBERT-no-interactions;

- `U4RASD/DRU-RE-Yehia` and `U4RASD/DRU-RE-Yehia-2`;
- `U4RASD/WojoodRelationsAnnotated`;
- `U4RASD/Yehia-RE-SFT`;
- `U4RASD/TypePrediction`; and
- `U4RASD/DRU-RE-Qwen`.

The repository identifiers retain their released names even where the paper uses the consolidated display names Yehia-RE and Qwen-RE.

I.2 Training and Selection Summary

I.3 Software, Hardware, and Model Revisions

The released artifacts do not contain one environment manifest shared by all experiments. Table 22 therefore reports exact recorded values where available and explicitly marks information that was not preserved rather than estimating it.

TRL is not listed as a dependency of the recorded Yehia-RE training environment. Exact Python and CUDA toolkit versions for Yehia-RE, and the corresponding complete software/hardware environment for Qwen-RE, are not recoverable from the archived releases and are therefore not inferred here.

Component	Backbone	Training	Output	Selection rule
TypePredictor	NeoAraBERT	Full fine-tuning, 4 epochs	21 type logits	Validation macro-F_1
TypedPair	Arabic encoders	Full fine-tuning, 4 epochs	Existence + 40 relation logits	Development positive micro-F_1
Yehia-RE	Yehia-7B	QLoRA, 3 epochs	One Arabic code token	Development positive micro-F_1
Qwen-RE-4B/9B	Qwen3.5-4B/9B	QLoRA, 8 epochs	Canonical label text	Development micro-F_1
Qwen-RE-9B-Cls	Qwen3.5-9B	QLoRA + 41-way head	Masked class logits	Development micro-F_1

Table 21: Cross-system summary of the principal training and selection choices. Detailed configurations are reported in the corresponding system appendices.

Abstract

This paper presents the ArmyForNER system for Subtask 1 of the KnowledgeGraphEval 2026 shared task on Arabic named entity recognition (NER). We address nested, cross-domain Arabic NER with a multi-stage pipeline built on ARBERTv2: (1) domain-adaptive pre-training (DAPT) via masked language modeling on unlabeled *Konooz* text, (2) fine-tuning with a multi-head BIO tagging architecture on the Wojood nested NER corpus, and (3) self-training on pseudo-labels produced by an intermediate DAPT ensemble over the *Konooz* domains. Soft-voting three self-trained checkpoints obtains 74.85 micro-F1 and 65.20 macro-F1 on the official test set, against a 63.00 / 44.00 baseline. Because both adaptation stages consume the blind *Konooz* test sentences, our system is listed among those that used *Konooz* during training, and its score is not comparable to systems that used *Konooz* for evaluation only. We state this setting explicitly and find that self-training gives consistent gains across seeds, whereas the benefit of DAPT is configuration- and seed-dependent.

1 Introduction

Arabic is spoken natively by more than 400 million people, yet NLP systems for Arabic continue to lag behind those for resource-rich languages, largely due to the language's complex morphology and orthography (Darwish et al., 2021; Mashaabi et al., 2024). Arabic's root-and-pattern morphology packs information such as gender, number, person, aspect, mood, and clitics into a single word, and diacritics are typically omitted in written text, leaving a word with a dozen or more possible morphological analyses (Darwish et al., 2021; Qu et al., 2024). Arabic script also lacks capitalization, removing a signal that flat NER systems in other languages rely on heavily (Qu et al., 2024). These properties, together with the gap between Modern Standard Arabic and regional dialects, make Arabic NER particularly challenging.

Arabic NER has advanced substantially with resources such as the Wojood corpus (Jarrar et al., 2022), comprising approximately 448K tokens and 72K entity mentions across 21 (possibly nested) entity types. Models trained on Wojood, however, generalize poorly to new domains: the official KnowledgeGraphEval 2026 baselines show an unadapted AraBERTv02 model (Antoun et al., 2020) dropping from 0.63 overall micro-F1 to 0.43 on the Agriculture domain of the *Konooz* corpus (Hamad et al., 2025) (Table 1).

KnowledgeGraphEval 2026 Subtask 1 (AdaptNER) (Aljabari et al., 2026) was designed to assess exactly this generalization gap. Systems are trained on Wojood and then evaluated on ten previously unseen *Konooz* domains without any target-domain labels. Therefore, the task combines two challenges: domain shift and nested entity structure.

In this paper, we present a nested NER system built to be robust to this domain shift. Our system uses DAPT to reduce the domain gap, a multi-head Beginning-Inside-Outside (BIO) architecture for nested spans, and self-training with ensemble-derived pseudo-labels. A 3-model soft-vote ensemble over the self-trained checkpoints produces the final predictions (Figure 1). Our submission obtained 74.85 micro-F1 and 65.20 macro-F1 on the official test set. Because both the DAPT and the self-training stages consume the blind *Konooz* test sentences, our system falls outside the group of systems that used *Konooz* for evaluation only, and the comparison in Section §5 is framed accordingly. Our contributions are:

- A multi-head BIO architecture that predicts nested entity over a shared encoder.
- A three-stage adaptation pipeline: DAPT, fine-

tuning, and pseudo-label self-training, that adapts a Wojood-trained model to unseen Konooz domains without target-domain labels.

- An empirical comparison showing self-training yields consistent gains across seeds while DAPT's benefit is configuration-dependent (Section §5).

2 Background

The KnowledgeGraphEval 2026 shared task decomposes Arabic knowledge graph construction into cross-domain NER (Subtask 1: AdaptNER) and relation extraction between identified entities (Subtask 2) (Aljabari et al., 2026). This paper only addresses Subtask 1.

For Subtask 1, models are trained on the Wojood NER corpus (448K tokens, 72K entity mentions, 21 entity types) (Jarrar et al., 2022) and evaluated on the *Konooz* MSA corpus (Hamad et al., 2025): 1,645 sentences (≈50K tokens) drawn from ten specialized domains (Agriculture, Art, Economics, Finance, Health, History, Law, Politics, Science, and Sport), with no target-domain annotations available during development.

Task challenges. (i) *Nested named entities:* entities in Wojood and *Konooz* can overlap (e.g., the geopolitical entity "Cairo" nested within the organization "Cairo University"), requiring a multi-column sequence-labeling format across 21 annotation columns (Aljabari et al., 2026). Nested NER is commonly approached with layered taggers (Ju et al., 2018) or second-best span decoding (Shibuya and Hovy, 2020). Our multi-head formulation (Section §3.1) is a simpler alternative that maps directly onto this multi-column format. (ii) *Domain generalization:* sequence labellers trained on news-domain text degrade substantially on specialized domains without target-domain training data, as Table 1 shows.

3 System Overview

3.1 Base Model and Architecture

We use **UBC-NLP/ARBERTv2** (Abdul-Mageed et al., 2021) as our encoder backbone: an Arabic BERT model with 12 layers, 768 hidden dimensions, and 163M parameters. For nested NER, we adopt a multi-head BIO architecture. The shared encoder produces a contextualized token representation, and 21 independent linear classification heads, one per entity type in the Wojood annotation guidelines, each predict `O`, `B`, or `I`. Any token can therefore be labeled with several entity types at once. This is equivalent to solving 21 BIO sequence-labeling tasks in parallel over a shared encoder, and avoids enumerating candidate spans.

Training objective. The loss is the mean cross-entropy across all 21 heads, computed only over non-padded, first-subword positions:

$$\mathcal{L} = \frac{1}{21} \sum_{t=1}^{21} \mathrm{CE}(\mathbf{W}_t \, \mathbf{h}, y_t) \qquad (1)$$

where $\mathbf{h}$ is the encoder output, $\mathbf{W}_t \in \mathbb{R}^{3 \times H}$ is the head for entity type t, and y_t is the gold BIO label.

BIO repair. Because the heads decode independently per token, they can emit invalid tag sequences. At inference we therefore apply a deterministic repair pass to each head's tag sequence, scanning left to right: an `I` tag that is not preceded by a `B` or `I` tag of the same entity type is rewritten as `B`, opening a new span at that position. No other tags are modified.

3.2 Domain-Adaptive Pre-Training (DAPT)

To bridge the gap between the Wojood training domain and the *Konooz* evaluation domains, we apply DAPT (Gururangan et al., 2020): we continue masked language modeling (MLM) on unlabeled target-domain text before fine-tuning for NER. The DAPT corpus is the set of blind test sentences from all ten *Konooz* domains (Section §4.1), with a masking probability of 0.15.

We trained three DAPT variants to create diverse adapted encoders for ensembling. All three use a

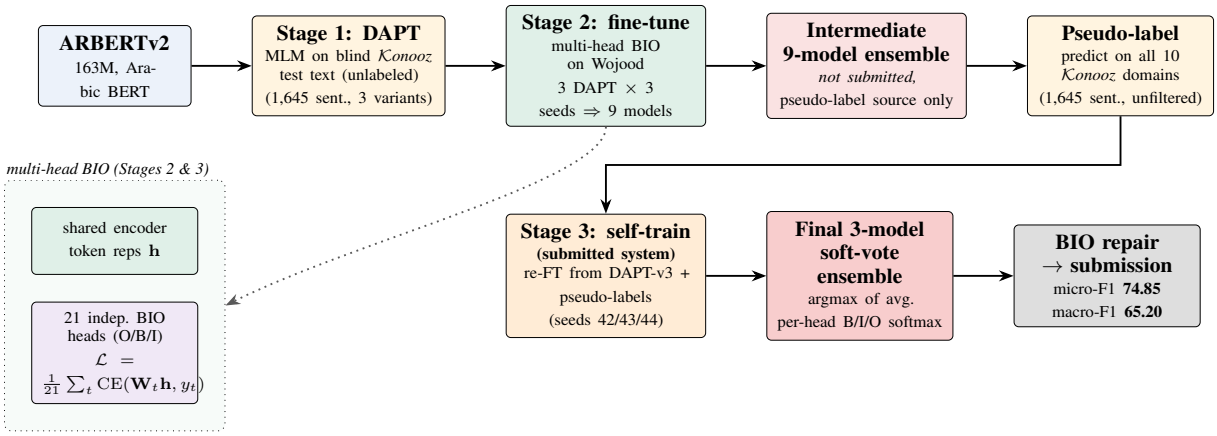

Figure 1: Our NER pipeline. DAPT adapts ARBERTv2 to the unlabeled *Konooz* text. The resulting encoders are fine-tuned with a multi-head BIO architecture on Wojood. Self-training then re-fine-tunes three new seeds from the DAPT-v3 checkpoint on Wojood plus pseudo-labels produced by the intermediate 9-model ensemble. Stage 1 and the pseudo-labeling step both consume the blind *Konooz* test sentences (without labels), making the pipeline transductive (§4.1).

learning rate of 5×10^{-5}; they differ as follows: DAPT-v1 and DAPT-v2 both run for 3 epochs with batch size 32 and differ only in random seed, while DAPT-v3 runs for 5 epochs with batch size 16. These settings were chosen to vary training length and batch size within our GPU budget rather than by a systematic search, which limits what the comparison in Section §5.3 can establish.

3.3 Fine-Tuning on Wojood

Each DAPT-adapted encoder is fine-tuned on the Wojood 1.1 nested NER corpus with learning rate 3×10^{-5}, batch size 16, weight decay 0.01, linear warmup over the first 10% of steps, gradient clipping at 1.0, maximum sequence length 256, and mixed-precision (FP16) training. We train for up to 10 epochs and keep the checkpoint with the best micro-F1 on the Wojood validation set. Three seeds (42, 43, 44) per DAPT variant give nine fine-tuned models, which are combined into an intermediate soft-vote ensemble used solely to generate pseudo-labels. This intermediate ensemble is not part of the submitted system.

3.4 Self-Training with Ensemble Pseudo-Labels

We run the intermediate 9-model ensemble on the 1,645 unlabeled *Konooz* sentences and keep all of its predictions as pseudo-labels, with no confidence threshold or agreement filtering. These sentences are appended to the Wojood training set (23,124 + 1,645 = 24,769 sentences), and we fine-tune three new seeds (42, 43, 44) starting from the DAPT-v3 checkpoint.

We note that DAPT-v3 was not the validation-preferred variant: DAPT-v2 was the most consistent on Wojood validation (Section §5.3). The DAPT-v3 checkpoint was selected before the per-variant validation comparison was complete, and we did not re-run self-training from DAPT-v2 within the shared-task timeline. Whether initializing from DAPT-v2 would have performed better therefore remains untested.

3.5 Soft-Vote Ensemble

Our final submission combines the three self-trained checkpoints by soft voting: for each token position and entity-type head, we average the three-way softmax distributions and select the highest-probability BIO tag. BIO repair is then applied to the ensemble output.

4 Experimental Setup

Data. We train on the Wojood 1.1 nested NER corpus (Jarrar et al., 2022): 23,124 training sentences (≈391K tokens) and 3,303 validation sentences (≈58K tokens) annotated with 21 entity types. The official test set is drawn from the *Konooz* corpus (Hamad et al., 2025), covering ten Arabic domains.

Hardware. All experiments were run on a single NVIDIA RTX 3070 Ti GPU (8 GB VRAM).

Implementation. Our code is built on HuggingFace Transformers (version 4.48.1) and PyTorch (version 2.2.2).

	Team	P	R	Mi-F1	Ma-F1

–	Baseline	63.87	62.30	63.00	44.00

Table 2: Final official Subtask 1 results. The first group used *Konooz* only for evaluation; the second, including our system, used *Konooz* data during training or adaptation.

4.1 Use of Target-Domain Data

Both adaptation stages of our pipeline consume the blind *Konooz* test sentences: DAPT performs MLM on their raw text, and self-training adds pseudo-labels for those same sentences to the training set. No *Konooz* gold labels were used at any point, and no labeled target-domain data was available to us. Our setting is therefore transductive: the evaluation sentences themselves, without their labels, are part of both adaptation stages.

In the official results, this places our system among those that used *Konooz* data during training rather than among the systems that were used *Konooz* for evaluation only. Scores across the two groups are not directly comparable, and we do not claim a rank relative to the systems in the first group.

5 Results and Analysis

5.1 Official Test Results

Table 2 reports the final official results. Our system obtains 74.85 micro-F1 and 65.20 macro-F1, improving over the official baseline by 11.85 and 21.20 points respectively. Precision (82.11) exceeds recall (68.77) by more than 13 points, so the residual error is dominated by entity mentions the system misses rather than by spurious predictions, which is the expected failure mode when a news-trained tagger meets specialized domain terminology.

The organizers report only aggregate scores, so we cannot give a per-domain *Konooz* breakdown and cannot tell whether the baseline's sharp drop on Agriculture (Table 1) was recovered.

5.2 Development Results

Table 3 reports micro-F1 on the Wojood validation set for each variant. These are source-domain scores: they measure the model on Wojood, not on the *Konooz* target domains, and §5.5 shows that they do not predict target-domain performance. We report them because they are the only labeled signal we had during development.

Model	Dev F1	Δ
ARBERTv2 (no DAPT, seed 42)	0.8297	–
DAPT-v1 + FT (seed 42)	0.8434	+1.37
DAPT-v1 + FT (seed 43)	0.8267	−0.30
DAPT-v1 + FT (seed 44)	0.8273	−0.24
DAPT-v2 + FT (seed 42)	0.8374	+0.77
DAPT-v2 + FT (seed 43)	0.8378	+0.81
DAPT-v2 + FT (seed 44)	0.8326	+0.29
DAPT-v3 + FT (seed 42)	0.8285	−0.12
DAPT-v3 + FT (seed 43)	0.8313	+0.16
DAPT-v3 + FT (seed 44)	0.8277	−0.20
Self-trained v3 (seed 42)	0.8335	+0.50
Self-trained v3 (seed 43)	0.8377	+0.64
Self-trained v3 (seed 44)	0.8444	+1.67

Table 3: Micro-F1 on the *Wojood validation set*. Δ is in F1 points, against the no-DAPT baseline for the DAPT rows and against the corresponding DAPT-v3 seed for the self-trained rows.

5.3 Effect of DAPT

DAPT does not help uniformly. DAPT-v1 gains 1.37 points for seed 42 but loses ground for seeds 43 and 44 (-0.30, -0.24). DAPT-v2 improves all three seeds ($+0.77$, $+0.81$, $+0.29$). DAPT-v3 stays near the baseline, ranging from -0.20 to $+0.16$. On Wojood validation, then, DAPT-v2 was the most consistently beneficial variant, and no single DAPT effect can be read off these numbers. Since these are source-domain scores, they also do not establish what DAPT contributed on *Konooz*. Isolating that would require target-domain labels or an official per-configuration submission, neither of which was available.

5.4 Effect of Self-Training

Self-training on top of DAPT-v3 improves every seed relative to its non-self-trained counterpart: $+0.50$, $+0.64$, and $+1.67$ points. Unlike the DAPT gains, this direction is consistent across all three seeds we ran, which is why we adopted self-training for the final system. The same caveat applies: the gain is measured on Wojood, while the pseudo-labels come from *Konooz*.

5.5 Source-Target Gap

Our Wojood validation scores cluster around 0.83-0.84, while our official *Konooz* micro-F1 is 0.7485, a drop of roughly 8-9 points. This is the cross-domain degradation the task is designed to expose, and it persists despite both adaptation stages: DAPT and self-training narrow the gap relative to the 0.63 baseline but do not close it.

The two numbers are not directly comparable, since they come from different corpora with different domain and label distributions, and the official metric is span-level over *Konooz*. The practical consequence for system building is that ranking variants by Wojood validation F1 is unreliable: the differences in Table 3 are mostly well under one point and of the same order as seed noise, and none of them was validated against target-domain performance.

5.6 Error Analysis

Manual inspection of system errors on the Wojood validation set reveals three main error categories. Because *Konooz* gold labels are not available to us, this analysis is conducted entirely on the source domain and is at best indirect evidence about target-domain behavior.

Boundary errors. A substantial fraction of errors are off-by-one span boundaries, where the entity type is correct but the span includes or excludes one token.

Nested entity confusion. The multi-head design permits nested predictions, but the model sometimes fails to predict the outer span when the inner entity is more salient.

Rare and domain-specific entities. Specialized terminology is under-represented in Wojood's largely news-domain text. The precision–recall asymmetry in the official results (82.11 vs. 68.77) is consistent with such mentions going undetected on *Konooz*, though we cannot confirm this without target-domain labels.

6 Limitations

Our system has several limitations. First, and most importantly, both adaptation stages use the blind *Konooz* test sentences (§4.1). The resulting system is transductive: it cannot be applied to a new domain without first collecting that domain's text and re-running DAPT and self-training, and its score is not comparable to systems that never touch the evaluation text. We did not measure how much of our gain over the baseline would survive if adaptation were restricted to a separate unlabeled pool, such as the provided *Konooz*-dev text.

Second, every ablation number we report is Wojood validation F1, a source-domain measurement, while DAPT and self-training are both aimed at the target domain. We therefore cannot attribute our official score to any individual stage, and we did not obtain official per-configuration scores that would allow us to.

Third, the pseudo-labels were used without confidence or agreement filtering, so systematic errors of the intermediate ensemble on specialized terminology may have been reinforced rather than corrected; we ran no filtered-versus-unfiltered comparison. Fourth, the self-training checkpoint was initialized from DAPT-v3 although DAPT-v2 was the validation-preferred variant (§3.4), and this choice was never tested. Fifth, the multi-head loss weights all 21 entity types equally regardless of frequency, which disadvantages rare types and plausibly contributes to the low recall in the official results. Sixth, producing the pseudo-labels required training and running a 9-model intermediate ensemble, a compute cost far larger than the submitted 3-model ensemble. Finally, each configuration was trained with only three seeds and the differences between several variants are smaller than the observed seed spread, so individual comparisons in Table 3 should be read as indicative rather than conclusive.

7 Conclusion

We presented a multi-stage system for Arabic nested NER combining domain-adaptive pretraining, multi-head BIO fine-tuning, and self-training with ensemble-derived pseudo-labels, submitted as a 3-model soft-vote ensemble. The system obtained 74.85 micro-F1 and 65.20 macro-F1 on the *Konooz* evaluation benchmark, well above the 63.00 / 44.00 baseline, in a transductive setting that uses the blind test sentences for both adaptation stages. Self-training gave a more consistent gain across seeds than DAPT, and Wojood validation performance did not predict *Konooz* test performance. The main open questions our experiments leave are whether confidence-filtered pseudo-labels would help, whether initializing self-training from the validation-preferred DAPT variant would change the outcome, and how much of the gain

survives when adaptation is restricted to a separate unlabeled target-domain pool.

Abstract

This paper presents Daleel 2026, the first shared task on argument mining in Arabic news editorials and competitive debates. Daleel includes two tasks: Task 1 identifies which of six argumentative discourse unit (ADU) categories are present in a paragraph, while Task 2 locates the units with their labels and exact text spans. The tasks are performed using a new corpus of 30 documents, 1,042 paragraphs, and about 76k words. Twenty-nine teams registered, 12 participated, and 10 submitted system papers. Both tasks have Closed and Open tracks. The best Closed-track results were 71.17 macro-F1 points for Task 1 and 75.47 modified-overlap F1 points for Task 2. The results show different insights: the best Closed-track score of each team was higher on debates than on editorials. A broad range of approaches was used in Task 1 submissions, including Arabic encoders, large language models, rules, and ensembles. Task 2 systems, in particular the top-ranked ones, were more similar and mainly used CRF or Viterbi decoding with combinations of models or training runs. The rare ADU categories remained difficult in both tasks, and identifying exact span boundaries was an additional challenge in Task 2.

1 Introduction

Argument mining aims to identify and analyze the argumentative structure of natural language text. It supports the automatic study of how arguments are expressed and how different parts of an argument function within a text (Lawrence and Reed, 2019). A central element in this process is the identification of argumentative discourse units (ADUs), which represent the text spans that serve an argumentative elements. Argument mining therefore involves both locating these units and determining the role they play in the argument (Stab and Gurevych, 2017). These tasks have been studied across several domains and annotation schemes. However, most established resources and methods have focused on English.

In recent years, argument mining in Arabic has received growing attention, but annotated resources remain limited. Recent work has introduced resources for Arabic competitive debates, including Munazarat, and for student argumentative writing through the Qatari Corpus of Argumentative Writing (QCAW) (Khader et al., 2024; Zaghouani et al., 2024). Other work has studied the classification of argument elements and styles in Arabic debates (Al-Zawqari et al., 2025). These resources provide important foundations, but they address different argumentation schemes and tasks. More recently, (Nabhani and Al Khatib, 2025) studied span-level argument mining in Arabic without native annotations, using cross-lingual transfer and translated training data. This leaves a need for native Arabic annotations that support ADU identification and classification across different forms of argumentative discourse.

Daleel 2026 addresses this gap by introducing a shared task on Arabic argumentative discourse mining across: 1) news editorials and 2) competitive debates. The task uses six ADU categories: Common Ground, Assumption, Testimony, Statistics, Anecdote, and Other, following the argumentation strategy scheme introduced by (Al-Khatib et al., 2016). It defines two related tasks over the same paragraphs. Task 1 requires systems to identify the ADU categories present in a paragraph as a multi-label classification problem. Task 2 requires systems to locate the corresponding ADUs and identify their exact character spans and categories. Both tasks are offered under Closed and Open tracks, allowing the evaluation of systems under different resource settings.

This paper presents an overview of the Daleel 2026 shared task. We describe the task design, the annotation process, and the resulting Arabic corpus. We also present the evaluation setup, metrics, base-

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1287–1298
October 28-29, 2026 ©2026 Association for Computational Linguistics

lines, and the development and testing phases. We then summarize the approaches developed by the participating teams and report the official results across both tasks and tracks. Finally, we analyze the main patterns that emerge from the shared task, with particular attention to genre differences, difficult ADU categories, span detection, system design choices, and cross-domain generalization.

2 Related Work

Argument mining research differs in how argumentative units and their roles are defined. Work on persuasive essays commonly distinguishes major claims, claims, premises, and the relations between them (Stab and Gurevych, 2014, 2017). Other work has addressed argumentative units in user-generated discourse (Habernal and Gurevych, 2017) or classified the semantic types of claims and premises (Hidey et al., 2017). A different view based on argumentation strategies in news editorials was proposed in (Al-Khatib et al., 2016), distinguishing six categories of evidence and discourse function. Later work examined how these strategies vary across topics (Al-Khatib et al., 2017).

Arabic argumentation resources have expanded in recent years and cover different forms of argumentative text. Munazarat 1.0 introduced a corpus of Arabic competitive debates (Khader et al., 2024). Subsequent work developed a hybrid annotation model for these debates and studied the neural classification of their argument elements and styles (Al-Sharafi et al., 2025; Al-Zawqari et al., 2025). Outside the debate setting, QCAW 1.0 provides a corpus of Arabic student argumentative writing (Zaghouani et al., 2024). Argumentation information has also been used as a feature in downstream Arabic tasks such as propaganda detection (Nabhani et al., 2025). These resources differ in genre, annotation scheme, and target task.

Modeling work on Arabic argument mining has also explored how to deal with the limited availability of native annotations. Cross-lingual transfer and translation-based approaches for Arabic argument mining without native annotations were studied in (Nabhani and Al Khatib, 2025), using an English argument mining corpus as the source data. In parallel, several pretrained language models have been developed for Arabic. AraBERT provides Arabic-specific Transformer representations (Antoun et al., 2020), and both ARBERT and MARBERT target Modern Standard Arabic and dialectal variation (Abdul-Mageed et al., 2021). CAMeLBERT further studies the effect of language variant, model size, and task type on Arabic language understanding (Inoue et al., 2021), while AraELECTRA provides an alternative discriminator-based pretraining approach (Antoun et al., 2021). Together, these models provide Arabic-specific backbones for classification and span detection tasks.

A separate line of research studies argument mining in debates and dialogue. In (Habernal and Gurevych, 2015), debate portals were used to study argument mining across domains in user-generated discourse. QT30 introduced a corpus of argument and conflict in broadcast debates (Hautli-Janisz et al., 2022), extending argument mining to spoken and transcribed interaction. Project Debater demonstrated argument mining and related technologies at the scale of an autonomous debating system (Slonim et al., 2021). More recently, DialAM-2024 introduced the first shared task on dialogical argument mining, combining propositional relations with speech illocutions (Ruiz-Dolz et al., 2024). This provides a relevant precedent for studying argumentation in interactive and spoken settings.

Shared tasks have also become an important part of Arabic NLP evaluation. AraIEval evaluated persuasion techniques and disinformation detection in Arabic, including span-level identification of persuasion techniques (Hasanain et al., 2023). More recently, the BAREC 2025 shared task evaluated Arabic readability assessment using multiple evaluation tracks (Elmadani et al., 2025). Such shared tasks provide common data, task definitions, and evaluation settings for comparing different modeling approaches. Daleel follows this shared-task setting for Arabic argument mining, combining paragraph-level ADU classification with span-level ADU detection. It also evaluates the two tasks across editorials and competitive debates, making genre and cross-domain performance part of the evaluation.

3 Shared Task Description

3.1 ADU Taxonomy

Both tasks use the same taxonomy of six ADU categories. The taxonomy follows the argumentation strategy scheme introduced in (Al-Khatib et al., 2016). The categories describe how each unit functions within the argumentative discourse. Table 1 gives their definitions. An ADU may receive more

than one category when several definitions apply.

Table 2 gives four annotated examples from the corpus, with two examples from each genre and four different ADU categories.

3.2 Task 1: ADU Classification

Task 1 identifies the ADU categories present at the paragraph level. The input is an Arabic paragraph x from a news editorial or competitive debate. The label inventory is $\mathcal{L} = \{\mathrm{CO}, \mathrm{AS}, \mathrm{TE}, \mathrm{ST}, \mathrm{AN}, \mathrm{OT}\}$. A system predicts a subset $Y_1 \subseteq \mathcal{L}$. Since several categories may occur in the same paragraph, Task 1 is a multi-label classification problem.

3.3 Task 2: ADU Detection

Task 2 identifies the individual ADUs in a paragraph and assigns their categories. It uses the same paragraph input and label inventory as Task 1. A system predicts $Y_2 = \{(\ell_i, s_i, e_i)\}_{i=1}^{m}$. Each triple gives an ADU category $\ell_i \in \mathcal{L}$ and its start and end character offsets s_i and e_i. The interval $[s_i, e_i)$ marks the corresponding span in the original paragraph. Multiple triples may share a span when an ADU has more than one category. Task 2 therefore combines span detection with ADU classification.

3.4 Relationship between the Tasks

Both tasks operate on the same paragraphs and use the same label inventory. Task 1 records only whether each ADU category occurs. Task 2 preserves the category and location of every unit. The Task 1 output can therefore be derived from the Task 2 output as

$$Y_1 = \{\ell_i \mid (\ell_i, s_i, e_i) \in Y_2\}. \quad (1)$$

This projection removes the span boundaries and repeated occurrences of the same category. The reverse operation is not possible because Task 1 does not contain boundary information. Figure 1 illustrates this relation.

3.5 Closed and Open Tracks

Both tasks are offered in Closed and Open tracks. The Closed track restricts the use of external data and larger or proprietary large language models (LLMs). The Open track relaxes these resource restrictions and allows additional resources. Both tracks permit prompting, fine-tuning, rule-based methods, and hybrid systems. Table 3 summarizes the main resource differences. Results for the two tracks are reported separately.

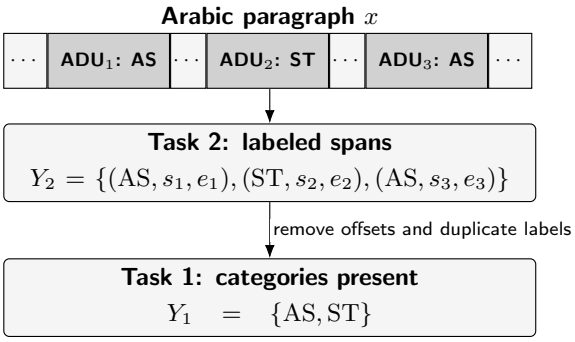

Figure 1: Relationship between the two tasks. Task 2 identifies each labeled span, and Task 1 retains only the distinct categories.

4 Dataset

Argumentation may vary depending on the type of text in which it occurs. Therefore, this shared task is designed not only to advance Arabic argument mining in general, but also to study how argumentation and argument mining differ across discourse genres. To investigate these differences, the shared task focuses on two genres: *Editorials* and *Debates*.

4.1 Data Sources

We constructed a corpus consisting of 20 news editorials and 10 debate transcripts, covering a range of topics and issues. Figure 2 shows the distribution of topics across editorials and debates in the corpus.

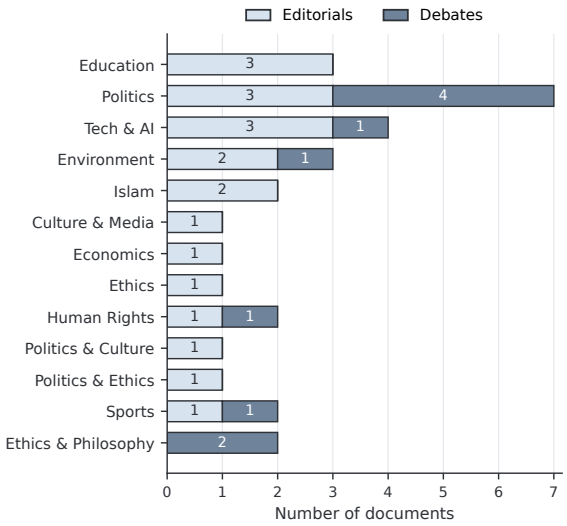

Figure 2: Topics distribution in the editorials and debate corpus.

Label	Category	Definition
AS	Assumption	States an assumption, conclusion, judgment, or opinion of the author, a general observation, possibly false fact, or similar. To make readers accept it, it is or would need to be supported by other units.
OT	Other	Does not, or hardly, add to the argumentative discourse, or does not match any of the other classes.
AN	Anecdote	Gives evidence by stating a personal experience of the author, an anecdote, a concrete example, an instance, a specific event, or similar.
TE	Testimony	Gives evidence by stating or quoting that a proposition was made by an expert, authority, witness, group, organization, or similar.
CO	Common Ground	States common knowledge, a self-evident fact, an accepted truth, or similar. It refers to general issues, not to specific events. Even if not known in advance, it will be accepted without proof or further support by all or nearly all possible readers.
ST	Statistics	Gives evidence by stating or quoting the results or conclusions of quantitative research, studies, empirical analyses of data, or similar. A reference may, but need not, be given.

Table 1: The six ADU categories used in Daleel 2026.

Genre	Category	Arabic example	English gloss
Editorial	Statistics (ST)	في عام 2024 ـ الذي شهد بالفعل تراجعات واضحة ـ حققت مرسيدس ربحا بلغ 10.4 مليار يورو	In 2024, despite clear declines, Mercedes made a profit of 10.4 billion euros.
Editorial	Testimony (TE)	تقول فيليز إن الناس لم يديروا ظهورهم للخصوصية، لكن كثيرين منهم يشعرون بالعجز حيالها	Velez says that people have not turned their backs on privacy, but many feel powerless about it.
Debate	Common Ground (CO)	حلف الناتو هو تحالف سياسي عسكري يقتضي أن يدافع عن الدول الموجودة فيه و الدول المشاركة فيه	NATO is a political and military alliance whose members are expected to defend the countries in the alliance.
Debate	Assumption (AS)	لابد من وضع سياسات و لا بد من التعاون الدولي بدون المساس بسيادة الدول لكي نعالج هذه المشكلة	Policies and international cooperation are needed to address this problem without infringing on state sovereignty.

Table 2: Annotated ADU examples from editorials and debates. The Arabic spans are taken directly from the corpus; English glosses are provided for readability.

Editorials. Editorials represent monological texts with extended argumentative writing, in which a single author develops and supports a position on an issue. The editorials were collected from different high-quality Arabic news portals (e.g., Al Jazeera, Al Araby, BBC, DW). Figure 3 shows the distribution of the selected editorials across these portals.

Debates. Debates represent dialogical argumentative discourse, in which multiple speakers present claims, respond to one another, and express agreement or disagreement. The debates were sampled from QatarDebate Center[1] tournament material.

4.2 Annotation process

The annotation process was based on the scheme proposed by Al-Khatib et al. (2016), originally developed to identify argumentative units in English texts. All annotators have a background in debating and participated in multiple training sessions, during which the scheme was slightly refined and adapted to suit the characteristics of Arabic Argumentation better. Each editorial and debate transcript was annotated independently by two annotators. Inter-annotator agreement (IAA) was measured using Soft γ (Mathet et al., 2015) and Intersection over Union (IoU), achieving average scores of 0.32 and 0.48, respectively.[2] Soft γ accounts for both label and positional mismatches, with disagreements in labels receiving a greater penalty than discrepancies in span position. The resulting annotations were then reviewed, and any disagreements were resolved by an expert in debate and

[1] https://qatardebate.org/

[2] IAA was calculated over 28 documents, excluding the two documents used for annotation training. IoU was calculated using a threshold of 0.5.

Resource	Closed	Open
Organizer training and development data	Yes	Yes
Public pretrained models and standard NLP tools	Yes	Yes
Open-weight LLMs ($\leq$70B parameters)	Yes	Yes
Additional datasets or external resources	No	Yes
Proprietary LLMs	No	Yes
Open-weight LLMs (>70B parameters)	No	Yes
External retrieval, data augmentation, or translation	No	Yes

Table 3: Allowed resources in the Closed and Open tracks.

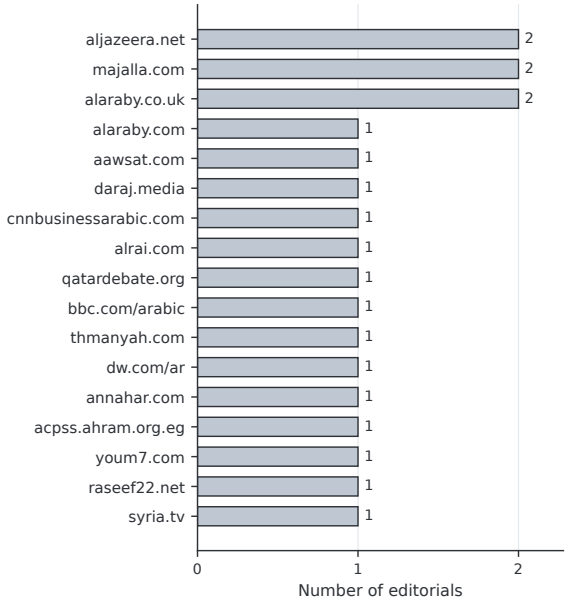

Figure 3: Number of editorials per news portal in the editorials corpus.

argumentation. During adjudication, the annotations produced by both annotators were compared against the guidelines, and, in cases of disagreement, the annotation that most closely adhered to the specified criteria was retained. Given the inherently subjective nature of label identification, some cases permitted multiple plausible interpretations. When both annotations could reasonably be supported by the guidelines, the decision was based on the interpretation most consistent with how similar cases had been handled across the dataset and by the annotators as a whole. Where neither initial annotation provided a sufficiently appropriate resolution, a new gold annotation was assigned based on the same interpretive rationale established in earlier adjudication decisions. The final annotation guidelines can be found in the shared task repository on GitHub.[3]

	Editorials	Debates	Overall
Corpus size			
Documents	20	10	30
Paragraphs	430	612	1,042
Words	22,733	53,327	76,060
Per-paragraph averages			
Words	52.87	87.14	72.99
Labels	1.57	1.92	1.78
ADUs	3.24	5.66	4.66

Table 4: Corpus statistics by genre.

4.3 Resulting Corpus

Table 4 shows summary statistics of the final corpus. Although the corpus is relatively small in terms of the number of documents, the documents are argument-rich. The 20 editorials average 1,137 words each, and the 10 debates average 5,333 words each, resulting in a total of approximately 76K words for the full corpus. The task is defined at the paragraph level. Therefore, the documents were segmented into paragraphs, resulting in a total of 1,042 paragraphs.

Figure 4 shows the distribution of ADU categories across the entire corpus, while Table 5 breaks this distribution down by genre.

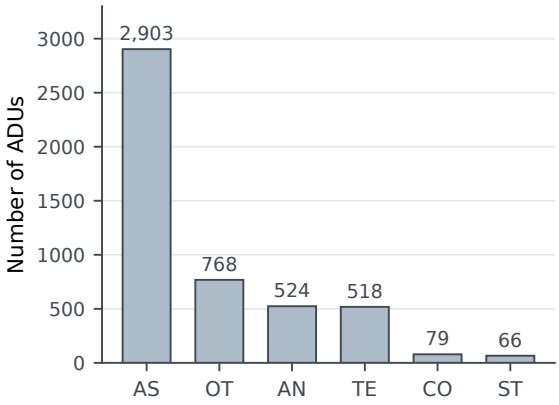

Figure 4: ADU category distribution across the corpus.

The final corpus is split into training, development, and test sets for the different stages of the shared task. The training set contains 612 paragraphs from 18 documents (6 debates and 12 editorials). The development set contains 217 paragraphs from 6 documents (2 debates and 4 editori-

[3] https://github.com/Argmining/Daleel2026

als), and the test set contains 213 paragraphs from 6 documents (2 debates and 4 editorials). This split ensures that all three sets include both genres and a comparable number of documents and paragraphs. The distribution of the ADU categories across the three data splits is shown in Table 5.

5 Evaluation

5.1 Development and Testing Phases

The shared task consisted of two phases: a development phase and an evaluation phase. In the development phase, participants were provided with the training data together with its gold annotations for both tasks, as well as the development input without annotations. Participants used these resources to develop and tune their systems and to evaluate their performance on the development set.

In the evaluation phase, which follows the development phase, participants received the gold labels for the development set and the input for the test set. Systems were then run on the test input, and the system outputs for the test set were used for the final evaluation and ranking.

In both phases, participants had the option of training their models using only editorials, only debate, or both genres. All submitted systems were subsequently evaluated on three test settings: editorials only, debate only, and the combination of both.

5.2 Metrics

Task 1 - ADU Classification. We use Macro F1 over the classes.

Task 2 - ADU Detection. We use an F1 measure adapted to account for partial matching between predicted and gold spans, following the evaluation measure used in previous shared tasks (Hasanain et al., 2024; Alam et al., 2022; Dimitrov et al., 2021). A predicted span is considered correct if it overlaps with a gold span and has the correct label, with the score adjusted according to the degree of overlap.

Let s be a predicted span, t a gold span, $l(s)$ and $l(t)$ their respective labels, and $|s \cap t|$ the length of the character overlap between s and t. The credit recevied by the (s, t) pair is defined as:

$$C(s, t, h) = \frac{|s \cap t|}{h} \quad \text{if } l(s) = l(t),$$

where h is the normalization length. For precision, we use the length of the predicted span:

$$P = \frac{1}{|S|} \sum_{s \in S} \sum_{t \in T} C(s, t, |s|).$$

For recall, we use the length of the gold span:

$$R = \frac{1}{|T|} \sum_{s \in S} \sum_{t \in T} C(s, t, |t|).$$

The final score is the harmonic mean of precision and recall:

$$F_1 = \frac{2PR}{P + R}.$$

5.3 Baselines

We provide a random baseline for both tasks.

Task 1 - ADU Classification. For Task 1, the baseline first samples a number of labels between 1 and 4 for each paragraph. It then assigns ADU categories randomly, taking their distribution in the corpus into account.

Task 2 - ADU Detection. For Task 2, the baseline similarly samples a number of ADU spans between 1 and 4 per paragraph. For each ADU span, it selects the categories at random, taking their distribution in the corpus into account. The start offset of each ADU span is chosen randomly between the beginning and the end of the paragraph, and the end offset is chosen randomly between the start offset and the end of the paragraph.

6 Participants and Systems

A total of 29 teams registered for the shared task, 12 teams participated, and 10 teams submitted system description papers. Five teams covered both tasks, three covered only Task 1, and two covered only Task 2. *TTLab* (Verma et al., 2026) submitted a ranked Task 1 run, although its paper describes only Task 2. Of the teams with papers, only *Durham-Jazan* (Saad Alshehri et al., 2026) entered both the Closed and Open tracks. *REGLAT* also has a ranked Task 1 Open run, but no system paper was available. Table 6 lists each team's final run in every task–track combination it entered.

6.1 Task 1 Systems

Closed track. Arabic encoders appeared in most Task 1 systems, either alone or as part of a hybrid. *Northwestern_12* (Sedqy Shlkamy and Zaghouani, 2026) fine-tuned CAMeLBERT-Mix with class-weighted loss and a separate threshold for each label. *BURHAN* (Osrf et al., 2026) fine-tuned

Label	Genre		Data split (both genres)		
	Editorials	Debates	Train	Dev.	Test
AS	793 (27.3%)	2,110 (72.7%)	1,739 (59.9%)	587 (20.2%)	577 (19.9%)
OT	42 (5.5%)	726 (94.5%)	492 (64.1%)	126 (16.4%)	150 (19.5%)
AN	289 (55.2%)	235 (44.8%)	343 (65.5%)	111 (21.2%)	70 (13.4%)
TE	181 (34.9%)	337 (65.1%)	313 (60.4%)	112 (21.6%)	93 (18.0%)
CO	36 (45.6%)	43 (54.4%)	50 (63.3%)	16 (20.3%)	13 (16.5%)
ST	52 (78.8%)	14 (21.2%)	38 (57.6%)	9 (13.6%)	19 (28.8%)

Table 5: Distribution of ADU categories by genre and data split. Genre shows the distribution between editorials and debates; data split shows the distribution across training, development, and test with both genres combined.

Team	Affiliation	Task 1		Task 2	
		Closed	Open	Closed	Open
BME-Daleel	Budapest University of Technology and Economics	2 (71.17)	–	1 (75.47)	–
Durham-Jazan	Durham University; Jazan University; University of Waikato	5 (65.68)	1 (66.93)	6 (72.92)	1 (73.61)
NU_Analytics	Precision AI; Nile University; Helwan University	4 (67.14)	–	2 (75.23)	–
SalahAbdo	Independent researcher	1 (71.17)	–	5 (73.16)	–
TTLab	Text Technology Lab, Goethe University Frankfurt	6 (64.51)	–	3 (73.74)	–

REGLAT†	–	–	2 (59.13)	–	–
Baseline	–	11 (36.44)	3 (36.44)	9 (28.53)	2 (28.53)

Table 6: Daleel 2026 participating teams and the organizer baseline. Each result cell gives the official rank followed by the score in parentheses. Task 1 uses macro-F1; Task 2 uses modified overlap F1. Scores are reported on a 0–100 scale and rounded to two decimal places. A dash means that the team had no final ranked submission in that task and track. † No accompanying system paper was available.

MARBERTv2 with label-weighted focal loss. It used multilabel-stratified five-fold cross-validation, calibrated a threshold for each label, ensembled the folds, and added a lexical rule for Statistics. *Solodiscourse* (Hussain Usmani, 2026) added handcrafted lexical features to CAMeLBERT-Mix and combined focal loss with a five-fold ensemble.

LLMs played a larger role in three submissions. *SalahAbdo* (Ali Abdo, 2026) assigned different labels to different components: Gemma voting, a CAMeLBERT classifier, signals derived from Task 2, or a fixed prediction-count rule for Common Ground. An LLM also verified Statistics predictions. *NU_Analytics* (Ahmad Saeed Abdelaziz et al., 2026) compared joint label generation with Qwen3.5-9B and independent yes/no scoring with ALLaM-7B; its final submission used ALLaM-7B. *Durham-Jazan* (Saad Alshehri et al., 2026) split the task by genre, using Qwen3-32B for editorials and an encoder ensemble for debates. *BME-Daleel* (Mohaisen, 2026) fused probabilities from paragraph-level, lexical, and CRF-based components. *AIDAL-ARG* (Salas-Jimenez et al., 2026) compared multitask CAMeLBERT models with a two-stage BIO segmentation and classification pipeline; an LLM settled ambiguous label decisions.

Open track. *Durham-Jazan* (Saad Alshehri et al., 2026) added 291 synthetic paragraphs and fused its paragraph classifier with labels derived from Task 2 span predictions.

6.2 Task 2 Systems

Closed track. Most Task 2 systems used sequence labeling, often with a structured decoder. *BME-Daleel* (Mohaisen, 2026) combined several en-

coder and CRF sources, projected their token distributions onto a common grid, and applied constrained Viterbi decoding. *NU_Analytics* (Ahmad Saeed Abdelaziz et al., 2026) adapted AraBERT-large to the task, trained BIO-CRF models with boundary-jitter augmentation, and combined four seeds in character space. *TTLab* (Verma et al., 2026) placed a two-layer BiLSTM and constrained CRF above MARBERTv2. It averaged emissions from five folds before a single Viterbi decode. *RabeeQasem–ImpactAi* (Al-Qasem, 2026) used an AraBERT encoder with a Conformer tagging head, processed long paragraphs in overlapping windows, and post-processed the resulting spans. *Durham-Jazan* (Saad Alshehri et al., 2026) used separate genre branches: a CAMeLBERT ensemble for editorials and a MARBERTv2 ensemble for debates, followed by metric-aware span compaction. *SalahAbdo* (Ali Abdo, 2026) first asked an LLM for label–quotation pairs. The quotations were aligned with the paragraph, after which a classifier and Viterbi decoding revised their labels. *AIDAL-ARG*'s best official run was a genre-specific multi-task ensemble. A separate two-stage pipeline used an LLM only when label decisions were uncertain or inconsistent.

Open track. *Durham-Jazan* (Saad Alshehri et al., 2026) added 158 synthetic span paragraphs and blended character-level probabilities from its CAMeLBERT and MARBERTv2 branches.

7 Results and Discussion

The best-ranked run from every team outperformed the corresponding baseline. In Task 1 Closed, *SalahAbdo* and *BME-Daleel* had nearly identical scores: both round to 71.17, with *SalahAbdo* ranked first. Task 2 Closed was also close at the top; 2.55 separated first and sixth place.

Only *Durham-Jazan* has documented submissions in both tracks. *Durham-Jazan*'s Open runs scored 1.25 higher in Task 1 and 0.69 higher in Task 2 after the team added synthetic data and changed how the component outputs were combined. These changes were made together, so the gains cannot be attributed to either one. No other team provides a non-identical Closed–Open comparison.

7.1 Genre and Cross-Domain Effects

Every team scored better on debates than on editorials in its best Closed-track run. Averaged across the ten Task 1 and eight Task 2 runs, with each team counted once, the debate-minus-editorial difference was 18.8 and 12, respectively. The training split contains 357 debate paragraphs and 255 editorial paragraphs, and the label frequencies also differ between the two genres. We therefore cannot tell from these results alone whether the difference is due to genre, training size, label balance, or a combination of these factors.

Per-genre scores were not reported in all system papers, but the available results show the same pattern. In Task 1, *BME-Daleel* reported 62.39 on editorials and 77.78 on debates, *Durham-Jazan* 50.10 and 74.10 in the Closed track, and *NU_Analytics* 47.51 and 74.18. In Task 2, *BME-Daleel* reported 66.53 on editorials and 79.41 on debates, *Durham-Jazan* 61.00 and 76.20, *NU_Analytics* 64.17 and 79.31, and *TTLab* 63.56 and 77.84. These numbers cover only the teams that reported comparable per-genre results.

Some teams also submitted runs trained on both genres and runs trained on one genre only. Whenever both were available, the mixed-genre run had the highest overall score. *TTLab* showed this in both tasks. Its Task 1 score was 64.51 with mixed-genre training, 60.19 with debate training, and 54.65 with editorial training. The corresponding Task 2 scores were 73.74, 70.68, and 61.25. *Durham-Jazan* and *REGLAT* followed the same ordering in Task 1, as did *Solodiscourse* across its two submitted settings. These were not controlled comparisons, so we cannot attribute the higher scores to mixed-genre training alone.

7.2 Label and Span-Level Challenges

Common Ground was the one Task 1 label that several papers identified as especially difficult. *NU_Analytics* called it its hardest label. *AIDAL-ARG* reported zero F1 for all three variants in its development and test results, while *BURHAN* obtained 9.5 F1 on the official test set. *SalahAbdo* used a fixed prediction-count rule after its other detectors remained unreliable.

The difficulty appeared in encoder, LLM, and hybrid systems, so it is not confined to one model family. Its rarity and semantic overlap with Assumption are two possible reasons. Statistics was another label that teams handled separately, using lexical rules, targeted augmentation, oversampling, or LLM verification.

The available Task 2 analyses point to boundary errors, not only label errors. *BME-Daleel* exam-

ined 961 gold spans in the development set. Only 15.9% matched exactly; another 59.0% had the correct label but imperfect boundaries. *AIDAL-ARG* reported exact boundaries for 25.8–27.7% of its matched development spans. *NU_Analytics* found that missed spans were markedly shorter than matched spans. It also noted that about 1% of paragraphs contain overlapping gold spans, which a single BIO sequence cannot represent.

7.3 System Design Trends

Task 1 did not converge on one architecture. Some teams used encoder classifiers with weighted losses and calibrated thresholds. Others assigned labels to different LLM or rule-based components, or fused signals from paragraph, token, lexical, and cross-task models. Genre-aware routing and ensembling appeared in several systems.

The three highest-ranked documented Task 2 systems in the Closed track all used CRF or Viterbi decoding and combined multiple folds, seeds, or models. None of the documented LLM-based systems prompted the LLM to return free-form character offsets. *SalahAbdo* aligned generated quotations with the source text, *AIDAL-ARG* used the LLM only to settle label decisions, and *Durham-Jazan* reconstructed ordered labeled segments and obtained offsets from their concatenation. In these systems, the LLM supplied text or labels; alignment or structured decoding fixed the boundaries.

7.4 Generalization and Future Evaluation

More editorial training examples, especially for rare labels, would help test whether the gap comes from genre, sample size, or label balance. The current runs cannot separate these explanations.

Individual components are also hard to compare across papers because teams used different development splits, cross-validation setups, and model-selection procedures. *BURHAN*, for example, reported about 68 macro-F1 in internal cross-validation but 56 on the official test set. A shared held-out analysis split would make these comparisons more reliable.

For Task 2, evaluation should separate label and boundary errors. A single BIO sequence cannot represent overlapping spans, and *NU_Analytics* found that short spans were more likely to be missed. Future work should compare representations that allow overlapping spans with BIO tagging and report performance by span length. This would show whether a system chose the wrong label, the wrong boundary, or both.

8 Conclusion

Daleel 2026 provides the first benchmark for Arabic argument mining in news editorials and competitive debates. Twenty-nine teams registered, 12 took part, and 10 teams submitted system description papers. The submitted systems used different methods, and all performed better than the baseline. The results give initial reference scores for identifying ADU categories and locating their spans in Arabic text. We plan to extend the corpus with political speeches and annotate the argumentative relations between ADUs. The relation annotations will add another level to the current tasks by showing how the identified units are connected. The extended corpus may later support new Daleel shared tasks on relation identification and argument mining across genres.

Limitations

The Daleel corpus comprises 30 documents and 1,042 paragraphs. Although the documents contain many argumentative units, the dataset remains relatively small. The corpus also covers only news editorials and competitive debates, so the results may not generalize to other forms of argumentative discourse. Also, the texts are limited to Modern Standard Arabic and do not cover Arabic dialects or code-switched language. Some ADU categories have few examples. Common Ground was particularly difficult for several systems. The results for these categories should therefore be interpreted carefully and may change as more annotated data become available.

The debate data come from competitive tournaments, so the results may not generalize to other forms of spoken or dialogical argumentation. Some annotation decisions were also difficult, especially when deciding the exact span or label. Although these cases were adjudicated, the agreement scores show that the annotation is not always clear-cut.

The two genres also differ in the number of training paragraphs and in their label distributions, so the higher scores on debates cannot be attributed to genre alone. In Task 2, the overlap-based F1 combines span detection and labeling in one score, which makes it difficult to tell whether an error comes from the label, the span boundary, or both.

Acknowledgments

The organizers thank Ammar Al Sharaa, Hamzah Zaybak, Mohamed Albuainain, Nidal El Ibrik, Omar Akoum, and Rawan Herchi for their contribution to the annotation process. We also thank Roxanne El Baff for her contribution to the reviewing process, and QatarDebate Center for providing funding and resources for the shared task.

BME-DALEEL at Daleel 2026: Joint Modeling, Structured Decoding, and Domain-Routed Ensembles for Arabic Argument Units

Mohammed Mohaisen
Budapest University of Technology and Economics
mohaisen@mit.bme.hu

Abstract

We present BME-DALEEL, our system for both Daleel 2026 Arabic argumentative discourse mining tasks. A joint Transformer predicts paragraph-level label presence and token-level BIO states; constrained decoding and domain-routed ensembles map spans to original character coordinates. Repeated out-of-fold comparisons gate domain specialists, while routing selected decoded outputs preserves other-genre rows exactly. Using organizer annotations and public pretrained models, our Closed-track system scores 0.7117 macro-F1 for paragraph classification and 0.7547 modified F1 for span detection.

1 Introduction

Argument mining identifies units that express claims and evidence (Lawrence and Reed, 2019). Arabic remains comparatively under-resourced at this level; Daleel 2026 addresses this gap with Arabic newspaper editorials and competitive debates (Nabhani et al., 2026).

Our main challenge is to combine diverse encoders given 217 development paragraphs. We therefore admit sources, weights, and decoder biases only through repeated out-of-fold comparisons. The resulting system contributes (i) joint paragraph and span prediction with legal BIO transitions and deterministic reconstruction on original character offsets, (ii) validation-gated domain specialists, and (iii) post-decode routing with an exact branch non-interference invariant. Code and frozen configurations are public at `github.com/Mo7aisen/BME-Daleel-2026`.

2 Background: Task and Data

Daleel defines six discourse-unit labels: assumption (AS), anecdote (AN), statistics (ST), testimony (TE), common ground (CO), and other (OT). TASK 1 returns the labels present in a paragraph; TASK 2 returns labeled half-open character intervals. A synthetic quoted authority followed by an unsupported claim, for example, yields $\{\mathrm{TE}, \mathrm{AS}\}$ and spans such as $(\mathrm{TE}, [12, 41))$ and $(\mathrm{AS}, [45, 88))$.

We use only organizer train and development labels. Train contains 255 editorial and 357 debate paragraphs (2,975 spans), development 88 and 129 (961 spans), and hidden-label test input 87 and 126. Text is preserved without normalization, translation, or external segmentation. TASK 1 uses six-label macro-F1; TASK 2 uses released modified F1, with fractional precision and recall credit for same-label character overlap. This paper reports both tasks in the Closed resource setting.

3 Related Work

Arabic argument-mining resources include projected multilingual news annotations (Sliwa et al., 2018), the Munazarat debate corpus (Khader et al., 2024), a higher-level hybrid debate scheme (Al-Sharafi et al., 2025), and cross-lingual transfer from non-Arabic labels (Nabhani and Al Khatib, 2025). Daleel instead provides native, function-labeled character spans in two Arabic genres; we neither translate nor import labeled examples.

Joint global/local prediction pairs intent with slots (Zhang et al., 2019), sentence classes with definition spans (Pouran Ben Veyseh et al., 2020), and argument sequence labels with roles or relations (Stab and Gurevych, 2017; Eger et al., 2017). We add constrained decoding, validated encoder admission, and post-decode routing. The pool covers XLM-R (Conneau et al., 2020), MARBERT (Abdul-Mageed et al., 2021), CAMeLBERT (Inoue et al., 2021), mDeBERTaV3 (He et al., 2023), and JHU English–Arabic (Yarmohammadi et al., 2021).

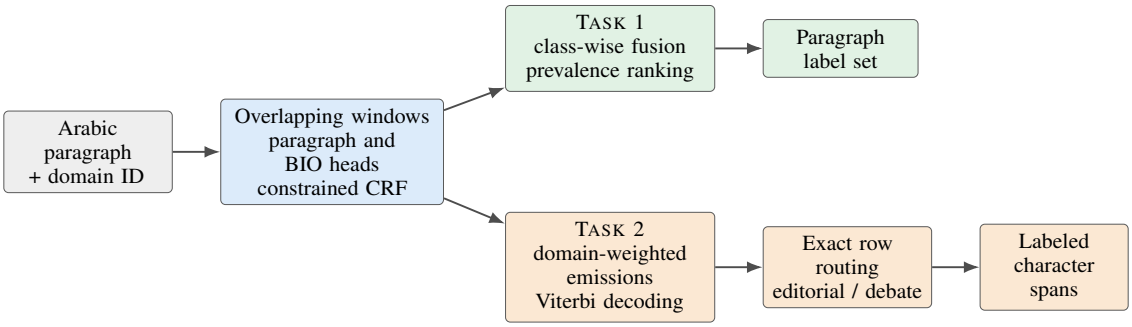

Figure 1: System overview. Training is joint; fusion, count selection, and final routing are domain-specific.

4 System Overview

Figure 1 summarizes the shared model and task-specific decision paths.

4.1 Joint paragraph and span model

Each fast tokenizer produces windows of at most 512 subwords with stride 96. Character offsets are retained, and token probabilities across overlapping windows are averaged with a symmetric linear distance-from-edge ramp. Gold spans map to O plus B/I states for the six labels. Where annotations overlap, BIO labels use fixed priority ST>CO>TE>AN>OT>AS.

A learned two-valued domain embedding is added to each Transformer representation h_i (Vaswani et al., 2017) and layer-normalized; three dropout views are averaged. The token head emits 13 BIO scores, while the paragraph head concatenates the first-token representation and masked mean pooling to predict six sigmoid probabilities. Initial loss is $\mathcal{L}_{\mathrm{CE}} + \lambda_p \mathcal{L}_{\mathrm{BCE}}$, with 0.02 token label smoothing and frequency weights. Selected models continue with a linear-chain CRF (Lafferty et al., 2001). Illegal starts and I-label transitions receive -10^4; structured loss is length-normalized CRF negative log likelihood plus $0.5\mathcal{L}_{\mathrm{CE}}$.

4.2 Task-specific fusion and routing

TASK 1 combines five probability sources: MARBERTv2 and XLM-R paragraph/token blends, a character/word TF–IDF logistic model, CRF-decoded presence, and maximum CRF marginal posterior. CRF-D/P derive from the XLM-R/CAMeLBERT/mDeBERTa CRF ensemble. Per-label convex weights and domain thresholds are fitted on repeated folds. Rows are ranked within domain and label, and the top k are selected from train+development prevalence.

Table 1 reports selected weights: CRF marginals receive high weight for rare ST, TE, and CO, while the lexical model contributes to AS and OT. For domain d with n_d test rows and label ℓ, we return the $k_{d\ell} = \mathrm{round}(n_d c_{d\ell}/N_d)$ highest probabilities, where $c_{d\ell}/N_d$ is the train+development occurrence rate. Thus prediction counts are set without hidden test labels.

Label	MAR	XLM	TF–IDF	CRF-D	CRF-P
AS	.1	.0	.4	.0	.5
AN	.2	.3	.0	.2	.3
ST	.1	.0	.0	.0	.9
TE	.3	.0	.0	.0	.7
CO	.0	.3	.0	.0	.7
OT	.0	.5	.4	.1	.0

Table 1: Final TASK 1 convex source weights. CRF-D is decoded presence; CRF-P is the marginal posterior.

For TASK 2, CAMeLBERT and mDeBERTa token distributions are projected to the XLM-R grid by character-overlap weighting, with XLM-R supplying CRF transitions. The base three-source mixture, ordered as XLM-R, CAMeLBERT, and mDeBERTa, uses weights $(0.8, 0.1, 0.1)$. Editorials add an XLM-R continuation directly as a fourth source with weights $(0.6, 0.1, 0.1, 0.2)$. Debates instead blend the base bundle at 0.8 with a JHU English–Arabic source at 0.2, giving effective four-source weights $(0.64, 0.08, 0.08, 0.20)$. After Viterbi decoding, editorial rows are copied from the frozen editorial branch and debate rows from the JHU-fused branch. No decode, presence filter, or span merge follows routing.

For target token interval I_t and source interval I_s, let $o_{ts} = |I_t \cap I_s|$. Source probabilities are projected as

$$\widetilde{p}_t = \frac{\sum_s o_{ts} p_s}{\sum_s o_{ts}}, \tag{1}$$

with the target distribution retained when the denominator is zero. Projection therefore supports differing tokenizer grids while preserving the primary

grid. Decoded BIO runs are mapped back through stored half-open offsets, trimmed only at whitespace and clause punctuation, and deduplicated in character order. "Character-exact reconstruction" means that each output is a direct slice of the original input; it does not claim exact agreement with gold boundaries.

4.3 Post-decode routing and non-interference

Let $\hat{y}_i^E$ and $\hat{y}_i^D$ be the already decoded editorial and debate branch outputs. Final routing is the deterministic operation

$$\hat{y}_i = \begin{cases} \hat{y}_i^E, & d_i = \text{editorial}, \\ \hat{y}_i^D, & d_i = \text{debate}. \end{cases} \tag{2}$$

This is not another soft ensemble: the chosen structured output is copied exactly. Consequently, admitting the debate specialist cannot change an editorial row, and vice versa. Routing thus preserves each selected branch's domain rows exactly and occurs after, rather than before, Viterbi decoding.

5 Experimental Setup

Table 2 identifies every final neural source. The full Hugging Face IDs are *FacebookAI/xlm-roberta-large*, *UBC-NLP/MARBERTv2*, *CAMeL-Lab/bert-base-arabic-camelbert-mix*, *microsoft/mdeberta-v3-base*, and *jhu-clsp/roberta-large-eng-ara-128k*. Full revision hashes and stage-specific settings are in the public configuration. The paragraph-loss coefficient λ_p is 0.7 for MARBERT, 0.6 for other initial fits, and 0.3 during CRF continuation.

All final neural models use AdamW (Loshchilov and Hutter, 2019), cosine decay, 0.05 warmup, weight decay 0.01, gradient clipping at 1.0, BF16, and deterministic seeds. Software is Python 3.11, PyTorch 2.4.1, Transformers 4.46.3, and scikit-learn 1.5.x. Training used one NVIDIA A100 40GB GPU on HUN-REN Cloud (Héder et al., 2022).

Three repeated balanced three-fold splits refit TASK 1 fusion and count selection. TASK 2 decoder fits use the same structure; the selected JHU weight is evaluated in 20 newly seeded three-fold repeats. No neural checkpoint is refitted inside these meta-level folds. After decisions are frozen, final checkpoints use train+development. Canonical JSONL, fixed ZIP timestamps, SHA-256 hashes, and fourteen tests verify all 213 test rows and a bit-for-bit archive rebuild. No external annotations, translation, pseudo-labels, or generated examples enter training.

6 Results and Analysis

Post-submission joint diagnostic. These organizer-development-set, pre-CRF XLM-R diagnostics share split and schedule, with the best development epoch selected separately per task ($n = 3$; mean±sample SD). For TASK 1, the joint model's tuned paragraph/token blend scores 0.7447 ± 0.0187 versus 0.6246 ± 0.0215 for the Task-1-only paragraph head; identical TASK 2 token decoding gives 0.6611 ± 0.0267 joint versus 0.6962 ± 0.0072 token-only. Paired differences are $+0.1201 \pm 0.0287$ and -0.0351 ± 0.0335. Because TASK 1 changes both loss and inference evidence, its delta describes a configuration rather than a causal joint-loss effect. Joint modeling is therefore not uniformly beneficial: under this development-selected setup, TASK 2 favors token-only training. This post-submission diagnostic did not alter official entries.

6.1 Out-of-fold comparisons

Table 3 reports repeated out-of-fold comparisons. CRF evidence raises TASK 1 macro-F1 within this procedure. For TASK 2, the frozen base mean is 0.7550 ± 0.0061 modified F1. The editorial continuation has mean paired changes of $+0.00348$ overall (17/20 positive) and $+0.01296$ editorial (18/20 positive), with debate unchanged. The JHU source then has mean paired changes of $+0.00791$ overall (19/20 positive) and $+0.01185$ debate (20/20 positive), with editorial unchanged. A proposed TASK 1 editorial replacement was rejected over 100 repeats (mean delta -0.00565, paired-bootstrap 95% CI $[-0.00730, -0.00398]$).

6.2 Official results

Table 4 gives the CodaBench scores for our Closed-track entries. Each task is reported once.

6.3 Error analysis

We descriptively audited stable full-development predictions; these are not untouched estimates. TASK 1 recovered the exact label set for 129/217 paragraphs, with 20 missed OT labels and 17 excess predictions each for AS and AN. For TASK 2, each gold independently takes the prediction with largest positive character intersection; ties take the lexicographically earliest (start, end, label). Matching is not one-to-one: one prediction may serve

Source (revision)	Final role	Initial epochs	Later epochs	Batch	Seed	Encoder / head learning rate
MARBERTv2 (`fe88db9`)	TASK 1	10	–	16	42	$2e{-}5/8e{-}5$
XLM-R-large (`c23d21b`)	Both	10	1 + 2 CRF	18	43/61	$1e{-}5/5e{-}5$; CRF $3e{-}6/3e{-}5 \rightarrow 2e{-}6/2e{-}5$
CAMeLBERT-mix (`9be3527`)	Both	11	4 CRF	16	55/62	$2e{-}5/8e{-}5$; CRF $3e{-}6/3e{-}5$
mDeBERTa-v3-base (`a048466`)	Both	8	2 CRF	16–20	44/64	$2e{-}5/8e{-}5$; CRF $3e{-}6/3e{-}5$
XLM-R editorial	TASK 2	–	4 continuation	18	92	$1e{-}6/1e{-}5$
JHU English–Arabic (`c1a082e`)	TASK 2	10	1 + 2 CRF; 4 refit	18	93/94	$1e{-}5/5e{-}5$; final $1e{-}6/1e{-}5$

Table 2: Training schedules. Batch is effective batch size; revisions are Git commit prefixes.

System	Overall	Editorial	Debate
TASK 1 base (3 sources)	0.7052	0.6811	0.7157
+ decoded CRF presence	0.7085	0.6879	0.7097
+ CRF marginal posterior	**0.7189**	**0.6908**	**0.7225**
TASK 2 frozen ensemble	0.7543	0.6980	0.7762
+ JHU debate source (0.20)	**0.7622**	0.6980	**0.7880**

Table 3: Repeated out-of-fold F1: 3×3 for TASK 1 and 20 newly seeded three-fold repeats for the JHU comparison.

Task	Track	Overall	Editorial	Debate
TASK 1	Closed	0.7117	0.6239	0.7778
TASK 2	Closed	0.7547	0.6653	0.7941

Table 4: Closed-track test scores for the submitted system.

multiple gold spans. Of 961 gold spans, 153 are exact (15.9%), 567 have the same label but wrong boundaries (59.0%), 236 substitute a label (24.6%), and five have no predicted overlap (0.5%). Table 5 shows that AN→AS, OT→AS, and TE→AS are most frequent. Under this diagnostic, boundary-only mismatches are more frequent than label substitutions.

One paraphrased debate error expanded a 39-character anecdote into a 313-character AN span. Three of five nonoverlapping OT units were only 4–12 characters long, suggesting split/merge and short-unit modeling.

7 Limitations and Ethical Considerations

Only 47 ST and 66 CO spans occur in train+development, leaving rare-label estimates unstable. BIO cannot represent nested units; character projection can blur boundaries; prevalence ranking assumes limited shift. Full-refit checkpoints lack untouched development estimates, so evidence comes from pre-refit comparisons. Labels describe discourse function—not truth, intent, or credibility—and must not be used to judge speakers. We add no personal data, external annotation, generated examples, or hidden test references.

Gold \ predicted	AS	AN	TE	OT
AS	–	19	16	7
AN	51	–	16	1
ST	3	1	5	0
TE	47	0	–	2
CO	12	2	1	0
OT	50	0	3	–

Table 5: Development label substitutions for maximum-overlap pairs; no mismatch was predicted as ST or CO.

Use of AI tools. Generative AI tools assisted with early outlining, software development, and language editing, but supplied no annotations or hidden test references. The author made all experimental and system-selection decisions, ran or supervised experiments, verified every reported value against saved artifacts, edited the manuscript, and takes full responsibility.

8 Conclusion

BME-DALEEL combines joint paragraph/span prediction and constrained decoding with validation-gated specialists. Post-decode routing preserves the selected domain outputs exactly. The frozen system attained the reported official scores; future work should model overlap, short units, and rare-label count selection without test feedback.

Acknowledgments. We thank the Daleel organizers and are grateful for the possibility to use HUN-REN Cloud, which supported the reported results (Héder et al., 2022).

TTLab at Daleel 2026: STAR-Ar, Sequence Tagging for Argument Recognition in Arabic

Bhuvanesh Verma, Ali Abusaleh, Alexander Mehler
Text Technology Lab (TTLab),
Goethe University Frankfurt
{verma,a.abusaleh,mehler}@em.uni-frankfurt.de

Abstract

Argument Mining (AM) is a critical NLP task that remains significantly under-resourced in Arabic. This paper presents STAR-Ar, a BERT-BiLSTM-CRF architecture for argument discourse detection and classification, as our system for Daleel 2026, the inaugural Arabic argument mining shared task. The task requires the identification and classification of argumentative discourse units (ADUs) in debate and editorial texts. We jointly model these two objectives as a token-level sequence labeling task using a BERT-BiLSTM-CRF architecture that combines contextual transformer embeddings with structural transition constraints to support accurate span detection. STAR-Ar achieves an F1-score of 72.69 on validation and 73.7 on test data. Our domain-specific analysis shows that models trained exclusively on editorials underperform those trained on debates, a disparity we primarily attribute to the smaller size of the editorial dataset. The code for STAR-Ar is available at TTLab at Daleel 2026

1 Introduction

Argument Mining (AM) is the automated extraction of argumentative structures and reasoning from natural language, with extensive applications across legal analysis, scientific literature, and public debates (Lawrence and Reed, 2019). While various theoretical frameworks govern AM research (Teufel, 1999; Walton et al., 2008), the Toulmin Model of Argument (Toulmin, 1958) remains a foundational paradigm. In this model, the primary components are claims, premises, and warrants, with the extraction of claims and premises serving as the primary objective for most modern AM systems.

The fundamental building block in these systems is the Argumentative Discourse Unit (ADU), a term formalized by Peldszus and Stede (2013) to describe the minimal atomic text span of an argument. An ADU can vary significantly in length, ranging from a short dependent clause to several consecutive sentences. Consequently, argument extraction inherently requires both precise boundary detection, identifying the exact span of the ADU within a broader text, and subsequent classification to assign that span to a specific argumentative function (e.g., distinguishing between an author's own claim and a background claim in scientific literature).

Despite significant algorithmic advancements, the vast majority of AM research has been strictly restricted to the English language. Addressing this critical linguistic gap, the Daleel 2026 shared task (Nabhani et al., 2026) introduces a pioneering benchmark for Argument Discourse Mining in Arabic. The shared task is divided into two distinct but related challenges operating over the same text: Task 1 requires paragraph-level multi-label classification to identify all ADU types present within a given text, while Task 2 demands precise token-level span detection and classification of those ADUs. We focus only on Task 2 and utilize a sequence tagging architecture. We employ a span-based classification approach inspired by Binder et al. (2022) to directly extract and classify ADU boundaries using contextualized representations from a pre-trained Arabic language model. Instead of building a complex system for a severely under-resourced and imbalanced dataset, we estbalished a highly stable, mathematically constrained baseline. Our proposed system, STAR-Ar, demonstrates robust cross-domain performance on both debate and editorial texts, ultimately achieving 3rd rank among 14 participating teams in the final Daleel 2026 shared task evaluation.

The paper is organized as follows: Section 2 provides the task description, dataset detail, and related work. Section 3 provides the details regarding the proposed system architecture. In Section 4, we present the experimental setup for the shared task. Section 5 provides a comprehensive analy-

sis of our experimental results alongside ablation studies. Finally, Section 6 concludes the paper.

2 Background

Argument mining (AM) focuses on automatically identifying and extracting reasoning structures from natural language, typically through sentence-level classification or span-level sequence tagging paradigms. Although this task have been widely studied in English, Arabic remains under-resourced. To this end, the Daleel 2026 introduced two shared tasks which focuses on the identification and classification of argumentative discourse units (ADUs) in Arabic Text.

2.1 Task 1: ADU Paragraph Classification

Task 1 is a multi-label classification challenge. Given a paragraph, the system must predict the presence of one or more ADU classes: *Common ground*, *Assumption*, *Testimony*, *Statistics*, *Anecdote* and *Other*. The training labels exhibit strong class imbalance; for instance, *Assumption* is the most frequent label (appearing in 75.5% of training paragraphs), while *Statistics* is the rarest (4.6%). On average, each paragraph is annotated with 2.0 labels.

2.2 Task 2: ADU Span Detection

Task 2 is a token-level sequence tagging task. Given a paragraph, systems must identify the exact character span of an ADU and classify it into its corresponding class. A single text can contain multiple ADU spans of the same or different classes. The training set consists of 2,975 ground-truth spans with exceptionally dense coverage, 84.6% of training paragraphs have between 80% and 100% of their text volume bound to a labeled span.

The dataset for the shared tasks is partitioned into a training set ($n = 612$), a development set ($n = 217$) and a final evaluation test set ($n = 213$). All splits share highly consistent domain distributions. However, distribution of labels although fairly consistent but highly skewed in both train and dev set. Common grounds and Statistics have the least amount of data instances (see Table 1).

We worked exclusively with task 2 under closed track rules which is essentially a sequence tagging task. Early sequence-based methods in argument mining used conditional random fields (CRFs) over BIO-encoded tokens to identify premises (Goudas et al., 2014). This approach was later extended to the joint extraction of major claims, claims, and premises from text (Stab and Gurevych, 2017). To capture complex long-range sequential dependencies more effectively, modern systems use deep learning and contextualized language models for end-to-end span extraction. Eger et al. (2017) advanced neural end-to-end argument mining by investigating BiLSTM-CRF sequence tagging models for identifying exact argument boundaries. Building on this line of work, Binder et al. (2022) introduced a BERT-BiLSTM-CRF architec-

Split	Genre	Paragraphs	AS	OT	AN	TE	CO	ST
Train	Overall	612	462 (75.5%)	222 (36.3%)	182 (29.7%)	160 (26.1%)	36 (5.9%)	28 (4.6%)
	Debate	357	287 (80.4%)	202 (56.6%)	69 (19.3%)	100 (28.0%)	22 (6.2%)	6 (1.7%)
	Editorial	255	175 (68.6%)	20 (7.8%)	113 (44.3%)	60 (23.5%)	14 (5.5%)	22 (8.6%)
Dev	Overall	217	157 (72.4%)	63 (29.0%)	68 (31.3%)	76 (35.0%)	12 (5.5%)	9 (4.1%)
	Debate	129	106 (82.2%)	52 (40.3%)	33 (25.6%)	43 (33.3%)	7 (5.4%)	1 (0.8%)
	Editorial	88	51 (58.0%)	11 (12.5%)	35 (39.8%)	33 (37.5%)	5 (5.7%)	8 (9.1%)

Table 1: Paragraph-level label coverage in the Daleel 2026 dataset. Each value reports the number and percentage of paragraphs containing at least one span of the corresponding label. Percentages are computed with respect to the number of paragraphs in each row and do not sum to 100% because a paragraph may contain multiple labels.

ture for identifying and classifying scientific argumentative discourse units (ADUs). Because the Daleel 2026 shared task requires precise extraction and classification of ADUs within Arabic texts, the framework established by Binder et al. (2022) serves as the foundational basis for our methodology.

3 System Overview

To account for the highly imbalanced and structured nature of ADU detection and classification, we formulate the problem as a sequence tagging task using a BIO (begin, inside, outside) tagging scheme. For this task, we propose `STAR-Ar`, a pretrained transformer architecture augmented with a recurrent layer and a structured prediction head.

3.1 Model Architecture

The core architecture uses a BERT-based text encoder pre-trained on Arabic corpora to extract contextualized representations of the input sequence. To capture longer-range dependencies and sequential argumentative structures, the transformer's final hidden states are passed to a bidirectional long short-term memory (BiLSTM) network. A linear classifier then projects the BiLSTM outputs into the BIO-encoded label space, producing emission scores. Finally, a conditional random field (CRF) layer is applied on top of these emission scores. To guarantee the structural validity of the predicted boundaries, we explicitly initialize the CRF transition matrix to heavily penalize invalid BIO sequences. Invalid paths such as sequence initializations starting directly with an `I`-tag, `O` $\rightarrow$ `I` transitions, and cross-label continuations (e.g., `B-AS` $\rightarrow$ `I-TE`), are assigned a mathematically prohibitive transition score (-10000.0). This strictly forces the Viterbi decoder to output structurally coherent label sequences.

3.2 Optimization and Loss Formulation

To directly counteract the severe class imbalance and density of the dataset, STAR-Ar bypasses standard uniform optimization in favor of a custom, cost-sensitive composite loss formulation. The primary objective is the negative log-likelihood of the CRF sequence (L_{CRF}). We supplement this with an auxiliary token-level Cross-Entropy loss (L_{CE}) applied directly to the BiLSTM emissions. The CE loss utilizes inverse-square-root class weights, with the *O* tag weight capped at 0.3 to prevent it from overwhelming the ADU classes. The final loss is defined as:

$$L_{total} = L_{CRF} + \lambda_{aux} L_{CE}$$

where λ_{aux} is an auxiliary weighting parameter.

4 Experimental Setup

To ensure robust evaluation and generalization, we utilize a 5-fold stratified cross-validation strategy. Stratification is based on the least frequent label present within a document to guarantee that rare classes are distributed evenly across folds. During training, we apply a weighted random sampler at the document level to over-sample paragraphs containing minority ADU classes.

To determine the optimal contextual representation for this task, we evaluated three distinct pretrained Arabic text encoders. We found `MARBERTv2` consistently outperformed both `AraBERT` variants across multi seed experiments, so we used `MARBERTv2` as text encoder for the final system (see Appendix A). Regarding other hyperparameters, we apply a transformer dropout rate of 0.1, and the two-layer BiLSTM utilizes a hidden size of 256 per direction. The network is optimized using AdamW for up to 20 epochs with a patience of 5 epochs for early stopping. We employ differential learning rates: 2×10^{-5} for the BERT encoder and 1×10^{-3}

Split	Evaluation	Editorial	Debate	Both
Dev	Editorial	60.80	51.30	**66.52**
	Debate	58.28	**75.29**	75.04
	Both	60.15	69.25	**72.69**
Test	Editorial	62.35	54.52	**63.56**
	Debate	60.07	76.17	**77.84**
	Both	61.25	70.68	**73.74**

Table 2: F1-score (%) for evaluation on the Daleel development and test sets. Columns denote the training domain, while rows denote the evaluation split and domain.

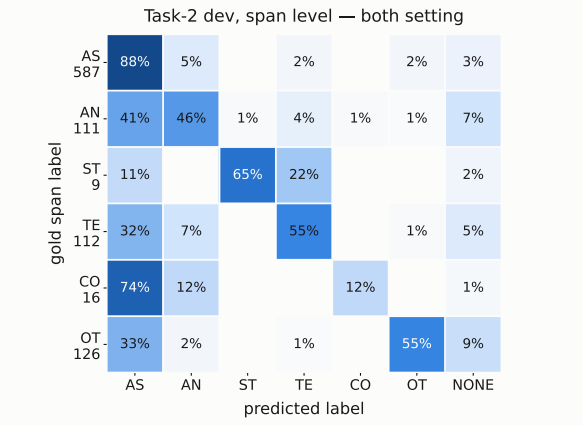

Figure 2: Cross-domain span-level confusion matrix. Rows are gold classes; cells show mean character-wise overlap with predictions. The diagonal represents span-level recall; 'NONE' captures false negatives.

for the randomly initialized top layers (BiLSTM, CRF, and linear heads), alongside a linear learning rate scheduler with a 10% warm-up phase and gradient clipping at 1.0.

The final system for test evaluation is trained with both train and dev set using same 5-fold stratifed cross validation strategy. For predictions, we leverage an ensembling technique at the emission level. Rather than applying majority voting to the final decoded label sequences, we compute token-wise averages of the raw CRF emission probabilities across all trained folds and perform a single Viterbi decoding step on the averaged emissions to produce the final predicted spans.

5 Results and Discussion

Table 2 presents STAR-Ar's performance on the development set as well as test set for Task 2. Overall, we see model performing better on test set which is likely because we added development data to train the final system. Furthermore, we observe that the model trained on both domains performs better on debates than on editorials which is understandable given the distribution of data across domains. Training on debate domain alone yields performance close to training on the both domains, suggesting that debate data captures many of the linguistic patterns needed for ADU identification. On the other hand, models trained only on editorials benefit more from incorporating debate data, likely because the editorial subset is smaller and exhibits greater label imbalance. Consequently, the additional debate examples provide useful supervision that improves generalization to editorials.

As detailed in Table 1, the dataset exhibits severe class imbalance. To evaluate the system's span-level boundary resolution across these skewed distributions, we analyze the character-overlap confusion matrix in Figure 2. Overall, the model exhibits a strong predictive bias toward the majority class, Assumption (AS). While AS achieves the highest recall (88.49%), the model systematically overpredicts this label across all other categories. This absorption effect is most severe for Common ground (CO), where 74.22% of gold characters are erroneously captured by AS predictions, reducing CO's recall to just 12.26%. Mid-frequency classes such as Anecdote (AN), Testimony (TE), and Other (OT) demonstrate moderate robustness, maintaining recall rates between 45% and 55%. However, they still lose a substantial portion of their span volume (ranging from 31% to 40%) to the majority AS class. Interestingly, despite being the rarest class, Statistics (ST) performs robustly as the second-best category with a recall of 64.77%. Because its explicit quantitative surface features provide a highly separable linguistic signal, it largely resists absorption into the majority class, with its primary misclassifications splitting between TE (22.06%) and AS (11.11%).

6 Conclusion

In this work, we present **STAR-Ar**, a BERT-BiLSTM-CRF framework tailored for argumentative discourse unit (ADU) extraction and classification in Arabic. On the shared task final test set, our system achieved a F_1 score of 73.74 on the both domain setting, ranking 3rd out of 14 participating teams. Our findings demonstrate that sequence labeling remains a competitive, highly efficient paradigm for joint span detection and classification in argument mining. Qualitative analysis reveals that while class re-balancing yields non-

uniform performance gains, label frequency alone fails to predict class-wise difficulty. Finally, cross-domain evaluations indicate a high sensitivity to domain shifts, highlighting the necessity for larger, more structurally diverse annotated corpora to further advance Arabic argument mining.

Limitations

We used small language models with 512-subword limit which truncates the long inputs. Although we verified that it affect negligible portion of the dataset (1.14% in train, 0.46% in dev and 0.47% in test), but it still constrains applicability of our system to longer documents. Another limitation of this work is its generalization capabilities across other Arabic text types and dialectical variations.

A Encoder Comparison

In order to decide which encoder is best for our system, we performed multi seed experiment using three different Arabic encoders. We ran same 5 fold stratified cross validation on train set across three different seeds to obtain results shown in Table 3.

Encoder Model	**Task 2 Overall F_1 (%)**
AraBERTv02-Twitter-b	63.75 ± 0.43
AraBERTv02-Twitter-l	65.82 ± 2.17
MARBERTv2	67.53 ± 1.53

Table 3: Ablation Study: Impact of different pre-trained text encoders on overall performance (models trained on the combined dataset).

B Paragraph Level Error Analysis

To evaluate the efficacy of our proposed system for the class imbalance, we analyze the development set confusion matrix (Figure 3). Overall, the model robustly identifies the majority class, Assumption (AS), alongside mid-frequency classes, Testimony (TE) and Other (OT). Misclassifications among minority classes are predominantly driven by false negatives (omissions) rather than cross-label confusion. Specifically, Anecdote (AN) and Common ground (CO) are most frequently misclassified as None rather than assigned competing labels.

Despite being the rarest class, Statistics (ST) achieves 100% precision (recovering 6 of 9 instances without false positives), as its explicit quantitative surface features provide a highly separable signal that cost-sensitive weighting exploits.

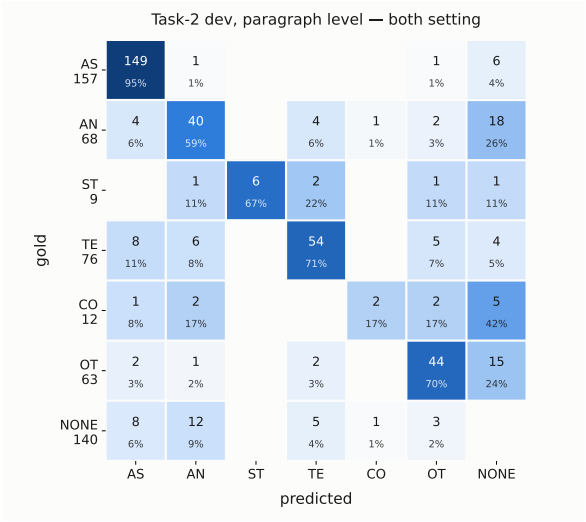

Figure 3: Paragraph-level dev-set heatmap (cross-domain trained). Rows list gold labels with paragraph support; the diagonal gives recall. Off-diagonal cells show spurious predictions on missed gold paragraphs.

Conversely, CO yields the lowest recall (2 of 12 instances), indicating that class-re-balancing techniques fail to surface minority classes that lack distinct lexical or structural cues. This pattern remains consistent in single-domain configurations, underscoring the necessity of multi-domain training which mitigates cross-domain sparsity by leveraging complementary label distributions.

SalahAbdo at Daleel 2026: Routing Each Label to LLM Votes, a Fine-Tuned Encoder, or Sequence Structure

Salah Abdo
Independent Researcher
salah.abdo.tech@gmail.com

Abstract

We describe the SalahAbdo closed-track systems for both Daleel 2026 subtasks: deciding which argumentative-unit types appear in an Arabic paragraph (Task 1) and locating their exact spans (Task 2), in editorials and debates. No single method was best for all six argumentative-unit types, so our Task 1 system routes each type to the method that measured best for it: assumption (AS), testimony (TE), and statistics (ST) are detected by sampling a `gemma-4-31b` classifier five times and firing when enough samples agree; anecdote (AN) and other (OT) by a fine-tuned CAMeL-BERT classifier; and the lowest-agreement type, common ground (CO), by ranking paragraphs and firing a fixed count. A final verifier shows the LLM examples of true and false ST paragraphs and removes likely false positives. Task 2 first extracts spans as verbatim LLM quotes, then re-labels them by blending encoder probabilities with label-sequence statistics under Viterbi decoding, with zero additional LLM calls. Every design change had to clear an adoption bar set before its result was read: 29 recorded decisions produced six adoptions, and composition arithmetic over already-scored legs predicted two development scores digit-for-digit. Development scores are 0.7089 macro-F_1 (Task 1) and 0.7247 span F_1 (Task 2); the pinned recipes scored 0.6499 and 0.7055 on test, and our final official submissions scored **0.712** and **0.7316**: **first of ten** and **fifth of eight** closed-track teams (§6 discloses the evaluation-phase protocol). Residual errors track the scheme's measured human agreement (κ as low as 0.114): types whose definitions a model can check against the text improved under LLM verification, while types defined by annotation convention resisted every prompting attack and were learned only from supervision and sequence structure.

1 Introduction

Argument mining is "the automatic identification and extraction of the structure of inference and reasoning expressed as arguments presented in natural language" (Lawrence and Reed, 2019). Daleel 2026 (Nabhani et al., 2026) asks for its first two steps (Peldszus and Stede, 2013) in Arabic: find the argumentative discourse units (ADUs) in a paragraph and decide which of six types each one is, in two genres. Prior Arabic resources target stance detection (Alhindi et al., 2021; Alturayeif et al., 2022) and debate component classification (Khader et al., 2024; Al-Zawqari et al., 2025), not this six-type evidence-unit scheme. The task is hard in a measurable way: whether a clause is *common ground* or an *assumption* is implicit content that, as Moens (2018) observes (quoted in the survey), "resides in the mind of communicator and audience." Even trained annotators agreed only slightly on such labels (κ=0.114; §2).

In this scheme, criteria can be checked; conventions cannot. Some Daleel labels are defined by criteria a model can *check* against the text: a statistics (ST) unit contains numbers or study results, a testimony (TE) unit attributes a statement to a source. Others are defined by conventions with no text-checkable rule to appeal to: whether shared background is common ground (CO) rather than an assumption (AS), or a settled event an anecdote (AN) rather than CO, is a line the annotation team drew. The distinction predicted our results: every LLM verification stage aimed at a checkable label worked, every prompting attack on a convention label failed, and convention labels entered the system only through a fine-tuned encoder and sequence structure.

Every change had to clear a bar set in advance. A change was adopted only if it beat a score bar fixed before its results existed, with the design and

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1310–1322
October 28-29, 2026 ©2026 Association for Computational Linguistics

both planned outcomes recorded in a ledger; failed changes were closed for good (§5; all twenty-nine in Appendix B). This caught two changes that looked good internally but failed externally, and predicted two development scores digit-for-digit (§6).

Contributions. (1) A Task 1 system that routes each label to the method that measured best for it, plus a verifier for the one label whose problem was precision (dev macro-F_1 0.6159 $\rightarrow$ 0.7089). (2) A Task 2 re-labeling stage that improves an LLM span pipeline by $+0.0400$ dev F_1 with no additional LLM calls, plus a placebo ablation separating structure's contribution from the encoder's. (3) A gated adoption methodology for shared-task conditions, publishing the gate registry, negative results, transfer ledger, and an analysis tying residual errors to measured human agreement and vote statistics. Code, prompts, scorer ports, and analysis artifacts: `https://github.com/Salah-Sal/daleel2026-salahabdo`.

2 Task, Data, and Measured Annotator Agreement

Setup. Daleel 2026 (Nabhani et al., 2026) provides Arabic paragraphs from two genres: news editorials and transcribed competitive debates (the Munazarat lineage; Khader et al., 2024; Al-Sharafi et al., 2025). Task 1 asks for the *set* of ADU types present in a paragraph (six labels, multi-label, empty sets legal); Task 2 asks for exact typed character spans. Example (editorial, translated): "Apple says privacy lies at the core of all its products, yet these products come at elevated prices" $\rightarrow$ Task 1 $\{\text{TE}, \text{CO}\}$; Task 2 a TE span over the Apple claim and a CO span over the pricing clause. Task 1 is scored by macro-F_1 over all six labels; Task 2 by a partial-match span F_1 in which each overlapping same-label (prediction, gold) pair adds overlap/len(prediction) to precision and overlap/len(gold) to recall (scorer ports parity-tested; Appendix D). The training release contains 612 paragraphs (357 debate, 255 editorial; 2,975 gold spans covering 91% of all text); the development input contains 217 and the test input 213 (126 debate, 87 editorial). Label priors are heavily skewed: AS appears in 75% of paragraphs, other (OT) 36%, AN 30%, TE 26%, CO 6%, ST 5%. For all 612 paragraphs the Task 1 label set equals the Task 2 span-label set, so one span model serves both tasks. We split the 612 training paragraphs into a 430-paragraph working pool (five genre-balanced folds; Appendix D) and a 182-paragraph held-out check. *Out-of-fold* (OOF) scoring fits on four folds and predicts the fifth. The first ten decisions (Appendix B) were gated on single-shot readouts of the 182; from row 11 on, design decisions used OOF scores on the 430 and the 182 was demoted to a sanity guard (§5).

The scheme and its measured agreement. The six types, common ground (CO), assumption (AS), testimony (TE), statistics (ST), anecdote (AN), other (OT), are those of the Webis-Editorials-16 annotation model (Al-Khatib et al., 2016), whose original annotation study *measured* per-type agreement (Fleiss' κ at segment level, before annotator judgments were merged into gold labels): from 0.613 for AS down to **0.114** for CO — slight agreement (Landis and Koch, 1977; Fleiss, 1971); full table in §C.1. Given one annotator chose CO, the probability another chose AS is 0.562, and CO/OT are also the rarest types in the source corpus (1.7%/1.2% of 14,313 units): low agreement and extreme rarity together bound what any system can learn. From those numbers we extrapolate a pooled Task 2 *reference point* of $\approx$0.75 and read residual errors against it: it is our estimate from a different corpus, language, and consolidation stage, not a published number and not a ceiling for Daleel.

3 Task 1: Routed Multi-Source Composition

No single method was best for all six labels (§6), so our final Task 1 system (**v2.2**) *routes* each label to the source that measured best for it, with every threshold fitted on training folds and applied to held-out folds (Table 1).

Sources. *(a) Self-consistency votes:* the frozen zero-shot chain-of-thought classifier (`gemma-4-31b-it`, winner of a pre-registered 14-model bake-off) is sampled k=5 times at T=0.7 (Wang et al., 2023); a label fires when at least θ_L of the five samples propose it (k=5 suffices: §C.2). *(b) Encoder:* CAMeLBERT-MSA-quarter (Inoue et al., 2021) fine-tuned to output a probability per label per paragraph (Appendix D), with decision thresholds fitted on OOF probabilities; the quarter-size variant was chosen in advance on external evidence (Al-Zawqari et al., 2025); the mix and DA variants scored higher encoder-only

Label	Source	Decision rule (deployment twin identical)	OOF F_1	Dev F_1
AS	LLM votes	fire iff $\geq \theta_{AS}=2$ of 5 rollout votes	0.9192	0.9046
TE	LLM votes	fire iff $\geq \theta_{TE}=4$ of 5	0.7782	0.8256
ST	votes + judge + verifier	fire iff $\geq \theta_{ST}=4$ of 5; drop iff a zero-shot $T=0$ judge says absent; then drop iff verifier says absent *and* a second-family model omits ST	0.7826	0.8421
AN	encoder ∪ spans	encoder OOF decision ∪ (span-derived AN ∧ votes ≥ 1)	0.7243	0.6309
OT	encoder	encoder OOF decision, as-is	0.7744	0.7344
CO	budgeted rank	top $2\times$ prior per fold by rank-mean(encoder sigmoid, vote fraction, span presence)	0.4000	0.3158
macro			0.7298	**0.7089**

Table 1: The v2.2 Task 1 router. "Votes" = $k=5$, $T=0.7$ rollouts of the frozen zero-shot `gemma-4-31b` classifier; encoder = CAMeLBERT-MSA-quarter (5-fold OOF); "spans" = Task 2 label sets; Dev = the final submission's development scores.

OOF (five-seed means 0.625 and 0.628 vs. 0.610) but stayed excluded ex ante, and mix lost a composed dev probe (row 13). *(c) Span-derived labels:* the Task 2 pipeline's label sets, used only in the AN union rule and the CO ranker.

The ST verifier. An OOF error audit showed ST recall already at 0.947 (18 of 19 golds found) while 19 of 37 fired paragraphs were false positives: a pure precision problem. A first filter, adopted with row 14, re-asks the same model at $T=0$ whether each fired paragraph contains ST and drops the label where it says absent (OOF ST F_1 0.5902 → 0.6429, dev 0.6923 → 0.7619; the counts above include it). The verifier then shows the LLM what true and false ST paragraphs look like: for a fired paragraph, its prompt holds the official definition plus all gold-ST paragraphs and all fired false positives from the *other* folds (∼15 each) as labeled examples; three samples at $T=0.7$ vote. A paragraph is dropped only if the verifier majority says absent *and* an independent model family (qwen3-32b or llama-3.3-70b) also omits ST — a two-key rule. On OOF it dropped 10 paragraphs, all false positives (ST F_1 0.6429 → 0.7826); on dev it dropped 2, again both false positives (0.7619 → 0.8421). The question is checkable, so verification transfers.

The CO budget. Nothing we tried could actually detect CO (§C.1), and for a label this uncertain, over-predicting is exactly what macro-F_1 rewards (Lipton et al., 2014). So we control how *much* fires rather than *what*: paragraphs are ranked by the mean rank of three signals (encoder probability, vote fraction, span presence), and the top $2\times$ training-frequency count is fired — a count, unlike a threshold, stays stable when scores drift across datasets (cf. Lin and Lin, 2023). On test the count held at 25 while gold CO fell to 10 of 213 paragraphs and F_1 to 0.1143 (§C.3): a count is only as stable as the prior behind it.

4 Task 2: Span Pipeline + Structural Re-Decode

v3: proposal → atom → role. LLMs are unreliable at character arithmetic, so the model never outputs offsets: the extraction stage asks for (label, *verbatim quote*) pairs, and a staged aligner locates each quote in the paragraph (exact, whitespace-tolerant, orthography-normalized, then fuzzy; re-aligning gold spans' own text scores F_1 0.999). The extracted text is then split at clause boundaries and connectives, and a classifier (SPANROLEDECISION) labels each piece with one of the six types or NONE; its prompt comes from the campaign's only adopted prompt-optimizer compile (GEPA (Agrawal et al., 2026) under DSPy (Khattab et al., 2024); selection never saw the scored fold): the five outer-fold compiles selected rewritten instructions, while the final compile on all 430, the deployed one, retained the unmodified seed instruction (candidate 0, no demonstrations). Extraction misses little: at most 4.2% of any label's gold mass falls outside every predicted span, so residual Task 2 error is overwhelmingly mislabeling of correctly extracted text.

S1: the structural re-decode. v3 labels each extracted span *independently*, yet gold labels are strongly sequential: an AN span follows another AN 39% of the time, against an 11.5% base rate. S1 therefore re-labels each paragraph's span sequence in five frozen steps: (1) a fine-tuned CAMeLBERT segment classifier gives each span a probability distribution over the six labels; (2) each label's probability is rescaled by the ratio (gold share of text) / (expected share under the encoder) — the $\tau=1$ point of logit adjustment (Menon et al., 2021); (3) each span's evidence is $p = (1-\lambda)\, p_{\text{enc}} + \lambda\, \text{onehot}(\text{v3 label})$, $\lambda=0.9$: the v3 label keeps most of the weight; (4) Viterbi decoding (Viterbi, 1967) picks the most probable label sequence under genre-specific transition ma-

trices estimated on training folds (Laplace α=1); (5) Rule-A: a decoded CO span must also appear in an independent zero-shot run, else it takes that run's dominant label. Everything is fitted per fold, and the bundle changes only labels, never boundaries, so segmentation credit is preserved by construction (Widmoser et al., 2021).

What S1 fixed. OOF pooled F_1 moved 0.6934 $\rightarrow$ 0.7206 ($+0.0272$, better on all 5 folds), changing 237 of 3,824 span labels. A *placebo ablation* — the identical decode with the encoder replaced by uniform distributions — scores 0.7133: structure alone contributes $\sim+0.02$ (Rule-A $+0.014$ of it, the sequence and label-mass priors the rest), encoder evidence the remaining $+0.0073$ (cf. the ¬DAPT control of Gururangan et al., 2020); Table 8 removes each step in turn and shows the shares interact. What the decode repairs is over-prediction of rare labels: predicted CO text fell from $3.98\times$ the gold amount to $1.78\times$ and ST from $1.38\times$ to $1.07\times$. The declared limit: predicted AN text sits at $0.48\times$ gold before and $0.49\times$ after: most gold AN text lies inside larger spans of another label, which re-labeling cannot split.

5 Adoption Discipline

Register, then run. Each candidate change was written into the ledger before its gate ran: design, grid, baseline, and both planned outcomes. Not all 29 decisions carry the same evidence, so we separate them rather than call them all preregistered. *Ten* (rows 1–10) predate the ledger convention and are documented only in the campaign reports. *Nine* have design and verdict in one commit or one same-day batch, so precedence over the run rests on the ledger's contemporaneous text and not on git order; they are daggered in Appendix B. *Ten* have a registration commit that precedes the run (rows 13, 19, and 22–29, the S1 adoption among them; from row 24 on each gate's config file also names its registration commit), so git order itself records that the plan came first. The six adoptions divide two, three, and one across those groups. Commit dates are author-set and the repository was published after the campaign, so the external anchors are the Codabench submission ids and timestamps. This is *preregistration* in intent, self-attested in practice: committing to the plan before the results exist (van Miltenburg et al., 2021).

The gate. A change is adopted only if the composed system's OOF score improves by at least $+0.02$ on the official metric *and* wins on at least 3 of the 5 folds. The margin tracks measured noise (identical LLM configurations rerun at ±0.03–0.04; estimated composed-OOF band $\sigma\approx0.015$); smaller gains are indistinguishable from it. The fold rule blocks adopting a spike on one lucky fold (CO has 25 positives, ST 19). Every gate run recomputes its baseline from identical inputs and aborts on mismatch; a rejected family closes permanently (a banked near-miss re-gates once, free, on cached artifacts when its baseline moves, as pre-registered; row 19): 29 decisions, six adoptions, no family reopened after rejection.

One bundled probe; external checks are sacred. Each adopted system earned one development-set submission (rows 12, 14, 21 for Task 1; 9, 24 for Task 2), plus a stage-0 baseline upload and the two reverts below; no threshold or rule was fitted to a leaderboard score during development, though the tier-1 routing table (row 12) also consulted the first submission's per-label scores, which the OOF per-label scores reproduce. Two failures justify the rule: an encoder swap that won a 4-way internal comparison collapsed on dev ($0.6955\rightarrow0.6364$), and a recomposed OT source reversed (-0.10 on its label); both were reverted to the previously gated leg. The 182-paragraph check failed as a predictor too: its champion readout, the maximum of a 14-model bake-off that re-scored 0.6613 on the same paragraphs, missed dev by -0.087 (selection optimism plus provider noise), so composed OOF on the 430 became the honest predictor.

Exact composition arithmetic. Macro-F_1 averages six per-label scores and the router decides each label independently, so swapping one label's source moves the system score by an exactly computable amount. This let us *predict* development scores: v2.1 (six already-scored legs re-averaged) and v2.2 (five scored legs plus a forecast for the new ST leg, recorded before upload) were predicted 0.6955 and 0.7089, and scored exactly that (Table 6).

6 Results

Tables 6 and 7 give the transfer ledger and progression; adopted changes transferred, S1's dev gain ($+0.0400$) *exceeding* its OOF gain ($+0.0272$). On test (213 paragraphs) the pinned recipes scored

0.6499 and 0.7055, the Task 2 move from dev (-0.019) inside the noise band. The Task 1 drop (-0.059) decomposes by label, not by system: AS, ST and OT improved on test, while the loss concentrates where frozen operating points met a shifted test set (CO, TE, AN); Appendix C decomposes both.

Evaluation-phase protocol (post-freeze, disclosed). When the organizers released the development gold labels and extended the deadline, we waived our own freeze for that window and ran one time-boxed, leaderboard-informed campaign: four probes per task in one evening plus two closing Task 2 uploads (legs and their fitting data in Table 2). Per-label scorer feedback moved the AS, TE, AN, and CO sourcing decisions across probes (Task 1 0.6499 $\rightarrow$ 0.712; Task 2 0.7055 $\rightarrow$ 0.7316, via span-drop filters keyed to Task 1 labels and encoder probabilities). The scorer log returned, per upload, per-label F_1 and the number of test paragraphs carrying each label; probes 2–4 set the editorial AN threshold and the CO budgets against those counts. The probes also re-used two gate-rejected families: span-sourced TE (row 10) and a five-seed encoder ensemble for the AN and CO legs (row 27), built from four encoder deployments trained that evening; the ensemble the gate had rejected at $+0.014$ OOF added $+0.034$ on test. Two stronger configurations missed the board through operational error (Appendix A). In the organizers' final standings (rankings sheet of 2026-08-11) we place **first of ten** closed-track teams on Task 1 and **fifth of eight** on Task 2 (leader 0.755). Our Task 1 lead is 3×10^{-5}, far inside our own noise band: we read the top two as tied. We report these gains separately: our methodological claims rest on the gated development phase, not the probe campaign. The gate refuses gains it cannot tell from noise on 430 paragraphs; a leaderboard with per-label feedback resolves some of them, which is why the probes beat the frozen recipes and why their gains are not evidence for the methodology.

Analysis. Appendix C develops it: prompting fails on convention labels while verification transfers on checkable ones (§C.1); $k{=}5$ votes suffice and rare-label operating points sit on needles (§C.2); S1's residual mirrors the human confusion matrix (§C.3). Paid API spend was ≈US$60 (Dodge et al., 2019).

7 Conclusion

Both systems place every component where measured evidence routed it, and every adoption cleared a pre-declared gate; the ranks matter less than the ledger behind them. Two sets of scores should not be conflated: the gated systems, frozen before we saw the test input, scored 0.6499 and 0.7055, and they are what the methodology claims; the 0.712 and 0.7316 we placed with came from the disclosed leaderboard-informed campaign that followed the freeze, and we claim them as ranks, not as evidence. Near this scheme's measured agreement, *verification* helps where definitions are checkable, while convention labels move only under supervision, priors, and structure. The registry guards against the winner's curse; extraction is the unreached lever.

Limitations

All selection statistics rest on a 430-paragraph OOF pool with 25 CO and 19 ST positives; our estimated composed-OOF noise band is $\sigma{\approx}0.015$, and our $+0.02$ gate is calibrated to it, not to a universal standard. The $\approx$0.75 Task 2 reference point is our extrapolation from the source corpus's agreement study (a different language, granularity, and consolidation stage) and serves as an interpretive anchor, not a bound and not a ceiling for this dataset; the comparison with the human confusion matrix in §C.3 sets differently normalized quantities side by side, so it is directional, not exact. LLM legs depend on a specific serving stack: the same checkpoint scored 0.048 lower on a different provider and identical configurations rerun at $\pm$0.03–0.04; pinning the model route, caching artifacts, and count-based rare-label rules reduce but do not eliminate this risk (the upstream serving provider was not pinned; Appendix D). The ST verifier's exemplar block is label-sorted, which long-context evidence suggests is suboptimal (Bertsch et al., 2024); the recipe was dev-validated as-is. The TAPT (task-adaptive pretraining) measurement is single-seed. Our systems are tuned to this scheme's conventions by design; we make no claim that the specific routing transfers to other argument-annotation schemes ("each data set appears to conceptualize claims quite differently," Daxenberger et al., 2017; Lawrence and Reed, 2019). The criteria/convention split is likewise a reading of *these* six labels under *these* prompts and models: we show it holds for

the four convention-directed attacks and the one criterion-directed verifier we ran, not that it partitions argument-annotation labels in general. The router's rule forms (the AN union, the OT source, the CO multiplier of 2) were chosen from pooled-OOF sweeps on the same 430 paragraphs that then gated them; only the thresholds inside them are cross-fitted, and the development submission was their sole external check. No confidence intervals accompany the adoptions; $\sigma \approx 0.015$ is an informal estimate from development-transfer residuals, not a bootstrap. Finally, the evaluation-phase probe campaign was leaderboard-informed (§6); we report it separately and do not claim its gains as evidence for the methodology.

A Closed-Track Disclosure

Per the task rules, all models, tools, prompts, and processing steps:

Models (all open-weight, $\leq$70B, licenses verified). `gemma-4-31b-it` (Gemma Team, Google DeepMind, 2026): every LLM stage (Task 1 classifier, quote proposals, role decisions, ST judge and verifier); Apache-2.0; served via OpenRouter (paid route pinned after free-route starvation); T=0 for reference/deploy runs, T=0.7 for rollouts; ChatAdapter with a deterministic retry ladder (a JSON-adapter failure mode on $\sim$2.8% of atom decisions was eliminated this way; a rare whitespace-flood degeneration on $\sim 1/430$ paragraphs, a ledger estimate, is contained as an empty prediction). Pretraining cutoff precedes the task's label release, so gold-label leakage is impossible; the underlying news/debate text may predate the cutoff. `qwen3-32b` (Qwen Team, 2025) and `llama-3.3-70b` (Llama Team, AI @ Meta, 2024): one zero-shot Task 1 run each, used only as the verifier's co-signal (and in rejected bundle experiments); T=0, which deviates from Qwen's recommended stochastic sampling; Arabic is not among Llama 3's officially supported languages: we use it only as a redundant negative signal; Llama 3.3 has no dedicated report, so we cite the herd paper, and the exact checkpoint is identified by its pinned route in the released configs. CAMeLBERT-MSA-quarter (Inoue et al., 2021), Apache-2.0, pinned to an immutable revision: Task 1 paragraph classifier and Task 2 segment classifier. DSPy 3.3.0b1 (Khattab et al., 2024); all six adopted GEPA role compiles (row 9, five cross-validation folds plus the deployed compile on all 430) used `gemma-4-31b-it` as their own reflection model, with no reflection-model override in any of their recorded invocations.

The one model outside the closed-track bar. `deepseek-v4-pro` (DeepSeek-AI, 2026) is the only model named in this paper that the closed track never admitted: at 1.6T parameters (49B activated) it is far above the track's 70B ceiling, so it was never eligible as a task model, and the script behind the adopted role compiles refuses a closed-track run whose task, prompt, or reflection model is unregistered or over that ceiling. It appears in this campaign only as the reflection model of three *rejected* optimizer compiles (rows 4, 5, and 8), whose verdict was to reject every optimizer and ship zero-shot seeds. Nothing it authored was deployed or submitted, and no reported score depends on it. GEPA reflection reads training-fold examples when it drafts candidate instructions, so during those rejected compiles it did see training-fold text; the claim above is about deployment, not exposure. No external labeled data; no dataset text in any committed artifact.

Components and their training data. Table 2 lists every stage of both systems, what supplies it, what it was fitted on, and whether it belongs to the pinned recipes, the evaluation-week probe entries, or both. Nothing in either system is trained on data other than the organizers' 612-paragraph training release: the 430-paragraph pool supplies every fitted quantity, the 182-paragraph split is a sanity guard, and the probe-only rows were set against per-label scorer feedback on the test input (§6), which is why they are marked as such.

Prompts. All prompts are audit-informed zero-shot seeds with the official label definitions in a single canonical phrasing (shared between programs and metric feedback); the ST verifier and rejected CO specialist add fold-external labeled exemplars as described in the text. Verbatim zero-shot prompt texts ship in the released repository (see §1); the deployed Task 2 role instruction is the seed docstring in the released source (§4), while the compiled state's demonstration-selector memory holds dataset text and is not distributed (a rerun rebuilds it).

Evaluation-phase upload record (§6). The rules allow unlimited uploads and score the last one pushed. Stronger configurations missed the leaderboard on both tasks. Our final Task 1 package (predicted 0.7182 by the composition arithmetic) was never uploaded: the closing upload meant to carry it held an earlier probe configuration by mistake (scoring 0.711) and was never pushed to the board, so the scored Task 1 entry is probe-3 (0.712), the last pushed of four uploads. Two closing Task 2 uploads scored 0.733 but were never pushed either, leaving probe-4 (0.7316) the scored Task 2 entry. Both are operational errors, not modeling choices, and neither is claimed as a

Stage	Source	Fitted on	Where
Task 1			
AS votes	gemma-4-31b, k=5, T=0.7	430 OOF (θ only)	both
TE votes	gemma-4-31b, k=5, T=0.7	430 OOF (θ only)	pinned
ST votes	gemma-4-31b, k=5	430 OOF (θ)	both
ST seed judge	gemma-4-31b, T=0	not fitted	both
ST verifier	gemma-4-31b + qwen3-32b / llama-3.3-70b	fold-external 430 exemplars	both
OT encoder	CAMeLBERT-quarter, 1 seed	430, 5-fold	both
AN encoder	CAMeLBERT-quarter, 1 seed	430, 5-fold	both
CO budget	rank-mean of 3 signals	430 prior ($2\times$)	pinned
TE from spans	Task 2 span labels	not fitted	probe
AN, CO ensemble	CAMeLBERT-quarter, 5 seeds	430; cutoffs on test feedback	probe
Task 2			
quote extraction	gemma-4-31b, zero-shot	not fitted	both
atomization	deterministic rules	not fitted	both
role labels	GEPA-compiled, gemma-4-31b; seed instruction deployed	430, 5-fold	both
segment posteriors	CAMeLBERT-quarter	430, 5-fold	both
calibration, λ, Viterbi, Rule-A	fitted rules	430, 5-fold	both
span-drop filters	Task 1 labels + posteriors	test feedback	probe

Table 2: Components of both systems, their sources, and the data each was fitted on. "pinned" = the frozen recipes v2.2 and S1 that produced 0.6499 and 0.7055; "probe" = a leg that exists only in the evaluation-week entries that scored 0.712 and 0.7316; "both" = shared. The single-seed AN encoder survives into the probe entries for the debate genre only; editorial AN there comes from the five-seed ensemble. No component uses data outside the organizers' training release, and only the probe rows saw any test-set feedback.

result.

Pre/post-processing. Whitespace-only gold spans dropped (training side only); Task 1 gold re-derived from span labels with parity assertion; deterministic clause/connective atomization for role decisions; verbatim-quote alignment (exact/whitespace/normalized/fuzzy ladder) for offsets; per-label vote thresholds, encoder thresholds, CO budget count, calibration weights, blend λ, and transition matrices all cross-fitted per fold on the 430-pool OOF artifacts; deployment twins take the median of the five per-fold vote thresholds (which coincide with the pooled-OOF optima) and Task 1 encoder thresholds fitted on the pooled OOF scores, with encoders and the S1 statistics refit on all 430; the rule forms themselves were fixed from pooled-OOF sweeps on the same pool before the gate (Limitations); exact-duplicate span dedup after decode. Empty prediction sets are legal outputs everywhere.

B The Gate Registry

Every recorded decision, in order (Table 3); gates are composed-OOF $+0.02$ with $\geq 3/5$ fold wins unless stated. "Killed" = failed a pre-declared cheaper screen before the full gate.

Summary: 29 decisions, 6 adoptions, 2 external failures caught and reverted by the one-probe rule (row 13 and the OT leg of row 14), no family reopened after rejection. Two registered measurement-only probes run in the evaluation phase (2026-07-29: a guideline-native single-program baseline and a provider-pin configuration probe) had no adoption branch, are not counted here, and are in the released ledger; their $\approx$1.2k paid calls fall outside the cost ledger of Appendix D. Rows 26–27 are the sharpest illustration of the margin's purpose: every banked component reproduced its estimate almost exactly and the honest sum was still $+0.016 < +0.02$; a $+0.016$ gain on 430 paragraphs does not earn a leaderboard probe.

C Analysis Detail

The four subsections below are the full development of the patterns summarized in §6.

C.1 Criteria verify; conventions require supervision or structure

The campaign ran four prompting attacks on convention-defined labels, all pre-declared, all failed: (i) zero-shot CO definitions (cross-fitted F_1 0.07); (ii) a CO definition judge as a fourth rank feature (0.3733 vs. 0.40 control); (iii) a CO contrastive many-shot specialist with the annotators' own exemplars and four induced not-CO conventions in context (0.3733 again: the model argued false positives *into* CO while quoting the rules); (iv) a span-level AN-vs-AS judge (flip precision 0.44 where $\geq$0.75 was needed). Meanwhile the ST verifier (aimed at a checkable criterion) validated twice and shipped. The Webis agreement numbers explain the asymmetry (Fleiss' κ, segment-level, pre-consolidation: AS 0.613, TE 0.591, ST 0.582, AN 0.399, OT 0.152, CO 0.114; Al-Khatib et al., 2016): CO's convention (κ=0.114, 0.562 confusion into AS *among humans*) is statistical, not definitional; there is nothing for a verifier to check. Consistently, gemma fired CO on all six calls (five rollouts and the T=0 run) for 41 paragraphs whose gold is not CO, and on none for 7 gold CO paragraphs: a *biased coin* no amount

#	Decision (task)	Gate / screen	Result	Verdict	Registered→verdict
1	quote-then-align vs. segment (T2 program)	paired $+0.02$ on frozen val	0.6805 vs. 0.6542	**adopt**	pre-ledger
2	BFRS compile (T1)	paired $+0.02$	-0.042	reject	pre-ledger
3	MIPROv2 compile (T1)	paired $+0.02$	negative	reject	pre-ledger
4	GEPA compile (T1, 3 variants)	paired $+0.02$	$\leq +0.003$	reject	pre-ledger
5	GEPA compile (T2)	paired $+0.02$	$+0.003$	reject	pre-ledger
6	zero-shot verify stage (T1)	paired $+0.02$	± 0.003	reject	pre-ledger

Table 3: The complete adoption registry. "pre-ledger" rows predate the in-repo registration convention and are documented in the corresponding campaign reports; later rows cite the ledger and verdict commits *in the released repository*, so every hash printed here resolves there. ‡: the entry changed only run directories or scripts, which entered that repository in its snapshot commit 8d494f1 rather than individually; the row-to-directory map is the "Registry rows and deployments" section of `experiments/README.md` there. ¶: the record is the submission log, which is not released; its scores are reproduced in this table and §6. †: design and verdict entered git together (same commit or same-day batch), so precedence over the run rests on the ledger's contemporaneous record, not git order. Every reject/kill closed its design family permanently; row 19 is the free re-gate of banked row 18 on the moved baseline, pre-registered inside row 24's ledger entry, not a reopening. Adoption bars are that day's baseline plus the registered margin: row 20's 0.7203 is the hand-rule composition it screened against (routed v2 with the local five-seed encoder ensemble), and row 22's 0.7498 is the v2.2 score of 0.7298 plus the registered $+0.02$.

of voting, prompting, or calibration can flip. A dev example makes the convention concrete: the router fired CO on a debate opening that merely *frames* the motion ("this House would ban for-profit companies from using social and political causes in marketing"): gold AS/OT, because a motion is assumed for the sake of debate, not shared ground. Over-prediction of such labels is even metric-rational (Lipton et al., 2014).

C.2 Vote-scaling: why k=5, and why voting cannot fix ST or AN

With q_p the observed fraction of the five rollouts firing on paragraph p, Table 5 turns three design choices into consequences of vote statistics (Chen et al., 2024; Wang et al., 2023; Loo, 2025). (1) k=5 *suffices:* for the three vote-routed labels, F_1 at k=5 with an optimal threshold is over 99% of the infinite-vote limit ($\geq$96.9% for all six); more same-prompt rollouts buy almost nothing. (2) *Voting cannot fix* ST*:* the sampler already finds every gold ST (p_1=0.99, zero inverted golds), but 26 non-gold paragraphs fire on a majority of calls: correlated false positives that more votes make *more* confident. Precision required an orthogonal signal: the verifier. (3) *Voting cannot fix* AN*:* half the gold AN paragraphs fire on a minority of calls (inv$^+$=0.50), capping the infinite-vote ceiling at 0.611, *below* the supervised encoder's 0.717; routing AN to the encoder is not a preference but an inequality. Finally, deployed thresholds coincide with their pooled-OOF optima (Table 4), but the interval retaining $\geq$95% of peak F_1 spans 0.77 of the score range for AS against 0.016 for ST and **0.006** for CO: rare-label operating points sit on needles, and any dev→eval score shift falls off the peak: the quantitative case for CO's count budget and ST's verifier.

C.3 What S1 did, seen against the human matrix

Grouping the six types into coarse families (evidence TE/ST/AN, subjective CO/AS, other) localizes S1's contribution: the within-family share of misassigned char mass fell 0.258 → 0.182 while family-level F_1 barely moved (0.7512 → 0.7541):

S1's gain is within-family disambiguation. The residual concentrates in the one cross-family confusion the decoder cannot reach, gold-AN mass labeled AS (0.330): on dev, the gold AN span "the reaffirmation to activate the Loss and Damage Fund" (a settled event, hence anecdote by convention) was absorbed into a larger AS span. The same confusion leads the human matrix (0.277; Al-Khatib et al., 2016), and our 6-label OOF (0.7206) against the 3-family score (0.7541) bounds what finer typing can still add (§2).

Per-label test decomposition (§6). Task 1 test F_1: AS 0.9408, ST 0.9286 (recall 1.0, so the verifier's zero drops were correct), OT 0.7805, TE 0.6724 (editorial recall 0.258 vs. 0.795 debate), AN 0.4628 (76 fired against 45 golds), CO 0.1143 (the frozen budget fired 25 paragraphs against 10 test golds, the recorded overfiring risk realized). Editorial OT scored 0.0 on 6 supports, the blind spot dev had already exposed.

C.4 Negative results

Every rejected family and its gate is in Appendix B; the sharpest three: the **cross-model vote bundle** delivered every banked component's estimate almost exactly and the honest sum was still $+0.0160 < +0.02$: closed without a probe, exactly the case the winner's-curse guard exists for; a **shuffled-graph placebo** scored within 0.0003 of the true discourse forest: the structured-prompt gain was graph-shape, not attachment; and **transductive TAPT** (Gururangan et al., 2020) lifted the raw encoder $+0.0476$ OOF but the composed system only $+0.0066$: textbook composition dilution (the encoder feeds only AN/OT and CO rank features). Also closed at their gates: prompt optimizers on monolithic signatures (-0.04 to $+0.003$; the only win came after decomposition to single decisions), a decision-level judge compile ($+0.033$ selection, $+0.001$ confirmation), learned stacking, learned span arbitration, calibration temperature, and synthetic-label routes (Xu et al., 2023; Fu et al., 2021; Zhang et al., 2024; Yung et al., 2025; Zhang et al., 2025; Di Palo et al., 2024; Xiao et al., 2023).

Threshold audit (§C.2). Deployed encoder thresholds vs. pooled-OOF optima, the $F^*/2$ plug-in point, and the width of the $\geq$95%-of-peak interval:

	θ_{dep}	θ^*	F^*	$F^*/2$	95%-width
CO	.181	.178	.350	.175	**.006**
AS	.473	.471	.916	.458	.774
TE	.288	.286	.661	.331	.158
ST	.164	.164	.326	.163	**.016**
AN	.384	.384	.717	.359	.288
OT	.484	.482	.814	.407	.376

Table 4: Every deployed threshold is at its pooled optimum and near the calibrated plug-in rule; what differs across labels by two orders of magnitude is the width of the safe operating region.

Vote thresholds. Deployed integer vote thresholds $(\theta_{\text{AS}}, \theta_{\text{TE}}, \theta_{\text{ST}}) = (2, 4, 4)$, the medians of the five per-fold fits, coincide with the pooled-OOF optima; the full F_1-by-θ and F_1-by-k curves (including the fixed-majority inverse-U on OT) accompany the released analysis artifacts. Table 5 gives the per-label vote model behind §C.2: with q_p the observed vote fraction of paragraph p, expected F_1 at k votes uses $E[\text{TP}] = \sum_{\text{gold}} P(\text{Binom}(k, q_p) \geq \theta)$ (and $E[\text{FP}]$ likewise) at the optimal integer θ; the $k \to \infty$ limit fires p iff $q_p > \tau$ at the best observed τ; inv$^+$ is the share of gold paragraphs with $q_p < 0.5$, unreachable by any majority.

	α	p_1	p_2	inv$^+$	F_1@5	F_1@∞
CO	.058	.63	.16	.36	.327	.337
AS	.756	.94	.35	.06	.920	.922
TE	.258	.86	.13	.13	.791	.793
ST	.044	.99	.07	.00	.609	.613
AN	.300	.49	.10	.50	.603	.611
OT	.372	.84	.25	.16	.746	.748

Table 5: Per-label vote model from the five rollouts: prevalence α, per-call fire rate on gold (p_1) and non-gold (p_2) paragraphs, fraction of gold items fired on $<50\%$ of calls (inv$^+$: unreachable by any majority), and expected F_1 at k=5 vs. the infinite-vote limit, both at the optimal integer threshold.

Transfer ledger (§6). What each development submission was predicted to score externally, by which estimator, and what it scored:

Submission	Predicted	Observed	Δ
champion (val 182)	0.7024	0.6159	-0.087
routed v1 (OOF)	0.6721	0.6642	-0.008
mix amendment (OOF)	0.6955	0.6364	-0.059
routed v2 (OOF)	0.7102	0.6788	-0.031
v2.1 (arithmetic)	0.6955	0.6955	± 0
v2.2 (arithmetic)	0.7089	0.7089	± 0
v3 (frozen 182)	0.6995	0.6847	-0.015
S1 (arithmetic+OOF)	$\approx$0.712	0.7247	$+0.013$

Table 6: The transfer ledger. Single-shot readouts on 182 paragraphs (rows 1, 7) carry $\pm$0.03–0.04 provider noise; cross-fitted composed OOF transfers between -0.008 and -0.059; exact composition arithmetic transfers exactly.

Progression and official scores (§6). Development-phase progression and official evaluation-phase scores:

System (chronological)	T1 dev	T2 dev
zero-shot champion	0.6159	—
v3 pipeline	—	0.6847
+ mix-encoder amendment†	0.6364	
routed v2.1 (OT revert)	0.6955	
routed v2.2 (+ST verifier)	**0.7089**	
S1 structural re-decode		**0.7247**
organizers' baseline	0.358	—
evaluation, frozen recipes (test, 213)	0.6499	0.7055
editorial only	0.4595	0.6195
debate only	0.7112	0.7364
evaluation, final probes	**0.712**	**0.7316**
editorial only	0.519	0.684
debate only	0.759	0.748
final rank (teams)	1/10	5/8

Table 7: Progression and official scores (closed track, *both* setting; intermediate routed v1 0.6642 and v2 0.6788 omitted for space). †Failed external check, reverted same day. The evaluation rows report (i) the pinned recipes v2.2 and S1 run once, unchanged, on the test input, and (ii) the final probe submissions of the disclosed evaluation-week campaign (§6).

Confusion mass (§C.3). Row-normalized gold char-mass destinations for the final S1 output, selected rows: gold-CO mass goes 0.563 to CO, 0.286 to AS; gold-AN mass goes 0.382 to AN, 0.330 to AS, 0.112 to TE, with only 0.037 uncovered by any predicted span: the AN deficit is typed-coverage, not extraction-coverage, and it is the one large cross-family residual. Full 6×7 matrices (before/after S1, including uncovered mass) are in the released analysis artifacts.

Leave-one-out ablation of S1 (§4). The placebo in §4 isolates the encoder's contribution; Table 8 carries it as a row and removes each other part of the bundle in turn. Every per-fold quantity, including λ, is re-fitted inside each variant, so each row is the honest out-of-fold score of *that* system rather than the full system's fit reused; the full row reproduces the recorded 0.7206 exactly. The blend is not a tuning knob but the bundle's backbone: the calibrated encoder alone (λ=0) falls to 0.6507, below v3 itself, and the fit chose the grid's upper edge, λ=0.9, on every fold (λ=1, v3 unchanged, is outside the grid). Removing Viterbi leaves a per-span argmax that at $\lambda\geq0.5$ can never overturn the v3 label, so that row is v3 plus Rule-A and nothing else (all 103 of its label changes are Rule-A's), and its re-fitted λ=0.5 is the first point of a flat plateau rather than a choice. Read together with the placebo row, the parts do not add: on top of v3, Rule-A alone is worth $+0.0139$, the sequence and label-mass priors a further $+0.0060$, and real encoder posteriors the remaining $+0.0073$; yet removing Rule-A from the full bundle costs only -0.0040, because Viterbi already repairs most of what Rule-A repairs. Genre conditioning and Rule-A are each worth about -0.004 when removed, well below the composed-OOF band $\sigma\approx0.015$ that the gate is calibrated to, so neither is separable from noise on 430 paragraphs. Prior calibration is inert ($+0.0004$ to remove it), consistent with row 28's flat τ curve. Ablations report; they never adopt, and S1 ships exactly as gated.

Variant	OOF F_1	vs. full	vs. v3
full S1 (as deployed)	0.7206	—	$+0.0272$
− prior calibration	0.7210	$+0.0004$	$+0.0276$
− genre conditioning	0.7167	-0.0039	$+0.0233$
− Rule-A	0.7166	-0.0040	$+0.0232$
placebo: uniform encoder (§4)	0.7133	-0.0073	$+0.0199$
− Viterbi (= v3 + Rule-A)	0.7073	-0.0133	$+0.0139$
encoder only (λ=0, no blend)	0.6507	-0.0699	-0.0427
v3, no re-decode	0.6934	-0.0272	—

Table 8: Leave-one-out ablation of the S1 re-decode on the 430-paragraph out-of-fold pool: each row removes one part and re-fits the rest. "− genre conditioning" replaces the two genre-specific transition matrices with one pooled matrix; "− Viterbi" labels each span by the argmax of its own emission, which at the re-fitted λ=0.5 never overturns the v3 label, so the row is v3 plus Rule-A; "encoder only" pins λ to 0; the placebo row is the full decode with the encoder replaced by uniform distributions. Report-only: no gate is defined over these variants.

D Reproducibility and Cost

LLM, encoder, and sparse-baseline runs write a hash-bound artifact set (exact config, data hashes, fold manifest, metrics, provenance, completion marker); composition, gate, and judge scripts record their exact arguments, upstream run names, and (Task 1) input hashes in config and metrics files, without a provenance file or completion receipt; adoption reports verify fold membership by hash; deployment twins reuse the immutable model/threshold contracts of their OOF runs; the evaluation-week probes (§6) were recomposed from cached LLM signals plus encoder deployments trained that week, outside this convention, and are recorded at rule level in the repository. Split seeds: 20260709 for the stratified 430/182 selection/confirmation split, 20260710 for the 5-fold paragraph-grouped, genre-stratified partition of the 430. Encoders are pinned to 40-hex revisions and trained fp32 on CPU for bit-stable de-

ployment parity (Task 1: six-sigmoid paragraph classifier, 4 epochs, lr $2{\cdot}10^{-5}$, 512-token windows with stride-128 overflow, max pooling; Task 2: seven-way segment classifier, same recipe); fp16 GPU replication of the primary encoder run reproduced digit-for-digit across duplicated jobs. LLM runs pin the OpenRouter model route, temperature, adapter, and date, not the upstream serving provider or its quantization (a post-freeze probe saw nine upstreams at differing quantizations in 20 calls), which contributes to the rerun band; every reported number is read from committed metrics files, while prediction files, compiled states, and the DSPy cache embed dataset text and are not distributed, so fresh LLM runs reproduce within provider noise rather than byte-for-byte. Splits, fold seeds, and threshold-fitting code are released; the official scorers are used through parity-tested ports. Approximate paid-API ledger: model bake-off $3.8; optimizer campaigns ≈$4; v3 role campaign ≈$13.5; routing/rollout evidence ≈$13; verifier, specialist, and rescue gates ≈$6; development probes and deploy twins ≈$6; development total ≈US$50. Encoder training: ≈30 Kaggle GPU-hours (screens and multi-seed evidence) plus CPU runs; the one TAPT measurement added ≈12 CPU-hours. Evaluation-phase inference (2026-07-27) was one pass per pinned stage over the 213-paragraph test input: quote extraction, role decisions on 1,912 atoms, five vote rollouts, two co-signal runs, the seed judge (16 calls) and verifier (45 calls), with the router recomposed after each (three router passes, the last submitted), ≈3.9k LLM calls in total, for ≈US$10, plus ≈35 CPU-minutes for the two encoder deploys; every stage completed error-free on the first attempt, and the two deploy-twin controls reproduced their development outputs byte-identically before any test inference ran.

RabeeQasem - ImpactAi at Daleel 2026: Conformer Based Arabic Argumentative Discourse Mining

Rabee Al-Qasem
AI Developer, GGateway
Nablus, Palestine
r.qasim@ggateway.tech

Abstract

We present our system for Daleel 2026 Task 2 on Arabic Argumentative Discourse Unit (ADU) detection. Our main contribution is a Conformer-based tagging architecture that combines a pretrained AraBERT encoder with a Conformer head to capture both global discourse context and local span-boundary cues. The system also uses overlapping token windows, class-weighted training, character-level span reconstruction, and lightweight post-processing. On the official hidden test set, our system achieved an overall F1 score of 0.732, substantially outperforming the official baseline of 0.285 and ranking fourth in the closed track.

1 Introduction

Argument mining aims to identify and classify the argumentative components that structure opinions, evidence, and reasoning in text (Nabhani et al., 2026),(Lawrence and Reed, 2019), (Stab and Gurevych, 2017). The Daleel 2026 shared task focuses on Arabic argumentative discourse mining, addressing an important gap in Arabic NLP, where discourse-level argument mining resources remain limited. The task covers two forms of Arabic argumentative discourse: news editorials and debates. In Task 2, systems are required to identify and classify Argumentative Discourse Units (ADUs) and determine their character-level boundaries. The task is evaluated using a modified F1 score that accounts for partial span overlap between gold and predicted annotations.

We participated in the closed track, which restricts systems to the organizer-provided training and development data, publicly available pretrained models, standard NLP tools, and rule-based or hybrid methods. Our main strategy formulates Task 2 as a sequence tagging problem using BIO labels over tokenized Arabic paragraphs (Ramshaw and Marcus, 1995). We fine-tuned an AraBERT-based encoder (Antoun et al., 2020) with a Conformer tagging head (Gulati et al., 2020) to capture both contextual evidence patterns and local boundary cues. Since argumentative spans often cover most of the paragraph, the system predicts token-level ADU labels and then maps them back to character-level spans. We further applied post-processing rules to improve span consistency, reduce fragmented predictions, and adjust selected label decisions based on development-set analysis.

Our system achieved 4th place in the closed-track leaderboard. our experiments show that Arabic ADU detection is highly sensitive to span boundaries, label imbalance, and confusion between semantically related evidence types such as Anecdote, Statistics, and Testimony. We also found that lightweight post-processing, especially merging fragmented spans and applying label-specific rules, improved the final submission without requiring additional training data. The code and resources used in our system are available at The code and resources used in our system are available on github.

2 Background

2.1 Task Setup

Daleel 2026 Task 2 is formulated as an Argumentative Discourse Unit (ADU) detection task for Arabic texts, covering two genres: news editorials and debate transcripts (Nabhani et al., 2026). Given an input paragraph, its identifier, and its genre, systems must identify all argumentative units by returning their exact character start and end offsets, along with one of six argumentation labels: Common Ground (CO), Assumption (AS), Testimony (TE), Statistics (ST), Anecdote (AN), and Other (OT).

For example, a training instance from a debate contains:

نتحدث الآن بنقطتين ومحورين أساسيين. المحور

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1323–1327
October 28-29, 2026 ©2026 Association for Computational Linguistics

الأول نتحدث فيه عن الصراع الروسي الأوكراني،
ونقطتنا الأولى أن هذا التوسع جعل الدول
الأخرى في حالة تأهب للحرب التي تهدد الأمن
العالمي...

The gold annotation marks the opening organizational segment as OT, while subsequent spans are annotated as AS, corresponding to argumentative assumptions about expansion and alliances. Such examples illustrate a primary difficulty of the task: precise boundary detection. Argumentative units are often lengthy, adjacent to one another, and separated only by punctuation or short discourse markers.

2.2 Dataset Details

The training data consists of 612 paragraphs (255 editorials and 357 debates), the development set contains 217 paragraphs (88 editorials and 129 debates), and the final hidden test set contains 213 paragraphs. As shown in Figure 1, the training set exhibits severe class imbalance. The most frequent label is AS (1,739 spans), followed by OT (492 spans), AN (343 spans), and TE (313 spans). The rarest labels are CO and ST, with only 50 and 38 spans respectively. This imbalance makes the detection of fine-grained evidence types particularly challenging.

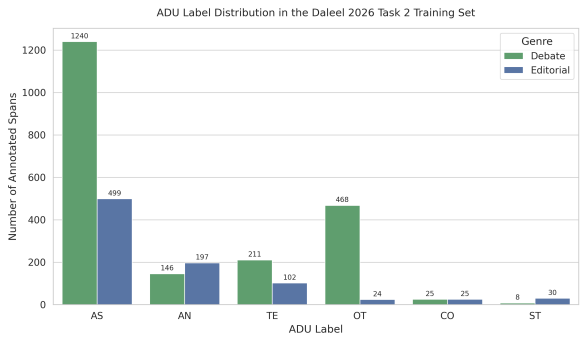

Figure 1: Distribution of ADU labels in the Daleel 2026 Task 2 training set across the two text genres: editorials and debates. The figure shows the strong class imbalance in the dataset, especially for CO and ST.

2.3 Related Work and Motivation

Argument mining has commonly been studied as a task that requires identifying argumentative components and assigning them discourse or argumentative roles. The Daleel label set is related to prior work on argumentation strategies in news editorials, where argumentative units are categorized according to the type of evidence or discourse function they provide, such as assumptions, testimony, statistics, anecdotes, and common ground . For Arabic NLP, pretrained transformer encoders such as AraBERT have shown strong performance across Arabic understanding and token-level tasks, making them a suitable backbone for Arabic ADU detection (Alatawi and Kadhem, 2025).

Our contribution focuses on adapting a Conformer-based architecture to Arabic argumentative discourse unit detection. The Conformer architecture was originally proposed for speech recognition, where it combines self-attention for global sequence context with convolution for local pattern modeling (Gulati et al., 2020). This combination is relevant to ADU detection because the task requires both paragraph-level contextual understanding and accurate local boundary recognition. As far as we know, our system is the first to apply a Conformer-based structure to Arabic argumentative discourse unit detection. This design allows the model to use attention for discourse-level evidence patterns while using convolution to capture local cues such as punctuation, discourse connectives, and short argumentative markers.

3 System Overview

Our system is designed as a span-level Arabic ADU detection model. The overall pipeline is shown in Figure 2. Given an Arabic paragraph, the text is tokenized using the AraBERT tokenizer and converted into token IDs, attention masks, and offset mappings. Long paragraphs are divided into overlapping token windows to handle the maximum input length of the encoder. The tokenized input is then passed through the AraBERT encoder, followed by a Conformer-based tagging head and a linear classification layer. Finally, token-level predictions are reconstructed into character-level ADU spans and refined using post-processing rules.

3.1 Model Architecture

Our model consists of three main modules: a pretrained AraBERT encoder, a Conformer tagging head, and a linear token-level classification layer. The AraBERT encoder provides contextualized representations of the input tokens, while the Conformer head further models both global con-

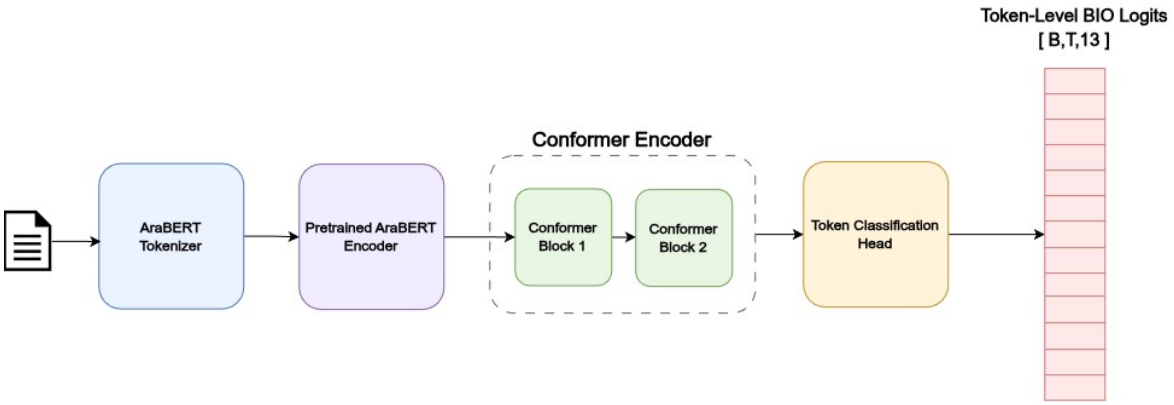

Figure 2: Overview of the proposed ADU detection pipeline. The system processes an Arabic paragraph using AraBERT tokenization, overlapping token windows, an AraBERT encoder, a Conformer tagging head, and a token-level classifier before reconstructing final character-level ADU spans.

textual dependencies and local boundary patterns. The resulting representations are then passed to the classification layer to produce token-level predictions for ADU detection and classification.

3.1.1 AraBERT Encoder

The first module is a pretrained AraBERT encoder. We use AraBERT to obtain contextualized Arabic token representations, which are important for distinguishing between argumentative functions that depend on sentence-level and paragraph-level context. Since the task is in Arabic and includes both editorials and debates, AraBERT provides a strong pretrained representation for Arabic text while remaining compatible with the closed-track setting.

3.1.2 Conformer Tagging Head

The second module is a Conformer-based tagging head composed of two Conformer blocks. The Conformer architecture combines self-attention and convolution, making it suitable for modelling both global context and local boundary patterns. In our task, self-attention helps capture discourse-level dependencies across the paragraph, while convolution helps detect local cues such as punctuation, connectives, and short argumentative markers. Figure 3 illustrates the Conformer block used in our system.

3.1.3 Token-Level Classification Layer

The final module is a linear classification layer that maps each token representation to an ADU tag. The classifier predicts whether each token belongs to one of the six ADU categories or falls outside an argumentative span. These token-level predictions are later converted into character-level spans using the tokenizer offset mappings.

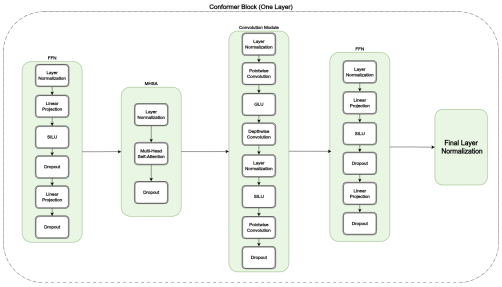

Figure 3: Structure of the Conformer block used in the tagging head. The block combines feed-forward layers, multi-head self-attention, and a convolution module to capture both global contextual information and local span-boundary cues.

3.2 Resources Used

The only external resource used in our system was the publicly available pretrained AraBERT model. We also used standard machine learning and NLP libraries, including PyTorch and Hugging Face Transformers (Wolf et al., 2020), alongside the official evaluation script released by the shared task organizers.

3.3 Addressing Task Challenges

The task presents several challenges: long paragraphs, class imbalance, span-boundary sensitivity, and confusion between semantically related labels. To process long paragraphs, similar to (Stefan and Nisioi, 2026) and (Wu et al., 2025), we split tokenized text into overlapping windows (max 512 tokens, stride 128) to preserve boundary context. We applied class-weighted loss during training to mitigate severe label imbalance

(especially for CO and ST). For precise boundary detection—which the official soft span-overlap F1 metric heavily rewards (Kosmopoulos et al., 2015)—we used tokenizer offset mappings to reconstruct character-level spans directly. Finally, lightweight post-processing rules were applied to merge fragmented spans, trim punctuation, and refine specific label predictions.

4 Experimental Setup

We used a stratified 10% validation split by genre for checkpoint selection. The model was trained for 12 epochs using AdamW, mixed precision, batch size 8, and gradient accumulation of 2. The learning rates were set to 3×10^{-5} for the encoder and 1×10^{-4} for the tagging head.

5 Results

5.1 Official Test Results

Table 1 compares our system's performance on the hidden test set against the baseline. Our system substantially outperformed the baseline across both genres, improving the overall F1 score by 0.447 absolute points and ranking 4th in the closed track.

System	Editorial	Debate	Overall
Official Baseline	0.272	0.293	0.285
Our System	**0.659**	**0.761**	**0.732**

Table 1: System vs. baseline F1 scores on the Daleel 2026 Task 2 hidden test set.

5.2 Discussion

As shown in Table 1, the model was more effective at capturing argumentative structure in debate transcripts than in editorials. Editorials remained challenging due to denser evidence types and subtle distinctions between AS, AN, TE, and ST.

Key design decisions that drove performance included the AraBERT contextual encoder, the Conformer tagging head, and span-fragmentation post-processing. Specifically, merging fragmented AN spans notably improved the official score, revealing that many model errors stemmed from over-segmentation rather than failed detection. Furthermore, a final rule converting selected numeric/value-based editorial AN spans into ST provided additional score gains.

6 Conclusion

We presented a closed-track system for Daleel 2026 Task 2 that combines a pretrained AraBERT encoder with a Conformer tagging head to detect Arabic Argumentative Discourse Units. By integrating overlapping token windows, class-weighted training, character-level span reconstruction, and lightweight post-processing, our system achieved a 0.732 overall F1 score.

Our analysis highlights that while debate texts are modeled effectively, fine-grained evidence classification in editorials remains challenging. Furthermore, resolving over-segmentation via post-processing is a highly effective strategy for span-overlap metrics. System limitations include reliance on a single encoder and validation split, making heuristics sensitive to data distribution. Future work will explore model ensembling, stronger Arabic encoders, constrained decoding, and data augmentation to better differentiate semantically close evidence types and improve rare-class detection.

Abstract

We describe the Durham-Jazan submissions to the Daleel 2026 shared task on Arabic argumentative discourse mining, which comprises multi-label paragraph classification (Task 1) and argumentative span detection (Task 2), each with a Closed and an Open track. Our Task 2 Closed system routes the Modern Standard Arabic editorials to CAMeLBERT and the noisier debate transcripts to MARBERTv2. The Open system blends the two families at character level and adds synthetic training data from a large language model for rare-class generalisation, generated by a segment-concatenation recipe that makes span offsets exact by construction. The Task 1 systems add back-translation, targeted augmentation of the rare classes, and a QLoRA-tuned Qwen3-32B for the editorials. Everything else trains on one 16 GB consumer GPU. Our official test scores are 0.729 and 0.736 overlap-F1 on Task 2 and 0.657 and 0.669 macro-F1 on Task 1 (Closed and Open). We placed first of two on Task 1 Open, first of one on Task 2 Open, fifth of ten on Task 1 Closed, and sixth of eight on Task 2 Closed. Our central finding concerns our own systems on this data. Recalibrating per-class thresholds on validation outputs overfits them. Under a controlled protocol the held-out effect is negative at every tuning-set size we tested, while the apparent in-sample gain shrinks as the tuning set grows. An audit of eighteen interventions from our campaign is consistent with this, though observational. A size-matched study links the editorial deficit that every team showed to the genre composition of the training data. We release our code and synthetic data.[1]

1 Introduction

Argument mining, the automatic identification of argumentative structure and strategies in text (Lawrence and Reed, 2019), remains under-resourced for Arabic. The Daleel 2026 shared task (Nabhani et al., 2026) addresses this with two subtasks over Arabic news editorials and debate transcripts. **Task 1** asks for multi-label classification of paragraphs into six argumentative categories and **Task 2** for character-level detection of labelled argumentative spans. Each subtask has a Closed track (public models and the provided data only) and an Open track (any resources, including proprietary large language models).

Team **Durham-Jazan** took part in all four tracks. On Task 2 Closed we routed the Modern Standard Arabic (MSA) editorials to CAMeLBERT-mix (Inoue et al., 2021) and the debates to the dialect-pretrained MARBERTv2 (Abdul-Mageed et al., 2021), and on Task 2 Open we blended the two families. We target the dominant error source, rare-class generalisation, with task-adaptive pretraining (Gururangan et al., 2020), back-translation (Sennrich et al., 2016), and synthetic data from a large language model, and, for Task 1, route the editorials to a Qwen3-32B (Yang et al., 2025) fine-tuned with QLoRA (Dettmers et al., 2023).

Our best official test scores are 0.729 and 0.736 overlap-F1 on Task 2 (Closed and Open) and 0.657 and 0.669 macro-F1 on Task 1, placing first on both Open tracks, fifth on Task 1 Closed, and sixth on Task 2 Closed (Table 1). Beyond the systems, we report two methods and two findings. The first is *segment-concatenation generation*, which makes LLM-generated span annotations exact by construction for ordered, non-overlapping spans (Section 3.3). The second is *metric-aware span compaction*, worth 0.017 on test at no GPU cost (Section 3.1). The third is a controlled experiment showing that, for our systems on this data, recalibrating thresholds on validation outputs overfits them at every tuning-set size we tested (Appendix C), with an observational audit of eighteen interventions from our campaign pointing the same

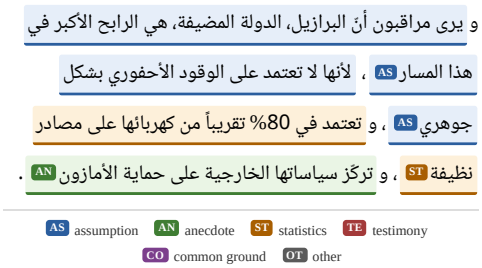

Figure 1: Gold Task 2 annotation of a development-set editorial paragraph, with the label key for the whole paper. Connectives such as *wa* ("and") fall outside the spans. The paragraph translates as *"Observers see host-country Brazil as the biggest winner, since it does not fundamentally depend on fossil fuels, derives about 80% of its electricity from clean sources, and centres its foreign policy on protecting the Amazon."* The Task 1 target is {AS, ST, AN}.

way (Figure 4). The fourth is a size-matched study linking the editorial deficit to training-data genre (Table 11, with the label-level pattern behind it in Figure 5).

2 Background

Task setup. The corpus contains paragraphs from Arabic news editorials and televised debates. In Task 1 the output for a paragraph is a subset of six evidence types, namely assumption (AS), anecdote (AN), statistics (ST), testimony (TE), common ground (CO), and other (OT), in the argumentation-strategy tradition of Al-Khatib et al. (2016). Task 2 asks for labelled character spans, and Figure 1 shows a worked gold example of both. Task 1 is scored with macro-F1 over the six labels. Task 2 uses an overlap-based F1 in which a predicted span p accrues $|p \cap g|/|p|$ over every same-label gold span g it overlaps and g symmetrically accrues $|p \cap g|/|g|$. Precision is normalised by the predicted span count and recall by the gold count.

Data. The data comprise 612 training, 217 development, and 213 test paragraphs (87 editorial and 126 debate), with the dev gold released for the evaluation phase. In the 612 training paragraphs the Task 1 label support is AS 462, OT 222, AN 182, TE 160, CO 36, and ST 28, and those same paragraphs carry 2,975 Task 2 spans, 4.86 per paragraph. Label distributions differ sharply by domain (editorials ST 22 and OT 20 against debates ST 6 and OT 202), motivating domain routing. In all tracks we trained on both domains, as declared to the organisers.

3 System Overview

3.1 Task 2: Span Detection

Base tagger. The encoder output passes through dropout and a linear layer with six per-token sigmoid units, and we train the tagger with clipped token-level class weighting (Appendix A). Spans are decoded as maximal token runs above per-class thresholds tuned against the official scorer, and mapped to characters through the tokeniser offset mapping. Sigmoid tagging, unlike BIO, can represent nested gold spans, and dev holds one (Figure 6).

Domain-routed ensemble. On the dev leaderboard the families were complementary per domain (0.664/0.699 for CAMeLBERT-mix against 0.626/0.715 for MARBERTv2), and our routed entry scored 0.706 (Appendix A, with a worked case in Figure 7). That entry also widened both ensembles, so it does not isolate routing. Three saved development decodes do, since the routed decode reuses the CAMeLBERT-mix editorial rows and the MARBERTv2 debate rows unchanged, and routing is worth 0.005 there over the stronger family alone. Encoder-family routing helped Task 2 only, and lost on Task 1 under the pooled macro metric. The final Closed system therefore routes each paragraph by its provided genre label, sending editorials to the mean of eight CAMeLBERT-mix seeds and debates to eight MARBERTv2 seeds, with domain-tuned thresholds. In the evaluation phase the encoders were further pretrained on the task text and trained on the combined train and dev gold (Section 4 and Figure 2). We label them DAPT-v2 throughout, the name used in our code, although the procedure is task-adaptive.

Metric-aware span compaction. Token-threshold decoding fragments long spans, and the partial-overlap metric counts every fragment in the precision denominator. Our post-processing merges same-label spans separated by at most G characters and drops spans shorter than L (G_{ed}=400, G_{db}=5, L=25). The gap and length values were grid-tuned on the dev gold by worst-case improvement across our Closed and Open routed development decodes, and the post-processing added 0.014 on test and 0.017 after a refined grid.

Open track. The Open system adds 158 synthetic span paragraphs (Section 3.3) and a character-

level probability blend across the two families (Appendix A). We rejected blending in the development phase because it fragmented spans at whitespace, and compaction removes that failure mode, reviving the blend (+0.005 on test, +0.012 on editorials). That submission also retuned the per-domain thresholds, which supply most of the out-of-fold editorial gain.

3.2 Task 1: Paragraph Classification

Encoder system (development phase). We use CAMeLBERT-mix with a six-way sigmoid head, a five-seed ensemble, and robust-median per-class thresholds over seeds. Three additions were validated on clean held-out splits (Section 4). Continued pretraining on the task paragraphs (task-adaptive pretraining, Gururangan et al., 2020) added 0.012, and back-translation through English with beam decoding on OPUS-MT added 0.040 (Tiedemann and Thottingal, 2020; Edunov et al., 2018). Targeted rare-class augmentation, two extra sampled back-translations for every ST or CO paragraph and three in total with the global pass, added a further 0.012. The amount of augmentation matters, as an eightfold version broke threshold calibration (dev 0.627 against 0.673).

Fine-tuned LLM routing (evaluation phase). The Closed track permits open-weight models up to 70B, fine-tuning included. We fine-tune Qwen3-32B with 4-bit QLoRA (r=16, loss on answer tokens only, Appendix A) as a generative classifier. On a controlled holdout it was the first model we tried that beat the tuned encoder ensemble (standalone seed mean 0.744, best 0.767, against 0.715), though with high seed variance. The final system therefore takes the union of three seeds' label sets on the editorials, a recall-oriented choice that entered without a separate validation, and keeps the encoder ensemble on the debates. A post-submission check on the same holdout supports it, with the union above its own seed mean in every three-of-four combination and above majority voting and intersection (Table 4). A one-seed routed submission added 0.008 to 0.011 on test, and the three-seed union a further 0.017 to 0.022. The Open variant changes only the debates, since both tracks route the editorials to the same Qwen3-32B union and return an identical official editorial score. It adds 291 synthetic paragraphs to the encoder's training data and span fusion from Task 2, uses per-domain per-class thresholds in place of the global out-of-fold recalibrated set, and keeps the single-family CAMeLBERT-mix ensemble where Closed blends in MARBERTv2 (Table 3).

Span fusion from Task 2 (Open). Paragraph labels can also be read off the Task 2 decode (a label counts as present when a compacted span of at least 25 characters carries it). Span-derived labels alone reached 0.727 out-of-fold macro-F1, against 0.725 for the deployed classifier. Fused with the classifier through per-class and per-domain rules, they lost on Closed and won on Open (Section 5.3).

3.3 Synthetic Data from an LLM (Open)

A proprietary large language model generated synthetic training paragraphs from few-shot prompts grounded in the official label definitions and real seed examples, targeting the rarest classes (ST, CO, editorial OT) and varying topic and register. Appendix B gives the protocol and two blind quality checks, one by a second model and one by a human annotator. For Task 1 we obtained 291 validated paragraphs in the same multi-label scheme. For Task 2 the model writes each paragraph as an ordered sequence of labelled segments, and joining them with single spaces yields exact character offsets by construction, a recipe we call *segment-concatenation generation*. Unlike inline markup, it needs no tag parsing or alignment, and it adapts generate-from-structure synthesis (Ding et al., 2020; Josifoski et al., 2023) to character-offset spans. We obtained 158 paragraphs with 772 spans at the real span density, boosting ST to 128 spans against 38. Synthetic data are used in training only, and threshold tuning and held-out evaluation always use real data. A larger pool did not help, as a 238-paragraph version gained on editorials and lost on debates (net -0.001).

4 Experimental Setup

Splits. The development phase used 5-fold cross-validation plus a clean held-out simulation (train on 395, predict 217 unseen), with dev scores from the Codabench leaderboard. The evaluation phase retrained on the 829 combined train and dev gold paragraphs, and local re-scoring of our saved dev submissions against the released gold reproduced all four leaderboard numbers exactly.

Models and preprocessing. We run CAMeLBERT-mix, MARBERTv2, and AraBERTv2 (Antoun et al., 2020) through

Track	Score	Ed	Db	Rank	Win.
Task 2 Open	0.736	0.627	0.766	1st	0.736
Task 2 Closed	0.729	0.610	0.762	6th	0.755
Task 1 Open	0.669	0.501	0.762	1st	0.669
Task 1 Closed	0.657	0.501	0.741	5th	0.712

Table 1: Final official test results. Ed and Db are the editorial and debate columns, and Win. the winning score, all taken from the organisers' official sheet. Task 1 drew ten Closed and two Open entrants, and Task 2 eight Closed and one Open, so we were the only team on Task 2 Open and the winning score in both Open rows is our own.

Transformers (Wolf et al., 2020), with maximum length 384 and fp16. DAPT-v2 continues masked language modelling for 30 epochs on all 1,042 task paragraphs (train, dev, and the unlabelled test text) in a transductive setting where labels are never used. Qwen3-32B uses 4-bit QLoRA with r=16. Per-task hyperparameters and library versions are in Appendix A.

Compute. One RTX 4080 SUPER (16 GB) ran all encoder work and models up to 14B parameters. One A100 80 GB at the Durham NCC ran Qwen3-32B for about six GPU hours.

5 Results

5.1 Official Results

Table 1 shows our final official test results, and Table 3 lists the components of each submission. At the close of the development phase we stood first on both Open boards and second and third on the Closed boards. The evaluation phase stayed close on the Closed boards, and our Task 1 Open score rose from 0.622 to 0.669 over four submissions. On Task 1 Open we lead the one other entrant by 0.078 overall, by 0.103 on editorials and by 0.110 on debates, and on Task 2 Open no other team entered.

5.2 Ablation Analysis

Table 2 breaks the Task 1 dev results down by class. The successive additions of DAPT, back-translation, rare-class augmentation, and synthetic data (holdout macros 0.644, 0.684, 0.696, and 0.723 from a 0.632 base, the synthetic step positive on all four holdout splits) chiefly lifted the classes they targeted. ST rises from 0.29 to 0.89 while the common classes barely move, and CO reaches only 0.21. On Task 2, dev gold with DAPT-v2 and wider ensembles added 0.014 on test (0.698 to 0.712),

T1 system	AS	AN	ST	TE	CO	OT	Mac.
pos_weight	.91	.54	.43	.70	.00	.70	.547
plain ens.	.93	.61	.29	.75	.00	.70	.546
DAPT + BT	.92	.63	.67	.79	.17	.69	.642
+ rare-aug 3×	.90	.65	.82	.84	.15	.67	**.673**
+ LLM-synth	.93	.64	.89	.81	.21	.67	**.691**

Table 2: Task 1 per-class dev F1, with every macro matching the development leaderboard exactly. BT is back-translation, and Mac. the macro-F1. The first two rows ensemble CAMeLBERT-mix with AraBERTv2, while the last three use DAPT-CAMeLBERT-mix with three, five and five seeds. The steps are therefore successive development submissions rather than single-factor ablations, and the controlled ladder is the clean holdout quoted in the text. Bold marks the two entries that led their development boards when they were submitted, the Closed board at .673 and the Open board at .691.

compaction another 0.014 and 0.003 more from a refined grid (0.729), and synthetic spans with the blend 0.007 on Open (0.736). A post-submission paired bootstrap over the development paragraphs puts compaction on a routed development configuration at +0.027 (95% interval [+0.014, +0.040], positive in all 2,000 resamples). Those parameters were tuned on the same paragraphs, so the interval is in-sample and not comparable to the test deltas above.

5.3 What Held Up, and What Did Not

Our central result concerns one intervention in our own pipeline, measured on this data under one protocol, and we claim it for that setting only. Recalibrating per-class thresholds on out-of-fold predictions overfits those predictions at every tuning-set size we tested. On a quarter of the out-of-fold data the recalibration appears to gain 0.033 in sample and loses 0.016 out of sample. Enlarging the tuning set to nine tenths shrinks the apparent gain to 0.010 while the held-out loss remains at 0.015 (Table 7). Tuning-set size changes the apparent gain, not the delivery. The result governs recalibration of an existing threshold set, not the presence of per-class thresholds, which every submitted configuration uses. Its comparison baseline is not fully blind, as Appendix C details.

The campaign audit is consistent with this but is observational and weaker. Model changes, meaning changes to data, encoders, or ensembles, gained in eight cases of twelve, against two of six for the decision rules, which are layers tuned on validation outputs. Validation overstated the delivered gain by

0.5 points on average for the former and 2.5 for the latter (Figure 4, Table 6). We attach no significance test, since the set records what we tried rather than a designed sample. The decision rules were also fitted on the predictions they are then scored against, while the model changes were judged on held-out data. That asymmetry runs in the direction of the contrast, so we treat the audit as context rather than evidence. Appendix C discusses a candidate explanation and the one entry that appears to contradict the controlled result.

5.4 Error Analysis

Every one of the twenty-one ranked entries on the four leaderboards scored lower on editorials than on debates. Our 0.610 is the lowest editorial column of the eight Task 2 Closed teams, against a best of 0.684 that belongs to a team other than the overall winner. Our own editorial column also fell from development to test on all four tracks, by 0.042 to 0.155, while our debate column rose by 0.040 to 0.075. Those four pairs compare different systems, since we rebuilt every track between the phases. Our only fixed-system comparison points the same way, as the development Task 2 Closed system re-run on test fell from 0.668 to 0.605 on editorials and rose from 0.722 to 0.739 on debates. Size-matched training reproduces the editorial-versus-debate gap from training composition alone (Appendix D). It does not account for our own development-to-test editorial drop, which we cannot explain from the data available to us. The organisers' sheet reports test scores only, so we cannot tell whether other teams saw the same drop. The leading Task 1 Closed entry, Salah Abdo at 0.712, beats us by 0.018 in each domain yet by 0.055 pooled. The pooled macro is computed over all 213 paragraphs rather than averaged over the two domain macros, so a gap of that shape has to come from labels that are rare within a domain, although we cannot confirm this without that team's per-label predictions.

6 Conclusion

We presented domain-routed and cross-family blended span ensembles with metric-aware compaction and, for Task 1, a hybrid of DAPT encoders and Qwen3-32B. Three things outlast the systems. Segment-concatenation generation makes LLM-generated span annotations exact by construction, and needs no alignment step. For our systems on this data, recalibrating thresholds on validation outputs overfits them at every tuning-set size we tested, under a controlled protocol whose limits we state. And the editorial deficit that every team showed follows the genre composition of the training data, which points to genre-balanced annotation rather than further modelling as the way to close it.

Limitations

Because DAPT-v2 is trained transductively on the unlabelled test paragraphs, the submitted pipeline cannot be applied unchanged to genuinely new text. The development-phase variant, trained without test text, is the inductive alternative. The evaluation phase allowed unlimited submissions. Most interventions were validated before submission. The exceptions are the final three-seed union, checked on the holdout only after submission (Table 4), and the configurations noted in Table 6. The choice among submitted variants used the shared leaderboard. Most test deltas in Table 6 come from single paired comparisons on 213 paragraphs. They are smaller than the unpaired bootstrap half-widths (Efron and Tibshirani, 1993) of the development set ($\pm$0.051 for Task 1 macro-F1 and $\pm$0.030 for Task 2), so we lean on the aggregate sign pattern. The same noise applies to rankings, including ours. The synthetic data come from a single proprietary generator whose vendor and version we withhold. A blind re-annotation of all 291 Task 1 paragraphs by a second model agrees with it at micro-F1 0.94, and a blind human check of 30 paragraphs at 0.84, with the targeted rare classes near-perfect (Appendix B). Segment concatenation cannot express nested spans (Figure 6). Appendices F and E give worked error examples and suggestions for the organisers. Finally, our editorial columns trail those of the winning systems on the two Closed tracks by 0.02 to 0.06. Appendix D traces most of the genre gap to the genre skew of the training spans, but how to close it remains open.

Ethics Statement

The synthetic training data released with this paper were generated throughout by a proprietary large language model. The statistics that appear inside synthetic evidence spans are plausible in form but invented. The repository documents these files as machine-generated, and they are suitable for training and methodological replication rather than as a source of factual claims. Synthetic data are

used in training only, and threshold tuning and held-out evaluation use the organisers' real data. The quality checks in Appendix B were run by a second large language model from the same family as the generator, which bounds annotation quality from above, and by the first author on a blind sample of 30 paragraphs. No wider human validation was performed.

The synthetic data are released under CC-BY-4.0 and the code under the MIT licence. The shared-task corpora are used under the organisers' terms and are not redistributed. The debate and editorial material concerns matters of public argument and contains no personal data beyond what the organisers released. Our evaluation-phase encoders continue masked language modelling on the unlabelled test paragraphs, a transductive setting that we describe in the Limitations, so systems intended for genuinely unseen text should use the inductive variant.

Argument mining systems of this kind identify what functions as evidence in a text. They do not assess whether that evidence is true, and should not be presented to readers as doing so.

A Hyperparameters, Software, and Prompts

Encoders. CAMeLBERT-mix (`CAMeL-Lab/bert-base-arabic-camelbert-mix`), MARBERTv2 (`UBC-NLP/MARBERTv2`), and AraBERTv2 (`aubmindlab/bert-base-arabertv2`). PyTorch 2.10, Transformers 5.5, fp16, maximum length 384. All training uses AdamW, in its 8-bit paged variant for Qwen3-32B, through the Transformers Trainer for Task 1 and a hand-written loop for Task 2.

Task 2 tagger. 10 epochs, learning rate 3e-5, batch 8, dropout 0.1, and per-class token-level $\text{pos\_weight} = \text{clip}(\sqrt{n_{\text{neg}}/n_{\text{pos}}}, 1, 8)$. Per-class decoding thresholds are tuned per domain by coordinate ascent on the official scorer. The thresholds of the final Closed decode (AS/AN/ST/TE/CO/OT) are [.6, .4, .55, .5, .3, .7] on editorials and [.45, .75, .8, .75, .8, .55] on debates, and the Open blend uses its own retuned set. The ensembles use seeds 42, 1, 2, 3, 4, 5, 6, and 7 for both encoder families. All per-system threshold configurations are released with the code. Final compaction uses G_{ed}=400, G_{db}=5, and minimum length 25, from a grid on the dev gold whose surface plateaus for $G_{\text{ed}}\geq$200. The plateau means the overlap metric favours merging essentially all same-label spans within an editorial paragraph, a property future scorers may wish to revisit. On the development leaderboard, routing scored 0.706 against 0.689 for the best single-family CAMeLBERT-mix submission and 0.687 for MARBERTv2 (per-domain editorials and debates, 0.664/0.699 against 0.626/0.715). Those three entries are not matched, since the routed one averaged five CAMeLBERT-mix seeds on the editorials and three MARBERTv2 seeds on the debates, while the single-family entries used one CAMeLBERT-mix seed and a two-seed MARBERTv2 mean. Three matched development decodes are released instead, the routed one taking its editorial rows from the CAMeLBERT-mix decode and its debate rows from the MARBERTv2 decode. Under the official scorer they reach 0.670, 0.687, and 0.692, so routing at matched components is worth 0.005 over the stronger family. The rest of the leaderboard difference is ensemble width and per-domain threshold tuning, which we cannot separate because no development probabilities were saved for the wider runs. The Open char-level blend projects each family's token probabilities to characters, taking the maximum over the tokens covering a character, and averages the families with w_{CAM}=0.5 on editorials and 0.35 on debates.

Seed variance and ensemble size. In a post-submission check we trained eight seeds of the Task 1 encoder on the full training set and evaluated them on dev with thresholds fixed at 0.5, so that no calibration enters the comparison. These are plain encoders without augmentation or DAPT, so the absolute values sit below those of our submitted system. Single seeds range from 0.468 to 0.552 macro-F1, a spread of 0.084 that is wider than most

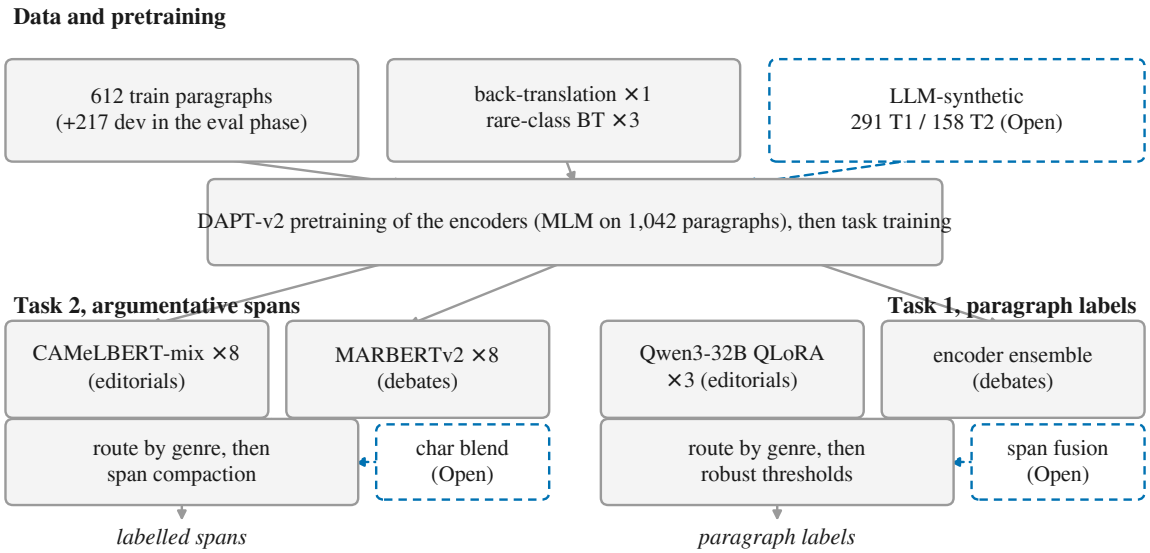

Figure 2: The four systems at a glance. Solid components form the Closed-track pipelines, and dashed blue components are the Open-track additions. Back-translation applies to Task 1 only, as it does not preserve offsets. DAPT-v2 pretraining uses the unlabelled task paragraphs and applies to the encoders only, since Qwen3-32B is fine-tuned from its released checkpoint. Back-translated and synthetic paragraphs enter the task training sets only.

Component	Task 2 Closed	Task 2 Open	Task 1 Closed	Task 1 Open
Official test score	0.729	0.736	0.657	0.669
Editorial model	8 CAMeLBERT-mix taggers	8 CAMeLBERT-mix + 8 MARBERTv2	union of 3 Qwen3-32B seeds	as Closed
Debate model	8 MARBERTv2 taggers	8 CAMeLBERT-mix + 8 MARBERTv2	8 CAMeLBERT-mix + 8 MARBERTv2	8 CAMeLBERT-mix
Encoder pretraining	DAPT-v2, 1,042 paragraphs	as Closed	as Task 2	as Closed
Gold training data	train and dev, 829	as Closed	train and dev, 829	as Closed
Back-translation	none	none	global pass, 3× on ST and CO	as Closed
Synthetic data	none	158 span paragraphs	none	291 paragraphs
Cross-family blend	none	char-level, w_{CAM} 0.5 / 0.35	probability blend, debates	none
Thresholds	per domain and class	per domain and class, retuned	global, OOF recalibrated	per domain and class
Span compaction	G_{ed} 400, G_{db} 5, L 25	as Closed	not applicable	not applicable
Span fusion from Task 2	not applicable	not applicable	none	per-class rules, debates

Table 3: Exact components of the four final submissions. "As Closed" means identical to the Closed entry of the same task. The Task 1 Closed blend averages CAMeLBERT-mix and MARBERTv2 class probabilities on debates, and the Task 1 Open fusion reads labels off the Open Task 2 decode. Threshold values and seeds are in the text of this appendix.

differences we pursued on the leaderboard, which is why score distributions rather than single runs are the appropriate unit of comparison (Reimers and Gurevych, 2017). Averaging seeds removes that variability, with the standard deviation across ensembles falling from 0.030 at one seed to 0.025 at three, 0.016 at five, and zero at eight by construction. At a fixed threshold it does not raise the mean, which drifts from 0.513 to 0.488, because averaging shrinks the probabilities of rare classes and costs their recall. The value of ensembling here is stability rather than raw score, and converting that stability into score requires the per-class calibration our system applies on top.

Span compaction procedure. For each paragraph, and for each label independently, we collect the decoded spans carrying that label and sort them by start offset. We then scan them left to right, merging a span into its predecessor whenever the gap between them is at most G characters, so that the merged span runs from the first start offset to the last end offset. Finally we discard every surviving span shorter than L characters. The permitted gap is G_{ed} on editorials and G_{db} on debates, and no span is ever merged across labels.

Task 1 encoder. 8 epochs, learning rate 2e-5, batch 16, five to eight seeds, and robust median per-class thresholds. The development-phase thresholds (AS/AN/ST/TE/CO/OT) are [.425, .25, .2, .3, .125, .275] for Closed and [.425, .275, .275, .375, .125, .35] for Open. The evaluation phase used a global recalibration tuned out of fold by 5-

fold cross-validation over the 829 combined paragraphs, and thresholds were never tuned on test feedback. All per-system configurations are released with the code. Back-translation uses OPUS-MT `Helsinki-NLP/opus-mt-ar-en` and `en-ar`, with beam decoding for the global single pass and sampled decoding for the two extra rare-class (ST and CO) passes.

DAPT. 30-epoch masked language modelling with learning rate 5e-5, effective batch 16, warmup ratio 0.05, and weight decay 0.01. MARBERTv2 reaches that batch as 8 with gradient accumulation 2, which its larger vocabulary head requires. The development phase used the 829 train and dev paragraphs. The evaluation phase (DAPT-v2) used all 1,042 task paragraphs, namely train, dev, and the unlabelled test text, with labels never used, for both encoder families.

Qwen3-32B. 4-bit NF4 quantisation with double quantisation and bfloat16 compute. LoRA is applied to all attention and feed-forward projection matrices, with r=16, alpha 32, and dropout 0.05. Training uses learning rate 2e-4 with a cosine schedule and 3% warmup, batch size 1 with gradient accumulation of 8, three epochs, maximum length 896, and the loss on answer tokens only. The prompt contains the official annotation-guideline label definitions. We train three seeds, and the editorial predictions are the union of the seeds' label sets. On a controlled holdout with an identical split, where the encoder ensemble scores 0.715, the 14B model reaches 0.714 and the three 32B seeds reach 0.738, 0.767, and 0.728 standalone. The generative framing matters more than the parameter count, since an earlier backbone search fine-tuned AceGPT-v2-8B (Liang et al., 2024) with a classification head, which reached only 0.382 on a clean holdout, against 0.619 to 0.632 for CAMeLBERT-mix.

Three-seed union, checked after submission. The submitted union entered without a separate validation. We recomputed it on the controlled holdout above, routing editorials to the LLM and debates to the encoder ensemble as in the submission. One submitted seed's holdout predictions were not retained, so the check uses the other two submitted seeds and two further seeds from the campaign. In all four three-seed combinations the union beats the mean of its own seeds, by 0.007 to 0.018, and also beats majority voting and intersection of the same seeds (Table 4). The recall-oriented rule is therefore the best of the three at this seed count. The three combinations containing the best seed score 0.760 to 0.763, and the one without it 0.743. On test the union added 0.017 to 0.022 over a one-seed routed submission, a gain of the same order as the holdout margins above, although the two baselines differ.

Editorial rule	**Min**	**Max**
Encoder ensemble (no LLM)	0.715	0.715
Single Qwen3-32B seed (four)	0.729	0.768
Union of three seeds	**0.743**	**0.763**
Majority vote of three seeds	0.735	0.759
Intersection of three seeds	0.725	0.737

Table 4: Post-submission check of the three-seed union on the controlled Task 1 holdout (206 paragraphs), macro-F1 over the four seeds or the four three-seed combinations. The single-seed mean is 0.744, and within each combination the union exceeds the mean of its three seeds. Every row keeps the encoder ensemble on the debates and applies the stated rule to the editorials.

Qwen3 fine-tuning prompt (translated from Arabic). *"Classify the following paragraph of type (editorial / debate) by the argumentative evidence types it contains. Definitions: AS (assumption): assumptions, inferences, opinions, judgements, or claims that need support. AN (anecdote): evidence through personal experience, a story, a real event, or a concrete example. ST (statistics): quantitative evidence, studies, percentages, and figures, where a source need not be cited. TE (testimony): quoting or citing experts, bodies, or specific sources. In debates, restating the opposing team's claims counts as testimony. CO (common ground): agreed-upon knowledge, self-evident facts, or an objective explanation of how a procedure works. OT (other): does not genuinely contribute to the argumentative discourse (greetings, organisation, transitions). Output only the comma-separated list of codes present, with no explanation. Paragraph: {text}"* The Arabic original and the synthetic-data generation prompt templates ship with the code.

B Synthetic Data Details

Generation protocol. The generator is a proprietary large language model whose vendor and version we do not disclose. It was run in batches through the vendor's interactive interface, with its default sampling settings and no temperature or length parameter set. Each batch prompt con-

tained the official label definitions, three to five real training paragraphs of the target classes with their gold labels (or their labelled spans for Task 2), a topic and register assignment, and the output format. Paragraphs were validated against the official label definitions and deduplicated, with offsets checked programmatically. For Task 1 we targeted ST, CO, and OT and obtained 291 validated unique paragraphs (171 in the development phase). For Task 2 the paragraphs were authored as ordered labelled segments joined by single spaces, which gives exact offsets by construction. We obtained 158 paragraphs with 772 spans (88 in the development phase), with the rare types boosted (ST 128 against 38 real and CO 99 against 50). All synthetic data are used in training only and are released with the code, documented as machine-generated. The statistics inside synthetic ST spans are plausible but invented, and the recipe emits ordered, non-overlapping spans, so it cannot express nested annotations such as that in Figure 6.

Check by a second model. After our final submission, a second proprietary large language model, from the same family as the generator but a different model, re-annotated all 291 Task 1 paragraphs, shown only the official label definitions and blind to the generator's labels. Being same-family, it bounds annotation quality from above rather than validating it independently. Exact label-set agreement is 79.0%, micro-F1 is 0.94, and per-label Cohen's κ ranges from 0.61 (TE) to 1.00 (ST), with near-perfect agreement on the targeted rare classes (ST 1.00, CO 0.99). The blind annotations and the agreement script are released with the code.

Check by a human annotator. For the camera-ready version the first author, a native speaker familiar with the annotation guidelines, labelled 30 Task 1 synthetic paragraphs blind to the generated labels, 15 per genre and sampled to cover the targeted classes. Each was also rated for naturalness on a three-point scale. Table 5 gives the result beside the second model's annotations of the same 30 paragraphs. Agreement with the generator is micro-F1 0.84, with the targeted classes near-perfect (ST κ 1.00, CO 0.93). The human confirmed 96% of the generator's labels while only 74% of the human's labels were in the generator's set, so the disagreements are almost all labels the generator omitted rather than labels it invented. Fourteen of the fifteen disagreements add a label, most often TE for a restated opposing claim or OT for an opening address in a debate turn, the two debate-specific rules of the guidelines. Naturalness averaged 2.93 of 3, and no paragraph was rated unnatural. On the same paragraphs the second model agrees with the generator more closely than the human does (0.89 against 0.84), the direction the same-family caveat predicts. The sheet, the key, and the scoring script are released with the code.

	Human	**Model**
Exact label-set agreement	0.50	0.63
Micro-F1 against generator	0.84	0.89
Generator labels confirmed	0.96	0.92
Own labels in generator set	0.74	0.85
κ ST / CO	1.00 / 0.93	1.00 / 0.93
κ AS / OT	0.67 / 0.66	0.87 / 0.77
Naturalness (1 to 3)	2.93	

Table 5: Blind checks of the Task 1 synthetic labels on the same 30 paragraphs, by the first author and by the second model. TE and AN have three and one generated instances in this sample, so their κ values are not informative and are omitted.

Figure 3 shows an example synthetic Task 2 editorial paragraph authored as four ordered segments, translated here from the Arabic, whose offsets are those of the Arabic original, namely CO *"No one denies that e-commerce has radically changed shopping habits"* [0,60), AS *"yet the forgotten side is the environmental cost of ever-growing delivery trips"* [61,124), ST *"last-mile delivery emissions rise by about 30% annually in congested cities"* [127,195), and AS *"organising smart distribution hubs near neighbourhoods could tangibly ease this burden"* [196,266). Joining the segments with single spaces, with an unlabelled connective (*wa*, "and") allowed between spans, yields exactly these character offsets. A Task 1 synthetic CO example in the debate register reads *"No one denies that the Earth orbits the Sun in a near-elliptical orbit, and that together with the planet's axial tilt this produces the succession of seasons. This is established astronomical knowledge that every pupil studies, beyond dispute in a climate debate."*

C Threshold Recalibration

Conditions on the controlled result. Two conditions bound the experiment reported above. The comparison baseline is the development-phase threshold set, which was itself tuned on 612 of the 829 paragraphs, so it is not blind to most of each held-out split. Under a fully blind protocol, tuning on those 612 and evaluating on the untouched

Figure 3: The synthetic Task 2 paragraph described above (CO is common ground, AS assumption, and ST statistics, as in Figure 1). The offsets are exact by segment concatenation.

217, the loss is 0.006 against the 0.014 that 621 tuning paragraphs give in Table 7. That is a single split, and the split-to-split standard deviation at that tuning size is 0.015, so the reduction is smaller but not separable from noise. And the experiment concerns recalibration of an existing threshold set rather than the use of per-class thresholds, which every submitted configuration applies.

Relation to known results. The mechanism is not new. Fitting a decision rule to validation output and then reporting the tuned score is a form of selection bias, whose consequences for model selection and for the repeated reuse of a holdout are established (Cawley and Talbot, 2010; Dwork et al., 2015). What we add is a measurement of its size for one practice that remains common in shared-task pipelines. Within the same campaign, changes to the model itself were overstated by considerably less, although that comparison is observational.

Why the two groups might separate. Tuning-set size does not by itself separate them, since the thresholds and fusion rules were fitted out of fold on the same 829 paragraphs. The candidate explanation we favour is the number of free parameters a rule fits relative to the evidence available to fix them. A per-class threshold vector sets six parameters against a macro-F1 whose rare-class terms rest on nine and twelve development instances, and the per-label rules carry more, whereas a data or encoder change is a single decision judged against the whole score. We did not test this, and say so. A sweep from a single global threshold to per-class and then per-class-per-domain thresholds under the protocol above would test it directly.

The global recalibration entry. Global recalibration on Task 1 appears in Table 6 with a realised gain of 2.5 points, which the controlled experiment would not predict. No split at 207, 414, or 621 tuning paragraphs reaches that value, and only 0.4% of the splits at 746 paragraphs do. The two are not the same operation. The thresholds in the deployed configuration were the development-phase values, which had become stale against the evaluation-phase encoders, and the number of paragraphs receiving no label at all had risen from 16 to 22 of 213. That intervention repaired a threshold set that had ceased to match its model, rather than re-tuning one that already matched it. We record it as such, and note that on the evidence available we cannot exclude the alternative reading that it is a single favourable draw.

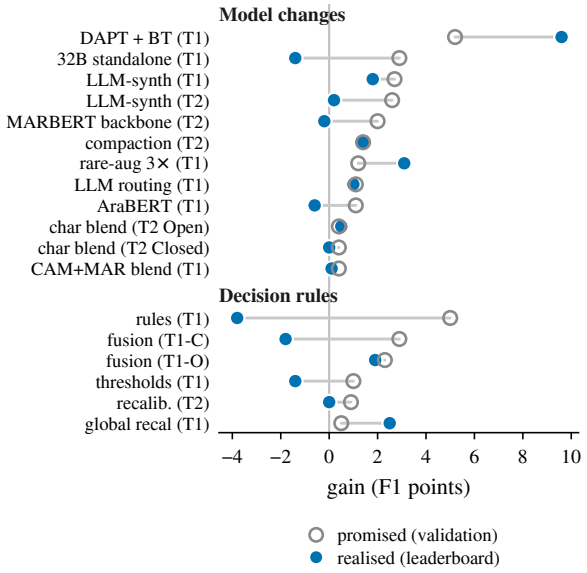

Figure 4: Promised validation gain (open) and realised leaderboard gain (filled) for the eighteen interventions, in F1 points, sorted by promise. Labels are abbreviated forms of the row names in Table 6, where the full data appear.

Notes on Table 6. The validation column is a pooled gain except for the Task 2 threshold recalibration row, whose entry averages the two per-domain gains of 1.2 and 0.6 points. The table lists the interventions for which we recorded both a validation estimate and a leaderboard delta. It was assembled from our own log after the fact, so it is necessarily incomplete, and an eightfold augmentation variant, class weighting, and domain routing on Task 1 were scored without a paired estimate and are omitted. Some realised deltas carry a co-occurring change. The MARBERTv2 backbone row also varied ensemble size, the Task 1 LLM-

Intervention	Val. basis	Val.	Real.
Model changes			
DAPT + BT (T1)	holdout	+5.2	+9.6
rare-aug 3× (T1)	holdout	+1.2	+3.1
LLM-synth (T1)	holdout	+2.7	+1.8
LLM-synth (T2)	holdout	+2.6	+0.2
span compaction (T2)‡	dev-tuned	+1.4	+1.4
char-level blend (T2 Open)	OOF	+0.4	+0.5
char-level blend (T2 Closed)	OOF	+0.4	0.0
LLM routing, one seed (T1)	holdout	+1.1	+1.0
AraBERTv2 in ensemble (T1)	holdout	+1.1	−0.6
32B standalone (T1)	holdout	+2.9	−1.4
CAM+MAR blend (T1)	OOF	+0.4	+0.1
MARBERTv2 backbone (T2)	CV	+2.0	−0.2
Decision-rule changes			
global recalib. (T1)	OOF	+0.5	+2.5
per-domain thresholds (T1)	OOF	+1.0	−1.4
span fusion (T1 Closed)†	OOF	+2.9	−1.8
span fusion (T1 Open)†	OOF	+2.3	+1.9
threshold recalib. (T2)	OOF	+0.9	0.0
per-label rules (T1)	holdout	+5.0	−3.8

Table 6: Data behind Figure 4, in F1 points. Val. is the gain on the stated validation basis, where OOF means out of fold, and Real. the gain on the official leaderboard, development or test according to the phase. Rows marked † entered together with the per-domain thresholds above them, and the row marked ‡ audits the first compaction grid. Notes on individual rows follow in the text.

synth row also carried a threshold retune, and both Task 2 char-level blend rows entered with a per-domain threshold retune. The blend was submitted on both Task 2 tracks from one validation estimate, gaining 0.5 on the Open board and nothing on the Closed one, where two distinct systems had already reached the same score. The two fusion rows entered together with the per-domain thresholds, so their isolated effect is smaller, and an isolating probe puts Closed fusion at −0.4. The compaction row audits the first grid, while the deployed configuration was worth 0.017 in total. DAPT and back-translation are bundled because they entered one submission, with separate holdout gains of +1.2 and +4.0. The routed-LLM holdout used the 14B model, and its realised entry averages the Closed and Open submissions (+0.8 and +1.1). The three-seed union is absent because it entered without a validation estimate, and its post-submission check is in Table 4. Validation estimates and realised gains are not usefully correlated within either group at this sample size, and each Pearson coefficient is set by one high-leverage intervention, so we do not rely on them. Compaction sits in the model group, although its dev-tuned gap thresholds would equally justify placing it among the decision rules.

Threshold recalibration under a controlled split. The leaderboard evidence in Figure 4 is observational, so we repeated the exercise under a controlled protocol, as a post-submission analysis, on the out-of-fold predictions of the Task 1 encoder ensemble, whose thresholds we recalibrated. For each of 500 random splits of the 829 paragraphs, rather than one fixed split (Gorman and Bedrick, 2019), we recalibrated the per-class thresholds on one part by an independent per-label grid search against the development-phase set, then measured the change in macro-F1 on both parts. Table 7 gives the result. Recalibrating on 207 paragraphs, roughly the size of the development set, appears to gain 0.033 but loses 0.016 held out and is non-positive in 97% of splits. Enlarging the tuning set shrinks the apparent gain to 0.010 at 746 paragraphs while the held-out loss does not move, so what depends on the size of the tuning set is the apparent gain rather than the gain delivered. The expected loss is close to the 0.014 that per-domain thresholds cost us on test. That is consistent with recalibration behaving this way at this data size, though one test delta of that size cannot be separated from sampling noise at the spread we observe. We repeated the experiment on Task 2, over the out-of-fold span probabilities of the submitted Closed system, scored with the official overlap-F1 and recalibrated by the same coordinate ascent that system uses, per genre on that genre's own score. The baseline is the development-phase threshold set of the submitted decode (Appendix A), fitted a month earlier on pre-DAPT-v2 cross-validation probabilities and therefore blind to the predictions under test, though, as on Task 1, not to the underlying texts. Over 200 splits, tuning on 207 paragraphs appears to gain 0.014 but loses 0.007 held out and is non-positive in 98% of splits. At 746 the apparent gain falls to 0.005 with the loss unchanged, and at an even split the figures are +0.008 in sample against −0.005 held out, non-positive in 92%. Task 2 therefore reproduces the Task 1 shape at roughly two fifths of the magnitude, so the effect is not particular to macro-F1 or to paragraph labels. Its size depends on the protocol, since ascending on the pooled objective rather than per genre halves the held-out loss to 0.003 and scoring the genre mean gives 0.002, but it is negative on average at every tuning-set size under every variant we tried. The held-out standard deviation is 0.004 to 0.008 and the splits are draws from one set of

829 paragraphs, so we attach no significance test, and the loss is carried mainly by the editorials. Our reimplementation reproduces the per-genre scores logged for that configuration, 0.729 on editorials and 0.733 on debates.

Tuned on	In-sample	Held-out	Held-out ≤ 0
207 paragraphs	+0.033	−0.016	97%
414 paragraphs	+0.019	−0.014	93%
621 paragraphs	+0.013	−0.014	87%
746 paragraphs	+0.010	−0.015	77%

Table 7: Threshold recalibration measured on the tuning subset and on the held-out remainder, averaged over 500 random splits of the 829 out-of-fold Task 1 paragraphs. The apparent gain shrinks with the tuning set while the held-out loss does not.

D Error Taxonomy

This appendix reports post-submission analyses on the released dev gold. Table 8 classifies every span of a routed dev decode, the same one used for the paired compaction bootstrap and weaker than the submitted routed system, before and after compaction. A gold span is *covered* when at least 80% of its characters receive same-label credit, *partial* when some do, and *missed* otherwise. A predicted span is *clean* when at least 80% of its characters earn same-label credit, *partial* when some but fewer than 80% do, a *label confusion* when it mostly overlaps gold spans of another label, and *hallucinated* when it earns no same-label credit and covers gold spans of other labels over less than half its length.

	Raw	Compacted
Gold spans (961)		
covered (≥80%)	642	656
partially covered	140	96
missed	179	209
Predicted spans		
total	1,167	605
clean (≥80%)	731	379
partial	82	105
label confusion	319	115
hallucinated	35	6
pred. spans per matched gold	1.20	1.02

Table 8: Task 2 error taxonomy on dev for the routed dev decode, before and after span compaction. The last row averages, over the gold spans that received any same-label credit, the number of predicted spans overlapping each one. It is not the ratio of the two totals above it.

We make three observations. First, compaction removes fragmentation almost entirely, since each matched gold span is covered by 1.02 predicted spans on average (1.20 raw) and hallucinated spans fall from 35 to 6, largely through the minimum-length filter. Second, the trade-off is explicit, as 30 further short gold spans are missed after filtering, a cost the pooled metric more than offsets. Third, the residual error mass is semantic rather than segmental, with 115 label-confusion spans and 209 whole-span misses. That is consistent with our later gains coming from data and models rather than from further decoding rules, although this taxonomy is post-submission and did not inform those choices.

Label	Support	FN	FP	Predicted instead
AS	157	6	26	TE (2)
AN	68	24	24	OT (7), AS (5)
ST	9	2	1	none
TE	76	13	11	OT (4), AN (2), AS (2)
CO	12	10	12	AN (4), AS (2)
OT	63	12	38	none

Table 9: Task 1 confusion on dev for the final Closed development system. FN and FP are per-label false negatives and positives. The last column lists every label that was predicted, but not gold, on at least two of the paragraphs where the gold label was missed.

Table 9 gives the Task 1 picture. CO fails by omission, with 10 of its 12 gold paragraphs missed and typically labelled AN or AS instead, exactly the confusion of Figure 9. ST, the target of our augmentation, is mostly solved (2 of 9 missed). The bulk of the errors sits on the boundary between AN and OT (7 of 24 missed AN paragraphs were called OT, and OT draws 38 false positives), and AS is essentially saturated. Rare-class semantics, not thresholding, is what remains.

Why editorials are harder. Every ranked team entry on the four leaderboards scored lower on editorials than on debates. The one reversal on the sheet is an unranked training-subset slot, ttlab's editorials-only Task 2 Closed variant at 0.623 against 0.601. Table 10 locates the cause in the training data rather than in any one system. The deficit is concentrated in two labels. OT is effectively a debate category, since only 5% of its training spans are editorial, and editorial OT is not recovered at all by this decode (F1 0.000 against 0.602 on debates). AS, the majority class in both genres, draws 71% of its training spans from debates. The labels whose training spans are mostly

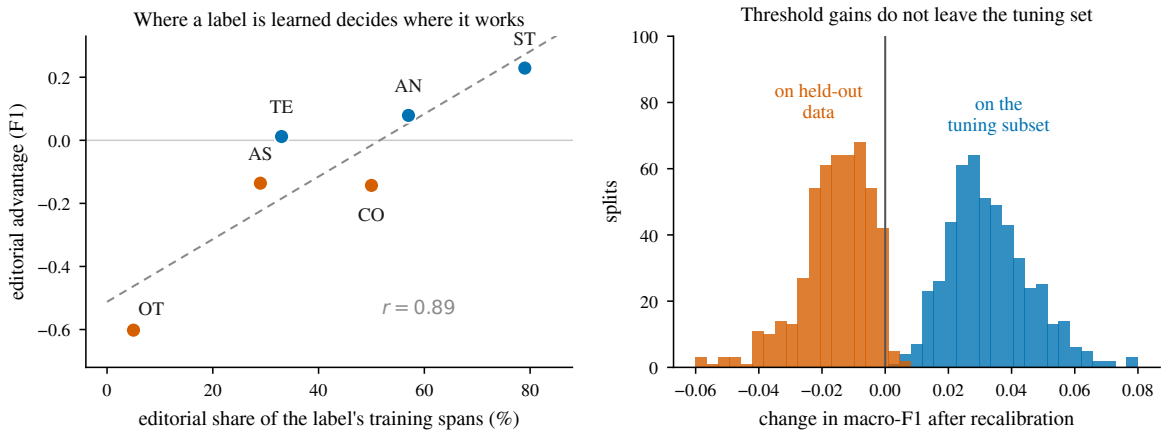

Figure 5: The two post-submission findings. Left, each label's editorial advantage on the development set against the editorial share of that label's training spans, with OT at the extreme and the dashed line a least-squares fit. Right, the change in Task 1 macro-F1 after recalibrating per-class thresholds on a quarter of the out-of-fold paragraphs, measured on the tuning subset and on the held-out remainder over 500 random splits. The in-sample distribution lies entirely above zero, while the held-out distribution is non-positive in 97% of splits.

editorial, ST and AN, are handled better on editorials, as is TE by a smaller margin. Across the six labels the editorial advantage tracks the editorial share of training spans, with a Pearson r of 0.89 over six points. The coefficient is stable under leave-one-out (0.78 to 0.95) but is anchored by the two extremes and is not significant without OT (p=0.117), so we read it as descriptive.

The pattern is not an artefact of our routing. It appears with the same strength in each encoder family alone (0.92 for CAMeLBERT-mix and 0.92 for MARBERTv2, against 0.88 for the routed decode, all before compaction), and on Task 1 the two extremes behave the same way, with OT at −0.34 and AN at +0.35. Span length is at most a secondary factor. Editorial gold spans are longer on average (99 against 76 characters), which costs more under the partial-overlap metric, but restricted to AS the difference is small (78.7 against 74.1). Editorials are also more label-diverse, with AS 55%, AN 20%, and TE 16% of gold spans against AS 63% and OT 16% in debates, so a system that fits the dominant debate pattern has less to fall back on.

Our synthetic data support this reading, as they were written with editorial cover for the rarest classes. The Task 1 systems with and without them differ in the synthetic paragraphs and the threshold recalibration these induce. The editorial column rises for the classes that received editorial synthetic paragraphs while the debate column stays flat, by +0.152 against −0.008 for CO and +0.075 against 0.000 for ST, on five and eight editorial dev paragraphs. The exception is OT, where the 30 editorial OT paragraphs of the development-phase pool did not help (−0.028), which suggests that a residual category defined by what it is not is harder to synthesise than a contentful one. Genre-balanced annotation of the rarest cells, rather than more modelling, is what we would expect to close this gap.

Label	Ed F1	n	Db F1	n	Diff	% ed
AS	0.655	144	0.791	443	−0.136	29
AN	0.557	51	0.478	60	+0.079	57
ST	0.652	8	0.423	1	+0.229	79
TE	0.772	41	0.760	71	+0.012	33
CO	0.000	5	0.143	11	−0.143	50
OT	0.000	12	0.602	114	−0.602	5

Table 10: Task 2 dev F1 by genre and label for the routed dev decode after compaction, against the editorial share of that label's training spans. The two labels drawing the smallest share of their training spans from editorials, OT and AS, are also the two on which the editorial deficit is concentrated. n is the gold span count for that label in that genre. Several cells rest on single-digit support, so individual F1 values there are unstable even where the pattern across labels is not.

A controlled genre-transfer test. The evidence above is correlational, so we ran a size-matched training experiment. We trained the Task 1 encoder on 255 editorial paragraphs, on 255 debate paragraphs, and on a half-and-half mixture of the same size, with thresholds fixed at 0.5 and three seeds each. We evaluated on the editorial and debate halves of the development set. These are deliberately small single models, not competitive configurations, so the absolute values sit far below

those of our submitted system, and only the contrast between them is meaningful. Table 11 gives the means. The crossover is clean and holds in all six seed comparisons, since training on editorials gives 0.350 on editorials against 0.271 on debates, while training on debates reverses this to 0.207 and 0.395. With architecture held fixed, genre composition alone moves a model's strength from one genre to the other, and the half-and-half mixture recovers nearly all of both columns. This does not show that architecture is irrelevant, only that composition suffices to produce the split, since the routing result of Section 3.1 shows two encoder families splitting by genre on identical data. One label does not follow this pattern. An editorials-only model scores 0.000 on OT at all three seeds and in both genres, because only 20 of the 222 OT training paragraphs are editorial (9%), so its 255-paragraph pool carries just 20 OT positives, whereas a debates-only model reaches 0.374 on editorial OT. Genre balance therefore helps only where the target genre exemplifies the label. Where the cell is thin, as it is for editorial OT, the remedy has to be annotation rather than rebalancing.

Trained on	Ed	Db
editorials only	**0.350** (0.038)	0.271 (0.036)
debates only	0.207 (0.008)	**0.395** (0.012)
half and half	0.319 (0.035)	0.390 (0.016)

Table 11: Size-matched genre-transfer test on Task 1 (255 training paragraphs each), dev macro-F1 by genre, averaged over three seeds with thresholds fixed at 0.5, and the standard deviation over seeds in brackets.

E Suggestions for Future Editions

The task is a valuable new resource, and we offer four observations for future editions in a constructive spirit. The cross-team figures below are post-submission, from the organisers' published sheet.

Report uncertainty. Task 1 macro-F1 at this data size carries a development-set resampling half-width of about ± 0.05. A bootstrap interval beside each leaderboard score, or larger rare-class test support, would make small ranking gaps interpretable.

Revisit the span scorer. The overlap scorer rewards merging essentially all same-label spans within an editorial paragraph (Appendix A). An IoU-style or length-normalised variant would remove that incentive.

Limit leaderboard feedback. With unlimited submissions the leaderboard doubles as a validation signal for every team, ourselves included. A small frozen holdout or a cap on scored submissions would sharpen the comparison.

Weight the genres. Debates supply 73% of the gold spans on the development set, and the test set has the same genre proportions, so the pooled Task 2 score is in effect a debate score. Across the eight Task 2 Closed teams the debate column correlates with the overall score at 0.96, while the editorial column, the harder part, correlates at 0.42 and barely affects rank. Among the top five on Task 1 the balance reverses and the editorial column is the separating one. Averaging the two domain scores, or reporting the per-domain columns as the primary result, would let editorial progress count towards the final standing.

F Qualitative Examples

All examples are from the released development set, and the translations are ours.

Nested gold spans. Figure 6 shows the development set's one *nested* annotation (editorial 962), where an ST span is embedded inside a sentence-length AN span. BIO-style tagging cannot represent this, while per-class sigmoid tagging can. The paragraph translates as *"Even if you are among those who read the small print before accepting privacy settings, which 56% of Americans do not do according to a 2023 study, some sites still request permission to share information about your visit."*

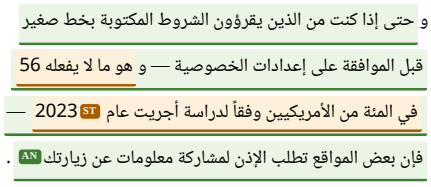

Figure 6: Nested gold annotation (editorial 962). An ST (statistics) span sits inside an AN (anecdote) span, whose green underline marks its extent. Our multi-label sigmoid tagger can predict both, while a BIO scheme cannot.

Why domain routing works. Figure 7 contrasts the two encoder families on debate turn 390, which is in a fully oral register. Both gold TE spans restate the opposing speaker's claims, which count as testimony under the guidelines' debate-specific rule.

CAMeLBERT-mix fragments the spans into pieces as short as three characters and drifts towards OT, while MARBERTv2 recovers both TE spans almost exactly and returns the two gold AS spans as one (paragraph overlap-F1 0.94 against 0.42, at full recall and precision 0.88). The turn translates as *"He said the pillars of the state are people, land, and government, and kept repeating that in the affected countries the land has been wiped away. Let him look at the nearest affected country while forgetting the state's elements in first-world countries, and ask yourself how this resolution affects the land pillar there."*

Figure 7: Gold against CAMeLBERT-mix and MARBERTv2 on debate turn 390 (TE is testimony, AS assumption, and OT other). CAMeLBERT-mix fragments and mislabels the spans, while the dialect-pretrained MARBERTv2 recovers the testimony spans and their extents, merging the two assumption spans into one. This is the complementarity behind our domain routing.

Span fragmentation (Task 2). Consider debate paragraph 186 (Figure 8). The gold AS span covers characters 154 to 316 and reads *"We came today as the proposition team, strongly in favour of the motion, namely that this house would prevent for-profit companies from using social and political causes in marketing."* The raw MARBERTv2 decode emits nine AS fragments in this paragraph, of which [185,197), [200,204), and [211,316) fall inside the gold span and [319,322) falls just past it. Token probabilities dip below threshold on short function words, leaving gaps of three to seven characters, and two fragments are under ten characters. Under the overlap metric each fragment is charged separately to precision. Gap merging joins fragments separated by at most five characters, but with $G_{\mathrm{db}}{=}5$ the chain continues past the gold boundary to [211,677). Compaction therefore removes the fragmentation at the cost of over-running the span, the trade-off that the plateau in Appendix A implies.

Figure 8: Fragmentation on debate paragraph 186. The gold AS (assumption) span (top) against the raw token-threshold decode (bottom), which splits it into fragments at short function words. Span compaction with $G_{\mathrm{db}}{=}5$ joins the last two fragments into a chain that runs to character 677, well past the gold boundary, while the first two merge into a 19-character span that the minimum-length filter then discards. Neither outcome is shown in the figure.

Rare-class confusion (Task 1). Editorial paragraph 95 (Figure 9), with gold {CO} and prediction {AS}, reads *"These tools include private web browsers, encrypted messaging apps, password managers, tracker blockers, and virtual private networks (VPNs)."* An objective, uncontested enumeration, which is common ground under the guidelines, is misread as an assumption. With only 36 CO training paragraphs, this boundary must be calibrated from a handful of examples, which is where our targeted augmentation was aimed.

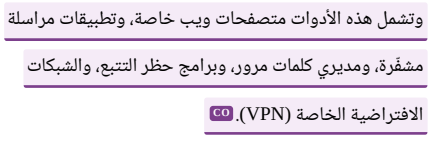

Figure 9: Editorial paragraph 95, an objective enumeration of privacy tools. The gold label is common ground (CO) and the prediction was assumption (AS).

Northwestern 12 at Daleel 2026: CAMeLBERT-Mix for Multi-Label Arabic Argumentative Discourse Unit Classification

Abstract

This paper presents our submission to Task 1 (Argumentative Discourse Unit Classification) of the Daleel 2026 Shared Task, which requires predicting all applicable discourse categories for an Arabic paragraph. which restricts training to the official task data and permits publicly available pretrained language models. Our system fine-tunes CAMeLBERT-Mix using class-weighted Binary Cross-Entropy loss and label-specific threshold optimization to address class imbalance, paragraph-type-aware input representation to account for genre variation, and head-tail tokenization to retain information from both ends of long paragraphs. After model selection and threshold tuning on the development set, the system achieves a Macro F1-score of 0.6121, a Micro F1-score of 0.7509, and a Samples F1-score of 0.6387. On the official hidden test set, it achieves a Macro F1-score of 0.5648, providing a baseline for Arabic multi-label argumentative discourse unit classification.

1 Introduction

Argument mining aims to automatically identify and analyze argumentative structures in natural language text, enabling applications such as opinion mining, debate analysis, fact verification, and decision support. One of its core tasks is Argumentative Discourse Unit (ADU) classification, which identifies the argumentative functions expressed within a text. Since a paragraph may contain multiple argumentative discourse units simultaneously, the task is naturally formulated as a multi-label classification problem.

Task 1 of the Daleel 2026 Shared Task addresses Arabic Argumentative Discourse Unit Classification under the Closed Track setting (dal). Participants are required to predict all discourse unit types present in an Arabic paragraph from six predefined categories using only the official training data. The task is challenging due to label co-occurrence, semantic overlap between discourse categories, class imbalance, and variation across paragraph genres.

In this paper, we present our submission to the Daleel 2026 Shared Task. Our system fine-tunes CAMeLBERT-Mix for multi-label classification. To address class imbalance, we use class-weighted Binary Cross-Entropy loss and label-specific threshold optimization. Paragraph-type-aware input representation incorporates genre information to account for differences between debates and editorials, while head-tail tokenization retains information from both the beginning and end of long paragraphs. These design choices provide a straightforward framework for Arabic argumentative discourse unit classification.

Our system achieved an Overall Macro-F1 score of 0.5648 on the official hidden test set and ranked 8th in Task 1 , according to the final organizer results. The development-set Macro-F1 of 0.6121 was obtained after model selection and threshold tuning on the same development set and should therefore be interpreted as a tuning-set score rather than an independent estimate of generalization. The lower official test performance highlights the need for further investigation of generalization and the individual contributions of the system components.

2 Background

Task Description Task 1 of the Daleel 2026 Shared Task focuses on Arabic Argumentative Discourse Unit Classification under the Closed Track setting. Given an Arabic paragraph, the objective is to predict all argumentative discourse unit types present in the paragraph, making the task a multi-label text classification problem.The official Daleel 2026 dataset is in Arabic and covers two genres: editorials and debates. Our system follows the Closed Track setting by using only the official training and

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1344–1348
October 28-29, 2026 ©2026 Association for Computational Linguistics

development data.The task defines six discourse categories: Common Ground (CO), Assumption (AS), Testimony (TE), Statistics (ST), Anecdote (AN), and Other (OT). Since multiple discourse units may co-occur within a single paragraph, the model must identify all applicable labels simultaneously.

Example. The following example illustrates the input representation used by our system.

Type: `editorial`

Input:

نوع النص: مقال رأي. النص: وما يثير الاهتمام، أن هذه الأرقام تأتي بالرغم من أن فريقه الخلود يجيء خامس أقل الفرق في معدل خلق الفرص في الدوري. ما يعني أنه رغم قلّة الفرص التي تُخلَق، فإن إنريكي دائمًا ما يكون بكامل تركيزه وحضوره الذهني لاستغلالها.

Output: {AS, AN}

Following the Closed Track rules, our system relies exclusively on the official training and development datasets together with publicly available pretrained language models, without using additional labeled resources.

Argument mining aims to automatically identify argumentative structures and discourse functions in natural language text. Recent pretrained transformer models have substantially improved performance on argument mining and text classification tasks by learning contextual representations (Lawrence and Reed, 2019; Antoun et al., 2020; Inoue et al., 2021).

For Arabic NLP, AraBERT (Antoun et al., 2020) and CAMeLBERT (Inoue et al., 2021) have achieved strong performance across a wide range of language understanding tasks.Bessghaier et al. (2025) extended AraBERT with a prompt-type embedding and a task-aware lexicon for Arabic automated essay scoring

However, Arabic argumentative discourse unit classification remains relatively underexplored, particularly in the multi-label setting where multiple discourse categories may co-occur within the same paragraph.Our work builds on CAMeLBERT-Mix and adapts it to the Daleel 2026 Shared Task through paragraph-type-aware input representation, head-tail tokenization, class-weighted BCEWithLogits loss, and label-specific threshold optimization, while fully complying with the Closed Track setting.

Table 1: Genre-aware input representation.

Component	Representation
Debate	مناظرة
Editorial	مقال رأي
Input Template	نوع النص: <genre>. النص: <paragraph>

3 System Overview

Our system fine-tunes CAMeLBERT-Mix for Arabic multi-label argumentative discourse unit classification. The input is constructed by prepending the paragraph type to the original text, followed by head-tail tokenization. The contextual representation produced by CAMeLBERT-Mix is passed to a linear classification layer with sigmoid activation to predict the six discourse categories independently. Training uses a class-weighted BCEWithLogits loss, while inference applies label-specific thresholds optimized on the development set.

The system consists of five stages: input representation, head-tail tokenization, CAMeLBERT-Mix fine-tuning, class-weighted BCEWithLogits loss, and label-specific threshold optimization.

3.1 Input Representation

Each paragraph is paired with its corresponding `type` field provided in the official Daleel 2026 dataset, indicating whether the paragraph originates from a *debate* or an *editorial*. During preprocessing, this type information is prepended to the original paragraph before tokenization using a fixed textual prompt. During preprocessing, the paragraph genre is first converted into its corresponding Arabic descriptor. The resulting genre information is then prepended to the original paragraph using a fixed textual prompt before tokenization. The final model input follows the template shown in Table 1

This representation allows CAMeLBERT-Mix to jointly encode the paragraph content together with its source context within a single input sequence. The type information is obtained directly from the official dataset and is neither predicted nor externally generated.

3.2 Head-Tail Tokenization

The input sequence is tokenized using the CAMeLBERT-Mix tokenizer with a maximum

length of 384 tokens. For sequences that exceed this limit, we apply a head-tail truncation strategy rather than retaining only the beginning of the paragraph. After reserving two positions for the special [CLS] and [SEP] tokens, the remaining token budget is divided equally: 191 tokens are retained from the beginning of the sequence and 191 tokens from the end. The selected segments are concatenated and enclosed by the two special tokens. For shorter sequences, all tokens are preserved.

Head-tail truncation was chosen as a simple, fixed-length strategy that retains information from both the opening and concluding portions of long paragraphs. Unlike overlapping-segment approaches, it requires only one forward pass per paragraph. However, it may discard informative spans in the middle. We did not conduct controlled comparisons against a 512-token setting or overlapping-segment alternatives.

3.3 Model Architecture

We fine-tune CAMeLBERT-Mix for multi-label classification. CAMeLBERT-Mix was selected as a reasonable starting point for the task's heterogeneous Arabic input. We did not compare it with AraBERT or CAMeLBERT-MSA and therefore make no claim of superiority over these alternatives.

The contextual representation of the [CLS] token is passed through a linear classification layer that produces one logit for each discourse category. Since multiple discourse categories may co-occur within the same paragraph, sigmoid activation is applied independently to obtain a probability for each label.

3.4 Loss Function

To address class imbalance, we employ the Binary Cross-Entropy with Logits (BCEWithLogits) loss using label-specific positive class weights. The positive weights are computed from the label distribution in the training data and assigned to each discourse category, encouraging the model to better learn underrepresented labels while maintaining stable optimization.

For each label, the positive class weight is computed as $N_{\text{neg}}/N_{\text{pos}}$ and clipped to the range $[1, 10]$ to avoid excessively large weights for rare labels.

3.5 Label-Specific Threshold Optimization

During training, predictions are evaluated using the default threshold of 0.5. After training, an independent threshold is selected for each discourse category using the development set. Candidate thresholds are evaluated with a step size of 0.01 within a predefined label-specific search range.

For each label, we first identify the maximum development F1-score. We then retain candidate thresholds whose F1-score is within 0.01 of this maximum and select the candidate with the highest precision. When multiple candidates obtain the same precision, the higher threshold is preferred. The resulting thresholds are applied unchanged during test-set inference.

Candidate thresholds are searched within the following label specific ranges: CO [0.20,0.70], AS [0.30,0.80], TE [0.25,0.75], ST [0.15,0.70], AN [0.25,0.75], and OT [0.25,0.75].

The final selected thresholds are 0.39 for CO, 0.60 for AS, 0.58 for TE, 0.20 for ST, 0.27 for AN, and 0.75 for OT. These values were obtained from the development set and applied unchanged to the official test set.

4 Experimental Setup

Experiments were conducted using the official training and development sets of the Daleel 2026 Shared Task. We fine-tuned CAMeLBERT-Mix with a maximum sequence length of 384 tokens using AdamW, a learning rate of 2×10^{-5}, weight decay of 0.01, and a warmup ratio of 0.1. The model was trained for up to eight epochs with an effective batch size of 16 and early stopping.

Performance was evaluated using Macro F1, Micro F1, and Samples F1, with Macro F1 used for model selection. Macro F1 averages the F1-scores across the six labels, giving equal importance to each category, while Micro F1 aggregates predictions across all labels before computing F1. Samples F1 computes the F1-score for each paragraph and then averages across paragraphs, providing a complementary measure of how well the system predicts the complete set of applicable labels for individual paragraphs.

Early stopping was based on the development Macro F1 score with a patience of two evaluation rounds. The model was evaluated after each epoch, and the best checkpoint was restored at the end of training. All experiments were conducted using a fixed random seed of 42 across Python, NumPy,

PyTorch, and the Hugging Face training pipeline to improve reproducibility. The system was implemented using PyTorch and the Hugging Face Transformers library.

The implementation and configuration files are available in the shared Google Colab notebook.

5 Results

Table 2 presents the overall performance of the proposed CAMeLBERT-Mix framework on the official development set. The system achieved a Macro F1-score of 0.6121, a Micro F1-score of 0.7509, and a Samples F1-score of 0.6387.

Table 2: Overall performance on the development set.

Metric	Score
Macro F1	0.6121
Micro F1	0.7509
Samples F1	0.6387

Table 3 reports the performance for each discourse category after applying label-specific threshold optimization.

As shown in Table 3, the proposed system achieves the highest performance on the *Assumption (AS)* category with an F1-score of 0.92, followed by *Testimony (TE)* (0.74), *Other (OT)* (0.66), and *Anecdote (AN)* (0.65). The *Statistics (ST)* and *Common Ground (CO)* categories remain the most challenging, achieving F1-scores of 0.52 and 0.18, respectively.

The official hidden test Macro-F1 of 0.5648 is lower than the development-set score of 0.6121, corresponding to an absolute decrease of 0.0473. Since the development set was used for both checkpoint selection and label-specific threshold tuning, the development score may be optimistic and should not be interpreted as an independent estimate of generalization. This repeated use of the development set may have contributed to the observed gap, although other factors, including differences between the development and test distributions, cannot be ruled out. The available experiments do not establish the relative contribution of these factors.

5.1 Error Analysis

We analyzed misclassified development examples using the final label-specific thresholds. Three main error patterns were observed. First, the model occasionally predicts additional discourse categories, particularly `CO`. For example, in Paragraph 5, the gold labels are {`AS`, `AN`, `OT`}, while the model additionally predicts `CO`. Second, the model sometimes misses one or more gold labels. For instance, Paragraph 13, labeled with {`CO`, `TE`}, receives no predicted labels. Finally, mixed errors are also observed. In Paragraph 56, the model correctly predicts `CO`, `AS`, and `AN`, but misses `TE` and `OT` while incorrectly predicting `ST`. These results indicate that distinguishing overlapping discourse categories remains the primary challenge in the task.

Table 3: Per-label performance on the development set.

Label	Precision	Recall	F1
CO	0.14	0.25	0.18
AS	0.92	0.93	0.92
TE	0.82	0.67	0.74
ST	0.36	0.89	0.52
AN	0.55	0.79	0.65
OT	0.73	0.60	0.66

Table 4: Representative development-set error examples.

ID	Gold	Prediction	Type
5	AS, AN, OT	CO, AS, AN, OT	Extra label
13	CO, TE	–	Missed labels
56	CO, AS, TE, AN, OT	CO, AS, ST, AN	Mixed error

6 Limitations

The present study does not include controlled ablation experiments to isolate the contributions of paragraph-type-aware input representation, head-tail truncation, class-weighted BCEWithLogits loss, and label-specific threshold optimization. Consequently, the individual effects of these components on performance cannot be established. We also did not compare CAMeLBERT-Mix with alternative Arabic pretrained models, evaluate multiple random seeds, or conduct a controlled comparison of sequence lengths and truncation strategies. These limitations restrict the conclusions that can be drawn about the relative effectiveness and generalizability of the proposed design choices. Future work will investigate these alternatives through systematic ablation studies and repeated experiments.All reported results are based on a single run with a fixed random seed of 42. We did not conduct repeated runs with different seeds or cross-validation.Our error analysis is limited to representative examples; systematic per-label and label co-occurrence analyses remain for

future work.

7 Conclusion

In this paper, we presented our submission to Task 1 of the Daleel 2026 Shared Task on Arabic argumentative discourse unit classification. Our system fine-tunes CAMeLBERT-Mix for multi-label classification by combining paragraph-type-aware input representation, head-tail tokenization, class-weighted BCEWithLogits loss, and label-specific threshold optimization under the Closed Track setting.

The system achieved a Macro-F1 score of 0.5648 on the official hidden test set and ranked 8th in Task 1 Closed, according to the final organizer results. These results provide a baseline for Arabic multi-label argumentative discourse unit classification while highlighting the challenges of generalization and distinguishing overlapping discourse categories.

Future work will investigate alternative Arabic pretrained language models, conduct systematic ablation studies and repeated experiments, and explore alternative approaches to long-context modeling and multi-label imbalance.

Abstract

This paper presents our systems for the Daleel 2026 Shared Task. We explore multitask learning, domain-specific ensembles, and a two-stage BIO segmentation and classification pipeline with LLM-based disambiguation, alongside classical machine-learning, Transformer, and LLM baselines. Results show that supervised Transformers outperform standalone LLM prompting, while LLMs are more effective for selectively resolving ambiguous predictions. The multitask model achieves the best test performance on Task 1, with an F1 score of 0.599, while the ensemble multitask model reaches 0.683 F1 on Task 2. Our results show the potential of LLM integration within Transformer systems for Arabic argumentative discourse mining.

1 Introduction

Argument Mining (AM) has advanced considerably with neural and LLM-based methods, but research remains largely centered on high-resource languages such as English, while Arabic suffers from limited annotated resources and additional linguistic challenges, including dialectal variation and code-switching. These limitations motivate the development of dedicated resources and methods for Arabic argumentative discourse mining. The Daleel 2026 Shared Task (Nabhani et al., 2026) addresses this gap through two subtasks across editorials and debates, covering six Argumentative Discourse Unit (ADU) categories: Common Ground (CO), Assumption (AS), Testimony (TE), Statistics (ST), Anecdote (AN), and Other (OT). Task 1 focuses on ADU classification, while Task 2 focuses on identifying the corresponding spans within a paragraph.

This paper presents our submissions to the Closed Track for both subtasks. We compare a pipeline that combines BIO-based segmentation, a transformer classifier, and LLM-based disambiguation of uncertain predictions with multitask architectures that jointly learn segmentation and classification. Our submissions ranked 7th out of 19 teams in Task 1 and 8th out of 14 teams in Task 2. The results show that the pipeline achieves the best performance on the development set, whereas the multitask approach achieves stronger performance on the official test set, particularly for Task 1. Finally, our analysis identifies the confusion between Common Ground and Assumption as one of the main remaining challenges, highlighting the semantic similarity between these categories. The code is publicly available on GitHub.[1]

2 Background

AM is a well-established area in computational linguistics concerned with the automatic identification and classification of argumentative structures (Berghegger et al., 2025; Cabrio and Villata, 2018; Lawrence and Reed, 2019). A fundamental step is the identification of Argumentative Discourse Units (ADUs), the minimal text spans serving distinct argumentative functions. While most AM research has focused on high-resource languages, recent efforts have begun developing resources and methods specifically for Arabic argumentative discourse. Khader et al. (2024) introduced Munazarat 1.0, a corpus of Arabic competitive debates designed to support argumentation mining, followed by work on dedicated annotation schemes for Arabic argumentative debates (Al-Sharafi et al., 2025) and neural classification of argument elements and styles (Al-Zawqari et al., 2025). More recently, Nabhani and Khatib (2025) studied Arabic argument component identification as a BIO sequence-labeling task, exploring cross-lingual transfer, translation-based training, and LLM prompting to address the scarcity of native annotated resources. Beyond ar-

gument mining, BIO-based segmentation has also proved effective for Arabic and multilingual discourse segmentation (Keskes et al., 2013; Pujol et al., 2025).

Recent work has combined conventional models or rules with LLMs used selectively for ambiguous cases. Grecu et al. (2026), for example, use structural heuristics with a zero-shot LLM fallback in the ArgMining 2026 shared task, reducing computational cost while maintaining competitive performance. Other studies have explored LLM-based embeddings for unsupervised segmentation (Krassovitskiy et al., 2025) and generative approaches to AM (Cabessa et al., 2025).

Argument mining commonly involves both identifying argumentative unit boundaries and determining their argumentative functions. These stages have traditionally been modeled separately, with argument-unit segmentation formulated as sequence labeling (Ajjour et al., 2017; Petasis, 2019). More recent work has explored joint and multitask architectures to exploit dependencies between related AM subtasks. For example, Habernal et al. (2024) jointly predict argument type and speaker role in legal texts using shared Transformer representations. Such joint learning allows related tasks to benefit from a common contextual representation rather than being optimized independently. This motivates our comparison between a pipeline that separates ADU segmentation and classification and a multitask architecture that learns both tasks through a shared Arabic Transformer encoder.

3 System Overview

This section describes our three best-performing systems: a multitask architecture for joint ADU segmentation and classification, its ensemble extension, and a pipeline combining separate segmentation and classification with ensemble disambiguation. For all three approaches, we focus on span identification and classification in Task 2. The multi-label paragraph output required for Task 1 is then derived by collecting the unique labels of all predicted spans within each paragraph. We also explored alternative approaches, with the best approaches reported in Section 5 and the remaining experiments summarized in Appendix A.

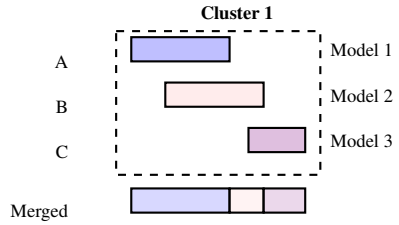

Figure 1: Example of character-level span clustering given 3 sets of predicted spans extracted from the same paragraph. Overlapping spans form a connected cluster and are merged using the minimum start and maximum end offsets.

3.1 Multitask

Our base model jointly learns ADU segmentation and classification using a shared Arabic transformer encoder: *CAMeL-Bert-mix* (Inoue et al., 2021). Two task-specific heads operate on the shared contextualized representations.

The segmentation head predicts BIO tags (B-ADU, I-ADU, O) through a token-level linear classifier. The classification head pools the hidden representations of each span using mean pooling and feeds the resulting vector into a feed-forward network to predict one of seven labels (CO, AS, TE, ST, AN, OT, or NT, the NT label is explained in Section 4).

During training, the classification head receives gold ADU boundaries (teacher forcing), while the segmentation head is optimized independently on the BIO tagging objective. Both tasks are trained jointly using a weighted sum of their focal losses.

3.2 Ensemble multitask

Our second system combines three multitask models trained on different subsets of the training data: one trained on the complete set, one using only debate documents, and one using only editorial documents. Each model is trained independently using the same architecture.

To compare and combine the arguments identified by each model we introduce a span-agreement mechanism. Given the 3 sets of predicted spans extracted from the same paragraph, we merge them based on their character-level overlap. First, all spans from all prediction models are represented as nodes. Two nodes are connected whenever their spans overlap.

We then compute connected components over this overlap relation. In this way, overlapping spans are grouped into clusters, including cases in which

two spans do not directly overlap but are connected through an intermediate overlapping span, for example the case of *A* and *C* in Figure 1. Only clusters containing predictions from all models are retained and merged into a single span whose boundaries correspond to the minimum start offset and maximum end offset among its members.

When all models assign the same label, it is kept as the final prediction. Otherwise, the disagreement is resolved using *CohereLabs/aya-expanse-8b* (Dang et al., 2024), which receives the candidate ADU, its paragraph context, and the set of possible labels, and selects the most appropriate argumentative category.

3.3 BIO segmentation + ensemble

We extend the standard BIO segmentation by assigning label-specific BIO tags (e.g., B-AS, I-AS, B-AN), using the same architecture as the multitask model. The predicted spans are then classified with *Arabertv02-twitter* (Antoun et al., 2020), which provides class probabilities used to identify sensitive cases, i.e., instances where the confidence difference between the top prediction and competing labels is below 0.1, or where the predicted label disagrees with the BIO tag. These sensitive cases are translated into English with *CohereLabs/aya-expanse-8b* and resolved by *Meta-Llama-3.1-8B-Instruct* (Dubey et al., 2024), which selects the final label using the ADU, its paragraph context, and the candidate labels.

4 Experimental Setup

During an initial inspection of the dataset, we analyzed the class distribution across the training, development, and test sets. As shown in Table 1, the distribution is largely consistent across splits, while also revealing a pronounced class imbalance: AS is the dominant category, accounting for approximately 41–42% of instances, whereas ST and CO each represent less than 4%, with OT, AN, and TE occupying intermediate proportions.

Split	AS	AN	ST	TE	CO	OT	Total
Train	42.4	16.7	2.6	14.7	3.3	20.4	1090
Dev	40.8	17.7	2.3	19.7	3.1	16.4	385
Test	41.2	12.0	3.5	18.6	2.7	22.1	376

Table 1: Class distribution (%) across the train, dev, and test sets.

We further observed that some paragraphs contain no gold ADU spans and are represented as *[]* in the original annotations. For training, we introduced an auxiliary *Nothing* (*NT*) label for these instances, allowing the model to learn that a paragraph may contain no ADU span. At prediction time, *NT* instances are converted back to *[]* to preserve the original shared task format.

Approach	Prec	Rec	F1
Dev set			
BIO seg. + ensemble	0.657	0.703	**0.679**
Multitask	0.596	0.570	0.575
Ensemble multitask	0.645	0.482	0.541
Test set			
BIO seg. + ensemble	0.616	0.584	0.579
Multitask	0.633	0.581	**0.599**
Ensemble multitask	0.642	0.493	0.546

Table 2: Performance of the three submitted systems on the dev and the test set. Results are reported in terms of macro values.

Each paragraph was split into its annotated ADUs (*span_text*), and the official training set was divided into training and validation partitions using an 80/20 *GroupShuffleSplit*[2], ensuring that ADUs from the same paragraph remained in the same partition. Importantly, this division is applied only for training. The results reported in Section 5 are evaluated on the official Dev and Test sets provided by the shared task organizers.

The first two approaches use 0.1 dropout, mean pooling for span representations, three training epochs, a learning rate of 2×10^{-5}, and equally weighted BIO and classification losses (1.0 each). For the third approach, both models are trained for five epochs with the same learning rate and a weight decay of 0.01, using batch sizes of 8 for segmentation and 16 for classification.

We use the official evaluation code provided by the organizers. Task 1 is evaluated using micro, macro, and weighted precision, recall, and F1, while Task 2 uses a span-overlap metric that assigns partial precision and recall according to the overlap between predicted and gold spans.

5 Results

This section presents the results and analysis for Tasks 1 and 2 in the Closed Track using the approaches described in Section 3. It is important to note that the Multitask and Ensemble Multitask systems were developed after the development phase.

[2] sklearn.model_selection.GroupShuffleSplit

Gold (ID 282): CO [90–193] , translated text:
"Climate change is something all countries agree on, whether they are first-world, second-world, or even third-world countries." , and

Multitask: AS [90–193 +2]
Ensemble multitask: AS [90–193 +2]
BIO seg. + ensemble: AS [90–193]

Figure 2: Translated example of the CO–AS confusion. All systems identify the span (BIO seg. + ensemble matches the gold boundaries exactly) but classify it as AS instead of CO, illustrating the main Task 1 error.

5.1 Task 1

Table 2 gives the macro-averaged precision, recall, and F1 of our three submitted approaches on the dev dataset (see Appendix B.1 for information about our experiments with additional approaches).

The BIO seg. + ensemble obtained the best performance on the dev set, outperforming both multitask variants. However, this did not transfer to the test set: its performance dropped noticeably, while the multitask model generalized better, achieving the highest test F1. The ensemble multitask achieved the highest test precision but substantially lower recall, limiting its F1.

The results provide some indication that multitask learning may improve generalization; however, this observation is based on a single comparison, and the differences in Task 2 are relatively small.

Table 3 reports per-class F1 scores for the three submitted systems. AS consistently achieves the highest F1 scores (> 0.85), whereas none of the systems correctly predicts CO. Since ST has fewer dev instances but substantially higher scores, data scarcity alone cannot explain this difficulty, suggesting possible semantic overlap between CO and AS. Figure 2 illustrates such a case.

Approach	AS	AN	ST	TE	CO	OT
Dev set						
Support	157	68	9	76	12	63
BIO seg. + ensemble	0.89	**0.66**	**0.87**	0.82	0.00	**0.67**
Multitask	**0.91**	0.59	0.53	0.78	0.00	0.62
Ensemble multitask	0.90	0.52	0.53	0.68	0.00	0.60
Test set						
Support	155	45	13	70	10	83
BIO seg. + ensemble	**0.94**	**0.50**	**0.76**	0.57	0.00	0.70
Multitask	0.90	0.48	0.72	**0.67**	0.00	**0.79**
Ensemble multitask	0.92	0.41	0.72	0.50	0.00	0.69

Table 3: Per-class F1 scores for the three submitted systems on the dev and test sets.

On the test set, BIO seg. + ensemble shows the sharpest degradation, particularly on TE (0.82 → 0.57), while Multitask remains more consistent, with OT F1 increasing from 0.62 to 0.79. This reinforces the earlier finding that jointly learning segmentation and classification generalizes better than combining independently trained components.

Table 4 summarizes the most frequent sensitive pairs identified by the ensembles. AS dominates the sensitive cases across both systems, with AS–OT being the most frequent pair on the test set, highlighting the difficulty of distinguishing assumptions from miscellaneous statements. On the dev set, BIO seg. + ensemble also shows frequent NT-related pairs, reflecting instances without an ADU. In contrast, the ensemble multitask exhibits a more stable AS–TE confusion, which remains among its most frequent pairs across both datasets.

System	Sensitive pair	Freq.
Dev set		
BIO seg. + ensemble	NT–OT	34.7%
	AS–NT	32.1%
	AS–OT	29.8%
Ensemble multitask	AS–TE	41.1%
	AN–AS	32.3%
	AS–OT	23.5%
Test dataset		
BIO seg. + ensemble	AS–OT	45.4%
	AN–AS	26.4%
	AS–TE	13.2%
Ensemble multitask	AS–OT	55.5%
	AN–AS	25.5%
	AS–TE	22.0%

Table 4: Most frequent sensitive label pairs for the BIO + ensemble and ensemble multitask systems on the dev and test sets. Frequencies are computed over sensitive cases.

5.2 Task 2

Table 5 reports the performance obtained on Task 2 for our three submissions (see Appendix B.2 for a discussion of the other approaches).

BIO seg. + ensemble achieved the highest performance on the development set. On the test set, however, the three approaches performed comparably, with the multitask and ensemble multitask models obtaining only slightly higher F1 scores than the BIO segmentation pipeline. This provides limited evidence that joint segmentation and classification may improve robustness.

To better understand the differences observed in Table 5, Table 6 analyzes the quality of the predicted span boundaries on the dev set. The BIO segmentation + ensemble obtains the highest recall in Task 2, consistent with its higher proportion of gold spans matched by the predicted spans.

Approach	Prec	Rec	F1
Dev dataset			
BIO seg. + ensemble	0.609	0.761	**0.677**
Multitask	0.610	0.677	0.642
Ensemble multitask	0.627	0.632	0.629
Test set			
BIO seg. + ensemble	0.724	0.635	0.677
Multitask	0.647	0.712	0.679
Ensemble multitask	–	–	**0.683**

Table 5: Performance comparison of the evaluated approaches for Task 2, using the best-performing Task 1 system as a reference and reporting the three submitted systems on the development and test sets.

In contrast, the multitask model predicts fewer spans but locates the beginning of ADUs more precisely, achieving the highest proportion of exact start boundaries and the smallest average start error.

Finally, the ensemble multitask model detects the fewest gold spans, explaining its lower recall. However, its boundary predictions remain relatively accurate, particularly at the end of ADUs, suggesting that the ensemble favors more conservative but consistent span predictions, Figure 2 shows an example.

Metric	BIO+Ens.	MT	Ens. MT
Matched spans	**81.6**	79.9	72.7
Exact boundaries	25.8	**27.7**	26.5
Exact start	38.5	**45.2**	43.9
Starts earlier	**24.6**	30.1	37.5
Starts later	36.9	24.7	**18.6**
Exact end	68.4	63.0	**62.7**
Ends earlier	14.4	16.0	**10.4**
Ends later	17.2	21.0	**26.9**
Avg. start error	14.6	**12.3**	14.0
Avg. end error	**16.5**	17.8	21.7

Table 6: Comparison of span boundary predictions on the development set. Percentages are computed over matched spans, and average boundary errors are reported in characters.

6 Conclusion

This paper presented our submissions to the closed Daleel 2026 Shared Tasks on Arabic Argumentative Discourse Mining, exploring supervised Transformers, LLM prompting, ensemble, and multitask learning for ADU segmentation and classification. Our results show that Transformers outperform standalone LLM prompting, while LLMs are more effective for resolving ambiguous predictions. Although the two-stage ensemble achieved the strongest development performance, the multitask architecture showed more stable performance on the official test set, particularly for Task 1. Overall, our findings suggest that joint segmentation and classification is a promising direction and that LLMs may be better suited as complementary components within hybrid systems than as standalone classifiers for low-resource Arabic AM.

A Additional Experiments

We describe all the variants, although we only report the best results of each category.

A.1 Segmentation rule-based

The following experiments use our first segmentation approach to split Arabic paragraphs using three types of linguistic cues: (1) question marks, (2) discourse markers, and (3) argumentative verbs.

Discursive markers: However, yet, nevertheless, on the other hand, because, since, whereas, consequently, therefore, for this reason, for example, despite, although, due to, in addition, furthermore, on the other hand, but, likewise.

Argument verbs: He said, they said, we said, you said, we proved, they assumed, you assumed, you explained, you did not explain, they did not answer.

A.2 Classic ML

As an initial baseline, we compared three classical algorithms: Naive Bayes (NB), Logistic Regression (LR), and Support Vector Machines (SVM) using Arabic *span_text* embeddings. Since NB achieved the best validation performance, it was selected for the remaining experiments in this category. We evaluated five embedding models: *Omartificial-Intelligence-Space/Arabert-all-nli-triplet-Matryoshka*, *Omartificial-Intelligence-Space/Arabic-Triplet-Matryoshka-V2* (Nacar and Koubaa, 2025), *sentence-transformers/paraphrase-multilingual-MiniLM-L12-v2* (Reimers and Gurevych, 2019), *Omartificial-Intelligence-Space/GATE-AraBert-v1* (Nacar et al., 2025), and *sentence-transformers/paraphrase-multilingual-mpnet-base-v2* (Reimers and Gurevych, 2019), of which the first consistently performed best (only these results are reported in Table 7). We also tested three document-type settings: combined debate+editorial, debate-only, and editorial-only, and, separately, translated the Arabic ADUs into English with *facebook/nllb-200-distilled-600M* (Team et al., 2022) and generated embeddings with *BAAI/bge-m3* (Chen et al., 2024) to train the same NB classifier on both document types.

A.3 Transformers

All Transformer models were fine-tuned for five epochs with a learning rate of 2×10^{-5}, batch size of 16, and weight decay of 0.01. We evaluated the following Arabic-centric models: *CAMeL-Lab/bert-base-arabic-camelbert-mix* (Inoue et al., 2021), *aubmindlab/bert-base-arabertv02*, *aubmindlab/bert-base-arabertv2_all*, *aubmindlab/bert-large-arabertv02*, and *aubmindlab/bert-base-arabertv02-twitter* (Antoun et al., 2020), with the latter achieving the best performance. We also evaluated two English-centric models, *distilroberta-base* (Sanh et al., 2020) and *answerdotai/ModernBERT-base* (Warner et al., 2025), using segments and paragraphs translated with *CohereLabs/aya-expanse-8b*. Finally, we trained separate models per document type (debate and editorial) and combined their predictions into a single output.

A.4 LLMs

Our initial prompting strategy jointly addressed both subtasks, prompting LLMs to extract ADUs and assign their labels. We first used free-text gen-

eration and then constrained the output to JSON format. We evaluated the Arabic-centric models *FreedomIntelligence/AceGPT-13B-chat* (Huang et al., 2024) and *CohereLabs/aya-expanse-8b*, and the English-centric models *meta-llama/Meta-Llama-3.1-8B-Instruct* and *Qwen/Qwen2.5-7B-Instruct* (Team, 2024). Decoding was performed with a maximum of 500 new tokens, *do_sample=False*, a repetition penalty of 1.15, and *no_repeat_ngram_size=4* to reduce repetition and improve span recovery.

A.5 Ensembles

Transformers + prompt sensitive cases

We first obtained class probabilities from the Transformer models (Section A.3). Predictions with a confidence margin above one percentage point were kept unchanged. For the remaining *sensitive cases*, we collected all candidate labels within one percentage point of the top score and prompted an LLM to select the final label using only the definitions of the candidate labels, thereby limiting the risk of hallucination.

We evaluated this strategy using predictions from *aubmindlab/bert-base-arabertv02-twitter* and *CAMeL-Lab/bert-base-arabic-camelbert-mix*, with *Meta-Llama-3.1-8B-Instruct* and *Qwen2.5-7B-Instruct* as the disambiguation LLMs.

Prompts were written in English using translated ADUs, with an additional Arabic-language experiment using Llama. Decoding followed the same configuration as in Section A.4. All prompts are available at `https://github.com/KarlaDSJ/Daleel2026-AIDAL-ARG/blob/main/experiments/run.ipynb`.

One model per label

We trained one binary classifier per label (target label = 1, all others = 0). At inference, if exactly one classifier predicted as positive a given instance, that prediction was accepted directly. Otherwise, when multiple classifiers predicted as positive the same instance, the sensitive case prompt was used with Llama to select the final label. As a baseline, we replaced the LLM decision with a random choice among the candidate labels.

Argument generation with positive and negative reasoning

Extending the sensitive-case strategy but restricted to predictions from *aubmindlab/bert-base-arabertv02-twitter* (the best-performing model), we used a multi-step prompt: for each candidate label, the LLM first generated an argument for and an argument against that label (given the ADU, its full paragraph as context, the target label, and the competing labels), and a final prompt then selected the most appropriate label based on all generated arguments.

LLMs with different temperatures

The LLM assigned a label to each segment at temperatures of 0.5, 0.7, and 0.9, and the resulting predictions were combined following the same procedure as in *One model per label*.

B Results of other approaches

B.1 Task 1

Table 7 gives the macro-averaged precision, recall, and F1 of the best evaluated approaches on the dev dataset.

Approach	Prec	Rec	F1

+ Llama (sensitive case)	0.686	0.657	**0.641**

Table 7: Performance of other approaches on the official dev set. Results are reported in terms of macro precision, recall, and F1.

Transformer models consistently outperformed Classic ML and prompting approaches, with *aubmindlab/bert-base-arabertv02-twitter* as the strongest individual classifier (0.600), only

marginally improved by training separate debate/editorial variants (0.603). Other pretrained models, particularly *arabertv02 large* (0.462), performed considerably worse. For Classic ML, translating ADUs into English before embedding (*NB all (eng/bge-m3)*) outperformed all Arabic-embedding variants, while splitting NB by document type hurt performance (debate: 0.463, editorial: 0.442) relative to the combined model (0.552). Prompting-based LLMs remained far less competitive than supervised approaches, with *Llama JSON* as the best of this family (0.444).

Among ensemble strategies, combining *arabertv02-twitter* with Llama as a sensitive-case disambiguation tie-breaker achieved the best result (0.641). Prompting the disambiguation step in Arabic yielded a nearly identical score (0.637), indicating the prompt language had little impact, while using Qwen instead of Llama for disambiguation was slightly less effective (0.621). Other ensemble variants, one-vs-rest with Llama or random tie-breaking, doc-type-split ensembling, and the for/against argument-generation strategy, all underperformed relative to the simple sensitive-case approach, and self-consistency across decoding temperatures was the weakest ensemble overall (0.411), suggesting that disagreement among independent classifiers is a more useful uncertainty signal than sampling variance from a single model.

B.2 Task 2

Table 8 reports Task 2 performance for the best model of each approach evaluated in Task 1. Results are consistent with Task 1: the Transformer classifier (*arabertv02-twitter* × *type*, F1=0.598) outperformed both Classic ML (0.494) and the standalone LLM (0.577), and the proposed ensemble further improved performance, raising the F1 score to 0.608, driven primarily by a gain in recall (0.647 vs. 0.563 for the Transformer alone).

Approach	Prec	Rec	F1
Dev dataset			
NB all (eng)	0.460	0.532	0.494
arabertv02-twitter × type	0.563	0.563	0.598
Llama JSON	0.523	0.478	0.577
arabertv02-twitter + Llama	0.573	0.647	**0.608**

Abstract

We present our closed-track systems for both subtasks of Daleel 2026, which targets Arabic argumentative discourse unit (ADU) mining over editorials and competitive debates. Task 1 is an imbalanced multi label paragraph classification problem, and Task 2 requires character-level detection and classification of ADU spans.

For Task 1 we investigate two parameter-efficient decoder-LLM formulations: joint label generation with Qwen3.5-9B and independent label scoring with ALLaM-7B. The latter decomposes each paragraph into six explicit Yes/No decisions, giving every label direct supervision and a separate decision score; it achieves **0.6714** Macro-F1 on the evaluation phase and ranked **4th**, while ablations show that additional class-balanced weighting degrades performance.

For Task 2 we combine task-adaptive pretraining, Beginning-Inside-Outside Conditional Random Field (BIO-CRF) sequence labeling, boundary-jitter augmentation, character-space ensembling, and span post-processing over AraBERT-large, achieving an official F1 of **0.7523** (**0.7931** on debates, **0.6417** on editorials) and ranking **second**.

Across both tasks, our results support explicit label-wise supervision and span-level ensemble decisions as effective ways to handle label imbalance and boundary noise without aggressive reweighting, while short spans, rare classes, and genre variation remain challenging.

1 Introduction

Argumentative discourse unit (ADU) mining aims to identify argumentative content and its discourse roles. Daleel 2026, organized as part of ArabicNLP 2026 (ara, 2026), introduces this setting for Arabic across editorial and competitive-debate text (Nabhani et al., 2026b). The shared task presents the problem at two levels of detail.

Task 1 requires identifying all argumentative discourse unit types expressed in a paragraph, resulting in an imbalanced multi-label classification problem in which frequent labels such as Assumption (`AS`) coexist with much rarer categories such as Statistics (`ST`) and Common Ground (`CO`).

Task 2 requires systems to identify character-level ADU boundaries and assign one of the same six discourse labels to each detected span. We participate in the closed track of both tasks. The two granularities call for different modeling families, and we treat them as such.

For Task 1 we investigate two parameter-efficient decoder-LLM formulations: Qwen3.5-9B is adapted with LoRA to generate the complete label set as structured JSON, while ALLaM-7B uses QLoRA and decomposes prediction into six independent Yes/No label decisions. This second formulation gives every label explicit supervision and exposes a separate decision score for threshold selection.

For Task 2 we use a BIO-CRF architecture built on Arabic pretrained encoders, combining task-adaptive pretraining (TAPT), boundary-jitter augmentation, class-aware supervision, character-space ensembling, and span post-processing. The two systems share a single data split and a common lightweight discourse-cue detector, which each formulation consumes in the way its input representation allows. Independent label scoring achieves strong Macro-F1 without aggressive minority-class weighting, and the Task 1 submission ranked **4th**; for Task 2, larger encoders and multi-seed ensembling both help, and our four-seed AraBERT-large submission ranked **second**. Short spans and the editorial/debate dif-

*Equal contribution.

ference remain challenging in both tasks. Code and configurations: https://github.com/Abdelrahman350/BoostedSpan.

2 Background

Daleel 2026 addresses Arabic argumentative discourse mining across *editorials* and *competitive debates* (Nabhani et al., 2026a). Both subtasks use the same six ADU types: Assumption (AS), Anecdote (AN), Statistics (ST), Testimony (TE), Common Ground (CO), and Other (OT). The released labeled data contain 612 paragraphs, which we use for both tasks. Task 1 requires predicting which of the six types occur in each paragraph; since multiple types may occur in the same paragraph, it is a multi-label classification problem. Task 2 requires detecting ADU character spans and assigning one of the six types to each, and is evaluated with a modified F1 measure that gives partial credit to overlapping predicted and gold spans. We participate in the closed track of both tasks.

Related work. Arabic-specific pretrained models such as AraBERT (Antoun et al., 2020) and ARBERT/MARBERT (Abdul-Mageed et al., 2021) established strong encoder-based approaches for Arabic text understanding and classification. More recent decoder-only LLMs extend this setting beyond task-specific classification heads. The Qwen family (Team, 2026) provides multilingual instruction-following models, while ALLaM (Bari et al., 2024) focuses specifically on Arabic-English language modeling. Argument mining more broadly has been widely studied in NLP (Lawrence and Reed, 2019), but Arabic remains comparatively under-resourced. Munazarat 1.0 provides Arabic competitive-debate data for argumentation research (Khader et al., 2024), while Nabhani and Al Khatib (2025) studied Arabic span-level argument mining using BIO labeling and cross-lingual transfer. Daleel provides native Arabic annotations across debate and editorial genres. Daleel Task 1 presents a different setting from standard single-label classification: several argumentative functions may occur in the same paragraph, and some labels have limited training support. We therefore study two decoder-LLM formulations for this setting, using Qwen3.5 for joint structured generation and ALLaM for independent label scoring and calibration. For Task 2, building on sequence-labeling approaches, we combine structured prediction with task adaptation, boundary augmentation, and character-space ensembling to address span boundaries and label imbalance.

Shared discourse cues. Both systems share one lightweight component. We use regex-based lexical cues for three labels with recognizable surface patterns: Testimony (TE), Statistics (ST), and Anecdote (AN). TE patterns capture reporting and attribution expressions, ST patterns capture numerical and statistical expressions, and AN patterns capture explicit personal-narrative expressions. The regular expressions are matched against the raw Arabic paragraph before any tokenization or prompt construction; the exact surface patterns covered by each cue family are listed in Appendix A. In both tasks, detected cues provide auxiliary lexical information and are never converted directly into predicted labels, so the model still makes the final decision from the complete paragraph. The two tasks differ only in how the cues enter the input. In Task 1, the detected cues are inserted into the ALLaM prompt as a natural-language hint. In Task 2, the detected label codes are inserted as a compact prefix such as `[CUES:TE,ST]` ahead of the paragraph, alongside a domain prefix, `[EDITORIAL]` or `[DEBATE]`.

3 Task 1: Multi-Label ADU Classification

We explored two formulations for adapting decoder LLMs to Task 1. Qwen3.5-9B predicts the complete label set through constrained generation, while ALLaM-7B scores each label independently through binary label scoring. Within the latter formulation, we further study class-imbalance handling and use label-specific decision thresholds. Figure 1 in Appendix K gives an overview of the Task 1 system.

3.1 Qwen3.5-9B: Constrained Generation

Our first system fine-tunes Qwen/Qwen3.5-9B with LoRA (Hu et al., 2022), formulating Task 1 as instruction-following generation rather than adding a classification head: the model emits the complete applicable label set as a compact JSON object of the form `{"labels":[...]}`. Imbalance is handled by oversampling the rare ST and CO classes rather than by class-weighted loss, and prediction is deterministic, so no threshold selection is used. Prompt formulation, output valida-

tion, and checkpoint selection are detailed in Appendix B.

3.2 ALLaM-7B: Independent Label Scoring

Our second system fine-tunes ALLaM-7B-Instruct-preview with QLoRA (Dettmers et al., 2023). The backbone is quantized to 4-bit NF4 and adapted using trainable LoRA parameters. Instead of predicting all labels jointly, we evaluate each label independently. Each paragraph is paired with each of the six ADU types, producing six binary training instances. For every paragraph–label pair, an Arabic instruction asks whether the paragraph contains the corresponding argumentative category.

During supervised fine-tuning, the target completion is the Arabic word for "Yes" for a positive pair and the Arabic word for "No" otherwise. The prompt tokens are masked from the loss, so supervision is applied only to the target answer.

Prompt formulation. The prompt specifies the paragraph domain, includes the original paragraph, provides an Arabic description of the candidate label, and requests a single Yes/No answer. Editorial paragraphs are described as newspaper editorials, while debate paragraphs are described as discussions or debates. When relevant discourse cues are detected (Section 2), they are inserted as a natural-language hint in the same prompt rather than used as prediction rules. The complete Arabic prompt template, label descriptions, discourse-cue descriptions, and exact Yes/No target completions are provided in Appendix D. At inference time, we do not generate the answer. Instead, we extract the next-token logits corresponding to the Arabic Yes and No answers. For label c, the decision score is

$$p_c = \frac{\exp(z^c_{\text{yes}})}{\exp(z^c_{\text{yes}}) + \exp(z^c_{\text{no}})}. \quad (1)$$

The normalized Yes/No logits provide a continuous score for each label. We do not assume that these scores are probabilistically calibrated; instead, they are treated as discriminative scores from which label-specific decision thresholds are selected on the validation set.

3.3 Imbalance and Threshold Selection

We study two complementary strategies for handling label imbalance in the ALLaM formulation: loss weighting during training and label-specific threshold selection at inference.

Imbalance handling. For the weighted variants, we assign each label c a positive-class weight based on its frequency in the training split:

$$w_c = \min\left(C, \frac{N - N^+_c}{N^+_c}\right),$$

where N is the number of training examples, N^+_c is the number of positive examples for label c, and C controls the maximum weight. The weight is applied only to positive instances of the corresponding label, increasing the loss contribution of rare positive examples. We evaluate two settings, $C = 8$ and a more conservative $C = 3$, together with an unweighted baseline.

Threshold selection. Checkpoint selection and threshold tuning are performed separately. During training, checkpoints are evaluated using Macro-F1 with a fixed threshold of 0.5, and the checkpoint with the highest validation score is retained. After model selection, a separate threshold is tuned for each label. We sweep thresholds from 0.05 to 0.95 in increments of 0.05 and select the value that maximizes the corresponding label's F1 score on the validation set. These thresholds are then fixed for final prediction.

4 Task 2: Character-Level Span Detection

We formulate Task 2 as BIO sequence labeling followed by character-level span reconstruction. Figure 2 in Appendix L summarizes the two stages of our pipeline: model development and inference. The submitted system uses AraBERT-large (Antoun et al., 2020) (`aubmindlab/bert-large-arabertv02`) with four independently trained runs.

The input representation and label-alignment procedure are detailed in Appendix E.

4.1 Training and Model Development

We first apply task-adaptive pretraining (TAPT) (Gururangan et al., 2020) by continuing masked-language-model training of AraBERT-large on the Daleel training and `dev_in` text without ADU labels. The adapted encoder is then fine-tuned for supervised span detection. Gold character spans are mapped to 13 BIO tags: `O`, `B-c`, and `I-c` for the six ADU classes, using tokenizer offset mappings (Ramshaw and Marcus, 1995). Before tokenization, the discourse-cue and domain prefixes

described in Section 2 are prepended to the paragraph.

Boundary-jitter augmentation. To reduce sensitivity to small annotation-boundary variations, we create additional training copies in which each gold span is perturbed independently. Its start and end offsets are each shifted by an integer sampled uniformly from $[-2, 2]$ characters. The shifted start is clipped to the valid text range, while the shifted end is clipped to the paragraph boundary and constrained to remain at least one character after the new start. BIO labels are then reconstructed from the perturbed spans. Because a single BIO sequence cannot represent overlapping spans, overlaps are resolved using a first-writer-wins policy: character positions already assigned to an earlier span are not overwritten by subsequent spans.

Structured prediction and weighted supervision. AraBERT representations are projected into BIO emission scores and decoded with a linear-chain CRF (Lafferty et al., 2001). The standard objective minimizes CRF negative log-likelihood. To address label imbalance, we additionally evaluate

$$\mathcal{L} = \mathcal{L}_{\text{CRF}} + \lambda \mathcal{L}_{\text{WCE}}, \tag{2}$$

where the auxiliary weighted cross-entropy assigns greater importance to rare BIO tags. Four AraBERT-large models are trained with different random seeds for the final ensemble.

4.2 Inference and Span Reconstruction

At inference, paragraphs are tokenized with character offsets and discourse-cue markers, CRF emissions are decoded with Viterbi, and BIO predictions are mapped back to character coordinates so runs can be combined in a common character space. For character j and class c, support is

$$V(j, c) = \sum_{m=1}^{M} w_m \, \mathbb{I}\left[j \in S_c^{(m)}\right] \tag{3}$$

where w_m is based on validation performance. We also evaluate span-cluster voting, which groups overlapping predicted spans before voting. Long-input handling, the isolated-`I` rule, and the span post-processing filters are in Appendix F.

5 Experimental Setup

Both tasks draw on the same 612 labeled Daleel paragraphs. The ALLaM Task 1 experiments and all Task 2 experiments use one fixed split of approximately 520 training and 92 internal-validation paragraphs; Qwen3.5 instead trains on all 612 and validates on the 217 development paragraphs, so the two Task 1 systems' validation scores are not a controlled comparison. Checkpoints are selected by validation Macro-F1 and per-label thresholds are tuned afterwards. Task 1 is scored with Micro-, Macro- and Weighted-F1; Task 2 with the official partial-overlap metric via the organizers' unmodified `task2_scoring.py` on the 92-paragraph split. All training runs on a single NVIDIA RTX 4080 12 GB GPU. Split construction, closed-track compliance, TAPT data, libraries and the full selection protocol are in Appendix G, and the complete optimization settings for both tasks in Appendix H.

Model	Domain	Micro	Macro	Weighted
Qwen3.5	All	0.7721	0.6215	0.7622
	Editorial	0.7730	0.5962	0.7504
	Debate	0.7715	0.4820	0.7622
ALLaM	All	0.7785	0.6714	0.7833
	Editorial	0.6493	0.4751	0.6252
	Debate	0.8460	0.7418	0.8514

Table 1: Task 1 phase-wise F1 scores. Qwen3.5 results are from the development phase and ALLaM results from the evaluation phase.

6 Results

6.1 Task 1 Results

Table 1 summarizes the available phase results for Task 1. Qwen3.5 is reported on the development phase, whereas ALLaM is reported on the evaluation phase; therefore, the scores are not treated as a controlled head-to-head comparison. Qwen3.5 obtained 0.6215 Macro-F1, with a larger degradation on debates (0.4820) than editorials (0.5962), despite similar Micro-F1 across genres. ALLaM reached 0.6714 Macro-F1 overall, with substantially stronger performance on debates (0.7418) than editorials (0.4751). Its strongest evaluation-phase classes were `AS` and `ST`, while `CO` remained the most difficult. Because both the backbone and evaluation phase differ, the numerical gap between Qwen3.5 and ALLaM should not be interpreted as a direct model comparison.

6.2 Task 2 Results

Table 2 reports the official closed-track results of our submitted Task 2 system. The system achieved an overall F1 of 0.7523, with 0.7931

Test subset	Precision	Recall	F1
Editorials	.6394	.6440	.6417
Debates	.7862	.8000	.7931
Overall	.7479	.7569	**.7523**

Table 2: Official Task 2 closed-track test results.

Configuration	Micro	Macro	Weighted
Base QLoRA	**0.8650**	**0.8337**	**0.8675**
Low-clip weighting	0.8538	0.8141	0.8558
Weighted loss	0.8507	0.7931	0.8515

Table 3: Task 1 ALLaM ablation results on the fixed validation split.

on debates and 0.6417 on editorials, ranking second on the Task 2 leaderboard. Recall is slightly higher than precision overall (0.7569 vs. 0.7479), with the same pattern in both genres, indicating no strong precision–recall imbalance. In contrast, the 0.1514 F1 gap between debates and editorials indicates genre variation. Since the test labels are hidden, we do not attribute this difference to a specific error type; instead, the following analyses use the held-out validation split.

6.3 Ablation Studies

Task 1: imbalance handling. Table 3 compares the ALLaM variants on the same fixed 92-paragraph validation split using the organizers' scorer. The unweighted system performs best. Class-balanced weighting with a maximum weight of 8 reduces Macro-F1 from 0.8337 to 0.7931; lowering the cap to 3 partially recovers performance to 0.8141. This suggests that aggressively upweighting the few positive instances of rare labels can give individual examples disproportionate influence.

Task 2: design choices. Table 4 reports the main Task 2 design choices on the same fixed 92-paragraph validation split using the official partial-overlap scorer. These are internal validation results and are separate from the official leaderboard score. Adding class-weighted cross-entropy increased F1 from 0.6967 to 0.7059. The gain mainly came from precision, while recall remained almost unchanged. This suggests that additional supervision for rare BIO tags helped reduce incorrect span predictions without reducing span coverage. Changing the ensemble decoder had a larger effect. Span-cluster decoding increased F1 from 0.7059 to 0.7294 and raised precision from 0.6651 to 0.7317. This supports our motivation for moving the ensemble decision from individual characters to groups of overlapping spans. Increasing the AraBERT-large ensemble from two to four independent runs improved validation F1 from 0.7352 to 0.7438. Further analysis of encoder capacity and ensemble size is provided in Appendix I.

Configuration	Precision	Recall	F1
Base Track A	0.6494	0.7514	0.6967
weighted CE	0.6651	0.7521	0.7059
span-cluster decoding	0.7317	0.7271	0.7294
AraBERT-large, 2 seeds	0.7120	0.7601	0.7352
AraBERT-large, 4 seeds	0.7308	0.7572	**0.7438**

Table 4: Task 2 validation results for the main design choices. The large-backbone experiments are controlled variants rather than cumulative additions to the clustered system.

6.4 Error Analysis

The main limitations are rare ADU labels, genre variation, short-span loss, and overlapping annotations. Detailed analyses are provided in Appendix J.

7 Conclusion

We presented closed-track systems for both subtasks of Daleel 2026. For Task 1 we compared two parameter-efficient decoder-LLM formulations, joint label generation with Qwen3.5-9B and independent label scoring with ALLaM-7B. Explicit label-wise supervision suits the imbalanced multi-label setting, while additional class-balanced weighting does not help; the ALLaM submission achieved **0.6714** Macro-F1 and ranked 4th. For Task 2, a BIO-CRF system combining task-adaptive pretraining, boundary augmentation, AraBERT-large and character-space ensembling ranked second with an official F1 of **0.7523**; larger encoders, multi-seed ensembling and span-cluster decoding each helped on validation. Across both tasks, short spans, rare ADU types such as `CO`, overlapping units, and cross-genre variation remain challenging. Future work should investigate label-specific threshold tuning, stronger methods for rare labels, and domain-aware training. A controlled comparison of the Task 1 formulations using the same backbone and data split, alongside span-based architectures for Task 2, would help address these limitations.

A Discourse-Cue Patterns

The shared discourse-cue detector described in Section 2 uses regular expressions for three labels with recognizable surface patterns.

- **TE** patterns capture reporting and attribution expressions, including equivalents of "said," "stated," "confirmed," "according to," and "mentioned that."
- **ST** patterns capture numerical and statistical expressions, including percentages and terms referring to studies, statistics, scientific research, and ratios.
- **AN** patterns capture explicit personal-narrative expressions, including equivalents of "I remember," "it happened to me," "once," "my story," and "my personal experience."

The regular expressions are matched against the raw Arabic paragraph before prompt construction (Task 1) or tokenization (Task 2). If one or more cues are detected, their semantic descriptions are added to the ALLaM prompt as an auxiliary natural-language hint (Task 1) or their label codes are inserted as a compact prefix such as `[CUES:TE,ST]` (Task 2). They are never converted directly into predicted labels.

B Qwen3.5 System Details

Our first system fine-tunes Qwen/Qwen3.5-9B with LoRA (Hu et al., 2022). Rather than adding a classification head, we formulate Task 1 as instruction-following generation. The model receives a system instruction defining the six ADU labels and the required output format, followed by a user message containing the paragraph domain and text. It generates the complete applicable label set as a compact JSON object of the form `{"labels":[...]}`.

Prompt formulation. The system prompt defines AS, AN, ST, TE, CO, and OT in Arabic and instructs the model to return valid JSON using only the `labels` key, without additional explanation. It also specifies the fixed output order AS, AN, ST, TE, CO, OT and permits an empty list when no category applies. The user message inserts `{DOMAIN}` and `{TEXT}` into an Arabic instruction of the form "text type: {DOMAIN}; paragraph: {TEXT}; classify the paragraph and return JSON only." The exact Arabic system and user prompts are provided in Appendix C. During supervised fine-tuning, the target is the gold label set serialized in the fixed order, for example `{"labels":["AS","TE"]}`. Prompt tokens are masked from the language-modeling loss, so supervision is applied only to the generated JSON response.

Imbalance handling. Unlike the ALLaM experiments, the Qwen system does not use class-weighted loss. Instead, we increase the exposure of the rare ST and CO classes through training-set oversampling. Every paragraph containing at least one of these labels is duplicated once, corresponding to a repeat factor of two, while other paragraphs appear once.

Prediction and model selection. Qwen predicts labels directly through deterministic generation (`do_sample=False`) rather than independent label scores. Consequently, no probability threshold or label-specific threshold selection is used. Generated responses are parsed as JSON and checked for the required `labels` key, valid label names, and duplicate labels; valid labels are then normalized to the fixed label order. The model is evaluated after every epoch, and the checkpoint with the highest validation Macro-F1 is retained.

C Qwen3.5 Prompt Specification

Qwen3.5 is trained in a chat-style instruction-following setup. Each training example contains a fixed Arabic system prompt, a user message constructed from the paragraph domain and text, and an assistant target containing the gold label set in JSON format.

System prompt. The exact system prompt used in our implementation is:

أنت نظام متخصص في تصنيف وحدات الخطاب الحجاجي العربي.
المهمة متعددة التصنيفات؛ قد تنطبق تسمية واحدة أو عدة تسميات على الفقرة.
التسميات المسموح بها فقط:
AS: موقف أو ادعاء أو حجة أساسية يعرضها الكاتب أو المتحدث.
AN: دليل أو مثال أو تفسير غير إحصائي يدعم موقفًا أو حجة.
ST: دليل رقمي أو إحصائي أو نسبة أو كمية تستخدم كدليل.
TE: نقل أو تلخيص أو مناقشة أو رد على كلام طرف أو متحدث آخر.

CO: مقارنة أو تعارض مباشر بين موقفين أو خيارين أو حالتين.
OT: محتوى تنظيمي أو تمهيدي أو ختامي أو خارج الوظائف السابقة.
قواعد الإجابة:
1. أعد JSON صحيحًا فقط دون شرح.
2. استخدم المفتاح labels فقط.
3. لا تستخدم أي تسمية خارج القائمة.
4. رتب التسميات هكذا: AS, AN, ST, TE, CO, OT.
5. استخدم قائمة فارغة فقط إذا لم تنطبق أي تسمية.
الشكل المطلوب:
`{"labels":["AS","TE"]}`

User prompt. For each paragraph, the user message is constructed as:

صنّف الفقرة {TEXT} الفقرة: {DOMAIN} نوع النص:
أعد JSON فقط.

Here, {DOMAIN} is the paragraph type (editorial or debate), and {TEXT} is the original Arabic paragraph.

Target output. During supervised fine-tuning, the assistant target is the gold set of labels serialized as compact JSON using the fixed order AS, AN, ST, TE, CO, OT. For example:

`{"labels":["AS","TE"]}`

If no label applies, the target is:

`{"labels":[]}`

Prompt tokens are masked from the language-modeling loss, so the loss is computed only over the assistant JSON response. At inference time, generation is deterministic, with sampling disabled, and the generated text is parsed to recover the predicted label set.

D ALLaM Prompt Specification

For each paragraph, ALLaM is queried independently for each of the six ADU labels. The prompt contains the paragraph domain, the original Arabic paragraph, an Arabic description of the candidate label, and an optional discourse-cue hint. The exact prompt template used in our implementation is shown below.

فيما يلي فقرة من {DOMAIN}: {TEXT}
هل تحتوي هذه الفقرة على عنصر حجاجي من النوع التالي:
{LABEL_DESCRIPTION} ؟
أجب بكلمة واحدة فقط: نعم أو لا. الإجابة:

The placeholders are instantiated as follows:

- {DOMAIN}: the paragraph domain, instantiated as افتتاحية صحفية for editorials and نقاش أو مناظرة for debates.
- {TEXT}: the original Arabic paragraph provided to the model.
- {LABEL_DESCRIPTION}: the Arabic natural-language description of the candidate ADU label currently being evaluated. Since each paragraph is evaluated against all six labels, this placeholder changes across the six paragraph–label instances.
- {CUE_NOTE}: an optional natural-language hint derived from detected discourse cues. It is empty when no cue is detected; otherwise, it contains one or more cue descriptions for TE, ST, and/or AN.

The six label descriptions are:

- **AS**: افتراض أو رأي شخصي غير مدعوم بدليل مباشر
- **AN**: قصة شخصية أو حكاية أو تجربة فردية
- **ST**: إحصائية أو بيانات رقمية أو نسبة مئوية
- **TE**: شهادة أو رأي منقول عن شخص أو مصدر آخر
- **CO**: أرضية مشتركة أو حقيقة متفق عليها بين الطرفين
- **OT**: نوع آخر من الحجج لا يندرج تحت الأنواع السابقة

When discourse cues are detected, {CUE_NOTE} is inserted after the label description using the following form:

(تحتوي الفقرة على مؤشرات لغوية قد تدل على:
{CUE_DESCRIPTION})

The cue descriptions are:

- **TE**: نقل كلام عن مصدر آخر
- **ST**: أرقام أو إحصاءات
- **AN**: سرد قصة أو تجربة شخصية

If multiple cues are detected, their descriptions are concatenated in the same hint. During supervised fine-tuning, the exact target completion is نعم for a positive paragraph–label pair and لا for a negative pair.
In the implementation, each target completion is preceded by a single whitespace character. At inference time, no answer is generated; instead, the next-token logits corresponding to these two Arabic answers are used to compute the label-specific decision score.

E Task 2: Input Representation and Label Alignment

Unlike Task 1, Task 2 is formulated as sequence labeling rather than generative prompting. Each input consists of the original Arabic paragraph preceded by a domain marker and, when applicable, a compact discourse-cue marker. The domain marker is `[EDITORIAL]` or `[DEBATE]`, while the cue marker contains the detected label codes, such as `[CUES:TE,ST]`. An illustrative input is:

```
[EDITORIAL] [CUES:TE,ST] <Arabic
paragraph>
```

The markers provide auxiliary domain and lexical information and are not converted directly into predicted ADU labels. The input is tokenized with character-offset mappings, and gold character spans are aligned with the corresponding paragraph tokens to construct the 13 BIO tags. At inference, predicted BIO sequences are mapped back to character coordinates to produce the required span-level output.

F Inference and Span Reconstruction Details

Approximately 99% of paragraphs fit within the 512-subword limit; inputs in the small long-input tail are processed using overlapping windows with stride 64. When CRF emissions are decoded with Viterbi, an incompatible isolated `I` tag is treated as the beginning of a new span. Mapping BIO predictions back to character coordinates matches the character-level output required by the task, and consecutive selected characters are reconstructed into spans. Span-cluster voting groups overlapping predicted spans before voting, which reduces the disagreement caused by small boundary shifts. Finally, we remove punctuation- or whitespace-only spans, expand boundaries falling inside words to word edges, and merge same-label spans separated by at most two punctuation or whitespace characters.

G Extended Experimental Setup

G.1 Data Splits

Both tasks draw on the same 612 labeled Daleel paragraphs. The ALLaM Task 1 experiments and all Task 2 experiments use the same fixed split of these paragraphs, with approximately 520 examples for training and 92 for internal validation; for Task 1 the split is stratified by domain and label combination and is kept fixed across the three ALLaM configurations, and for Task 2 the validation set is used for model selection, ensemble weighting, and ablation analysis. For Qwen3.5, we instead use all 612 labeled training paragraphs for fine-tuning and the 217 labeled development paragraphs for validation, with oversampling applied only to the training set. Since Qwen and ALLaM therefore use different validation sets, their internal validation scores are reported separately rather than treated as a controlled comparison.

For task-adaptive pretraining in Task 2, we use the raw text from the training data together with the provided `dev_in` text, without using any development or test labels. All submitted systems follow the closed-track restrictions.

G.2 Training Configuration

The full optimization settings for both tasks are reported in Appendix H; we summarize the choices that matter for interpreting the results here. All ALLaM variants use the same QLoRA configuration and differ only in their loss weighting.

For Qwen3.5, we use AdamW with a linear learning-rate schedule and gradient clipping at 1.0. The batch size of 1 with eight gradient accumulation steps gives an effective batch size of 8. Training uses bfloat16 when supported and float16 otherwise. Paragraphs containing `ST` or `CO` are duplicated once before training.

For ALLaM, the backbone is quantized using 4-bit NF4 with double quantization and bfloat16 computation. LoRA is applied to the attention projections (`q`, `k`, `v`, and `o`) and the MLP projections (`gate`, `up`, and `down`). A batch size of 2 with 32 accumulation steps gives an effective batch size of 64. Gradient checkpointing is enabled for both systems. The base ALLaM configuration uses the standard unweighted SFT objective. The weighted variant applies class-balanced per-example loss weighting with a maximum weight of 8, while the low-clip variant reduces this maximum to 3. All other training settings are kept unchanged across the three variants.

For Task 2, our final system uses `aubmindlab/bert-large-arabertv02` as the encoder. We first apply task-adaptive masked-language-model pretraining and then fine-tune the resulting checkpoint with the BIO-CRF span detector described in Section 4. The

final configuration consists of four independently trained AraBERT-large models with different random seeds. Inputs are limited to 512 subword tokens; longer paragraphs are processed using overlapping windows with a stride of 64 tokens. Boundary-jitter augmentation shifts span boundaries by at most two characters during training. For the weighted-loss ablation, the CRF objective is augmented with class-weighted token-level cross-entropy. We also compare character-level voting with span-cluster decoding, base- and large-capacity encoders, and different ensemble sizes. Unless otherwise stated, all other preprocessing and post-processing settings are kept fixed across comparisons.

G.3 Model Selection and Calibration

For Qwen3.5, we evaluate the model after each epoch and retain the checkpoint with the highest validation Macro-F1. Validation predictions are generated greedily with at most 48 new tokens. ALLaM checkpoints are also selected by validation Macro-F1, using a fixed threshold of 0.5 during checkpoint selection. After training, a separate decision threshold is selected for each label to maximize its F1 score on the validation set.

G.4 Evaluation

For Task 1, we report Micro-, Macro-, and Weighted-F1 for the development experiments and use Macro-F1 for model selection. Per-label precision, recall, and F1 are used for further analysis. For Task 2, we evaluate span predictions using the official Daleel Task 2 partial-overlap precision, recall, and F1 metric; all Task 2 validation results reported in Section 6 are computed by running the organizers' unmodified `task2_scoring.py` script on the 92-paragraph validation split. Official shared-task results for both tasks are reported separately in Section 6 and are not used for model selection.

Our Task 1 implementation uses PyTorch, Hugging Face Transformers, PEFT, scikit-learn, and bitsandbytes for the ALLaM QLoRA experiments. Task 2 models are implemented in PyTorch using Hugging Face Transformers and `torchcrf`. All training for both tasks is performed on a single NVIDIA RTX 4080 12 GB GPU.

H Training Configurations

Table 5 reports the main training configurations for the two Task 1 systems, and Table 6 reports the main experimental settings for the Task 2 system.

Setting	Qwen3.5	ALLaM
Backbone	Qwen3.5-9B	ALLaM-7B-Instruct
Adaptation	LoRA	QLoRA
Quantization	None	4-bit NF4
LoRA rank	16	16
LoRA α	32	32
LoRA dropout	0.05	0.05
Max. length	512	1024
Epochs	10	3
Batch size	1	2
Grad. accumulation	8	32
Learning rate	1×10^{-4}	2×10^{-4}
Weight decay	0.01	0.01
Warmup ratio	0.10	0.10
Seed	42	42

Final ensemble	4 seeds
Ensemble weighting	Validation F1
TAPT objective	MLM
MLM probability	0.15
TAPT epochs	10
TAPT learning rate	5e-5

Table 6: Main experimental settings for Task 2.

I Additional Design-Choice Analysis

Increasing encoder capacity produced another improvement. Replacing the base-size encoders with AraBERT-large reached 0.7352 F1 with two seeds. Increasing the AraBERT-large ensemble from two to four independent runs further improved F1 to 0.7438, mainly through higher precision. This was the strongest validation configuration and was selected for the final submission. Overall, the experiments indicate that performance gains come from complementary sources: weighted supervision improves handling of imbalanced tags, span-level voting reduces boundary disagreement, and larger multi-seed ensembles improve prediction stability.

J Extended Error Analysis

Additional main-text error analysis. For Task 1, `CO` is the hardest class for both systems and ALLaM shows a pronounced genre effect

(0.7418 Macro-F1 on debates versus 0.4751 on editorials). For Task 2, the dominant error source is short-span loss during character-level ensembling, which motivated the span-cluster decoder, alongside severe span-level label imbalance and the inability of a single BIO sequence to represent the roughly 1% of paragraphs with overlapping gold spans. Per-label error profiles, span-length statistics, and a comparison of how the two Task 1 formulations differ in supervision are in Appendix J.

Task 1. Qwen3.5's main weakness is rare-label recall: `CO` achieves only 0.1538 F1 on validation despite perfect precision, while all generated outputs remain valid JSON. ALLaM shows a different error profile on the evaluation phase: `AN` is over-predicted ($P = 0.4500$, $R = 0.8000$), whereas `TE` is conservative ($P = 0.9211$, $R = 0.5000$). `CO` remains difficult for both systems. ALLaM also exhibits a pronounced genre effect, with 0.7418 Macro-F1 on debates versus 0.4751 on editorials.

Task 2. Our development analysis identified short-span loss during character-level ensembling as an important error source. Character voting removed approximately 26% of gold spans that had been detected by the individual models. These missed spans were considerably shorter on average; about 50 characters compared with about 90 characters for successfully matched spans, while the individual runs recalled 96--99% of them. Small differences in predicted boundaries distributed the ensemble votes across nearby characters, which motivated the span-cluster decoder. A second difficulty is label imbalance: the training data contain 1,739 AS spans but only 50 CO and 38 ST spans, and the improvement obtained from weighted supervision suggests that additional emphasis on rare BIO tags helps mitigate this imbalance. Finally, BIO tagging has a structural limitation: approximately 1% of the paragraphs contain overlapping gold spans, which cannot be represented by a single BIO sequence. These cases remain a limitation of the submitted system and motivate span-based architectures that can predict overlapping units directly.

Effect of the Task 1 prediction formulation. Beyond the backbone difference, the two Task 1 systems provide fundamentally different supervision. Qwen3.5 learns one jointly generated label sequence per paragraph, whereas ALLaM creates six paragraph–label instances with explicit Yes/No targets, giving each label a direct training signal for every paragraph. This is particularly useful for imbalanced labels, as reflected in the conservative behavior of Qwen3.5 on `CO`, which achieves 1.00 precision but only 0.0833 recall on validation. ALLaM further provides a separate normalized Yes/No score for each label, enabling label-specific threshold selection and more flexible control of the precision–recall trade-off. Together, these properties make independent label scoring a natural fit for the imbalanced multi-label setting. In our experiments, the ALLaM-based formulation achieves strong performance without class-balanced weighting, while the weighting ablations show that aggressively increasing the contribution of minority labels can instead hurt performance. Although the comparison involves different backbones and training setups, the results highlight independent label scoring as a promising formulation for addressing label imbalance in Arabic argument classification.

BURHAN at Daleel Shared Task Subtask-1: A Multi-Label Transformer Pipeline for Arabic Argumentative Discourse Unit Classification

Ahmed Osrf[1], Eid Abo Baid[1], Shadi Abudalfa[2,1]
[1]University College of Applied Sciences, Palestine
[2]Onaizah Colleges, Saudi Arabia
Correspondence: osrfahmed@gmail.com

Abstract

This paper presents our system for Task 1 of the Daleel 2026 shared task, which assigns multiple discourse-function labels to Arabic paragraphs from editorials and debate transcripts. We fine-tune a monolingual Arabic encoder (MARBERTv2) with a label-weighted focal loss, multilabel-stratified k-fold cross-validation, out-of-fold per-label threshold calibration, k-fold ensembling, and a genre-conditioning prefix, in a two-stage protocol that first trains on the training split alone and then retrains on training+development. Internal cross-validation macro-F1 rises from 0.667 to 0.680 across the two stages. On the official test set, the system attains micro-F1 = 0.766 and macro-F1 = 0.560, with markedly stronger micro-F1 on debate paragraphs (0.825) than editorials (0.633), and a smaller but consistent macro-F1 gap (0.554 vs. 0.456). *Assumption* is classified most reliably (F1 = 0.88–0.94) and *Common Ground* least reliably (F1 $\leq$ 0.12), mirroring the low inter-annotator agreement reported for the same category in the source English scheme. We find a $\sim$0.12 gap between internal cross-validation and official test macro-F1, concentrated in low-support, genre-sensitive categories. Our code is publicly available at `https://github.com/EidAhmed1/daleel2026_task1_project`.

1 Introduction

Argument mining for Arabic presents several challenges that arise from characteristics of the language itself, including rich morphology, variation in orthographic representation, inconsistent use of diacritics, and differences in writing conventions. These difficulties are further amplified by the comparatively limited availability of large-scale annotated Arabic argumentation resources when compared with English (Al-Khatib et al., 2016; Khader et al., 2024).

Existing Arabic resources are typically genre-level argumentative corpora without discourse-unit typing (Khader et al., 2024; Zaghouani et al., 2024), while prior modeling work has relied on machine-translated, projection-labeled English data, where projection noise is a dominant performance bottleneck (Nabhani and Al-Khatib, 2025). The Daleel 2026 shared task (Nabhani et al., 2026) contributes to addressing this limitation by introducing Arabic paragraphs from editorials and debates annotated according to their argumentative discourse-unit functions. In subtask 1, the classification problem is explicitly multi-label because an individual paragraph can perform several discourse functions simultaneously. For example, the same paragraph may state an assertion while also providing statistical evidence. Consequently, a successful system must identify all applicable discourse categories rather than selecting a single class.

Our submission makes four main contributions. First, we develop a multi-label learning pipeline that integrates multilabel-stratified k-fold cross-validation, out-of-fold (OOF) calibration of label-specific decision thresholds, and ensemble prediction across folds; stratification and per-label threshold calibration mitigate the effects of label imbalance, while fold ensembling primarily improves prediction stability. Second, we motivate our approach to class imbalance by relating it to findings on annotation difficulty reported for the closest comparable English argumentative discourse unit (ADU) annotation scheme. Third, rather than reporting only the post-retraining internal estimate, we report cross-validation results transparently at both training stages – train-only (used for development-set validation) and train+development (used for the final submitted model) – exposing any optimism in the internal estimate before it is compared against official test performance. Finally, we conduct genre-stratified evaluation and examine the discrepancy between cross-validation results and performance on the official test set. These components together provide

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1370–1374
October 28-29, 2026 ©2026 Association for Computational Linguistics

a systematic framework for training, calibration, evaluation, and analysis of the presented system.

The remainder of this paper describes the complete processing pipeline, beginning with data preparation and ending with final test prediction, while also explaining the rationale and practical considerations associated with the principal design decisions.

2 Background

Daleel Shared Task Subtask-1 is formulated as a multi-label classification problem over Arabic paragraphs, where each paragraph may be assigned one or more of six possible discourse-function labels: AS (Assumption), AN (Anecdote), ST (Statistics), TE (Testimony), CO (Common Ground), and OT (Other), forming the label set $L = \mathrm{AS}, \mathrm{AN}, \mathrm{ST}, \mathrm{TE}, \mathrm{CO}, \mathrm{OT}$. In addition to the discourse labels, each paragraph is associated with a genre attribute indicating whether it originates from an editorial or a debate. The training and development data contain 829 paragraphs in total, comprising 612 training and 217 development instances, while the test set contains 213 paragraphs (87 editorial, 126 debate), forming the official evaluation set described in Section 5.

The shared task scores per-label precision/recall/F1, aggregated into micro-, macro-, weighted-, and samples-averaged scores, over the combined set and separately per genre. Macro-F1 is the official task metric and treats all labels equally regardless of frequency; we additionally report micro-F1, which reflects overall label-assignment accuracy dominated by the most frequent labels, and weighted-F1, which weights each label's F1 by its support as a middle ground between the two. We additionally report leakage-free OOF cross-validation estimates during development, where each training example is scored only by fold models that excluded it.

The label inventory descends from Al-Khatib et al. (2016), who annotate 300 English editorials with substantial overall agreement (Fleiss' $\kappa = 0.56$) but much lower agreement for *Common Ground* ($\kappa = 0.114$) and *Other* ($\kappa = 0.152$), also the rarest categories (1.7% and 1.2% of units). We use this as external evidence that these categories are both rare and intrinsically hard, motivating our imbalance-aware training. Related but incompatible annotation schemes include the microtext scheme of Peldszus and Stede (2015) and the convincingness-oriented annotations of Habernal and Gurevych (2016).

On Arabic resources, Khader et al. (2024) and Zaghouani et al. (2024) release argumentative corpora (against general Arabic speech resources Al-Fetyani et al., 2023; Mubarak et al., 2021 and the bilingual corpus of Habash and Palfreyman, 2022) but without ADU-type labels compatible with our scheme. The closest modeling precedent, Nabhani and Al-Khatib (2025), compares cross-lingual transfer, translate-train, and zero-shot LLM prompting on the English essays of Stab and Gurevych (2017), machine-translated with NLLB (Costa-jussà et al., 2022) and label-projected via FastAlign (Dyer et al., 2013), following Eger et al. (2018). They find a monolingual Arabic encoder (Antoun et al., 2020) trained on translated data beats multilingual alternatives (Conneau et al., 2019) and zero-shot LLMs, but projection noise (64–69% paragraph-level error) dominates over translation error itself (0.6% token-level). Because our data is natively Arabic rather than translated and projected, this dominant noise source does not apply by construction, while we retain the preference for a monolingual encoder.

3 System Overview

3.1 Pipeline

The pipeline begins by parsing the JSON Lines files into a consistent tabular representation in which each paragraph is associated with its text, genre, and, when available, gold labels. The text is then normalized, with an optional genre-specific prefix added to provide explicit information about the source type. The gold labels are converted into fixed six-dimensional binary vectors corresponding to the target discourse categories.

In Stage 1, five multilabel-stratified folds are trained on the training split, and OOF sigmoid probabilities are collected for each label. These pooled OOF probabilities are subsequently used to determine a separate decision threshold for each label by maximizing binary F1. The five Stage-1 models are then ensembled by averaging their predictions and evaluated on the development set.

In Stage 2, the same training and threshold-calibration procedure is repeated after combining the training and development sets. Finally, the Stage-2 ensemble, together with the calibrated label-specific thresholds, is used to generate the predictions submitted for the test set.

3.2 Data processing

A regex normalizer strips diacritics and tatweel, unifies alef/alef-maksura/ya and hamza variants, collapses repeated-character runs and whitespace, applied identically to all splits. A short Arabic genre token ("opinion article:"/"debate:") is optionally prepended. Tokenization uses the model's tokenizer with 320-subword truncation and padding.

3.3 Model

We select MARBERTv2 over alternative Arabic encoders such as CAMeLBERT because it is pretrained on a large corpus spanning both Modern Standard Arabic and dialectal/social-media text, which we expect to transfer better to our mixed genres (formal-register editorials and spoken-register debates) than encoders pretrained predominantly on MSA news text; we do not ablate this choice against other encoders and leave a systematic comparison to future work.

We fine-tune `UBC-NLP/MARBERTv2` with a linear six-way sigmoid head (dropout 0.3), freezing the embeddings and first four encoder layers throughout both stages.

3.4 Imbalance handling

We use a label-weighted focal loss plus per-label threshold calibration, with a supplementary lexical rule boosting Statistics recall.

For Statistics, if the threshold is not reached but a percentage sign or a lexical marker (e.g., "study", "survey/poll") appears and $\hat{P}_c > 0.15$, the label is still assigned.

4 Experimental Setup

No hyperparameter optimization was conducted. Instead, all training configurations were predetermined and kept constant, as summarized in Table 1. Experiments were carried out on Google Colab, with an approximate runtime of 4–6 minutes per fold for Stage 1 and 5–10 minutes per fold for Stage 2. The implementation relied on Hugging Face `transformers`/PyTorch, along with scikit-learn and `iterative-stratification` for model development and data splitting.

Setting	Value
Encoder	MARBERTv2
Head	Linear, 6 outputs, sigmoid
Dropout	0.3
Frozen layers	Embeddings + first 4
Loss	Focal (γ=2.0), $\alpha \in [.5, .9]$
Optimizer / LR	AdamW / 2×10^{-5}
Weight decay / warmup	0.01 / 0.10
Epochs (max) / batch	8 / 16
Early stopping	Patience 3, F1@0.5
CV	MultilabelStratified, K=5
Max length	320 subwords

Table 1: Training configuration.

5 Results

5.1 Cross-Validation

Table 2 reports per-label OOF thresholds and F1. Stage 1 (train only, $N\approx612$) reaches macro-F1 = 0.6667; Stage 2 (train+dev, $N\approx829$) reaches 0.6799 (+0.0132). AS, ST, and TE improve with more data; AN, CO, and OT decline slightly, with CO showing the largest relative drop (−0.0667). The mean fixed-0.5-threshold macro-F1 across folds (0.6652 Stage 1, 0.6548 Stage 2) is consistently below the pooled, per-label-calibrated OOF macro-F1, confirming that threshold calibration helps over a fixed cutoff.

Label	Stage 1		Stage 2	
	t^*	F1	t^*	F1
AS	0.49	0.920	0.53	0.929
AN	0.51	0.715	0.47	0.708
ST	0.51	0.455	0.59	0.559
TE	0.53	0.734	0.57	0.795
CO	0.51	0.400	0.51	0.333
OT	0.45	0.778	0.51	0.756
Macro	–	0.667	–	0.680

Table 2: Per-label out-of-fold (OOF) decision thresholds (t^*) and binary F1, comparing Stage 1 (trained on the training split only, $N\approx612$) and Stage 2 (trained on training+development, $N\approx829$). The Macro row reports macro-averaged F1 across all six labels.

5.2 Official Evaluation

Table 3 reports overall metrics and Table 4 per-label F1 by evaluation condition (N=213 combined, 87 editorial, 126 debate). The combined micro-F1 is 0.766 and macro-F1 is 0.560. The performance is strongly genre-dependent: micro-F1 reaches 0.825 on debates but only 0.633 on editorials (a 19-point gap), with a smaller but consistent macro-F1 gap (0.554 vs. 0.456). The cross-validation macro-F1 (≈0.68) exceeds the official combined macro-F1 (0.560) by about 0.12 absolute.

5.3 Discussion

Threshold calibration consistently beats a fixed 0.5 cutoff. However, cross-validation overestimates

Set	Micro-F1	Macro-F1	Wtd-F1
Combined	0.766	0.560	0.760
Editorial	0.633	0.456	0.595
Debate	0.825	0.554	0.828

Table 3: Official overall metrics by evaluation condition.

Label	Comb.	Edit.	Debate
AS	0.920	0.881	0.941
AN	0.551	0.492	0.625
ST	0.333	0.429	0.000
TE	0.620	0.270	0.790
CO	0.095	0.000	0.118
OT	0.840	0.667	0.849
Macro	0.560	0.456	0.554

Table 4: Official per-label F1 by evaluation condition.

test generalization by $\sim$0.12 macro-F1, concentrated in low-support categories (CO, ST) whose small size inflates CV variance. Editorial paragraphs are consistently harder than debate paragraphs, suggesting the single genre-prefix mechanism under-models register differences; the Statistics rule in particular fails to generalize to debate. Early stopping in most Stage-1 folds also suggests a mismatch between the fixed-threshold model-selection criterion and the per-label thresholds used at inference.

6 Conclusion

We present a multi-label Arabic ADU classification system for Daleel 2026 shared task subtask-1, combining a monolingual encoder, focal loss, stratified k-fold CV, OOF threshold calibration, ensembling, and two-stage training. The system attains official micro-F1 = 0.766 and macro-F1 = 0.560, with *Assumption* and *Other* classified most reliably and *Common Ground* least reliably, mirroring low human agreement on that category in related English annotation. Internal cross-validation overestimates official test macro-F1 by $\sim$0.12, a gap concentrated in rare, genre-sensitive labels. Future work includes ablating the loss, genre-conditioning mechanism, and Statistics rule; genre-specific calibration; and confusion-matrix-level error analysis once per-example predictions are available.

Solodiscourse at Daleel 2026: Lexically-Augmented Focal-Loss Ensembling for Arabic Argumentative Discourse Unit Classification

Turab Hussain Usmani
Independent Researcher
turabofficial2003@gmail.com

Abstract

We describe our submission to Task 1 (Argumentative Discourse Unit Classification) of the Daleel 2026 shared task on Arabic argument mining, in the closed track. Given a paragraph from an Arabic editorial or debate transcript, the task is to predict the multi-label set of argumentative functions it contains, drawn from six classes: common ground, assumption, testimony, statistics, anecdote, and other. Our system fine-tunes a pretrained Arabic encoder, comparing AraBERT, MARBERT, and CAMeLBERT-mix, augmented with a small side-channel of hand-crafted lexical features motivated directly by the task's class definitions (e.g., reporting verbs for testimony, digit/percentage patterns for statistics), trained with a class-balanced focal loss and combined into a 5-fold cross-validation ensemble; CAMeLBERT-mix was selected as the final encoder for all submitted configurations. In the dev phase, our *Both*-domain configuration achieved an overall macro-F1 of 0.560 (editorial 0.435, debate 0.490). On the official test-phase Codabench leaderboard, our *Both*-domain configuration achieved an overall macro-F1 of 0.527 (editorial 0.384, debate 0.494), ranking 10th; our *Editorial*-only configuration reached an overall macro-F1 of 0.454 (editorial 0.325, debate 0.451). We report two findings grounded in these results: overall (pooled) macro-F1 consistently exceeds the macro-F1 computed on either genre subset alone, and our editorial-only model unexpectedly scores higher macro-F1 on the out-of-domain debate subset than on its own in-domain editorial subset. We discuss both as likely artifacts of per-class support sparsity at the smaller genre-subset scale rather than genuine cross-domain superiority, though we did not conduct a formal ablation study or systematic error analysis to confirm this, which we flag as the primary limitation of this report. Our code is available at https://github.com/turab-usmani/daleel-task1-closedtrack.

1 Introduction

Argument mining – the automatic identification and classification of argumentative structure in text – underlies applications ranging from opinion analysis and media literacy to explainable AI and the evaluation of language-model outputs (Stab and Gurevych, 2017). Despite this broad utility, Arabic remains comparatively under-resourced for argument mining, and in particular for discourse-level analysis that goes beyond sentence-level stance or claim detection. The Daleel 2026 shared task (Nabhani et al., 2026) addresses this gap by introducing an annotated corpus of Arabic argumentative discourse spanning two genres – editorials and debate transcripts – and defining six discourse-level argumentative functions: *common ground*, *assumption*, *testimony*, *statistics*, *anecdote*, and *other*.

We participate in **Task 1: Argumentative Discourse Unit Classification**, a paragraph-level multi-label task, under the **closed track** (provided training data, open-weight pretrained models under 70B parameters, standard NLP tooling only).

Our system strategy combines three components: (1) a pretrained Arabic transformer encoder fine-tuned as a multi-label classifier, (2) a small auxiliary feature vector of lexical cues drawn directly from the task's own class definitions (e.g., reporting verbs signal *testimony*, digit/percentage patterns and words like *dirāsa* ("study") signal *statistics*), concatenated to the pooled encoder representation before classification, and (3) a class-balanced focal loss combined with 5-fold cross-validation, which both stabilizes per-label decision-threshold tuning and yields a free ensembling gain at inference time.

Our key findings, based on the shared task's dev and test results: (1) CAMeLBERT-mix outperformed AraBERT-large and MARBERTv2 in our informal, non-ablated comparison across the

Split	Total	Editorial	Debate
Train	612	255	357
Dev (blind)	217	88	129
Test (blind)	213	87	126

Table 1: Number of paragraphs per split and genre (`train_task_1.jsonl`, `dev_in.jsonl`, `test_in.jsonl`). Dev and test files are distributed without gold labels; scoring is performed server-side on Codabench.

three configurations, and was used as the final encoder for all submissions; (2) pooled macro-F1 across both genres consistently exceeds the macro-F1 computed on either genre subset individually; and (3) our editorial-only configuration unexpectedly scores higher macro-F1 on the out-of-domain debate subset than on its own in-domain editorial subset. We discuss (2) and (3) in §5 and argue both are most plausibly explained by per-class support sparsity at the smaller genre-subset evaluation scale, though we did not run the ablation or error analysis needed to confirm this, which we identify explicitly as this report's main limitation rather than omit.

Code, trained-model configuration files, and inference scripts are available at `https://github.com/turab-usmani/daleel-task1-closedtrack`.

2 Background

Task setup. Task 1 requires predicting a multi-label subset $Y \subseteq \mathcal{L} = \{\text{CO}, \text{AS}, \text{TE}, \text{ST}, \text{AN}, \text{OT}\}$ for an Arabic paragraph x from editorials or debate transcripts.

Tracks. The closed track permits provided data, open-weight models under 70B parameters, and standard NLP tooling, prohibiting external labels or proprietary LLMs. We evaluate *editorial-only* and *both* configurations.

Dataset. The corpus consists of Arabic paragraphs from two genres: *editorials* (edited, formal MSA prose) and *debates* (transcribed spoken argumentation, comparatively disfluent, with dialectal features). Table 1 reports split sizes; debate is consistently larger than editorial across all splits. Systems are evaluated *in-domain* (train/test on the same genre) and *cross-domain* (train on one genre, test on the other), jointly testing multi-label classification and robustness to register shift.

Related work. Prior argument mining predominantly targets English component or premise detection (Stab and Gurevych, 2017), whereas Arabic resources focus mainly on stance and sentiment. We adapt pretrained Arabic encoders (Antoun et al., 2020; Abdul-Mageed et al., 2021) to discourse typing. While pretrained transformers excel at general semantic representation, incorporating domain-specific or task-derived lexical features via auxiliary side-channels has been widely shown to improve performance and data efficiency in low-resource and class-imbalanced classification settings. Concatenating explicit lexical markers with contextual embeddings provides an inductive bias that helps disambiguate subtle discourse boundaries under closed-track constraints.

3 System Overview

3.1 Base Model

We fine-tune a pretrained Arabic transformer as a multi-label classifier, comparing three publicly available encoders: `aubmindlab/bert-large-arabertv02` (Antoun et al., 2020), `UBC-NLP/MARBERTv2` (Abdul-Mageed et al., 2021), and `CAMeL-Lab/bert-base-arabic-camelbert-mix` (Inoue et al., 2021) (MSA, dialectal, and classical Arabic mix). Based on an informal comparison across our configurations (not a controlled ablation; §5.3), CAMeLBERT-mix was used for all final submitted results. Each paragraph is prefixed with a domain tag, `[EDITORIAL]` or `[DEBATE]`, added to the tokenizer vocabulary, so one model conditions on genre for both in-domain and cross-domain evaluation.

3.2 Lexical Feature Injection

The task's class definitions are, by design, partly lexically grounded: *testimony* is defined by attribution to an expert or authority, *statistics* by quantitative results, *anecdote* by concrete first-person experience, and *common ground* by "self-evident" framing. We hypothesize a small set of hand-crafted surface features targeting these definitions supplies signal that is hard for an encoder to reliably recover from a few hundred examples, and can be injected essentially for free.

To construct the keyword lists, we manually extracted high-precision indicator terms and discourse markers directly from the official task definition guidelines (such as explicit reporting verbs for testimony and epistemic modals for opinion), supplemented by inspecting high-frequency unigrams and bigrams characteristic of each class in the train-

Category	Representative cues (transliterated)
Reporting	*qāla*, *ṣarraḥa*, *afāda*, *bi-ḥasab*
Study/stats	*dirāsa*, *iḥṣā'iyya*, *istiṭlā'*
Modal/opinion	*yajibu*, *a'taqidu*, *min al-murajjaḥ*
Common ground	*min al-ma'rūf*, *lā shakka anna*
Anecdote	*atadhakkaru*, *jarrabtu*, *bi-nafsī*
Meta-discourse	*al-miḥwar al-awwal*, *sa-uwaḍḍiḥu*

Table 2: Representative keyword categories used for lexical feature extraction (§3.2). Keywords are matched in the original Arabic script in code; transliterations are shown here for readability given the pdfLaTeX compilation pipeline.

ing split.

For a paragraph with word tokens $w_1, \ldots, w_n$, we compute $\mathbf{f} \in \mathbb{R}^{10}$: six keyword-density features (occurrences per 100 words of curated Arabic keyword lists for *reporting*, *study/statistics*, *modal/opinion*, *common-knowledge*, *anecdotal*, and *meta-discourse* markers, e.g. "the first axis"), a percent/digit binary indicator pair, a quotation-mark density, and $\log(1+n)$. Table 2 lists representative keywords.

Let $h_{\text{CLS}} \in \mathbb{R}^d$ be the pooled `[CLS]` representation. We project $\mathbf{f}$ via $g(\mathbf{f}) = \text{ReLU}(W_1\mathbf{f} + b_1) \in \mathbb{R}^{32}$ and classify from the concatenation:

$$\hat{y} = \sigma\big(W_2\,[h_{\text{CLS}}\,;\,g(\mathbf{f})] + b_2\big) \in [0,1]^{|\mathcal{L}|}. \quad (1)$$

3.3 Class-Balanced Focal Loss

Due to severe label imbalance across the six classes and the substantial variation in classification difficulty between frequent and rare argumentative functions, standard binary cross-entropy can lead to degraded performance on underrepresented labels. We instead employ focal loss (Lin et al., 2017) with a *capped* class weight to prevent runaway over-prediction:

$$\alpha_c = \frac{\min\big(\max(1,\ \frac{1/\sqrt{\hat{p}_c}}{\min_{c'} 1/\sqrt{\hat{p}_{c'}}}),\ 3\big)}{\min\big(\ldots\big) + 1}, \quad (2)$$

where $\hat{p}_c$ is the empirical frequency of class c, and the per-example loss is

$$\mathcal{L} = -\frac{1}{|\mathcal{L}|}\sum_c \alpha_{c,y}(1-p_t)^\gamma \log p_t, \quad (3)$$

with $p_t = \hat{y}_c$ if $y_c{=}1$ else $1{-}\hat{y}_c$, $\alpha_{c,y} = \alpha_c$ if $y_c{=}1$ else $1{-}\alpha_c$, and $\gamma{=}2$. Capping the weight at $3\times$ retains the intended down-weighting of easy majority-class examples (via the focal term $(1-p_t)^\gamma$) while preventing runaway over-prediction of rare classes.

3.4 Cross-Validated Threshold Tuning and Ensembling

Rather than a single noisy held-out split, we train with 5-fold cross-validation and concatenate out-of-fold (OOF) predicted probabilities across folds to get estimates for the entire training set. We tune a per-class threshold τ_c by grid search over $\{0.05, \ldots, 0.95\}$ to directly maximize per-class F1 on these OOF predictions, since the task is F1-scored and a blind 0.5 cutoff is not calibrated to that objective. At inference, we average the sigmoid outputs of all 5 fold checkpoints (bagging) before applying τ_c; if no class clears its threshold, we fall back to the single highest-probability class, so the empty-set prediction never occurs.

3.5 Configurations

We evaluate two training settings: **Editorial** (editorial paragraphs only) and **Both** (the union, with the domain tag above). Both share the architecture and training procedure of this section, differing only in training data.

4 Experimental Setup

Data splits. We use the organizer-provided `train.jsonl` for both model fitting and, via 5-fold cross-validation (`sklearn.model_selection.KFold`, shuffled, seed 42), for threshold tuning, since the organizer-provided `dev_in.jsonl` file is distributed without gold labels (evaluation is performed server-side on Codabench). Final predictions are produced by ensembling the 5 fold checkpoints and evaluated on both the dev-phase and official test-phase blind splits.

Preprocessing. We strip diacritics and tatweel and collapse whitespace, avoiding aggressive normalization to preserve subword tokenizer alignment (max length 256 tokens).

Hyperparameters. We explored several hyperparameter combinations during development; we report the configuration used for our final submitted results. We fine-tune each fold for up to 12 epochs (batch size 8, gradient accumulation 2; AdamW, lr 2×10^{-5}, 10% warmup, weight decay 0.01, fp16, gradient checkpointing to fit 16GB VRAM), retaining the best-macro-F1 epoch per fold rather than the last. Focal loss uses $\gamma = 2$ with the capped class weight of §3.3. Full hyperparameters are in Appendix A (Table 4).

Phase	Config	Overall	Edit.	Deb.	Rank
Dev	Both	0.560	0.435	0.490	–
Test	Both	0.527	0.384	0.494	10
	Editorial	0.454	0.325	0.451	–

Table 3: Dev-phase and official test-phase Codabench leaderboard macro-F1 scores (per official `scoring.py`): *Overall* pools all instances; *Edit./Deb.* evaluate editorial/debate subsets.

Tools and models. Built with PyTorch 2.11, HuggingFace `transformers` 5.13.1 (Wolf et al., 2020), and `scikit-learn` 1.6.1. We compare `aubmindlab/bert-large-arabertv02` (Antoun et al., 2020), `UBC-NLP/MARBERTv2` (Abdul-Mageed et al., 2021), and select `CAMeL-Lab/bert-base-arabic-camelbert-mix` (Inoue et al., 2021).

Metrics. Following the official evaluation script, we report macro-F1 over the six labels computed with `scikit-learn` (`precision_recall_fscore_support`) jointly over both genres and separately per genre (editorial-only, debate-only), matching the organizers' `scoring.py`.

5 Results

5.1 Leaderboard Results

Table 3 reports our validation results from the development phase alongside official evaluation results on the Daleel 2026 test-phase Codabench leaderboard, computed server-side by the organizers' `scoring.py`. The evaluation script computes macro-F1 three times per submission: pooling all instances (*Overall*), and separately on the editorial-only and debate-only subsets.

In the development phase, our *Both*-domain configuration achieved an overall macro-F1 of 0.560 (0.435 on editorial, 0.490 on debate). On the official blind test set, our *Both*-domain submission achieved an overall macro-F1 of 0.527 (0.384 on editorial, 0.494 on debate), securing 10th place on the official task leaderboard. Our test-phase *Editorial*-only configuration achieved an overall macro-F1 of 0.454 (0.325 on editorial, 0.451 on debate).

5.2 Analysis

Two patterns in Table 3 are counter-intuitive; we discuss both despite lacking the ablation and per-class breakdown needed to fully explain them (§5.3).

Pooled macro-F1 exceeds either subset's macro-F1. Overall macro-F1 consistently exceeds individual editorial and debate scores across dev and test phases. This is hypothesized to be an artifact of small subset sizes (87–129 instances), where rare classes with sparse support disproportionately drag down unweighted macro-F1, whereas pooling genres increases support and smooths the metric—though confirming this requires an uncomputed per-class breakdown.

Editorial-only training scores higher out-of-domain. On the test set, the *Editorial* model scored higher on out-of-domain debates (0.451) than in-domain editorials (0.325). This is likely caused by the smaller editorial split size (255 train / 87 test paragraphs), leading to rarer class underfitting and heightened macro-F1 penalty from support sparsity.

5.3 Limitations of This Analysis

We did not conduct a controlled ablation (isolating the lexical feature side-channel, capped focal loss, or CV ensembling of §3) or a systematic error analysis (confusion matrices, categorized examples), due to time constraints. The CAMeLBERT-mix vs. AraBERT vs. MARBERT comparison in §4 was likewise an informal development-time choice, not a controlled comparison. Completing both is the most direct next step (§6).

6 Conclusion

We presented our Daleel 2026 Task 1 submission: fine-tuned CAMeLBERT-mix with definition-derived lexical features, capped focal loss, and 5-fold CV threshold ensembling, achieving 0.527 test macro-F1 (10th place). We observed two evaluation-scale anomalies (pooled macro-F1 superiority and inverted domain performance), which likely stem from per-class support sparsity in small genre subsets.

Limitations. We did not run a controlled ablation or systematic error analysis (§5.3), so the design rationale for the lexical features and capped focal loss (§3) reflects motivating hypotheses, not measured contributions. Keyword lists were built manually and likely under-cover dialectal debate register. We did not explore open-weight instruction-tuned LLMs (permitted up to 70B parameters).

Future work. The immediate next step is the ablation and error analysis flagged above, particularly a per-class precision/recall breakdown to test the support-sparsity explanation in §5.2. Further directions: sentence/clause-level auxiliary supervi-

sion aggregated to paragraph level; ensembling CAMeLBERT-mix with AraBERT/MARBERT; and, once error analysis identifies the most-confused label pairs, checking whether that reflects an inter-annotator-agreement ceiling.

A Implementation Details

Table 4 lists the complete hyperparameter settings and hardware configuration used for all training folds.

Hyperparameter	**Value**
Base encoder	CAMeLBERT-mix
Max sequence length	256 subwords
Batch size (per device)	8
Gradient accumulation	2 (effective 16)
Epochs (max, per fold)	12
Learning rate	2×10^{-5}
Warmup ratio	0.10
Weight decay	0.01
Optimizer	AdamW
Precision	fp16
Focal loss γ	2.0
Max class weight cap	$3\times$
Lexical feature projection dim	32
Cross-validation folds	5
Threshold grid	$\{0.05, 0.10, \ldots, 0.95\}$
Random seed	42
GPU	$1\times$ NVIDIA T4 (16GB)

Table 4: Full hyperparameter configuration.

B Lexical Feature Keyword Lists

Table 5 reproduces the complete keyword lists used for lexical feature extraction (§3.2), shown here transliterated for readability; matching is performed against the original Arabic-script strings in code.

Category	**Keywords (transliterated)**
Reporting	qāla, ṣarraḥa, akkada, a'lana, ḥasab, wafqan li, bi-ḥasab, dhakara, afāda, naqala, awḍaḥa, shaddada
Study/stats	dirāsa, dirāsāt, baḥth 'ilmī, iḥṣā'iyya, iḥṣā', istiṭlā', bayānāt, taqrīr ṣādir, nisba
Modal/opinion	yajibu, yanbaghī, min al-mafrūḍ, a'taqidu, fī ra'yī, min al-wāḍiḥ, yabdū anna, min al-murajjaḥ, arā anna, min al-ḍarūrī
Common knowledge	min al-ma'rūf, min al-badīhī, lā yakhfā 'alā aḥad, badīhī, min al-musallam bihi, kamā huwa ma'rūf, lā shakka anna
Anecdote	atadhakkaru, jarrabtu, shahidtu, 'ishtu, ra'aytu, ḥadatha ma'ī, qiṣṣatī, tajribatī, bi-nafsī, ḥaṣala ma'ī
Meta-discourse	al-miḥwar al-awwal, al-miḥwar al-thānī, al-nuqṭa al-ūlā, al-nuqṭa al-thāniya, sa-uwaḍḍiḥu, sa-ataḥaddathu, da'ūnī, kamā dhakartu, bidāya, akhīran

Table 5: Complete keyword lists per category used for lexical feature extraction (§3.2). Keywords are counted as substring occurrences per 100 words of paragraph text.

DialectSentEval 2026: Arabic Dialect Sentiment Analysis and Swapping Shared Task

Abstract

Sentiment analysis is a fundamental problem in Natural Language Processing (NLP). Standard sentiment classification for the Arabic language remains challenging due to the high volume of dialectal Arabic. To advance research in this area, this paper proposes the Shared Task on Sentiment Analysis and Swapping in Arabic Dialects (DialectSentEval), hosted with the Arabic Natural Language Processing Conference (ArabicNLP 2026). This shared task consists of two subtasks: Subtask 1 focuses on multi-class and multi-dialect sentiment analysis, requiring models to identify sentiment polarity across various Arabic dialects. Subtask 2 introduces a generative task for Arabic sentiment swap, challenging models to invert sentiment polarity while preserving core semantics. In this overview paper, we present the motivation, dataset creation, and summarize the main findings from participating models.

1 Introduction

Sentiment analysis remains a key task in Natural Language Processing (NLP), with critical real-world applications ranging from social media monitoring to customer feedback analysis. While significant progress has been made for many languages, and multiple types have been defined (document, sentence, and feature/aspect level), the Arabic language presents unique challenges due to its rich morphology and extensive dialectal variation. Most user-generated content, the primary source for sentiment data, is written in dialectal Arabic, which is often under-resourced and differs significantly from Modern Standard Arabic (MSA).

To address these challenges and foster innovation in Arabic NLP, we propose a novel Shared Task on Sentiment Analysis and Swapping in Arabic Dialects (DialectSentEval), hosted with the Arabic Natural Language Processing Conference (ArabicNLP 2026)[1]. This task is designed to move beyond standard sentiment classification by evaluating both the understanding and generation of sentiment in diverse Arabic contexts. DialectSentEval comprises two distinct but complementary subtasks:

- **Subtask 1: Arabic Dialect Sentiment Analysis**: A multi-class classification task focused on identifying the sentiment (positive, negative, or neutral) of texts written in various Arabic dialects. This subtask emphasizes the need for robust models that can handle the lexical and syntactic diversity of the Arab world.
- **Subtask 2: Arabic Sentiment Swap**: A generative task where participants' systems must rewrite a given sentence to invert its sentiment polarity (e.g., positive to negative) while preserving its core meaning. This challenges models to go beyond surface-level cues and demonstrate a deeper grasp of semantics and syntax.

2 Motivation

The motivation for DialectSentEval is grounded in both linguistic and methodological gaps in current Arabic NLP research.

First, despite sustained interest in sentiment analysis for Arabic, there remains a clear shortage of robust benchmarks that adequately capture dialectal diversity. Earlier shared tasks and evaluation campaigns (El-Beltagy et al., 2017; Rosenthal et al., 2017) have advanced sentiment classification for Arabic, yet most resources are either limited to MSA or focus on a narrow set of dialects and domains (El-Haj, 2026, 2020). In practice, however, the majority of user-generated content, including reviews, social media posts, and online discussions, is written in dialectal Arabic. These dialects exhibit substantial lexical, morphological, and syntactic

October 28-29, 2026 ©2026 Association for Computational Linguistics

variation, which often leads to performance degradation when models trained on MSA are applied to real-world data. Prior work has highlighted the fragmentation of Arabic sentiment resources and the difficulty of transferring models across dialects (Nwesri et al., 2025; Alwakid et al., 2022), reinforcing the need for more representative evaluation benchmarks. By introducing a balanced, multi-dialect benchmark informed by recent benchmarking efforts (Alharbi et al., 2025c), DialectSentEval seeks to promote the development of sentiment models that generalise across dialects and better reflect authentic language use in the Arab world.

Second, the task aims to extend evaluation beyond classification into controlled text generation. While sentiment classification has reached a relatively mature stage in Arabic NLP, generative sentiment manipulation remains underexplored (Abudalfa et al., 2025). Sentiment swapping, framed as a form of style transfer, requires systems to invert polarity while preserving core propositional content. This problem has been investigated in English (Shen et al., 2017; Li et al., 2018), where style transfer research has demonstrated the complexity of disentangling content from sentiment and other stylistic attributes. Comparable resources and systematic evaluation frameworks are scarce for Arabic, limiting progress in controllable generation (Abudalfa et al., 2024; Abdu et al., 2025). The limited availability of high-quality parallel datasets has constrained progress in this area. By introducing a dedicated sentiment swap subtask, DialectSentEval encourages research on semantic preservation, polarity control, and evaluation methodologies for Arabic natural language generation. Such capabilities have practical implications for data augmentation, controllable dialogue systems, and adaptive content generation, particularly in low-resource and dialectally diverse settings.

By combining a dialect-aware classification task with a challenging generative task, DialectSentEval offers a unified benchmark for both sentiment understanding and sentiment manipulation in Arabic. This dual focus is intended to stimulate research that moves beyond surface-level polarity detection towards more semantically grounded and controllable language technologies for Arabic.

3 Data Collection and Creation

The datasets for both subtasks were collected and annotated prior to the task launch. Figure 1 illustrates the dataset creation process for both subtasks.

3.1 Subtask 1: Dialect Sentiment Analysis

The dataset for this task, Multi-Dialect-Sent (MDS-3), currently consists of 3,000 sentences annotated for three-class sentiment (positive, negative, neutral). The dataset is balanced across five major dialects: Moroccan, Egyptian, Lebanese, Jordanian, and Saudi. The data was sourced from hotel reviews from the ADOR dataset (Alharbi et al., 2025b), then translated and annotated by native speakers of each dialect. The sentences are parallel across dialects, with balanced sentiment representation across all included dialects. An initial version of the dataset was verified in recently organised shared tasks Ahasis (Alharbi et al., 2025a) and AraSentEval (Ezzini et al., 2026).

The dataset was split into 80% for training and 20% for testing. The split was performed based on sentence IDs to ensure that parallel sentences remain in the same set, to prevent potential data leakage between the training and test sets.

3.2 Subtask 2: Sentiment Swap

This subtask draws on a dataset built as an extension of MA'AKS (Mughaus et al., 2026), comprising a total of 9,647 sentence-pair instances. Each pair centers on a shared topic but conveys contrasting sentiment orientations, with one member expressing a positive stance and the other a negative one. Of the full collection, 5,331 instances (55.3%) carry a Negative label, while the remaining 4,316 (44.7%) are tagged Positive.

Whereas the original MA'AKS resource was built predominantly around MSA, the present corpus is drawn entirely from regional Arabic dialects and spans four principal dialectal families: Gulf (5,893 pairs, 61.1% of the total), Levantine (1,655 pairs, 17.2%), Egyptian (1,561 pairs, 16.2%), and Maghrebi (538 pairs, 5.6%).

To ensure reliability, every pair passed through a rigorous validation process assessing fluency, semantic fidelity, and the correctness of the sentiment reversal. The corpus comes with fixed training, validation, and test partitions, requiring models to capture both the meaning and the sentiment structure of each sentence. These partitions consist of 6,752 pairs for training, 964 for validation, and 1,931 for testing.

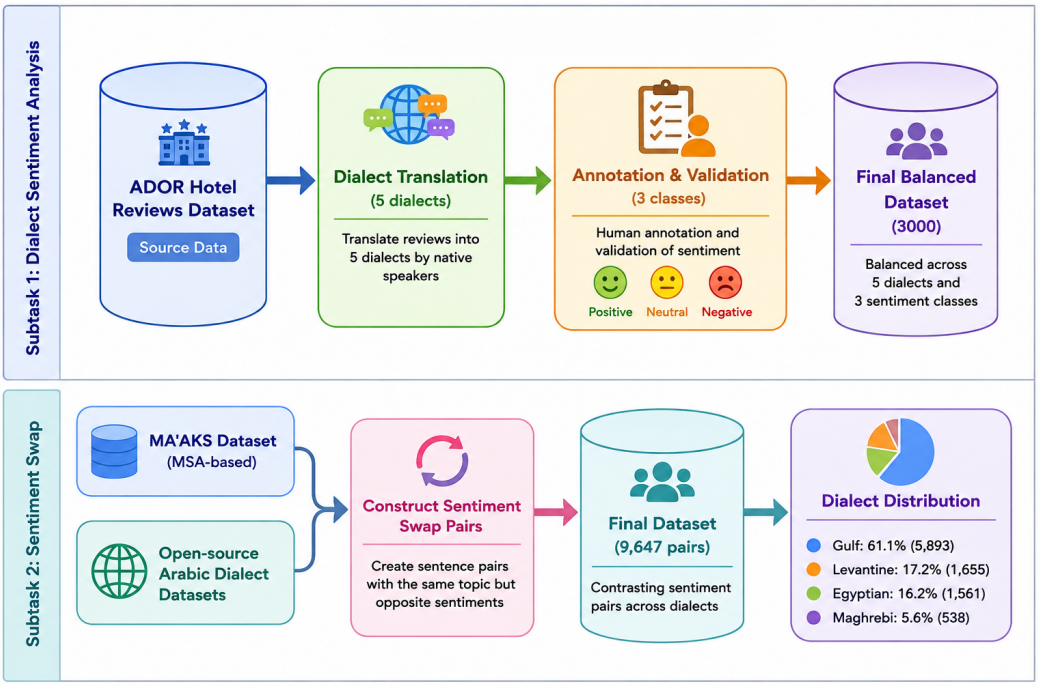

Figure 1: Data creation process for both subtasks.

4 Task Description and Evaluation

In this section, we describe in detail the subtasks that define our shared task. Participants were allowed to participate in either one or both subtasks. The official evaluation was conducted on the **CodaBench** platform, an open-source platform designed to organize Artificial Intelligence benchmarks by defining tasks, including datasets, submission pipelines, and evaluation metrics. It provides an automated and transparent framework for evaluating system submissions.

4.1 Subtask 1: Arabic Dialect Sentiment Analysis

In this subtask, participants are required to build a system that classifies the sentiment expressed in sentences written in five different and linguistically challenging Arabic dialects: Moroccan, Egyptian, Lebanese, Jordanian, and Saudi. The goal of this task is to evaluate the ability of models to handle dialectal variation in Arabic while accurately identifying the sentiment conveyed in each sentence.

Formally, the objective is to design a sentence-level classifier C such that, given an input sentence x, the system predicts a sentiment label S, where:

$$S = C(x), \quad S \in \{\text{Positive}, \text{Neutral}, \text{Negative}\}.$$

- **Input**: A sentence written in Arabic using one of the target dialects (Moroccan, Egyptian, Lebanese, Jordanian, or Saudi).
- **Output**: A sentiment label selected from the set {Positive, Neutral, Negative}.
- **Evaluation Metric**: Systems are evaluated using the **Macro F1-score**. This metric is chosen because it gives equal importance to all classes and is therefore more suitable in scenarios where class distributions may be imbalanced.

4.2 Subtask 2: Arabic Sentiment Swap

In the second subtask, participants are expected to design models able to generate a new sentence that expresses the opposite sentiment of a given sentence while preserving its original semantic content. The input sentences are written in one of several Arabic dialect groups: Maghreb, Egyptian, Gulf, and Levantine. This task evaluates a model's ability to perform controlled sentiment transformation while maintaining semantic fidelity.

Formally, the objective is to train a model M capable of performing sentiment-controlled text generation. Given an input sentence x expressing a sentiment S, the model should generate a new sentence x' that conveys the opposite sentiment S', while preserving the core meaning and topic of the original sentence, such that:

$$x' = M(x), \quad S' = \text{Opposite}(S)$$

where $S, S' \in \{\text{Positive}, \text{Negative}\}$ and $S' \neq S$.

- **Input**: An Arabic sentence along with its original sentiment polarity (e.g., "هذا المطعم رائع للغاية", Positive).
- **Output**: A rewritten Arabic sentence that preserves the main meaning of the input while expressing the opposite sentiment polarity (e.g., "هذا المطعم سيء للغاية").
- **Evaluation Metrics**: The generated outputs are evaluated using both sentiment accuracy and text similarity metrics to ensure correct sentiment transfer while maintaining semantic consistency.
  - **Sentiment Style Accuracy**: A pretrained sentiment classifier from CamelLab[2] is used to measure the percentage of generated sentences that correctly express the target polarity.
  - **BLEU and chrF**: These metrics are used to evaluate the degree of lexical and character-level similarity between the generated sentence and the reference sentence, providing an indication of semantic preservation.

5 Participant Systems

Across both subtasks, a total of 15 unique teams participated in the competition, with 16 system description papers submitted. Below, we describe the methodologies and system architectures proposed by the participating teams, categorized by subtask.

5.1 Subtask 1: Arabic Dialect Sentiment Analysis

Participating teams for Subtask 1 investigated a diverse range of pretrained transformer architectures, ensembling strategies, loss function formulations, and domain-adaptation techniques to tackle multi-dialect variation and zero-shot dialect transfer.

- **ALEXIS** (Username: *momen_ibrahim-870387*) (Ibrahim et al., 2026a): Ranked **1st** overall with a Macro F1-score of **0.8667**. The team proposed an adversarial training and iterative self-training pipeline built on top of MARBERTv2. Specifically, they utilized the Fast Gradient Method (FGM) during fine-tuning to regularize the feature space against dialectal perturbations. To address zero-shot generalization on unlabelled dialects (notably Lebanese), they implemented a confidence-thresholded pseudo-labeling strategy that iteratively incorporated high-confidence test predictions back into training.
- **Axiom** (Username: *ajwad_hossain-867052*) (Hossain, 2026): Ranked **2nd** with a Macro F1-score of **0.8210**. They developed a dialect-aware ensemble framework combining MARBERTv2 and AraBERTv2. Their system utilized Stratified 5-Fold Cross-Validation, text normalization tailored to dialectal orthography, and an automated soft-voting probability aggregation scheme.
- **PTUK-NLP** (Username: *tasneemduridi-857223*) (Duridi et al., 2026): Ranked **3rd** with a Macro F1-score of **0.8174**. The team fine-tuned MARBERT with domain-specific cleaning pipelines. They demonstrated that representations learned from geographically and linguistically proximate Levantine variants (Jordanian) transfer effectively in a zero-shot fashion to Lebanese. They also provided an extensive qualitative error analysis identifying mixed-polarity reviews as the primary source of classification errors.
- **NU-SentEval** (Username: *habiba_ayman-867381*) (Ayman et al., 2026): Ranked **4th** with a Macro F1-score of **0.8140**. They developed a stacked model blending predictions from MARBERTv2, AraBERTv02, and QARiB. Crucially, they integrated Focal Loss during training to mitigate class imbalance and focus gradient updates on hard-to-classify neutral examples.
- **Gradient Descenders** (Username: *normalman159-857755*) (Nhan et al., 2026): Ranked **5th** with a Macro F1-score of **0.8010**. The team performed an empirical comparison across multiple Arabic encoders (MARBERT, ARBERT, and AraBERT), concluding that fine-tuned MARBERTv2 combined with class-weighted cross-entropy loss and linear learning-rate warm-up yielded optimal multi-dialect performance.

[2] CAMeL-Lab/bert-base-arabic-camelbert-da-sentiment

- **LahjaSensei** (Username: *ahmadalmoustafa-856400*) (Almoustafa, 2026): Ranked **6th** with a Macro F1-score of **0.7977**. They utilized fine-tuned transformer backbones accompanied by dialect-specific token normalization and prompt-based tuning.

- **NAMAA Community** (Username: *mona_-871069 / hsnhb7*) (Abdelazim et al., 2026): Ranked **7th** with a Macro F1-score of **0.7953**. They constructed an ensemble merging MARBERTv2, AraBERTv2, and AraModernBERT, using dialect classification heads to dynamically weigh base-model outputs.

- **faisalm93** (Username: *faisalm93-869067*) (Adam, 2026): Ranked **8th** with a Macro F1-score of **0.7939**. The author developed a 5-fold cross-validated MARBERTv2 bagging ensemble utilizing soft voting across fold models, Cosine Annealing learning rate schedules, and layer-wise learning rate decay.

- **Lahja** (Username: *shadenalzeer-867546*) (Alzeer, 2026): Ranked **10th** with a Macro F1-score of **0.7894**. They implemented a multi-seed ensembled MARBERT architecture designed to stabilize zero-shot transfer for the unrepresented Lebanese dialect by exploiting cross-dialect semantic regularities.

- **Northwestern** (Username: *monmon2000*) (Shlkamy and Zaghouani, 2026): Explored a comparative study of MARBERTv2 and AraBERT under various dialectal splits, demonstrating that dialect-specific pretraining provides significant robustness gains over general MSA models.

5.2 Subtask 2: Arabic Sentiment Swap

Subtask 2 saw participating systems leverage generative large language models (LLMs), parameter-efficient adapters, candidate reranking pipelines, and preference alignment techniques to tackle the complex dual objective of sentiment polarity inversion and semantic fidelity.

- **ALEXIS** (Username: *momen_ibrahim-870527*) (Ibrahim et al., 2026b): Ranked **1st** across all evaluation metrics, achieving a Sentiment Style Accuracy of **0.9581**, a BLEU score of **56.91**, and a chrF of **72.18**. They introduced a multi-stage framework combining: (1) dialect-aware Retrieval-Augmented Generation (RAG) using semantic similarity over training pairs, (2) Direct Preference Optimization (DPO) to align open-weight generative backbones towards clean polarity transfer, and (3) a classifier-guided candidate reranker that filters out candidates failing the target sentiment direction.

- **AKARROUCH** (Username: *akarrouch-871040*) (Akarrouch, 2026): Ranked **2nd** with a Sentiment Style Accuracy of **0.7851**, BLEU of **49.82**, and chrF of **70.12**. The system employed a generate-and-rerank architecture where an instruction-tuned LLM produced multiple candidate rewrites via temperature sampling, followed by a fine-tuned sentiment classifier to select the candidate maximizing target polarity probability.

- **LahjaSensei** (Username: *ahmadalmoustafa-865064*) (Almoustafa, 2026): Ranked **3rd** with a Sentiment Style Accuracy of **0.7789**, BLEU of **41.48**, and chrF of **64.45**. They proposed few-shot in-context prompting combined with Model Merging via Spherical Linear Interpolation (SLERP) across fine-tuned dialect checkpoints.

- **NAMAA** (Username: *mona_-871054 / hsnhb7-868552*) (Barmandah et al., 2026): Ranked **4th** with a Sentiment Style Accuracy of **0.7597**, BLEU of **51.58**, and chrF of **71.02**. The team introduced a cross-backbone ensembling framework combining candidate hypotheses from Qwen2.5, Llama-3, and AraT5, reranked by an auxiliary sentiment verification classifier.

- **Sabaa** (Username: *mohamedsabaa-855812*) (Sabaa and Said, 2026): Ranked **6th** with a Sentiment Style Accuracy of **0.7447**, BLEU of **49.07**, and chrF of **69.33**. They utilized fine-tuned AraT5 sequence-to-sequence models combined with an external MARBERT-based sentiment classifier to rerank beam-search hypotheses.

- **NU-SentEval** (Username: *areejkhaled-868894*) (Tamer et al., 2026): Ranked **8th** with a Sentiment Style Accuracy of **0.6898**, achieving a top-tier chrF of **72.61** and BLEU of **54.63**. They fine-tuned AraT5-base models conditioned on explicit dialect and polarity transformation prefix tokens.

- **NileNLP** (Username: *mohammed_bahgat-863352* / *ehabashraf-863355*) (Bahgat et al., 2026): Ranked **9th–10th** with a Sentiment Style Accuracy of **0.6732**, BLEU of **41.38**, and chrF of **65.84**. They developed *SWAP-PER*, a parameter-efficient adapter framework applying Low-Rank Adaptation (LoRA) to generative Arabic models.

6 Results and Analysis

6.1 Subtask 1: Arabic Dialect Sentiment Analysis

Table 1 reports the official evaluation results on the test set for Subtask 1, ranked by Macro F1-score.

Analysis of Subtask 1 Results. Several key findings emerge from the experimental outcomes of Subtask 1:

1. **Pretrained Dialectal Encoders Outperform Generative LLMs**: All top-performing submissions relied on dedicated dialectal encoder models—most notably MARBERTv2 and AraBERTv02. Models exposed to substantial dialectal social media data during pretraining consistently outperformed general Modern Standard Arabic (MSA) baselines and zero-shot prompting of large generative models.

2. **Robustness via Adversarial Training and Pseudo-Labeling**: The winning system, **ALEXIS**, achieved a substantial lead (+4.57% Macro F1 over 2nd place). This gain was primarily driven by Fast Gradient Method (FGM) adversarial training, which forces the model representations to remain invariant to dialectal surface lexical variations, paired with iterative self-training that effectively bootstrapped representations for the unlabelled Lebanese test instances.

3. **Ensembling and Loss Engineering**: Teams that implemented stratified K-fold ensembling (**Axiom**, **faisalm93**) and model stacking across distinct pretraining families (**NU-SentEval**, **NAMAA**) demonstrated higher stability. Furthermore, incorporating Focal Loss (**NU-SentEval**) effectively addressed the subtle semantic boundaries between neutral and mildly opinionated dialectal phrases.

4. **Zero-Shot Levantine Transferability**: Analysis by **PTUK-NLP** and **Lahja** showed that models trained on geographically proximate dialects (Jordanian) exhibit strong zero-shot cross-lingual transfer to Lebanese, confirming shared lexical roots within the Levantine dialect family.

6.2 Subtask 2: Arabic Sentiment Swap

Table 2 presents the official evaluation results for Subtask 2, sorted by the primary metric, Sentiment Style Accuracy, alongside semantic preservation metrics (BLEU and chrF).

Analysis of Subtask 2 Results. Evaluating generative sentiment swapping across Arabic dialects revealed several critical insights:

1. **The Polarity Transfer vs. Content Preservation Trade-off**: Generative sentiment style transfer poses an intrinsic tension between modifying sentiment markers (necessary for high Sentiment Style Accuracy) and retaining non-sentiment lexical content (measured by BLEU and chrF). Submissions that modified too few words achieved high BLEU but failed to invert sentiment (e.g., lower accuracy), while unconstrained generative rewrites suffered severe lexical drift.

2. **The Impact of Preference Optimization (DPO)**: The winning team, **ALEXIS**, dominated across all dimensions (0.9581 accuracy, 56.91 BLEU, 72.18 chrF). By directly training on paired contrastive preferences using DPO, their system learned to apply minimal, surgical edits to dialectal sentiment words (e.g., negating adjectives or swapping affective idioms) while strictly preserving sentence structure.

3. **Generate-and-Rerank Pipelines as an Essential Safety Mechanism**: Teams employing generate-and-rerank pipelines (**AKARROUCH**, **NAMAA**, **Sabaa**) achieved consistently higher style transfer accuracy ($> 74\%$) than unguided generation. Filtering candidate rewrites with an external sentiment classifier prevented output hallucination and ensured the target polarity was reliably achieved.

4. **Model Merging and PEFT for Dialect Specialization**: Advanced parameter-efficient techniques, such as SLERP model merging across dialect checkpoints (**LahjaSensei**) and

Table 2: Official evaluation results for Subtask 2: Arabic Sentiment Swap.

Low-Rank Adaptation (**NileNLP**), proved competitive while requiring substantially lower computational footprints during fine-tuning.

7 Conclusion

This overview paper presented the results and findings of the DialectSentEval shared task, held at ArabicNLP 2026. The shared task benchmarked two core dimensions of dialectal NLP: multi-class Arabic dialect sentiment classification (Subtask 1) and generative sentiment style transfer across four major Arabic dialect groups (Subtask 2).

A total of 15 teams actively participated in the competition. The evaluation demonstrated the continued superiority of dialect-pretrained masked encoders when paired with adversarial regularization and self-training for classification, as well as the immense potential of Direct Preference Optimization (DPO) and classifier-guided reranking for controlled generative style transfer in low-resource and dialectally diverse environments.

Abstract

Sentiment swap asks a system to rewrite a sentence so that its polarity is inverted while everything else stays the same, two halves of an instruction that pull against each other. This paper describes how the Sabaa system navigates that trade-off for Arabic dialects in Subtask 2 of DialectSentEval 2026. Rather than asking one model for a single correct rewrite, we ask two fine-tuned Arabic sequence-to-sequence models to each propose several, then choose among the pooled proposals with a scoring function built from the signals the task grades us on. The system scores 49.07 BLEU, 69.33 chrF, and 0.7447 sentiment accuracy on the official test set. That last figure is the most informative result here: the system places 90.37% of its outputs at the polarity it was aiming for, and the shortfall traces to inferring each sentence's original polarity, which the test data withholds. Measured against gold labels on development, that inference is correct only 74.07% of the time, and sixteen points of sentiment accuracy separate our submission from a perfect estimator. [1]

1 Introduction

Consider the Egyptian Arabic sentence كل حاجه جميله (“everything is beautiful”). Asked to invert its sentiment, a system could return كل حاجه ضلمه (“everything is bleak”), changing one adjective, or a fluent but unrelated complaint. Both flip the polarity; only the first preserves the content, phrasing, and dialect. Subtask 2 of DialectSentEval 2026 (Ezzini et al., 2026a) scores both properties at once, sentiment accuracy through a fixed classifier and content preservation through BLEU and chrF, rewarding a system precisely for preferring the first output over the second.

[1] https://github.com/mohamedkamalsabaa/Sabaa_DialectSentEval_2026_Subtask-2

This framing shapes our design. A model trained only to maximise likelihood has no reason to prefer a minimal edit over a wholesale rewrite, since both are fluent continuations of the same instruction. What it does reliably produce is a *set* of plausible rewrites, some minimal and some not. Our system therefore separates generation from selection: two fine-tuned Arabic encoder–decoder models propose, and a scoring function assembled from the task's own evaluation signals decides. Pooling candidates from two models pretrained on different corpora widens that set, and their proposals tend to fail in different ways, so a candidate one model truncates the other often does not.

The system obtains 0.9564 sentiment accuracy, 52.26 BLEU, and 70.64 chrF on the development leaderboard, and 49.07 BLEU, 69.33 chrF, and 0.7447 sentiment accuracy on test. The drop in sentiment demands an explanation, and supplying one leads to the paper's main finding (§5.3): the generator is not what changed. The test set withholds the source polarity, forcing the system to infer the swap direction, and an incorrect direction guarantees an incorrect output however good the rewrite that follows.

2 Background

What the task asks for. Each instance pairs a source sentence with its polarity, and the system must return a sentence of the opposite polarity that otherwise preserves the original. The following pair from the training data shows the shape of the intended output:

Source (Positive):
بنقول لنفسنا كل حاجه جميله
Target (Negative):
بنقول لنفسنا كل حاجه ضلمه

One word carries the sentiment and one word changes; the dialectal spelling, the subject, and the

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1389–1393
October 28-29, 2026 ©2026 Association for Computational Linguistics

sentence frame all survive. This is the behaviour our reranker is built to select for.

Data. We train on MA'AKS (Mughaus et al., 2026), a manually-curated parallel corpus for Arabic sentiment swap, which supplies 6,752 training and 964 development pairs carrying `id`, `source`, `source_polarity`, and `target`; training polarities are mildly imbalanced at 3,731 negative to 3,021 positive.

The 1,931-sentence test set differs in a way that matters a great deal: it supplies only `id` and `source`. The target is withheld, as expected, but so is `source_polarity`, so a system must work out the swap direction for itself (§3.4). The predecessor AraSentEval task (Ezzini et al., 2026b) established this formulation and we follow its evaluation protocol.

3 System Overview

3.1 Doubling the training data for free

Sentiment swap is symmetric: if t is a valid polarity-inverted rewrite of s, then s is equally a valid rewrite of t. Every training instance therefore contains a second that costs nothing to extract, so for each pair (s, t) with source polarity p we add (t, s) with polarity $\overline{p}$ under an offset identifier. This doubles the data to 13,504 pairs and balances the polarity distribution exactly at 6,752 each, so the model sees both swap directions equally often, which matters because at test time it performs both.

3.2 Two generators, one instruction

We fine-tune two Arabic-specific encoder–decoder models on this augmented data: **AraT5v2-base-1024** (Nagoudi et al., 2022), a 220M-parameter Arabic T5 pretrained on both Modern Standard Arabic and dialectal text, and **AraBART** (Kamal Eddine et al., 2022), a 139M-parameter Arabic BART pretrained on news. Both receive an identical protocol and instruction, so the only difference between the two candidate streams is the model behind it:

> اعكس قطبية النص من `{src_pol}` إلى `{tgt_pol}`: `{source}`
>
> ("Invert the polarity of the text from `{src_pol}` to `{tgt_pol}`")

The instruction is Arabic by design: both models were pretrained exclusively on Arabic, and an English frame would ask them to parse a token sequence unlike anything in their pretraining before reaching the sentence itself.

3.3 Choosing among proposals

At inference each model produces k candidates by beam search, and the two sets are pooled into a single candidate set $\mathcal{C}$ of size $2k$. Every candidate in this pool is then scored on three properties.

The first is whether it carries the right sentiment. We ask the official evaluation classifier, CAMeLBERT-DA (Inoue et al., 2021), writing $\hat{y}(c)$ for its label, $\sigma(c)$ for its confidence, and τ for the target polarity: $S_{\text{sent}}(c) = +\sigma(c)$ if $\hat{y}(c) = \tau$ and $-\sigma(c)$ otherwise. Signing the confidence rather than using a binary indicator penalises a confidently wrong candidate more heavily than an uncertain one.

The second property is whether the candidate resembles its peers. Following the Minimum Bayes Risk principle (Eikema and Aziz, 2020, 2022), $S_{\text{cons}}(c)$ is the mean chrF between c and every other member of $\mathcal{C}$, scaled to $[0, 1]$. The justification is empirical: pool outliers were overwhelmingly truncations, repetitions, and hallucinations rather than unusually good rewrites.

The third property is whether the content survived, measured as the chrF of the candidate against the source, $S_{\text{cont}}(c) = \text{chrF}(c, s)/100$. This is what makes minimal edits attractive to the selector, since a rewrite changing one word scores far higher against the source than one that rephrases.

The output is the candidate maximising $w_1 S_{\text{sent}} + w_2 S_{\text{cons}} + w_3 S_{\text{cont}}$. A candidate decoding to an empty string is replaced by the source, guaranteeing every input a non-empty, on-topic output.

3.4 Recovering the swap direction

Everything above assumes τ is known. On development it is, since `source_polarity` is supplied. On test it is not, so we recover it with the same classifier we use for reranking. CAMeLBERT-DA is three-way, and its Neutral class names no direction to swap in, so we discard the Neutral logit and read the source polarity off the remaining two: assigning $\hat{p}(s) =$ Positive when $P_{\text{pos}}(s) \geq P_{\text{neg}}(s)$ and Negative otherwise, then taking $\tau = \overline{\hat{p}(s)}$. On test this assigns 977 sentences a positive source polarity and 954 a negative one. This step is the only substantive difference between our development and test pipelines, and §5.3 shows it is where most of our test-set sentiment loss originates.

4 Experimental Setup

Both generators are trained on the full augmented training split of 13,504 pairs under identical settings: maximum sequence length 128, per-device batch size 4 with two gradient accumulation steps, AdamW at learning rate 5×10^{-5}, 500 warmup steps, weight decay 0.01, 15 epochs, and mixed-precision training. Label smoothing is disabled, for reasons taken up in §5.2. Decoding uses `no_repeat_ngram_size` 3, repetition penalty 1.2, and length penalty 1.0.

Two settings differ between the development and test submissions. Development used $k = 5$ per model with weights $(0.6, 0.2, 0.2)$; the test run widened the pool to $k = 8$ and rebalanced to $(0.45, 0.10, 0.45)$, giving sentiment and content near-equal influence since the task scores both. These changes were made together, and the test set also introduced polarity inference, so we cannot attribute the difference between the runs to any one of them.

We use Transformers 4.44.0 (Wolf et al., 2020) and sacreBLEU (Post, 2018) for BLEU (Papineni et al., 2002) and chrF (Popović, 2015), on 2×NVIDIA T4 GPUs, where the complete pipeline takes about 2.5 hours.

One caveat applies to every content figure we compute ourselves: our offline reimplementation of BLEU and chrF did not reproduce the official scorer under any pairing or aggregation tried, including output-against-reference and output-against-input at sentence and corpus level. We therefore report official leaderboard numbers as headline results and label our own measurements as internal diagnostics.

5 Results

5.1 Official scores

Table 1 reports every official score we obtained. Content preservation is stable between the two splits, losing 3.2 BLEU and 1.3 chrF on the larger, dialect-oriented test set. Sentiment accuracy behaves very differently, falling by more than twenty points, and that asymmetry is what §5.3 examines.

5.2 What each component contributes

Table 1 follows the system as it was built. Replacing Adafactor with AdamW and training for 15 rather than 10 epochs is the single largest change, adding 5.9 points of sentiment accuracy and 1.1 BLEU, entirely a matter of optimisation rather than architecture.

Configuration	Sent.	BLEU	chrF
Development split			
Single generator, Adafactor	0.8651	51.17	70.11
+ AdamW, 15 epochs	0.9243	52.30	71.08
- smoothing, + consensus	0.9284	**52.61**	**71.08**
+ second generator	**0.9564**	52.26	70.64
Test split, submitted system			
inferred polarity, k=8	0.7447	49.07	69.33

Table 1: Official leaderboard scores. **Sent.** is sentiment style accuracy in $[0, 1]$; BLEU and chrF are on a 0–100 scale. Development rows are cumulative, each adding to the one above. The final row is the submitted test run, which also widened the pool to k=8 and reweighted to $(0.45, 0.10, 0.45)$. One run per configuration.

Removing label smoothing and adding the consensus term together produce the best content scores we recorded. The label smoothing result initially surprised us, since smoothing lowered training loss as usual. The explanation is that our system consumes not the single best output but a ranking over many: label smoothing flattens the output distribution (Meister et al., 2020), and a flatter distribution discriminates less sharply among candidates, so a regulariser that helps single-best decoding can hurt reranked decoding.

Adding the second generator buys 2.8 points of sentiment accuracy for 0.35 BLEU and 0.44 chrF. We judged this favourable given that the task scores both axes, and submitted it, while flagging that it was a judgement call: without a validated local copy of the official metric we could not tune the trade-off empirically.

5.3 Where the sentiment score went

Sentiment accuracy falls from 0.9564 on development to 0.7447 on test. The generators, the training data, and the reranking procedure are the same in both runs, so an explanation is required.

Two measurements localise it. The first comes from instrumentation in the test pipeline: we recorded how often the output carried the polarity the system was *aiming* for, the opposite of the polarity it had inferred. That figure is 1,745 of 1,931, or $h = 0.9037$. The system hit its own target on test about as reliably as on development; what it could not guarantee was that its own target was right.

The second measurement addresses that. The development split supplies gold `source_polarity`,

so the inference step of §3.4 can be run there and scored directly. It is correct for 714 of 964 sentences, an accuracy of 0.7407, and the errors are near-symmetric rather than a bias toward one class: 140 Negative sources are read as Positive against 110 in the reverse direction, giving recall of 0.7373 and 0.7448 respectively. Misclassified sources are somewhat shorter than average, at 10.7 words against 12.5.

Combining the two measurements tests the decomposition rather than assuming it. Let p be the accuracy of polarity inference. A right direction scores correct with probability h; a wrong one, if the system reached its own mistaken target, would score correct only in the residual $1 - h$, giving $p\,h + (1-p)(1-h) = 0.6943$ against an official 0.7447.

The gap is informative. Writing r for the true probability of scoring correct on a wrong-direction item, solving $0.7447 = p\,h + (1-p)\,r$ at $p = 0.7407$ gives $r = 0.29$, three times what the simple account predicts: something recovers roughly a third of the misdirected items. A plausible mechanism, which we flag as a hypothesis consistent with the arithmetic rather than an established fact, is that both generators saw nothing but polarity-flipping pairs and so tend to flip regardless of the instruction, which on a misdirected item is correct.

The ceiling does not depend on any of this: under every value of p considered, a perfect polarity estimator would have left the official score at $h = 0.9037$, so sixteen points separate our submission from that ceiling and none are attributable to the generators. One caveat is that p is measured on development, and the test split may be easier or harder to classify.

5.4 Error analysis

Our internal content diagnostic rises monotonically with source length, from 58.6 chrF on inputs of four words or fewer ($n = 143$) to 80.7 on inputs of 26 or more ($n = 102$): in a short sentence the word that must change is a large fraction of the text, so even a correct minimal edit registers as a large proportional change. The lowest-scoring test item shows this: جو مشاوي [GRINNING] becomes جو حلو [GRINNING], a defensible rewrite scoring 11.3 chrF.

Three failure modes recur. In 39 cases (2.0%) the output is byte-identical to the input, no swap having been performed; these cluster in sentences whose sentiment is idiomatic rather than lexical, leaving no obvious substitution target. On some short inputs the model over-edits, replacing the sentence rather than adjusting it, as in وين رحتي [PENSIVE] becoming فرحانتي . Finally, it sometimes flips the textual sentiment while leaving a contradictory emoji in place. Replacing each emoji with a textual gloss before training looks the more promising remedy, since it keeps the signal inside the token stream; stripping emoji discards it, and flipping them post hoc needs a polarity lexicon the task does not supply.

Set against these, the successful outputs are precisely the minimal edits the reranker was designed to favour: كل حاجه ضلمه becomes كل حاجه جميله at 85.5 chrF, changing one adjective. Across the test set the mean output/input length ratio is 0.993, direct evidence that the selection stage works, choosing minimal edits from a pool containing both those and wholesale rewrites.

6 Conclusion

We have described a system that treats sentiment swap as a selection problem as much as a generation problem: two Arabic sequence-to-sequence models propose a pool of rewrites, and a scoring function built from the task's own evaluation signals chooses among them. It scores 49.07 BLEU, 69.33 chrF, and 0.7447 sentiment accuracy on the official test set, with the shortfall lying in recovering the swap direction rather than in the rewriting itself. That points to the clearest next step: rather than committing to a direction before generation, a system could generate in both and let the reranker choose, turning an unrecoverable error into an ordinary ranking decision.

Limitations. Each configuration was run once, so seed variance is not separable from real effects, and the last three development rows of Table 1 differ by little enough for this to matter. The reranking weights were judged rather than tuned, since no validated local copy of the official metric was available. The development and test runs differ in pool size, weighting, and polarity inference at once, preventing clean attribution.

Abstract

We describe the AKARROUCH submission to DialectSentEval 2026 Subtask 2, which requires reversing the sentiment of an Arabic dialect sentence while preserving its content. We fine-tune AraT5v2 for direction-controlled generation and use it to produce multiple candidates. We then rerank these candidates using CAMeLBERT target-sentiment probabilities and source-to-candidate chrF. The system ranked second in the official evaluation, achieving 78.51% sentiment accuracy, 49.82 BLEU, and 70.12 chrF.

1 Introduction

DialectSentEval 2026 Subtask 2 asks systems to reverse the sentiment of an Arabic dialect sentence while retaining the information expressed by the source (Ezzini et al., 2026a). The task extends AraSentEval's work on Arabic sentiment analysis and swapping (Ezzini et al., 2026b). Our work uses a direction-controlled AraT5v2 generator followed by inference-time reranking. CAMeLBERT is used only during inference and is not jointly trained with the generator. Code and the executable notebook are available at https://github.com/MedAkarrouch/DialectSentEval2026.

2 Background

Sentiment swapping is a text style transfer problem in which a target attribute is changed while other content is retained as far as possible. The shared-task training and validation records contain a source sentence, its polarity, and an opposite-sentiment target, while the test records provide sources for generation. Parallel resources remain limited for Arabic. Ma'aks provides manually curated Arabic sentence pairs expressing opposite sentiments about the same subject (Mughaus et al., 2026). Prior work shows that limited parallel data can support supervised sentiment transfer (Mukherjee and Dusek, 2023).

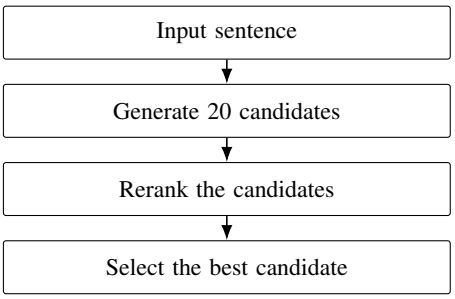

Figure 1: Overview of the generate-and-rerank inference workflow.

Generate-and-rerank methods separate candidate production from final selection. In text style transfer, Suzgun et al. (2022) generate several target-style candidates and rank them using style strength, textual similarity, and fluency. Our system follows this general structure with models and ranking signals chosen for the shared task.

3 System Description

Figure 1 gives an overview. One input produces 20 candidates, which are reranked before the highest-ranked candidate is selected.

3.1 Direction-Controlled Generation

We initialize the generator from UBC-NLP/AraT5v2-base-1024, an Arabic text-to-text model associated with the Octopus toolkit (Elmadany et al., 2023; UBC Deep Learning and NLP Lab, 2023). Fine-tuning treats sentiment swapping as conditional sequence generation: the source sentence and the requested direction form the model input, and the paired sentiment-swapped sentence is the target. All AraT5v2 parameters are updated.

The two transformation directions are represented by special tokens. Table 1 shows how the

Positive	Negative	`<positive_to_negative> {source}`

Table 1: Direction-controlled input templates used for fine-tuning and generation.

corresponding token is prepended to the source sentence for each direction.

The complete validation set is evaluated once per epoch for model selection. Training stops after three consecutive epochs without an improvement in validation loss, and the checkpoint with the lowest loss is used for inference. At inference, CAMeLBERT compares its positive and negative probabilities for the source. The larger value determines the inferred source polarity, so neutral does not participate in this binary decision. The opposite polarity selects the direction token.

3.2 Candidate Generation and Reranking

The selected AraT5v2 checkpoint uses deterministic beam search with 20 beams to return 20 candidates. No sampling is applied, and the method does not assume that the candidates are unique. For each candidate y_i, CAMeLBERT supplies the probability q_i of the requested positive or negative label (Inoue et al., 2021; CAMeL Lab, 2021).

The second score, h_i, is sentence-level chrF between the source and candidate (Popović, 2015). It measures character-level overlap and is used as a content-preservation proxy, not as direct evidence of semantic equivalence. During inference-time evaluation, the gold validation targets are used to calculate BLEU and chrF only after selection. They do not rank the generated candidates.

Algorithm 1 presents the complete decision procedure. Candidates are indexed in beam order. When the preceding scores are identical, the $-i$ term favors the candidate with the lower beam index. Tuple maximization is lexicographic from left to right.

The threshold separates the two ranking priorities. Candidates meeting it are ranked first by source-to-candidate chrF, then target-sentiment probability, and finally beam position. If none reaches the threshold, target-sentiment probability becomes the primary criterion, followed by chrF and beam position.

4 Experimental Setup

We use the official training set for supervised fine-tuning and the complete validation set for epoch-level validation loss, early stopping, and checkpoint selection. Fine-tuning is performed in FP16 on two NVIDIA Tesla T4 GPUs. AdamW uses a learning rate of 5×10^{-5} and a linear schedule with 5% warmup. Appendix A reports the remaining reproducibility settings. Core software comprises PyTorch 2.10.0+cu128, Transformers 4.49.0, and SacreBLEU 2.5.1 (Post, 2018).

At inference, the selected checkpoint generates 20 candidates per input and Algorithm 1 selects one prediction. CAMeLBERT is used only for source-direction inference and candidate scoring. It contributes no AraT5v2 training loss and receives no updates. The official evaluation reports sentiment accuracy, BLEU (Papineni et al., 2002), and chrF. Sentiment accuracy evaluates the requested polarity, while BLEU and chrF measure overlap with reference outputs.

5 Results and Discussion

Table 2 presents the official test results.

Sentiment accuracy reflects how often an output received the requested polarity under the official evaluation. BLEU and chrF measure overlap with the reference outputs, with chrF providing character-level sensitivity to morphological and orthographic variation. Together, these values report the end-to-end performance of the submitted system.

Metric	Official test result
Sentiment accuracy	78.51%
BLEU	49.82
chrF	70.12

Table 3 shows one positive-to-negative example and one negative-to-positive example. For each input, the model generates 20 candidates, reranks them using Algorithm 1, and selects the highest-ranked candidate as the output.

6 Conclusion

We presented direction-controlled AraT5v2 generation with CAMeLBERT- and chrF-based reranking. Future work could either modify fine-tuning with explicit task-specific penalty terms for sentiment reversal and content preservation, or apply preference optimization such as DPO over chosen and rejected generated candidates (Rafailov et al., 2023). Controlled inference ablations should also examine candidate count and beam width, deterministic beam search versus sampling, sentiment threshold, and length penalty.

Limitations

Because CAMeLBERT determines source polarity and scores candidates, its errors could affect both transformation-direction selection and reranking. Reliance on the same classifier used by the official sentiment metric may align the system with its decision boundary rather than broader human sentiment judgments. For the submitted model, we used a fixed inference configuration of 20 deterministic candidates, no sampling, and a 0.85 threshold. We did not conduct controlled ablations of these settings, and the selected configuration may therefore be suboptimal.

Acknowledgments

We thank the DialectSentEval organizers, contributors, and reviewers. We used ChatGPT for coding assistance, including the generation of individual functions. We used AI assistants for rephrasing and grammatical error correction in our writing.

Abstract

We describe our participation in Subtask 2 of the DialectSentEval 2026 Shared Task (Ezzini et al., 2026a), whose goal is to rewrite an Arabic dialectal sentence so its sentiment polarity is reversed while its meaning, entities, and dialect are preserved. Our system, SWAPPER (Sentiment-SWAPping with Parameter-Efficient adapteRs), is an ensemble of LoRA-adapted mBART-50 (Tang et al., 2020; Hu et al., 2022) checkpoints in which the adapters are extended beyond attention into the feed-forward sublayers, where the actual lexical rewriting is learned. Three design choices carried most of the weight: (i) a minimal Arabic instruction prefix (اعكس المشاعر:) that reserves encoder capacity for content; (ii) feed-forward LoRA; (iii) forcing the decoder's beginning-of-sequence token to `ar_AR` so mBART-50 does not drift into other scripts. On the official blind test SWAPPER reaches Sentiment-Style Accuracy 0.6732, BLEU 41.38, and chrF 65.84. As a secondary contribution, we introduce the J-Gap ($\Delta J = J_{\text{tgt}} - J_{\text{src}}$), a Jaccard-based copy-collapse diagnostic that cleanly separates genuine sentiment swappers from models that merely copy their input, and explains why superficially strong backbones such as AraT5v2 fail the task despite high surface metrics.

1 Introduction

DialectSentEval 2026 (Ezzini et al., 2026a), colocated with ArabicNLP 2026, extends prior Arabic sentiment shared-task efforts (Alharbi et al., 2025b; Ezzini et al., 2026b) by pairing classification (Subtask 1) with controlled generation (Subtask 2): given a dialectal Arabic sentence and its polarity label, produce a paraphrase whose polarity is reversed while its content stays put.[1] The task is grounded in the Ma'aks parallel corpus (Mughaus et al., 2026).

[1]Code: https://github.com/MBAHGAT2000/DialectSentEval-ArabicNLP-2026

Sentiment swap is harder than it looks. Positive and negative utterances that describe the same object typically overlap in the vast majority of their tokens: only the affective carriers need to change. A seq2seq model trained with a standard teacher-forced cross-entropy objective is therefore under enormous pressure to copy the input – doing so already minimises the loss on roughly 90% of the tokens. We observed exactly this failure in three of the four backbones we tried (Section 5) and address it with SWAPPER (Sentiment-SWAPping with Parameter-Efficient adapteRs), a compact recipe that (i) keeps the mBART-50 backbone frozen, (ii) injects trainable low-rank adapters into every attention and feed-forward projection, and (iii) forces Arabic BOS at decoding. Our final submission is an ensemble of three independently-trained SWAPPER checkpoints that outperforms every single-model configuration on every metric we measured.

As a diagnostic tool that generalises beyond our system, we also introduce the J-Gap, defined as $\Delta J = J_{\text{tgt}} - J_{\text{src}}$, where J_{src} and J_{tgt} are the token-level Jaccard overlaps of the prediction against the source and against the target reference respectively. A genuine sentiment swap requires $\Delta J > 0$; a copy-collapsed model has $\Delta J \leq 0$. The J-Gap is a single-number check any Arabic-generation practitioner can drop into their training loop.

2 Related Work

Arabic sentiment analysis. The ADOR corpus (Alharbi et al., 2025c) and the LLM-evaluation study (Alharbi et al., 2025a) preceded the Ahasis shared task (Alharbi et al., 2025b) and the AraSentEval initiative (Ezzini et al., 2026b). DialectSentEval 2026 is a direct continuation of that line, adding the swap track.

Text style / sentiment transfer. See Jin et al. (2022) for a comprehensive survey of English-

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1398–1402
October 28-29, 2026 ©2026 Association for Computational Linguistics

language approaches (unsupervised disentanglement, delete-retrieve-generate, and paraphrase-based formulations). Ma'aks (Mughaus et al., 2026) makes the Arabic setting a fully-supervised seq2seq problem.

Multilingual seq2seq and PEFT. Multilingual denoising pre-training (Tang et al., 2020) provides a strong starting point for Arabic generation. LoRA (Hu et al., 2022) updates $\ll 1\%$ of the parameters. Most LoRA recipes restrict adapters to attention (`q_proj`, `v_proj`); a contribution of our system is extending them into the feed-forward layers, which store the lexical substitutions the swap actually requires. Arabic-specialised backbones such as AraT5 (Nagoudi et al., 2022) were considered but proved less stable than mBART-50 in our setting.

3 System Overview

Figure 1 summarises the pipeline. Sources are normalised (diacritics stripped; alef/ya/hamza variants canonicalised following Obeid et al., 2020), prefixed with اعكس المشاعر:, and tokenised by the mBART-50 tokenizer with source and target languages both set to `ar_AR`. The tokenised sequence is consumed by a frozen mBART-50 encoder–decoder (610M parameters). LoRA adapters (Hu et al., 2022) with r=32, α=64, dropout 0.05 are attached to `q_proj`, `k_proj`, `v_proj`, `out_proj`, `fc1`, `fc2`:

$$h = W_0 x + \frac{\alpha}{r} BAx, \qquad A \in \mathbb{R}^{r\times k},\ B \in \mathbb{R}^{d\times r}.$$

At inference we decode with beam search (5 beams), a mild repetition penalty of 1.1, and `forced_bos_token_id` = `ar_AR` to prevent script drift.

4 Experimental Setup

Model selection. Before adopting mBART-50 we ran three earlier attempts: mT5-small (Xue et al., 2021) under-fit; AraT5-tweet diverged; AraT5v2-base-1024 was stable but tended to copy the input. mBART-50 was adopted for its stability and its multilingual tokeniser, which handles dialectal orthography without special preprocessing.

Hyperparameters. We fine-tune for up to 15 epochs with early stopping (patience 3, monitored on validation loss). AdamW with lr 2×10^{-4}, cosine schedule, warm-up ratio 0.05, weight decay 0.01. Per-device batch size 4 with gradient accumulation 8 (effective batch 32). Max input/target length 128. LoRA trainable params: $\approx$47M ($\sim$7.7% of the backbone). Single NVIDIA T4, seed 42.

Evaluation. The primary metric is Sentiment-Style Accuracy (Obeid et al., 2020), judged by the same Arabic dialect classifier (`CAMeL-Lab/bert-base-arabic-camelbert-da-sentiment`) that the organisers use. We complement it with BLEU, chrF, BERTScore (Zhang et al., 2020), external AraGPT2 (Antoun et al., 2021) fluency perplexity, and a copy-collapse Jaccard diagnostic: $J_{\text{src}} = |P \cap S|/|P \cup S|$ and $J_{\text{tgt}} = |P \cap T|/|P \cup T|$. A healthy swapper satisfies $J_{\text{tgt}} > J_{\text{src}}$.

5 Results

Zero-shot backbones (before fine-tuning). Table 1 reports the zero-shot performance of every candidate backbone on the development split, using the same اعكس المشاعر: prompt but with no task-specific training. All four backbones fail catastrophically: Sentiment-Style Accuracy stays below the 0.33 chance level of a three-way classifier, BLEU is in the single digits, and every model has $J_{\text{tgt}} < J_{\text{src}}$ – a strictly negative J-Gap that flags all four as unusable out of the box. This confirms the intuition motivating our approach: the sentiment-swap capability is not present in the pre-training distributions of these models and must be learned from Ma'aks.

After LoRA fine-tuning. Table 2 shows the same models after LoRA fine-tuning on the Subtask 2 training split, plus the SWAPPER ensemble we ultimately submitted. Two patterns stand out.

First, the older Arabic-specialised backbones behave very differently from the multilingual mBART-50 even after fine-tuning. mT5-small recovers to 0.42 accuracy but still under-fits; AraT5-tweet (Nagoudi et al., 2022) diverges outright, with a training loss that stayed around 190 under standard hyperparameters. AraT5v2-base-1024 looks strong on the surface metrics (BLEU 68.4, chrF 82.1, BERTScore 0.94), but its Sentiment-Style Accuracy of 0.15 and a Jaccard overlap with the source of $J_{\text{src}} = 0.94$ reveal what is happening: the fine-tuned model has collapsed onto the copy solution. Reference paraphrases share most of their

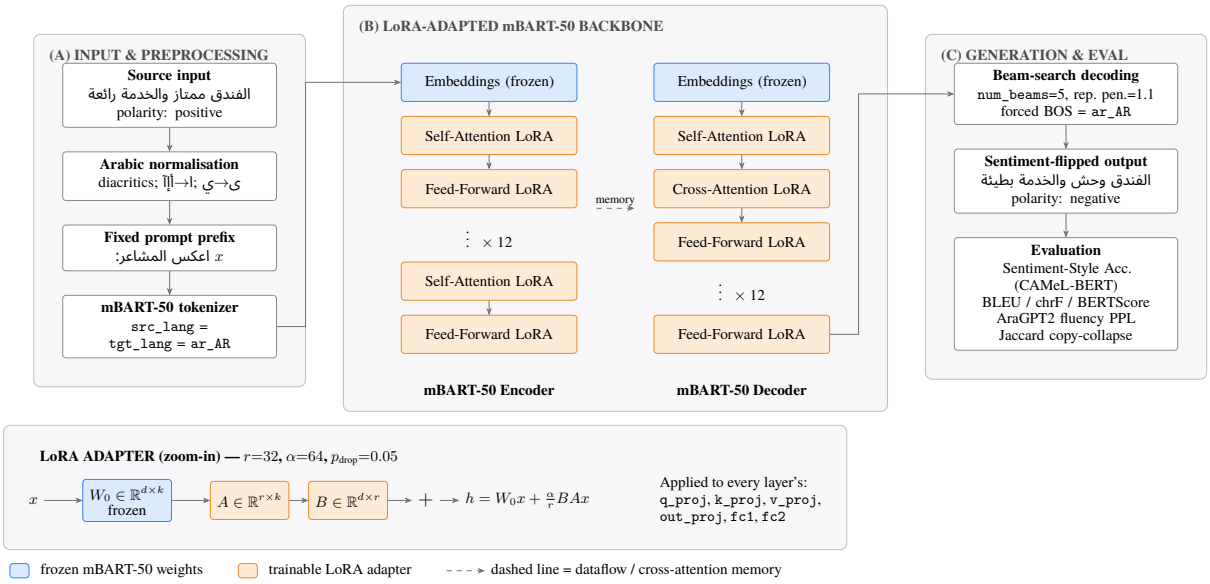

Figure 1: Overall system architecture. (A) Source dialectal Arabic text is normalised (diacritics stripped; alef/yaa/hamza variants canonicalised) and wrapped in a fixed اعكس المشاعر: prefix before being tokenised by the mBART-50 tokenizer with both source and target languages set to `ar_AR`. (B) The tokenised sequence is consumed by a frozen mBART-50 encoder–decoder (≈610M parameters); low-rank LoRA adapters are attached to every attention and feed-forward projection (`q_proj`, `k_proj`, `v_proj`, `out_proj`, `fc1`, `fc2`). (C) At inference, beam search with `forced_bos_token_id` set to `ar_AR` produces the sentiment-flipped Arabic sentence, which is scored with the official Sentiment-Style Accuracy metric alongside BLEU, chrF, BERTScore, an external AraGPT2 fluency perplexity, and our Jaccard copy-collapse diagnostic. The bottom inset details a single LoRA adapter: only the low-rank factors A and B are trained (r=32, α=64), while the base projection W_0 remains frozen.

tokens with the source, so a copy scores highly on any reference-based surface metric even though the task is completely unsolved. Under the J-Gap diagnostic, AraT5v2 sits at $\Delta J = -0.29$ – strongly copy-collapsed.

Second, SWAPPER is the only single model for which $\Delta J > 0$ ($J_{\text{tgt}} = 0.77 > J_{\text{src}} = 0.69$), i.e. whose outputs sit closer to the target reference than to the source – the signature of a genuine sentiment swap.

Ensembling. Our final submission ensembles three independently-trained SWAPPER checkpoints obtained by varying (i) the random seed, (ii) the LoRA dropout, and (iii) the effective batch size. At inference we generate a candidate from each checkpoint with beam search (5 beams), then rank the three candidates by the sum of the CAMeL-BERT sentiment classifier's confidence in the target polarity and their mutual chrF agreement; the highest-scoring candidate is emitted. The ensemble improves every metric over the best single SWAPPER checkpoint (Table 2), including a +2.5-point gain in Sentiment-Style Accuracy and a +0.02-point gain in J-Gap on the development split.

Dev vs. blind test. Table 3 contrasts the ensemble's internal development scores with the scores returned by the organisers on the blind test. The gap on the primary metric is $\Delta = 6.2$ absolute points, which we attribute to standard overfitting to the development split (used for early stopping and hyperparameter selection).

Ablations. Table 4 isolates the contribution of each design decision on top of a base LoRA configuration. The biggest single gain comes from opening up the LoRA target modules to include `fc1` and `fc2`: attention re-weights information already in the input, while feed-forward layers store the lexical substitutions the swap requires.

6 Conclusion

We described SWAPPER, a LoRA-adapted mBART-50 ensemble for Arabic sentiment swap. The J-Gap diagnostic separated genuine swappers from copy-collapsed models and explained why AraT5v2 – best on surface metrics – was in fact the weakest system. On the blind test SWAPPER reached Sent-Acc 0.6732, BLEU 41.38, chrF 65.84. Future work: select on Sent-Acc directly, and add a polarity-classifier-in-the-loop signal at

	Style transfer		Content preservation			Fluency	Copy-collapse	
Backbone (zero-shot)	Sent-Acc↑	Sent-F1↑	BLEU↑	chrF↑	BERTSc.↑	PPL↓	J_{src} ↓	J_{tgt} ↑
mT5-small (Xue et al., 2021)	0.048	0.041	0.9	6.4	0.412	728.4	0.03	0.02
AraT5-tweet (Nagoudi et al., 2022)	0.118	0.104	3.2	15.6	0.582	385.6	0.09	0.08
AraT5v2-base-1024	0.164	0.152	8.7	24.1	0.647	178.3	0.22	0.18
mBART-50 (backbone)	0.098	0.087	2.5	11.8	0.531	412.9	0.06	0.05

Table 1: **Zero-shot (before fine-tuning).** Every backbone we considered, evaluated on the DialectSentEval 2026 Subtask 2 development split with the same اعكس المشاعر: prompt but without any task-specific fine-tuning. All backbones fail catastrophically: Sentiment-Style Accuracy stays below chance for a three-way classifier (0.33), and every model has $J_{\text{tgt}} < J_{\text{src}}$ (negative J-Gap). This motivates the LoRA fine-tuning recipe of Section 3, whose post-training numbers are shown in Table 2.

	Style transfer		Content preservation			Fluency	Copy-collapse	
System	Sent-Acc↑	Sent-F1↑	BLEU↑	chrF↑	BERTSc.↑	PPL↓	J_{src} ↓	J_{tgt} ↑
mT5-small (Xue et al., 2021)	0.421	0.402	12.5	38.2	0.721	165.4	0.42	0.37
AraT5-tweet (Nagoudi et al., 2022)	0.284	0.271	4.2	18.7	0.613	340.2	**0.18**	0.15
AraT5v2-base-1024	0.152	0.148	**68.4**	**82.1**	**0.943**	**41.2**	0.94	0.65
SWAPPER (single ckpt.)	0.710	0.694	44.1	68.1	0.851	48.6	0.69	0.77
SWAPPER (3-ckpt. ensemble)	**0.735**	**0.719**	46.8	70.5	0.862	45.2	0.67	**0.79**

Table 2: **After LoRA fine-tuning.** Head-to-head comparison of every model we trained, plus the submitted SWAPPER ensemble, on the DialectSentEval 2026 Subtask 2 development split. Best value per column in bold. AraT5v2's superficially strong content-preservation scores are a copy-collapse artefact: $J_{\text{src}} = 0.94$ shows the model is essentially copying the input, and its Sentiment-Style Accuracy of only 0.152 confirms it is not actually swapping polarity. SWAPPER is the only single-model configuration where $J_{\text{tgt}} > J_{\text{src}}$; the ensemble further widens that margin. Compare with the pre-training numbers in Table 1.

Metric	Dev	Blind Test
Sentiment-Style Acc. ↑	0.7350	0.6732

training time.

Limitations

Single-seed T4 run; no confidence intervals. Cross-entropy selection mildly favours copying, and the CAMeL-BERT metric may miss rare dialectal expressions.

Abstract

Arabic dialect sentiment swapping requires systems to reverse the affective orientation of an utterance while preserving its core meaning, dialectal form, and fluency. This task is particularly challenging because sentiment may be conveyed through dialect-specific vocabulary, negation patterns, and spelling variation. We present LahjaSensei, our system for Subtask 2 of the DialectSentEval shared task. We investigate two complementary approaches: prompt-based generation with GPT-5.6 and parameter-efficient fine-tuning of Qwen2.5-7B. We evaluate GPT-5.6 under zero-shot, retrieved few-shot, stronger Arabic instructions, and direction-aware configurations. The direction-aware GPT-5.6 pipeline explicitly predicts source polarity before retrieving direction-matched demonstrations and generating the rewrite. For Qwen2.5-7B, we compare pooled QLoRA with linear and TIES merges of direction-specific adapters. Direction-aware GPT-5.6 prompting achieves the highest test sentiment accuracy and remains stable across development and test. Pooled QLoRA produces the highest development BLEU and chrF, while linear merging obtains the highest test BLEU and chrF but lower sentiment accuracy. These findings highlight the central trade-off between sentiment control and preservation of semantic content and demonstrate the value of explicit direction modeling for Arabic dialect sentiment swapping.

1 Introduction

Sentiment style transfer modifies a text's affective orientation while preserving its semantic content. Unlike sentiment classification, sentiment swapping requires generating an output with the target polarity while retaining the source's events, entities, and central message. These goals can conflict: conservative rewrites may leave sentiment cues unchanged, while aggressive rewrites may cause semantic drift.

This challenge is particularly acute in dialectal Arabic. Sentiment may be expressed through dialect-specific vocabulary, morphology, negation patterns, orthographic variation, code-switching, hashtags, and emoji. DialectSentEval 2026 extends prior work on Arabic sentiment analysis and swapping (Ezzini et al., 2026b) across Maghreb, Egyptian, Gulf, and Levantine dialect groups. In Subtask 2, systems must rewrite a dialectal Arabic sentence to express the opposite sentiment while retaining its core meaning (Ezzini et al., 2026a). The task therefore jointly evaluates dialect understanding, sentiment control, and preservation of the source content during generation.

LahjaSensei investigates two complementary modeling approaches. The first uses GPT-5.6 (OpenAI, 2026) in a direction-aware pipeline for sentiment swapping that first predicts the source polarity and then retrieves demonstrations from the corresponding transformation direction before generating the rewrite. The second adapts Qwen2.5-7B (Qwen Team, 2024) using QLoRA (Dettmers et al., 2023). We compare a pooled adapter trained jointly on both directions with linear merging and TIES-Merging (Yadav et al., 2023) of separately trained directional adapters.

Our experiments show that direction control produces the most reliable sentiment inversion. Pooled QLoRA achieves the best development BLEU and chrF, while linear merging obtains the best test BLEU and chrF but lower sentiment accuracy. These findings highlight the trade-off between polarity control and preservation of content.

Our main contributions are:

- We develop a direction-aware few-shot pipeline combining source-polarity prediction with direction-matched retrieval.
- We compare zero-shot and few-shot prompting with pooled QLoRA and linear and TIES merges of direction-specific adapters.

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1403–1408
October 28-29, 2026 ©2026 Association for Computational Linguistics

- We analyze the trade-off between polarity inversion and content preservation, including the contribution of each pipeline stage to sentiment failures.

Code and prompts are available at our repository.[1]

2 Background

2.1 Task and Dataset

Task. DialectSentEval Subtask 2 focuses on sentiment swapping in Arabic dialects. Training and development instances include source polarity, and systems must generate the opposite polarity while preserving the source's entities, events, and meaning (Ezzini et al., 2026a). For example, "a very wonderful program" is rewritten as "a very bad program." The released test file contains instance identifiers and source sentences; therefore, systems must infer the transformation direction at inference time. LahjaSensei participated only in Subtask 2.

Dataset. We use MA'AKS Extended, the DialectSentEval shared-task dataset, which builds on the manually curated MA'AKS parallel corpus (Mughaus et al., 2026). It contains 6,752 training, 964 development, and 1,931 test instances spanning Maghreb, Egyptian, Gulf, and Levantine dialect groups. Training and development instances include source polarity and an opposite-polarity reference rewrite, while the released files do not provide dialect labels for individual instances.

2.2 Related Work

Arabic sentiment swapping can be viewed as a controlled text generation task in which sentiment is modified while semantic content is preserved. MA'AKS provides manually curated positive–negative sentence pairs for studying this problem (Mughaus et al., 2026). Its annotation analysis shows that human rewrites rely primarily on lexical substitution and negation, while many examples require combinations of multiple editing operations. These findings demonstrate that sentiment inversion cannot be reduced to simply adding or removing a negation marker. The MA'AKS experiments also show the potential of both prompting and parameter-efficient fine-tuning for Arabic sentiment transfer.

Recent Arabic sentiment-swapping systems have explored decomposed prompting and supervised generation. Alami et al. (2026) use separate LLM calls to identify sentiment-bearing expressions, generate their opposites, and reconstruct the sentence. This decomposition makes intermediate steps explicit but may propagate upstream errors and introduce unnecessary changes. Bichi and Yassine (2026) fine-tune mT5-small with an Arabic target-polarity instruction, offering a simpler end-to-end formulation but frequently copying the source without sufficiently reversing its sentiment. Prompt design is also important in dialectal Arabic, where the benefit of aligning the instruction language or dialect with the input varies across models (Alharbi et al., 2025).

These findings motivate our comparison of Arabic prompt formulations, retrieved demonstrations, explicit direction control, and merged direction-specific Qwen adapters. Unlike the decomposed pipeline of Alami et al. (2026), our main method uses one polarity-prediction call followed by one direction-conditioned whole-sentence rewrite. This design reduces intermediate generation stages, which may limit opportunities for error propagation and unnecessary content changes while retaining explicit control over the transformation direction.

3 System Overview

3.1 GPT-5.6 Prompting

All GPT-based systems use the `GPT-5.6` model through the OpenAI Responses API, with reasoning effort set to `none`, text verbosity to `low`, and temperature and top-p left at their default values.

Two-stage directional prompting. Our submitted GPT-5.6 system uses a two-stage direction-aware pipeline: it first predicts the source polarity, then rewrites the input in the opposite direction using four direction-matched demonstrations. The pipeline is defined as

$$\begin{aligned} \hat{s} &= f_{\text{cls}}(x), \\ D_x &= \text{Retrieve}_4(x \mid s = \hat{s}), \\ y &= f_{\text{rw}}\big(x, \hat{s}, \text{opp}(\hat{s}), D_x\big). \end{aligned}$$

Here, x denotes the source sentence, $\hat{s}$ its predicted polarity, and D_x the retrieved demonstration set. The rewriting prompt explicitly specifies the source and target polarities and requests a minimal, fluent rewrite while preserving the dialect, entities, events, numbers, punctuation, and non-sentiment emoji.

[1] https://github.com/ahmadalmoustafa/LahjaSensei-DialectSentEval-2026

Single-stage prompt variants. For comparison, we evaluate four single-stage baselines using two Arabic prompt formulations under zero-shot and retrieved four-shot settings. The original prompt requests a minimal rewrite expressing the opposite sentiment. The stronger prompt adds preservation constraints for the dialect, entities, events, numbers, punctuation, and non-sentiment emoji while changing only sentiment-bearing expressions. Unlike the two-stage system, these baselines directly request sentiment reversal without predicting and specifying the source polarity. In the four-shot settings, retrieved source–target pairs are presented as separate user–assistant exchanges.

Demonstration retrieval. The demonstration-selection is based on the same procedure, with the two-stage system additionally restricting candidates to the predicted transformation direction. Demonstrations are drawn exclusively from the training data. Arabic text is normalized by removing diacritics and tatweel and standardizing common orthographic variants. Candidate pairs are filtered to remove unchanged pairs, exact source matches, and examples that fail preservation, similarity, or length constraints.

Relevance combines character- and word-level TF–IDF similarity. We then apply maximum marginal relevance (MMR) (Carbonell and Goldstein, 1998) to select four demonstrations that balance relevance and diversity. For the single-stage baselines, candidates may represent either transformation direction. For the two-stage system, retrieval is restricted to examples whose source polarity matches $\hat{s}$, so all four demonstrations represent the same positive-to-negative or negative-to-positive direction.

3.2 Qwen2.5-7B Adapter Merging

We evaluate three configurations based on `Qwen/Qwen2.5-7B-Instruct`. The pooled baseline fine-tunes one QLoRA adapter on both transformation directions. Its prompt specifies the source and target polarities and requests only the rewritten Arabic sentence. The other configurations fine-tune separate positive-to-negative and negative-to-positive adapters.

We combine the direction-specific adapters through weighted adapter merging. Linear merging averages their parameter updates with equal weights. TIES-Merging removes low-magnitude updates, resolves sign conflicts, and combines updates that agree in direction. We use unit adapter weights and a TIES density of $d = 0.2$. At inference time, CAMeLBERT (Inoue et al., 2021) determines the source polarity by comparing its positive and negative probabilities, and the opposite label specifies the target generation direction.

4 Experimental Setup

We use the official training, development, and test partitions. The development set guides prompt selection, retrieval design, and Qwen configuration selection. Test labels and reference rewrites remain hidden during development, and the shared-task organizers compute the official test scores.

We evaluate five GPT configurations: four single-stage systems combining the original and stronger Arabic prompts with zero-shot and retrieved four-shot settings, and the two-stage directional system. For Qwen, we compare the pooled QLoRA baseline with linear and TIES merges of direction-specific adapters. The development search considers four candidate linear weighting schemes and three alternative TIES densities, from which we report the best configuration of each merging method. Each configuration is evaluated once; therefore, run-to-run variation is not estimated. Complete implementation settings are provided in Appendix C.

The official evaluation uses sentiment accuracy, BLEU (Papineni et al., 2002), and chrF (Popović, 2015). Sentiment accuracy is computed with the dialectal CAMeLBERT classifier; BLEU and chrF assess preservation of semantic content through overlap with the reference rewrite.

5 Results and Analysis

5.1 Quantitative Results

Tables 1 and 2 compare performance on the development and test sets. Higher BLEU and chrF do not consistently correspond to higher sentiment accuracy, highlighting the tension between preserving content and reversing polarity.

The two-stage directional system achieves the highest test sentiment accuracy of 0.779, compared with 0.693 for the original four-shot system. This improvement comes with a decrease in BLEU from 44.76 to 41.48 and in chrF from 65.95 to 64.45. The directional system also remains stable across splits, changing from 0.785 on development to 0.779 on test. In contrast, the original four-shot

System	BLEU	chrF	Sent. Acc.
GPT directional 4-shot	42.84	64.01	0.785
GPT stronger 4-shot	43.16	63.98	0.717
GPT original 4-shot	46.81	66.38	**0.809**
GPT stronger zero-shot	42.22	63.45	0.682
GPT original zero-shot	46.01	65.97	0.771
Qwen pooled QLoRA	**53.08**	**71.21**	0.784
Qwen linear merge	51.72	68.91	0.689
Qwen TIES merge	50.09	67.92	0.711

Table 1: Development results. The best score for each metric is shown in bold.

System	BLEU	chrF	Sent. Acc.
GPT directional 4-shot	41.48	64.45	**0.779**
GPT stronger 4-shot	42.26	64.54	0.694
GPT original 4-shot	44.76	65.95	0.693
GPT stronger zero-shot	40.56	63.52	0.696
GPT original zero-shot	43.40	65.28	0.662
Qwen pooled QLoRA	49.82	68.11	0.652
Qwen linear merge	**49.90**	**68.56**	0.627
Qwen TIES merge	47.72	67.13	0.608

Table 2: Official test results. The best score for each metric is shown in bold.

system decreases from 0.809 to 0.693. Explicit direction prediction therefore provides more consistent sentiment control.

Retrieved demonstrations improve test BLEU and chrF for both prompt formulations relative to their zero-shot variants. Their effect on sentiment accuracy is less consistent. Four-shot prompting improves the original prompt but slightly reduces the accuracy of the stronger prompt. Retrieved examples therefore improve BLEU and chrF but do not guarantee polarity reversal without explicit direction control.

Among the Qwen configurations, pooled QLoRA achieves the highest development scores, with 53.08 BLEU, 71.21 chrF, and 0.784 sentiment accuracy. On the test set, linear merging slightly improves BLEU from 49.82 to 49.90 and chrF from 68.11 to 68.56 compared with pooled QLoRA. However, its sentiment accuracy decreases from 0.652 to 0.627. TIES underperforms pooled QLoRA on all three test metrics. Thus, merging direction-specific adapters offers no consistent advantage over joint bidirectional fine-tuning, reinforcing the need to interpret all three metrics jointly.

5.2 Error Analysis

We analyze the two stages of the directional GPT-5.6 system to identify where sentiment failures arise. On the development set, GPT-5.6 correctly predicts the source polarity for 880 of 964 examples, while CAMeLBERT assigns the target polarity to 757 final outputs. Since the number of correct direction predictions exceeds the number of successful final outputs, at least 123 examples with correctly predicted source polarity still fail to express the target sentiment after rewriting. This indicates that direction prediction is not the sole source of error and that failures also arise during the rewriting stage.

Manual inspection of the test outputs identifies three content-related error types. Incomplete cue revision can produce internally inconsistent sentences, semantic drift may change the state of an event, and numerical alteration may modify factual details during polarity reversal. Representative examples are presented in Appendix A.

6 Conclusion

We presented LahjaSensei, our system for DialectSentEval 2026 Subtask 2. We compared GPT prompting, pooled QLoRA, and linear and TIES merges of direction-specific Qwen adapters. Direction-aware prompting achieved the most reliable inversion, while pooled QLoRA produced the highest development BLEU and chrF and linear merging the highest test BLEU and chrF. Merging did not consistently outperform pooled fine-tuning, highlighting the trade-off between polarity control and preservation of semantic content. Analysis shows that correct direction prediction does not guarantee successful rewriting. Future work includes repeated experiments under additional controlled settings, broader error analysis, and human evaluation.

7 Limitations

Our study has several important limitations. Each configuration is evaluated only once during our experiments, without human evaluation of semantic preservation, fluency, or dialectal naturalness. Missing instance-level dialect labels prevent detailed dialect-specific analysis, and the manual error categories remain subjective.

Acknowledgments

We thank the DialectSentEval 2026 organizers for coordinating the task, providing data, and maintaining the evaluation platform. This work was supported by JST CREST JPMJCR2565, Japan.

A Qualitative Examples

Table 3 presents three representative errors from the submitted two-stage directional GPT-5.6 system. The examples illustrate incomplete cue revision, semantic drift, and alteration of numerical details.

ID	Example
3036	**Type:** Incomplete cue revision **Source:** سيئ جدا للأسف يتم التوقف بشكل كبير **Output:** ممتاز جدا لحسن الحظ يتم التوقف بشكل كبير
3011	**Type:** Semantic drift **Source:** للأسف التطبيق لا يعمل بعد التحديث الاخير الرجاء حل المشكله **Output:** لحسن الحظ التطبيق يعمل بعد التحديث الاخير شكرًا لكم على حل المشكله
2378	**Type:** Numerical alteration **Source:** اطلب بيتزا هت خمسه يعطوني 3 اش هذا النصب **Output:** اطلب بيتزا هت خمسه يعطوني 5 اش هذا الكرم

Table 3: Examples of manually identified errors in the submitted two-stage directional GPT-5.6 system.

B Prompt Templates

The submitted system uses separate Arabic prompts for source-polarity prediction and directional sentiment rewriting. Faithful English

translations are provided below, preserving the original instructions and output constraints.

B.1 Source-Polarity Classification

System message.

> Act as a classifier specialized in identifying the overall sentiment of Arabic texts written in different dialects. Classify the sentence as positive or negative. Select the dominant sentiment even when the sentence contains mixed expressions. Base the decision on the speaker's attitude rather than an isolated word. Do not rewrite the sentence or provide an explanation. Return only one label: positive or negative.

User template.

> Determine the overall sentiment of the following sentence:
>
> `{source}`

The returned label is parsed as the predicted source polarity and reversed to obtain the target polarity.

B.2 Directional Rewriting

System message.

> Act as a system specialized in reversing sentiment in Arabic texts written in different dialects. Rewrite the sentence from its current polarity to the requested polarity while preserving its core meaning. Change as few sentiment-bearing words or expressions as possible. Preserve the topic, events, entities, actions, roles, locations, numbers, and other factual details. Maintain the original dialect, writing style, and word order where possible, and do not convert dialectal text into Modern Standard Arabic. Preserve links, mentions, hashtags, and non-sentiment emoji. Make the target sentiment explicit rather than relying on negation alone. Do not introduce new reasons, events, or information. Return only the rewritten sentence without labels, explanations, quotation marks, or alternative outputs.

User template.

> Current sentiment: `{source_polarity}`
> Target sentiment: `{target_polarity}`
> Sentence: `{source}`

B.3 Four-Shot Message Construction

The four retrieved demonstrations are presented as alternating user–assistant messages. All demonstrations represent the same transformation direction as the predicted source polarity:

> **User:** Current sentiment, target sentiment, and retrieved source.
> **Assistant:** Retrieved target rewrite.
> ⋮
> **User:** Current sentiment, target sentiment, and actual input.

The final user message contains the test input, while the preceding four exchanges contain the direction-matched training examples selected by the retrieval method.

C Implementation Details

GPT inference. All GPT experiments use the `gpt-5.6` alias through the Responses API, with reasoning effort set to `none` and text verbosity to `low`. Temperature and top-p are left at their default values. Classification and rewriting use maximum output lengths of 16 and 128 tokens, respectively. API requests use a 120-second timeout and up to five retries.

Retrieval. Arabic text is normalized by removing diacritics and tatweel and unifying common Alef forms and Alef Maqsura. We exclude unchanged pairs, exact source matches, and examples that fail basic preservation, similarity, or length constraints. Relevance combines character- and word-level TF–IDF similarity. From the 40 highest-scoring candidates, maximum marginal relevance (MMR) selects four diverse demonstrations using $\lambda = 0.8$. For the two-stage system, candidates are restricted to the predicted transformation direction.

Qwen training. The pooled adapter and both directional adapters are trained for three epochs with sequence length 512, batch size 1, and gradient accumulation over 16 steps. We use QLoRA with four-bit NF4 quantization, double quantization, LoRA rank 16, $\alpha = 32$, and dropout 0.05. LoRA is applied to the attention and feed-forward projection layers. Optimization uses `paged_adamw_8bit`, a learning rate of 2×10^{-4}, cosine scheduling, and a warmup ratio of 0.05.

Merging and generation. Linear merging uses weights $(0.5, 0.5)$, while TIES uses weights $(1.0, 1.0)$ and density 0.2. Generation is greedy with batch size 8, maximum input length 512, and maximum output length 96.

Northwestern at DialectSentEval 2026: A Comparative Study of MARBERTv2 and AraBERT for Arabic Dialect Sentiment Analysis

Abstract

This paper describes our submission to **Subtask 1 of DialectSentEval 2026**, which focuses on three class sentiment classification for Arabic dialectal text. The task aims to classify sentences written in five Arabic dialects into *positive*, *negative*, or *neutral* sentiment categories. We investigate the effectiveness of transformer-based Arabic language models through a series of controlled experiments. Specifically, we compare MARBERTv2 and AraBERT while maintaining identical pre processing, training, and evaluation settings to ensure a fair comparison. In addition, we examine whether explicitly providing dialect information as part of the input improves classification performance.

Experimental results on an internal validation split show that MARBERTv2 consistently outperforms AraBERT on this task. Furthermore, removing the explicit dialect tag from the input slightly improves performance, suggesting that MARBERTv2 can effectively capture dialect-specific linguistic patterns directly from the sentence. Our best configuration, which uses MARBERTv2 with sentence-only input, achieves a Macro F1-score of **0.9394** and an accuracy of **94.24%**. These findings demonstrate the effectiveness of dialect-aware pre-trained language models for Arabic sentiment analysis and establish a strong baseline for the official shared task evaluation.

1 Introduction

Sentiment analysis is a fundamental Natural Language Processing (NLP) task that aims to identify the polarity of opinions expressed in text. Despite the remarkable progress of transformer-based language models, Arabic dialect sentiment analysis remains challenging due to substantial lexical, morphological, and syntactic variation across regional dialects.

The DialectSentEval 2026 Shared Task (Ezzini et al., 2026a) (Ezzini et al., 2026b) addresses this challenge by introducing a benchmark for sentiment classification across five Arabic dialects: Moroccan, Egyptian, Lebanese, Jordanian, and Saudi. In Subtask 1, systems are required to classify each input sentence into one of three sentiment categories: positive, negative, or neutral.To address this task, we conduct a controlled empirical comparison of two Arabic pretrained transformer models, MARBERTv2 and AraBERT. In addition, we investigate whether explicitly incorporating dialect information into the model input improves sentiment classification performance. All experiments employ identical preprocessing, data splitting, training, and evaluation settings to ensure a fair comparison between model architectures and input representations.Experimental results on an internal validation split show that MARBERTv2 consistently outperforms AraBERT. Furthermore, explicitly prepending dialect labels does not improve performance, indicating that MARBERTv2 effectively captures dialect specific linguistic characteristics directly from the input sentence.The best performing configuration achieves a Macro F1-score of 0.9394 using sentence only input, demonstrating the effectiveness of dialect aware pre trained language models for Arabic sentiment analysis.

Recent work has further evaluated large language models for Arabic dialect sentiment analysis and introduced shared-task benchmarks for sentiment analysis across Arabic dialects (Alharbi et al., 2025a,b).

2 Background

DialectSentEval 2026 Subtask 1 addresses multiclass sentiment classification for Arabic dialectal text. Given an input sentence written in one of five Arabic dialects, namely Moroccan, Egyptian, Lebanese, Jordanian, and Saudi, the task requires predicting one of three sentiment labels: *positive*,

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1409–1413
October 28-29, 2026 ©2026 Association for Computational Linguistics

negative, or *neutral*. For example, a sentence expressing satisfaction is assigned the label *positive*, whereas a sentence expressing dissatisfaction is labeled *negative*.

The released training dataset contains approximately 1.7K manually annotated Arabic sentences translated from hotel reviews and annotated by native speakers of the target dialects. During system development, only the released training data were available, while the official test labels remained hidden. Our submission participated in Subtask 1, which focuses on three-class sentiment classification.

Transformer-based pretrained language models have substantially advanced Arabic NLP. AraBERT (Antoun et al., 2020) introduced an Arabic-specific BERT model that achieved state-of-the-art performance on multiple Arabic NLP tasks. MARBERT (Abdul-Mageed et al., 2021) was pretrained on large-scale multi-dialect Arabic Twitter data, while MARBERTv2 further extends MARBERT with additional Modern Standard Arabic data and a longer maximum sequence length. Shared tasks such as NADI (Abdul-Mageed et al., 2022) further highlighted the importance of robust dialect processing, whereas recent surveys (Shi and Agrawal, 2025) identify dialectal diversity and limited annotated resources as major challenges for Arabic sentiment analysis. MA'AKS (Mughaus et al., 2026) introduced a manually curated parallel Arabic dataset for sentiment style transfer, providing 5,000 positive negative sentence pairs.Motivated by these challenges, we conduct a controlled comparison of AraBERT and MARBERTv2 while investigating the impact of explicitly incorporating dialect information to identify the best-performing system for the DialectSentEval 2026 shared task.

3 System Overview

Our system formulates DialectSentEval 2026 Subtask 1 as a supervised three-class sentiment classification task using pretrained transformer-based transformer models. Given an input sentence, the selected tokenizer converts the text into subword tokens, which are processed by the transformer encoder. The contextual representation produced by the encoder is passed to a task-specific classification head that predicts one of three sentiment labels: positive, negative, or neutral.

The proposed system relies on publicly available pretrained language models as external resources beyond the provided training data. Specifically, we evaluate MARBERTv2 and AraBERT, both initialized from their released pretrained checkpoints. No additional datasets, sentiment lexicons, or external linguistic resources are used during training.

To address the lexical and linguistic diversity of Arabic dialects, we investigate two design choices. First, we compare a dialect-oriented pretrained model (MARBERTv2) with a general Arabic pretrained model (AraBERT). Second, we examine whether explicitly providing the dialect name as part of the input improves sentiment classification performance.

Three controlled system configurations are evaluated. The first fine-tunes MARBERTv2 using the sentence preceded by its dialect label (e.g., [Egyptian]). The second fine-tunes MARBERTv2 using only the original sentence without the dialect tag. The third replaces MARBERTv2 with AraBERT while keeping all preprocessing, training, and evaluation settings identical. This controlled design isolates the effect of both the pretrained language model and the input representation on sentiment classification performance.

4 Experimental Setup

Our system is based on transformer-based Arabic language models fine-tuned for three-class sentiment classification. The overall pipeline consists of four main stages: data preparation, text preprocessing, model fine-tuning, and prediction.

Given an input sentence, the text is first preprocessed using the tokenizer associated with the selected pre-trained language model. The tokenized sequence is then passed to a transformer encoder followed by a classification head that predicts one of three sentiment labels: *positive*, *negative*, or *neutral*.To identify the most suitable architecture for the shared task, we conducted three controlled experiments. The first experiment fine-tuned MARBERTv2 using the sentence together with its dialect label as input. The second experiment evaluated MARBERTv2 using only the sentence text, without explicitly providing dialect information. Finally, the third experiment replaced MARBERTv2 with AraBERT while keeping all preprocessing steps, training settings, and evaluation procedures identical. This controlled design allowed us to isolate the effect of the language

model and the input representation on sentiment classification performance. The following subsections describe the dataset, preprocessing pipeline, evaluated models, and experimental setup in detail.

4.1 Dataset

We used the training data provided by the organizers of DialectSentEval 2026 Subtask 1. The dataset consists of approximately 1.7K manually annotated Arabic sentences covering five dialects: Moroccan (Darija), Egyptian, Lebanese, Jordanian, and Saudi. Each sentence is assigned one of three sentiment labels: *positive*, *negative*, or *neutral*.

The dataset originates from hotel reviews that were translated and annotated by native speakers of the corresponding dialects. Since the official test labels were not available during the development phase, all experiments were conducted using the released training data. An internal validation split was created to evaluate different system configurations before the official evaluation phase.

4.2 Preprocessing

A lightweight preprocessing pipeline was adopted to preserve the original linguistic characteristics of the dialectal text. We removed records containing missing values and normalized the sentiment labels to lowercase. No stemming, lemmatization, or manual text normalization was applied, allowing the transformer models to exploit the original lexical and morphological information.

The sentiment labels were mapped to numerical identifiers (*negative*=0, *neutral*=1, and *positive*=2) for model training.

To investigate the impact of explicit dialect information, two input representations were evaluated. In the first configuration, the dialect name was prepended to each sentence (e.g., "[Egyptian] sentence"). In the second configuration, only the original sentence text was used as model input.

4.3 Models

Two transformer-based Arabic language models were evaluated.

MARBERTv2 is a transformer model pretrained on large-scale Arabic social media text with extensive coverage of Arabic dialects. Owing to its dialect-oriented pre-training, it is expected to capture dialect-specific lexical and syntactic variations effectively.

AraBERT is a widely used Arabic pre-trained language model primarily trained on Modern Standard Arabic and diverse Arabic text collections. It serves as a strong baseline for many Arabic NLP tasks and was included to provide a fair comparison against MARBERTv2.

Both models were fine-tuned by replacing the original classification layer with a three-class classification head corresponding to the sentiment categories defined in the shared task.

To ensure a fair comparison, all experiments employed identical preprocessing steps, training settings, and evaluation protocol. The released training data were divided into training and validation sets using an 80/20 stratified split with a fixed random seed of 42, preserving the original class distribution.Models were fine-tuned using the Hugging Face Transformers library. The AdamW optimizer was employed with a learning rate of 2×10^{-5}, a batch size of 16, five training epochs, weight decay of 0.01, and a maximum sequence length of 128 tokens. The best-performing checkpoint was selected according to the validation Macro F1-score.

Three controlled experiments were conducted:

1. Fine-tuning MARBERTv2 using the sentence preceded by its dialect label.
2. Fine-tuning MARBERTv2 using the sentence only.
3. Fine-tuning AraBERT using the sentence only.

The primary evaluation metric was Macro F1-score, following the official shared task evaluation protocol. Overall accuracy, precision, and recall were also reported for comparative analysis.

The implementation was developed in Python 3.12.13 using PyTorch 2.11.0[1], Hugging Face Transformers 5.13.1[2], scikit-learn 1.6.1[3], pandas 2.2.2[4], NumPy 2.0.2[5], and Accelerate 1.14.0[6].

5 Results

5.1 Validation Results

Table 1 summarizes the performance of the three evaluated configurations on the internal validation split.

[6] https://github.com/huggingface/accelerate

Table 1: Performance on the internal validation split.

Configuration	Macro F1	Accuracy
MARBERTv2 + Dialect Tag	0.9359	0.9395
MARBERTv2 + Sentence Only	**0.9394**	**0.9424**
AraBERT + Sentence Only	0.9161	0.9222

Three controlled experiments were conducted on the internal validation split while keeping the preprocessing pipeline, training procedure, and evaluation protocol identical.The first experiment evaluated whether explicitly providing dialect information improves sentiment classification. Contrary to our expectation, prepending the dialect label slightly reduced performance. MARBERTv2 achieved a Macro F1-score of 0.9359 when the dialect tag was included, compared with 0.9394 when only the original sentence was used. This suggests that MARBERTv2 is capable of capturing dialect-specific linguistic patterns directly from the sentence without requiring explicit dialect information.The second experiment compared MARBERTv2 with AraBERT under identical experimental settings. MARBERTv2 achieved a higher Macro F1-score (0.9394) than AraBERT (0.9161), indicating that the dialect-oriented pretraining of MARBERTv2 is more suitable for Arabic dialect sentiment classification.At the class level, both models achieved strong performance on the positive and negative classes, whereas the neutral class remained comparatively more challenging. Neutral expressions often share lexical characteristics with both positive and negative instances, making them inherently more difficult to classify.The ablation study demonstrates that removing the explicit dialect tag consistently improves performance, while replacing MARBERTv2 with AraBERT results in a noticeable reduction in Macro F1-score.

5.2 Error Analysis

The best-performing system achieved F1-scores of 0.9695, 0.9005, and 0.9378 for the negative, neutral, and positive classes, respectively. The neutral class obtained the lowest F1-score, indicating that it was the most challenging sentiment category. This is expected because neutral expressions frequently overlap lexically with both positive and negative opinions, increasing the likelihood of ambiguous predictions.

6 Conclusion

This paper presented our system for Subtask 1 of DialectSentEval 2026 on Arabic dialect sentiment classification. We conducted a controlled comparison of MARBERTv2 and AraBERT and further investigated the impact of explicitly incorporating dialect information into the model input.Experimental results on an internal validation split showed that MARBERTv2 achieved the best overall performance, obtaining a Macro F1-score of 0.9394 when using the sentence alone as input. Furthermore, adding explicit dialect labels did not improve classification performance, indicating that the model can effectively learn dialectal characteristics directly from the text.Although the proposed system achieved strong performance, the evaluation was limited to an internal validation split because the official test labels were unavailable during system development.Based on these findings, MARBERTv2 with sentence-only input was selected as our final system for the shared task. Future work includes evaluating the system on the official test set and investigating ensemble learning, data augmentation, and parameter efficient fine tuning to further improve sentiment classification across Arabic dialects.

Abstract

This paper presents the Gradient Descenders system for DialectSentEval Subtask 1 on multi-dialect Arabic sentiment analysis. Because general-purpose models often miss dialectal nuances, we compare three pretrained encoders with distinct linguistic orientations: MARBERTv2, DarijaBERT, and AraBERT. We formulate the task as three-class classification, employing a parameter-efficient head-only adaptation strategy that freezes encoder parameters. Our results show MARBERTv2 outperforms the others, achieving a Macro F1 of 80.11% and Accuracy of 81.90%, securing fifth place overall. These findings emphasize that backbone selection is critical; specifically, broad dialect-oriented pretraining yields the most transferable representations for multi-dialect generalization.

1 Introduction

Arabic sentiment analysis is significantly complicated by the linguistic diversity of regional dialects. Unlike Modern Standard Arabic (MSA), dialectal Arabic exhibits considerable variations in vocabulary, morphology, syntax, and informal expressions, often alongside weakly standardized written forms. These differences hinder sentiment classification systems from generalizing consistently, as sentiment-bearing expressions and their surface realizations vary widely across regions. Consequently, recent work increasingly leverages dialect-aware pretrained language models and multi-dialect evaluation settings. This motivates the development of robust systems capable of handling heterogeneous Arabic varieties rather than optimizing for a single dialect.

DialectSentEval 2026 addresses these challenges through a shared task focusing on Arabic sentiment analysis and swapping (Ezzini et al., 2026a). We participate in Subtask 1: Arabic Dialect Sentiment Analysis, formulated as a three-class classification problem where inputs are labeled positive, negative, or neutral. This task utilizes the Multi-Dialect-Sent (MDS-3) dataset (Ezzini et al., 2026b), which comprises 3,000 sentences spanning five Arabic dialects: Darija, Egyptian, Lebanese, Jordanian, and Saudi. The official evaluation employs the Macro F1-Score as the primary metric, thereby encouraging systems to maintain balanced predictive performance across sentiment classes instead of favoring frequent labels.

In this paper, we investigate the effectiveness of fine-tuning Arabic pretrained encoders for multi-dialect sentiment classification. We specifically experiment with three Arabic pretrained encoders (Abdul-Mageed et al., 2021; Gaanoun et al., 2023; Antoun et al., 2020) that provide varying degrees of alignment with dialectal and general Arabic text (Inoue et al., 2021). Our study offers two primary contributions: (i) we evaluate multiple Arabic pretrained encoder models under a uniform fine-tuning setting on the MDS-3 dataset; and (ii) we comprehensively compare their performance using the official Macro F1-Score alongside Accuracy to analyze differences among the resulting systems.

2 Background

2.1 Benchmark Construction

Arabic sentiment analysis relies on annotated benchmarks that initially focused on specific varieties or domains. Early resources like ASTD and ArSenTD-Lev established foundational evaluation settings (Nabil et al., 2015). Recent shared tasks, such as NADI (Abdul-Mageed et al., 2024) and AHaSIS (Alharbi et al., 2025b,c), have shifted toward standardized multi-dialect evaluations. AraSentEval 2026 extends this via the unified MDS-3 benchmark (Ezzini et al., 2026b). Historically, inconsistencies in dialect coverage, do-

October 28-29, 2026 ©2026 Association for Computational Linguistics

mains, and label spaces have complicated cross-study comparisons, underscoring the critical need for unified multi-dialect evaluations.

2.2 Lexicon and Feature-based Approach

Early Arabic sentiment systems heavily utilized sentiment lexicons (e.g., SLSA, NileULex) to capture polarity-bearing colloquialisms (Mohammad et al., 2016; El-Beltagy, 2016). These were commonly combined with handcrafted features (such as n-grams, TF-IDF, or embeddings) and traditional classifiers like SVMs or Naive Bayes. While these approaches demonstrated the utility of Arabic-specific lexical data, their effectiveness relies strictly on lexicon coverage and explicit feature design. This dependence restricts their scalability in multi-dialect settings, where extensive lexical and orthographic variations hinder cross-dialect transferability.

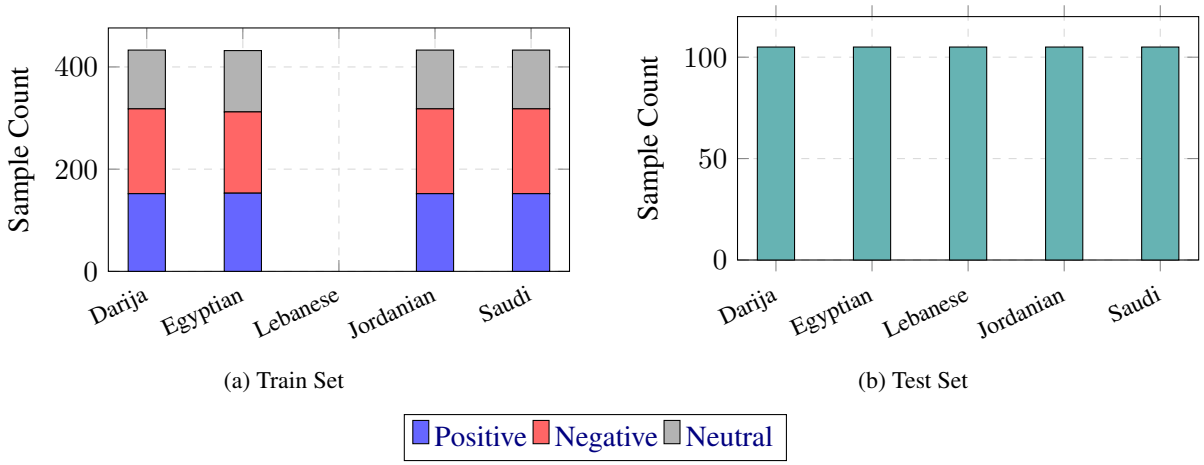
2.3 Language Model Approach

Arabic pretrained Transformers shifted sentiment classification toward contextual learning (Alharbi et al., 2025a). AraBERT established general Arabic pretraining for downstream tasks (Antoun et al., 2020). Later models incorporated broader linguistic variations: MARBERT and MARBERTv2 emphasized dialectal social-media data, while CAMeLBERT encompassed Modern Standard, Classical, and dialectal Arabic (Abdul-Mageed et al., 2021; Inoue et al., 2021). Concurrently, dialect-specialized encoders emerged, such as DarijaBERT for Moroccan Arabic (Gaanoun et al., 2023). These advances indicate that pretraining scope significantly impacts multi-dialect performance. However, varying datasets and protocols across existing studies prevent direct comparisons. Consequently, our work evaluates general, broadly dialect-oriented, and dialect-specialized encoders uniformly under the MDS-3 fine-tuning setting.

3 Dataset Analysis

Figure 1 shows a largely balanced distribution across both dialects and sentiment classes, with an important difference between the training and test sets. The training data contain comparable numbers of positive, negative, and neutral instances for Darija, Egyptian, Jordanian, and Saudi, while Lebanese is absent from the training split. In contrast, the test set is evenly distributed across all five dialects, including Lebanese. The main takeaway is therefore that, although class and dialect imbalance is limited for the observed training varieties, the evaluation additionally requires the models to generalize to Lebanese as an unseen dialect, making cross-dialect transfer an important aspect of system performance.

Table 1: Overview of the pretrained encoder architectures. Tok: Tokenization method; SP: SentencePiece; WP: WordPiece. Param: Number of parameters.



Model	Vocabulary		Param
	Tok	Size	
MARBERTv2	WP	100K	163M
DarijaBERT	WP	80K	100M
AraBERT	SP	64K	136M

4 System Overview

Our system formulates Arabic dialect sentiment analysis as a three-class sequence classification problem. Given an input sentence, the system predicts one of three sentiment labels: positive, negative, or neutral. We investigate three pretrained Arabic encoder models—MARBERTv2 (Abdul-Mageed et al., 2021), DarijaBERT (Gaanoun et al., 2023), and AraBERT (Antoun et al., 2020)—which differ in the linguistic scope and characteristics of their pretraining data. For task adaptation, we retain the pretrained encoder parameters and train a sequence-classification head for sentiment prediction.

4.1 Pretrained Encoder Models

Table 1 presents the configurations of Arabic language pretraining. AraBERT provides a general Arabic pretrained encoder and serves as a reference point for evaluating models developed with stronger exposure to dialectal Arabic (Antoun et al., 2020). MARBERTv2 builds on pretraining that incorporates large-scale Arabic social-media content and substantial dialectal variation, making it relevant to sentiment analysis of informal and dialectal text (Abdul-Mageed et al., 2021). In contrast, DarijaBERT is specifically designed for Darija and represents a dialect-specialized pretraining strategy (Gaanoun et al., 2023). This combination enables us to compare general Arabic, broadly dialect-oriented, and dialect-specific representations within the same multi-dialect sentiment classification task.

(a) Train Set

(b) Test Set

Figure 1: Distribution of samples across the five Arabic dialects and three sentiment classes in the dataset. The test set contains an equal number of samples for each dialect, while the training set has no Lebanese samples.

Table 2: Hyperparameter settings

Hyperparameter	PLM / Value
Learning rate	2e−5
Batch size	16
Epochs	10
Optimizer	AdamW
Warmup	10% of steps
Max sequence length	512
Seed	42

4.2 Sequence Classification and Parameter-Efficient Adaptation

For each encoder, we attach a sequence-classification head that maps the sentence representation to the three sentiment labels: positive, negative, and neutral. During adaptation, the pretrained encoder parameters are kept frozen, and only the parameters of the classification head are updated. This head-only adaptation substantially reduces the number of trainable parameters while preserving the representations learned during pretraining.

The same adaptation strategy is applied to MARBERTv2, DarijaBERT, and AraBERT, ensuring a consistent downstream architecture across all systems. Consequently, differences in performance primarily reflect the representations provided by the respective pretrained encoders rather than differences in the classification mechanism.

5 Experimental Setup

We use the official training and test splits provided by the shared-task organizers. Each input sentence is processed with the tokenizer associated with its corresponding pretrained encoder, and no additional preprocessing is applied. The training hyperparameters are kept consistent across all evaluated models and are summarized in Table 2.

The system is implemented with PyTorch Lightning (Falcon and The PyTorch Lightning team, 2019), while Weights & Biases (W&B) is used for experiment monitoring and logging. Following the official evaluation protocol, Macro F1-Score is used as the primary metric, with Accuracy reported as a complementary measure of overall classification performance.

6 Results

Table 3 reports our three systems' performances alongside the leading submissions on the official leaderboard. Among our models, MARBERTv2 achieves the best performance, with a Macro F1 of 80.11% and Accuracy of 81.90%, placing our submission fifth overall in Subtask 1. AraBERT obtains a Macro F1 of 75.52%, while DarijaBERT reaches 72.74%. MARBERTv2 therefore improves over AraBERT and DarijaBERT by 4.59 and 7.37 Macro F1 points, respectively, maintaining this performance ordering across all reported metrics.

The sizable performance differences among the three systems indicate that backbone selection critically impacts the final classification performance. Since the evaluated systems use the same downstream sequence-classification architecture and head-only adaptation strategy, changing the pretrained encoder results in substantial differences in Macro F1 and Accuracy. In particular, MARBERTv2 consistently outperforms the other two backbones, whereas AraBERT occupies an inter-

Table 3: Leaderboard results for DialectSentEval Subtask 1. Macro F1 Score (%) is the primary metric for comparison across all systems. The top four systems are shown in the first group, while our three submissions are presented in the second group. The best-performing system is highlighted in gray.

Team / System	Metric				Rank
	Macro F1	Accuracy	Precision	Recall	
Other Systems					
Momen_Ibrahim	86.67	88.57	86.38	87.10	1
Axiom	82.11	84.38	81.88	82.42	2
Tasneemduridi	81.75	84.19	81.89	81.62	3

AraBERT	75.52	77.33	76.12	76.33	

mediate position and DarijaBERT yields the lowest aggregate performance.

Results also show that the broadly dialect-oriented MARBERTv2 performs better in the aggregate evaluation than both the general Arabic AraBERT and the dialect-specialized DarijaBERT. This pattern suggests that exposure to linguistically diverse dialectal Arabic during pretraining provides representations that transfer more effectively to a multi-dialect sentiment classification setting. At the same time, DarijaBERT's specialization in Moroccan Darija does not translate into stronger overall performance across the complete test set. While specialization toward a single dialect may provide less transferable representations when evaluating across several dialectal varieties, we cannot confirm whether DarijaBERT retains an advantage specifically for Moroccan examples without a fine-grained evaluation.

An additional challenge arises from the dataset composition: Lebanese appears in the test set but is absent from the training split, requiring systems to process a dialect unseen during task-specific training. The stronger aggregate performance of MARBERTv2 may therefore associate with greater cross-dialect transfer from its broader pretraining exposure. Nevertheless, aggregate scores alone cannot isolate performance on Lebanese or distinguish unseen-dialect generalization from improvements on dialects observed during training. Because the gold labels for the official test set were not released by the task organizers, our analysis is strictly constrained to these aggregate metrics. Consequently, a fine-grained, per-dialect evaluation to definitively verify these hypotheses regarding cross-dialect transfer and dialect-specific advantages could not be performed on the official test split.

7 Conclusion

This work evaluates three pretrained Arabic encoders—MARBERTv2, DarijaBERT, and AraBERT—on Subtask 1 of the DialectSentEval shared task for multi-dialect sentiment analysis. Formulating the task as three-class sequence classification, we employed a parameter-efficient head-only adaptation strategy, keeping pretrained encoder parameters frozen while optimizing the classification head. Our results demonstrate that MARBERTv2 achieves the highest performance, yielding 80.11% Macro F1 and 81.90% Accuracy, securing fifth place overall. These findings highlight the importance of backbone selection, suggesting that broader, dialect-oriented pretraining provides more transferable representations for multi-dialect sentiment classification.

Despite our system's competitive performance, a primary limitation is the reliance on aggregate metrics. Because organizers did not release gold labels for the official test set, fine-grained per-dialect evaluation could not be conducted. Upon their availability, future research should prioritize per-dialect analysis to better understand each encoder's strengths and weaknesses, particularly regarding zero-shot generalization to unseen dialects like Lebanese. Furthermore, exploring alternative adaptation strategies—such as leveraging decoder-only Large Language Models (LLMs) or incorporating dialect-specific preprocessing—could further enhance performance. Overall, this study contributes to understanding pretrained Arabic models in multi-dialect contexts, establishing a solid foundation for future research.

Axiom at DialectSentEval 2026: Dialect-Aware Ensembling of MARBERTv2 and AraBERTv2 for Arabic Sentiment Analysis

Md. Ajwad Hossain
Chittagong University of Engineering & Technology
Chittagong, Bangladesh
md.ajwadhossain@gmail.com

Abstract

Sentiment analysis of regional Arabic dialects presents a formidable challenge due to severe orthographic variation, morphological complexity, and a scarcity of annotated resources. To tackle these linguistic hurdles within Subtask-1 of the DialectSentEval 2026 Shared Task, team **Axiom** proposes a heavily regularized, dialect-aware ensemble framework combining two domain-complementary language models: `MARBERTv2` and `AraBERTv2`. Our pipeline incorporates preprocessed dialect tags appended directly to input sequences, Stochastic Weight Averaging (SWA) for flat-minima convergence, and simple probability averaging across model outputs. Empirical results on the hidden test set demonstrate the robustness of this approach, with our system securing **2nd place** overall and achieving an official **Macro F1-Score of 0.8211**.

1 Introduction

Arabic sentiment analysis has witnessed significant progress with the development of transformer-based Pretrained Language Models (PLMs). However, transferring these models to regional Arabic dialects remains fundamentally challenging. Unlike Modern Standard Arabic (MSA), dialects exhibit diglossia, severe orthographic ambiguity, rich but non-standardized morphology, and frequent code-switching (Farghaly and Shaalan, 2009; Hamed et al., 2025; Alayba, 2025). Because dialectal Arabic is primarily spoken and lacks standardized orthography, the resulting token sparsity and surface-form variations severely degrade the performance of models trained exclusively on formal MSA (Alhafni et al., 2024; Asadi and Asli-Badarneh, 2026).

The DialectSentEval 2026 shared task provides a critical benchmark for evaluating sentiment analysis systems across diverse Arabic dialects (Ezzini et al., 2026a,b). Building upon foundational dialectal datasets, benchmarks, and shared task initiatives (Alharbi et al., 2025c,a,b), Subtask-1 focuses on 3-class sentiment classification (Negative, Neutral, Positive) over dialectal text sequences.

In this work, we present team **Axiom**'s submission for Subtask-1. We take the stance that when modeling noisy, moderately sized dialectal datasets, optimization stability and domain complementarity are vastly more effective than scaling model capacity or relying on unstable meta-learning stacks. To this end, we propose a highly regularized, zero-added-parameter dual-model ensemble combining `MARBERTv2` (Abdul-Mageed et al., 2021) and `AraBERTv2` (Antoun et al., 2020). By coupling explicit dialect token prefixing with Stochastic Weight Averaging (SWA) (Izmailov et al., 2018; Lu et al., 2022) to find flatter local optima, our pipeline effectively captures both dialectal slang and formal sentiment cues while heavily resisting overfitting. On the official leaderboard, our system achieved **2nd place** overall with an official **Macro F1-Score of 0.8211** and an **Accuracy of 0.8438**.

Our main contributions are summarized as follows:

- The implementation of a simple yet highly effective mechanism that explicitly conditions transformer attention heads on regional metadata to mitigate cross-dialect ambiguity.
- The demonstration that integrating Stochastic Weight Averaging (SWA) into the fine-tuning of Arabic PLMs successfully traverses sharp local minima, stabilizing convergence on highly variable text.
- The construction of a robust probability ensemble that seamlessly fuses the informal semantic representations of MARBERTv2 with the structural MSA bias of AraBERTv2, delivering superior generalization without the overhead of stacked architectures.

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1419–1425

The remainder of this paper is organized as follows: Section 2 reviews the linguistic challenges and modeling strategies in Arabic dialect NLP. Section 3 outlines our preprocessing, base architectures, and optimization framework. Section 4 presents the experimental setup, official leaderboard results, and ablation analysis. Finally, Section 5 concludes the paper.

2 Related Work

2.1 Linguistic and Orthographic Challenges

Dialectal Arabic sentiment classification is computationally more challenging than MSA processing due to structural diglossia and non-standardized spelling conventions (Boulesnam and Boucetti, 2025; Jaleel, 2025). Dialects differ from MSA across lexical, morphological, and syntactic dimensions (Inoue et al., 2021b; Joubran-Awadie and Shalhoub-Awwad, 2023). Because social media users write dialects phonetically without fixed orthographic standards, token-based NLP models suffer from severe data sparsity (Moaiad et al., 2024; Alnajjar and Hämäläinen, 2024). Consequently, sentiment-bearing adjectives, idioms, and negation patterns frequently appear in forms unobserved by MSA-trained models (Alshemali, 2026; Khalak et al., 2026), underscoring the necessity of dialect-aware normalization and modeling frameworks (Iwidat and Helou, 2026).

2.2 Base Model Selection and Cross-Dialect Transfer

Empirical evidence in Arabic PLM transfer demonstrates that variant proximity between pretraining data and downstream task variety often outweighs raw model size (Inoue et al., 2021a). For informal social media text, `MARBERT` pretrained on a massive Arabic Twitter corpus regularly outperforms general MSA models on dialectal sentiment benchmarks (Abdul-Mageed et al., 2021; Nwesri et al., 2025). Conversely, MSA-pretrained encoders such as `AraBERT` retain superior syntactic and structural representations that generalize remarkably well to unseen dialects and formal expressions (Antoun et al., 2020; Boudad et al., 2023; Muller et al., 2020). Combining these distinct model biases provides a balanced coverage of both informal dialectal expressions and structured sentiment syntax.

2.3 SWA and Ensembling in Low-Resource NLP

Fine-tuning transformer models on small datasets risks converging into sharp, non-generalizable local minima. Stochastic Weight Averaging (SWA) addresses this by averaging SGD trajectory weights during training, effectively guiding the parameters toward wider, flatter regions of the loss landscape that demonstrate superior out-of-distribution generalization (Izmailov et al., 2018; Lu et al., 2022; Demir et al., 2024). Furthermore, ensembling diverse PLMs provides proven gains in uncertainty estimation and predictive robustness (Arango et al., 2024). Prior works in dialectal sentiment analysis confirm that multi-model transformer ensembles consistently outperform single-checkpoint baselines (Mansour et al., 2025; Boughareb et al., 2025), validating our choice of probability-averaged ensembling under tight dataset constraints.

3 Methodology

To address the challenges of dialectal variation and the risk of overfitting on a moderately sized dataset, we eschewed complex meta-learning architectures in favor of a highly regularized, dialect-aware ensemble. Our pipeline consists of four primary stages: text preprocessing, base model selection, fine-tuning via Stochastic Weight Averaging (SWA), and probability-based ensembling.

The high-level data flow of this pipeline is illustrated in Figure 1. As depicted, raw dialectal input is first normalized and augmented with regional tags before branching into two parallel, domain-specific transformer encoders, ultimately fusing their regularized probabilistic outputs to produce the final sentiment classification.

3.1 Preprocessing and Representation

Standard Modern Standard Arabic (MSA) preprocessing often aggressively filters characters, which can inadvertently destroy crucial dialectal markers. We utilized the `ArabertPreprocessor` to clean the text while preserving essential morpho-syntactic boundaries.

To explicitly condition the transformer architectures on regional dialects, we appended a specific dialect token as a prefix to the input sequence. The final input representation is formulated as:

$$x_{\text{input}} = \text{`['} \parallel \text{dialect} \parallel \text{`]'} \parallel \text{preprocess}(s) \quad (1)$$

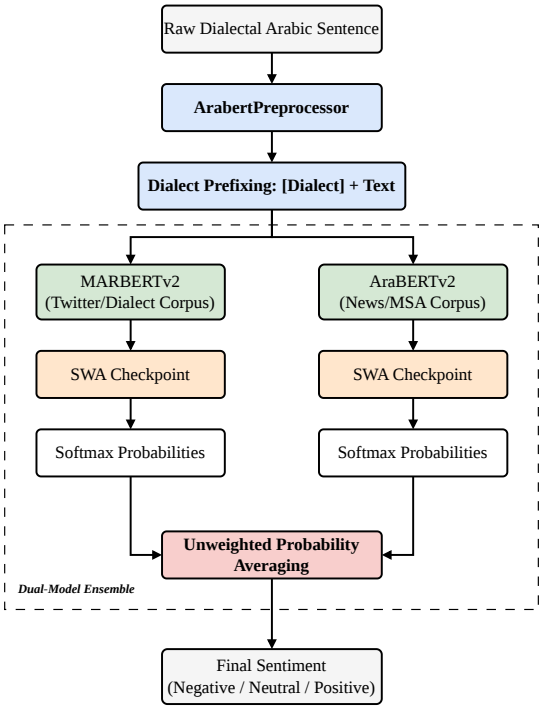

Figure 1: Overall architecture of the Axiom dialect-aware sentiment analysis pipeline.

where s denotes the raw input sentence and $\|$ denotes string concatenation. This prefixing mechanism acts as a soft prompt, guiding the attention heads to contextualize subsequent vocabulary based on the indicated regional dialect.

3.2 Base Architectures

We selected two robust, domain-complementary Transformer encoders to ensure representational diversity within our ensemble:

- **MARBERTv2** (Abdul-Mageed et al., 2021): Pretrained heavily on a massive corpus of Arabic tweets, providing strong zero-shot comprehension of informal phrasing, missing diacritics, and regional slang.
- **AraBERTv2** (Antoun et al., 2020): Pretrained predominantly on news corpora, offering a rigid understanding of structural MSA and formal sentiment expressions that often anchor longer sequences.

3.3 Fine-Tuning and Optimization

To prevent data leakage, we partitioned the training data into a 90/10 stratified split based on the 3-class sentiment labels. Both models were fine-tuned independently using standard Cross-Entropy loss, as margin-based losses (e.g., Focal Loss) were empirically found to overfit on noisy labels in the training set.

To smooth the loss landscape and prevent convergence into sharp local minima, we applied Stochastic Weight Averaging (SWA) (Izmailov et al., 2018). Complete hyperparameter configurations, including learning rate schedules, SWA transition dynamics, and batch statistics, are detailed in Appendix A.

3.4 Ensembling Strategy

For the final predictive framework, we relied on unweighted probability averaging rather than a stacked meta-learner. The output logits from the SWA checkpoints of both models were converted into probability distributions via a Softmax layer. The final sentiment probability was calculated as:

$$P_{\text{ens}}(y|x) = \frac{1}{2}\left[P_{\text{MAR}}(y|x) + P_{\text{Ara}}(y|x)\right] \quad (2)$$

The final predicted class $\hat{y}$ corresponds to $\text{argmax}_y P_{\text{ens}}(y|x)$.

4 Experiments and Results

4.1 Experimental Setup

All models were trained using PyTorch with Automatic Mixed Precision (AMP) on an NVIDIA GPU environment. To facilitate exact replication, comprehensive hardware details, sequence lengths, and optimization configurations are provided in Appendix A.

4.2 Local Validation

During local evaluation on our 10% stratified hold-out set ($N = 174$), both models demonstrated strong convergence. `MARBERTv2` achieved a standalone Macro F1 of 0.9410, while `AraBERTv2` achieved 0.8962. By ensembling both models via probability averaging, the local Macro F1 score peaked at **0.9560**, demonstrating the complementary nature of the two architectures.

4.3 Official Shared Task Results

Our proposed ensemble was evaluated blindly on the official CodaLab test set for Subtask-1. The **Axiom** system achieved **2nd place** overall, recording an official **Macro F1-Score of 0.8211**, an Accuracy of 0.8438, Precision of 0.8188, and Recall of 0.8242.

For context within the competition overview, the first-place system achieved a Macro F1 of 0.8667,

while our ensemble comfortably outperformed the third-place baseline (Macro F1: 0.8175) and the rest of the participating field. These results confirm that our dialect-aware preprocessing paired with flat-minima optimization successfully generalized to unseen dialectal texts, securing a top-tier rank without relying on external datasets or complex meta-learners.

4.4 Ablation and Analysis

To quantify the contribution of our architectural decisions, we tracked the performance of individual components on the official CodaLab blind test set. Table 1 illustrates how our ensembling strategy compares to standalone models and alternative stacking methods. A comprehensive breakdown of all secondary metrics (Accuracy, Precision, Recall) is available in Appendix B.

Model Configuration	Macro F1
MARBERTv2 (Standalone)	0.8096
AraBERTv2 (Standalone)	0.7646
CAMeLBERT-DA (Standalone)	0.7656
Dual-Model Ensemble (Ours)	**0.8211**
Ensemble + LR Meta-Learner	0.8134
3-Model Ensemble (+ CAMeLBERT)	0.7932

Table 1: Summary of official test scores. Detailed metrics are provided in Appendix B.

Base Model Performance: In isolation, MARBERTv2 proved to be the strongest standalone architecture (0.8096 F1), validating the hypothesis that pretraining on social media text aligns better with the noisy dialectal target domain. Conversely, AraBERTv2 and CAMeLBERT-DA struggled to generalize when acting alone.

The Power of Complementary Ensembling: Despite AraBERTv2's weaker standalone performance, fusing its probabilistic outputs with MARBERTv2 yielded our highest official score, culminating in an F1-Score of **0.8211**. This confirms that AraBERT captures distinct structural or formal sentiment cues that MARBERT misses, making them highly complementary.

Detrimental Additions: Throughout development, we observed that adding complexity often harmed generalization. Replacing our simple probability average with a Logistic Regression stacking meta-learner degraded the F1 score to 0.8134, likely due to the meta-learner overfitting the highly confident out-of-fold predictions from the small training set. Similarly, introducing CAMeLBERT-DA as a third model introduced destructive noise. This indicates that misaligned pretraining vocabularies can actively harm small-scale probability ensembles, reinforcing the necessity of strict model curation.

4.5 Error Analysis

While our ensemble generalized exceptionally well locally, a qualitative review of the misclassified validation samples revealed three primary failure modes driven by linguistic complexity. **(1) Subjective Neutrality:** Texts containing implicit complaints alongside neutral anchors were often aggressively predicted as *Negative* by both models, despite being ground-truthed as *Neutral*. **(2) Conflicting Polarities:** Sentences balancing negative aspects with positive justifications confused the models, causing the ensemble to default to *Neutral*. **(3) Negated Negativity:** Formal phrases implying a positive experience through the negation of a negative were conservatively misclassified as *Neutral*. A detailed breakdown with specific Arabic text examples is provided in Appendix C.

5 Conclusion

In this paper, we described team Axiom's 2nd-place submission for Subtask-1 of the DialectSentEval 2026 Shared Task. We demonstrated that for highly dialectal Arabic sentiment analysis on constrained datasets, a heavily regularized dual-model ensemble consisting of MARBERTv2 and AraBERTv2 yields highly competitive results. By combining explicit dialect tagging with Stochastic Weight Averaging and unweighted probability averaging, our system effectively mitigated overfitting while maximizing representational diversity between social media and formal MSA distributions. Future work will explore the integration of generative data augmentation or adversarial training methods to further close the performance gap on rare dialectal structures without degrading model calibration.

6 Limitations

Despite its strong empirical performance, our approach presents three primary limitations. First, ensembling `MARBERTv2` and `AraBERTv2` inherently doubles inference latency and memory overhead compared to standalone models. Second, our maximum sequence length of 128 tokens risks truncating long-range context in extended dialectal narratives. Finally, our dialect prefixing mechanism relies on gold-standard regional metadata; deploy-

ing this pipeline in the wild would necessitate an upstream dialect identification module, potentially introducing cascading classification errors.

Acknowledgments

We extend our gratitude to the organizers of the DialectSentEval 2026 Shared Task and the Fourth Arabic Natural Language Processing Conference for providing the datasets and fostering collaborative research in Arabic NLP.

A Implementation and Hyperparameter Details

To facilitate reproducibility, we provide the exact hyperparameters utilized during the training phase. All models were trained utilizing a maximum sequence length of 128 tokens and a batch size of 16. We employed the AdamW optimizer with a base learning rate of 2×10^{-5} and a weight decay of 0.01. A linear learning rate scheduler with a 10% warmup period was applied during the initial phase.

Stochastic Weight Averaging (SWA) (Izmailov et al., 2018) was activated at epoch 3, transitioning to an SWA-specific learning rate of 1×10^{-5}. The SWA weights were updated according to the following schedule:

$$w_{\text{SWA}} \leftarrow \frac{w_{\text{SWA}} \cdot n_{\text{models}} + w}{n_{\text{models}} + 1} \tag{3}$$

Batch Normalization statistics were updated across the entire training loader at the conclusion of the 10th epoch. All training was conducted using PyTorch with Automatic Mixed Precision (AMP) to optimize VRAM utilization on an NVIDIA GPU.

B Detailed Ablation Metrics

Table 2 provides the comprehensive evaluation metrics (Accuracy, Precision, Recall, and Macro F1) for all tested configurations on the official blind test set.

C Qualitative Error Analysis Examples

Table 3 provides specific examples from our local 10% validation holdout where the dual-model ensemble failed to predict the correct sentiment. These examples illustrate the primary failure modes discussed in Section 4.5, specifically highlighting the difficulty of resolving conflicting polarities and implicit sentiment in dialectal Arabic.

Model Configuration	Accuracy	Precision	Recall	Macro F1
Standalone Base Models:				
MARBERTv2	0.8324	0.8067	0.8138	0.8096
CAMeLBERT-DA	0.7829	0.7667	0.7765	0.7656
AraBERTv2	0.7886	0.7652	0.7700	0.7646
Dual-Model Ensemble (Ours)	**0.8438**	**0.8188**	**0.8242**	**0.8211**
Alternative Formulations:				
Dual-Ensemble + LR Meta-Learner	0.8305	0.8121	0.8207	0.8134
3-Model Ensemble (+ CAMeLBERT)	0.8133	0.7920	0.8012	0.7932

Table 2: Comprehensive ablation study of official test scores, demonstrating the impact of base model selection and various ensembling strategies.

Raw Arabic Input & Translation	True	Pred.	Failure Mode
متوسط، ممكن يكون أحسن و توقعنا ان الغرف والحمامات تكون أنظف قضينا يومين من ليالينا الأولى في القاهرة هناك *(Average, could be better and we expected the rooms and bathrooms to be cleaner...)*	Neutral	Negative	Subjective Neutrality / Implicit Complaint
بالرغم من بلي فندق كايعطي شي ثمن كبيرا مقارنة بالجيران، و لكن أنا كنت بيه عشان كان مشهور و كان عندو تقييمات. *(Even though the hotel charges a high price compared to neighbors, I stayed because it was famous...)*	Negative	Neutral	Conflicting Polarities (Mixed Sentiment)
وصلنا هناك قبل يوم من الموعد المحدد، لكن هذا لا مشكلة في فهمي. *(We arrived there a day before the scheduled time, but this is no problem...)*	Positive	Neutral	Negated Negativity (Implicit Positivity)

Table 3: A representative sample of misclassified instances from the local validation set, highlighting the challenges of implicit phrasing and boundary ambiguity in dialectal Arabic.

Abstract

We present our system for Subtask 1 (three-class sentiment classification) of the DialectSentEval 2026 shared task, which evaluates five Arabic dialects using the Multi-Dialect-Sent (MDS-3) hotel-review corpus. Our approach fine-tunes MARBERT with a stratified train/validation split and class-weighted cross-entropy loss. On the official test set, our system achieves an F1 score of 0.8175 and an accuracy of 0.8419, ranking 3rd on the official leaderboard. We identify a substantial dialect mismatch in the dataset: the training set contains no Lebanese reviews, while approximately 20% of the test set is Lebanese. Adding additional Lebanese reviews from OCLAR partially reduces this gap, but does not eliminate it. The error analysis also shows that misclassifications are concentrated in the neutral class and in reviews that express mixed feelings, often with high confidence. These findings highlight the challenges of cross-dialect sentiment classification under unseen-dialect conditions.

1 Introduction

As Arabic-language content on social media and review platforms continues to grow, automatic sentiment analysis (SA) has become increasingly important for applications such as business intelligence (Jakha et al., 2025), public-opinion monitoring (Azmi and Alzanin, 2014), and customer feedback analysis (Alsemaree et al., 2024). However, Arabic SA presents several challenges, including rich morphology, relatively flexible word order, and substantial variation between Modern Standard Arabic (MSA) and regional dialects. While many NLP resources focus on MSA, everyday online communication is dominated by dialects such as Moroccan, Egyptian, Levantine, and Gulf Arabic. Consequently, models trained primarily on MSA or a single dialect may generalize poorly to other dialects, while dialect-specific sentiment resources remain relatively limited (Jaber et al., 2025; Duridi et al., 2025).

The DialectSentEval 2026 shared task addresses this challenge through Subtask 1, which requires three-class sentiment classification of hotel reviews from the Multi-Dialect-Sent (MDS-3) corpus across five Arabic dialects: Moroccan (Darija), Egyptian, Lebanese, Jordanian, and Saudi. This setting provides a practical evaluation of cross-dialect generalization.

We present our MARBERT-based (Abdul-Mageed et al., 2021) system submitted by team PTUK-NLP. The remainder of this paper is organized as follows: 3 reviews related work; 4 describes our system and experimental setup and results; 5 presents our analysis of Lebanese-dialect coverage; 6 discusses the error analysis; and 7 concludes the paper.

2 Task Description

DialectSentEval 2026 (Ezzini et al., 2026a) is a shared task on sentiment analysis and sentiment swapping in Arabic dialects, building on the earlier AraSentEval task (Ezzini et al., 2026b). We participated in on Subtask 1, a three-class sentiment classification task in which systems predict whether a given Arabic sentence expresses positive,

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1426–1430
October 28-29, 2026 ©2026 Association for Computational Linguistics

negative, neutral sentiment. The subtask covers five dialects—Moroccan, Egyptian, Lebanese, Jordanian, and Saudi—and is designed to evaluate robustness to the lexical and syntactic variation across Arabic dialects. Our team, PTUK-NLP, participated in Subtask 1 using the MARBERT-based system described in the following section.

3 Related Work

Arabic sentiment analysis is challenging due to the language's rich morphology and the substantial variation between MSA and regional dialects, which differ in vocabulary, orthography, and syntax. Early approaches relied largely on classical machine-learning methods and handcrafted lexical features, with limited ability to generalize across dialects. The emergence of pretrained Arabic transformers has substantially improved downstream performance. AraBERT (Antoun et al., 2020) was pretrained primarily on MSA and curated Arabic text, while CAMeLBERT (Inoue et al., 2021) introduced separate checkpoints for MSA, dialectal, and mixed-domain pretraining to investigate the effect of corpus composition on downstream performance. MARBERT (Abdul-Mageed et al., 2021), in contrast, was pretrained on a large multi-dialect Arabic Twitter corpus and is therefore particularly suited to informal and dialect-diverse text. Given the dialectal nature of MDS-3, we adopt MARBERT as the backbone of our system.

Several recent studies are closely related to our setting. ADOR (Alharbi et al., 2025c) introduced a human-benchmarked dataset of Arabic dialectal hotel reviews for sentiment analysis, sharing both the hotel-review domain and multi-dialect focus of MDS-3. The AHASIS shared task (Alharbi et al., 2025b) likewise investigated sentiment analysis across Arabic dialects, providing a relevant precedent for our shared-task setting. More recently, Alharbi et al. (2025a) evaluated large language models for Arabic dialect sentiment analysis and showed that dialect coverage in training and prompting data can substantially affect downstream performance. This finding is particularly relevant to our study, where the absence of Lebanese examples from the released training data creates a pronounced train–test dialect mismatch that we investigate in 5.

4 System Description

Figure 1 summarizes our full pipeline, from data preparation through evaluation.

4.1 Data

The released training data (`sent_train_v2.csv`) contains 1,731 labeled sentences, with fields for sentence ID, text, sentiment label, and dialect. The sentiment distribution is negative (657), positive (609), and neutral (465), corresponding to 38%, 35%, and 27% of the data, respectively, indicating a moderate class imbalance. As shown in Figure 2, the training data covers only four of the five target dialects: Darija, Saudi, Jordanian, and Egyptian, with approximately 433 sentences per dialect. Lebanese is absent from the released training data.

We apply minimal preprocessing intended primarily to remove noise while preserving dialect-specific characteristics. Specifically, we remove Arabic diacritics, URLs, and @-mentions, and reduce extreme character elongation by replacing sequences of four or more repeated characters with three characters. We deliberately avoid dialect-to-MSA normalization to retain lexical and orthographic features that may be informative for dialect-specific sentiment classification.

4.2 Model and Training

We fine-tune (UBC-NLP/MARBERT) for three-class sequence classification, using a maximum sequence length of 128 subword tokens. A length audit confirmed that no training examples were truncated, with the 99th percentile at 75 tokens. We use a single stratified 90/10 train/validation split and class-weighted cross-entropy loss with inverse-frequency class weights to address the moderate class imbalance. Training uses AdamW with a learning rate of 2×10^{-5}, batch size 16, weight decay of 0.01, and up to five epochs. Early stopping with a patience of two epochs is applied based on validation macro-F1. No learning-rate warmup or scheduler is used.

4.3 Results and Training Variance

Our submitted configuration achieved an F1 score of 0.8175 and an accuracy of 0.8419 on the official test set, ranking third among participating teams. To assess training variability, we repeated the same configuration twice without code changes. The two additional runs achieved F1 scores of 0.8146

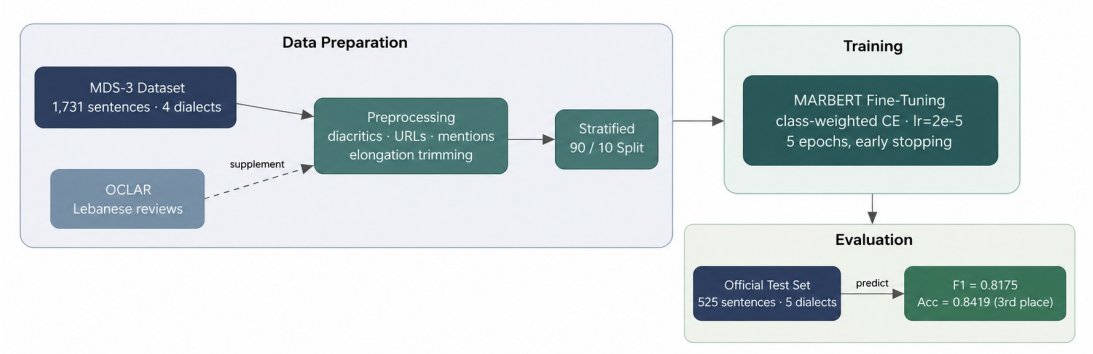

Figure 1: Overview of our system pipeline

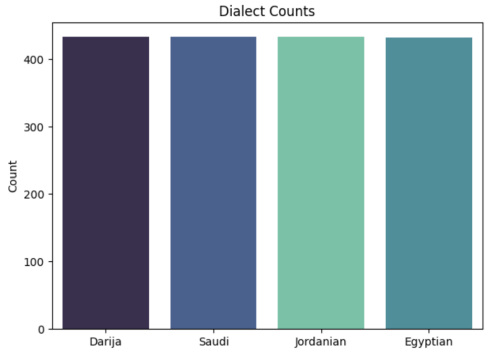

Figure 2: Dialect distribution in the training data. Only four dialects are represented; Lebanese is absent

(accuracy 0.8362) and 0.8031 (accuracy 0.8305). Across the three runs, F1 ranged from 0.8031 to 0.8175, corresponding to a spread of 1.44 F1 points. This variability may arise from stochastic factors during training, including random initialization and GPU-related non-determinism. Given the relatively small training set of 1,731 examples, we report this range to provide a more transparent indication of training variability rather than relying solely on a single run.

5 Investigating the Lebanese Dialect Gap

Although the MDS-3 corpus description specifies five balanced dialects, inspection of the released training data shows that only four are represented: Darija (433), Saudi (433), Jordanian (433), and Egyptian (432). A case-insensitive search of the dialect field found no Lebanese examples. Thus, the training data contains no Lebanese-dialect instances. In contrast, the official test set contains 105 examples from each of the five dialects, meaning that approximately 20% of the test set represents a dialect unseen during training.

Supplementing with OCLAR. To investigate whether additional Lebanese data could alleviate this mismatch, we used the Opinion Corpus for Lebanese Arabic Reviews (OCLAR; Al Omari et al., 2019), a domain-related corpus of Lebanese reviews covering hotel, restaurant, and service experiences. We mapped its 1–5 star ratings to the three sentiment classes as follows: 4–5→positive, 3→neutral, and 1–2→negative. We evaluated two configurations: an unbalanced variant containing 1,771 OCLAR examples, with only the positive class capped, and a dialect-balanced variant capped at 432 examples to approximately match the size of the other MDS-3 dialects. No other system settings were changed.

The unbalanced and balanced configurations achieved official-test F1 scores of 0.791 and 0.792, respectively, both below the original baseline of 0.8175. Notably, the two configurations produced nearly identical results despite the substantially different amounts of supplementary data. This suggests that simply increasing the amount of Lebanese training data is insufficient to overcome the dialect and dataset mismatch.

We further conducted a leave-Lebanese-out diagnostic evaluation in which the model was trained on the four original MDS-3 dialects together with non-held-out OCLAR data and evaluated exclusively on held-out OCLAR examples. The resulting macro-F1 was 0.62, compared with 0.85–0.95 on the four dialects represented in the training data. This substantial difference confirms the difficulty of generalizing to Lebanese Arabic. The limited improvement from OCLAR may partly reflect differences between the two resources, including domain framing (general service reviews versus hotel-specific reviews) and label construction (star ratings versus direct sentiment annotation).

We also evaluated several additional strategies,

including k-fold cross-validation with ensembling, focal loss, back-translation, Arabic orthographic normalization, and automated label-conflict cleaning. None improved over the baseline. Given the limited gains and space constraints, we focus the remainder of the paper on the baseline system and its error analysis.

6 Error Analysis

We analyze the baseline model's errors on the internal validation split (174 sentences). The model achieves a macro-F1 of 0.958, compared with 0.8175 on the official test set, a gap of 14.05 percentage points. This difference is likely influenced by the small validation set and its limited dialect coverage, as it contains no Lebanese examples and therefore does not fully reflect the diversity of the official test set.

6.1 Error Patterns

Table 1 presents the validation confusion matrix. Of the seven errors, six involve the neutral class as either the true or predicted label, indicating that neutral is particularly difficult to distinguish from positive and negative sentiment. This may be partly attributed to its minority representation in the training data (27%) and the semantic ambiguity of reviews containing both positive and negative cues.

	Predicted		
True	pos	neg	neu
positive	60	0	1
negative	1	63	2
neutral	2	1	44

Table 1: Confusion matrix, validation split ($n = 174$).

Qualitative inspection indicates that several errors involve mixed-sentiment reviews, where positive and negative cues occur together. The model tends to rely on a dominant sentiment-bearing expression rather than integrating conflicting cues across the review. For example, a neutral review describing an experience as *"Average, could be better"* while criticizing room and bathroom cleanliness is classified as negative with 99.9% confidence. Similarly, a neutral review praising one receptionist while criticizing other staff is classified as positive with 99.8% confidence.

The model is also highly confident in its incorrect predictions: 171 of 174 predictions (98.3%) have confidence above 0.9, including six of the seven errors. This suggests that the model may be overconfident when processing ambiguous, mixed-sentiment reviews. This observation is consistent with our earlier findings (5), where automated cleaning of label disagreements reduced performance, suggesting that some apparent disagreements may reflect genuine ambiguity rather than annotation noise.

7 Conclusion

Our submitted system is a MARBERT classifier fine-tuned with a single 90/10 stratified split and class-weighted cross-entropy loss, achieving F1 = 0.8175 on the official DialectSentEval 2026 Subtask 1 test set (ranking 3rd on the official evaluation leaderboard), with a measured run-to-run variance of about 1.4 F1 points. We identified and investigated a complete absence of Lebanese-dialect data in the training set; supplementing with a domain-matched Lebanese corpus (OCLAR) narrowed but did not close a substantial generalization gap (0.62 vs. 0.85–0.95 macro-F1). Our error analysis shows the model's failures concentrate on mixed-sentiment reviews labeled neutral, which it misclassifies with high confidence by overweighting a single dominant sentiment cue – a pattern we recommend future work on MDS-3 address directly, for example via explicit modeling of aspect-level or mixed sentiment, rather than through the data-level interventions we found ineffective.

Limitations

Our variance estimate (4.3) is based on three runs of one configuration; a fully rigorous estimate would require more repetitions and should also be established for the OCLAR-augmented variants, whose results in 5 fall within our measured variance range and should not be read as precise rankings. Our diagnosis of the missing-Lebanese-dialect issue is specific to the released `sent_train_v2.csv` file as of our access date. OCLAR differs from MDS-3 in domain scope and label derivation (star ratings vs. direct annotation), limiting how directly its results generalize. Our error analysis is based on a 174-sentence validation split that itself excludes the Lebanese dialect, so it cannot directly characterize Lebanese-specific error patterns.

Abstract

Arabic dialect sentiment analysis is challenging because regional varieties show considerable lexical, morphological, syntactical, and orthographic variation. This paper presents a transformer-based system developed for DialectSentEval 2026 Subtask 1, a three-class sentiment classification task covering Moroccan, Egyptian, Jordanian, and Saudi Arabic. The system independently fine-tunes three pretrained Arabic language models: AraBERTv2, MARBERTv2, and CAMeLBERT, using a common training protocol. The implementation uses an 80/20 stratified train-validation split, a maximum sequence length of 128, a batch size of 16, a learning rate of 2×10^{-5}, and focal loss with $\gamma = 2$=2. Model selection was conducted based on validation macro F1. Using the published labeled test set, MARBERTv2 achieves the strongest independent result with 94.07% macro F1, followed by CAMeLBERT at 81.96% and AraBERTv2 at 79.77%. The results demonstrate the importance of Arabic pretraining and dialect-oriented representations and establish MARBERTv2 as the strongest standalone backbone in the current system.

1 Introduction

Arabic dialect sentiment analysis remains challenging because of regional variation, morphological richness, orthographic inconsistency, and frequent divergence from Modern Standard Arabic (MSA) (Nwesri et al., 2025). These characteristics are evident in user-generated content, where dialectal vocabulary, informal spelling, code-switching, and non-standard forms are common. Consequently, sentiment classifiers trained primarily on standardized Arabic may not transfer uniformly across dialects.

DialectSentEval 2026 Subtask 1 (Ezzini et al., 2026a) provides a controlled benchmark for this setting. The task requires sentence-level prediction of negative, neutral, or positive sentiment across Moroccan, Egyptian, Jordanian, and Saudi Arabic. The shared-task resource is derived from hotel reviews in the ADOR dataset (Alharbi et al., 2025c) and contains parallel sentences across dialects, with balanced sentiment representation (Ezzini et al., 2026b).

The official benchmark uses an 80/20 train-test split based on sentence identifiers so parallel sentences remain in the same partition, reducing leakage risk. The official evaluation uses macro F1, which assigns equal weight to the three sentiment classes. The system's main objective is to enable a reproducible comparison of three Arabic pretrained encoders under a common fine-tuning regime.

2 Related Work

Arabic-specific pretraining has consistently improved downstream Arabic NLP performance. AraBERT (Antoun et al., 2020) demonstrated the effectiveness of language-specific BERT pretraining across several tasks, including sentiment analysis, and motivated subsequent Arabic-focused encoders. ARBERT and MARBERT (Abdul-Mageed et al., 2021) extended this direction by targeting the diversity of Arabic varieties, with MARBERT emphasizing dialectal Arabic and achieving strong results on the multi-dialect ARLUE benchmark.

The importance of pretraining-data composition was further examined by (Inoue et al., 2021), who showed that similarity between the pretraining language variety and the downstream data can be more important than corpus size alone. More recently, AraModernBERT (Elshehy et al., 2026) introduced transtokenized initialization and long-context Arabic encoder modeling, further demonstrating the value of specialized Arabic representations.

These findings are consistent with broader comparative studies of Arabic NLP architectures. (Mohamed and Alosman, 2025) reported that pretrained transformer models outperform earlier RNN- and

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1431–1435
October 28-29, 2026 ©2026 Association for Computational Linguistics

CNN-based approaches across multiple Arabic NLP tasks, including sentiment analysis and dialect identification.Recent work has further emphasized the importance of evaluating sentiment analysis methods specifically in dialectal Arabic settings. Alharbi et al. (Alharbi et al., 2025a) examined large language models for Arabic dialect sentiment analysis, while the AHASIS shared task provided a dedicated evaluation setting for sentiment analysis across Arabic dialects (Alharbi et al., 2025b). Together, this prior work motivates our comparison of Arabic encoders with different pretraining characteristics for multi-dialect sentiment classification.

3 Data Description

3.1 Dataset Statistics

The experiments used the supplied DialectSentEval Subtask 1 training and test files. Table 1 shows the distribution of sentiment labels across the four Arabic dialects. The training file contains 1,731 labeled Arabic sentences, while the test file contains 312 instances. The training records include ID, sentence, sentiment, and dialect fields. Sentiment is represented as a three-class problem: Class 0 (negative), Class 1 (neutral), and Class 2 (positive). The data cover four Arabic varieties: Moroccan Darija, Egyptian, Jordanian, and Saudi Arabic.

The training set is almost perfectly balanced across dialects, as shown in Table 1. Moroccan Darija, Saudi, and Jordanian each contribute 433 instances, whereas Egyptian contributes 432 instances. Thus, each dialect represents approximately one quarter of the training corpus. By contrast, the sentiment distribution is moderately imbalanced: negative examples account for 657 instances (37.95%), positive examples for 609 (35.18%), and neutral examples for 465 (26.86%). The smaller neutral class is particularly relevant to model selection because sentences with weakly polarized sentiment can be more difficult to distinguish from both positive and negative examples.

Table 1: Distribution of Sentiment Labels Across Arabic Dialects

Dialect	**Neg.**	**Neu.**	**Pos.**	**Total**
Darija	166	115	152	433
Egyptian	159	120	153	432
Jordanian	166	115	152	433
Saudi	166	115	152	433
Total	**657**	**465**	**609**	**1,731**

3.2 Training Validation Protocol

For model development, the 1,731 labelled training instances are divided using an 80/20 stratified split with random seed 42. Stratification was performed on the sentiment label to preserve the relative proportions of the three classes in the training and validation subsets. This produces approximately 1,385 training instances and 346 validation instances. The 312-instance test set is kept separate from this local validation process and is not used for model selection. This distinction is important when interpreting the reported results. The validation set monitors convergence and selects the best checkpoint, whereas the supplied test set represents the held-out evaluation data. The experiments therefore avoid using test performance to determine model configuration or checkpoint selection.

3.3 Input Representation and Preprocessing

The sentence field is used as the model input without additional handcrafted linguistic features. Each sentence is tokenised using the model-specific tokeniser, padded to a maximum sequence length of 128 tokens, and truncated when necessary. No external sentiment lexicon, stemming, lemmatisation, or manually engineered dialect features are introduced. This design isolates the contribution of the pretrained Arabic transformer representations.

4 Model Selection and Experimental Configuration

4.1 Model Selection Strategy

Three Arabic pretrained transformer backbones are evaluated: AraBERTv2, MARBERTv2, and CAMeLBERT. They were selected to provide complementary Arabic representations and, in particular, to contrast a general Arabic pretrained encoder with models developed to better represent Arabic dialectal variation. All three models are fine-tuned under an identical protocol so that differences in performance can be attributed primarily to the pretrained representations rather than model-specific optimization choices.

4.2 AraBERTv2

AraBERTv2 represents the AraBERT family of Arabic-specific pretrained language models. AraBERT demonstrated the effectiveness of language-specific BERT pretraining for Arabic natural language understanding and downstream sentiment-related tasks (Antoun et al., 2020). In this study, AraBERTv2 provides a strong general Arabic baseline against which more dialect-oriented representations can be compared.

4.3 MARABERTv2

MARBERTv2 is particularly relevant to the present task because the MARBERT family was developed to address the diversity of Arabic language varieties. (Abdul-Mageed et al., 2021) introduced MARBERT together with ARBERT and evaluated the models on ARLUE, a multi-dialect Arabic language-understanding benchmark. Their findings demonstrated strong performance across diverse Arabic NLP tasks. Moreover, (Inoue et al., 2021) showed that the proximity between the pretraining language variant and downstream data can be more important than pretraining-data size. These findings motivate MARBERTv2 as the principal dialect-oriented candidate in the current comparison.

4.4 CAMeLBERT

CAMeLBERT is included as a complementary Arabic pretrained representation from the CAMeL-Lab model family (Inoue et al., 2021). Its inclusion provides an additional Arabic-specific baseline and helps distinguish the general benefits of Arabic pretraining from the more dialect-focused characteristics of MARBERTv2.

4.5 Common Fine-Tuning Configuration

All three backbones use the same fine-tuning configuration: a maximum sequence length of 128 tokens, training and evaluation batch sizes of 16, a learning rate of 2×10^{-5}, 10 training epochs, focal loss with $\gamma = 2$, and random seed 42. Evaluation is performed after each epoch, and the checkpoint with the highest validation Macro-F1 is retained.

To emphasize difficult training examples, the system uses focal loss. Given the cross-entropy loss

$$p_t = \exp(-CE) \tag{1}$$

, and focusing parameter $\gamma = 2$, the loss is defined as

$$\mathcal{L}_{\text{focal}} = (1 - p_t)^{\gamma} CE \tag{2}$$

. The same objective is applied to all three models, ensuring that the comparison does not confound backbone selection with different optimization objectives.

Table 2: Performance comparison of pretrained Arabic language models.

Model	Epoch	Accuracy	Macro P	Macro R	macro F1
AraBERTv2	7	0.9164	0.9092	0.9095	0.9092
MARBERTv2	6	0.9568	0.9531	0.9547	0.9539
CAMeLBERT	9	0.8991	0.8918	0.8935	0.8923

5 Results

5.1 Validation Performance

Table 1 summarizes the strongest validation checkpoint observed during the training. The three models exhibit different convergence profiles. MARBERTv2 reaches its maximum macro F1 at epoch 6, whereas AraBERTv2 peaks at epoch 7 and CAMeLBERT at epoch 9. The distinction between best-epoch validation performance and final-epoch performance is important because the checkpoint-selection criterion is validation macro F1.

5.2 Class-Level Behavior

The per-class validation results reveal a consistent difficulty pattern. For MARBERTv2 at its best epoch, Class 0 reaches F1=0.9771, Class 1 reaches F1=0.9255, and Class 2 reaches F1=0.9590. AraBERTv2 obtains Class 0, Class 1, and Class 2 F1 values of 0.9699, 0.8449, and 0.9129 at its best epoch, respectively. CAMeLBERT obtains 0.9535, 0.8211, and 0.9024 at its best epoch. Thus, the neutral class (Class 1) is the most challenging class for all three models, whereas negative sentiment (Class 0) is consistently the easiest.

As shown in Table 2, MARBERTv2 not only achieves the highest macro F1 but also maintains comparatively strong performance on the neutral class. This behavior suggests that its pretrained representations provide more discriminative contextual information for cases that are less lexically polarized.

5.3 Dialect-wise System Performance

To assess robustness across Arabic varieties, we evaluated predictions on the 1,731 labeled training instances, which are nearly evenly distributed

Dialect	Model	Accuracy	Macro-P	Macro-R	Macro-F1
Moroccan	AraBERTv2	94.23	93.69	94.01	93.82
	MARBERTv2	**97.46**	**97.23**	**97.52**	**97.36**
	CAMeLBERT	97.00	96.98	96.83	96.90
Egyptian	AraBERTv2	94.68	94.62	94.05	94.26
	MARBERTv2	**96.99**	**96.94**	**96.76**	**96.84**
	CAMeLBERT	95.60	95.45	95.28	95.36
Jordanian	AraBERTv2	97.46	97.20	97.27	97.23
	MARBERTv2	**99.54**	**99.49**	**99.49**	**99.49**
	CAMeLBERT	98.38	98.35	98.22	98.28
Saudi	AraBERTv2	96.30	96.36	95.64	95.94
	MARBERTv2	**98.61**	**98.57**	**98.40**	**98.48**
	CAMeLBERT	98.38	98.46	98.04	98.23

Table 3: Performance of the three encoder models across the four Arabic dialects. Results are reported as percentages. Bold indicates the best score for each dialect and metric.

across Moroccan Darija (433), Egyptian (432), Jordanian (433), and Saudi (433). This balance enables direct comparison across dialects without major sample-size effects.

As shown in Table 3, MARBERTv2 consistently achieves the best Macro-F1 across all dialects, with 99.49% on Jordanian, 98.48% on Saudi, 97.36% on Moroccan Darija, and 96.84% on Egyptian Arabic. AraBERTv2 shows greater variation, ranging from 93.82% on Moroccan Darija to 97.23% on Jordanian, while CAMeLBERT ranges from 95.36% on Egyptian to 98.28% on Jordanian.

Overall, Jordanian Arabic is the easiest dialect across all three models, while Moroccan Darija and Egyptian Arabic are comparatively more challenging. MARBERTv2's consistent advantage suggests that its dialect-oriented pretraining provides stronger representations for the linguistic variability in this task, which is also reflected in the held-out evaluation, where it achieves 94.07% Macro-F1 compared with 81.96% for CAMeLBERT and 79.77% for AraBERTv2.

5.4 Convergence and Generalization

AraBERTv2 improves rapidly during the first three epochs, reaching macro F1=0.9038 at epoch 3, followed by smaller fluctuations and a maximum of 0.9092 at epoch 7. MARBERTv2 improves from 0.7112 at epoch 1 to 0.9441 at epoch 5 and reaches 0.9539 at epoch 6, after which its validation performance stabilizes near 0.951. CAMeLBERT exhibits a slower but sustained improvement, increasing from 0.6601 at epoch 1 to 0.8923 at epoch 9 before a small decline at epoch 10. These trajectories justify retaining the best checkpoint rather than automatically using the final epoch.

6 Discussion

The experimental results indicated that pretrained representation choice is a major determinant of performance in this multi-dialect setting. MARBERTv2 consistently outperforms AraBERTv2 and CAMeLBERT under the same optimization system. This result is consistent with prior findings that dialectal data exposure and pretraining variant proximity matter for downstream Arabic NLP tasks. It also aligns with the literature review's observation that MARBERTv2 has performed strongly on dialectal sentiment benchmarks.

The neutral-class weakness deserves particular attention. Although the benchmark is balanced at the dataset level, neutral sentiment is semantically less polarized than negative or positive sentiment and may contain lexical cues that overlap with both classes. The substantially higher neutral F1 obtained by MARBERTv2 suggests that dialect-oriented pretraining may help capture contextual distinctions that are difficult for more general Arabic representations.

7 Conclusion

This study presented a transformer-based system for DialectSentEval 2026 Subtask 1 and evaluated AraBERTv2, MARBERTv2, and CAMeLBERT independently under a shared training protocol. The system uses stratified validation, fixed random seeds, and validation macro-F1 checkpoint selection to promote the best model. Across the validation runs, MARBERTv2 achieved the highest performance with a macro F1 of 0.9539 using only

6 epochs, and then AraBERTv2 and CAMeLBERT achieved macro F1 of 0.9092 and 0.8923, respectively. Additionally, MARBERTv2 also showed the strongest class-balanced behavior, particularly for the neutral class.

Abstract

Arabic sentiment swap aims to reverse the polarity of a dialectal sentence while preserving its underlying meaning. We present NAMAA's system for DialectSentEval 2026 Subtask 2. Fine-tuning AraT5v2 achieves 79.56 development sentiment-style accuracy, while reranked sampling over eight candidates, using sentiment agreement and content-overlap signals, raises this to 93.57. Cross-backbone ensembling further reaches a development score of 96.78. On the hidden test set, however, this ordering does not transfer: a widened rerank pool with a re-tuned content weight achieves our best official score of 0.7597, whereas the most complex all-source ensemble scores 0.7343. We identify two likely contributors to this development-to-test mismatch: the absence of gold source-polarity labels at test time, which requires classifier-based polarity inference, and train–development sentence duplication that may inflate development performance. These results show that additional generation and ensemble complexity can improve development metrics substantially without guaranteeing better generalization under shifted evaluation conditions.

1 Introduction

Sentiment style transfer aims to reverse the polarity of a sentence while preserving its underlying meaning and relevant content. This task is particularly challenging for Arabic because sentiment is expressed across substantial morphological, lexical, orthographic, and dialectal variation, often alongside code-switching. DialectSentEval 2026 Subtask 2 (Ezzini et al., 2026a) formulates this problem as dialectal Arabic sentiment swap using an extended, dialect-augmented version of the MA'AKS parallel corpus (Mughaus et al., 2026). The task requires systems to balance two competing objectives: reliably reversing sentiment polarity while maintaining content close to the intended rewritten sentence.

We approach the task with a sequence-to-sequence generation framework augmented by candidate reranking and cross-backbone ensembling. Fine-tuned Arabic generation models provide the initial candidate space, after which multiple sampled hypotheses are evaluated using sentiment agreement and content preservation signals. This substantially improves development performance: reranked sampling raises sentiment-style accuracy from 79.56 to 93.57, while cross-backbone ensembling reaches 96.78. However, this development-time advantage does not translate directly to the hidden test set, where our best official submission achieves 0.7597 and a simpler reranking configuration outperforms the most complex ensemble.

Our main contributions are threefold. First, we introduce a reranked-sampling strategy that selects among multiple generated candidates using sentiment and chrF-based content signals, providing the largest improvement over single-output decoding. Second, we investigate cross-backbone ensembling together with non-neural lexical baselines, including antonym substitution, negation editing, and masked-span infilling, to characterize the value of generative model diversity. Third, we analyze the substantial development-to-test mismatch and identify two important factors: the absence of gold source-polarity labels at test time and measurable train-development duplication. These findings suggest that increasing generation and ensemble complexity is not sufficient when evaluation-time conditions differ from those available during development.

2 Related Work

DialectSentEval 2026 Subtask 2 (Ezzini et al., 2026a) formulates Arabic sentiment swap as a controlled generation task: given a dialectal Arabic sentence and its source polarity, the system must produce a sentence with the opposite sentiment while preserving the original semantic content. The

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1436–1440

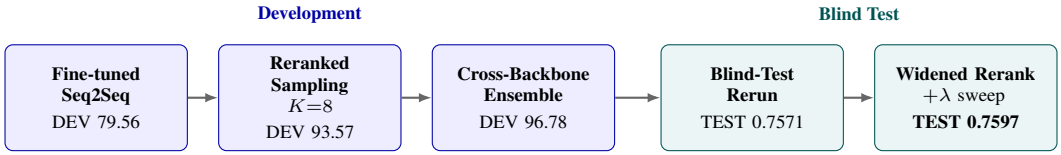

Figure 1: System progression from fine-tuned Seq2Seq models through reranked sampling and cross-backbone ensembling.

task covers four broad dialect groups—Maghrebi, Egyptian, Gulf, and Levantine—although individual examples are not accompanied by explicit dialect labels. Its dataset, *MA'AKS Extended*, expands the original 5,000-pair MSA-only MA'AKS corpus (Mughaus et al., 2026) with dialectal data, yielding 9,647 pairs: 6,752 for training, 964 for development, and 1,931 for blind testing. Training and development examples provide parallel target rewrites, whereas the blind test contains only `id` and `source`.

Evaluation considers both sentiment reversal and content preservation. Sentiment style accuracy is computed with CAMeLBERT-DA-sentiment (Inoue et al., 2021), measuring whether the generated sentence matches the intended opposite polarity. Content preservation is evaluated with BLEU and chrF against the reference rewrite. From CodaBench scorer outputs, we verified that this comparison is performed against the gold target rather than the source sentence. The exact formula used to combine these criteria into the single leaderboard score is not publicly specified; accordingly, we report the official composite scores without inferring their internal weighting and use an identity system as our own development baseline.

Prior Arabic sentiment-analysis research has progressed from lexical and classical machine-learning approaches toward pretrained Transformer models, while robustness across dialects remains challenging (Shi and Agrawal, 2025). Sentiment swap is more closely related to controllable text and style-transfer generation than to conventional sentiment classification. Early style-transfer work demonstrated that textual attributes can be modified while attempting to preserve semantic content (Shen et al., 2017). For generation, sampling and reranking provide an alternative to deterministic beam or greedy decoding, whose mode-seeking behavior may not reflect the broader model distribution (Eikema and Aziz, 2020). Related optimization approaches include REINFORCE (Williams, 1992) and Minimum Risk Training (Shen et al., 2016), which directly optimize non-differentiable sequence-level objectives.

A closely related but separate evaluation, AraSentEval (Ezzini et al., 2026b), uses the original MSA-only MA'AKS data for sentiment swap. Its winning system combines AraBART and AraT5v2 with targeted data augmentation (Hamdy et al., 2026). Although AraSentEval and DialectSentEval share dataset lineage and task framing, they are distinct competitions with different data conditions and should therefore not be compared by directly merging their reported scores.

3 System Overview

Figure 1 summarizes our approach: fine-tuned backbones, reranked sampling, then cross-backbone ensembling, with non-neural lexical baselines for contrast.

3.1 Fine-tuned Sequence-to-Sequence Backbones

We fine-tuned four encoder-decoder backbones on the 6,752 training pairs (AraT5v2-base-1024, AraT5-base, mT5-base, AraBART) under two input formats: a control-code *prefix tag* and an *Arabic instruction prompt*. AraT5v2 with the Arabic prompt (S06a) was strongest at 79.56 development sentiment-style accuracy; AraT5-base trailed at 60.27, mT5-base at 67.12, AraBART at 76.87 as shown in Table 1. A beam width sweep (4→8) moved this by only −0.20, showing decoding width was not the bottleneck.

3.2 Reranked Sampling

Rather than decoding greedily, we sample K=8 candidates (temperature 0.9, top-p 0.95) from the strongest checkpoint, classify each with the scoring classifier, and pick the candidate maximizing $100 \cdot \mathbb{1}[\text{style match}] + \lambda \cdot \text{chrF}(\text{candidate}, \text{source})$, λ=0.3 (reranked against *source*, not the unavailable gold target, to stay deployable). This raised development accuracy from 79.56 to 93.57, a 14-point jump for no extra training cost. It was the biggest lever we found.

3.3 Cross-Backbone Ensembling

Reranked sampling on a second backbone (AraBART), combined with the AraT5v2 pool and

a beam-decoded source, reranked jointly: diversity compounded a 3-source ensemble to 88.28, a 5-source ensemble to 90.04, and our "grand ensemble" (AraT5v2 reranked + AraBART reranked + beam control) to 96.78, our development ceiling (Table 1).

Non-neural lexical baselines. Three training-free contrastive baselines: a mined *antonym substitution table* (48.76, word-aligned majority replacements, 860/964 rows covered); *rule-based negation insertion/removal* (23.34, barely above identity); and *masked-span substitution* via occlusion saliency + BERT fill-mask (53.53–58.40), extended to a tag-then-infill variant (57.78). All trail the fine-tuned backbones by a wide margin. Figure 2 shows why: most of the 560 failures need more than a single-word fix, consistent with reranked generation's much larger gain (Section 3.2).

4 Experimental Setup

Data. Training (6,752) and development (964) are fully parallel; the blind test file (1,931) carries only `id` and `source`. Since our pipeline needs the current polarity to flip, we infer `source_polarity` on test via the scoring classifier on the source, remapping Neutral to the higher-scoring polarity (9.4% of rows); this circular step is one cause of the development/test gap (Section 6).

Training and decoding. Fine-tuned with the Hugging Face `Seq2SeqTrainer` (Wolf et al., 2020): batch size 16 (32 for the earliest run), 8 epochs, lr 3×10^{-4}, 10% warmup, early stopping (patience 3) on development style accuracy, max length 96, beam width 4. Reranked sampling: temperature 0.9, top-p 0.95, K=8, λ=0.3 (Section 3.2).

Reproducibility of test-phase submissions. Ten systems were submitted for the blind test phase (named in Table 2): fixed/widened reranked-ensemble reruns (1, 5), added candidate sources (2, 9), iterative self-refinement (4), a Minimum-Risk-Training fine-tune (Shen et al., 2016) against the reranking reward (6), a λ-bracketing probe (7, 8), and a grand ensemble (10). Only system (5)'s lineage is fully locally reproducible; the rest were submitted directly to CodaBench, and we report their official scores (see Limitations).

Metrics and tools. We evaluate content preservation with BLEU using `sacrebleu` (Post, 2018) and chrF (Popović, 2015). Model training and inference use Hugging Face `transformers` (Wolf et al., 2020), including AraT5v2 (Elmadany et al., 2023; Nagoudi et al., 2022), AraBART (Kamal Eddine et al., 2022), mT5 (Xue et al., 2021), and CAMeLBERT-DA-sentiment (Inoue et al., 2021). Official blind-test evaluation is performed through CodaBench (Xu et al., 2022). Our code[1] and released checkpoints[2] are publicly available.

(10) Grand ensemble (all sources)	0.7343

Table 2: Official CodaBench Sentiment Swap composite scores for the blind test phase.

5.3 Error Analysis

Systems (7) and (8) rerank the identical candidate pool with λ pushed toward opposite extremes (near-pure style vs. content) and score identically at 0.7582, matching system (1)'s unmodified λ=0.3: within this candidate pool, the leaderboard composite appears insensitive to this reranking weight, suggesting the pool's diversity, not the rerank weighting, binds this test distribution. System (6), the only submission that fine-tunes further (Minimum-Risk-Training against the reranking reward), scores lowest among the gradient-based variants (0.7193), below even the identity-style rerank baselines, indicating this reward does not transfer cleanly into a training objective at this scale. Most strikingly, system (10), the richest ensemble folding in every candidate source we built, scores 0.7343, below every system except (6) and (2), and well below system (1)'s much simpler fixed rerun (0.7582): the diversity-via-ensembling pattern that reliably improved development sentiment-style accuracy (Section 3.3) does not reproduce on test, where the reranker chooses among noisier, inferred-polarity candidates rather than clean, gold-polarity ones.

6 Discussion

The development log as shown in Table 1 is not predictive of test-set ranking, not from simple overfitting: no system trains on or copies development gold targets, since reranking deliberately scores against *source*, not *target*, avoiding a non-deployable oracle as shown in Section 3.2. Two factors likely contribute to the gap. First, every system needs a gold `source_polarity` label to know which direction to flip; development gives this as ground truth, but the blind test file does not, forcing a circular classifier-based inference as referred to in Section 4 that likely drives why the development-winning ensemble's direct carry-over (0.7571) sits far below its 96.78 development score. Second, using EDA on the released source text, we found 123/964 (12.8%) development source sentences exactly duplicate training sentences, plus substantial within-split duplication (17% training, 7% development), inflating the development ceiling for anything that indirectly relies on having seen a near-identical training example. Development ranking is accordingly a poor guide to generalization: the simplest carried-over system (5) outperforms the most elaborate one (10) on the split that matters.

7 Conclusion

We presented a reranked-sampling and cross-backbone ensemble for Arabic dialectal sentiment swap. Reranking was the strongest development-time improvement, while the best hidden-test result came from a simpler widened rerank pool, reaching 0.7597. The development-to-test gap is likely influenced by missing test-time polarity labels and train-development duplication, while the unpublished leaderboard formula and reliance on the same sentiment classifier for reranking and evaluation further limit interpretation. Future work should prioritize robust polarity inference and cleaner evaluation over additional ensemble complexity.

Ethical Considerations

Automated sentiment-polarity inversion is dual-use: it could fabricate opposite-sentiment reviews at scale; we release it for research only. Our EDA found uneven dialect-marker representation (Levantine 20.5% of rows, Maghrebi 2.2%), so performance may vary across unlabeled dialects.

Abstract

We describe our submission to DialectSentEval 2026 Subtask 1, a three-class sentiment task covering Moroccan, Egyptian, Lebanese, Jordanian, and Saudi Arabic. Our system fine-tunes MARBERTv2 in five stratified folds and averages their test probabilities. Using raw text without explicit dialect conditioning or external task-specific data, the official submission obtained 0.7939 macro-F1, 0.8152 accuracy, 0.7917 macro precision, and 0.7987 macro recall, ranking eighth among twelve systems in the supplied snapshot. In post-submission MARBERTv2 validation, final-epoch mean fold macro-F1 decreases from 0.9038 with row-stratified folds to 0.8095 when connected components linking repeated ID–label groups and normalized duplicate texts are kept within folds, an absolute difference of 0.0944. These internal validation scores do not alter the official test result. Best-epoch selection, normalization, and dialect tags provide no material gain under the strict protocol.

1 Introduction

Dialectal Arabic sentiment analysis must handle non-standard spelling, code-switching, regional vocabulary, negation, and sentiment-bearing emoji or elongation (Shi and Agrawal, 2025). DialectSentEval 2026 Subtask 1 evaluates sentence-level sentiment prediction across five Arabic dialects (Ezzini et al., 2026a). The task is important because a model trained on one regional variety may misinterpret expressions from another.

Our strategy is a uniform soft-voting ensemble of five MARBERTv2 models. MARBERT is pretrained on Arabic social-media text and is therefore well matched to dialectal language (Abdul-Mageed et al., 2021). We fine-tune one model per cross-validation fold and average their probability vectors. The system achieved 0.7939 official macro-F1 and placed eighth in the supplied twelve-entry leaderboard snapshot. Because macro precision and macro recall differ by only 0.0070, the aggregate scores do not identify a single dominant error type. Our contribution is twofold: we document the official five-fold MARBERTv2 configuration and result, and we provide a post-submission MARBERTv2 comparison showing that internal validation is substantially sensitive to whether linked instances cross folds.

2 Background

2.1 Task and dataset

For an input sentence x, the system predicts $y \in \{\texttt{negative}, \texttt{neutral}, \texttt{positive}\}$. For example, the constructed Egyptian transliteration *el-film da gamil awi* ("this film is very nice") should receive `positive`. This example illustrates the input–output format and is not taken from the evaluation data.

The official task description identifies the resource as Multi-Dialect-Sent (MDS-3), a balanced dataset of 3,000 Moroccan, Egyptian, Lebanese, Jordanian, and Saudi sentences (Ezzini et al., 2026a). The dataset consists of hotel reviews translated and sentiment-annotated by native speakers of the respective dialects. The actual training artifact contains 1,731 rows: 657 negative, 465 neutral, and 609 positive. It contains Darija (433), Egyptian (432), Jordanian (433), and Saudi (433), but no Lebanese training row. The training artifact therefore provides no supervised Lebanese examples. The artifacts used in our submission comprised 1,731 labeled training instances and 525 test instances, totaling 2,256 examples. We report these artifact-level counts without making assumptions about the allocation of the remaining 744 examples, which could not be determined from the supplied artifacts. We participated only in Subtask 1 and used no explicit dialect feature in the official system.

2.2 Related work

BERT-style encoders support end-to-end classification without a manually constructed sentiment lexicon (Devlin et al., 2019). Arabic models such as MARBERT improve domain alignment by pretraining on large Arabic corpora with substantial dialectal social-media coverage (Abdul-Mageed et al., 2021). ADOR provides a human benchmark of Arabic-dialect hotel reviews (Alharbi et al., 2025b), while the AHaSIS shared task established a related hospitality-domain sentiment benchmark (Alharbi et al., 2025a). Large language models have also been evaluated on sentiment classification across Arabic varieties (Alharbi et al., 2025c). The related AraSentEval shared task jointly studied multi-dialect sentiment classification and Arabic sentiment swapping (Ezzini et al., 2026b). Within this setting, we document the submitted ensemble and complement accuracy-oriented reporting with an audit of whether repeated and duplicate instances can compromise internal validation.

3 System Overview

3.1 Input representation and model

We initialize `UBC-NLP/MARBERTv2` with a randomly initialized three-label sequence-classification head. Each sentence is converted to a string and passed directly to the model tokenizer. Inputs are truncated or padded to 128 tokens, a compute-conscious setting for the short-review domain; the submitted run did not log the proportion of truncated examples. We apply no Arabic normalization, stemming, or segmentation. Alef and ya variants, ta marbuta, diacritics, tatweel, punctuation, emoji, and elongation are left unchanged. We use no external task-specific corpus, lexicon, or pseudo-labeled data; the only external resource is the pretrained MARBERTv2 checkpoint.

3.2 Five-fold ensemble

We construct five sentiment-stratified folds using seed 42. Four folds are used for training and one for validation in each run. A fresh MARBERTv2 model is trained for four epochs. Let $p_m(y \mid x)$ be the probability assigned by fold model m. The submission uses uniform soft voting:

$$\bar{p}(y \mid x) = \frac{1}{5} \sum_{m=1}^{5} p_m(y \mid x), \qquad \hat{y} = \arg\max_{y} \bar{p}(y \mid x). \tag{1}$$

Setting	Value
Encoder	MARBERTv2
Folds / epochs	5 / 4
Batch size / max length	16 / 128
Learning rate	2×10^{-5}
Weight decay / warm-up	0.01 / 0.10
Random seed	42

Table 1: Submitted system configuration.

This is the only configuration included in the official submission.

4 Experimental Setup

The submitted notebook divides rows through five-fold sentiment-stratified cross-validation; the 525-instance test set is used only to produce the official submission. No separate organizer development set is used. Training uses AdamW (Loshchilov and Hutter, 2019), linear decay with 10% warm-up, and gradient clipping at 1.0. Table 1 lists the main settings.

The implementation uses PyTorch, Hugging Face Transformers, pandas, NumPy, and scikit-learn. Training comprised five MARBERTv2 fine-tuning runs, one per fold. It ran on a Google Colab CUDA device, but the exact software versions, GPU model, and wall-clock runtime were not preserved. Validation accuracy and macro-F1 are computed each epoch, but the archived system uses the final rather than the best validation epoch. The fold-level metric logs and OOF probabilities generated during execution were not retained in the archived submission.

Post-submission inspection revealed only 376 unique IDs. All 376 occur in multiple dialects, 397 of the 596 ID–label groups span multiple dialects, and 204 IDs occur with more than one sentiment label. Because grouping by ID alone would merge label-distinct items, we link rows that share either a `(ID, Sentiment)` pair or normalized duplicate text. Transitive closure produces 591 connected components, the largest containing 12 rows, with no component containing conflicting labels. For the MARBERTv2 follow-up, shuffled `StratifiedGroupKFold` with seed 42 assigns these components to folds of 339, 338, 355, 353, and 346 rows. Leakage checks find no component, ID–label group, or normalized text shared across a training–validation boundary.

The official ranking metric is macro-F1, $F_{1,\text{macro}} = \frac{1}{3}\sum_c F_{1,c}$, which weights the three

Official measure	Score

classes equally. The server also reports accuracy, macro precision, and macro recall.

5 Results and Analysis

5.1 Official submission results

Table 2 reports official test results for submission ID 869067. No post-submission result is mixed into this table.

The seventh-place score is only 0.0014 higher, and the fifth-place score is 0.0072 higher. The leader reaches 0.8667, a gap of 0.0728. Macro recall exceeds macro precision by 0.0070, while accuracy exceeds macro-F1 by 0.0213. This profile confirms that accuracy alone is not a suitable selection criterion, but the available official aggregates do not reveal which classes or error directions account for the difference.

Only the ensemble was submitted to the official server. Because neither a separate single-model test submission nor the fold-level test probabilities were retained, these results document the achieved configuration but do not isolate the gain from probability averaging. Similarly, the higher-ranked systems were not reproduced, so the rank and score gaps above are descriptive rather than controlled comparisons. Gold test labels and submitted-system OOF predictions were unavailable for a MARBERTv2 confusion matrix or dialect-level error analysis.

5.2 Post-submission MARBERTv2 validation

We retrain MARBERTv2 with the submitted hyperparameters to compare the original row-stratified validation design against the connected-component split. Table 3 reports the mean and sample standard deviation of the five fold-level macro-F1 scores. These are post-submission internal validation results, not official test scores.

Using the final epoch, which matches the official checkpoint policy, the mean score decreases from 0.9038 under row stratification to 0.8095 under strict grouping, an absolute difference of 0.0944. The best-checkpoint gain is only 0.0002 for the row split and 0.0005 for the strict split, so checkpoint selection does not explain the split effect. Under strict evaluation, normalization and dialect tagging are slightly below raw text. Because the validation partitions differ, these results demonstrate split sensitivity but should not be interpreted as a numerical correction to the official test score. They are means of fold-level macro-F1 rather than pooled OOF scores.

6 Conclusion

We presented a five-fold MARBERTv2 ensemble for DialectSentEval 2026 Subtask 1. The system uses minimal preprocessing and no explicit dialect conditioning, obtaining 0.7939 official macro-F1 and ranking eighth in the supplied snapshot. Its principal limitations are the lack of preserved system-specific OOF predictions, final-epoch checkpointing, and the susceptibility of the original row-level design to linked instances crossing folds. A post-submission MARBERTv2 comparison confirms this sensitivity: final-epoch mean fold macro-F1 decreases by 0.0944 under connected-component validation. Best-epoch selection, normalization, and dialect tags do not improve the strict-split mean. Future work should isolate the contribution of ensembling on a common labeled test set and preserve OOF predictions for class- and dialect-level analysis.

Limitations

The submitted notebook does not preserve package versions, exact GPU, wall-clock time, fold-level metric logs, MARBERT out-of-fold predictions, or instance-level system errors. The training procedure generated validation probabilities in memory, but they were not retained in the archived artifacts. It also cannot be rerun unchanged because a packaging cell overwrites an input path with generated output. This does not affect the recorded official score, but a release should separate immutable inputs from generated files and add schema valida-

tion. The run also did not record the number of inputs truncated at 128 tokens.

No official single-model test result was preserved, so the contribution of five-fold probability averaging cannot be isolated. The post-submission MARBERTv2 comparison uses one split seed and reports fold-level means from a single training run per fold; it does not provide uncertainty across training seeds. Its OOF predictions were not exported, preventing pooled OOF, class-level, dialect-level, or instance-level analysis. The unavailable gold test labels also prevent a controlled single-model versus ensemble test comparison. Aggregate scores can conceal uneven behavior across dialects and should not support high-impact decisions without human review.

Ethical Considerations

Sentiment predictions may reproduce dialect and class imbalances in the training data. The system should not be used for automated moderation, profiling, or other high-impact decisions without dialect-aware evaluation and human oversight. We include no user identifiers. Any reuse or redistribution of the task data should follow the organizers' licensing and access conditions.

A Submitted-System Reproducibility Details

The archived submission notebook maps `negative`, `neutral`, and `positive` to label IDs 0, 1, and 2, respectively. It seeds NumPy, PyTorch, and all CUDA devices with 42. The submitted procedure is:

1. Read the training and test CSV files and convert each sentence to a string without text normalization or dialect prefixes.
2. Construct five folds with shuffled `StratifiedKFold`, stratifying by sentiment label and using random state 42.
3. For each fold, initialize a fresh `UBC-NLP/MARBERTv2` sequence classifier with three output labels. Tokenize to 128 positions with truncation and fixed-length padding.
4. Train for four epochs with shuffled training batches of size 16. Use AdamW with learning rate 2×10^{-5} and weight decay 0.01, a linear scheduler whose first 10% of steps are warm-up steps, and a gradient-norm limit of 1.0.
5. After the fourth epoch, compute validation and test softmax probabilities. Use the validation probabilities as in-memory OOF predictions and add one fifth of the test probabilities to the ensemble accumulator. The OOF arrays were not written to a retained artifact, and no best-epoch checkpoint is selected.
6. Apply `argmax` to the averaged test probabilities, map the indices back to the three text labels, and export the `ID` and `Sentiment` columns.

Training batches are shuffled, whereas validation and test batches are not. The notebook records validation accuracy and macro-F1 after every epoch and saves the final state of each fold model. It does not preserve deterministic backend settings, package versions, the GPU model, or elapsed training time.

B Strict Post-Submission MARBERTv2 Split Construction

The strict folds are used only for the post-submission MARBERTv2 comparison. They do not alter the official result. We first construct a normalized duplicate key by applying Unicode NFKC normalization, removing tatweel, diacritics, and punctuation, converting to lowercase, and collapsing whitespace. Rows are then joined into connected components when they share either the same `(ID, Sentiment)` pair or the same normalized text. A normalized duplicate with conflicting sentiment labels causes the procedure to stop for manual resolution rather than being silently split. No such conflicting normalized group was observed in the 1,731-row training artifact.

The construction yields 591 connected components, with a largest component of 12 rows. We pass the component identifiers to shuffled `StratifiedGroupKFold` with five splits and random state 42. The fold sizes are 339, 338, 355, 353, and 346. Leakage checks confirm that no component, linked ID–label group, or normalized duplicate crosses a training–validation boundary.

C Scope of the Post-Submission MARBERTv2 Results

The follow-up uses the same encoder, optimizer, sequence length, batch size, learning rate, epoch count, and base seed as the submitted system, with fold-specific seeds $42 + m$ for fold index m. It ran with Python 3.13.15, PyTorch 2.11.0+cu128, and an NVIDIA Tesla T4. Table 3 reports the mean and sample standard deviation of five fold-level macro-F1 values. Best checkpoints are selected by validation macro-F1 within each fold. The notebook did not export the OOF prediction arrays, and its test-data stage was not completed because the expected test filename was unavailable. Consequently, the results do not include a single-model versus ensemble test comparison or MARBERTv2 error analysis and must not be presented as official leaderboard scores.

Lahja at DialectSentEval Shared Task Subtask-1: Seed-Ensembled MARBERT for Multi-Dialect Arabic Sentiment Analysis with Zero-Shot Lebanese Transfer

Shaden Alzeer

raja.akram@abdn.ac.uk

Abstract

Arabic sentiment analysis must cope with dialects that differ in vocabulary, morphology and spelling. Subtask 1 of the DialectSentEval 2026 shared task poses this problem directly: systems label hotel review sentences from five Arabic dialects as positive, negative or neutral, and one dialect (Lebanese) appears only in the test set. In this paper, we describe the Lahja submission. Since the training corpus is small (1,731 sentences) and consists of parallel translations, we treat unreliable measurement (i.e. leaky validation splits and single training runs) rather than model capacity as the main risk. We fine-tune MARBERTv2 under three random seeds, average their softmax outputs, and validate on a split grouped by review identifier so that all dialect versions of a review stay on the same side. The ensemble reached 0.790 macro-F1 on the official test set, ranking 10th of 12 teams, and lost only about two points from validation to test despite the unseen dialect. Our ablations show that the variation between seeds (about 1.5 points) exceeds the effect of orthographic normalisation or class weighting, and that the normalised ensemble, although best on validation, generalised worst on test. We therefore recommend grouped validation and seed-spread reporting as standard practice for small-data shared tasks.

1 Introduction

Sentiment analysis for Arabic is complicated by the dialectal diversity of the language. The varieties spoken across the Arab world differ in vocabulary, morphology and orthographic habits, and systems trained on one variety often degrade on others. The DialectSentEval 2026 shared task (Ezzini et al., 2026a) is the successor to the AraSentEval pilot (Ezzini et al., 2026b) and includes a companion sentiment-swapping subtask built on the MA'AKS dataset (Mughaus et al., 2026). Subtask 1 frames the dialect challenge concretely: systems classify hotel review sentences from five dialects as positive, negative or neutral, and are evaluated by macro-F1. The twist that shaped our approach is that one dialect, Lebanese, appears *only* in the test set, so a fifth of the evaluation is zero-shot dialect transfer.

With fewer than two thousand training sentences arranged as parallel translations, the question we set out to answer was a practical one: can such a corpus support trustworthy system development at all? Anyone who has tuned a classifier on a corpus of this size knows how easily a lucky seed can pass for an improvement. Therefore, we judged that the main risk was not underfitting but *mismeasurement* (i.e. validation splits that leak parallel content and conclusions drawn from single runs), and we wrapped a deliberately simple system, a fine-tuned MARBERTv2 ensembled over three seeds, in careful measurement.[1] The salient contributions of this paper are as follows. First, we present a seed-ensembled MARBERTv2 system that reached 0.790 test macro-F1 (10th of 12 final-phase teams) and was trained in under ten minutes on a consumer laptop. Second, we describe an ID-grouped validation protocol for parallel dialect corpora whose dev scores predicted official test performance within 1.5 to 2.3 points despite the unseen dialect. Third, we report a transparent ablation study showing that seed variance (about 1.5 F1) exceeds the effect of orthographic normalisation and class weighting, neither of which transferred to the test set.

2 Related Work

Arabic sentiment analysis has largely moved from feature-based models over Modern Standard Arabic (MSA) to pretrained transformers. Dialect-focused encoders, such as MARBERT (Abdul-

October 28-29, 2026 ©2026 Association for Computational Linguistics

Mageed et al., 2021), trained on tweet-scale dialectal text, and the CAMeLBERT family (Inoue et al., 2021), which studies the interplay of language variant and task, consistently outperform MSA-centric models such as AraBERT (Antoun et al., 2020) on dialectal benchmarks. Shared tasks have driven much of this progress. AHaSIS (Alharbi et al., 2025a) and the related ADOR benchmark (Alharbi et al., 2025b) evaluated hotel review sentiment in Saudi and Moroccan dialects (twelve systems, best macro-F1 0.81), large language models have been evaluated on the same problem (Alharbi et al., 2025c), and DialectSentEval builds on the AraSentEval pilot (Ezzini et al., 2026b). To our knowledge, it is among the first shared tasks to evaluate sentiment transfer to a dialect that is entirely unseen in training. Our contribution is less a new architecture than a measurement protocol for such parallel, low-resource settings, following work that shows that seed variance in fine-tuning rivals reported improvements (Reimers and Gurevych, 2017; Dodge et al., 2020; Mosbach et al., 2021) and that the way a corpus is split shapes the conclusions drawn from it (Gorman and Bedrick, 2019; Søgaard et al., 2021).

3 Data

The Subtask 1 release of the MDS-3 corpus (Ezzini et al., 2026a) contains 1,731 training sentences in four dialects (Moroccan Darija, Egyptian, Jordanian and Saudi, approximately 433 each) and 525 blind test sentences in five dialects (105 each), with **Lebanese appearing only at test time**. The sentences are hotel reviews rendered into each dialect by native speakers. Therefore, the corpus has a *parallel* structure: the same underlying review appears in every dialect under a shared identifier (ID). Training has 376 review IDs; reviews of more than one sentence share an ID, and one review lacks an Egyptian version, hence 1,731 sentences. The labels are *positive*, *negative* and *neutral* (38%, 35% and 27% of the training data, respectively). Interestingly, 201 of the 376 training review IDs carry *different* gold labels across their dialect versions, which suggests that dialectal rendering can shift perceived sentiment.

To gauge the difficulty of the unseen dialect, we measured word-level Jaccard overlap between dialect vocabularies (Figure 1). Training dialects overlap each other at 0.19 to 0.48, whereas the Lebanese test vocabulary overlaps each training dialect at only 0.07 to 0.11. Zero-shot transfer to Lebanese therefore cannot rely on shared surface vocabulary and must come from the pretrained encoder. For transparency, we note that 58 Egyptian test sentences occur verbatim, with labels, in the training data (an artefact of the data preparation); we did not exploit this overlap in any way.

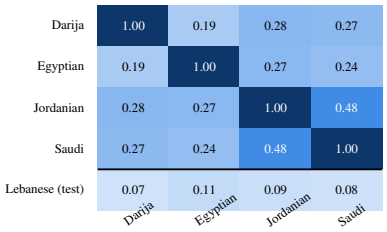

Figure 1: Word-level Jaccard overlap between dialect vocabularies. Training dialects (above the line) share 0.19 to 0.48 of their vocabulary, whereas the test-only Lebanese data (below the line) share just 0.07 to 0.11 with every training dialect. Therefore, zero-shot transfer cannot rely on lexical memorisation.

4 System Description

Validation protocol. As the corpus is parallel, a conventional row-level random split would place different dialect versions of the *same* review on both sides of the train/validation boundary, and a model could then score on content that it has effectively seen. We instead split *by review ID* (85/15, stratified by the most frequent label of each ID, with a fixed seed), keeping all dialect versions of a review on the same side. This yields 1,467 training and 264 validation sentences with zero content overlap. As Section 5 shows, this protocol predicted official test performance within 1.5 to 2.3 macro-F1 points although 20% of the test set is an unseen dialect, and we therefore consider it a prerequisite for trustworthy development on parallel dialect corpora.

Model. Our backbone is MARBERTv2 (Abdul-Mageed et al., 2021), a BERT-base encoder pretrained on roughly one billion Arabic tweets and further pretrained on MSA text with 512-token sequences. The choice follows directly from the vocabulary analysis in Section 3. Since zero-shot Lebanese transfer cannot rely on surface overlap with the training dialects, it must come from the pretraining of the encoder, and tweet-scale pretraining offers the broadest dialectal exposure available. We fine-tune the encoder with a standard classification head using the Transformers li-

brary (Wolf et al., 2020), with a learning rate of 2×10^{-5}, a batch size of 16, 4 epochs, AdamW with 10% linear warm-up, a weight decay of 0.01 and a maximum sequence length of 128 (the 99th percentile of MARBERT token lengths in the data is 77, so no truncation occurs in practice). After each epoch we evaluate on the validation split and keep the checkpoint with the best macro-F1 (full configuration in Appendix A).

Final system. We train three runs that differ only in their random seed (42, 43 and 44) and average their softmax distributions at inference, which is the deep-ensemble recipe of Lakshminarayanan et al. (2017); majority voting can tie with three models, whereas probability averaging cannot.[2] Each run takes about three minutes on a consumer laptop (Apple M-series, MPS backend), so the entire final system costs under ten minutes of compute. As a sanity floor, we also report a linear SVM over TF-IDF features (word 1–2-grams and character 3–5-grams).

5 Experiments and Results

Table 1 summarises our experiments. The classical floor (TF-IDF features with a linear SVM) reaches 0.728 dev and 0.709 test macro-F1. A single fine-tuned MARBERTv2 adds roughly seven points (0.802 dev and 0.787 test), and averaging three seeds adds a further 0.3 (test) to 1.1 (dev) points. This yields our final official score of **0.790 test macro-F1** (accuracy 0.813), which placed our system **10th of the 12 teams** on the final-phase leaderboard. However, ranks 5 to 11 span only 1.5 macro-F1 points (0.801 to 0.786), a band no wider than the seed variance we measure in Section 6. Therefore, mid-table orderings in this task

[2]Code: https://github.com/Shaden-Saad/DialectSentEval2026.

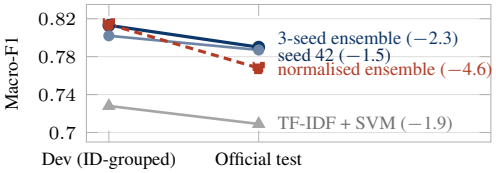

Figure 2: Dev-to-test generalisation of the four submitted systems (Table 1): raw-text systems lose 1.5 to 2.3 points, whereas the normalised ensemble loses 4.6.

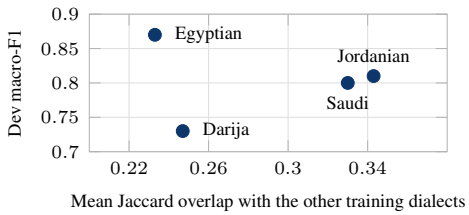

Figure 3: Per-dialect dev macro-F1 (single seed) against lexical distance (mean Jaccard overlap in Figure 1): the two most distinct dialects are the easiest and the hardest.

are likely to be statistically fragile (Dror et al., 2018).

Two comparisons are as informative as the headline number. First, Figure 2 plots the *dev-to-test gap* of each submitted system: our raw-text submissions lost only 1.5 to 2.3 points from dev to test, even though one fifth of the test set is a dialect absent from training, which is evidence both that ID-grouped validation is trustworthy and that the dialectal pretraining of MARBERT transfers to an unseen dialect. By contrast, the normalised ensemble scored highest on dev (0.814) yet dropped 4.6 points on test (0.768), the largest generalisation failure we observed; Section 6 examines why. Second, Figure 3 plots per-dialect dev scores against the vocabulary distances of Section 3, and the two only partially agree: the most lexically distinct dialects sit at opposite ends of the range, as Darija is hardest (0.73 macro-F1) while Egyptian is easiest (0.87), with Jordanian and Saudi in between (0.81 and 0.80; Appendix B).

6 Analysis

Where the errors live. Of the 47 errors that our single-seed model makes on the validation split, 45 involve the *neutral* class; the positive/negative boundary is almost solved (two errors). Typical failures are mixed-evaluation sentences, such as the Darija review *shi ghuraf 3andhum mandhar, u shi ghuraf ma 3andhumsh* ("some rooms have

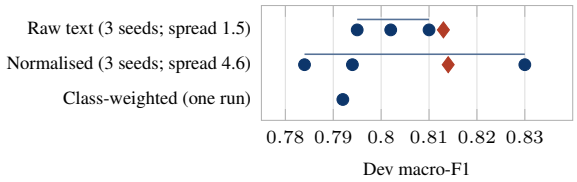

Figure 4: Seed variance versus interventions on dev: single runs (dots) span 1.5 points for raw text, normalisation widens the spread to 4.6, and the two ensembles (diamonds) are indistinguishable.

a view and some do not"; gold NEUTRAL, predicted NEGATIVE), and pleasant-topic descriptive sentences (e.g. "one minute from the nightclubs, cafés and restaurants"; gold NEUTRAL, predicted POSITIVE), where the gold label itself is sometimes debatable. Error position is also dialect-sensitive: of the 27 reviews with at least one erroneous dialect version, 16 are misclassified in *exactly one* dialect while their parallel versions are handled correctly, so most errors are triggered by the surface realisation of a review rather than by its content.

Seed variance exceeds every intervention we tried. Figure 4 shows every run we trained. Across seeds 42, 43 and 44, the identical configuration scores 0.802, 0.810 and 0.795 dev macro-F1, a spread of 1.5 points, and no preprocessing intervention we evaluated had a larger effect. Inverse-frequency class weighting *lost* a net 1.0 point (Appendix B), and orthographic normalisation (i.e. diacritic stripping, alef/ya/teh-marbuta unification and de-elongation) moved individual seeds by -1.8, $+2.0$ and -0.1 points, which is indistinguishable from noise. We conclude that single-run comparisons on corpora of this size are not interpretable, and we encourage future shared-task reports to publish seed spreads alongside headline scores (Reimers and Gurevych, 2017).

Normalisation fails exactly where it must not. Although the ensemble of three *normalised* runs scored highest on dev (0.814), it collapsed on test (0.768), a 4.6-point generalisation gap that is roughly double the largest gap among our raw-text submissions. Our hypothesis is that normalisation deletes precisely the orthographic cues that distinguish dialects, so MARBERT, which is pretrained on raw, un-normalised tweets, receives Lebanese input unlike anything that normalisation produced from the training dialects. Without per-dialect test scores we cannot verify this directly. However, a companion classical system that we built with comparable orthographic normalisation (a TF-IDF soft-voting ensemble of logistic regression and complement naive Bayes) showed the same signature, dropping from 0.763 under ID-grouped cross-validation to 0.668 on test. Finally, a six-model ensemble mixing raw and normalised inputs underperformed both three-model trios (0.810 dev), which suggests that averaging probabilities across models that read *different representations* of the input dilutes rather than diversifies the signal.

7 Conclusion

In this paper, we have described a simple, reproducible and rigorously measured system (MARBERTv2, three seeds and softmax averaging) that proved competitive on multi-dialect Arabic sentiment analysis and transferred to an unseen dialect with a dev-to-test gap of only two points. The interventions that promised more (class weighting and normalisation) delivered less, and the one that looked best on dev generalised worst on test. Our broader takeaway for small-data shared tasks is methodological: grouped validation and seed-spread reporting are cheap, and without them both system development and leaderboard interpretation rest on noise. Future work includes dialect-adaptive pretraining and better modelling of the neutral class.

Limitations

The training set is small (1,731 sentences) and single-domain, so our conclusions may not transfer to other genres. Without per-dialect test scores, our hypothesis that normalisation harms zero-shot Lebanese remains indirect. Three seeds estimate variance only coarsely, and some neutral-class errors reflect ambiguous gold labels (201 of 376 review IDs change label across dialects).

Ethical Considerations

We use the MDS-3 data solely under the terms of the shared task, do not redistribute them, and disclosed rather than exploited the train/test overlap (Section 3). Our per-dialect gaps (14 dev F1 points between Darija and Egyptian) show that deployment without per-dialect evaluation could disadvantage speakers of less-resourced varieties.

Acknowledgements

We thank the DialectSentEval 2026 organisers for a well-run shared task.

Appendices

The appendices record the configuration and the per-run results behind Sections 4 to 6 so that the system can be reproduced. They contain no new experiments: every number either appears in the main text or is derived from numbers that do.

A Training and Evaluation Details

Table 2 lists the configuration of the final system, of the two ablations and of the classical systems.

B Per-Run and Per-Dialect Results

Table 3 gives the dev macro-F1 of every run behind Table 1 and Figure 4. The per-seed scores of the normalised runs are derived from the raw-text scores and the per-seed changes reported in Section 6. Class weighting raised neutral recall from 0.66 to 0.70 but sacrificed neutral precision and the positive/negative boundary, hence its net loss of 1.0 point. Table 4 gives the per-dialect dev scores of the single-seed model together with the lexical distance used in Figure 3.

Dialect	Dev macro-F1	Mean Jaccard overlap
Moroccan Darija	0.73	0.247
Egyptian	0.87	0.233
Jordanian	0.81	0.343
Saudi	0.80	0.330

Table 4: Per-dialect dev macro-F1 of the single-seed model and the mean word-level Jaccard overlap of each dialect with the other three training dialects (from Figure 1).

Component	Setting
Data split	By review ID, 85/15, stratified by the most frequent label of each ID, fixed seed; 1,467 training and 264 validation sentences
Backbone	MARBERTv2 (BERT-base; tweet pretraining, then MSA continued pretraining with 512-token sequences)
Head	Standard sequence-classification head, three classes
Optimiser	AdamW, learning rate 2×10^{-5}, weight decay 0.01, 10% linear warm-up
Batch size, epochs	16, 4
Sequence length	128 tokens (99th percentile of token lengths in the data: 77)
Checkpoint	Best validation macro-F1 across epochs
Seeds	42, 43, 44 (otherwise identical configuration)
Ensembling	Mean of the softmax distributions of the three runs at inference
Hardware, time	Apple M-series laptop (MPS backend); about three minutes per run, under ten minutes in total
Software	Transformers library (Wolf et al., 2020)
Normalisation (ablation)	Diacritic stripping, alef/ya/teh-marbuta unification and de-elongation applied to the input text
Class weighting (ablation)	Inverse-frequency class weights (computed on the training split, normalised to mean 1) in the cross-entropy loss
Classical baseline	Linear SVM (balanced class weights) over TF-IDF word 1–2-grams and character 3–5-grams (classical-track submission)
Companion classical system	TF-IDF soft-voting ensemble of logistic regression and complement naive Bayes on normalised input; evaluated with ID-grouped cross-validation

Table 2: Configuration of the systems reported in this paper.

	Dev, per seed			Ensemble	
Configuration	42	43	44	Dev	Test
Raw text	0.802	0.810	0.795	0.813	0.790
Normalised	0.784	0.830	0.794	0.814	0.768
Class-weighted	0.792 (one run)			—	—
Raw + normalised	six models above			0.810	—

Table 3: Dev macro-F1 of the individual runs and of the ensembles. Raw-text runs have a mean of 0.802 and a standard deviation of 0.008; normalised runs 0.803 and 0.024.

NU-SentEval at DialectSentEval Shared Task Subtask-2: Fine-Tuning AraT5 for Arabic Dialect Sentiment Swap

Alaa Tamer, Areej Khaled*, Mariam Mazen, Ensaf H. Mohamed,
Correspondence: A.khaled2351@nu.edu.eg

Abstract

Sentiment style transfer aims to reverse a sentence's sentiment polarity while preserving its content. This task remains underexplored for dialectal Arabic due to non-standardized orthography, code-switching, and dialect-specific variation. We present our system for **DialectSentEval 2026 Shared Task Subtask 2: Arabic Dialect Sentiment Swap**, in which we fine-tune **AraT5v2-base-1024** as an end-to-end sequence-to-sequence model mapping a `(source_polarity, source sentence)` pair to a sentiment-inverted target sentence, using 4-beam search. Our system achieves **55.60 BLEU, 72.27 chrF, 77.90% sentiment preservation** on the Development phase, and **54.63 BLEU, 72.61 chrF, 68.98% sentiment preservation** on the Final Evaluation phase. Manual analysis shows strong performance on short, simple sentences, with occasional failures where secondary cues (e.g., emojis) remain unchanged after the polarity-bearing word is inverted. The drop in sentiment preservation between phases is likely partly due to missing gold `source_polarity` labels in the Final Evaluation set, requiring automatic prediction before generation.

1 Introduction

Sentiment style transfer rewrites a sentence to reverse its sentiment while preserving its content. It remains underexplored for dialectal Arabic, where non-standardized orthography and dialectal variation add extra challenges. The DialectSentEval 2026 Shared Task addresses this through Subtask 2, *Arabic Dialect Sentiment Swap*, which requires rewriting a dialectal sentence to express the opposite polarity while preserving its meaning. Performance is measured by content preservation (BLEU, chrF) and sentiment reversal (via an external classifier).

We present the NU-SentEval team's submission to Subtask 2. We fine-tune **AraT5v2-base-1024** as an end-to-end sequence-to-sequence model that generates a sentiment-inverted sentence from a `(source_polarity, source sentence)` pair, decoded with 4-beam search. We evaluate the system on both shared task phases, reporting BLEU, chrF, and sentiment-preservation scores, along with a manual error analysis. The model performs well on short sentences but sometimes leaves secondary cues, such as emojis, unchanged. The Final Evaluation phase also lacked gold `source_polarity` labels, requiring automatic prediction that may introduce errors.

2 Background

DialectSentEval 2026 Subtask 2 (Ezzini et al., 2026a) provides dialectal Arabic sentence pairs annotated with source sentiment polarity (positive/negative) and, in the Development phase, a gold sentiment-inverted target. Data comes from the MA'AKS dataset (Mughaus et al., 2026), part of the broader AraSentEval framework (Ezzini et al., 2026b) for Arabic sentiment generation tasks. Systems must generate a sentence expressing the opposite polarity while preserving topic and content. Evaluation uses two axes: *content preservation* (BLEU, chrF against the source) and *sentiment preservation* (% of outputs classified as successfully flipped by an external classifier). Submissions require a `predictions.zip` containing `predictions.xlsx` with `id` and `style` columns. The Final Evaluation test set omits the gold target and polarity label, requiring participants to predict polarity automatically before generation.

3 System Overview

We cast Subtask-2 (Sentiment Swap) as a conditional sequence-to-sequence generation problem: given a dialectal Arabic sentence and its current sentiment polarity, the model must generate a new sentence that expresses the *opposite* polarity while

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1452–1456
October 28-29, 2026 ©2026 Association for Computational Linguistics

preserving as much of the original content as possible.

3.1 Base Model

We fine-tune **AraT5v2-base-1024** (Elmadany et al., 2023), an encoder–decoder Transformer following the T5 architecture and pre-trained on large-scale Arabic data (Modern Standard Arabic and dialectal varieties) with an extended input sequence length of 1,024 tokens.https://huggingface.co/UBC-NLP/AraT5v2-base-1024 We use the model's slow, SentencePiece-based tokenizer, which we found necessary for compatibility with the pinned `transformers` version (the fast Rust tokenizer failed to load AraT5's legacy vocabulary).

3.2 Input/Output Formulation

We convert every training pair (`source`, `source_polarity`, `target`) into a single prompt-conditioned input string. The source polarity is injected as an explicit Arabic tag so the model always knows *which direction* to invert:

اعكس المشاعر (<polarity>): <source>

where <polarity> is either إيجابي or سلبي, depending on `source_polarity`. The decoder target is simply the gold `target` sentence, i.e. the same sentence rewritten with inverted sentiment. This prompt-based conditioning lets a single model handle both directions of the swap (positive→negative and negative→positive) without separate models or output heads.

3.3 Decoding

At inference time we generate with standard beam search (4 beams, no sampling), capping generation at the same maximum length used for training targets. No re-ranking or post-editing is applied to the raw model output.

4 Experimental Setup

4.1 Data

We use the official DialectSentEval 2026 Subtask-2 (Sentiment Swap) splits. Table 1 reports the size of each split used in our pipeline.

Split	# examples
Train (official)	6,752
– used for updates	6,077
– internal dev (10%)	675
Development (official val)	964
Final Evaluation (test)	1,931

Table 1: Data splits used for training and evaluation.

The official training set is moderately imbalanced toward negative-source examples (3,731 negative vs. 3,021 positive); we did not apply reweighting or oversampling in our submitted system (see Limitations). We hold out a random 10% of the official training set (675 examples, fixed seed) purely to monitor chrF during training for checkpoint selection; the official Development file is reserved for generating the Development-phase submission, and the official test file is used only once for the Final Evaluation submission.

An important asymmetry between the two phases is that the released Development-phase file includes the gold `source_polarity` label for every example, whereas the real Final Evaluation test file provides only `id` and `source`. For the Final Evaluation submission we therefore predict `source_polarity` ourselves with the same CAMeL sentiment classifier used for scoring (Section 4, below) before constructing the model input, since a positive/negative tag is required to tell the model which direction to invert.

4.2 Preprocessing

Preprocessing is minimal by design, consistent with a pre-trained text-to-text model: no manual normalization, diacritic stripping, or segmentation is applied beyond the tokenizer's own SentencePiece tokenization, so that dialectal spelling, code-switching, and emojis in the input are preserved as signal for the model. Inputs and targets are truncated to a maximum of 96 sub-word tokens each, which comfortably covers the length of the (mostly single- to few-sentence) social-media-style data in this task.

4.3 Training Configuration

The model is fine-tuned with the Hugging Face `Seq2SeqTrainer`. Table 2 lists the hyperparameters used for our submitted system.

We select the checkpoint with the highest chrF (Popović, 2015) on the internal 675-example devel-

Hyperparameter	Value
Epochs	8
Train batch size	16
Eval batch size	32
Learning rate	3e-4
Weight decay	0.01
Warmup ratio	0.06
Max input length	96 tokens
Max target length	96 tokens
Beam size (decoding)	4
Precision	fp16
Seed	42

Table 2: Fine-tuning hyperparameters.

opment split (evaluated once per epoch) as our final model, rather than the last training epoch, using `predict_with_generate` with the same 4-beam decoding used at test time.

4.4 Hardware and Software

Training was run on a single Kaggle GPU accelerator (T4/P100) and took approximately 40 minutes end-to-end for 8 epochs. We use `transformers` 4.46.3, `tokenizers` 0.20.3, `datasets` 3.1.0, and `accelerate` 1.1.1; these specific, pinned versions were required because more recent `transformers`/`tokenizers` releases fail to load AraT5's legacy SentencePiece tokenizer.

4.5 Evaluation Metrics

Following the shared task specification, we report: (i) **BLEU** (Papineni et al., 2002) and **chrF** (Popović, 2015) computed between the *input* (`source`) and the *generated output* (`style`) as a measure of content preservation, and (ii) **Sentiment Style Accuracy**, the percentage of generated outputs whose predicted polarity — according to CAMELBERT-DA (Inoue et al., 2021) sentiment classifier — matches the expected opposite of the source polarity. These are computed identically for the Development and Final Evaluation phases, with the only difference being that `source_polarity` is gold-provided in the former and classifier-predicted in the latter (Section 4).

5 Results

Table 1 reports the official platform results for our fine-tuned AraT5v2-base-1024 system across both evaluation phases of the shared task.

We discuss a likely cause for the drop in Sentiment Preservation between the two phases in the Discussion and Error Analysis and Limitations sections below.

Phase	BLEU	chrF	Sentiment Preservation
Development (964)	55.60	72.27	77.90%
Final Evaluation (1,931)	54.63	72.61	68.98%

Table 3: Official leaderboard results by evaluation phase

Overall, our system reaches a chrF above 72 and a BLEU above 54 in both phases, together with a sentiment-preservation score of approximately 69% on the final official test leaderboard, indicating that the model reliably rewrites Arabic dialectal sentences into the opposite sentiment while retaining a substantial share of the original content.

5.1 Error Analysis

We manually inspected model outputs on the Development-phase validation set and identified two recurring patterns.

Exact or near-exact match with the human reference. For a large share of short, single-clause inputs, the model's output matches the gold target almost word-for-word. For example, the input "صادقه شباصه" (negative) is rewritten as "صادقه حلوة", identical to the gold target, showing the model has learned a reliable direct mapping for common short evaluative phrases. Similarly, for the input "الرساله لا تكفي لبوح كل مافي القلب" (negative), accompanied by a broken heart emoji, the gold target is "الرساله تكفي بكثير لبوح كل مافي القلب ♡", and our model generates "الرساله تكفي لبوح كل مافي القلب" with a sparkling heart emoji: the negation is correctly removed and the emoji is correctly flipped to a positive one, closely matching the intended meaning of the gold target.

Residual, unflipped cues leaving a mixed-signal output. A second pattern is that the model sometimes flips the main polarity-bearing word but leaves a secondary cue (an emoji) from the original polarity in place. For example, "يا محلي عمري والأيام ♡" (positive) is rewritten as "يا مضيع

عمري والأيام ♡”: the adjective is correctly inverted (sweetness → waster), but the heart symbol (♡) is carried over unchanged, whereas the gold target replaces it with a broken heart emoji. The resulting output therefore mixes a negative statement with a positive visual cue.

A likely contributor to the Sentiment Preservation drop between the Development and Final Evaluation phases (Table 3) is that the released Development-phase file included the gold `source_polarity` label for each example, while the Final Evaluation test file did not. For the final test submission we therefore had to predict `source_polarity` ourselves using the same CAMeL sentiment classifier before generation, so that the model would know which direction to invert. Any misclassification at this step directs the model to invert in the wrong direction, and this compounding error most likely explains a meaningful share of the gap between the two phases' Sentiment Preservation scores.

5.2 Limitations

Error propagation from predicted source polarity. As noted above, the Final Evaluation test file does not include gold `source_polarity`, so we predict it with an external sentiment classifier before generation. Misclassifications at this step propagate into the final output and likely explain part of the drop in Sentiment Preservation between the Development and Final Evaluation phases.

No data augmentation or candidate reranking. Our final system trains directly on the provided source→target pairs with standard beam search decoding (4 beams), without bidirectional data augmentation or multi-candidate reranking at inference time. It is possible that such techniques would further improve either content preservation or sentiment accuracy, but we did not adopt them in our submitted system.

Classifier-based sentiment scoring. Our reliance on a single external classifier (CAMeL-Lab's Arabic dialectal sentiment model) — both to infer `source_polarity` at test time and, per the task setup, for automatic sentiment scoring — means any systematic bias in that classifier affects our results and may not fully align with human judgment.

Secondary polarity cues. As shown in the Error Analysis, the model does not always propagate the sentiment flip to non-lexical cues such as emojis, which can leave a mixed-signal output even when the main wording is correctly inverted.

No human evaluation. All reported numbers are automatic (BLEU, chrF, classifier-based sentiment accuracy). We do not conduct human evaluation of fluency, dialectal naturalness, or perceived sentiment.

6 Conclusion

We presented NU-SentEval's system for DialectSentEval 2026 Subtask 2 (Arabic Dialect Sentiment Swap): a fine-tuned AraT5v2-base-1024 sequence-to-sequence model trained directly on the shared task's source-target pairs and decoded with standard beam search. Our system reaches 55.60 BLEU, 72.27 chrF, and 77.90% sentiment preservation in the Development phase, and 54.63 BLEU, 72.61 chrF, and 68.98% sentiment preservation on the official Final Evaluation test leaderboard. Our error analysis shows the model reliably inverts sentiment for short, single-clause inputs, often matching the human reference exactly, and frequently produces sentiment-correct rewrites that use different but equally valid wording than the gold target. The main remaining weaknesses are inconsistent handling of secondary polarity cues such as emojis, and error propagation from automatically predicted source polarity at test time, which we identify as the most likely contributor to the drop in sentiment-preservation score between the two evaluation phases.

7 Acknowledgments

We thank the DialectSentEval 2026 organizers for coordinating the shared task and providing the MA'AKS dataset and evaluation platform.

A Replication Details

We fine-tune UBC-NLP/AraT5v2-base-1024 for 8 epochs (batch size 16, learning rate 3e-4, weight decay 0.01, warmup ratio 0.06, fp16), using beam search decoding with 4 beams (max input/target length: 96 tokens). Training uses 6,752 examples (6,077 for gradient updates, 675 held out internally to monitor chrF for checkpoint selection), and completes in approximately 40 minutes. Sentiment labels (both for predicting `source_polarity` at test time and for automatic evaluation) are obtained from CAMeL-Lab/bert-base-arabic-camelbert-da-sentiment. Library versions: transformers 4.46.3, tokenizers 0.20.3, datasets 3.1.0, accelerate 1.1.1. The fine-tuned model is

publicly available at https://huggingface.co/areejkhaled33/arat5-sentiment-swap.

Abstract

This paper presents the system developed by the **NU-SentEval** team for Subtask 1 (Sentiment Analysis in Dialectal Arabic) of the DialectSentEval 2026 Shared Task. Arabic dialect sentiment classification is challenging due to morphological complexity, orthographic variation across regional dialects, and class imbalances in user reviews. To address these challenges, we propose an ensembled architecture leveraging five diverse Pre-trained Language Models (PLMs): MARBERTv2, MARBERT, CAMeLBERT-DA, AraBERTv0.2-Twitter, and Twitter-XLM-RoBERTa. All models were fine-tuned using a customized Focal Loss objective combined with Label Smoothing to mitigate majority class bias and prevent overconfidence. Out-of-fold probability representations from individual models were aggregated through a Logistic Regression stacking meta-classifier (`stacking_c1`). On the official test set, our system achieved a Macro F1-score of **0.8141** and an Accuracy of **0.8343**, demonstrating the effectiveness of combining specialized dialectal representations with loss regularization and meta-learning.

1 Introduction

Sentiment analysis of user-generated content in Arabic has become an essential area of research across social media monitoring, customer feedback analysis, and opinion mining. However, analyzing sentiment in Arabic is hindered by substantial linguistic heterogeneity. Modern Standard Arabic (MSA) differs considerably from the numerous regional dialects (e.g., Egyptian, Levantine, Gulf, and Maghrebi) commonly used across digital platforms. These dialects lack standardized orthography, feature non-conventional phonetic spellings, and frequently employ subtle cultural idioms, irony, and sarcasm.

To benchmark and advance modeling capabilities on dialectal Arabic text, the DialectSentEval 2026 Shared Task (Ezzini et al., 2026a) was organized at the ArabicNLP 2026 Conference. The shared task comprises two tracks: Subtask 1 (Arabic Dialect Sentiment Analysis) and Subtask 2 (Arabic Sentiment Swapping).

In this work, we describe our participation in **Subtask 1**. Our primary contribution is an end-to-end framework that couples comprehensive Arabic text normalization with an ensemble of five diverse Transformer-based language models. To tackle the challenge of class imbalance and boundary ambiguity, we train each model using Focal Loss regularized by Label Smoothing. Finally, we implement a Stacking meta-classifier that dynamically learns optimal decision boundaries across all model representations. Our final system delivered competitive performance on the official leaderboard, reaching a Macro F1-score of 0.8141.

2 Background

2.1 Task and Dataset Setup

The objective of Subtask 1 is multi-class sentiment classification for dialectal Arabic. The provided training dataset consists of 1,731 hotel and accommodation reviews written in four major Arabic dialect groups: Egyptian (432 samples), Moroccan Darija (433 samples), Saudi/Gulf (433 samples), and Jordanian/Levantine (433 samples). The dataset is annotated across three sentiment classes: Negative (657 samples, 38.0%), Positive (609 samples, 35.2%), and Neutral (465 samples, 26.9%).

Given an input review x, the system must predict a discrete sentiment label $y \in \{\text{Positive}, \text{Negative}, \text{Neutral}\}$. Representative examples from the dataset include:

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1457–1461
October 28-29, 2026 ©2026 Association for Computational Linguistics

- **Input (Positive):** الفطور ممتاز، والخدمة رائعة والطاقم كايعاون (*"The breakfast is excellent, the service is wonderful, and the staff is helpful"*) → **Output:** Positive

- **Input (Negative):** ماكاينش إنترنت ف الغرفة، الواي فاي غالي بزاف (*"There is no internet in the room, Wi-Fi is very expensive"*) → **Output:** Negative

- **Input (Neutral):** الوصول والخروج كانو مزيانين (*"Check-in and check-out were fine"*) → **Output:** Neutral

2.2 Related Work

Recent years have witnessed concerted efforts toward benchmarking sentiment analysis on dialectal Arabic. The AraSentEval shared task (Ezzini et al., 2026b) evaluated sentiment classification and dialectal swapping across regional varieties. Similarly, the ADOR benchmark (Alharbi et al., 2025c) provided a human-annotated corpus of multi-dialectal Arabic hotel reviews, highlighting the performance drop of general-purpose models when transferred to informal regional speech. The Ahasis shared task (Alharbi et al., 2025b) further demonstrated the utility of pre-trained transformer backbones fine-tuned on targeted dialectal benchmarks.

More recently, Alharbi et al. (2025a) evaluated Large Language Models (LLMs) on dialectal Arabic sentiment analysis, showing that specialized Arabic encoder models fine-tuned with domain-adapted objectives frequently match or surpass general closed-source LLMs while maintaining significantly higher inference efficiency. Building upon these insights, our work focuses on maximizing the collective representational strength of multiple dialect-adapted transformer models.

3 System Overview

Our proposed pipeline consists of three core components: (1) Domain-specific Text Normalization, (2) Diverse Base Model Fine-Tuning with Focal Loss, and (3) Logistic Regression Stacking Meta-Classification.

3.1 Text Preprocessing

Social media reviews often contain non-standard punctuation, decorative elongations, and platform-specific entities. We apply a targeted normalization pipeline:

1. **Diacritic & Tatweel Removal:** Stripping short vowel marks (Tashkeel) and character stretchers (Tatweel: `\u0640`).

2. **Letter Normalization:** Unifying all forms of Alef with Hamza to bare Alef (ا), replacing Alif Maksura (ى) with Yaa (ي), and Taa Marbuta (ة) with Haa (ه).

3. **Entity Masking:** Replacing user handles (`@username`) with `@USER` and hyperlinks with `URL`.

4. **Noise Reduction:** Collapsing repeating characters to a maximum of two consecutive letters and removing standalone punctuation.

3.2 Base Language Models

To ensure complementary linguistic representations across multiple Arabic dialects, we select five Pre-trained Language Models (PLMs):

1. **MARBERTv2** and **MARBERT**: Masked language models pre-trained on massive collections of Arabic tweets, providing strong dialectal coverage. in our evaluation, Marbert achieved macro F1 of 0.9461, and marbert v2 of macro f1 score of 0.9264.

2. **CAMeLBERT-DA**: A dedicated BERT variant pre-trained on Dialectal Arabic texts. In our evaluation,CAMeLBERT-DA achieved macro F1 of 0.9249.

3. **AraBERTv0.2-Twitter**: Pre-trained on Arabic news and millions of social media tweets,

and in our evaluation it achieved macro F1 score of 0.9599 which was the highest score among the other models.

4. **Twitter-XLM-RoBERTa**: A cross-lingual RoBERTa model adapted on multilingual Twitter streams.This model achieved macro F1 score of 0.9198.

3.3 Focal Loss with Label Smoothing

To address class imbalance and reduce overconfident probabilities on ambiguous samples, we implement a customized Focal Loss with Label Smoothing. Given predicted class probabilities $p \in [0, 1]^K$ and ground truth class y, standard cross-entropy is replaced by:

$$\mathcal{L}_{\text{FL}} = -\sum_{k=1}^{K} \tilde{y}_k (1 - p_k)^{\gamma} \log(p_k) \qquad (1)$$

where $\gamma = 2.0$ is the focusing parameter that down-weights easy examples, and $\tilde{y}_k$ represents the smoothed target distribution:

$$\tilde{y}_k = (1 - \epsilon) \cdot I(y = k) + \frac{\epsilon}{K} \qquad (2)$$

with label smoothing factor $\epsilon = 0.1$ and $K = 3$ sentiment classes.

3.4 Stacking Meta-Classifier (`stacking_c1`)

Instead of heuristic voting, we construct a second-level Meta-Classifier. For each sample x, the predicted logit vectors from all $M = 5$ base models are concatenated into a joint meta-feature vector $z = [z^{(1)}, z^{(2)}, \ldots, z^{(5)}] \in R^{15}$. We train an L_2-regularized Logistic Regression model ($C = 1.0$) on the validation logit representations to learn optimal model confidence weights and decision boundaries.

4 Experimental Setup

4.1 Training Strategy and Data Splits

We structured our training pipeline into two sequential phases:

- **Phase 1 (Validation & Epoch Tuning):** The dataset was partitioned into an 85% training split and a 15% stratified validation split. Each model was trained for up to 15 epochs with early stopping (patience = 3 based on validation Macro F1). The validation predictions were harvested to train the stacking meta-classifier.

Metric	Official Test Score
Macro F1-Score	**0.8141**
Accuracy	0.8343
Macro Precision	0.8115
Macro Recall	0.8197

Table 1: Official evaluation results of the NU-SentEval system on the Subtask 1 test set.

- **Phase 2 (Full Re-training):** With the optimal epoch count established for each base model, all five models were freshly re-initialized and re-trained on 100% of the provided training data before generating final test set predictions.

4.2 Hyperparameters and Environment

All models were implemented using PyTorch 2.x and Hugging Face `transformers` alongside `scikit-learn`. Models were fine-tuned with a maximum token length of 256, batch size of 16 with gradient accumulation steps of 2 (effective batch size = 32), AdamW optimizer with initial learning rate $\eta = 2 \times 10^{-5}$, 150 linear warmup steps, cosine learning rate scheduling, and weight decay of 0.01.

4.3 Evaluation Metrics

Following official task guidelines, performance is evaluated using **Macro F1-Score** as the primary metric, alongside Accuracy, Macro Precision, and Macro Recall.

5 Results

5.1 Official Test Results

Table 1 displays the official performance of our system on the unlabelled test set of DialectSentEval 2026 Subtask 1. Our ensemble system achieved a competitive Macro F1-score of **0.8141** and an Accuracy of **0.8343**.

5.2 Ablation Study of Ensemble Strategies

To quantify the benefit of our stacking meta-classifier, we evaluated several ensembling schemes on our Phase 1 validation split. As detailed in Table 2, the Logistic Regression meta-classifier (`stacking_c1`) achieved the highest performance across all evaluation metrics, outperforming top-k weighted averaging, power weighting, and temperature-scaled heuristics.

Strategy	Acc.	Prec.	Rec.	Macro F1
stacking_c1	**0.9654**	**0.9644**	**0.9621**	**0.9632**
top3_weighted	0.9615	0.9597	0.9585	0.9591
power_weighted	0.9577	0.9561	0.9551	0.9556
temp_f1_weighted	0.9538	0.9524	0.9503	0.9513

Table 2: Comparison of ensembling strategies on the Phase 1 validation split.

5.3 Class-wise Performance and Error Analysis

Table 3 provides the detailed class-level breakdown for the best-performing stacking_c1 model on the validation split.

Class	Prec.	Rec.	F1-Score	Support
Positive (0)	0.9700	0.9798	0.9749	99
Negative (1)	0.9559	0.9286	0.9420	70
Neutral (2)	0.9674	0.9780	0.9727	91
Macro Avg	**0.9644**	**0.9621**	**0.9632**	260

Table 3: Class-wise classification report of stacking_c1 on the Phase 1 validation split.

A closer inspection of model errors revealed two prominent failure patterns:

1. **Sarcasm and Polite Dissatisfaction:** In several customer reviews, users employed positive blessing phrases (e.g., الله يعطيكم العافية بس الخدمة ضايعة, meaning *"May God give you health, but the service is lost"*) to deliver negative feedback. In borderline cases, the strong positive sentiment lexicons biased base models toward Positive or Neutral.

2. **Mixed Dialectal Colloquialisms:** Infrequent regional slang words (e.g., specialized Maghrebi terms like ماشي مزيان or بزاف) occasionally led to dispersed probability distributions among models. The stacking meta-classifier successfully resolved the majority of these ambiguities by leaning on the most confident dialect-specific backbones (such as CAMeLBERT-DA and MARBERTv2).

6 Conclusion

In this paper, we detailed the NU-SentEval system for Subtask 1 of the DialectSentEval 2026 Shared Task. By combining five specialized Arabic Pre-trained Language Models with Focal Loss, Label Smoothing, and a Logistic Regression stacking meta-classifier, our approach demonstrated robust performance on diverse dialectal sentiment inputs, securing a test Macro F1-score of 0.8141. Future work will investigate dialect identification pre-filtering and synthetic data augmentation using generative LLMs.

Limitations

While our ensemble framework provides strong empirical accuracy, ensembling five large Transformer architectures increases inference latency and memory requirements compared to a single distilled model. Additionally, performance on highly localized colloquialisms remains dependent on pre-training corpus representation.

Acknowledgments

We would like to express our deepest gratitude and sincere appreciation to Dr. Ensaf Hussein, Associate Professor at Nile University, for her invaluable supervision, continuous guidance, and insightful feedback throughout the development of this work. We also extend our gratitude to the organizers of the DialectSentEval 2026 Shared Task and the ArabicNLP 2026 Conference for providing the benchmark dataset and evaluation platform.

Abstract

Dialect sentiment analysis asks for the polarity of a sentence written in a regional Arabic variety rather than Modern Standard Arabic. We present a system for Subtask 1 of DialectSentEval built on two observations about the data. First, the task is one of zero-shot transfer rather than classification: the test set introduces Lebanese, a dialect with no labeled training data and the highest out-of-vocabulary rate in the task (52.0% of word types, against 19.5–41.0% for the seen dialects). Second, k-fold cross-validation cannot see this, since it measures generalization to unseen sentences and never to an unseen dialect. We therefore validate with a leave-one-dialect-out diagnostic and score every component on the official leaderboard. Three dialectally diverse encoders (MARBERTv2, CAMeLBERT-DA, AraBERTv2) are trained with Fast Gradient Method adversarial training (Miyato et al., 2017), then refined by confidence-filtered self-training on the unlabeled test set and character-level noise augmentation (Srivastava and Chiang, 2023). Adversarial training contributes +0.040 Macro F1 over a gold-only ensemble, self-training a further +0.027, and per-class pseudo-label filtering +0.018. The final system reaches 0.8667 Macro F1, ranking **1st** of 12 submissions, 4.6 points above the runner-up.

1 Introduction

Sentiment analysis is a mature task in Arabic NLP, but most user-generated Arabic text is dialectal rather than Modern Standard Arabic (MSA). Dialects differ enough in vocabulary and orthography that a model tuned on one can fail on another, which makes cross-dialect transfer the interesting part of the problem.

Subtask 1 of DialectSentEval (Ezzini et al., 2026a), hosted with the Arabic Natural Language Processing Conference (ArabicNLP 2026),[1] asks participants to classify hotel-review sentences from the MDS-3 dataset (Alharbi et al., 2025c) into {positive, negative, neutral} for Moroccan (Darija), Egyptian, Jordanian, and Saudi. The released test set adds a fifth dialect, Lebanese, with no labeled training data at all. The subtask continues the AraSentEval (Ezzini et al., 2026b) and AHASIS (Alharbi et al., 2025b) shared tasks, and our design draws on prior benchmarking of fine-tuned encoders and large language models on closely related Arabic dialect sentiment data (Alharbi et al., 2025a). Treating an unseen dialect as its own generalization regime follows prior work on quantifying dialectal distance (Sakr et al., 2024) and on identifying a dialect from only a handful of labeled examples (Yusuf et al., 2022).

Hypothesis. Our starting point is that standard in-distribution validation is the wrong instrument for this task. k-fold cross-validation measures generalization to unseen *sentences* drawn from dialects the model has already seen; it says nothing about generalization to an unseen *dialect*. Our exploratory analysis confirms that Lebanese is exactly the out-of-distribution case: it has the highest word-type out-of-vocabulary rate of any test dialect (52.0%, against 19.5–41.0% for the four seen dialects), and, as a Levantine variety, it is linguistically closest to Jordanian.

That diagnosis motivates two decisions, each aimed at an identified failure mode rather than adopted as a generic best practice:

- A **leave-one-dialect-out (LODO)** protocol that simulates the real unseen-dialect condition during development.
- **Embedding- and character-level perturbation** (FGM and character noise) as explicit proxies for the lexical and orthographic distance between a seen dialect's surface forms and an unseen one's.

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1462–1466
October 28-29, 2026 ©2026 Association for Computational Linguistics

We tested the hypothesis with a controlled ablation across five axes: pooling, adversarial and consistency regularization, domain invariance, character-aware architectures, and self-training. Each variant was scored independently on the leaderboard against a common single-backbone baseline. As Section 5 shows, the interventions that match the diagnosed failure mode survived; the generic regularizers and domain-invariance objectives did not.

2 Data and Exploratory Analysis

MDS-3 (Alharbi et al., 2025c) contains 1,731 labeled training rows and 525 unlabeled test rows of hotel-review sentences, each translated into every dialect from a shared underlying set of reviews. Table 1 gives the split.

Dialect	Train	Test
Darija (Moroccan)	433	105
Egyptian	432	105
Jordanian	433	105
Saudi	433	105
Lebanese	0	105
Total	**1,731**	**525**

Table 1: Rows per dialect. Lebanese has zero training examples.

Labels are not a confound. The three classes are close to balanced (negative 38.0%, positive 35.2%, neutral 26.9%) and near-uniform across dialects. Any dialect-wise performance gap therefore reflects genuine transfer difficulty rather than a shifting label distribution.

Duplication. Seventeen training sentences are exact duplicates of one another, and 58 test sentences are byte-identical to a training sentence. Both facts shape the system: the first determines how we group cross-validation folds, the second motivates the exact-match lookup described in Section 3.

Vocabulary overlap. Figure 1 plots the fraction of whole-word token *occurrences* in each test dialect that are absent from the training vocabulary. On this measure Lebanese reaches 34.3%, more than 1.5× the rate of any seen dialect; measured over token *types* instead, the gap is wider still (52.0%, quoted above). Either way the conclusion is the same: a model that leans on memorizing dialect-specific function words will fail on Lebanese in particular. This is what pushed us toward dialectally pretrained backbones (Section 3) and toward LODO rather than random k-fold validation alone.

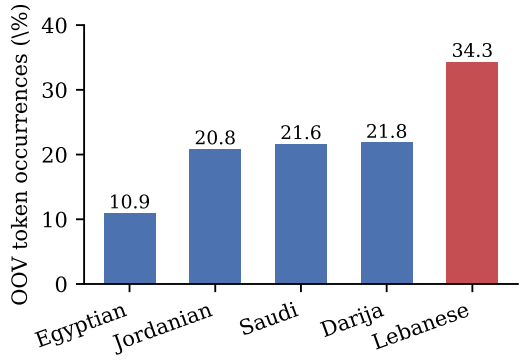

Figure 1: Out-of-vocabulary token-occurrence rate by test dialect. Lebanese (highlighted), absent from training, has the highest rate.

Negation and length. Negation markers appear in 44.4% of negative sentences but also in 37.8% of neutral ones, so surface cues alone separate the classes poorly and a contextual transformer is preferable to a lexicon- or rule-based classifier. Sentences are short to medium (median 16–19 words), so capping input at 128 sub-words discards almost nothing.

3 System Overview

Backbones. We fine-tune three encoders, chosen for dialectal-Arabic coverage and for diversity from one another. `UBC-NLP/MARBERTv2` (Abdul-Mageed et al., 2021) was the strongest single model on the AHASIS pilot of a related dataset (Alharbi et al., 2025b). `CAMeL-Lab/bert-base-arabic-camelbert-da` (Inoue et al., 2021) is pretrained on Dialectal Arabic and is the organizers' official sentiment classifier for Subtask 2. `aubmindlab/bert-base-arabertv2` (Antoun et al., 2020) is MSA-centric and is included precisely because it errs differently from the other two.

Pooling and loss. Each backbone uses masked mean pooling rather than the `[CLS]` token, so that a handful of unfamiliar Lebanese sub-words cannot dominate a single aggregation point. Training uses class-weighted cross-entropy to offset the mild under-representation of the neutral class (26.9% of

rows), which matters because Macro F1 penalizes minority-class errors heavily.

Adversarial training. Every backbone is trained with Fast Gradient Method (FGM) adversarial training (Miyato et al., 2017). At each step a bounded perturbation is added to the word-embedding layer along the direction of the loss gradient, and the model backpropagates through the perturbed forward pass as well as the clean one. This is the single largest individual gain in our search (Section 5). We read it as a proxy for the robustness a model needs when moving from a seen dialect's embedding neighborhood to an unseen one's.

Iterative self-training. We exploit the unlabeled test set directly, over three rounds. In each round a committee of the current best models labels the test set; rows on which the committee agrees above a confidence threshold enter the training pool as pseudo-labels with a reduced loss weight ($0.7\times$), and a fresh model is trained on gold plus pseudo-labeled data. Round 3 adds a mild per-class confidence filter that trims the least-confident 10% of each class's own pseudo-labels. The per-class form matters: a flat threshold systematically underrepresents the neutral class, whose predictions are less confident than positive or negative ones. Coverage grew from 386 of 525 rows in round 1 to 499 by round 3.

Character-level noise augmentation. Following Srivastava and Chiang (2023), who show that character noise injected during fine-tuning improves zero-shot transfer to unseen dialects, we add one noised duplicate of every gold row. The noise combines Arabic letter-variant substitutions (ة/ه, ى/ي), which reflect real orthographic variation, with generic delete, duplicate, and swap operations at roughly 6% per character. This attacks the Lebanese OOV gap directly and makes no assumption about Lebanese class proportions.

Ensembling and dataset-overlap control. The three backbones are combined by uniform averaging of softmax probabilities. Our exploratory analysis also surfaced the 58 test sentences (11.0%) that are byte-identical to training sentences, an artifact of how the shared task's data was constructed. Left alone, these rows conflate memorization with generalization. We treat them as a data-quality issue rather than a scoring opportunity: an exact-match lookup returns the known gold label for them, so the model predictions and the ablation comparisons in Section 5 are evaluated on the 89.0% of rows that genuinely require generalization.

4 Experimental Setup

All models are fine-tuned on the full 1,731 labeled rows, plus self-training pseudo-labels where applicable. Development used two validation protocols side by side. The first is five-fold Stratified-GroupKFold, grouped by exact sentence text so that the 17 duplicated training sentences never straddle a fold boundary. The second is leave-one-dialect-out, holding out each seen dialect in turn; only LODO approximates the test set's unseen-Lebanese condition, so it served as our primary diagnostic. Table 2 lists the final recipe's key hyperparameters.

Hyperparameter	Value
Max sequence length	128 sub-words
Pooling	Masked mean
Loss	Class-weighted CE
Class weights	sklearn 'balanced'
(neg./pos./neu., per-fold)	≈0.88 / 0.95 / 1.24
FGM perturbation norm (ϵ)	1.0
Self-training rounds	3
Committee confidence threshold	0.55
Pseudo-label loss weight	$0.7\times$
Char-noise rate (per character)	≈6%
Ensemble combination	Uniform softmax avg.

Table 2: Key hyperparameters of the final deployed system.

5 Results

Table 3 reproduces the official leaderboard. Our final submission reached Macro F1 = 0.8667 and Accuracy = 0.8857, ranking first of twelve teams and 4.6 points ahead of the runner-up (0.8210).

#	Team/Participant	Macro F1
1	**ALEXIS (momen_ibrahim)-870387**	**0.8667**
2	ajwad_hossain-867052	0.8210
3	tasneemduridi-857223	0.8174
4	habiba_ayman-867381	0.8140
5	normalman159-857755	0.8010
6	ahmadalmoustafa-856400	0.7977
7	mona_-871069	0.7953
8	faisalm93-869067	0.7939
9	hoanguitcs-866914	0.7936
10	shadenalzeer-867546	0.7894
11	hh03112005-869469	0.7859
12	23020073-870754	0.7722

Table 3: Official Subtask 1 leaderboard: Arabic dialect sentiment analysis.

5.1 Ablation

Every row of Table 4 is an independently leaderboard-scored configuration rather than an internal estimate. The upper block traces the deployed system through its four milestones; each hypothesis-motivated component earns its place.

Configuration	F1
Baseline (gold-only ensemble)	0.7806
+ FGM adversarial (single backbone)	0.8204
+ Self-training, 3 rounds	0.8477
+ Mild per-class pseudo-label filter	0.8656
+ Char-noise augmentation (final)	**0.8667**
Other regularizers[a]	0.785–0.807
Fish (Shi et al., 2021)	0.3215
ByT5 backbone (5-fold CV)	0.376

Table 4: Top: cumulative deployed-system ablation, each row independently leaderboard-scored. Bottom: alternative single-backbone techniques tried and not deployed, none surpassing FGM's 0.8204. (ByT5 (Xue et al., 2022) was never submitted; its CV number is not comparable to the official F1.) [a]R-Drop (Liang et al., 2021), SWAD (Cha et al., 2021), Invariant Risk Minimization (Arjovsky et al., 2019), CORAL (Sun and Saenko, 2016), Supervised Contrastive Loss (Khosla et al., 2020), MixStyle (Zhou et al., 2021), and character CNN/BiLSTM hybrids.

The most instructive result is a failure, and it is a methodological one. An earlier, more aggressive pseudo-label filter forced class proportions to match those of the four *seen* dialects exactly, and it regressed on the real leaderboard (0.8336 against 0.8477). It failed for the same reason the whole task is hard: it assumed Lebanese shares the seen dialects' distribution. The milder, dialect-agnostic filter makes no such assumption, and it is what we deployed.

The pattern in the lower block is consistent with our hypothesis. Every non-surviving technique targets generic regularization or broad domain invariance rather than the specific OOV mechanism identified in Section 2. Fish and ByT5 did not merely underperform; they failed outright.

5.2 Error Analysis

Table 5 breaks LODO performance down by held-out dialect and class. Jordanian, Lebanese's Levantine relative, is the easiest to recover zero-shot (F1 = 0.980) and is our closest available proxy, though an optimistic one: LODO still draws held-out examples from the same translated-review pipeline as training, whereas Lebanese is genuinely unseen. Egyptian is the hardest held-out case (F1 = 0.899) despite no particular linguistic distance from the rest, so dialect family alone does not fully predict transfer difficulty. Neutral is the hardest class to recover across all four splits.

Held-out	Neg. F1	Neu. F1	Pos. F1
Jordanian	0.988	0.970	0.983
Saudi	0.976	0.950	0.984
Darija	0.911	0.888	0.933
Egyptian	0.928	0.856	0.914

Table 5: LODO per-class F1 when each seen dialect is held out. Neutral is consistently the hardest class to recover zero-shot.

6 Conclusion

Team ALEXIS's Subtask 1 submission ranked first of twelve teams with Macro F1 = 0.8667, by diagnosing one failure mode, zero-shot transfer to an unseen dialect, choosing interventions that match it, and validating throughout with a LODO protocol ordinary cross-validation cannot provide.

The gap between seen-dialect performance (Macro F1 above 0.93 in cross-validation) and the official score confirms Lebanese remains the dominant error source even for the best system. Closing it further will likely require genuine Lebanese-domain signal rather than more regularization on the dialects we already have.

Abstract

Sentiment swap is the task of rewriting a sentence so that it carries the opposite polarity while its topic stays the same. We present a system for Arabic sentiment swap built on two observations about the data. First, the swap is a local edit rather than a paraphrase: 91% of reference rewrites stay within two words of their source. Second, the polarity to swap *away from* has to be predicted, because the test data does not provide it. We therefore fine-tune mT5 (Xue et al., 2021) and refine it with Direct Preference Optimization (Rafailov et al., 2023) under a reward that balances target-polarity probability against content preservation. At inference we pool candidates from four generators, one of them a minimal-edit tagger (Malmi et al., 2019; Mallinson et al., 2020), together with a retrieval index, rerank them with the same balance, and repair them with polarity-flip lexicons mined from the training set. Source polarity is supplied by a dedicated classifier that reaches 97.3% accuracy, against 74.3% for the off-the-shelf sentiment model that the evaluation itself uses. Every component was scored on the official leaderboard: generation-side work contributes +0.044 Sentiment Style Accuracy, and the dedicated polarity classifier a further +0.155. The final system reaches 0.9581 Sentiment Style Accuracy, 56.91 BLEU and 72.18 chrF, ranking **1st** of 15 submissions.

1 Introduction

Sentiment swap asks for a rewrite that inverts a sentence's polarity and changes as little else as possible. Two objectives pull against each other: the output must land firmly on the opposite side of the polarity boundary, yet stay close to the source, since content preservation is measured against a human rewrite that is itself a small edit. Push too hard on polarity and the rewrite drifts off topic; push too hard on similarity and the polarity does not flip. Most work on this problem is in English; Arabic has received far less attention (Section 2).

Subtask 2 of DialectSentEval (Ezzini et al., 2026a), held with the Arabic Natural Language Processing Conference (ArabicNLP 2026),[1] provides a benchmark for this setting and continues the sentiment-swap component piloted in AraSentEval (Ezzini et al., 2026b). It uses the MA'AKS dataset (Mughaus et al., 2026): 9,647 Modern Standard Arabic sentence pairs, split 6,752/964/1,931 into train, validation and test, whose members share a topic but carry opposite polarities. Systems are scored on Sentiment Style Accuracy (SSA), the fraction of outputs whose polarity matches the target according to a fixed CAMeLBERT sentiment classifier (Inoue et al., 2021), together with BLEU (Papineni et al., 2002) and chrF (Popović, 2015) against the reference rewrite.

One detail of the released data shaped the whole system. The task description says the source sentence's polarity is given as input, and the train and validation files do contain a `source_polarity` column, but the test file does not. Source polarity therefore has to be predicted at inference time. The obvious way to do that is to reuse the classifier that grades the task, and that is what we did at first. Measured against gold labels, it gets the source polarity right only 74.3% of the time. Roughly a quarter of the test set was being rewritten towards the wrong target, and no amount of tuning on the generator could see the problem.

This paper makes four contributions:

- A minimal-edit treatment of Arabic sentiment swap, motivated by corpus statistics and realized through retrieval, an edit-tagging model, and a content term in the reranker.
- A dedicated source-polarity classifier for the label the test set omits: 97.3% against 74.3%

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1467–1472
October 28-29, 2026 ©2026 Association for Computational Linguistics

for the evaluation classifier, worth +0.155 SSA.

- A DPO reward combining polarity confidence with content preservation, and evidence that it must use the raw three-way probability rather than a renormalized binary one.
- A cumulative ablation in which every configuration was scored on the official leaderboard, not a local proxy.

2 Related Work

Text style transfer. Sentiment transfer is usually studied without parallel data, so methods either disentangle content from attribute by adversarial cross-alignment (Shen et al., 2017), or delete attribute markers, retrieve replacements and regenerate (Li et al., 2018); Jin et al. (2022) survey the field. MA'AKS is unusual in supplying human-written parallel rewrites. We can therefore fine-tune a sequence-to-sequence model directly, and keep the marker-lexicon idea of Li et al. (2018) for retrieval and post-processing rather than making it the main model. Where source and target overlap heavily, token-level tagging models (Malmi et al., 2019; Mallinson et al., 2020) are also a natural fit; we use one as a pool member. Rewriting under a fixed topic is also central to Arabic conversational question rewriting (Hassib et al., 2025), though there the rewrite target is context completion rather than sentiment.

Evaluation. Style accuracy from a fixed classifier is the standard metric, but classifier-based evaluation is fragile, and optimizing hard against an imperfect proxy degrades true performance (Gao et al., 2023). Sections 4 and 6 report a concrete instance of each.

Sentiment analysis. Arabic sentiment analysis is well served by pre-trained encoders (Inoue et al., 2021), and Arabic-specific generative models exist (Nagoudi et al., 2022), but Arabic style transfer remains comparatively unexplored.

3 Task and Data

MA'AKS (Mughaus et al., 2026) pairs each source sentence with a human-written rewrite of the opposite polarity (Table 1). Sources lean slightly negative (3,731 against 3,021 in training), and the register is noisy social media text, with emoji in 60.7–63.7% of sentences. Three properties of the corpus each motivated a component of our system.

	Train	Val	Test
Pairs	6,752	964	1,931
Unique sources	5,517	–	–
Has `source_polarity`	Yes	Yes	**No**
Exact dup. of train source	–	20.4%	22.8%

Table 1: Dataset splits. Unlike train and validation, the test file carries no `source_polarity` column.

Repetition. Sources repeat across splits: 22.8% of test sentences are byte-identical to a train or validation source. For those, a gold rewrite already exists, so retrieval supplies a strong candidate at no modelling cost.

Locality. The swap is a local edit. 91.0% of training pairs are within two words of their source's length, and character-level similarity between source and target is tightly concentrated (median 0.82, interquartile range 0.75–0.88). A training pair shows the pattern: تجربة جميلة سعر كتير مناسب شكرا لكم (*'a nice experience, reasonable price, thank you'*) becomes تجربة سيئة سعر كتير غير مناسب لا شكرا علكم (*'a bad experience, unreasonable price, no thanks'*). A few words change; the structure and length do not. Constrained editing is therefore closer to what the references look like than open-ended paraphrasing.

Lexical regularity. The same polarity markers flip over and over. We mined 323 aligned emoji flips (broken-heart → sparkling-heart and similar) and short antonym pairs such as جميلة → كريهة ('hideous' → 'beautiful', 115 occurrences). This gives a small deterministic lexicon that can catch markers a neural model leaves behind.

4 System

The pipeline has three stages (Figure 1). We predict the polarity of the source, which fixes the target polarity t that everything downstream aims at; we collect candidate rewrites from four generators and a retrieval index; and we score the pool, return the best candidate, and repair what the models left behind.

One scoring function ties the last two stages together. For a source x and a candidate rewrite y,

$$s(y) = \alpha\, p_t(y) + (1 - \alpha)\, \mathrm{chrF}(y, x), \quad (1)$$

where $p_t(y)$ is the probability the evaluation classifier assigns to the target polarity t, read off its

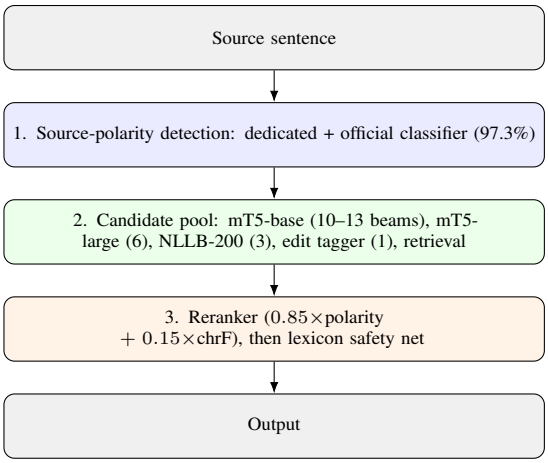

Figure 1: Inference pipeline. Retrieved near-duplicates are ordinary candidates, not a bypass, and four generators feed a single reranker.

raw three-way softmax over positive, negative and neutral. The two terms are the competing objectives of Section 1, and α sets the trade-off; we use $\alpha = 0.85$ when reranking and the same form as the DPO reward. Putting the grading classifier inside s is deliberate: from here on, agreeing with the grader is the objective.

Source-polarity detection. The test file omits `source_polarity`, so we predict it and set t to the opposite label. Using the grading classifier zero-shot is the self-consistent choice, but on this job it is right only 74.3% of the time. A classifier fine-tuned on the 7,716 labeled pairs reaches 96.7%, and since the two fail in different places, a 50/50 vote between them reaches 97.3%.

Primary generator. We fully fine-tune `google/mt5-base` (Xue et al., 2021) on all 7,716 pairs and decode with 10 beams, or 13 when the source is predicted negative. Negative-to-positive is the harder direction on validation (chrF 78.94, SSA 94.37%, against 84.27 and 96.06% the other way), an asymmetry also reported for sentiment transfer more broadly (Mukherjee et al., 2022). We select checkpoints by the chrF of beam-search output rather than by teacher-forced loss, because the two disagreed in an early run: the lowest-loss checkpoint wrote measurably worse text once it had to decode freely. Two Arabic-specific T5 checkpoints (Nagoudi et al., 2022) were tried and discarded: an unparseable tokenizer format in one, incoherent zero-shot output in the other.

Preference optimization. We refine the generator with Direct Preference Optimization (Rafailov et al., 2023) on 4,500 examples. For each we sample four candidates, add the gold rewrite, score all five with Equation 1, and train the model to prefer the higher-scoring member of a pair. An early version of the reward dropped the neutral class and renormalized the remaining two probabilities. That version is exploitable: a rewrite can look confidently on-target once neutral is ignored while the grader still reads it as neutral, so the model learns to satisfy the proxy instead of the objective (Gao et al., 2023). Keeping the raw three-way probability closes the loophole, and Section 6 measures what it was costing.

Widening the pool. Three further systems contribute candidates, each failing differently from mT5-base. `facebook/nllb-200-distilled-600M` (NLLB Team et al., 2022), fine-tuned as a monolingual Arabic-to-Arabic "translator", adds architectural diversity (3 beams). An `mT5-large` instance of the same recipe adds capacity (6 beams). An edit-tagging model in the style of LaserTagger (Malmi et al., 2019) and FELIX (Mallinson et al., 2020) labels each source token KEEP, DELETE or REPLACE-with-a-mined-word; it cannot paraphrase at all, which is why it helps, and still reaches the reference for 90.6% of validation sources. Retrieval, in the spirit of Li et al. (2018) and of sentence-embedding similarity scoring more generally (Ibrahim et al., 2023), contributes the gold rewrite of any training source within 0.90 cosine similarity of x, covering the 22.8% of test sentences that recur verbatim.

Reranking and repair. Every candidate, retrieved ones included, is ranked by Equation 1 and the top one is returned; a retrieved rewrite has to win on the same terms as a generated one. A final deterministic pass applies the mined lexicons of Section 3, flipping any emoji or antonym that still carries the source polarity.

5 Experimental Setup

Table 2 lists the deployed configuration. The submitted generator is trained on all 7,716 train and validation pairs; validation figures quoted during development come from the held-out 964-row split. We grid-searched α and the near-duplicate threshold on validation, but that signal was misleading on one axis. Its best setting was $\alpha = 1$, all weight on polarity and none on content, and submitting it lowered BLEU and chrF on the leaderboard. We

therefore moved part of the way towards each validation optimum rather than adopting it outright.

Hyperparameter	Value
Primary generator	mT5-base
Primary beams (std. / hard dir.)	10 / 13
NLLB-200 beams (pooled)	3
mT5-large beams (pooled)	6
DPO preference examples	4,500
DPO candidates/example	4 sampled + gold
DPO epochs	7
Reranking weight α (polarity)	0.85
Reranking weight $1-\alpha$ (chrF)	0.15
Retrieval similarity threshold	$\geq$0.90 (cosine)

Table 2: Key hyperparameters of the final deployed system.

6 Results

Our submission reached SSA = 0.9581, BLEU = 56.91 and chrF = 72.18, first of fifteen submissions and 17.3 SSA points ahead of the second-placed system (Table 3). The margin is specific to SSA: several systems are within a few points on BLEU and chrF and differ mainly in whether the polarity actually flipped.

#	Team/Participant	SSA	BLEU	chrF
1	**ALEXIS (momen_ibrahim)**	**0.9581**	**56.91**	**72.18**
2	akarrouch	0.7851	49.82	70.12
3	ahmadalmoustafa	0.7789	41.48	64.45
4	mona_	0.7597	51.58	71.02
5	melmoussaoui	0.7530	49.03	69.53
6	mohamedsabaa	0.7447	49.07	69.33
7	hsnhb7	0.7343	46.80	67.10
8	areejkhaled	0.6898	54.63	72.61
9	mohammed_bahgat	0.6732	41.38	65.84
10	ehabashraf	0.6732	41.38	65.84
11	ahmad_alshattha	0.6354	25.07	56.33
12	hoanguitcs	0.6220	49.27	68.26
13	normalman159	0.5997	11.31	38.22
14	mustafaelkady	0.4772	0.03	10.04
15	mohamedmhaouach	0.2807	43.06	64.61

Table 3: Official Subtask 2 leaderboard. Our submission is shown in bold.

What each component contributed. Table 4 traces the system's development. Every row was submitted and scored on the leaderboard, so the gains are real test-set gains rather than validation estimates. Starting from mT5-base with retrieval and reranking (0.7452), the edit tagger and a wider candidate pool added +0.017, and DPO together with the NLLB-200 and mT5-large generators added a further +0.027. Replacing the evaluation classifier with our dedicated one for source-polarity detection added +0.155, more than three times the two generation-side gains combined. Correcting p_t, first in the reranker and then in the DPO reward, added the last +0.015.

The reason is simple: if the source polarity is wrong, the system rewrites a negative sentence to be more negative, and no beam width or reranking weight recovers from that. Everything before this fix was tuning how well the system reached a target that was wrong on a quarter of the test set.

Configuration	SSA	Δ
mT5-base + retrieval + reranking	0.7452	–
+ edit tagger, wider pool	0.7618	+0.017
+ DPO, NLLB & mT5-large	0.7887	+0.027
+ dedicated polarity clf.	**0.9436**	**+0.155**
+ hard polarity gate	0.8933	−0.050
+ raw-softmax reranking	0.9498	+0.006
+ DPO reward fix (final)	**0.9581**	+0.008

Table 4: Cumulative ablation; every row is an independent leaderboard submission. Δ is measured against the previous *retained* configuration: the hard polarity gate was reverted after it regressed, so the two following rows are measured from 0.9436.

A change that looked safe and was not. One row in Table 4 is a regression. We added a hard gate that discarded any candidate the classifier did not label with the target polarity. It appeared to cost nothing on held-out validation, so we submitted it, and the score fell by 0.050. The flaw was in the check: the same classifier chose the candidates and judged them, so it could not detect where it disagrees with the grader. A reranking rule validated only against the signal it optimizes will always look correct. We reverted the gate and moved to the raw three-way softmax, which recovered the loss and then some.

Cost. Running four generators, a tagger and a retrieval index at inference is expensive, and Table 4 shows where to economise: the pooled generators are worth about +0.044 in total, against +0.155 for the polarity classifier alone. A latency-sensitive deployment could keep only mT5-base and the classifier.

7 Conclusion

We presented a system for Arabic sentiment swap that treats the task as constrained editing and makes the target polarity explicit. One scoring function holds polarity and content in balance, serving both as the DPO reward and as the reranker over a pool

of four generators and a retrieval index. The system ranked first of fifteen submissions.

The largest single gain, however, came from predicting a label the task assumed would be given. The natural substitute, the classifier that grades the task, is unreliable at that job. When a shared task is built around an auxiliary classifier, it is worth measuring that classifier on the sub-task it is asked to perform before trusting it.

Abstract

We present ArA-DF 2026, the first shared task for Arabic speech deepfake detection, held at ArabicNLP 2026. Unlike existing benchmarks that conflate all distribution shift into a single evaluation set, ArA-DF 2026 separates dialect generalization (Track 1: unseen Arabic dialects and speakers) from acoustic robustness (Track 2: codec compression, noise, reverberation, re-encoding). We release 43,500 labeled training utterances spanning MSA and regional dialects, plus blind evaluation sets of 144,210 (Track 1) and 127,746 (Track 2) utterances, ranking systems by EER. Fourteen teams competed on Track 1 and twelve on Track 2, with eight system description papers submitted. The best submissions cut EER from 14.54% to 0.87% (Track 1) and from 27.11% to 0.66% (Track 2). Across independent submissions, three findings recur: augmentation and data curation move performance far more than architecture; simpler pooling heads often outperform graph-attention back-ends once augmentation is applied; and external synthetic Arabic speech with mismatched generation artifacts hurts rather than helps. Residual errors concentrate on short utterances and on spoofed audio misclassified as bona fide.

1 Introduction

Neural text-to-speech (TTS) and voice conversion (VC) have reached the point where synthetic speech is difficult to distinguish from genuine recordings by ear. In a controlled listening study, human listeners identified deepfake audio correctly only 73% of the time, and familiarizing them with examples improved performance only marginally (Mai et al., 2023); a large-scale evaluation reached similar conclusions (Warren et al., 2024). The same technologies that enable accessible speech interfaces (Tan, 2023; Chen et al., 2025) also enable impersonation, voice fraud and the fabrication of audio evidence (Li et al., 2025), which makes reliable automatic detection a practical safeguard rather than an academic exercise.

The research community has responded with a decade of organized evaluation, from the ASVspoof series (Wu et al., 2017) through the single-language and single-domain challenges that followed (Figure 1). That work has produced a stable recipe of a self-supervised (SSL) front end, a lightweight back end and heavy augmentation (Section 2). Despite this convergence, the field's central problem remains open: detectors that are near-perfect in-domain degrade sharply on unseen synthesis methods, unseen channels and unseen recording conditions (Müller et al., 2022; Liu et al., 2023; Wang et al., 2024). Recent large-scale comparisons make the point quantitatively, across 400 trained systems, the choice of pre-trained front end and of training corpus dominates the variance in cross-domain performance, while the back-end classifier contributes less than one point of EER (El Kheir et al., 2026a).

Almost all of this evidence comes from English. Arabic is spoken by roughly 450 million people, is served by a growing set of commercial and open Arabic TTS and VC systems, and presents a form of variation that English benchmarks do not exercise: Modern Standard Arabic (MSA) and the regional dialects differ substantially in phonology, morphology and prosody, so that a detector trained on one variety may not transfer to another. Arabic-specific resources have begun to appear (Section 2), but before this task there was no shared, blind benchmark on which Arabic detectors could be compared under a common protocol.

ArA-DF 2026 fills that gap. Its distinguishing design choice is that it varies dialect and acoustics *independently* across two tracks rather than pooling them. This matters because the two failure modes have the same symptom, an accepted spoof, but different remedies, and a single aggregate score cannot tell an organizer or a practitioner which

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1473–1485
October 28-29, 2026 ©2026 Association for Computational Linguistics

one they are looking at. The separation proved informative: the two tracks rank systems differently and reward different designs (Section 7). Our contributions are: (1) **task design**, two tracks that isolate dialect shift from acoustic shift under a single labeling convention and metric; (2) **dataset release**, a labeled Arabic bona fide/spoofed corpus with dialect-family and gender metadata, plus blind evaluation partitions of 144,210 and 127,746 utterances; (3) **baseline and infrastructure**, a public XLS-R+AASIST baseline, scoring code, and two Codabench leaderboards; and (4) **findings**, an analysis of eight system description papers identifying what actually moved the needle, plus reproducible *negative* results on external synthetic data that we believe are as useful as the positive ones.

2 Related Work

Benchmarks and challenges. Figure 1 places ArA-DF 2026 in the lineage of organized evaluation. The ASVspoof series (Kinnunen et al., 2017; Wang et al., 2020; Liu et al., 2023; Wang et al., 2024) established the conventions the present task inherits: a binary bona fide/spoofed decision, threshold-free scoring by equal error rate, and a blind evaluation partition; ASVspoof 2021's codec and telephony condition definitions were reused directly by several ArA-DF 2026 participants. The ADD challenges (Yi et al., 2022, 2023) narrowed organized evaluation to a single language, Mandarin, the branch this task extends to Arabic. For generalization specifically, the In-the-Wild corpus (Müller et al., 2022) showed that detectors trained on controlled data collapse on uncurated audio, MLAAD (Müller et al., 2024) extended the problem past 50 languages, and SpoofCeleb (Jung et al., 2025) scaled it to thousands of speakers. Aggregation efforts such as Speech-DF-Arena (Dowerah et al., 2026) and AUDDT (Zhu et al., 2025) place many of these sets behind a single interface, and report that AASIST-based systems generalize comparatively poorly out of domain (see Section 8).

Front ends, back ends and augmentation. Hand-crafted spectral features (Todisco et al., 2017; Yang et al., 2019) have largely given way to SSL encoders: wav2vec 2.0 (Baevski et al., 2020), its cross-lingual extension XLS-R (Babu et al., 2022; El Kheir et al., 2025a), WavLM (Chen et al., 2022), HuBERT (Hsu et al., 2021) and W2V-BERT-2.0 (Barrault et al., 2023). Layer-wise analyses show that intermediate layers carry more spoofing-relevant information than the final one (El Kheir et al., 2025c; Xiao and Vu, 2025), motivating the learnable weighted-sum aggregation that most ArA-DF 2026 systems adopt; fine-tuning such an encoder end-to-end with heavy augmentation is now the reference recipe (Tak et al., 2022b). On the back-end side, AASIST (Jung et al., 2022) remains the default, alongside RawNet2 (Tak et al., 2021), ECAPA-TDNN (Desplanques et al., 2020), attentive statistics pooling (Okabe et al., 2018), temporal-channel modeling (Truong et al., 2024), Nes2Net (Liu et al., 2025) and BiCrossMamba-ST (Kheir et al., 2025). Augmentation is the third pillar: RawBoost (Tak et al., 2022a), room impulse responses (Ko et al., 2017) and MUSAN noise (Snyder et al., 2015) are near-universal, and post-training on large artifact-bearing corpora has recently been shown to improve transfer (Ge et al., 2025). DeepFense (El Kheir et al., 2026a) packages these components as interchangeable modules; two ArA-DF 2026 teams built their pipelines on it.

Arabic speech and Arabic anti-spoofing. Arabic speech technology has grown rapidly, from dialect-aware recognition and large multi-dialect corpora such as SADA (Alowisheq et al., 2024) to open Arabic speech synthesis (Toyin et al., 2025). Arabic anti-spoofing is newer: ArFake (Elsetohy et al., 2025) introduced a multi-dialect benchmark with leave-one-generator-out and leave-one-dialect-out protocols targeting the same two generalization axes as this task; AFAD-MSA (Issa, 2026) released MSA-focused fake-audio data; and MLAAD (Müller et al., 2024) includes an Arabic split. These resources informed systems from several of our participants. ArA-DF 2026 builds on this momentum, following prior ArabicNLP shared tasks such as Iqra'Eval (El Kheir et al., 2025b), by contributing a hosted benchmark with a large blind evaluation partition, an open baseline and tutorial, a live leaderboard, and two tracks that vary dialect and acoustic condition independently.

3 Task Motivation and Overview

3.1 Motivation and Task Definition

Zero-shot TTS and voice cloning APIs are available in abundance making impersonation, fraud, and fabricating audio evidence much easier than ever. Among anti-spoofing benchmarks, Arabic remains under-represented despite a demanding mix of MSA and regional dialects that differ in

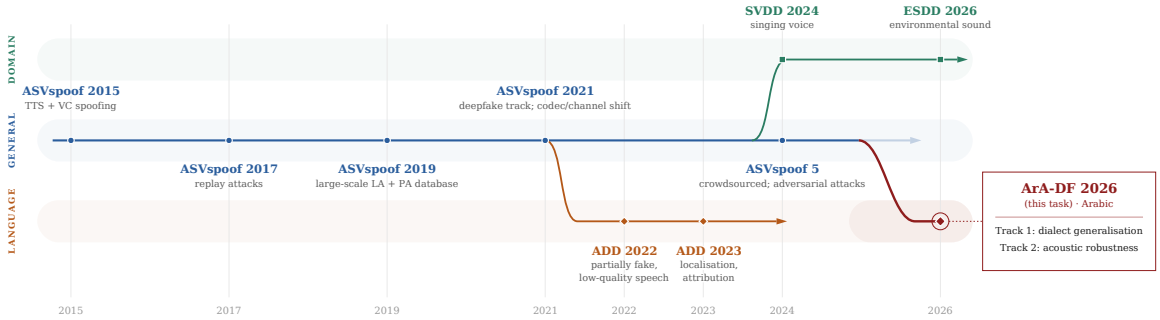

Figure 1: Timeline of speech deepfake detection challenges, grouped by benchmark scope: general-purpose (the English-dominant ASVspoof series), single-language (ADD, Mandarin; ArA-DF 2026, Arabic, in red), and single-domain (SVDD (Zhang et al., 2024), ESDD (Yin et al., 2025)).

phonology, prosody and lexical patterns. We therefore position ArA-DF 2026 as, to the best of our knowledge, the first dedicated blind shared task for Arabic speech deepfake detection.

We have chosen binary utterance classification (bonafide or spoofed) over generator attribution to lower the entry barrier while retaining questions of calibration and robustness both acoustically and towards unseen dialects. Systems receive 16-kHz mono speech; label `1` is bona fide and `0` is synthetic. System submissions include `audio_id,logit`, where larger logits favor bona fide speech. In order to rank systems, we use Equal Error Rate (EER) (Section 5) as the metric, so that there is no common threshold required. The spoofed split of the final benchmark contains TTS spoofs, and not identified voice-conversion or partial-spoof category.

3.2 Tracks

Track 1: Dialect Generalization and Beyond The first track of the challenge is to measure the robustness to dialects and synthesis conditions beyond what is represented in supervised training data. The training and development splits provide MSA, Egyptian, and Gulf Arabic as the dialect labels along with the bona fide or spoof binary label. In the testing phase, Track 1 additionally introduces Levantine and Maghrebi samples and held-out generation methods. Every test sample also receives one telephony-style logical-access (LA) transform and one distribution-format (DF) transform. Track 1, therefore is deliberately a joint dialect, generator, and channel-shift problem, rather than measuring the robustness of dialect alone (though it is our main focus).

Track 2: Acoustic Robustness. The second track retains the three core dialect families (MSA, Egyptian and Gulf) and probes whether the systems are robust to downstream acoustic changes. Approximately 20% of its tests are from clean signal, while the remainder is divided nearly equally among lossy coding, additive environmental noise, and room reverberation. Held-out synthesis systems also occur, so errors may reflect the acoustic shift, the generator shift, or their interaction. This reflects the usual deployment setting, where synthetic audio is commonly compressed, transmitted, or re-encoded prior to analysis. The train/development splits are common across tracks. The evaluation uses separate CodaBench competitions. Teams could enter either or both. Because their processed tests derive substantially from common sources, cross-track scores are complementary rather than independent experiments or controlled estimates of channel effects.

4 Dataset and Resources

4.1 Release Snapshot

The public Hugging Face repository (Arabic-Speech, 2026) is the authoritative release. Its six canonical partitions contain 345,672 utterances (884.88 hours). Four post-challenge labeled configurations mirror the test metadata and add gold labels without duplicating audio. All recordings are 16-kHz mono PCM-16 FLAC, packaged in WebDataset TAR shards (Breuel, 2020) with JSON sidecars and Parquet metadata. Table 1 gives exact partition and class counts; hours are rounded to two decimals.

Split	Rows	Hours	BF	Spoof
Train	22,500	59.56	7,500	15,000
Development	21,000	52.69	6,952	14,048
T1 dev-test	16,023	40.94	4,097	11,926
T1 final	144,210	366.16	36,903	107,307
T2 dev-test	14,193	36.51	3,510	10,683
T2 final	127,746	329.03	31,490	96,256
Total	**345,672**	**884.88**	**90,452**	**255,220**

Table 1: Canonical published partitions. BF denotes bona fide; test labels were hidden during the challenge and released afterwards.

4.2 Source Collections and Eligibility

The manifests combine ADI-17/ADI-20 and MGB-lineage speech (Shon et al., 2020; Ali et al., 2019; Elleuch et al., 2025) with organizer-held collections. MSA draws from audiobooks, news anchors, Tunisian MSA, MSA YouTube, and MediaSpeech (Kolobov et al., 2021); Egyptian from an internal Egyptian collection and ADI-17; and Gulf from Saudi podcasts, ADI-17, and Bahraini YouTube. Test-only Levantine draws from Lebanese, Jordanian, and Syrian recordings, Jordanian YouTube, and ADI-17. Test-only Maghrebi draws from Moroccan and Tunisian recordings, ADI-17, and TunSwitch (Ben Abdallah et al., 2024). Every selected utterance retains its source in the organizer manifest.

Following the broad MGB-3 convention (Ali et al., 2017), manifest codes were grouped as MSA; Egyptian (EGY); Gulf (KSA, UAE, KUW, QAT, BAH, OMA, YEM, and IRA); Levantine (JOR, LEB, SYR, and PAL); or Maghrebi (TUN, MOR, MAU, ALG, and LIB). An utterance was eligible if it had UTMOS ≥ 3.0 (Saeki et al., 2022), a nonempty Zipformer-XL ASR transcript (Yao et al., 2024), and duration in $[0, 15)$ seconds; the transcript gate removed 88 records. Core-family sampling used seed 42 and preserved the available proportions of the $[0, 5)$, $[5, 10)$, and $[10, 15)$-second bands.

The test-only families used equal band quotas with backfill. Levantine contributed 834/833/833 utterances across the three bands. Maghrebi supplied all 387 eligible short utterances and 1,057/1,056 from the longer bands. Levantine comprises 1,294 JOR, 1,012 LEB, 141 SYR, and 53 PAL records; Maghrebi comprises 1,438 TUN, 629 MOR, 313 MAU, 89 ALG, and 31 LIB records. Levantine sources comprise 972 Lebanese, 631 Jordanian, 62 Syrian, 658 Jordanian YouTube, and 177 ADI-17 recordings. Maghrebi sources comprise 604 Moroccan, 420 Tunisian, 1,018 TunSwitch recordings, including 42 code-switched items, and 458 ADI-17 recordings.

4.3 Role-Based Source Pools

Figure 2 shows the two-lane construction. Pool 1 supplies bona fide speech. Pool 2 contains real recordings whose transcripts and voices serve as targets for synthesis. Levantine and Maghrebi are reserved for Track 1. The eligible inventories contain 11,220 MSA, 18,079 Egyptian, 72,037 Gulf, 8,875 Levantine, and 6,395 Maghrebi utterances. Each core pool has 77,500 records: MSA contributes 2,500 to each source split, Egyptian 2,500/7,500/7,500, and Gulf 2,500/25,000/25,000 for train/development/test. Each test-only family contributes 2,500 records.

Pool 2 uses EGY for Egyptian synthesis and KSA for Gulf synthesis. Pool 1 prioritizes non-Saudi Gulf recordings, but KSA still accounts for 70,461 of the 72,037 eligible Gulf records. A direct comparison of utterance IDs shows that Pool 1 and Pool 2 overlap by 1,259/1,260/1,261 MSA records, 2,431/7,294/7,296 Egyptian records, and 1,249/15,858/15,856 Gulf records across train/development/test. This planned overlap supplies matched real and synthetic examples; the remaining Pool 2 records add unpaired targets. Saudi podcasts supply 69,850 Gulf records, while MSA includes 6,693 audiobook and 2,292 news-anchor records.

4.4 Source-Linked Synthesis

Each synthetic utterance uses one Pool 2 record: its ASR transcript provides the text and its audio provides the cloning reference. References underwent Resemble Enhance (Resemble AI, 2023), loudness normalization, and model-rate resampling; supported systems also received Arabic family or dialect hints. Pool overlap creates matched real–synthetic cases, while the remaining targets add unpaired synthetic examples.

The internal HumainVoice-Internal-TTS system occurs in every split, as does VoxCPM2 (Zhou et al., 2026). F5-TTS, Fish Speech 1.5, and ElevenLabs (Chen et al., 2024; Liao et al., 2024; ElevenLabs, 2026) are test-only: F5-TTS covers Gulf, Fish Speech covers Egyptian and MSA, and ElevenLabs covers all five families. Withholding generated ElevenLabs train/development material preserves it as a held-out system. Table 2 reports final challenge rows. Train has 7,500 bona fide and

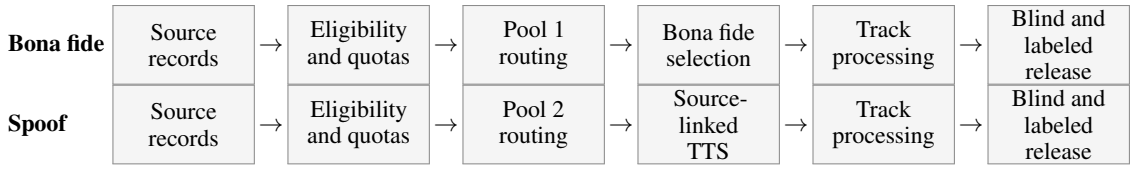

Figure 2: Two-lane construction process. Numerical split, generator, dialect, and condition composition is kept in Tables 1–2 rather than duplicated in the diagram.

7,500 utterances from each seen synthesizer; development has 6,952, 7,045, and 7,003, respectively. Both seen synthesizers re-synthesize 4,939 training sources also released as bona fide.

Track 1 additionally contains 2,000 records imported from MLAAD (Müller et al., 2024): 1,000 spoofed and 1,000 bona fide. The imported component pairs generated speech with English M-AILABS audiobook recordings, adding a focused cross-lingual condition. Its bona fide side contributes 87 development-test and 913 final-test trials. The 1,000 spoofed trials form one MLAAD source category for evaluation and reporting.

4.5 Test Assembly and Track Processing

The Track 1 pool contains 160,233 rows: 16,023 development-test and 144,210 final-test. Track 2 contains 141,939 rows: 14,193 and 127,746, respectively. We partitioned released trials rather than underlying source utterances to retain broad generator, family, and condition coverage in both phases. Thus, 12,866 Track 1 source IDs appear in both through different trials.

Every Track 1 item passes through one logical-access (LA) transform followed by one deepfake-channel (DF) transform. The six LA choices are 8-kHz A-law; a 300–3,400-Hz PSTN simulation with gain in $[-3, 3]$ dB followed by an A-law/GSM tandem; 16-kHz G.722; 8-kHz μ-law; GSM full-rate; and Opus at 8, 12, or 16 kbps (Valin et al., 2012). The eight DF choices are MP3 at 32/128 kbps, M4A at 32/128 kbps, Ogg Vorbis at quality 0/6, MP3-32→M4A-64, and Ogg-q0→M4A-64. All 48 LA–DF combinations occur, with near-balanced LA and DF marginals. Bona fide and spoofed speech receive the same processing, so the track tests detection after a complete transmission-and-compression chain.

Track 2 assigns exactly one condition to each item: clean (28,388 rows), codec round-trip (37,850), additive noise (37,851), or reverberation (37,850). Codec conditions use M4A at 20–32 or 96–112 kbps, MP3 at 80–120 or 220–260 kbps, and Ogg Vorbis at quality 0 or 6. Noise uses 930 MUSAN noise recordings, excluding music and babble (Snyder et al., 2015), at an SNR in $[0, 15)$ dB; 34,325 assignments use FreeSound recordings and 3,526 use SoundBible recordings. Reverberation uses 4,094 room impulse responses: 12,366 small-room, 12,425 medium-room, 12,759 large-room, and 300 real-RIR assignments from RIRS_NOISES/OpenSLR 28 (Ko et al., 2017). Together, they cover common coding, noise, and room-acoustic effects.

Dimension	Category	Train	Dev	T1 test	T2 test
Source family	MSA	7,500	1,459	10,647	10,647
	Egyptian	7,500	4,529	30,645	30,645
	Gulf	7,500	15,012	100,647	100,647
	Levantine	0	0	8,147	0
	Maghrebi	0	0	8,147	0
	MLAAD	0	0	2,000	0
Class/system	Bona fide	7,500	6,952	41,000	35,000
	HumainVoice-Internal-TTS	7,500	7,045	40,000	35,000
	VoxCPM2	7,500	7,003	40,000	35,000
	F5-TTS	0	0	25,000	25,000
	Fish Speech 1.5	0	0	9,998	9,998
	ElevenLabs	0	0	3,235	1,941
	MLAAD spoof	0	0	1,000	0
Test condition	T1 LA×DF	–	–	160,233	–
	T2 clean	–	–	–	28,388
	T2 codec	–	–	–	37,850
	T2 noise	–	–	–	37,851
	T2 RIR	–	–	–	37,850

Table 2: Final composition by separate descriptive axes. T1/T2 columns combine development-test and final-test; the panels describe the same rows. The MLAAD source family contains 1,000 bona fide and 1,000 spoofed trials.

4.6 Packaging, Blindness, and Integrity

The release uses 88 WebDataset shards of at most 4,096 FLAC/JSON pairs. Parquet and compressed-CSV indexes record paths, audio properties, SHA-256 hashes, and byte sizes. Hugging Face exposes nine configurations: `train_dev`, four challenge-era blind tests, and four labeled mirrors. Since `train_dev` contains train and development, the loader exposes ten splits.

Train/development names include family and a predicted-gender token. Test names follow `test_<7-digit-id>` and hide label and provenance. Each labeled mirror preserves its blind split's IDs, order, paths, hashes, and durations,

adding only the label. Test IDs are configuration-local: 203 recur across development-test configurations and 2,013 across final-test configurations, so the record key is `(configuration, id)`.

The organizer mapping connects all 345,672 records to their source, transcript, family, generator, and condition. Validation confirmed unique record keys, agreement between metadata and shard membership, uniform 16-kHz mono audio, and exact ID/path/duration/hash correspondence between blind and labeled configurations. The mapping supports reproducible scoring and the subgroup analyses reported here.

5 Evaluation

5.1 Metric

Both tracks are ranked by **Equal Error Rate (EER)**, the standard anti-spoofing metric: the point where the false acceptance rate (spoofed audio accepted as genuine) equals the false rejection rate (genuine audio rejected as spoofed) as the decision threshold varies.

5.2 Submission and Leaderboards

Both tracks were hosted on Codabench, which scored submissions automatically and maintained a live leaderboard. Participants uploaded a CSV of `audio_id,score` pairs covering every utterance in the relevant partition; malformed or incomplete files were rejected by the scoring program. Resources, dataset, baseline checkpoint, scoring script and submission templates, were consolidated on the Hugging Face organization page so that participants could reproduce the official metric locally before submitting.

Participation was substantial. Track 1 attracted 35 registered participants who made 616 scored submissions across the two phases, and Track 2 attracted 30 participants and 419 submissions. Since the evaluation phase capped submissions per team, the great majority of these were development-phase runs, roughly 18 and 14 per participant respectively.

6 Baseline

We provide a single baseline for both tracks, chosen to represent the prevailing recipe in the anti-spoofing literature rather than to be competitive: an **XLS-R 300M** front end (Babu et al., 2022) paired with an **AASIST** graph-attention back end (Jung et al., 2022), trained on the official training split with no augmentation. The front end is fully fine-tuned; the back end reads a single SSL layer and produces a two-class output, and the submitted score is the difference between the bona fide and spoof logits. Inputs are cropped or padded to 64,600 samples (≈ 4.04 s) at 16 kHz.

The baseline is implemented in **DeepFense** (El Kheir et al., 2026a), an open-source PyTorch toolkit in which the front end, back end, loss and augmentation are interchangeable components specified through a single configuration file. We chose it so that participants could vary one component at a time without re-implementing the surrounding pipeline, and so that our own setup is fully recoverable from the released configuration. The checkpoint, the YAML configuration and a step-by-step tutorial for reproducing the reported numbers and extending the recipe are available at `https://huggingface.co/ArabicSpeech/ArA-DF-Baseline`. Two participating teams built their submissions directly on DeepFense.

The baseline reaches 14.54% EER on the Track 1 final test and 27.11% on Track 2 (14.65% and 27.21% respectively on the corresponding development-test partitions). Two observations are worth recording. First, the gap between the two tracks is large: the same system loses roughly 13 points of EER when moving from dialect shift to acoustic shift, confirming that unaugmented training keys on channel characteristics that the Track 2 degradations destroy. Second, the baseline is beaten by a wide margin, by more than an order of magnitude at the top of both leaderboards, and, as Section 8 shows, most of that gain is attributable to the data pipeline rather than to the architecture.

7 Results

Table 4 first characterizes the eight systems with description papers along the axes that distinguished them (front end, adaptation strategy, back end, augmentation and fusion scheme), with the comparison across those axes taken up in Section 8.

Tables 5 and 6 give the official evaluation-phase leaderboards.[1] Fourteen teams were ranked on Track 1 and twelve on Track 2, with ten appearing on both.

[1] Some system description papers report slightly different ranks or team totals, having been written against an earlier leaderboard snapshot; the tables here reflect the final official standings.

Table 6: Track 2 (Acoustic Robustness) official leaderboard, 127,746 utterances; the baseline is placed in score order.

Four observations frame the discussion that follows.

Nearly every submission beat the baseline. All fourteen ranked Track 1 teams finished below the 14.54% baseline, and eleven of twelve did so on Track 2, with a single entry at 33.53% falling short. The margins at the top are an order of magnitude: 0.87% on Track 1 and 0.66% on Track 2.

The top of each track is a statistical tie. On Track 1, ranks one to four span 0.055 percentage points (0.8719 to 0.9265 at the four-decimal precision reported by Ehab et al. (2026)), and the margin between first and second is 0.0088. On Track 2 the top four span 0.66 points, but every adjacent gap within that group is below 0.35. Both are small relative to the run-to-run variance Raid AI estimate from three seeds, a standard deviation of 0.25 points and a range of 0.47 (Ehab et al., 2026). We therefore describe the leading systems on each track as competitive with one another rather than strictly ordered, and regard the ranking as informative from roughly rank five downward, where the gaps exceed a point.

The two tracks do not rank systems the same way. Ten teams appear on both leaderboards, and their rankings correlate at Spearman $\rho = 0.58$: related, but far from interchangeable. The movements are large, pi-labs.ai placing fourth on Track 1 at 0.93% but tenth on Track 2 at 14.40% and Minh-Hoang Le moving the opposite way, from last to seventh; only two teams hold the same relative position on both. This is the clearest support for

separating the two conditions: a pooled evaluation would have averaged these movements away.

Acoustic shift is severe when untreated and tractable when addressed. Track 2 starts harder than Track 1 by baseline (27.11% vs 14.54%) but ends easier at the top (0.66% vs 0.87%), because augmentation closes the acoustic gap directly (Fang et al., 2026), giving Track 2 a wider spread than Track 1. Dialect shift has no such fix: PogranichnyZashchitnik's heavily-augmented system scores 5.66% on Track 2 but 12.54% on Track 1, with 11.5% of Track 1 spoofs scored as confidently bona fide (Le, 2026). UZH-CL find the converse, their dialect-specialized detector *raising* EER in the Track 2 fusion (Farhadipour et al., 2026), so adapting to one shift can hurt the other.

8 Lessons from the First Arabic Speech Deepfake Challenge

Despite their methodological diversity, the eight systems converge on a small set of design choices. Participant-reported ablations quantify the effects of several of these choices, as summarized in Table 7. Because the teams used distinct end-to-end pipelines, the reported effects are derived from *within-system* ablations rather than controlled cross-team comparisons. Section 9 discusses the implications of this constraint.

Models. Every system builds on a pre-trained SSL encoder, XLS-R in seven of eight, and half the field replaces the final layer with a learnable weighted sum over all layers (El Kheir et al., 2025c; Xiao and Vu, 2025). Three teams found AASIST beaten by a simpler pooling head, matching evidence that graph-attention back ends generalize poorly out of domain (Sakr and Elzahaby, 2026; Dowerah et al., 2026; El Kheir et al., 2026a). Parameter-efficient adaptation was competitive: UZH-CL's prompt tuning updates under 1% of parameters and places third on Track 2.

Data. Data was the largest lever in every ablation that isolated it, moving a fixed architecture from 13.13% to 1.37% in the clearest case (Ehab et al., 2026; Fang et al., 2026; Albani and Sonbol, 2026). The most useful negative finding also lives here: **adding external synthetic Arabic speech reliably hurt**, whether ArFake (Elsetohy et al., 2025), ArVoice (Toyin et al., 2025), copy-synthesis pseudo-spoofs (Alowisheq et al., 2024; Siuzdak, 2023) or MLAAD. The cause appears to be artifact rather than topical mismatch, and the harm scales with the mismatched fraction (Sakr and Elzahaby, 2026). A distinct use case was reported by UZH-CL, which used external corpora to increase diversity among ensemble components rather than to improve any individual model.

Design choice	Teams	Reported within-system effect (EER)
SSL encoder front end	8/8	universally adopted; no non-SSL comparison
Learnable layer aggregation	4/8	adopted; effect not isolated
Pooling head instead of AASIST	5/8	20.2→7.0; 5.2→4.4
Channel-matched augmentation	8/8	7.0→1.5; 6.3→2.3
Data curation (excluding OOD data)	–	2.6→1.5
External synthetic Arabic	4/8	degraded performance in 3 of 4 reported uses
Longer analysis window (4→10 s)	–	28.7→20.2
Multi-crop test-time augmentation	2/8	18.3% relative reduction in one study; track-dependent in another
Score fusion	7/8	≥40% relative reduction vs. the best component
Encoder scale (0.3B→2B)	3/8	≤0.09 percentage-point change

Table 7: Design choices reported across the eight system papers and their effects when evaluated through within-system ablations ((Fang et al., 2026; Sakr and Elzahaby, 2026; Albani and Sonbol, 2026; Ehab et al., 2026; Alhammad and Aldahlawi, 2026); Sections 7–8). Adoption counts denote the number of system papers reporting each choice; "–" indicates that the adoption count was not consistently reported. Reported effects are changes in EER within individual systems and should not be compared directly across rows.

Training and inference. Three cheap techniques paid off: longer analysis windows, multi-crop averaging at test time (which helps Track 1 but hurts Track 2 (Farhadipour et al., 2026)), and score fusion, used by seven of eight teams. Thakaa show why fusion works, contribution tracking error *independence* rather than individual accuracy (Alhammad and Aldahlawi, 2026).

Recommendations. The participant-reported ablations suggest five practical recommendations for future work on Arabic deepfake detection. (1) Prioritize channel-matched augmentation and training-data curation over increasing encoder scale. Data-focused interventions reduced EER by up to an order of magnitude, whereas encoder scaling changed EER by at most 0.09 percentage points in the reported comparisons. (2) Before incorporating an external synthetic corpus at scale, evaluate it at small mixture proportions and assess whether its generation artifacts are compatible with the target domain. Performance degraded in three of four reported uses, with larger degradation at higher proportions of mismatched data. (3) Select ensemble components based on error *complementarity*, as assessed using score correlation or error overlap, rather than standalone accuracy. (4) Use duration-aware handling for utterances shorter than the analysis window. Short utterances accounted for a dis-

proportionate share of the residual errors in every reported duration-based analysis. (5) Report variability across random seeds. The only reported multi-seed analysis had a standard deviation of 0.25 percentage points and a range of 0.47 percentage points in EER, exceeding all leaderboard gaps among the top four systems on both tracks. Differences of this magnitude from single runs should therefore not be interpreted as reliable evidence of method-level improvements.

9 Conclusion

We presented ArA-DF 2026, the first shared task on Arabic speech deepfake detection, with two tracks separating dialect generalization from acoustic robustness. Training data and augmentation, rather than architecture, drove the order-of-magnitude gains over the baseline, and the two tracks ranked systems differently ($\rho = 0.58$), supporting their separation. Short utterances and dialect shift remain open; a second edition should add duration-stratified evaluation with duration-adaptive scoring, broader dialect and generator coverage under leave-one-generator-out protocols (Elsetohy et al., 2025), source tracing, localization (Zhang et al., 2023), explanation (El Kheir et al., 2026b), and group-wise fairness and calibration reporting (El Kheir et al., 2026a).

Limitations

The eight systems differ simultaneously in their encoders, back-end architectures, training data, augmentation strategies, and fusion methods; cross-team score differences therefore cannot be attributed to individual techniques. Accordingly, claims in Section 8 about the effects of specific techniques rely on participant-reported within-system ablations. With one exception, these results are based on single runs. The sole multi-seed analysis reported a standard deviation of 0.25 percentage points and a range of 0.47 percentage points in EER, suggesting that differences below approximately 0.5 percentage points should be interpreted cautiously. Duration correlates with the label in every partition (clips under 2 s are 7.7% bona fide against 25.6% overall), so the per-duration error rates we cite assume skewed priors, and the labeled data is over 80% male. We rank by EER alone, which says nothing about calibration, and did not regulate transductive use of the evaluation audio, which two teams made use of (P and Iyengar, 2026; Farhadipour et al., 2026).

Ethics Statement

Speech deepfake detection is dual-use, but release is favorable: the generation systems are already public whereas robust Arabic detection resources were not. The bona fide speech comes from publicly available online media (Shon et al., 2020; Ali et al., 2019; Elleuch et al., 2025), and the spoofed partition clones a subset of it without individual consent, which we judge proportionate for an anonymized, research-only release built to defend against this misuse. A reported EER below 1% is not a deployment guarantee, and since error is dominated by spoofs accepted as bona fide, evidentiary use should keep a human in the loop.

Acknowledgments

We thank all participating teams for their submissions and system descriptions, and the ArabicNLP 2026 organizers for hosting the shared task. We thank Feidi Kallel for the reviewing support.

Abstract

This paper presents the SparkShield system submitted to ArA-DF 2026 Track 2, which focuses on robust Arabic speech deepfake detection under realistic acoustic degradations. To improve robustness, we apply a comprehensive augmentation pipeline involving background noise, reverberation, codec compression, re-encoding, and volume perturbation. Our system consists of three parallel subsystems using XLS-R models with 300M, 1B, and 2B parameters as front-end feature extractors. Each subsystem employs learnable layer-wise feature fusion, followed by a Multi-kernel gated Convolution (MultiConv) module and Multi-Head Attention Pooling (MHAP) for utterance-level spoof detection. The output logits of the three independently trained subsystems are finally fused. The proposed system achieves an EER of 0.6575% on the evaluation set and ranks first in ArA-DF 2026 Track 2.

1 Introduction

Recent advances in neural speech generation technologies have significantly improved the quality and naturalness of synthetic speech. Modern text-to-speech (TTS) and voice conversion (VC) systems are capable of producing highly realistic speech that closely resembles human recordings (Du et al., 2025; Chen et al., 2026; Liu, 2024; Zheng et al., 2026). Although these technologies provide valuable applications in human-computer interaction and personalized speech services, they also introduce potential security risks, including speaker impersonation, voice fraud, and the generation of misleading audio content. Therefore, reliable speech deepfake detection has become an important research problem in speech processing and multimedia security.

Many speech deepfake detection studies are conducted under relatively controlled acoustic conditions. However, detecting deepfake speech in real-world environments remains challenging because background noise, reverberation, codec compression, bandwidth limitations, and social-media re-encoding can obscure the artifacts introduced by speech generation systems. Such degradations may suppress subtle synthesis traces and cause a substantial mismatch between clean training data and real-world audio. Recent benchmark efforts, such as ASVspoof 2021, ASVspoof 5 and Audio Deepfake Detection (ADD) challenge, have started to consider more challenging scenarios involving environmental variations and transmission effects (Yamagishi et al., 2021; Wang et al., 2024; Yi et al., 2022, 2023). Nevertheless, existing evaluations have focused primarily on English speech, leaving other languages underexplored. Arabic speech introduces additional challenges because of its dialectal diversity and distinctive phonetic characteristics. Accordingly, ArA-DF 2026 Track 2 evaluates detection robustness under realistic acoustic distortions, providing a practical benchmark for real-world deployment.

In this paper, we present the SparkShield system for ArA-DF 2026 Track 2. Our approach combines realistic audio augmentation with complementary representations extracted from XLS-R models of different scales (Babu et al., 2022). Each subsystem applies learnable layer-wise feature fusion and a MultiConv–MHAP classifier (Tran et al., 2025) to capture spoofing artifacts over different temporal contexts. Finally, the outputs of the three independently trained subsystems are fused to improve detection robustness. Experimental results demonstrate the effectiveness of the proposed approach under realistic acoustic degradations.

2 Task Description and Dataset

2.1 Task Description

We participate in Track 2 of the ArA-DF 2026 shared task, the first benchmark dedicated to robust

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1486–1490
October 28-29, 2026 ©2026 Association for Computational Linguistics

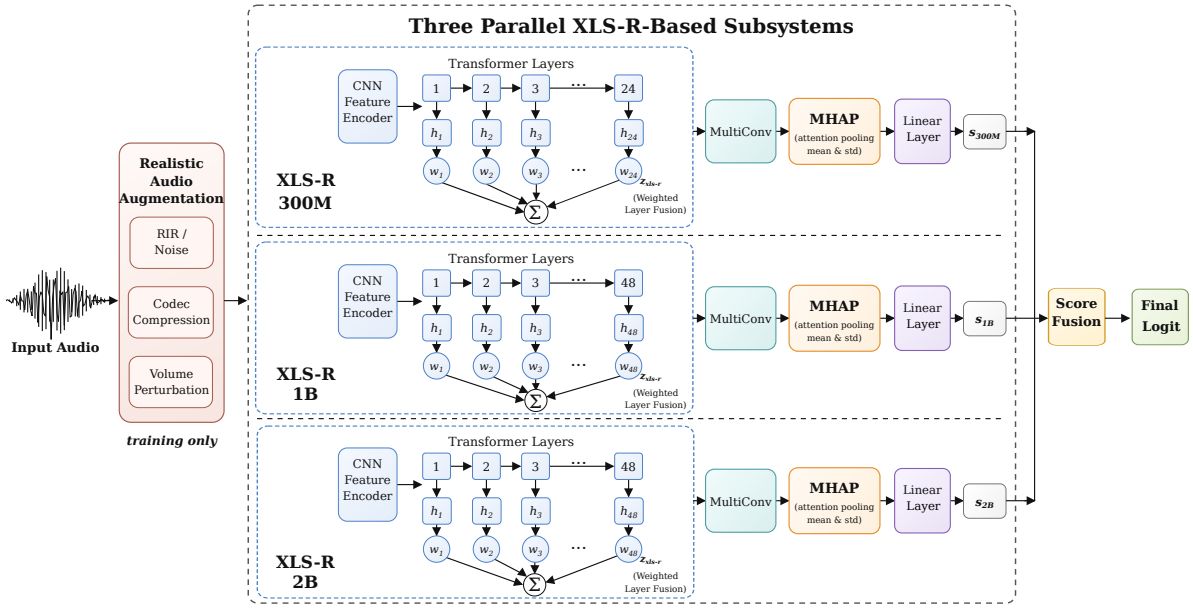

Figure 1: Overview of the proposed system. Realistic audio augmentation simulates environmental and transmission degradations during training. Each subsystem uses an XLS-R front end with learnable layer-wise weighted fusion, followed by a MultiConv–MHAP back end. The scores of the three subsystems are fused to produce the final logit.

Arabic audio deepfake detection. This track targets acoustic robustness: participating systems are evaluated on speech samples corrupted by realistic, real-world distortions, including codec compression, additive background noise, and social-media re-encoding. The task is formulated as a binary classification problem. Each input audio segment is classified as either spoofed or bonafide:

- **Spoofed speech**: synthetic speech from TTS or VC.
- **Bonafide speech**: genuine human speech from native Arabic speakers.

Participants are required to submit logit scores corresponding to the bonafide class, where higher scores indicate a greater probability that the speech is genuine. The primary evaluation metric is the Equal Error Rate (EER), with lower EER representing better detection performance under degraded acoustic conditions.

2.2 Dataset

The dataset is divided into train, dev, dev-test, and test sets containing 22,500, 21,000, 14,193, and 127,746 segments, respectively. The train and dev sets provide labels and dialect-family and gender information in their filenames, while the two test sets are unlabeled and anonymized. All recordings are 16-kHz mono PCM audio. Overall, the mean and median durations across all splits fall within the range of 9.0-9.6 seconds, showing consistent central tendency across splits. Most utterances are between 5 and 15s long. Apart from duration statistics, we also analyze the quantity distribution of bonafide and spoofed audio samples, where bonafide-to-spoof ratio is approximately 1:2. These observations provide practical guidelines for model training and inference.

3 Systems Overview

Figure 1 provides an overview of the proposed system. The system consists of three main components: realistic audio augmentation, XLS-R-based feature extraction with layer-wise weighted fusion, and multi-system score fusion.

3.1 Data Augmentation

We employ a hierarchical data augmentation strategy during training to enhance model robustness. The augmentation pipeline consists of three independent layers: (1) acoustic environment augmentation (80% probability) applying either room impulse response (Ko et al., 2017) or background noise (SNR: 1-20 dB) (Snyder et al., 2015); (2) codec compression (80% probability) using either MP3 compression (32-128 kbps) or random codec chains with multiple encoding passes; and (3) volume adjustment (30% probability) with gain ranging from -2.5 to +2.0 dB, corresponding to ampli-

tude scaling factors of approximately 0.75 to 1.26. This approach simulates real-world audio degradation from both the recording environment (e.g., room impulse response and background noise) and the transmission chain (e.g., codec compression and cross-platform re-encoding).

3.2 Model Architecture

3.2.1 Front-end Feature Extractor

We adopt pre-trained XLS-R (Babu et al., 2022) as our front-end speech feature extractor. XLS-R is a cross-lingual self-supervised pre-trained model built on the wav2vec 2.0 paradigm, pre-trained on over 436k hours of speech covering 128 languages, which delivers robust generalizable representations for low-resource Arabic speech under degraded acoustic conditions.

To enrich feature diversity and strengthen anti-degradation capability, we employ three differently sized XLS-R variants with 300M, 1B and 2B parameters separately. Each variant takes raw 16 kHz mono waveforms as input and outputs frame-level contextual speech embeddings from multiple Transformer layers. Instead of using only the final-layer representation, we introduce a learnable layer-wise weighted fusion strategy to adaptively aggregate the hidden representations from different layers. Specifically, the outputs of all Transformer layers are weighted and summed to obtain a more discriminative fused representation for subsequent spoof detection. Within each subsystem, the XLS-R backbone and its downstream classifier are jointly fine-tuned, while the three subsystems are trained independently.

3.2.2 Back-end Classifier

We adopt an identical back-end classifier for each XLS-R branch, composed of MultiConv and MHAP (Tran et al., 2025). The MultiConv module utilizes convolution kernels of diverse sizes to simultaneously capture local transient artifacts and long-range contextual patterns introduced by speech synthesis and voice conversion. Gated convolution further suppresses irrelevant acoustic information and highlights discriminative spoofing clues within frame-level embeddings. Subsequently, MHAP aggregates sequential frame embeddings into a single fixed-dimensional utterance-level representation. Compared with simple average pooling, attention pooling adaptively assigns higher weights to frames containing critical fake-speech traces. Finally, a linear projection layer outputs the detection score. During inference, we obtain the final score by taking the unweighted average of their predicted bonafide logits.

4 Experiment Setup

All models are trained on two NVIDIA H20 GPUs. We adopt batch sizes of 48, 32, and 32 for the 300M, 1B, and 2B XLS-R variants, respectively. Models are trained using randomly sampled 10-second audio segments; shorter utterances are zero-padded to reach 10 seconds. During inference, we adopt a sliding window strategy with a window length of 18 seconds. For long utterances, five windows are extracted and the final prediction score is averaged; for audio shorter than 18 seconds, only a single window is used.

We adopt the AdamW (Loshchilov and Hutter, 2019) optimizer with discriminative module-wise learning rates. Model parameters are split into two modules: the front-end SSL feature extractor and the back-end classifier. We set separate maximum learning rates and weight decay coefficients for each module. Specifically, the front-end extractor is optimized with a maximum learning rate of $1\mathrm{e}{-5}$ and weight decay of 0.001, while the classifier uses a higher maximum learning rate of $1\mathrm{e}{-4}$ together with weight decay of 0.01. A OneCycle learning rate policy is employed to schedule the learning rate. The warm-up phase occupies the first 30% of total training iterations, where the learning rate linearly rises from $max\_lr/10$ to the predefined peak value. Afterward, the learning rate gradually decays until reaching $max\_lr/10000$ at the end of training.

We use a class-weighted cross-entropy loss to address label imbalance in the training set. Given the predominance of spoofed samples, class weights of 0.33 (spoof) and 0.67 (bonafide) are applied, assigning greater importance to the minority bonafide class.

5 Results and Analysis

5.1 Ablation Studies

We conduct ablation experiments to evaluate the effects of key model, augmentation, and inference choices, as summarized in **Table 1**.

The first group reproduces the official baseline (XLS-R-300M+AASIST). Our reproduction obtains an EER of 29.0294%, compared with 27.2097% for the official baseline, while adding RawBoost (Tak et al., 2022) and SpecAug

Table 1: Ablation studies of model, training configurations and inference strategies on *dev-test* of Track 2.

Model	Training Data	Augmentation	Inference Scheme	EER (%)
XLS-R-300M + AASIST	Train & 4s	None	Single 4s win	29.0294
	Train & 4s	Rawboost_algo5 + SpecAug	Single 4s win	28.6900
	Train & 10s	Rawboost_algo5 + SpecAug	Single 10s win	20.1763
XLS-R-300M + MultiConv + MHAP	Train & 10s	None	Single 10s win	6.9533
	Train+ArVoice & 10s	None	Single 10s win	15.6131
XLS-R-300M + MultiConv + MHAP	Train & 10s	RIR/Noise + Codec + Volume	Single 10s win	1.5038
			Avg of 5 × 10s win	1.2210
			Single 15s win	1.1361
			Avg of 5 × 15s win	1.1125
			Avg of 5 × 18s win	**0.9428**

Table 2: Performance comparison of different XLS-R-based systems on ArA-DF 2026 Track 2.

Model	EER (%)	
	dev-test	test
Official baseline	27.2097	27.1132
XLS-R-300M + MultiConv + MHAP	0.9428	0.9654
XLS-R-1B + MultiConv + MHAP	0.9947	1.0514
XLS-R-2B + MultiConv + MHAP	0.8014	0.8034
Fusion of Scores	**0.6553**	**0.6575**

(Park et al., 2019) yields only a marginal improvement. Extending both the training and inference window from 4s to 10s, however, reduces the EER substantially from 28.6900% to 20.1763%, confirming that longer speech segments provide more discriminative evidence for spoof detection.

Switching from the AASIST-based configuration (Jung et al., 2022) to MultiConv+MHAP reduces the EER from 20.1763% to 6.9533%, even without data augmentation, demonstrating the effectiveness of the adopted back end. Introducing the full augmentation pipeline described in Section 3.1 then drives the EER down sharply from 6.9533% to 1.5038%, underscoring the importance of simulating realistic acoustic degradations during training.

We further analyze the effect of inference window length and multi-window ensembling. Longer inference windows generally improve performance, while averaging predictions over multiple windows provides additional gains. The best configuration averages five 18-s windows and achieves an EER of 0.9428%.

Finally, we enrich the training set with publicly available Arabic synthetic speech, i.e., ArVoice (Toyin et al., 2025). Contrary to expectation, this leads to a clear degradation, which we attribute to the domain mismatch between the external synthetic data and the target evaluation distribution.

5.2 Results of Subsystems and Fused System

Table 2 summarizes the performance of our proposed systems on the development-phase dev-test set and evaluation-phase test set of ArA-DF 2026 Track 2. The official baseline yields EER values of 27.2097% and 27.1132% on these two partitions, respectively. Our three individual subsystems obtain EER values of 0.9428%, 0.9947% and 0.8014% on the dev-test set, and 0.9654%, 1.0514% and 0.8034% on the test set, respectively. Score fusion of the three models further reduces the EER to 0.6553% on dev-test, and achieves an EER of 0.6575% on the final evaluation test set. This result ranks our system first on the official leaderboard of the ArA-DF 2026 Track 2 challenge.

6 Conclusion

This paper presents our submission to the ArA-DF 2026 Track 2, which targets robust Arabic speech deepfake detection. To address the challenges, we utilize a comprehensive system built upon three key strategies: (1) extensive data augmentation simulating real-world acoustic conditions, (2) a parallel architecture consisting of three XLS-R-based subsystems, each equipped with a MultiConv+MHAP back-end classifier, and (3) multi-window inference that aggregates evidence from different regions of long utterances. Our ablation studies demonstrate that extending the training and inference window from 4s to 10s yields substantial performance gains, while the comprehensive augmentation pipeline significantly improves robustness by exposing the model to diverse degradation patterns during training. Fusion of predictions from three XLS-R-based subsystems further reduces the EER to 0.6553% on the dev-test set and 0.6575% on the final evaluation test set, securing first place in the challenge and verifying the effectiveness of our approach.

Abstract

This paper describes the system submitted by team **PogranichnyZashchitnik** to the ArA-DF 2026 shared task on Arabic Audio Deepfake Detection. We build on **WavLM Large** as a self-supervised feature extractor, fine-tuned with **Low-Rank Adaptation (LoRA)** so that only a small fraction of parameters need updating. Representations from all 25 hidden layers are blended via a **learnable weighted sum**, pooled into utterance-level embeddings with **Attentive Statistics Pooling**, and classified by an **OC-Softmax** head that treats bonafide speech as the target class. Combined with an augmentation pipeline of codec compression, additive noise, and reverberation, this single system achieves **12.54%** EER on Track 1 (Dialect Generalization, 14th/15) and **5.66%** EER on Track 2 (Acoustic Robustness, 8th/14), outperforming the organizer baseline on both tracks. Post-evaluation analysis shows that utterances shorter than two seconds are disproportionately difficult, and that a non-trivial fraction of spoofed samples are scored as confidently bonafide under dialect mismatch.

1 Introduction

As text-to-speech and voice conversion tools become increasingly accessible, the risk of audio deepfakes - synthetic speech designed to impersonate real speakers - grows alongside them. Most anti-spoofing research has concentrated on English through the ASVspoof series (Yamagishi et al., 2021; Wang et al., 2024), leaving many languages with limited coverage.

The ArA-DF 2026 shared task turns the spotlight on **Arabic**, a language whose many regional dialects and variable recording conditions make deepfake detection especially challenging. Participants are asked to classify each audio clip as bonafide or spoofed under two settings: Track 1 tests whether a detector still works when the dialect or speaker was never seen during training, while Track 2 probes robustness to real-world degradations like background noise, lossy compression, and re-recording.

Our approach rests on three ideas. First, we draw on WavLM Large (Chen et al., 2022) for its rich, pretrained speech representations, adapting it efficiently through LoRA (Hu et al., 2022) so that fewer than 2M parameters are actually trained. LoRA has already shown promise for spoofing detection in English (Wang et al., 2023; Laakkonen et al., 2025); we apply it here to Arabic. Second, we use OC-Softmax (Zhang et al., 2021) - a one-class objective that models only what bonafide speech looks like, rather than trying to carve out a decision boundary between two classes - on the premise that spoofing attacks are open-ended and a closed-set classifier will always be one step behind. Third, we lean heavily on data augmentation (codec compression, environmental noise, reverberation) to bridge the gap between clean training data and messy real-world conditions.

We submit a single model to both tracks without any track-specific tuning. Our contribution is not methodological - each component has established precedents - but rather the combination and evaluation of these techniques for Arabic, along with an honest analysis of where the system succeeds and where it falls short. Two findings stand out from our post-evaluation analysis: (1) the system handles acoustic degradation far better than dialectal mismatch, and (2) very short clips ($<$2 s) remain a weak spot, with error rates roughly doubling.

2 Task and Data

Task. Each input is an Arabic audio clip; the system must decide whether it is *bonafide* (label 1) or *spoofed* (label 0). The primary metric is Equal Error Rate (EER).

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1491–1495

Split	Total	Bonafide	Spoof
Train	22,500	7,500	15,000
Track 1 Test	144,210	36,903	107,307
Track 2 Test	127,746	31,490	96,256

Table 1: Dataset statistics.

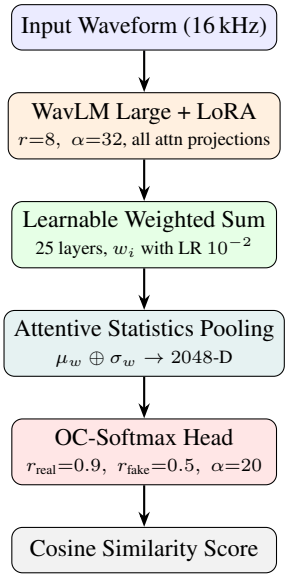

Figure 1: System architecture. The same model is used for both tracks.

Tracks. Track 1 (**Dialect Generalization**)[1] tests detection on dialects and speakers absent from the training data. Track 2 (**Acoustic Robustness**)[2] introduces realistic degradations - noise, codec artifacts, re-recording - at test time.

Data. Table 1 summarizes the ArA-DF 2026 dataset.[3] The training split covers three Arabic dialect groups (Egyptian, Gulf, and MSA). Both test sets skew heavily toward spoofed samples (roughly 3:1).

3 System Description

The system has three stages: a WavLM Large frontend adapted with LoRA, an Attentive Statistics Pooling layer, and an OC-Softmax classification head. Figure 1 gives an overview.

3.1 WavLM Large Frontend

WavLM Large[4] (Chen et al., 2022) stacks a CNN feature encoder and 24 Transformer layers (hidden size 1024). Rather than taking only the final layer, we let the model decide which layers matter by learning a **weighted sum** over all 25 hidden states:

$$\mathbf{x}_{\text{agg}} = \sum_{i=0}^{24} \text{softmax}(\mathbf{w})_i \cdot \mathbf{h}_i \tag{1}$$

The weight vector $\mathbf{w} \in \mathbb{R}^{25}$ starts at uniform values and is trained at 10^{-2}, 100× the learning rate of other parameters, so it can adapt quickly.

To keep fine-tuning lightweight, we insert **LoRA** modules (Hu et al., 2022) into every self-attention projection (`q_proj`, `k_proj`, `v_proj`, `out_proj`) with rank r=8, scaling α=32, and dropout 0.1. The rest of WavLM stays frozen, leaving roughly **1.7M trainable parameters** out of 316M total.

3.2 Attentive Statistics Pooling

Attentive Statistics Pooling (ASP) (Okabe et al., 2018) converts the variable-length frame sequence into a single utterance vector. A small attention network scores each frame's relevance; those scores weight both the mean and standard deviation across time, and the two are concatenated into a 2048-dimensional embedding (2×1024). In practice, this lets the model focus on the frames that carry the most spoofing evidence while downweighting silence or uninformative regions.

3.3 OC-Softmax Classification Head

A standard binary classifier learns boundaries for both classes, but spoofed speech is an open set - new generation methods appear constantly, and a model trained against today's attacks may miss tomorrow's. OC-Softmax (Zhang et al., 2021) sidesteps this by modeling only the bonafide class. It learns a center vector $\mathbf{c}$ and scores each input by cosine similarity:

$$s = \frac{\mathbf{e}}{||\mathbf{e}||} \cdot \frac{\mathbf{c}}{||\mathbf{c}||} \tag{2}$$

Training pulls bonafide embeddings toward $\mathbf{c}$ (target r_{real}=0.9) and pushes spoofed ones away (r_{fake}=0.5), scaled by α=20. At test time, a high score means the model thinks the clip sounds like genuine speech.

4 Experimental Setup

4.1 Data Augmentation

We found augmentation to be the single most impactful ingredient for Track 2, so we apply a fairly

Augmentation	Prob.	Details
MP3 compression	15%	FFmpeg codec
AAC compression	15%	FFmpeg codec
OGG compression	20%	FFmpeg codec
SpecAverage	50%	2 bands, width=10
Additive noise	50%	MUSAN, SNR 10–25 dB
Reverberation	50%	RIRS_NOISES
SpecAugment	—	p_t=p_f=0.05, drop=0.1

Table 2: Online data augmentation pipeline applied to waveforms during training.

aggressive pipeline directly to the waveforms during training (Table 2). Codec compression through FFmpeg (MP3, AAC, OGG) is meant to mimic what happens when audio passes through social media platforms or messaging apps. Additive noise sampled from the MUSAN corpus (Snyder et al., 2015) and convolution with room impulse responses from RIRS_NOISES (Ko et al., 2017) simulate noisy, reverberant environments. On top of this, WavLM's built-in SpecAugment (Park et al., 2019) masks random time–frequency regions.

4.2 Training Details

Audio clips are truncated to at most 9.0 s during training to keep memory usage manageable. We optimize with AdamW (learning rate 10^{-4}, weight decay 10^{-5}) for all parameters except the layer aggregation weights, which use a learning rate of 10^{-2}. With a per-device batch size of 4 and 4 gradient accumulation steps (effective batch 16), we train for 5 epochs under a flat learning rate. The checkpoint at epoch 4, which gave the lowest EER on the validation split (0.63%), is kept for submission. Training uses mixed-precision (bfloat16) on a single laptop GPU.

4.3 Inference

Each test file is loaded up to 9.0 s and split into non-overlapping **4.0 s chunks**; anything shorter is zero-padded to 4.0 s. Chunks are fed through the model in sub-batches of 16, and the resulting embeddings are averaged per file before the OC-Softmax head produces a final score:

$$\mathbf{e}_{\text{file}} = \frac{1}{N} \sum_{n=1}^{N} \mathbf{e}_{\text{chunk},n} \tag{3}$$

No ensembling or track-specific post-processing is applied.

Track	EER (%)	Rank	Baseline
1 (Dialect)	12.54	14/15	14.54
2 (Acoustic)	5.66	8/14	27.11

Table 3: Official test results. Baseline: Wav2Vec2 XLS-R 300M + AASIST.

Duration	T1 EER (%)	T2 EER (%)
0–2 s	29.83	16.34
2–4 s	16.03	8.09
4–6 s	12.13	4.95
6–8 s	12.20	4.75
8–10 s	12.00	5.02
10–30 s	12.18	5.84
Overall	**12.54**	**5.66**

Table 4: EER by utterance duration. Clips shorter than 2 s are dramatically harder.

5 Results and Analysis

5.1 Official Results

Table 3 shows our leaderboard scores next to the organizer baseline (Wav2Vec2 XLS-R 300M + AASIST). We beat the baseline on both tracks, but the margin is far larger on Track 2, an EER of 5.66% versus the baseline's 27.11%. This gap strongly suggests that our augmentation pipeline does a good job of matching the kinds of degradation present in the Track 2 test set, while dialectal variation in Track 1 calls for something more than signal-level augmentation.

5.2 Effect of Utterance Duration

Breaking EER down by utterance length (Table 4) reveals a striking pattern: clips under 2 s are far harder to classify, with EER jumping to 29.8% on Track 1 and 16.3% on Track 2. This makes sense given our chunking strategy - a 1.5 s clip gets padded to 4 s, so more than half the input is silence, and the model has little genuine signal to work with. Once clips exceed 4 s, performance stabilizes and roughly matches the overall average, confirming that the chunk window is well-sized for typical-length recordings.

5.3 Score Distribution

Table 5 summarizes the OC-Softmax cosine scores on each test set. The two classes are reasonably well-separated on both tracks, but Track 1 has a troubling tail: **11.5% of all spoofed samples** (12,368 out of 107,307) receive scores of 0.98 or higher - essentially indistinguishable from bonafide

Track	Class	Mean	Std	Min	Max
T1	Bonafide	0.962	0.112	−0.110	0.988
	Spoof	0.417	0.325	−0.315	0.988
T2	Bonafide	0.950	0.126	0.004	0.988
	Spoof	0.189	0.249	−0.406	0.988

Table 5: OC-Softmax cosine score statistics on each test set. Higher scores indicate bonafide.

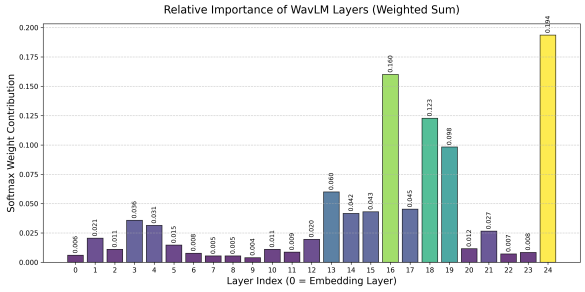

Figure 2: Learned layer weights (softmax-normalized). The model relies most on the upper Transformer layers.

speech. Among these, 3,471 hit the maximum model output of 0.988. These are presumably high-quality deepfakes from dialectal contexts the model never saw during training: if the model has only learned what Egyptian or Gulf bonafide speech "looks like," a convincing Levantine deepfake can slip right past. Track 2 shows much cleaner separation, with a wider gap between class means and far fewer false positives near the decision boundary.

5.4 Layer Weight Analysis

Figure 2 plots the learned layer weights after training. The model leans heavily on the **top Transformer layers**: layers 24, 16, and 18 together claim 48.7% of the total weight, while every layer below 10 contributes under 2%. This is consistent with speaker verification work (Desplanques et al., 2020), where upper layers capture the kind of abstract speaker and style information most useful for spotting synthetic artifacts.

Limitations

Several limitations are worth noting. We do not perform any dialect-aware training or adaptation, which is likely the main reason Track 1 lags behind. We also do not present a component-level ablation study: each design choice (WavLM, LoRA, ASP, OC-Softmax) is motivated by prior work, but we have not isolated their individual contributions on this dataset. Training runs for only 5 epochs, leaving room for longer schedules or curriculum strategies. Truncating audio at 9 s throws away information in longer recordings. We rely on a single model with no ensembling. Finally, the OC-Softmax center vector may overspecialize to the dialects present in training, which would explain why so many out-of-distribution deepfakes receive confident bonafide scores.

6 Conclusion

We described a straightforward system - WavLM Large, LoRA, Attentive Statistics Pooling, and OC-Softmax - that beats the shared-task baseline on both tracks of ArA-DF 2026. The augmentation pipeline proves especially effective for acoustic robustness (Track 2 EER 5.66% vs. the baseline's 27.11%), but dialect generalization remains the harder problem. Going forward, the most promising directions seem to be dialect-aware training or adaptation strategies, better handling of very short clips (e.g., through overlapping chunks or duration-adaptive padding), and model ensembling.

Abstract

We describe our submission to ArA-DF 2026, the ArabicNLP shared task on Arabic speech deepfake detection, in which systems classify audio as real or deepfake. We participated in both tracks: Track 1 (Dialect Generalization) and Track 2 (Acoustic Robustness). Our systems investigated finetuning three large self-supervised speech encoders — WavLM, wav2vec2-XLS-R, and HuBERT — with a learnable attentive-pooling head. We evaluated each encoder separately and further combined encoders through a logistic-regression meta-classifier. In addition to improve robustness we apply an acoustic degradation pipeline (additive noise, lossy codec re-encoding, band-limiting, and gain) to 50% of the training data. For track one the best achieved result is, a fully fine-tuned WavLM with attentive pooling and augmentation, which scored 2.19% EER test set, and a deepfake-pretrained XLS-R achieves 7.80% EER on Track 2 — which out performed the official baseline. Our ablation study shows that augmentation and backbone choice are the primary factors, while adding correlated ensemble members yields no gain.

1 Introduction

Speech synthesis and voice-conversion systems have advanced to the point where synthetic speech is difficult to distinguish from genuine recordings by ear: in a controlled listening study, participants identified deepfake audio correctly only 73% of the time, and familiarising them with examples improved performance only marginally (Mai et al., 2023). Reliable automatic detection is therefore an increasingly important safeguard against fraud, impersonation, and misinformation, motivating benchmark efforts such as the ASVspoof series, whose 2021 edition introduced a dedicated speech deepfake track (Yamagishi et al., 2021; Liu et al., 2023).

Recent work replaces hand-crafted features with self-supervised speech representations. Encoders such as wav2vec2.0 (Baevski et al., 2020), its multilingual extension XLS-R (Babu et al., 2022), HuBERT (Hsu et al., 2021), and WavLM (Chen et al., 2022) transfer strongly to anti-spoofing, where fine-tuning an SSL backbone and extracting a compact audio embedding have now become state-of-the-art approaches (Tak et al., 2022).

Although some works have proposed solutions for Arabic deepfake detection (Issa, 2026; Elsetohy et al., 2026), the field remains under-explored, especially when handling out-of-domain or distorted recordings.

ArA-DF 2026 provides a focused benchmark for detecting deepfake Arabic audio from genuine recordings. Each recording is labelled real, for genuine human speech, or spoofed, for synthetic speech produced by text-to-speech or voice-conversion systems, and systems are ranked by Equal Error Rate (EER), a threshold-independent metric standard in anti-spoofing evaluation. The two tracks probe complementary failure modes. Track 1 (Dialect Generalization) measures whether a detector remains reliable on dialects and speakers absent from training. Track 2 (Acoustic Robustness) tests resilience to practical distortions such as compression artefacts, background noise, and re-recording effects.

2 Task Setup and Data

The ArA-DF 2026 dataset is released by ArabicSpeech. As shown in Table 1, it consists of 22,500 labelled training and 21,000 labelled development recordings, with unlabelled development-test and blind final-test sets for each track. The Track 1 final-test set contains 144,210 recordings and the Track 2 final-test set 127,746.

The organisers provide a baseline pairing an XLS-R 300M front-end with an AASIST back-end (Jung et al., 2022), reporting 14.54% EER on the Track 1 final test and 27.11% on Track 2.

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1496–1500

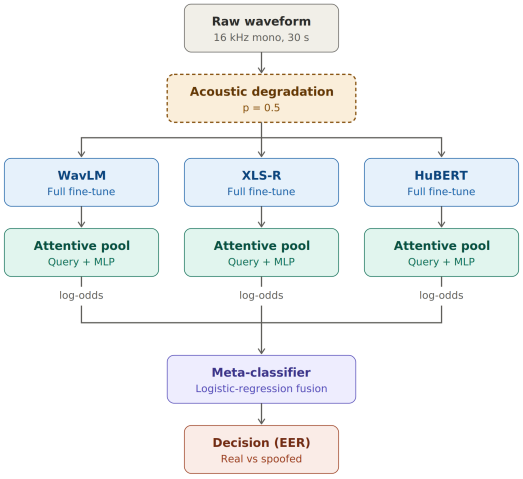

Figure 1: Overview of the proposed system. The raw waveform is first passed through the acoustic degradation pipeline, drawn with a dashed outline to indicate that it is applied stochastically with probability $p = 0.5$. The (optionally degraded) waveform then feeds three fine-tuned self-supervised encoders, each with an attentive-pooling head. The resulting bonafide log-odds are fused by a logistic-regression meta-classifier to produce the real-vs-spoofed decision.

Split	Rows	With Labels
Train	22,500	Yes
Dev	21,000	Yes
Track 1 development-test	16,023	No
Track 1 final-test	144,210	No
Track 2 development-test	14,193	No
Track 2 final-test	127,746	No

Table 1: Dataset splits and label availability. Official scoring uses the blind final-test sets.

Systems are ranked by **Equal Error Rate (EER)**, the standard anti-spoofing metric. A detector outputs a score per utterance; applying a threshold yields a false-acceptance rate (spoofed audio accepted as genuine) and a false-rejection rate (genuine audio rejected). As the threshold varies, one rises while the other falls, and the EER is the operating point where they are equal. Lower is better, and because it is read at this fixed crossover, EER summarises performance without committing to a threshold.

3 System Overview

The following subsections describe our system: the overall architecture (Section 3.1), the self-supervised encoders and pooling head that turn an utterance into a score (Sections 3.1.1–3.1.2), the fine-tuning regimes we compared (Section 3.2), the acoustic augmentation pipeline (Section 3.3), and the meta-classifier that fuses encoders (Section 3.4).

3.1 Proposed Architecture

All of our detectors share a common template: a pre-trained SSL Transformer encoder maps the raw waveform to a sequence of frame embeddings, which a pooling head aggregates into a single vector for binary classification.

3.1.1 Self-supervised encoders

We use three encoders at this stage:

- **WavLM-Large** (Chen et al., 2022), pre-trained predominantly on English speech with joint masked-speech prediction and denoising, which suits noisy conditions.
- **XLS-R** (Babu et al., 2022), a wav2vec2.0 model (Baevski et al., 2020) pre-trained on 436k hours across 128 languages; we adopt a publicly available variant already fine-tuned for deepfake audio classification.
- **HuBERT-Large** (Hsu et al., 2021), pre-trained on English speech, supplying a third, independently pre-trained representation.

Of the three encoders, only XLS-R has substantial multilingual exposure, yet we use all three despite their mostly non-Arabic pre-training. Spoofing detection relies less on linguistic content than most speech tasks: the key cues are low-level synthesis artefacts — unnatural spectra, phase inconsistencies, and vocoder signatures — that are largely language-independent, and SSL encoders fine-tuned for anti-spoofing transfer well across languages (Tak et al., 2022). Language still has some effect, since dialectal acoustics change the genuine-speech distribution, but much less than in recognition tasks; in fact, English-pretrained WavLM gives our strongest Track 1 result after fine-tuning.

3.1.2 Pooling heads

We compare two pooling strategies.

Mean pooling averages frame embeddings over valid positions and passes the result through an MLP.

Attentive pooling introduces a single learnable query vector $\mathbf{q}$ that attends over the sequence of frame embeddings $\mathbf{H}$ via multi-head attention, $\mathbf{u} = \mathrm{MHA}(\mathbf{q}, \mathbf{H}, \mathbf{H})$, with padded positions masked out. The query learns to assign higher attention weights to frames that are more useful for the real-vs-spoofed decision, producing a weighted sum

rather than the uniform average of mean pooling. The pooled vector $\mathbf{u}$ is layer-normalised and passed through an MLP.

3.2 Fine-tuning strategies

We contrast three fine-tuning methods: (i) **head-only** training with a frozen encoder; (ii) **full fine-tuning**, updating the entire encoder and head jointly from the first step; Full fine-tuning gave the best results, but requires care: a randomly initialised head can destabilise pre-trained weights early in training, so we use a low encoder learning rate, linear warmup, and gradient clipping.

3.3 Data Degradation

To improve robustness, we degrade 50% of the training records. This forces the model to focus on the underlying synthesis features that persist through degradation, rather than on shallow cues tied to clean-recording conditions that fail to generalize to real-world degradations (codec compression, background noise, and social-media re-encoding).

Each degraded clip passes through a random chain of the following:

- **Additive Gaussian noise** at 8–30 dB SNR;
- **Lossy codec re-encoding** (MP3 at 32–96 kbps, or AAC, Opus, or Ogg Vorbis at low bitrates), emulating social-media transmission;
- **Band-limiting** with a high-pass filter at 50–150 Hz and a low-pass filter at 6–8 kHz, approximating telephone-quality channels;
- **Random gain shift** of ± 6 dB.

3.4 Meta-classifier

Using the validation set, we selected the best-performing backbones based on their individual classification performance and used them to train a meta-classifier. The selected backbones were kept frozen, and their bonafide log-odds were combined and fed into a logistic-regression meta-classifier, whose learned weights were then applied to test and blind-evaluation scores.

4 Experimental Setup

Data usage. Because final-test labels are withheld, model selection relies on an internal split. We merge the labelled train and dev pools, hold out 10% as an internal test set and a further 10% of the remainder as validation, with a fixed seed so every experiment sees identical partitions. Validation is used for early stopping and for fitting the meta-classifier; the internal test set is used for ablations. Development-test and final-test EERs are official leaderboard scores.

Hyperparameter	Value
Sample rate	16 kHz
Max audio length	30 s
Encoder LR (full FT)	1×10^{-5}
Head LR	1×10^{-4}
Optimiser	AdamW, wd 1×10^{-4}
LR schedule	cosine, 5% warmup
Effective batch size	$\approx$32
Gradient clipping	1.0
Augmented fraction	0.5
Noise SNR range	8–30 dB

Table 2: Principal training and augmentation hyperparameters, shared across full-fine-tuning experiments.

Preprocessing. Audio is decoded from FLAC, converted to mono, resampled to 16 kHz, and truncated to 30 seconds; waveforms are normalised by the encoder's feature extractor. Class imbalance is handled with inverse-frequency weighting in the loss.

Hyperparameters. Table 2 lists the principal settings. Separate learning rates for the pre-trained encoder and the randomly initialised head prevent catastrophic forgetting while letting the head adapt quickly.

Metric. EER is the operating point where false-acceptance and false-rejection rates coincide. It is symmetric under label inversion, so the choice of positive class does not affect its value; we verified our internal EERs matched the official development-test leaderboard before the blind evaluation.

5 Results and Analysis

In the following subsections, we will present the results for the development set and the testing set.

5.1 Development Set Results

Table 3 shows the best results for the development set. The fully fine-tuned WavLM with attentive pooling and 50% augmentation (Exp 1) is our strongest individual model on Track 1, reaching **2.30% EER**. For Track 2, the deepfake-pretrained XLS-R with 50% degradation (Exp 2) is best at **7.80% EER**.

Exp ID	Encoder	FT	Degradation	T1-dev	T2-dev
1	WavLM	Full	50%	**2.30**	16.73
2	XLS-R	Full	50%	3.41	**7.80**
3	WavLM	Full	—	6.30	9.66
4	WavLM‡	Head	—	6.10	19.95
5	HuBERT‡	Head	—	7.83	21.28
6	XLS-R	Full	—	8.16	—

Table 3: Individual system EER (%) on the official development-test split; best per column in **bold**. All systems use attentive pooling except those marked ‡ (mean pooling).

Three ablation patterns are notable. First, **fine-tuning depth matters**: full fine-tuning beats head-only training for every encoder. The two head-only systems (Exps 4 and 5) are the weakest on Track 1. Second, **attentive pooling beats mean pooling** across every encoder and fine-tuning regime we tested. Third, **the effect of degradation is track- and backbone-dependent**: adding 50% degradation to WavLM lowers Track 1 development EER from 6.30% to 2.30% (Exps 3 vs. 1), and the XLS-R system (Exp 2) far outperforms its un-degraded counterpart (Exp 6) on Track 2, where the latter fails to produce a usable result. Degradation is not uniformly beneficial, however: for WavLM on Track 2 it hurts, raising development EER from 9.66% (Exp 3) to 16.73% (Exp 1). The gains from degradation are thus clearest on Track 1 and for the deepfake-pretrained XLS-R on Track 2; the latter suggests that an un-degraded XLS-R detector keys on channel characteristics that the Track 2 distortions destroy, while WavLM's un-degraded Track 2 behaviour does not follow the same pattern.

5.2 Official Testing Set Results

We took the best two models for each track and evaluated them on the official final test set, shown in Table 4.

Exp ID	Encoder	FT	Degradation	T1-test	T2-test
1	WavLM	Full	50%	**2.1948**	—
2	XLS-R	Full	50%	3.4112	**7.7960**
3	WavLM	Full	No	—	9.7202

Table 4: Individual system EER (%) on the official final test set; best per column in **bold**.

We further combined the best two models for each track using a logistic-regression meta-classifier, reported in Table 5.

5.3 Discussion

Our best systems are strikingly stable between the development and blind final-test splits. On Track 1, the augmented WavLM (Exp 1) moves from 2.30% to **2.19%** EER, and on Track 2 the augmented XLS-R (Exp 2) holds at **7.80%**, essentially unchanged despite the far larger final-test sets — indicating that model selection did not overfit the development split.

System	T1-Test	T2-Test
META (1+2)	**2.39**	—
META (2+3)	—	**7.21**

Table 5: Meta-classifier and multi-layer aggregation, EER (%). Systems are indexed by the constituent model IDs from Table 4.

Two factors drive these results: First, **degradation helps the XLS-R Track 2 system**: on Track 2 the augmented XLS-R (7.80%) far outperforms its un-degraded counterpart, and the un-degraded WavLM (Exp 3) trails at 9.72%, indicating that for XLS-R, without exposure to codec, noise, and band-limiting artefacts a detector keys on channel cues rather than synthesis artefacts. The benefit is not universal — degradation hurts WavLM on Track 2 (Table 3) — so it is best read as a backbone-specific effect rather than a blanket robustness gain. Second, **fusion rewards decorrelation**: pairing the augmented XLS-R with the un-degraded WavLM (META 2+3) improves Track 2 to **7.21%**, below either constituent, because the two make complementary errors.

6 Conclusion

In this paper we presented our participation in both tracks in ArA-DF 2026. We proposed an approach that employ self-supervised finetuned models for Arabic speech deepfake detection. Full fine-tuning of WavLM and XLS-R with attentive pooling plus an acoustic degradation pipeline achieves 2.19% EER on the Track 1 final test and 7.80% on Track 2, which greatly outperformed the AASIST baseline. Future works include other attention mechanisms for frame fusion, wider range of degradation styles, and per-dialect error analysis.

Acknowledgments

We thank the ArA-DF 2026 organisers for hosting the shared task and providing the dataset, baseline, and evaluation infrastructure.

SaAr-DF at ArA-DF 2026: When More Data Hurts — Diversity-Driven Ensembling for Arabic Speech Deepfake Detection

Abdelrahman Sakr and Amr Elzahaby
Alexandria University
es-Abdelrahmansakr2023@alexu.edu.eg, Elzahaby31@gmail.com

Abstract

We describe our system for Track 1 (dialect-generalization) of the ArA-DF-2026 Arabic speech deepfake detection shared task. Starting from the organizers' XLS-R+AASIST baseline (14.65% EER on the development test set), we show that (i) raw-waveform augmentation (RawBoost) roughly halves the error rate, (ii) replacing the AASIST back-end with a simple mean-pooling head over a post-trained self-supervised frontend removes a hard performance ceiling that persists even after full convergence, and (iii) a large, architecturally diverse ensemble is the only lever that keeps improving once single-model performance saturates. Our final system, a 13-member weighted ensemble spanning three frontend sizes, two back-ends, and four training-data recipes, reaches 2.34% EER on the development-test leaderboard and 2.42% EER on the official held-out blind evaluation set (144,210 utterances, 9× larger than the development test). We also report two negative results of practical value: injecting a large (54k-clip) multi-system Arabic text-to-speech corpus and a vocoder-copy-synthesis pseudo-spoof corpus both *degrade* accuracy, indicating that indiscriminately adding synthetic speech is harmful when its generation artifacts do not match the target domain. Our code is publicly available at https://github.com/Body123/aradf-2026-saar-df.

1 Introduction

Detecting synthetic ("spoofed") speech in Arabic is complicated by dialectal variation, code-switching, and a scarcity of large labeled deepfake corpora relative to English. The ArA-DF-2026 shared task (ArA-DF-2026 Organizing Committee, 2026) Track 1 targets *dialect generalization*: a Track-1 system trained on Egyptian, Gulf, and Modern Standard Arabic (MSA) speech is evaluated, in the blind phase, on a held-out test set almost an order of magnitude larger than the public development-test split, using Equal Error Rate (EER) as the sole, threshold-free metric.

We report a system-building process organized around three questions: (1) which architectural choices raise a *single* model's ceiling, (2) once that ceiling is reached, what further lowers error, and (3) which commonly-recommended interventions (extra synthetic data, signal-processing-based pseudo-spoof augmentation) actually help under this specific train/test distribution shift.

Our contributions are:

- An empirical ablation showing that back-end choice (AASIST vs. a plain mean-pooling head) dominates single-model performance once raw-waveform augmentation is applied, reversing the ranking observed before augmentation.
- Evidence that, once single-model performance saturates, weighted ensembling over architecturally *diverse* members is the only remaining lever with a reliable, repeated effect across our development cycle, even when individual added members are weaker in isolation.
- Two controlled negative results: a large multi-TTS-system external Arabic corpus and a vocoder-copy-synthesis pseudo-spoof corpus each *increase* error, both for a single model and inside the ensemble, despite targeting the task's known weak point (Gulf-dialect false accepts).

2 Related Work

Back-ends and frontends. AASIST (Jung et al., 2022) models spectro-temporal artifacts with a heterogeneous graph attention network and is a common back-end in anti-spoofing systems built on self-supervised speech encoders such as

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1501–1506
October 28-29, 2026 ©2026 Association for Computational Linguistics

wav2vec 2.0 (Baevski et al., 2020) and its massively multilingual successor XLS-R (Babu et al., 2021). Truong et al. (2024) instead augment a Transformer/Conformer back-end with an explicit temporal-channel modeling (TCM) module. Ge et al. (2025) post-train wav2vec 2.0/HuBERT-family encoders specifically for deepfake detection on a very large multilingual corpus of genuine and artifact-bearing speech, and release these *post-trained* checkpoints (which we refer to as "AntiDeepfake" frontends).

Augmentation and data. RawBoost (Tak et al., 2022) augments raw waveforms with convolutive and additive noise to simulate channel and codec variation and is a standard component of ASVspoof-style pipelines. ASVspoof 2019 (Wang et al., 2020) and MLAAD (Müller et al., 2024) are widely used sources of non-Arabic and multilingual synthetic-speech attacks for co-training. For Arabic specifically, ArFake (Elsetohy et al., 2025) recently introduced a multi-dialect benchmark generated with four TTS/voice-conversion systems (XTTS-v2, FishSpeech, ArTST, VITS); we use a subset of this resource as an external data source (§4.3). Separately, vocoder-based copy-synthesis (resynthesizing genuine speech through a neural vocoder and relabeling it spoof) has been used to manufacture spoof training data cheaply (Wang and Yamagishi, 2023), but its benefit is contingent on the vocoder(s) used matching the target attacks' artifacts, and injecting such data at the supervised fine-tuning stage rather than as self-supervised pre-training can instead hurt performance (Wang and Yamagishi, 2024). More broadly, Müller et al. (2022) show that deepfake-detector generalization is highly sensitive to train/test artifact-distribution mismatch, the frame we adopt for our own negative results (§4.3).

Benchmarking and frameworks. Dowerah et al. (2025) benchmark open- and closed-source detectors across 14 evaluation sets and report that AASIST-based systems generalize comparatively poorly out-of-domain, motivating our back-end ablation in §4. We build our training pipeline on DeepFense (El Kheir et al., 2026), an open-source, modular framework that separates frontend, back-end, loss, and augmentation as interchangeable components.

3 System Description

3.1 Data

Our in-domain data is the ArA-DF-2026 Track-1 training split (Egyptian, Gulf, and MSA dialects). We co-train with three external attack sources: ASVspoof 2019 Logical Access (Wang et al., 2020) (non-Arabic synthetic/converted speech, for generic attack-type diversity), MLAAD's Arabic subset (Müller et al., 2024) (multilingual TTS attacks), and an Arabic-dialect spoof/bona-fide subset (dialect-diverse synthetic speech, including Gulf, our hardest dialect; §4). Every training recipe below is a named combination of these sources.

3.2 Frontend and back-end

We use post-trained self-supervised frontends from the AntiDeepfake family (Ge et al., 2025) at three sizes (300M/1B/2B parameters, built on MMS and XLS-R encoders), feeding either (a) AASIST (Jung et al., 2022), a graph-attention back-end used by the task baseline, or (b) a minimal mean-pooling ("Pool") head: temporal mean-pooling of the frontend's final hidden states followed by a single linear classification layer. Pool has orders of magnitude fewer parameters than AASIST and no explicit temporal or spectral modeling of its own.

3.3 Augmentation

All non-baseline models are trained with RawBoost (Tak et al., 2022) (convolutive plus additive raw-waveform noise, applied stochastically per batch). We separately test cropping each training utterance to a random 1–4 s window before repeat-padding ("short-crop"), intended to target short-utterance failures (§4).

3.4 Training

All models are fine-tuned end-to-end with cross-entropy loss (bona-fide vs. spoof, class-weighted 3:1 toward spoof), Adam, and an exponential learning-rate schedule, using the frontend's native sample rate (16 kHz) and a repeat-padded 4.0 s window at training time. Checkpoints are selected on a held-out development split; because this split is used for early stopping by every model, we treat its absolute EER as *saturated* (uninformative in absolute terms; see §4) and use the shared task's public development-test leaderboard as our primary validation signal instead.

3.5 Ensembling

Our final system averages per-utterance logits (higher = more bona-fide) across N independently trained members, $s = \frac{1}{\sum_i w_i} \sum_{i=1}^{N} w_i \, \ell_i$, with integer weights $w_i \in \{1, 2\}$ set by a small amount of manual up-weighting of the single strongest member; we found rank- and z-score-normalized fusion gave no consistent improvement over this raw logit average in our setting. Members are chosen to differ along at least one axis (frontend size, back-end, or training-data recipe) rather than being re-runs of the same recipe with a different random seed.

Figure 1 summarizes the full pipeline, including the two data sources we tested and excluded.

4 Experiments and Results

4.1 Setup

We report EER on two signals: the shared task's public *development-test* leaderboard (16,023 utterances; used throughout system development) and the official *blind evaluation* set (144,210 utterances, released only in the final evaluation phase, with a hard cap of ten submissions). We first establish every architectural finding on the development-test leaderboard, then validate the final recipe once on the blind set.

4.2 Main progression

Table 1 shows the development-test EER at each major milestone. Two findings stand out. First, augmentation is the single largest individual lever: RawBoost alone roughly halves EER relative to the unaugmented baseline. Second, back-end choice *reverses* once augmentation is applied: with RawBoost, our AASIST-based single model plateaus at 5.20% even after full convergence and after adding external attack data (via ASVspoof 2019), while replacing AASIST with the far simpler Pool head lowers the same frontend's error to 4.42%, and adding external data on top of Pool reaches our best *single*-model result, 3.27%. We attribute the AASIST plateau to poor cross-domain generalization of graph-attention back-ends, consistent with the benchmark findings of Dowerah et al. (2025).

Beyond the single-model ceiling, only ensembling continued to lower error: widening the ensemble from 2 to 13 architecturally diverse members lowered EER from 3.08% to 2.34% in five successive steps, and this held even when an added member was individually *weaker* than the ensemble it joined (e.g., two members scoring 3.37% and 3.42% in isolation each still lowered the ensemble EER on addition). Re-weighting members after the ensemble saturated, by contrast, produced no further gain (a 3% relative *regression* in one trial), indicating diminishing returns once member diversity — not member count or weighting — is exhausted.

System	EER (%)
Baseline (XLS-R + AASIST, no aug.)	14.65
+ RawBoost	6.54
+ 2-model ensemble	5.51
+ external data (ASVspoof)	5.42
+ post-trained SSL frontend	5.20
Pool head (single, replaces AASIST)	4.42
+ external data (ASVspoof + MLAAD)	**3.27**
Final diverse ensemble (13 members)	**2.34**

Table 1: Development-test EER progression. "Final diverse ensemble" is our submitted development-phase system (§3.5).

4.3 Negative results

Per-dialect analysis of our best single model showed Gulf-dialect utterances as the hardest subgroup and false accepts (spoof scored as bona-fide) outnumbering false rejects roughly 2:1, concentrated in utterances under 2 s. Motivated by this, we tested two interventions targeting exactly this failure mode, both of which *increased* error:

- **Short-crop augmentation** (random 1–4 s training crops, targeting the short-utterance failure): single-model EER rose from 3.27% to 3.49%.
- **External multi-TTS Arabic corpus** (a ∼54k-clip subset of ArFake (Elsetohy et al., 2025), spanning four TTS/voice-conversion systems and multiple dialects including Gulf): single-model EER rose to 3.91%, and adding it to our best ensemble raised ensemble EER from 2.34% to 2.54%.
- **Vocoder-copy-synthesis pseudo-spoof** (bona-fide Gulf/Saudi speech from SADA (Alharbi et al., 2024), resynthesized through a neural vocoder (Siuzdak, 2023) and relabeled spoof, to manufacture additional Gulf-dialect attack data): adding this data to the ensemble raised EER from 2.34% to 2.57%, consistent with Wang and Yamagishi (2024)'s finding that large-scale vocoded data can help as self-supervised pre-training but hurt when injected directly into supervised

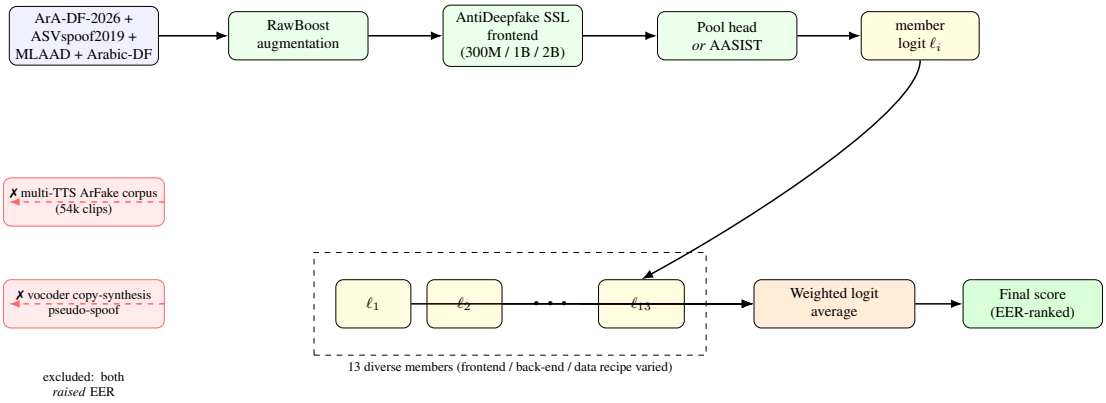

Figure 1: System overview. Each ensemble member is trained with the same augmentation and loss but a different frontend size, back-end, or training-data recipe (top pipeline, repeated 13 times with varied choices). Two additional external data sources (left) were tested and *excluded* after controlled experiments showed they raise EER rather than lowering it (§4.3). Member logits are combined by weighted averaging (bottom right) to produce the submitted score.

fine-tuning (our setting), and with the broader domain-mismatch account of Müller et al. (2022).

We interpret all three as instances of the same failure: augmentation or external data that does not share the target domain's artifact distribution can move a model *away* from the test distribution even when it is topically well-targeted (correct dialect, correct short-duration regime). Notably, a smaller-scale pilot with the same multi-TTS corpus (2.6k clips, i.e. under 5% of that model's training mix) left the ensemble statistically unchanged, suggesting the effect scales with the fraction of mismatched data in the training mix rather than being an all-or-nothing effect.

4.4 Blind evaluation

Our final system (Table 1, last row, re-inferred on the blind split) reached **2.42% EER** on the official 144,210-utterance blind test — close to its 2.34% development-test score, indicating the diverse ensemble generalizes rather than overfitting the smaller development-test set. On the final public blind leaderboard, this ranked our system 8th of the 8 teams listed, with the top-ranked system reported at 0.87% EER — a substantially better score than we were able to reach with the architectures and data available to us, and one we attribute to a materially different training recipe rather than to ensembling or augmentation choices alone.

5 Discussion

Two patterns from our development cycle generalize beyond this shared task. First, a validation split used for checkpoint selection saturates quickly for this kind of high-capacity, SSL-frontend model, so absolute numbers on it stop discriminating between systems; we relied on the public leaderboard as an external, harder validation signal once this saturation was evident. Second, and more surprisingly, more synthetic training data is not a free lunch even when it is topically matched to a known weakness: both of our negative-result interventions specifically targeted Gulf-dialect short utterances and both made that exact subgroup worse, underlining that the choice of *synthesis technique* used to generate extra spoof data matters as much as its topical relevance. These patterns mirror opposite lessons from other Arabic NLP work: general-domain pre-fine-tuning helps for punctuation restoration (Sakr and Torki, 2023), whereas injecting mismatched external data mid-pipeline hurts here, while a continuous dialectness score (Sakr et al., 2024) could sharpen our own coarse (Egyptian/Gulf/MSA) per-dialect error analysis.

6 Conclusion

We presented a Track-1 ArA-DF-2026 system built around three findings: augmentation is the largest single lever before architecture matters, back-end choice (a minimal pooling head over graph attention) determines the single-model ceiling once augmentation is applied, and diverse ensembling is the only lever that keeps paying off after that ceiling

is reached. We also reported two controlled negative results — a large external multi-TTS corpus and a vocoder-based pseudo-spoof corpus both increased error — that we hope are useful cautionary evidence for future participants considering similar data-augmentation strategies.

Limitations

Our study is limited to one shared task's data distribution and label convention; the negative results in §4.3 may not generalize to other spoof corpora or synthesis techniques, and we did not have the compute budget to fully disentangle whether the harm from added data stems from domain mismatch, from diluting the in-domain training signal, or from the specific text-to-speech/vocoder systems used to build that data. Our development-test validation signal comes from a leaderboard with a limited daily submission budget, which constrained the granularity of some ablations (e.g., we could not systematically sweep ensemble weights). Finally, our best single model's absolute performance is well above the best-performing system on the shared task's public leaderboard, so the architectural choices reported here should be read as a solid but not state-of-the-art recipe for this problem.

Thakaa at ArA-DF 2026: Fusing Self-Supervised and Signal-Processing Detectors for Arabic Speech Deepfake Detection

Abeer Alhammad **Abdullah Aldahlawi**
Thakaa, Advanced Company for Information Technology
Riyadh, Saudi Arabia
{a.alhammad, aldahlawi}@thakaait.net

Abstract

ArA-DF 2026 is a shared task on binary Arabic speech deepfake detection, with two tracks: dialect generalisation and acoustic robustness. For both we submit rank-normalised score fusions of complementary detectors. Track 1 fuses five components in two stages: three fine-tuned XLS-R-300M networks and two ResNet-18 classifiers over linear-prediction residual and group-delay representations. Track 2 fuses two XLS-R-300M detectors differing in augmentation strategy. We reach 2.8961 EER on Track 1 and 2.7626 on Track 2, against baselines of 14.54 and 27.11. Our analysis on the released test labels shows individual EER to be a poor guide to fusion contribution, which depends on error independence: both fusions improve on their best member by over 40%, and components far weaker in isolation than any we submitted improve them further.

1 Introduction

ArA-DF 2026 (ArA-DF 2026 Organizers, 2026) is a shared task at ArabicNLP 2026 on binary Arabic speech deepfake detection. Track 1, *dialect generalisation*, tests reliability on dialects and speakers absent from training; Track 2, *acoustic robustness*, tests degraded acoustic and channel conditions. Both are ranked by equal error rate (EER).

The task matters because it varies dialect and acoustics independently: in a single pooled test set, failing on an unfamiliar dialect and failing on a degraded recording produce the same symptom. Both problems matter for Arabic: Modern Standard Arabic and the regional dialects differ enough that a detector trained on one variety may not transfer to another, and audio encountered in practice carries compression, background noise and re-recording effects rather than studio conditions.

Our submitted systems reach 2.8961 EER on Track 1 and 2.7626 on Track 2. Our strategy on both tracks was score-level fusion under rank normalisation: we kept components that made *different* mistakes from the system we already had, rather than those with the best individual scores. On Track 1 we pursued that difference architecturally, fusing three fine-tuned transformers (Babu et al., 2022) alongside two classifiers that read processed representations rather than the waveform; on Track 2 we pursued it through training, pairing a component targeted at a measured failure mode with one augmented more generically.

We report three findings. Individual EER was a poor guide to fusion contribution: the fusions improve on their best member by 40% and 44%, and two components at 14.59 and 10.17 EER that we never scored on the evaluation set improve the Track-2 fusion further. Development-set scores did not predict it either: **rev-noise** scored 6.0670 on the held-out development-phase partition, yet removing it from the two-component Track-2 fusion leaves **reverb** alone at 4.9370, a cost of 79%. Finally, the condition we targeted for augmentation proves close to benign on the released labels, at $1.3\times$ the clean error rate, while the worst condition, an elevated noise floor, costs $2.1\times$.

2 Background and Task Setup

2.1 Input and Output

Systems receive single-channel audio utterances and must distinguish bona fide speech from the output of a text-to-speech or voice-conversion system. Submissions are continuous scores, one per utterance, ranked by equal error rate.

2.2 Dataset

The ArA-DF 2026 dataset (ArA-DF 2026 Organizers, 2026) provides 22,500 unique training utterances at 2:1 spoofed to bona fide, balanced across Modern Standard, Gulf and Egyptian; development holds 21,000 at the same class ratio but 71.5% Gulf. The evaluation sets hold 144,210 (Track 1) and

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1507–1511

Model	Tr.	Backbone	Distinguishing feature
base	1	XLS-R	5 augmentation classes
rev-noise	2	XLS-R	9 augmentation classes
reverb	1, 2	XLS-R	room simulation, $p = 0.6$
dial-inv	1	XLS-R	AASIST, $\lambda = 1$
lp-res	1	ResNet-18	LP residual
gd	1	ResNet-18	group delay

Table 1: Component detectors and the track (Tr.) each is used on. The XLS-R models are 1.27 GB; **lp-res** and **gd** are 0.01 GB and use no pretrained model. All XLS-R components carry a gradient-reversed dialect head; **base** and **rev-noise** additionally carry a reversed acoustic-condition head.

127,746 (Track 2); labels were released after the evaluation phase closed and we use them for the post-submission analysis in Section 5. Their class balance is more skewed than the training partition, at roughly 3:1 spoofed. Our combined training index holds 67,500 entries: the 22,500 originals plus two pre-rendered augmented copies of each, carrying an elevated noise floor. Two components extend this with the development partition (Section 4.1).

2.3 Related Work

Detectors built on large self-supervised speech encoders such as XLS-R (Babu et al., 2022) now dominate anti-spoofing, typically by fine-tuning the encoder and reading it with a lightweight graph-attention back-end (Jung et al., 2022). Such systems are commonly fused at the score level, though the components often share that front-end. Phase-based representations predate this convergence and remain complementary to magnitude-spectral features (Sanchez et al., 2015; Yang et al., 2021). Domain-adversarial training (Ganin and Lempitsky, 2015) suppresses nuisance factors in the learned representation, and augmentation with recorded room impulse responses (Ko et al., 2017) addresses conditions absent from training. We fine-tune such an encoder, use both adversarial training and impulse-response augmentation, and add classical representations alongside.

3 System Overview

3.1 Model Architecture

Four of the six components (Table 1) fine-tune XLS-R-300M (Babu et al., 2022): the convolutional front-end is frozen and the upper transformer layers are updated. Three use statistics pooling, concatenating the mean and standard deviation of the frame representations over time; **dial-inv** instead uses an AASIST graph-attention back-end (Jung et al., 2022). Each carries a spoof classifier and a gradient-reversed dialect head (Ganin and Lempitsky, 2015), intended to discourage the encoder from using dialect as a proxy for the spoof decision. **base** and **rev-noise** additionally carry a reversed head over the acoustic condition applied by augmentation — five classes and nine respectively — so that the model cannot infer the spoof label from the type of degradation present. **reverb** and **dial-inv** carry the dialect head only.

Two components use no pretrained model. **lp-res** reads an STFT of the linear-prediction residual, which isolates the excitation once the vocal-tract envelope is removed; **gd** reads a group-delay spectrum, a phase-domain representation that discards magnitude (Sanchez et al., 2015; Yang et al., 2021). Both are ResNet-18 classifiers (He et al., 2016) over four-second windows with log-sum-exp pooling, roughly 1% the size of the transformers.

3.2 Fusion Algorithm

Components are combined at the score level. For component m we replace raw scores by percentile ranks $R_m(i) \in (0, 1]$ over the evaluation set and combine them linearly, $s(i) = \sum_m w_m R_m(i)$ with $\sum_m w_m = 1$. Rank normalisation is what makes the weights meaningful: the components emit scores on incompatible scales, and without it the widest-ranged component dominates regardless of w_m. It is lossless with respect to the metric, since EER depends only on the induced ordering. Track 2 applies this once; Track 1 uses multi-stage fusion (Kurnaz et al., 2025), with **reverb** entering at both stages.

3.3 Design Choices

Score fusion improves on its components only to the extent that they make different errors. Augmentation gives some diversity, since a component weights evidence according to what it was trained to survive, but components sharing an encoder and an input remain correlated. This constraint shaped which components we retained.

Track 1. The five components vary along three dimensions — objective, training regime and input representation — with **base** as the reference. **dial-inv** varies the objective, penalising dialect recoverability three times more strongly and replacing statistics pooling with attention over frames.

reverb varies the training regime, updating six transformer layers rather than twelve under room-simulation augmentation. **lp-res** and **gd** vary the input itself, discarding the spectral envelope and the magnitude spectrum respectively, and so read the signal on a different axis from the transformers.

Track 2. Both components read the waveform through XLS-R, so we varied augmentation and fine-tuning depth: **rev-noise** was augmented against the degradation combination we had measured as most costly and updates twelve transformer layers; **reverb**, the same component used in Track 1, applies room simulation and updates six transformer layers.

3.4 External Resources

We use the pretrained XLS-R-300M encoder (`facebook/wav2vec2-xls-r-300m`) (Babu et al., 2022), the AASIST back-end architecture (Jung et al., 2022) for **dial-inv**, and the OpenSLR-28 room impulse response and noise corpus (Ko et al., 2017) for augmentation. No external training audio or additional pretrained models were used.

3.5 Submitted Systems

Track 1. A multi-stage fusion. The inner stage combines all five components at weights 0.3645, 0.1869, 0.1589, 0.1495 and 0.1402 for **base**, **reverb**, **dial-inv**, **lp-res** and **gd** respectively, giving an intermediate score p. The outer stage re-ranks p and fuses it with **reverb**, which therefore enters twice:

$$s = 0.60\,R(p) + 0.40\,R_{\text{rev}}. \tag{1}$$

The inner weights were set by a weight search; the outer weighting was selected by comparing leaderboard scores across submissions.

Track 2. A single-stage fusion of **rev-noise** at 0.35 and **reverb** at 0.65, the weighting again selected by comparing leaderboard scores.

4 Experimental Setup

4.1 Train, Development and Test Usage

All components train on the 67,500-entry index of Section 2.2. **base** and **rev-noise** additionally concatenate the development partition into training and select checkpoints on that same data, so their training-time development EER is not held out; the remaining four train on the training partition only, which we verified excludes the development partition. Each track has its own unlabelled development-phase partition — 16,023 utterances on Track 1 and 14,193 on Track 2, both disjoint from the 21,000 labelled split — so scores on them remain held out for all components. Every development-phase figure we report was scored on the Track 2 partition. No component trains on the evaluation partition.

4.2 Preprocessing

Audio is resampled to 16 kHz and cropped to four seconds. Eight- and twelve-second windows scored 3.9598 and 3.6204 on the development phase, against 3.3894 at four seconds; neither is submitted. **rev-noise**, **base** and **dial-inv** take a random crop offset during training and a centre crop at evaluation; **reverb** takes the leading four seconds throughout. The two signal-processing components analyse the full utterance. All peak-normalise. At inference each utterance is scored in a single forward pass; the transformers use no multi-crop averaging.

4.3 Augmentation

Augmentation is applied on the fly, in addition to the pre-rendered copies in the training index. **base**, **rev-noise** and **dial-inv** share a shortcut-breaking step, which for **dial-inv** is the whole of its augmentation: the spoofed class carried more digital silence and a quieter noise floor than bona fide speech, so digital zeros are filled, DC offset and floor randomised identically for both classes, and rooms applied at probability 0.30. **rev-noise** then draws from nine acoustic classes: a clean pass, five single degradations — reverberation, events, sustained noise, channel simulation and band-limiting — and three combinations, with 34% of draws on reverberation-plus-noise; its noise is sampled from OpenSLR-28 (Ko et al., 2017). **base** uses a five-class version of the same scheme. **reverb** applies room simulation at probability 0.6 with procedurally synthesised background and no shortcut-breaking step. Impulse responses come from the same corpus. **lp-res** and **gd** use the pre-rendered copies only. We verified the acoustic modules by instrumenting the samplers and counting draws, confirming the configured priors.

4.4 Hyperparameters

All transformer components use AdamW at learning rate 10^{-5} with $\lambda = 0.3$, except **dial-inv** at $\lambda = 1$ and 10^{-4}. **base** and **rev-noise** train for 14 epochs at batch size 8; **reverb** for 12 epochs at

batch size 16; **dial-inv** for 10 epochs at batch size 4. **lp-res** and **gd** train for 7 and 8 epochs at batch sizes 24 and 32, learning rate 3×10^{-4}. Checkpoints are selected by lowest development EER, which for **dial-inv**, **lp-res** and **gd** was the final epoch trained.

4.5 Software and Evaluation

PyTorch 2.1.0 (CUDA 12.1), `transformers` 4.35.2, `torchaudio` 2.1.0 and `librosa` 0.11.0, on NVIDIA RTX A6000 GPUs. Systems are ranked by equal error rate. All reported figures come from single training runs rather than seed averages.

5 Results and Analysis

5.1 Official Results and Ranking

Our submitted fusions reach 2.8961 EER on Track 1 and 2.7626 on Track 2, against organiser baselines of 14.54 and 27.11, placing ninth and sixth respectively.

5.2 Ablations

Single-component submissions (official). Submitting **reverb** alone, without the other components, scores 4.8423 on Track 1 and 4.9370 on Track 2 — costs of 67% and 79%: it is valuable in combination but weak in isolation.

Fusion against its components (post-submission). The evaluation labels are used below for measurement only; we reproduced both submitted systems exactly from their component scores. Individually the Track-1 components span 4.8423 to 10.4923 against 2.8961 fused; on Track 2, 4.9370 (**reverb**) and 5.8047 (**rev-noise**) against 2.7626. **gd** and **base**, both Track-1 components, were also scored on the Track-2 development-phase partition, the only set held out from every component, and ranked differently there: **gd** scored best, at 3.3894, yet is second-worst on the Track-1 evaluation set and carries the smallest inner weight, while **base**, worst at 6.5290, carries the largest; **rev-noise** scored 6.0670 there. Correlations point the same way: independence, not EER, is what earns weight. On Track 2 the pair correlates at 0.554, with only 27% error overlap. On Track 1 correlations with the inner fusion span 0.847 to 0.933, with **reverb** least correlated, and 34–49% of each component's errors are unique.

Unsubmitted components (post-submission). Of several components never scored on the evaluation set, two use frozen HuBERT and Whisper encoders with light classifiers. Both are far weaker in isolation than any submitted component, at 14.59 and 10.17 EER, yet overlap the Track-2 submitted pair's errors at only 9.0% and 5.3%, where the submitted components themselves overlap it at 31.6% and 44.5%. Adding either at weights between 0.05 and 0.15 improves the fusion to 2.6509 and 2.6604 on the released labels; adding both reaches 2.6221.

Condition	% of set	EER	vs. clean
silence-heavy	4.9%	1.46	0.6×
event	6.6%	2.00	0.8×
clean	57.6%	2.47	—
reverberant	21.9%	3.09	1.3×
low SNR	9.0%	5.15	2.1×

Table 2: Track-2 EER (%) by dominant acoustic condition, classified by our own signal-based analysis over all 127,746 evaluation utterances. Post-submission.

5.3 Error Analysis

By acoustic condition. Classifying the Track-2 evaluation audio by dominant degradation (Table 2) shows error is not concentrated where we had aimed. An elevated noise floor is the worst condition at 2.1× the clean rate despite covering only 9.0%, while reverberation costs 1.3×. Silence-heavy audio scores best of any condition and is 89% spoofed, matching the training-set association that the shortcut-breaking augmentation targets.

Confusion pattern. At a threshold matched to the evaluation prior, the systems reach 98.2% accuracy on spoofed speech and 94.8% on bona fide: the dominant failure is a false accusation rather than a missed spoof.

Scope. Our error analysis is necessarily confined to acoustics, since dialect labels are not part of the released evaluation metadata.

6 Conclusion

We described rank-normalised score fusions for both ArA-DF 2026 tracks, reaching 2.8961 and 2.7626 EER — more than 40% better than the best single component. Offline measurement guided us poorly: development ranking inverted against fusion weight, and the combination we targeted proved benign while noise alone, which we had treated only in combination, proved worst. Future work will retarget augmentation at the noise floor alone.

Limitations

All figures come from single training runs rather than seed averages, so small differences between components may not be stable. Our fusion weights were selected from development-leaderboard feedback, the only signal available before the evaluation labels were released; refitting on those labels improves Track 1 by 0.13 EER and Track 2 not at all. **base** and **rev-noise** select checkpoints on data they also train on, so their development EER is not held out. Every analysis using the released evaluation labels is exploratory: the unsubmitted-component weights in Section 5 were chosen with those labels visible, so 2.6221 is an upper bound rather than a blind score. Finally, the released metadata carries no dialect field, so no dialect-level error analysis was possible on Track 1.

Ethical Considerations

Deepfake detection is dual-use: the error analysis in Section 5 identifies which acoustic conditions defeat our system, and could guide an attacker toward them.

Our two error types carry different consequences. A missed spoof leaves a synthetic recording unchallenged; a false accusation attributes a fabrication to a real speaker. Our systems fail predominantly in the second direction, misclassifying 5.2% of bona fide utterances against 1.8% of spoofed ones at the prior-matched threshold used for analysis. Any deployment should set the operating point according to which error is more costly in that setting.

The dataset covers Egyptian, Gulf and Modern Standard Arabic; performance on other varieties is untested, and the released evaluation metadata carries no dialect field, so per-dialect error rates cannot be measured even on the varieties present. We used only the audio released by the organisers.

Acknowledgments

We thank the ArA-DF 2026 organisers for the shared task, and Thakaa for supporting this work.

Abstract

We describe Raid AI's entry to Track 1 (Dialect Generalization) of the ArA-DF 2026 shared task on Arabic speech deepfake detection, which placed 1st of 15 teams at 0.8719% Equal Error Rate against a 14.54% official baseline. The configuration of the submitted system is proprietary and is not disclosed. We instead report the ablation behind it, re-scored on the official $144{,}210$-clip evaluation partition against the labels released after the challenge, with bootstrap confidence intervals and paired tests throughout. On development-test, corpus and augmentation alone move a fixed architecture from 13.13% to 1.37% EER. Encoder scale is not monotonic: a 1B encoder beats a 2B under a recipe matched on corpus, augmentation, learning rate, class weights and effective batch size, though the gap is inside the run-to-run spread we measure from three seeds. Three-crop test-time augmentation improves all ten models tested, by 17.4% relative on average, and is the only effect immune to seed variance because it is measured within a checkpoint; a per-crop decomposition shows the gain comes from averaging rather than from choosing a better window.

1 Introduction

Speech deepfake detection has advanced quickly for English, driven largely by the ASVspoof series (Yamagishi et al., 2021), but Arabic remains underrepresented despite a large speaker population and pronounced dialectal variation. ArA-DF 2026 addresses this gap. Track 1 asks whether a detector trained on one distribution of Arabic speech still works on dialects absent from training.

Our submission placed 1st of 15 teams, but the top four span 0.0546 percentage points and our margin over 2nd is 0.0088, so that ordering is not by itself informative. This paper reports the ablation behind the entry rather than the ranking: three encoder scales, five training corpora and two backends, including the runs that lost.

Two properties distinguish these measurements from the development-leaderboard feedback available during the challenge. The organisers released evaluation labels after it closed, so every model is re-scored on the official $144{,}210$-clip partition, and every comparison carries bootstrap intervals and paired tests, with run-to-run variance estimated from three seeds. Several differences that look meaningful as point estimates do not survive that treatment, and we mark them.

Related work. Self-supervised encoders are the standard anti-spoofing frontend: wav2vec 2.0 (Baevski et al., 2020) and its cross-lingual extension XLS-R (Babu et al., 2022). AASIST (Jung et al., 2022) and attentive statistics pooling (Okabe et al., 2018) are common backends, and the ArA-DF baseline pairs XLS-R 300M with AASIST. Codec and transmission augmentation was central to ASVspoof 2021 (Yamagishi et al., 2021), whose condition sets we reuse, and MLAAD (Müller et al., 2024) supplies multilingual spoofed speech. Shared tooling has emerged to make such results comparable: AUDDT (Zhu et al., 2025) puts 31 audio deepfake datasets behind one benchmark interface, and DeepFense (El Kheir et al., 2026), in which our models are implemented, standardises architectures, losses and augmentation over 100 recipes and reports from 400+ models that curated training data drives cross-domain generalization. Lin et al. (2026) lead the 14-set Speech DF Arena benchmark (Dowerah et al., 2025) with a Conformer encoder, crediting multi-source data, balanced sampling and augmentation rather than architecture; our N-ALL result qualifies this, since adding out-of-domain data *without* rebalancing hurt. Multi-crop evaluation is established in vision (Krizhevsky et al., 2012) but is rarely ablated in anti-spoofing; Section 5.3 measures it here.

2 Task Setup

Track 1. Systems perform binary bonafide-versus-spoof classification on Arabic speech, ranked by Equal Error Rate (EER), the task's only metric; the evaluation emphasises dialects absent from training.

Partitions and baseline. One hidden test set is split into two *disjoint* partitions, with no clip in both: the development phase scored 16,023 clips (25.57% bonafide), 10% of the test set, and the evaluation phase the remaining 144,210 (25.59% bonafide). The evaluation phase permitted three submissions per team, best taken as the official score. The organisers' baseline, XLS-R 300M with an AASIST backend, scores 14.65% on development-test and 14.54% on the evaluation partition. We train the same architecture in Table 3, which separates the contribution of our data pipeline from that of the architecture.

Scores. Submissions are `audio_id,logit` pairs with higher values indicating bonafide. We emit the log-likelihood ratio $\mathrm{LLR} = z_{\text{bona}} - z_{\text{spoof}}$ from the classifier logits. EER is invariant under monotonic transforms, so it needs no calibration.

3 Models and Training Corpora

Architecture. Every model shares a three-stage design: a self-supervised encoder, a backend, and a two-class head. We use XLS-R (Babu et al., 2022) at 300M (315,438,720 parameters), 1B (962,497,408) and 2B (2,159,259,648), each fully fine-tuned. Inputs are 64,600 samples at 16 kHz (4.04 s); shorter clips are repeat-tiled rather than zero-padded, because leading-silence duration is a documented shortcut in anti-spoofing corpora (Müller et al., 2021) and zero-padding manufactures that cue. The default backend is temporal-channel modelling (Truong et al., 2024) with attentive statistics pooling (Okabe et al., 2018) under inverse-frequency weighted cross-entropy; one model uses an AASIST backend (Jung et al., 2022) on the same frontend.

Codec-simulation augmentation. Each training clip is re-rendered offline under a set of transmission conditions following the ASVspoof 2021 definitions (Yamagishi et al., 2021). The **narrow** set has the seven LA telephony conditions: pass-through, A-law, μ-law, G.722, GSM full-rate, Opus, and a PSTN approximation (300–3400 Hz band-pass, then 8 kHz A-law, then GSM). The **broad** set adds the nine DF compression conditions: its own pass-through, MP3 and AAC at 32 and 128 kbps, Ogg Vorbis at $q0$ and $q6$, and two double round-trips (MP3 to AAC, Ogg to AAC). Sixteen in total, two of them uncompressed. Training also applies room impulse response convolution and MUSAN (Snyder et al., 2015) additive noise (SNR 0–20 dB) on the fly, at p=0.25 each for narrow-set runs and p=0.5 each for broad-set runs. Table 1 lists the corpora. Narrow-to-broad is therefore a regime change, not a controlled variable.

Corpus	Sources	Cond.	Rows	Bona.
N-AR	AR	7	157,500	33.3%
N-AR+EN	AR, EN	7	335,160	21.1%
N-ALL	AR, EN, ML	7	961,275	7.3%
B-AR	AR	16	360,000	33.3%
B-AR+EN	AR, EN	16	766,080	21.1%

Table 1: Training corpora. AR is the ArA-DF training split (22,500 clips), EN is ASVspoof2019 (Todisco et al., 2019) train, ML is MLAAD (Müller et al., 2024). N and B denote the narrow (7) and broad (16) condition sets. Rows is sources × conditions.

Submitted system. Our official Track 1 submission, the Raid AI model, is built from the components and training data above. Its configuration is proprietary and is not disclosed here; it is not one of the models in Table 3 and is not reproducible from this paper. Of the axes that table reports we can place it on one: the three-crop test-time augmentation of Section 5.3 was applied to it. Limitations names the four we do not answer.

4 Experimental Setup

Training. All models are fully fine-tuned with Adam at 1×10^{-6} and exponential decay (γ=0.9) in bfloat16 autocast, with inverse-frequency class weights per corpus. Effective batch size is 64 for every run, over 8×A100-80GB for the 2B models (per-GPU batch 2, accumulation 4), 8×A100-40GB for the 1B (4, 2) and 4×L40S for the 300M (16, 1); the AASIST model uses one L40S (16, 4). Software is PyTorch 2.6.0. Checkpoints were selected per run on the development leaderboard, so the selected epoch differs across rows and is reported for each. Epoch budgets were also not fixed: under a bounded compute allowance we extended only the configurations that looked promising early, so a row's epoch count partly reflects its own early results (see Limitations).

Rank	Team	EER (%)
1	**Raid AI (ours)**	**0.8719**
2	haitao_xu	0.8807
3	hassan111	0.8917
4	pi-labs.ai	0.9265
	official baseline	14.5400

Table 2: Official ArA-DF 2026 Track 1 evaluation-phase leaderboard, top four of fifteen teams, with the organisers' baseline. Evaluation partition, 144,210 clips. EER is the task's only ranking metric; against the released labels our submission also reaches 99.13% accuracy and 98.86 macro-F_1 at its own EER threshold, and 79.85%/78.05 at τ=0.

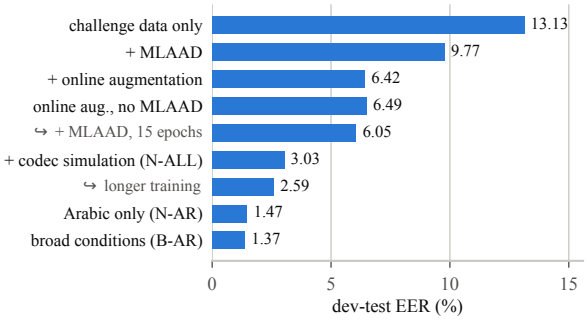

Figure 1: One 300M encoder across successive training regimes, development-test EER, all post-hoc. Grey sub-rows are variants of the row above; corpora are defined in Table 1.

Scoring protocol. The leaderboard result in Table 2 is the only figure scored during the challenge. The rest is computed afterwards by re-scoring stored predictions against the released labels; re-scoring our winning submission with the same code recovers the official 0.8719% to four decimals, which validates the procedure. Every evaluation-partition figure for a model, at one crop and at three, comes from one inference pass, so the two are paired by construction.

Uncertainty. We report two variance sources separately. *Evaluation variance* is a percentile bootstrap over clips: 2,000 resamples of the evaluation partition with replacement, reporting the 2.5/97.5 percentiles. Comparisons use a paired bootstrap, scoring both systems on the same resample so that between-clip variance cancels. *Training variance* is estimated from three runs of one configuration (300M on N-AR) differing only in random seed, which give 1.47, 1.85 and 1.93% on development-test: an unrounded standard deviation of 0.25 and range of 0.47 points. Training variance is therefore the larger of the two.

5 Results

5.1 Training Regime

Figure 1 tracks a fixed 300M architecture across training regimes. Most of these models predate the evaluation phase and were never scored on it, so this comparison is development-test throughout.

The span is an order of magnitude, 13.13% to 1.37%, with the same encoder, backend and optimiser. Adding MLAAD to the challenge data removes a quarter of the error and online room-impulse and noise augmentation a further third. Codec simulation then halves what remains (6.05 to 3.03%), the largest single effect we measured. All four steps exceed the 0.47-point seed range of Section 4.

The lower bars qualify the value of data volume. Dropping MLAAD and ASVspoof2019 from the codec-simulated corpus, a reduction from 961,275 rows to 157,500, improves EER from 2.59% to 1.47%. Out-of-domain data was harmful at this stage. Class balance is a partial confound, since the larger corpus is 7.3% bonafide against 33.3%, and we did not separate the two.

5.2 Encoder Scale

Table 3 gives the model comparison on the evaluation partition. Every model improves on the 14.54% baseline by at least five times, the seven strongest by roughly an order of magnitude. The AASIST row shares the baseline's architecture exactly and scores 2.05% on the same partition, so the data pipeline rather than the backend accounts for most of the gain.

A 1B beat a 2B. The 1B and 2B rows on N-AR share corpus, augmentation, learning rate, class weights and effective batch size. The 1B wins by 0.18 points, and the paired bootstrap interval $[-0.22, -0.11]$ excludes zero. The effect is nonetheless smaller than the 0.47-point seed range, and the two selected checkpoints sit at different epochs (10 against 11), so we report it as a counterexample to defaulting to the largest encoder rather than as a property of the architectures.

Scale and augmentation are of similar size. Holding the corpus at N-AR and growing the encoder from 300M to 2B is worth 0.10 points $[+0.04, +0.18]$; broadening the augmentation regime at 300M is worth 0.10 $[+0.05, +0.17]$.

			EER (%)			
Encoder	Corpus	Ep.	Dev	Eval	3-crop	Δ
2B	B-AR	9	1.07	**1.19**	1.00	−0.19
2B	B-AR+EN	5	1.22	1.21	**0.96**	−0.26
1B	N-AR	10	1.20	1.25	1.12	−0.14
300M	N-AR+EN	10	1.27	1.37	1.14	−0.22
300M	B-AR	8	1.37	1.42	1.14	−0.28
2B	N-AR	11	1.39	1.43	1.12	−0.31
300M	N-AR	17	1.47	1.53	1.18	−0.34
300M	N-AR†	18	1.93	1.95	1.56	−0.39
300M	N-AR‡	17	2.12	2.05	1.61	−0.44
300M	N-ALL	7	2.59	2.78	2.66	−0.12

Table 3: Single-model EER, all rows post-hoc, sorted by Eval. Dev is development-test (16,023 clips); Eval and 3-crop are the evaluation partition (144,210 clips) scored at one and at three crops in the same inference pass, and Δ is their difference computed before rounding. Ep. is the selected epoch. †: a second random seed (240) of the row above. ‡: AASIST backend in place of TCM. Bootstrap 95% intervals on the Eval column are ±0.06 to ±0.09 points, and ±0.14 on the N-ALL row.

Both exclude zero and are the same size, so the data does not rank the two interventions. It does support treating a 300M encoder under the broad regime and a 2B under the narrow one as indistinguishable (-0.01, $[-0.07, +0.06]$) at $7\times$ fewer parameters.

Adding ASVspoof2019 to B-AR likewise more than doubles the corpus and moves the 2B by $+0.02$ points $[-0.03, +0.08]$, the wrong way and within noise: no measurable benefit from out-of-domain English on a dialect-generalization track.

5.3 Test-Time Augmentation

Each clip is scored under three deterministic windows instead of one, at offsets 0, 0.5 and 1 of the slack between the clip length and the 4.04 s window: head-aligned, centred and tail-aligned. Clips shorter than the window are repeat-tiled as at training time, so their crops coincide. The three log-likelihood ratios are averaged; nothing is retrained.

The gain is significant for all ten models, ranging from 0.12 to 0.44 points (17.4% relative on average, mean 0.27 points). Every paired interval excludes zero. Because both scores come from the same checkpoint, training variance cancels, which makes this the only comparison in the paper not confounded by the seed spread of Section 4.

The per-crop scores decompose the effect. The head crop is the best single crop for all ten models, at 1.62% mean EER, while the centre and tail crops are worse at 1.83% each. The mean of the three nevertheless beats every individual crop for every model, reaching 1.35%: two individually weaker views still help. Section 5.4 confirms the mechanism.

Duration	Clips	Bona.	1 crop	3 crops	Δ
< 4.04 s	11,488	18.1%	5.67	5.67	+0.00
4.04–8 s	45,614	24.2%	1.56	1.43	−0.13
8–12 s	55,940	25.0%	1.23	0.86	−0.37
≥ 12 s	31,168	31.4%	1.08	0.64	−0.44

Table 4: EER (%) by clip duration on the evaluation partition, averaged over the ten models of Table 3. The analysis window is 4.04 s.

Averaging two of the three crops places a point between. Averaged over the two pairs that contain it, the head crop plus one other gives 1.40%, so the second crop buys 82% of the total gain and the third the remaining 18%, and three beat that two-crop average for all ten models. Returns diminish but had not stopped by three; we did not run more.

5.4 Error Analysis

The released metadata carries per-clip duration, which partitions the evaluation set along the axis our window length acts on (Table 4).

Errors concentrate on short utterances. Clips below the window are 8.0% of the set but carry an EER of 5.67%, three to five times the rate elsewhere, and are the most spoof-heavy bucket. This is the dominant residual error mode for every model we trained, and a property of the input rather than of any architecture.

The table also isolates the test-time augmentation mechanism. Below the window the crops coincide and the method cannot act: the gain is exactly zero for all ten models. Above it the gain grows monotonically with slack, 0.13 to 0.44 points. Averaging predicts this; a better-window account does not, since a longer clip gives no reason for one window to be better.

6 Conclusion

Our submission placed first on ArA-DF 2026 Track 1, 0.8719% EER against a 14.54% baseline. The system itself is not disclosed; the ablation behind it is. Data and augmentation moved a fixed architecture by an order of magnitude, encoder scale was not monotonic, and three-crop test-time augmentation improved all ten models at no cost.

Limitations

The submitted system is not described. The configuration of the Raid AI model is proprietary. Components, corpora and augmentation are reported in full, but the submitted system cannot be reproduced from this paper and is not among the models tabulated. Of the five axes of Table 3 we report one, that three-crop test-time augmentation was applied to it. We do not report its encoder scale, its backend, its training corpus or its augmentation regime, because answering any of them would disclose how the system is built. A reader can therefore locate the submitted system on one axis of the ablation and on none of the other four, and the leaderboard result and the ablation study should be read as separate contributions.

Training variance is estimated from one configuration. Our seed spread comes from three runs of the 300M model on N-AR, measured on development-test. We assume it transfers to the 1B and 2B rows and to the evaluation partition, which we did not verify; retraining the larger encoders across seeds was beyond our compute budget. Differences smaller than 0.47 points should be read with that in mind.

Epoch budgets were allocated adaptively, not fixed. Training the 2B models is expensive, so we could not give every configuration the same number of epochs. We ran each configuration for a few epochs, inspected the development leaderboard, and spent the remaining budget on the ones that looked promising, stopping the others early to free capacity for further experiments. The epoch counts in Table 3 are therefore an outcome of that triage rather than a controlled setting, and they correlate with how well a configuration was already doing. A row that trained longer had earned the right to; a row that stopped early may not have converged. Differences between rows consequently confound encoder, corpus and optimisation budget, and none of our comparisons should be read as holding training length constant.

Uncontrolled confounds. Checkpoints were selected per run on the development leaderboard, so the epoch differs across rows, and several runs were stopped before the epoch budget completed. Expanding the codec condition set also expands the corpus and coincided with a higher on-the-fly augmentation rate. The corpora differ in class balance, which we did not separate from domain in the N-ALL result.

Development-leaderboard selection. Every challenge decision came from the public development leaderboard, a disjoint partition 11% the size of the evaluation one, so model selection could have fitted it. Across the ten models the two partitions correlate at Spearman $\rho{=}0.99$, with development EER optimistic by 0.06 points, so the effect appears small here; we did not reserve a clean partition to bound it.

Effect sizes sit close to the noise floor. Evaluation intervals are ±0.06 to ±0.09 points wide and the seed standard deviation is 0.25. The training-regime steps of Figure 1 and the test-time augmentation gains clear both; the scale and augmentation comparisons of Section 5 clear only the first. Our leaderboard margin of 0.0088 clears neither, which is why we regard our result as competitive with rather than superior to the systems behind it.

The analysis window was never varied. Short clips are the dominant error mode, and a shorter or duration-adaptive window is the obvious response. We did not test one. The $4.04\,\mathrm{s}$ window is inherited from the pretrained encoder's own training recipe, and changing it means retraining every model rather than re-scoring stored predictions. The crop count stops at three for a different reason: a fourth or fifth crop needs a fresh inference pass over the evaluation partition for every model, whereas the two-crop point of Section 5.3 is a subset of the three we already had.

Re-scoring is not bit-reproducible. Under bfloat16 autocast a repeated inference pass does not reproduce its own scores: for three of the seven models we scored twice, 55–62% of clips moved, by a mean 0.03 log-likelihood-ratio points, changing EER by at most 0.01. Every evaluation-partition figure for a model therefore comes from one pass, so that its one-crop and three-crop columns are paired.

Post-hoc scoring. All figures except the leaderboard result were computed after the challenge closed against released labels. They had no bearing on the standing, and the model selection that produced the submission was made without them.

Scope, and why calibration is absent. We report Track 1 only and rank by EER, the task's

metric. EER is threshold-free and says nothing about whether a deployed operating point would be well calibrated. We did not investigate calibration: no calibration set was released, the challenge score did not depend on it, and our models emit an uncalibrated LLR. The cost is visible in the caption of Table 2, where the submitted system reaches 99.13% accuracy at its own EER threshold and 79.85% at $\tau{=}0$, a 19-point gap that is entirely threshold placement. Error at a fixed threshold is also asymmetric: at $\tau{=}0$ the three strongest models of Table 3 reject 0.5–0.6% of bonafide clips while accepting 1.9–2.6% of spoofs, so residual error is dominated by spoofs passing as genuine. Every such rate describes an uncalibrated operating point.

Ethics Statement

Detecting synthetic speech is a defensive application, but the ablation that shows what makes a detector strong also shows where detectors are weak, and we report those weaknesses rather than only the win. Error on utterances shorter than the 4.04 s analysis window is three to five times the rate elsewhere, and a system deployed at a fixed threshold instead of one fitted on labelled data gives up nineteen points of accuracy. An attacker can measure both properties from any deployed system, so stating them is more useful to a defender than withholding them is protective.

All data is the organisers' ArA-DF 2026 release together with ASVspoof2019 (Todisco et al., 2019), MLAAD (Müller et al., 2024) and MUSAN (Snyder et al., 2015), used under their published terms. We collected no speech, and none of our analysis identifies a speaker. Track 1 is a dialect-generalization task, so error rates can differ by dialect; the released labels do not carry dialect, we did not measure per-dialect error, and that gap should be closed before a system of this kind informs a decision about a speaker. A detector of this accuracy is a filter, not evidence, and the accuracy is conditional on a fitted threshold: at $\tau{=}0$ the strongest models of Table 3 still accept about one spoofed clip in fifty, and the submitted system, whose scores are uncalibrated, accepts more than one in four.

Abstract

Detecting synthetic and voice-converted speech remains difficult for low-resource languages with dialectal diversity, where systems must generalize across regional dialects and unseen acoustic channels. We present the UZH-CL submission to the ArA-DF 2026 Shared Task on Arabic speech deepfake detection, covering Track 1 (dialect generalization) and Track 2 (acoustic robustness). We freeze a W2V-BERT-2.0 backbone and adapt it with *Wavelet Prompt Tuning*, updating under 1% of parameters, and aggregate multi-layer representations with cross-layer attention and a general attentive-statistics pooling head rather than a specialized graph backend. Complementary detectors are obtained by varying adaptation strategy, training data, augmentation, and encoder family. We find that the two shift types require different fusion regimes: a broad multi-window ensemble for dialect generalization, and a compact, channel-matched, center-crop ensemble for acoustic robustness. Official evaluation yields 1.96% EER on Track 1 (6th place) and 1.04% EER on Track 2 (3rd place), corresponding to 87% and 96% relative reductions over the XLS-R+AASIST baselines.

1 Introduction

Neural text-to-speech (TTS) and voice conversion (VC) can generate synthetic Arabic speech that can be used for media forgery, impersonation, and fraud. Detecting such speech is more difficult than in English-centric settings, because Arabic includes Modern Standard Arabic (MSA) and regional dialects that differ in phonology, morphology, and prosody, and because recordings may include codec compression, background noise, room reverberation, and transmission filtering. The ArA-DF 2026 Shared Task evaluates these conditions in two tracks: Track 1 (*dialect generalization*) and Track 2 (*acoustic robustness*).

We address both tracks with parameter-efficient adaptation of a speech foundation model and with score fusion that depends on the type of shift. Fine-tuning a large speech model on a small in-domain set can overfit and overwrite pre-trained features. We freeze W2V-BERT-2.0 (Barrault et al., 2023) and train *Wavelet Prompt Tuning* (WPT) (Farhadipour et al., 2026). WPT prepends standard prompts and Haar-wavelet prompts to the input of each transformer layer, so less than 1% of the parameters are updated.

Many anti-spoofing systems, including the official baseline, take features from a single SSL layer and classify them with AASIST (Jung et al., 2022). We instead combine all transformer layers with cross-layer attention and a multi-head attentive-statistics pooling head. Lower layers tend to carry spectral artifacts; higher layers carry more linguistic content. Using all layers lets us keep a general pooling head rather than a graph backend such as AASIST.

We also train detectors that differ in adaptation, training data, and augmentation, and that use other encoders besides W2V-BERT: XLS-R 300M, Dasheng 1.2B, and the Qwen3-Omni audio encoder. Score fusion is set separately for each track. Track 1 benefits from overlapping windows and a larger set of less correlated detectors; Track 2 benefits from a short center crop and a smaller set of channel-augmented models.

2 Background and Task Setup

Related work. Speech anti-spoofing systems typically combine a self-supervised learning (SSL) frontend (such as wav2vec 2.0 (Baevski et al., 2020) or XLS-R (Babu et al., 2022)) with graph neural network backends such as AASIST (Jung et al., 2022; Tak et al., 2022b). However, full fine-tuning of large SSL backbones is computationally expensive and prone to overfitting on small target datasets. Parameter-efficient fine-tuning (PEFT)

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1519–1524

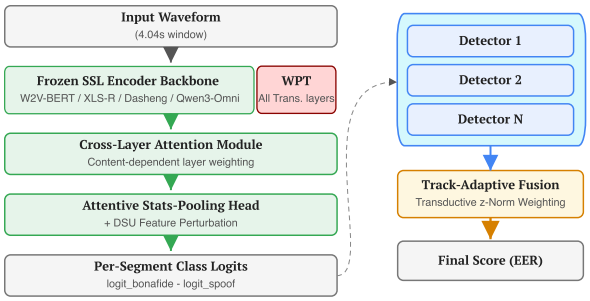

Figure 1: System architecture: per-detector scoring followed by track-adaptive late fusion.

methods, including prefix tuning (Li and Liang, 2021) and visual prompt tuning (Jia et al., 2022), address this by inserting small trainable prompt vectors into transformer blocks while freezing backbone weights. WPT (Farhadipour et al., 2026) extends prompt tuning to speech signals by incorporating multi-resolution frequency subbands via discrete wavelet transforms.

Task and corpus setup. The ArA-DF 2026 Shared Task evaluates binary classification of 16 kHz single-channel audio recordings into *bonafide* (authentic) or *spoofed* (synthetic or voice-converted) speech. The dataset provides 22.5k labeled training utterances and 21k labeled development utterances covering MSA and regional Arabic dialects. Evaluation is divided into two tracks, each featuring an unlabeled development-test set (16.0k files for Track 1; 14.2k for Track 2) used during challenge development, and an unlabeled final-test set (144.2k files for Track 1; 127.7k for Track 2) for official benchmark ranking. The evaluation metric is Equal Error Rate (EER). The official baseline system (XLS-R 300M + AASIST) yields final-test EERs of 14.54% on Track 1 and 27.11% on Track 2. Ground-truth test labels were released post-evaluation, enabling the per-detector diagnostics in Section 5.2.

3 System Architecture

Figure 1 shows the two-stage pipeline. Each detector adapts a frozen SSL backbone (WPT or FTN), aggregates layers with cross-layer attention and attentive-statistics pooling, and outputs a scalar score. Late fusion then z-normalizes and weights those scores: multi-window averaging on Track 1 and a center crop on Track 2.

3.1 WPT Core Detector

The primary core detector uses a frozen W2V-BERT-2.0 backbone (Barrault et al., 2023) consisting of $L = 24$ Conformer layers with hidden dimension $d = 1024$. At layer ℓ, given input frame representations $H_{\ell-1} \in R^{T\times d}$, WPT prepends $n_p = 6$ standard prompt vectors $P_\ell \in R^{n_p\times d}$ and $n_w = 4$ wavelet prompt vectors derived from trainable parameters $Q_\ell \in R^{n_w\times d}$ via a discrete Haar wavelet transform block Ψ:

$$(A_\ell, D_\ell) = \mathrm{DWT}_{\mathrm{haar}}(Q_\ell),$$
$$\Psi(Q_\ell) = \mathrm{Proj}\big([A_\ell\,;\,D_\ell]\big), \quad (1)$$
$$H'_{\ell-1} = [\,\Psi(Q_\ell)\,;\,P_\ell\,;\,H_{\ell-1}\,], \quad (2)$$

where $A_\ell, D_\ell \in R^{n_w\times(d/2)}$ denote low-frequency approximation and high-frequency detail subbands, and Proj projects the concatenated subbands back to dimension d. The modified sequence $H'_{\ell-1}$ passes through transformer block f_ℓ, after which prompt representations are removed prior to layer $\ell+1$: $H_\ell = f_\ell(H'_{\ell-1})_{[n_w+n_p:]}$. During training, backbone weights f_ℓ remain frozen; only prompt parameters $\{P_\ell, Q_\ell, \Psi\}$, cross-layer modules, and downstream pooling heads are optimized ($< 1\%$ of parameters).

To aggregate representations across depth, a 4-head *cross-layer attention* module computes content-dependent weights over layer outputs $\{H_\ell\}_{\ell=1}^{24}$, reflecting that spectral artifacts and high-level linguistic content concentrate at different encoder layers. The aggregated representation is processed by a multi-head attentive-statistics pooling head (Okabe et al., 2018; Desplanques et al., 2020) (4 heads, 128-d bottleneck, 256-d embedding) to produce binary class logits. Feature perturbation via Domain-Shift-with-Uncertainty (DSU) (Li et al., 2022) is applied inside the pooling head during training alongside a class-weighted cross-entropy loss (weight 3.0 on bonafide). The scalar detection score for an input x is defined as $g(x) = \mathrm{logit}_{\mathrm{bonafide}}(x) - \mathrm{logit}_{\mathrm{spoof}}(x)$.

3.2 Detector Ensemble Diversification

To obtain complementary error patterns across constituent models, we diversify detectors along four operational axes (Table 1):

1. **Adaptation strategy:** We contrast frozen WPT against *partial backbone fine-tuning* (FTN), unfreezing the top $N \in \{12, 16\}$ layers at 10^{-5} from a pre-trained WPT model.

ID	Encoder	Adapt.	Training Data	Augmentation	dev	Track 1 EER (%)		Track 2 EER (%)	
					in-dist	dev-test	final	dev-test	final
T1	W2V-BERT-2.0	WPT	ArA-DF (22.5k)	DSU	0.04	9.06	9.34	16.81	17.32

Best single model					–	2.76	3.01	1.45	1.39
Track-adaptive fusion (ours)					–	**1.83**	**1.96**	**1.17**	**1.04**

Table 1: Constituent base detector specifications and per-split EER (%). Adaptation: WPT (frozen backbone) or FTN (top-N layers fine-tuned). Training data: ArA-DF = official training set (22.5k clips); Arabic = expanded Arabic pool (≈100k clips); Multi = multilingual pool (≈264k clips). Augmentation: RB = RawBoost, MR = MUSAN/RIR noise/reverberation. Column "dev" reflects in-distribution validation EER (single 4 s crop). Track 1 and Track 2 test columns report scores under track-specific segment aggregation (multi-window vs. center-crop).

FTBB, FTX, and FTXA in Table 1 are detector IDs using FT16 or FT12.

2. **Encoder family:** Beyond W2V-BERT, we evaluate XLS-R 300M (Babu et al., 2022) (waveform frontend), Dasheng-1.2B (Dinkel et al., 2024) (spectrogram ViT), and the audio encoder extracted from Qwen3-Omni-30B-A3B (Qwen Team, 2025) (32 layers, mel-spectrogram frontend).
3. **Training data composition:** We evaluate three training pools: official ArA-DF; an expanded *Arabic pool* (≈100k clips) incorporating ArFake (Elsetohy et al., 2025), AFAD-MSA (Issa, 2026), an Arabic deepfake corpus (DeepFake-Audio-Rangers, 2024), and Arabic splits from MLAAD (Müller et al., 2024); and a *multilingual pool* (≈264k clips) adding SpoofCeleb (Jung et al., 2025) and ASVspoof 5 (Wang et al., 2024), which covers a range of codecs.
4. **Data augmentation pipelines:** Combinations of DSU, RawBoost (Tak et al., 2022a), MUSAN noise (Snyder et al., 2015), RIR reverberation (Ko et al., 2017), lossy compression (MP3/OGG), and speed perturbation (0.9–1.1×). A specialized dialect model (DIA) applies speed perturbation and DSU without acoustic filtering.

3.3 Track-Adaptive Scoring and Fusion

Segment aggregation. For an input utterance u and detector i, scoring uses either multi-window averaging or center cropping. *Multi-segment scoring* divides u into K_u overlapping windows $\{c_1, \ldots, c_{K_u}\}$ of 4.04 s (stride 2.02 s) and computes the mean score, providing stable estimates over variable-length dialectal recordings in Track 1. Conversely, *center-crop scoring* evaluates a single 4 s window, which performed better under Track 2 channel distortions where averaging across clean and distorted segments reduced performance.

Late score fusion. To handle score calibration differences across models, raw output scores s_i are normalized via transductive z-score standardization over the evaluation set $\mathcal{E}$ and aggregated using non-negative fusion weights $\{w_i\}$:

$$z_i(u) = \frac{s_i(u) - \mu_i}{\sigma_i}, \qquad S(u) = \frac{\sum_i w_i z_i(u)}{\sum_i w_i}, \tag{3}$$

where μ_i and σ_i denote the mean and standard deviation of detector i over $\mathcal{E}$. This z-norm is transductive: a fused score depends on the rest of $\mathcal{E}$ and would not be reproduced by scoring files one at a time.

Track-adaptive weighting. The weight distribution differs between evaluation tracks. For *Track 1* (dialect generalization), fusion uses a broad ensemble of decorrelated detectors, with complemen-

tary models (FTX, MEGA, FTXA) up-weighted ($w_i = 1.5$). For *Track 2* (acoustic robustness), performance is highest with a compact core ensemble of channel-matched detectors at $w_i = 1.0$, with auxiliary models (FTX, MEGA, QWN) included at reduced weights ($w_i = 0.5$). Including track-mismatched detectors at full weight increased Track 2 EER.

4 Experimental Setup

Audio clips are resampled to 16 kHz and padded or cropped to 64,600 samples (≈4.04 s) during training. WPT models are trained for 8 epochs using AdamW (Loshchilov and Hutter, 2019) ($\beta_1 = 0.9, \beta_2 = 0.999$, weight decay 10^{-4}) with an initial learning rate of 10^{-4}, a batch size of 8, and a 500-step linear warmup followed by cosine decay. Partially fine-tuned models (FTBB, FTX, FTXA) train for 4 epochs with learning rates of 5×10^{-5} for the pooling head and 10^{-5} for unfrozen backbone layers. DSU perturbation probability is set between 0.5 and 0.7. Checkpoints are selected by minimum official-development EER, except CDEV (trained on train+dev), for which we use the final epoch. Fusion weights and segment aggregation were chosen after training from cached scores on the development set and the dev-test leaderboard, without final-test labels.

5 Results and Discussion

5.1 Official Submission Results

On the official final tests, fusion of the detectors in Table 1 yields **1.96% EER** on Track 1 and **1.04% EER** on Track 2, against XLS-R+AASIST baselines of 14.54% and 27.11% (87% and 96% relative reductions). On Track 1, a six-model W2V-BERT ensemble (T2, S123, S456, C123, C456, FTBB) scores 2.16%; adding and up-weighting less correlated models trained on external data (FTX, MEGA, FTXA) lowers EER to 1.96%. On Track 2, a compact core (FTBB, C456, T2) scores 1.06% and reaches 1.04% when FTX, MEGA, and QWN are added at w=0.5. Full-weight auxiliaries (1.10%) or the dialect-only DIA model (1.09%) raise EER.

5.2 Per-Detector Cross-Split Analysis

Following the release of ground-truth test labels, we evaluate base detectors across challenge splits (Table 1).

First, score fusion outperforms every individual constituent detector across all test splits (Track 1 final: 3.01% → 1.96%; Track 2 final: 1.39% → 1.04%). 1,000-sample bootstrap resampling on the final-test splits yields non-overlapping 95% confidence intervals for fusion vs. the best single model on Track 1 ($[1.88, 2.05]$ vs. $[2.90, 3.12]$) and Track 2 ($[0.97, 1.10]$ vs. $[1.33, 1.47]$).

Second, W2V-BERT models consistently outperform alternative backbones. XLS-R (5.84%) and Dasheng (12.10%) struggle under Track 1 dialect shift, while Qwen3-Omni reaches 3.03% EER on Track 2 and is useful in that fusion. We hypothesize that Dasheng and Qwen3-Omni, both spectrogram frontends pre-trained on general audio, preserve channel cues more than dialectal structure, which matches their weak Track 1 EERs (12.10%, 8.88%) and stronger Track 2 EERs (3.60%, 3.03%).

Third, in-distribution dev EER (0.04–1.37%) is not a proxy for out-of-distribution robustness: base-detector test EERs rise to 2.76–17.32% (5–200× depending on model and shift).

5.3 Asymmetric Fusion Dynamics

Dialect shift and acoustic channel shift respond to different fusion strategies:

- **Track 1 (Dialect shift):** Benefits from multi-window utterance averaging and an ensemble of decorrelated detectors. W2V-BERT models form correlated clusters ($r = 0.85$–0.97), whereas models trained on external corpora (FTX, MEGA) yield less correlated predictions ($r = 0.46$–0.62). Up-weighting these decorrelated candidates improves Track 1 performance.
- **Track 2 (Acoustic shift):** Benefits from center-crop scoring and a compact core ensemble anchored by channel-augmented models. Adding auxiliary detectors at full weight increases variance, whereas down-weighting them ($w = 0.5$) maintains performance under channel distortions.

6 Conclusion

We described the UZH-CL systems for the ArADF 2026 Shared Task. Frozen W2V-BERT-2.0 with Wavelet Prompt Tuning, combined with track-specific score fusion, reached 1.96% EER on Track 1 and 1.04% EER on Track 2. Dialect shift and acoustic channel shift did not favor the same ensemble: a broader multi-window fusion helped Track 1, and a smaller channel-matched set with center-crop scoring helped Track 2.

7 Limitations

Fusion uses transductive z-norm over the evaluation set, so a file's fused score depends on the rest of the batch; we do not report an inductive variant with development-set statistics. Each detector is a single training run, and close Track 1 EERs in Table 1 (e.g., 3.01–3.15) should not be read as stable without seed variance. We did not deduplicate the external Arabic and multilingual pools against ArA-DF evaluation material by speaker, recording, or synthesis system, because those identities were not released under blind evaluation; the Track 1 fusion includes external-data models (FTX, MEGA, FTXA) and should be interpreted with that caveat. We also do not report the task's secondary metrics (Accuracy and macro-F1).

8 Ethics Statement

This work is a defensive deepfake detector for Arabic speech. We use official ArA-DF data and publicly cited corpora under their licenses, and we do not release a generation system. Speech can identify speakers; we do not attempt re-identification. Reported EERs apply only to the shared-task conditions and are not a guarantee of unconstrained robustness.

pi-labs.ai

Abstract

This paper presents our submission to the ArA-DF 2026 Shared Task on Arabic Audio Deepfake Detection, focusing on Track 1, which evaluates robustness to previously unseen Arabic dialects. Our proposed system combines two complementary self-supervised speech encoders, XLS-R-300M and WavLM-Large, each integrated with an AASIST graph-attention back-end for spoofing detection. The final prediction is obtained through score-level fusion of the two independently trained models, enabling the system to leverage the complementary representations learned by each encoder. To improve robustness to domain shift, we introduce two complementary adaptation strategies: telephony channel augmentation to reduce the mismatch between the training and evaluation domains, and an iterative pseudo-label self-training framework that exploits high-confidence predictions on unlabeled evaluation data for progressive model refinement. On the official ArA-DF 2026 Track 1 evaluation set, our system achieved an Equal Error Rate (EER) of 0.9265%, ranking 4th on the official leaderboard. These results demonstrate that combining complementary self-supervised speech representations with domain-aware adaptation techniques provides an effective and robust solution for cross-dialect Arabic audio deepfake detection.

1 Introduction

Recent advances in neural speech synthesis and voice conversion have made synthetic speech increasingly realistic, creating significant challenges for reliable audio deepfake detection. A key difficulty is domain generalization, where variations in recording conditions, synthesis methods, and language characteristics degrade performance.

The ArA-DF 2026 Shared Task addresses this problem through Track 1 (Dialect Generalization), requiring systems to detect spoofed speech from previously unseen Arabic dialects. The primary challenge lies in maintaining reliable detection performance under domain shifts caused by unseen dialects and telephony recording conditions. To address this challenge, we propose a score-level fusion framework based on complementary self-supervised speech encoders and an AASIST back-end (Jung et al., 2022). To improve robustness under domain shift, we further employ telephony channel augmentation and iterative pseudo-label self-training using high-confidence unlabeled evaluation data. Our results suggest that combining complementary SSL representations with domain adaptation techniques is effective for improving robustness to cross-dialect distribution shifts.

Our main contributions are:

- A score-level fusion framework combining complementary SSL encoders with an AASIST back-end for Arabic audio deepfake detection.
- Telephony-aware augmentation and iterative pseudo-label self-training for improved cross-dialect robustness.
- Achieved an Equal Error Rate (EER) of **0.9265%**, which is only 0.05 higher compared to the top-1 system, ranking **4th** on the official ArA-DF 2026 Track 1 leaderboard.

2 Background and Task Setup

2.1 Task

We participate in Track 1 (Dialect Generalization) of the ArA-DF 2026 Shared Task, which evaluates audio deepfake detection under previously unseen Arabic dialects. Given an input speech recording, the objective is to assign a spoofing score to distinguish bona fide from spoofed speech. The primary challenge is to maintain reliable detection performance when the dialect and recording conditions

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1525–1530
October 28-29, 2026 ©2026 Association for Computational Linguistics

differ from those observed during training. Performance is evaluated using the Equal Error Rate (EER).

2.2 Data

Our system is trained on the ArA-DF training corpus (ArabicSpeech, 2026), which contains approximately 43.5K samples in the labelled train-development split. To prevent leakage between segments originating from the same recording, we reconstructed the development partition using recording-level separation. Following segmentation, the resulting model-development split comprised 86,627 training segments and 13,428 validation segments, including 5,799 bona fide and 7,629 spoofed validation samples.

2.3 Models and Related Work

Recent audio deepfake detection systems increasingly combine self-supervised representations with graph-based anti-spoofing back-ends. AASIST (Jung et al., 2022) has demonstrated strong performance by modeling spectro-temporal relationships using graph-attention, while self-supervised speech models (Baevski et al., 2020; Babu et al., 2022; Chen et al., 2022) have demonstrated strong transferability across spoofing detection tasks. Motivated by prior SSL+AASIST approaches (Tak et al., 2022), we extend this paradigm by combining two complementary SSL encoders through score-level fusion and incorporating domain-adaptation strategies tailored to cross-dialect Arabic deepfake detection.

3 System Overview

Figure 1 shows the proposed dual-branch framework, in which XLS-R-300M+AASIST and WavLM-Large+AASIST independently produce spoofing scores that are subsequently normalized and fused to obtain the final prediction.

3.1 Dual SSL Encoders with AASIST Back-Ends

Although both branches employ Transformer-based SSL encoders, they differ in their pretraining objectives. XLS-R is pretrained using a multilingual contrastive learning objective (Babu et al., 2022), whereas WavLM incorporates masked speech prediction together with denoising and speech enhancement objectives (Chen et al., 2022). These complementary learning paradigms motivate combining the two encoders through score-level fusion.

For each input waveform, the XLS-R-300M and WavLM-Large front-ends produce contextual frame-level representations through their Transformer encoder layers. Rather than using only the final-layer representation, we apply a learnable softmax-weighted aggregation across the encoder layers to capture information at different representation levels. The resulting 1024-dimensional SSL features are projected to 128 dimensions and passed to the AASIST back-end for spoofing detection.

The projected features are passed to AASIST (Jung et al., 2022), whose spectral and temporal graph-attention branches produce spoofing representations for binary bona fide/spoof classification. The utterance-level spoofing score is computed as the difference between the bona fide and spoof logits.

3.2 Domain Adaptation

Motivated by a pronounced telephone-band mismatch observed between the training and evaluation audio, we apply telephony channel augmentation during training by exposing the models to bandwidth-limited and codec-degraded speech. A detailed spectral analysis of this mismatch is provided in Appendix 7.2. We further employ iterative pseudo-label self-training. After each training round, both models independently score the unlabeled evaluation recordings, and only samples receiving consistent, high-confidence predictions are incorporated into the next training round as pseudo-labeled data. Each iteration is warm-started from the best checkpoint of the previous round and retained only if it improves validation EER.

3.3 Score-Level Fusion

The two SSL+AASIST models are trained independently, and their normalized prediction scores are combined using a weighted linear fusion. Compared with feature-level fusion, this approach preserves the independently learned representations without requiring joint end-to-end optimization.

For each utterance, prediction scores are first normalized using z-score normalization and subsequently fused using

$$S_{\text{fusion}} = wS_{\text{XLSR}} + (1 - w)S_{\text{WavLM}}, \qquad (1)$$

where w is selected by minimizing the EER on the validation set.

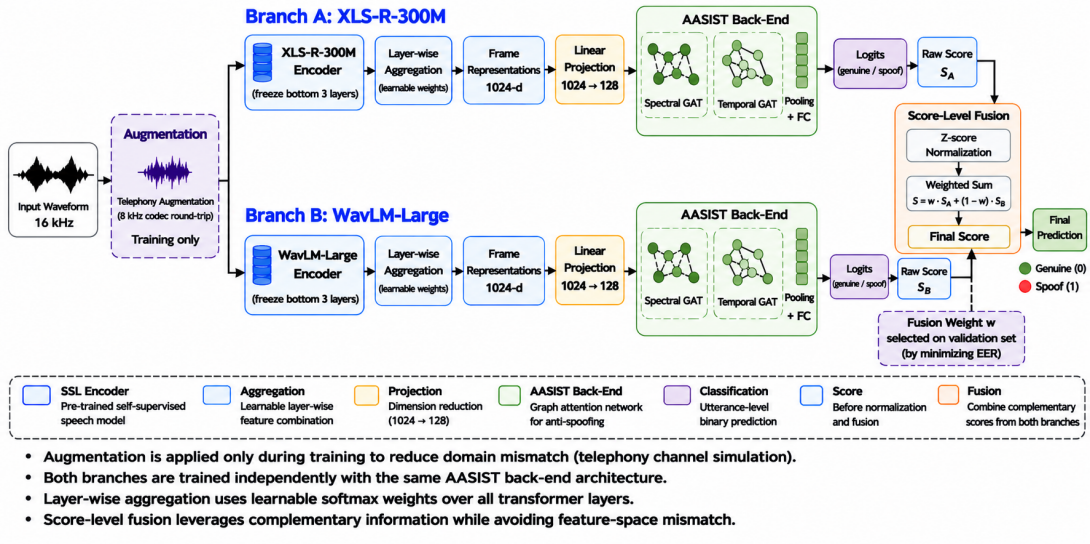

Figure 1: Proposed dual-branch SSL+AASIST architecture with weighted score-level fusion.

4 Experimental Setup

4.1 Preprocessing

All recordings are converted to mono and resampled to 16 kHz. For training, each recording is segmented into fixed-length 6-second speech segments, which are used as model inputs. During inference, recordings longer than 6 seconds are processed using consecutive 6-second windows, and the window-level prediction scores are averaged to obtain the final utterance-level score.

4.2 Training Configuration

Both SSL encoders are initialized from publicly available pretrained checkpoints, while the AASIST back-end is initialized from weights pretrained on the ASVspoof 2019 LA dataset (Jung et al., 2022; Todisco et al., 2019). Models are trained on NVIDIA H200 GPUs using AdamW with cosine annealing, mixed-precision training, inverse-frequency class weighting, and cross-entropy loss.

The SSL encoders and AASIST back-ends are optimized using separate learning rates. Telephony channel augmentation using 8 kHz G.711/GSM codec round-trips is applied during training. Pseudo-label self-training is performed iteratively, with each round warm-started from the previous checkpoint and retained only if it improves validation EER. Grid search on the validation set selected fusion weights of 0.53 and 0.47 for XLS-R and WavLM, respectively. Additional optimization and implementation details are provided in Appendix 7.1.

Table 1: Validation performance of the individual SSL models and the final score-level fusion on the reconstructed validation set (13,428 segments).

Model	Validation EER (%)
XLS-R-300M	2.43
WavLM-Large	3.50
Score-level Fusion	**2.24**

Table 2: Validation EER (%) across successive pseudo-label self-training rounds. Values correspond to the validation EER recorded during iterative training; final selected models were subsequently rescored on the full validation set.

Model	Init	R1	R2	R3	R4
XLS-R-300M	–	4.47	3.36	2.63	**2.44**
WavLM-Large	–	4.87	**3.47**	–	–

5 Results and Analysis

5.1 Performance Overview

Our final official submission achieved an EER of **0.9265%** on the ArA-DF 2026 Track 1 evaluation set, ranking **4th** on the official leaderboard. Table 1 compares the individual SSL models and their score-level fusion on the reconstructed validation set, while Table 2 summarizes the effect of successive pseudo-label self-training rounds. On the internal validation set, fusion reduces validation EER from 2.43% for XLS-R to 2.24%, indicating complementary information across the two SSL encoders.

Successive pseudo-label rounds reduced validation EER for both encoders, with XLS-R reaching 2.44% after four rounds and WavLM reaching

Table 3: Ablation study on the official Track 1 evaluation set comparing individual SSL+AASIST models with the proposed score-level fusion. ROC-AUC and EER are threshold-independent metrics, while accuracy is reported at the corresponding EER operating threshold.

Model	ROC-AUC	EER (%)	Accuracy@EER (%)
XLS-R	0.9995	0.88	99.12
WavLM	0.9973	2.03	97.97
Fused	0.9993	0.93	99.07

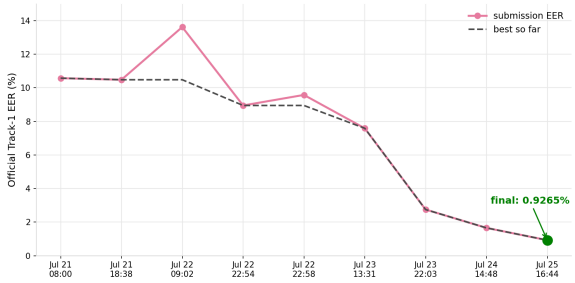

Figure 2: Official Track 1 EER across our nine submissions. Each point represents one leaderboard submission, and the dashed line indicates the best score obtained up to that point. The final selected submission achieved an EER of 0.9265%.

3.47% after two rounds. Further details on the iterative training procedure and stopping criterion are provided in Appendix 7.1.

5.2 System Comparison and Ablation

Table 3 compares the individual SSL models and their fusion. XLS-R provides the strongest standalone performance with 0.88% EER, compared with 2.03% for WavLM. Interestingly, although fusion improves the internal validation EER from 2.43% to 2.24%, its EER in this comparison (0.93%) is marginally higher than XLS-R alone. This suggests that validation-optimized fusion does not necessarily outperform its strongest member under distribution shift.

At the EER operating threshold of 0.4697, the fused system achieves 99.07% bona fide recall and 99.07% spoof recall. Of the 36,903 bona fide samples, 342 are misclassified as spoofed, while 993 of the 107,307 spoofed samples are misclassified as bona fide. This corresponds to an overall accuracy of 99.07% at the EER operating point. Since the official evaluation set does not provide dialect-level labels, our error analysis is limited to aggregate class behavior and acoustic/channel characteristics.

5.3 Development Trajectory

Figure 2 illustrates the evolution of Track 1 EER across our nine leaderboard submissions. Starting from an SSL+AASIST baseline with an EER above 10%, the system showed substantial performance improvements during development. The largest improvement coincided with the introduction of telephony channel augmentation, while subsequent pseudo-label self-training further improved performance. Since these submissions reflect iterative system development rather than controlled single-factor experiments, the trajectory should be interpreted as a development log rather than a formal ablation.

5.4 Validation–Evaluation Gap

Despite the distribution mismatch between the reconstructed validation split and the hidden evaluation set, improvements in validation EER generally translated to improved leaderboard performance, largely because telephony augmentation was also applied to the validation set to better approximate the target channel conditions. This supported the use of validation EER for checkpoint selection and fusion-weight tuning. Moreover, Table 1 shows that score-level fusion outperformed either individual SSL encoder on the internal validation set, supporting the use of complementary representations during model development.

6 Conclusion

We presented a domain-adaptive SSL+AASIST framework for Arabic audio deepfake detection using score-level fusion, telephony augmentation, and iterative pseudo-label self-training. Our final submission achieved an EER of **0.9265%**, ranking **4th** on the ArA-DF 2026 Track 1 leaderboard. Fine-grained dialect analysis was limited by the absence of dialect labels in the evaluation data; future work will investigate robustness across individual dialects and broader recording conditions.

7 Appendix

7.1 Additional Training Details

Optimization configuration. The SSL encoders and AASIST back-ends are optimized using separate learning rates. XLS-R uses 3×10^{-6} and 3×10^{-5} for the encoder and back-end, respectively, while WavLM uses 4×10^{-6} and 4×10^{-5}. Both models are trained with batch size 32, weight decay 10^{-4}, and the bottom three transformer layers frozen during fine-tuning. Models are trained for 2–3 epochs, with checkpoint selection based on the best validation EER.

Learning-rate scheduling. The learning rate is scheduled using cosine annealing, with the minimum learning rate set to

$$\eta_{\min} = \frac{\eta_{\mathrm{SSL}}}{20}, \tag{2}$$

where η_{SSL} denotes the initial learning rate of the corresponding SSL encoder.

Telephony augmentation. Telephony augmentation is applied randomly to the training set to increase channel diversity. For the validation set, augmentation is applied deterministically using a path-hashed random number generator, ensuring reproducible validation EER while maintaining a channel condition representative of the target domain.

Pseudo-label self-training. Pseudo-label self-training is performed iteratively for each SSL+AASIST model. At each round, the current model is used to generate predictions for the evaluation recordings, and samples satisfying the high-confidence selection criterion are incorporated as pseudo-labeled training data for the subsequent round. Each round is warm-started from the best checkpoint of the preceding round, and validation EER is used to determine whether the updated model is retained. For XLS-R, validation EER continued to improve through four rounds, reaching 2.44%. A fifth round did not improve upon the fourth round and was therefore discarded. For WavLM, the best validation EER of 3.47% was obtained after two rounds.

Implementation. The implementation uses PyTorch 2.2, torchaudio 2.2, and Hugging Face Transformers 4.43. Audio preprocessing is performed using FFmpeg.

7.2 Spectral Analysis of Training and Evaluation Data

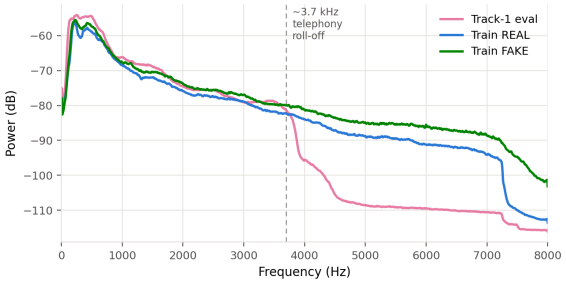

Figure 3: Average spectral characteristics of the reconstructed training data and the official evaluation recordings. The evaluation data exhibits a pronounced telephone-band spectrum with substantially reduced high-frequency energy, indicating a significant channel mismatch.

Figure 3 compares the average spectral characteristics of the reconstructed development data and the official evaluation recordings. The evaluation data exhibits a clear telephone-band response with substantial attenuation above approximately 4 kHz, revealing a pronounced channel mismatch. This observation motivated the use of telephony-aware augmentation during training.

To ensure that bandwidth itself could not serve as a shortcut for classification, the augmentation was applied equally to both bona fide and spoofed recordings, encouraging the detector to learn spoofing artifacts that remain robust across different

recording conditions.

Despite the pronounced channel mismatch, bandwidth itself is not discriminative of bona fide and spoofed speech. A simple classifier based only on high-frequency energy yields an EER of approximately 48%, close to chance. Thus, the benefit of telephony augmentation arises from reducing channel mismatch rather than providing a trivial bandwidth-based cue.

AISA-ArabicFC: The First Shared Task on Arabic Function Calling for Agentic AI Systems

Omer Nacar[1*], Wareef Alzubaidi[1], Mohammed Alkhalifah[1]

[1] Tuwaiq Academy

o.najar@tuwaiq.edu.sa wareefalharbi51@gmail.com m.alkhalifa@tuwaiq.edu.sa

Abstract

Function calling connects language models to external tools, but Arabic structured tool use remains insufficiently evaluated. We present AISA-ArabicFC, a shared task at ArabicNLP 2026 built around 12,220 Arabic requests spanning five dialect groups and eight service domains. Each request has four candidate schemas drawn from a registry of 27 tools, including seven tools that never occur as gold calls; 223 requests require abstention. Systems decide whether to call, select a function, and extract its arguments. Two ranked tracks evaluate core calling and reasoning-trace compliance, with a third diagnostic examining dialect robustness. Twenty-two teams submitted to the blind phase, and 21 produced valid predictions on 1,125 test requests. We analyze 73 submissions and 13 system descriptions. A LoRA-adapted 4B model ranks first on both competition tracks, with scores of 0.9279 and 0.9400, while argument exact match peaks at 0.8816. However, a deterministic rule combining candidate order and released metadata matches the best observed function-name accuracy of 0.9973, limiting what this metric establishes about language understanding. Exact argument extraction provides most of the competitive separation. Maghrebi has the lowest score for every system, although its small test subset and differences in example composition limit interpretation. We provide public task data, a baseline checkpoint, the scorer, and final rankings, and document evaluation shortcuts and remaining reproducibility limitations.[1]

1 Introduction

Large language models increasingly serve as the *action layer* of agentic systems, converting natural-language requests into structured calls that external runtimes can validate and execute. Yet reliable function calling remains difficult under realistic schemas (Patil et al., 2025; Guo et al., 2024), and performance degrades further outside English; MASSIVE-Agents (Kulkarni et al., 2025) reports substantial cross-lingual disparities across 52 languages.

Arabic NLP has strong pretrained and instruction-tuned models (Antoun et al., 2020; Abdul-Mageed et al., 2021; Sengupta et al., 2023; Huang et al., 2024a). Evaluating structured tool use nevertheless requires more than measuring Arabic text understanding or generation. A system must identify whether a request warrants a call, choose an appropriate function, and populate the expected arguments. AISA-ArabicFC provides a shared evaluation of these components using a blind submission phase, a public scorer, and comparisons across participant systems.

Task design. An instance is one Arabic user request together with four candidate tool schemas. A schema specifies a function's name, purpose, argument fields, and value constraints. For example, a currency-conversion function needs an amount and source and target currencies; identifying the function alone is insufficient. The task has three prediction subtasks: *decide* whether a call is needed, *select* its function, and *extract* the annotated arguments. Each instance has at most one gold call; otherwise, the correct output is abstention. These subtasks are shared across the evaluation tracks. Track A evaluates function-name accuracy (FnAcc) and normalized argument exact match (ArgEM). Track B evaluates the same outputs and additionally rewards the presence of a reasoning trace (ThinkRate). Track C is a diagnostic that averages Track A scores across the five dialect groups. Section 3 defines the metrics and

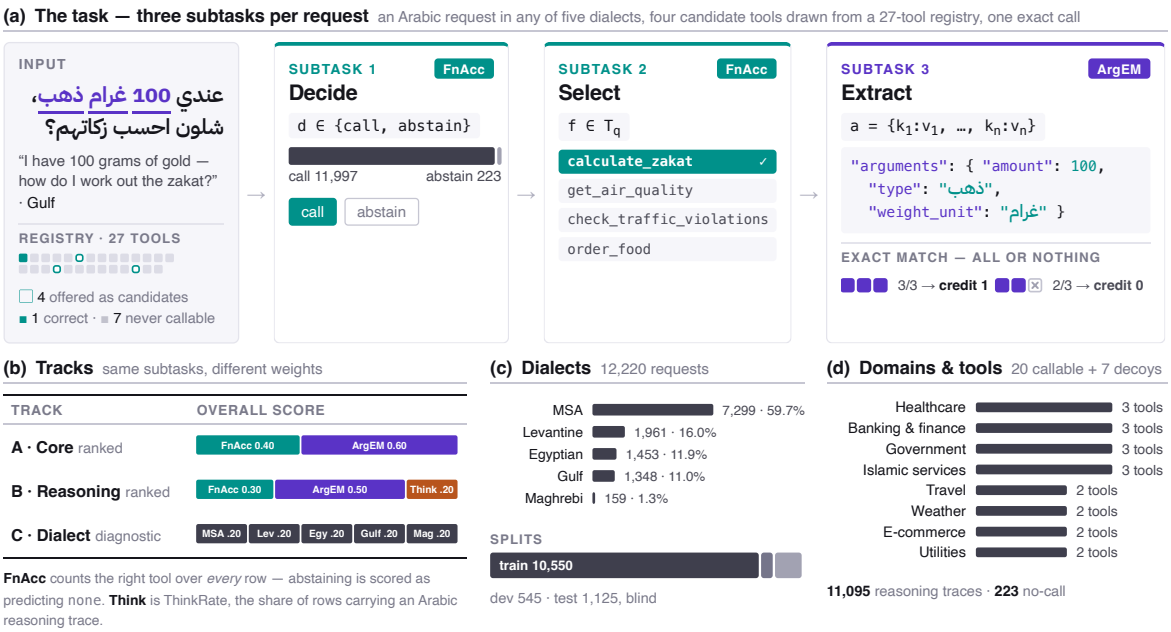

Figure 1: Overview of the AISA-ArabicFC shared task. Each request requires either one structured function call or abstention. Tracks A and B evaluate submitted predictions; Track C provides a dialect-level diagnostic.

their weights. Figure 1 summarizes the setup.

Our contributions.

- **An Arabic function-calling shared evaluation.** We organize a shared task over 12,220 requests, five dialect groups, eight domains, and 27 tool schemas, including 223 no-call instances and 11,095 released training and development reasoning traces.
- **Complementary evaluation views.** Two ranked tracks assess function selection, argument extraction, and reasoning-trace compliance; a dialect diagnostic exposes variation hidden by aggregate scores.
- **Results and benchmark diagnostics.** We analyze 21 valid team entries and 13 system descriptions, identify argument extraction as the main source of competitive separation, and quantify candidate-order and metadata shortcuts that qualify the interpretation of function-name accuracy.

2 Related Work

Tool-calling benchmarks. ToolLLM and ToolBench (Qin et al., 2024), ToolQA (Zhuang et al., 2023), StableToolBench (Guo et al., 2024), UltraTool (Huang et al., 2024b), and BFCL (Patil et al., 2025) establish structured tool use as a core evaluation problem, exposing schema, hallucination, argument, and abstention failures. These benchmarks are largely English-first; MASSIVE-Agents (Kulkarni et al., 2025) extends evaluation to 52 languages but does not target Arabic tool use, dialectal variation, or production-style schemas. AISA-ArabicFC addresses these dimensions directly.

Arabic NLP and function calling. Arabic NLP has produced strong encoders and generative models, including AraBERT (Antoun et al., 2020), ARBERT/MARBERT (Abdul-Mageed et al., 2021), Jais (Sengupta et al., 2023), AceGPT (Huang et al., 2024a), and ALLaM (Bari et al., 2025), alongside advances in Arabic representation learning and embeddings (Elshehy et al., 2026; Nacar and Koubaa, 2025; Nacar et al., 2025). These systems improve understanding and generation but do not directly evaluate whether a model can emit an executable, schema-conformant action. That distinction motivates AISA-ArabicFC: fluent Arabic understanding does not by itself imply reliable tool selection, abstention, or argument realization.

Interfaces, compact backbones, and agentic evaluation. Closed APIs expose native function-calling interfaces (OpenAI, 2024; Anthropic, 2026), while compact open models can be specialized through parameter-efficient adaptation such as LoRA (Hu et al., 2021). The released model card identifies our 270M-parameter AISA-ARFunctionCall-Think baseline as a LoRA adaptation of Gemma 3 (Team et al., 2025). Strong

Dialect	Train	Dev	Test (released)	Test (Track C gold)	Total	%

Maghrebi	142	6	11	34	159	1.3
Total	**10,550**	**545**	**1,125**	**1,125**	**12,220**	**100**
No-call rows	50	45	128	128	223	1.8

Table 1: Corpus composition. Dialect totals and percentages use the released labels. The separate final-gold test column shows the labels used for Track C after 179 dialect reassignments; test membership is unchanged. No-call counts use the final test function labels. Dialect relabeling itself does not change call labels, but separate gold revisions did change function labels.

adapted open-model submissions motivate further study of task-specific supervision; however, differences between submitted pipelines prevent isolating the effects of model size or backbone. More broadly, agentic systems require orchestration, evaluation, and governance (Wu et al., 2023; Anthropic, 2024; Model Context Protocol, 2025; Liu et al., 2024; AI, 2023; International Organization for Standardization, 2023b,a); AISA-ArabicFC addresses structured Arabic prediction within that broader setting.

3 Task Definition

Inputs and outputs. A tool schema describes a function's name, intended operation, argument names and types, and any required fields or allowed values. Let $\mathcal{T}$ contain the 27 registry schemas. Each instance (q, T_q) contains an Arabic request q and exactly four candidate schemas $T_q \subset \mathcal{T}$. Positive instances have one gold function among the candidates; negative instances require no call. The setting is single-turn and single-call: it does not evaluate requests requiring several tools or retrieval from an unrestricted tool registry.

Systems perform three related subtasks:

- **Decide:** determine whether the request requires a call.
- **Select:** predict the function name if a call is needed.
- **Extract:** predict the argument dictionary specified by the annotation policy.

The policy includes information explicitly stated or unambiguously derivable from the request; absent information should not be invented solely to fill a schema field. Evaluation compares predictions with the reference dictionary under the official normalizer. It does not execute the call or establish that a downstream service would accept it.

The four candidates define the available choice set, rather than the number of functions semantically related to a request. Twenty registry tools occur as gold calls; seven occur only as distractors. This restricted setting reduces selection difficulty. Candidate order and additional released metadata create further shortcuts, quantified in Section 7.1.

Submissions use JSON Lines with one object per test instance containing `id`, `tool_called`, and `arguments`; Track B additionally uses `think`. Predicting the reserved function label `none` denotes abstention, so the call decision is represented through the function-name output rather than a separate scored field.

Metrics. Let N be the number of evaluated rows and let $\mathcal{P}$ contain the N_+ rows requiring a call. Let f_i, a_i, and t_i denote a function label, argument dictionary, and trace, respectively; hats indicate predictions. Define $\equiv_{\mathcal{N}}$ as equality under the official argument normalizer. The scorer computes

$$\textsc{FnAcc} = \frac{1}{N}\sum_{i=1}^{N} \mathbb{1}[\hat{f}_i = f_i], \tag{1}$$

$$\textsc{ArgEM} = \frac{1}{N_+}\sum_{i\in\mathcal{P}} \mathbb{1}[\hat{a}_i \equiv_{\mathcal{N}} a_i], \tag{2}$$

$$\textsc{ThinkRate} = \frac{1}{N}\sum_{i=1}^{N} \mathbb{1}[|\operatorname{strip}(\hat{t}_i)| > 5]. \tag{3}$$

FnAcc includes negative rows, whose reference label is `none`. It therefore penalizes false calls and missed calls as well as incorrect tool names. ArgEM is an all-or-nothing dictionary match on positive rows and is computed independently of function-name correctness; it is not a joint measure of a fully correct call. Missing predictions receive no credit. For ThinkRate, only a string containing more than five characters after stripping surrounding whitespace qualifies. Although

Track B requests Arabic reasoning, the scorer does not verify its language, factual quality, generation order, or contribution to the prediction.

Argument normalization. The published normalizer maps selected representational variants to common forms before comparison. It handles Arabic-Indic and Western digits, diacritics and *tatweel*, selected Arabic orthographic variants, numeric representations, documented list-field comparisons, and field-specific aliases. These conventions reduce penalties for some equivalent forms but do not establish general semantic equivalence or runtime schema validity. The same final scorer and normalizer are used for all reported final scores.

Tracks and weights. Track A ranks core calling with

$$S_A = 0.40\,\textsc{FnAcc} + 0.60\,\textsc{ArgEM}. \quad (4)$$

Track B adds trace compliance:

$$S_B = 0.30\,\textsc{FnAcc}{+}0.50\,\textsc{ArgEM}{+}0.20\,\textsc{ThinkRate}. \quad (5)$$

These weights were specified in the task proposal and published before the blind evaluation. They express the organizers' decision to give argument extraction greater weight as the primary challenge; they were not optimized against the final submissions, and no claim of weight optimality is made.

Track C is a dialect diagnostic:

$$S_C = \frac{1}{5}\sum_{g\in\mathcal{D}} \left(0.40\,\textsc{FnAcc}_g + 0.60\,\textsc{ArgEM}_g\right), \quad (6)$$

where $\mathcal{D}$ contains MSA, Gulf, Egyptian, Levantine, and Maghrebi. Function accuracy within a dialect uses all its rows; argument exact match uses only its positive rows. This equal-dialect average differs from weighting by dialect frequency. The ordered Track C table is a descriptive comparison; Tracks A and B are the ranked competition tracks.

4 Data

Provenance and construction. The corpus derives from the Arabic Function Calling collection (Haroon, 2024). Preparation included schema and argument corrections, value canonicalization, four-candidate tool sets, and no-call examples. Versioned scripts and a changelog document successive annotation-policy changes. However, the surviving records do not fully establish how dialectal requests, abstention examples, and reasoning traces were originally produced. We therefore do not infer a human-only or LLM-assisted generation procedure from the evaluation artifacts.

Composition. Table 1 reports 10,550 training, 545 development, and 1,125 test requests. Using the final test call labels, the corpus contains 11,997 positive and 223 no-call instances. No-call counts are 50, 45, and 128 across the three splits, corresponding to 0.47%, 8.26%, and 11.38%; abstention prevalence therefore differs substantially across splits. The no-call examples span eleven recorded categories, including non-actionable domain questions, completed actions, hypothetical requests, and meta-questions. The training and development splits provide 11,095 Arabic reasoning traces in total. Test reference traces and gold calls were withheld during the blind phase.

Tool registry. The registry contains 27 schemas across eight service domains, of which 20 occur as gold calls and seven occur only as distractors (Table 3). Each request is presented with four candidate schemas. This defines a restricted candidate-selection setting; the candidate-order and metadata shortcuts documented in Section 7.1 limit conclusions about semantic discrimination between tools.

5 Baselines and Evaluation

Platform and evaluation phases. The competition used a custom Hugging Face Space for development submissions and final results.[2] During development, the leaderboard scored predictions against the development split and returned results immediately. During the blind phase, participants received test inputs without reference calls, and the portal collected submissions and validated their format without returning test scores. The organizers scored submissions offline against the final gold and published the results after the phase closed.

Submissions and selection. Twenty-two teams submitted to the blind phase. One team's files for both ranked tracks contained no parseable predictions and were recorded as invalid with zero scores; 21 teams therefore appear in the valid-result tables. The submission record contains 73 entries. Teams could submit at most three runs per ranked track. For each team, the published Track A and Track B

System	FnAcc	ArgEM	A	B
GPT-4o, zero-shot	0.9324	0.7442	0.8195	n/a
GPT-4o, 3-shot	0.8676	0.6991	0.7665	n/a
AISA-AR-FunctionCall-Think 270M	0.9813	0.6790	0.8000	0.8074
Archived random run	0.0418	0.0060	0.0203	0.0155
Participant median	**0.9893**	**0.8506**	**0.8928**	**0.9106**
Participant best	**0.9973**	**0.8816**	**0.9279**	**0.9400**

Table 2: Archived baseline predictions rescored against the final test gold with the official scorer. Participant reference points are column-wise summaries, using Track A entries for its component metrics and each track's entries for its Overall score. GPT-4o was not prompted for traces. The random run is retained as a historical result; its generation procedure was not recovered and it is not an established four-candidate chance baseline.

Domain	Tools	Examples
Healthcare	3	appointments, medication
Banking & finance	3	transfer, currency
Government	3	iqama, visa, violations
Islamic services	3	zakat, qibla, Quran
Travel	2	hotels, umrah packages
Weather	2	forecast, air quality
E-commerce	2	price comparison, food
Utilities	2	translation, end of service
Callable	**20**	
Distractors	7	never the correct answer

Table 3: The 27-tool registry. Four schemas are shown as candidates per request.

entries are the runs with the highest respective track score. The two track tables each contain 17 valid teams, with 13 teams in common and four teams unique to each track.

Baselines. Table 2 reports scores recomputed from four archived prediction files using the same final gold and scorer as the participant evaluation. The released AISA-AR-FunctionCall-Think checkpoint contains 270M parameters. Its model card identifies Gemma 3 as the base model and describes LoRA adaptation with rank 64, three training epochs, and a cosine learning-rate schedule.[3] The original complete training configuration was not recovered; these model-card details should not be read as a complete retraining specification.

For GPT-4o, the retained inference script uses the unpinned API alias `gpt-4o`, temperature 0, and a maximum of 300 output tokens. The three-shot condition uses three manually authored demonstrations, including one no-call example, rather than examples sampled from the training split. The script specifies `max_retries=3` with exponential backoff, removes Markdown code fences, and uses a regular-expression fallback to recover JSON. Its documented failure default is `none`. The original API snapshot cannot be recovered from the alias alone. Appendix E records the recoverable configuration and its limits.

The archived random predictions also reproduce their published scores, but the generator is unavailable. We retain this row for historical transparency and do not describe it as uniform candidate sampling. With 997 positive rows, uniform sampling among four candidates and no abstention would instead have expected FnAcc of $(997/1125)/4 = 0.2216$.

Baseline results. The 270M baseline has higher FnAcc than zero-shot GPT-4o (0.9813 versus 0.9324), whereas GPT-4o has higher ArgEM (0.7442 versus 0.6790). GPT-4o therefore obtains the stronger baseline Track A score, 0.8195. Its three-shot configuration scores 0.7665, showing that this particular set of authored demonstrations did not improve the reported run. This single comparison does not establish a general disadvantage of few-shot prompting. The best participant reaches ArgEM 0.8816. Candidate-order and metadata shortcuts limit the interpretation of high FnAcc independently of argument extraction (Section 7.1).

6 Participant Systems

We summarize 13 system descriptions associated with teams in the valid-result tables. The leaderboards contain 21 valid team entries in total; for the remaining eight, available metadata may identify a model or approach, but does not support the same level of methodological analysis.

The submissions differ on one axis far more than on any other. Mean function name accuracy in Track A was near the ceiling at 0.9749, though for reasons partly attributable to the benchmark rather than to the systems, while argument exact match averaged 0.8185 over a range nearly three times

[3] https://huggingface.co/TuwaiqAcademy/AISA-AR-FunctionCall-Think

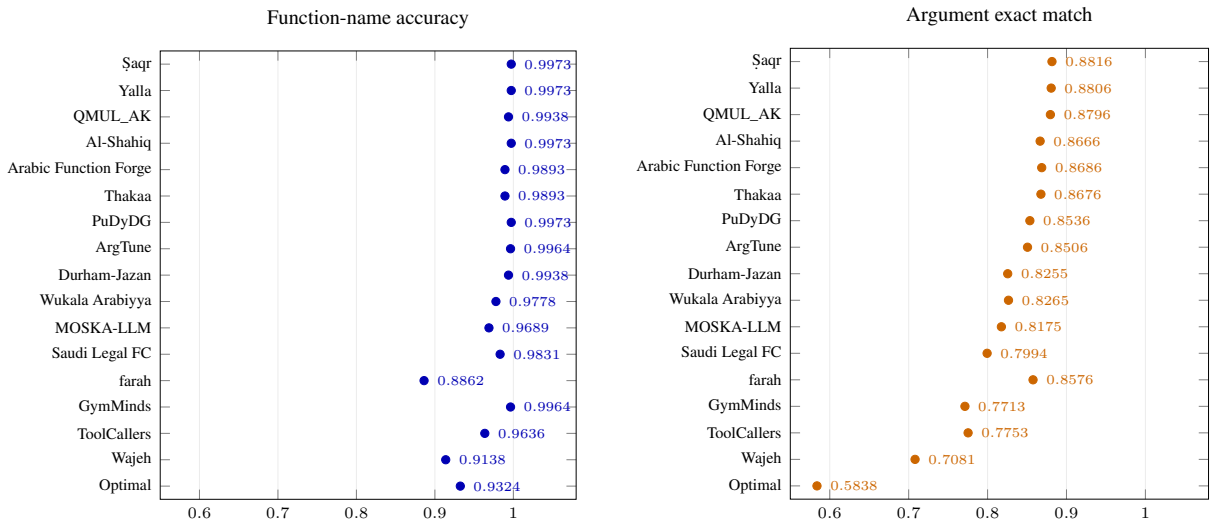

Figure 2: Component scores for all 17 Track A systems in official rank order. The panels share the same horizontal range. High function-name accuracy must be interpreted in light of the input shortcuts in Section 7.1.

as wide. Figure 2 shows how far the two metrics diverge: teams were separated almost entirely by how they wrote arguments rather than by which tool they chose.

6.1 Fine-Tuned Open Models

Ten of the thirteen system papers adapted open models, and this family occupied the top three places. Ṣaqr (Khaled Abdelfattah et al., 2026) won with a single LoRA-tuned Qwen3-4B trained for two epochs on the provided data; inference-time reasoning prefill and schema-typed parsing added 0.0063 to Overall A and 0.0223 to Overall B without retraining. Yalla (Joshi, 2026) placed second with three diverse Qwen 4B/7B LoRA models combined by per-argument voting; supervising only the scored object, 30.3% of the distributed target, yielded its largest measured gain of +0.020 ArgEM. QMUL_AK (Khairallah and Zubiaga, 2026) placed third on Tracks A/B and first on Track C using LoRA-tuned ALLaM-7B with schema-aware prompting, token-weighted loss, deterministic validation, and no-call/minority-dialect resampling, achieving the smallest dialect gap (0.077).

Two teams built directly on the released 270M baseline. PuDyDG (Dang Phu and Dang Van, 2026) decomposed training into five objectives and added 500 validated function-centric synthetic examples, while ArgTune (Baothman, 2026) separated tool selection from general and specialist argument extraction, reaching eighth place on T4 GPUs. Durham-Jazan (Alshehri et al., 2026) combined six QLoRA adapters with field-wise voting and train-derived rules on a single 16 GB GPU; Saudi Legal FC (Almohammedi, 2026) used completion-only loss masking, improving development ArgEM from 0.732 to 0.778; and Siraj (Alanazi and Alshammari, 2026) added a separately trained argument repairer behind a conservative acceptance filter. Makeen (Alzahrany et al., 2026) combined a label-semantic span extractor with a hint-grounded generator and confidence-gated argument routing and additionally released 5,758 Arabic tool-use examples covering 1,442 tools for unseen-tool generalization. Optimal (Alowjan et al., 2026) paired a 4-bit QLoRA Qwen2.5-7B with deterministic parsing, validation, and type casting, shifting schema compliance from the model to a post-processing layer.

6.2 Training-Free Systems

Among the teams whose system descriptions we analyze, Arabic Function Forge and Thakaa submitted prompt-only systems and placed fifth and sixth in Track A, respectively. Arabic Function Forge (Alshehri and Aljubayri, 2026) prompted a single off-the-shelf open-weights model once per request. Its error analysis identified over-interpretation as a dominant failure mode, including translating argument values, converting dates to ISO form, and supplying fields absent from the request. Its prompt explicitly discouraged these transformations.

Thakaa (Alqaeri et al., 2026) placed sixth with a prompt-only pipeline over gemma-4-31B-it and separately analyzed a gemma-4-12B-it fine-tune that was never scored on the test. Two results follow. Stating the annotation conventions outright is worth

Rank	Team	Overall	FnAcc	ArgEM	Paper	Approach	Base model(s)

	Archived random run	*0.0203*	*0.0418*	*0.0060*		*Unrecovered*	–

Table 4: Track A leaderboard, ranked by $0.40\,\mathrm{FnAcc} + 0.60\,\mathrm{ArgEM}$. The grouped, italicized baseline rows use the same order as Table 2 and are not competition entries. All displayed scores use the final gold and scorer. The archived random generator is unavailable. Dashes indicate unavailable or non-applicable information.

7.5 ArgEM points to a model that has not seen them and nothing to one that has. Its search over rules, retrieval, prompting, selection, reranking, and fusion did not yield a gain that survived the team's replication procedure. This finding concerns the tested configurations and development data; it does not establish a universal minimum detectable effect from the split size alone.

6.3 A System Without a Language Model

Wajeh (Shehri and Aldosari, 2026) submitted NABIQ, which contains no large language model, no neural network, no external API, and no GPU. It routes tools by character n-gram TF-IDF with logistic regression, populates arguments by per-tool nearest-neighbor retrieval over training data, and gates every value through an evidence test: a candidate may be emitted only if it is a normalized substring of the utterance, a member of a closed canonical map, or a date whose tokens occur in the text. It reached 0.7904 overall on CPU, and its methodological result is discussed in Section 7.

6.4 Reasoning Traces and Dialect Handling

Across Track B, the trace requirement was met almost universally, with 12 of the 17 scored systems emitting a trace on every instance. How it was produced varied more than the scores suggest. Saudi Legal FC generates it in a single autoregressive output sequence, emitting an Arabic `think` field inside the same JSON object as the call, so that abstention on a negative instance carries an explicit rationale. Others attached it separately, and two teams satisfied the requirement by construction, a point taken up in Section 8 and in the Limitations.

Several teams considered or incorporated dialect-related strategies, but only QMUL_AK explicitly reports dialect-specific handling as part of the submitted system and links it to the intended robustness objective. QMUL_AK resampled minority-dialect examples during training and is the only top-three Track A system to have done so. One team investigated its own dialect gap rather than acting on it: Saudi Legal FC found that Levantine, its weakest dialect, was already over-represented in training relative to development, so under-exposure could not explain the deficit, and a manual review of sixteen Levantine failures attributed twelve to the enumeration and date-format patterns that also dominate its MSA failures. It therefore made no dialect-specific intervention, concluding instead that the observed gap reflected recurring formatting patterns rather than insufficient dialect exposure, consistent with Section 8.

7 Results

We report 17 systems each for Tracks A and B and 21 for Track C, which covers all valid teams entering

either ranked track. The Track A leaderboard appears in the main text; complete Track B and Track C results are provided in Appendices A and B, respectively.

7.1 Track A: Core Function Calling

Table 4 shows a closely grouped leading set: Ṣaqr scores 0.9279, Yalla 0.9273, and QMUL_AK 0.9253. Their argument dictionaries match on 879, 878, and 877 of the 997 positive rows, respectively. Ṣaqr and Yalla have the same number of correct function labels, so their score difference is exactly one net argument match, contributing $0.60/997 = 0.000602$ to Track A. This is a difference in total correct counts; it does not establish that the systems disagree on only one row or are statistically equivalent.

Across all 17 Track A systems, ArgEM ranges from 0.5838 to 0.8816, and 15 systems exceed zero-shot GPT-4o's 0.7442. Argument extraction therefore provides substantial separation under the final normalization policy. However, the near-ceiling function scores require a different interpretation.

Candidate-order and metadata shortcuts. The gold tool occupies the first candidate position on all 997 positive test rows. Always choosing that position therefore gives FnAcc $997/1125 = 0.8862$. In addition, the released `negative_category` field is non-null on 125 rows, all negative under the final gold; it identifies $125/128 = 97.66\%$ of final no-call rows without any false positives. A rule that predicts `none` when this field is non-null and otherwise chooses the first candidate consequently obtains

$$\text{FnAcc}_{\text{shortcut}} = \frac{125 + 997}{1125} = 0.9973. \quad (7)$$

This analytical count matches the best observed participant FnAcc without interpreting the request. Table 5 reports these label-only diagnostics; neither rule supplies an argument dictionary. The result does not establish that any participant used the shortcut, but it prevents interpreting the observed maximum as evidence that Arabic tool selection is solved.

Abstention diagnostic. For QMUL_AK, inspection of the archived submission attributes all seven function-label errors to the call decision: six false calls on 128 negative rows and one missed call on 997 positive rows. The corresponding rates are 4.69% and 0.10%. There are no wrong-tool errors among positive rows for which the system predicts a call. This localizes this system's function-label errors, but the released shortcuts prevent attributing the remaining correctness solely to semantic understanding, and this single-system analysis does not characterize all entrants.

Label-only rule	Correct	FnAcc
First candidate	997/1125	0.8862
Metadata + first candidate	1122/1125	0.9973

Table 5: Analytical function-label diagnostics derived from the released input properties and final labels. These are not argument-prediction systems or ranked submissions.

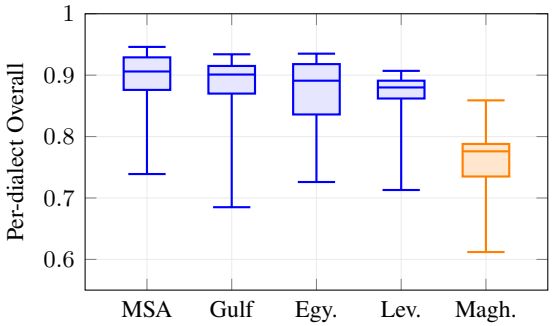

Figure 3: Per-dialect Overall scores across the 21 Track C systems. Boxes show the interquartile range, internal lines show medians, and whiskers show minima and maxima. Maghrebi has the lowest score for every system; its maximum (0.859) is below the median of each other dialect group.

7.2 Track B: Reasoning Function Calling

Track B preserves the top ordering from Track A: Ṣaqr ranks first at 0.9400, followed by Yalla at 0.9395 and QMUL_AK at 0.9380. Reasoning-trace compliance is nearly saturated, with 12 of 17 systems reaching ThinkRate = 1.0, so most ranking separation again comes from ArgEM rather than trace presence. Four teams entered Track B without a Track A submission. The full leaderboard is reported in Appendix A.

8 Discussion

Similar scores, different pipelines. Ṣaqr uses one adapted 4B model with reasoning prefill and schema-typed parsing, whereas Yalla combines three models through per-argument voting. Their Track A difference is one net argument match; paired predictions are needed to assess error overlap and uncertainty. Likewise, the close scores of Ṣaqr and QMUL_AK do not isolate backbone ef-

fects: besides using different models, their pipelines differ in sampling, loss weighting, prompting, and validation.

Approach families. Adapted models occupy the top three Track A positions, followed by three prompt-only systems. Wajeh achieves 0.7904 without a neural language model. These results demonstrate several competitive approaches within the fixed-registry setting, but unstandardized training and inference budgets prevent efficiency comparisons. Candidate-order and metadata shortcuts also limit conclusions about semantic tool selection and generalization beyond this setting.

Argument supervision and output conventions. Yalla reports a 0.020 absolute ArgEM gain from supervising only the scored object; Saudi Legal FC improves development ArgEM from 0.732 to 0.778 with completion-only loss; and Thakaa gains 7.5 percentage points by stating annotation conventions explicitly. These within-team effects are not directly comparable, but support attention to supervision and output representation. Participant error analyses similarly identify incorrect values despite correct tools or keys, alongside translation, date rewriting, and unsupported field completion. However, reference mismatches need not imply invalid executable actions; multiple references or execution checks could distinguish acceptable alternatives from errors.

Dialect and trace diagnostics. QMUL_AK obtains the highest dialect macro score and uses minority-dialect resampling, whose contribution was not isolated by ablation. All systems score lowest on Maghrebi, motivating larger dialect subsets matched for tool and argument composition. Meanwhile, 12 of 17 Track B systems attain full trace compliance, sometimes through separately attached traces. Because the scorer checks length rather than language, consistency, or faithfulness, these results do not establish that reasoning improves calls. Appendix C provides detailed supporting evidence.

9 Conclusion

AISA-ArabicFC provides a shared evaluation of Arabic function selection, abstention, and argument extraction across five dialect groups. Twenty-one teams produced valid blind-test predictions, and compact adapted models and prompt-only systems both achieved competitive results. Exact argument extraction supplies most of the separation among leading entries, while candidate-order and metadata shortcuts substantially limit the interpretation of near-ceiling function-name accuracy. The dialect diagnostic consistently identifies lower Maghrebi scores, subject to small-sample and composition effects, and the reasoning track primarily measures trace presence. These results and design findings motivate cleaner input releases, better documented annotation, broader dialect coverage, and evaluation that separates argument grounding, valid execution, and reasoning quality.

Limitations

AISA-ArabicFC evaluates single-turn requests with at most one call and four candidates from a fixed registry, limiting conclusions about multi-tool planning, unrestricted retrieval, and external execution. Candidate ordering and label-proxy metadata jointly enable a deterministic rule to match the best reported FnAcc without interpreting requests, although this does not establish that participants used these shortcuts. Annotation and normalizer revisions limit comparisons across versions; all final scores use the same final gold and scorer. Incomplete records of data generation, reviewer identities and expertise, and independent annotations prevent a complete construction account or a verified annotator count and agreement statistic. Track C uses corrected dialect labels that differ from the released inputs. Its small Maghrebi subset (34 rows), uncontrolled differences in example composition, and the absence of paired uncertainty estimates limit interpretation of dialect differences and close rankings. Furthermore, ThinkRate checks trace length rather than language, faithfulness, or contribution to prediction, while ArgEM evaluates normalized arguments independently of function correctness and does not establish executable-call validity. Reproducibility is constrained by the unpinned GPT-4o alias, unavailable random-baseline generator, and incomplete original 270M training configuration. Independent rescoring requires access to the exact final gold, predictions, scorer, and normalizer revisions.

Acknowledgements

We thank all registered teams, the 22 teams that submitted to the blind phase, and the reviewers for their feedback. Tuwaiq Academy organized and sponsored the task.

A Track B Leaderboard

Table 6 reports all 17 valid Track B team entries. The score is $0.30\,\textsc{FnAcc} + 0.50\,\textsc{ArgEM} + 0.20\,\textsc{ThinkRate}$. The leading three teams are unchanged from Track A, and 12 of 17 systems attain $\textsc{ThinkRate} = 1.0$. Four teams entered Track B without a Track A entry. For each team, the table reports the submitted run with the highest Track B score, subject to the limit of three runs per team per ranked track.

B Track C: Cross-Dialect Robustness

Table 7 orders the dialect diagnostic by equal-dialect macro score. QMUL_AK obtains the highest value, 0.9075, followed by Al-Shahiq at 0.9031 and Ṣaqr at 0.8994. Restricting the comparison to teams also entering Track A, the reordering occurs among the leading six; the relative order of the remaining shared entrants is unchanged. Track-B-only teams change their absolute positions in the full table.

The diagnostic uses final test dialect labels: 660 MSA, 175 Egyptian, 128 Gulf, 128 Levantine, and 34 Maghrebi rows. The released input file contains earlier labels, including only 11 Maghrebi rows, and should not be used to recover the final scoring denominators. Appendix D records the 179 reassignments.

Maghrebi is the lowest-scoring group for all 21 systems, and its best score, 0.859, is below the median score of each other group (Figure 3). This pattern motivates further evaluation, but does not isolate a causal effect of dialect: dialect subsets can differ in tools, argument patterns, no-call prevalence, and annotation properties. The small Maghrebi subset also makes close macro-score comparisons sensitive to few outcomes. Specifically, one additional argument match in a dialect with $N_{+,g}$ positive rows changes the macro score by $0.12/N_{+,g}$ when function correctness is unchanged. We report the diagnostic ordering descriptively and make no statistical-significance claim about close differences.

C Additional Discussion Evidence

Intervention inventory. Table 8 summarizes interventions credited with a gain in the 13 system descriptions analyzed in this paper. A method is counted only when the description reports its use in the submitted system and attributes an improvement to it; methods tested and rejected are excluded. A team can contribute to several categories. These counts summarize participant reports, not organizer-run ablations, and the reported effect sizes below retain their original evaluation settings.

Training signal and output shaping. Yalla (Joshi, 2026) reports that the scored object constitutes only 30.3% of the distributed target and obtains a 0.020 absolute increase in ArgEM by supervising that object alone, exceeding the gain from its subsequent reinforcement-learning stage. Saudi Legal FC (Almohammedi, 2026) improves development ArgEM from 0.732 to 0.778 using completion-only loss masking. Thakaa (Alqaeri et al., 2026) reports a 7.5-percentage-point gain from explicitly stating annotation conventions in the prompt. Ṣaqr (Khaled Abdelfattah et al., 2026) reports inference-time gains from reasoning prefill and schema-typed parsing without retraining. These within-team comparisons motivate attention to supervision and output representation, but their magnitudes are not directly comparable across different models and evaluation settings.

Failure localization. Arabic Function Forge (Alshehri and Aljubayri, 2026) identifies over-interpretation as a recurring error: translating argument values, changing date representations, or supplying fields absent from the request. PuDyDG (Dang Phu and Dang Van, 2026) reports that 55 of 78 development argument failures (70.5%) retain the correct key set and differ in one or more values. ArgTune (Baothman, 2026) reports incorrect argument dictionaries on 93 of the 500 positive development examples, with the correct tool predicted in all 93 cases. These analyses locate substantial remaining error in argument values under the annotation and normalization policy; they do not independently establish whether every alternative prediction would fail in a downstream service.

Diminishing returns from additional complexity. Ṣaqr reports improvements from 270M through 4B under its tested configurations, without a corresponding improvement from every larger model.

Rank	Team	Overall	FnAcc	ArgEM	ThinkRate
1	Ṣaqr	0.9400	0.9973	0.8816	1.0000
2	Yalla	0.9395	0.9973	0.8806	1.0000

Table 6: Complete Track B leaderboard using the final gold and official scorer. Overall is $0.30\,\mathrm{FnAcc}+0.50\,\mathrm{ArgEM}+0.20\,\mathrm{ThinkRate}$. Trace compliance measures the presence of a qualifying string, not reasoning quality.

Thakaa evaluates rules, retrieval, prompting, selection, reranking, and fusion without obtaining a reliably replicated gain beyond its fine-tuning reference. For 60.7% of its remaining development failures, the gold argument dictionary appears in a pool of 20 samples, but the tested selectors do not reliably recover it. Siraj (Alanazi and Alshammari, 2026) rejects five candidate post-editing rules evaluated on out-of-fold predictions; the retained post-editing stage yields only a small reported blind-test improvement. These findings concern the tested recipes and data, rather than establishing a general disadvantage of larger models or more complex pipelines.

Reasoning traces. Twelve of the 17 Track B systems attain $\textsc{ThinkRate} = 1.0$. Yalla reports that, for 97.7% of rows, its trace is attached after prediction from a separate reasoning-trained model whose tool call matches the submitted call. Other systems use deterministic or separately constructed traces. The official length-based check does not verify Arabic language, trace–call consistency, faithfulness, or the trace's role in producing the prediction. High compliance therefore supports a claim about output format, not the causal benefit of reasoning.

Dialect handling. QMUL_AK (Khairallah and Zubiaga, 2026) incorporates minority-dialect resampling and obtains the highest Track C macro score, with a dialect gap of 0.077. The contribution of resampling is not isolated by an ablation. Saudi Legal FC instead attributes many inspected Levantine errors to enumeration and date-format patterns also found in MSA. These observations motivate distinguishing linguistic coverage from differences in argument patterns and annotation conventions across dialect subsets.

D Test Annotation Audit

Review scope. The archived review file marks all $1{,}125$ test instances as reviewed and contains 173 distinct written rationale strings. The review interface displays the request, candidate schemas, reference function, and arguments, and saves edits to a working copy. Comments document both dialect-label normalization and dialect reassignment. The distinct strings are review notes; they do not represent independent annotations or a reviewer count. The retained records do not identify reviewers, establish their expertise, or document independently duplicated judgments. Consequently, no inter-annotator agreement statistic is reported, and the recorded test review is not extended into a claim of complete human verification of the training and development data.

Gold-version changes. Comparing the v1.6 test annotations with the final scoring gold identifies 419 changed argument dictionaries and eight changed function labels (Table 9). These counts refer to that specific test-version comparison. A row may have both changes, and the counts are not a breakdown of all original schema faults in the source collection.

Dialect relabeling. The final Track C labels differ from the released test labels on 179 rows. Table 10 gives every transition, and Table 11 gives the re-

Rank	Team	Macro	Δ	MSA	Gulf	Egyptian	Levantine	Maghrebi	Gap

	Mean	*0.8546*		*0.8918*	*0.8794*	*0.8719*	*0.8656*	*0.7647*	*0.1335*

Table 7: Track C diagnostic, ordered by the unweighted mean of five within-dialect Track A scores. Δ compares ranks after restricting both orderings to shared Track A entrants; *n/a* denotes no Track A entry. Gap is the highest minus lowest dialect score and does not determine the ordering. Final test dialect labels are used.

Intervention credited with a gain	Teams
Deterministic post-processing or repair	12
Data augmentation or resampling	6
Prompt or schema formatting	5
Training-objective or loss shaping	4
Reasoning-trace handling	3
Ensembling or voting	2
Dialect-specific handling	1

Table 8: Interventions credited with a gain in the 13 analyzed system descriptions. Categories overlap.

Comparison	Rows
Argument dictionaries: v1.6 test gold to final gold	419
Function labels: v1.6 test gold to final gold	8
Dialect labels: released test inputs to final gold	179

Table 9: Version-specific test annotation changes. Counts can overlap and must not be summed as unique affected instances.

sulting counts. Relabeling does not change test membership. The final Maghrebi subset contains 34 rows; the 11 rows in the released input labels are not its official scoring denominator. Within each dialect, FnAcc uses all rows, whereas ArgEM uses only positive rows.

Call-label composition. The final test gold contains 997 call rows and 128 no-call rows. Training and development contain 50 and 45 no-call rows, respectively. Their no-call proportions are 0.47%, 8.26%, and 11.38% across train, development, and test, so abstention prevalence differs substantially across splits. The corpus contains 223 no-call rows under the final test labels and eleven recorded abstention categories. The 11,095 released reasoning traces belong to training and development.

Released	Final	Rows
MSA	Egyptian	75
MSA	Gulf	53
MSA	Levantine	27
MSA	Maghrebi	10
Gulf	Maghrebi	9
Egyptian	Maghrebi	4
Levantine	Gulf	1
Total		**179**

Table 10: All test dialect-label transitions between the released input labels and the final scoring labels.

E Recoverable Baseline Configuration

GPT-4o settings. Table 12 records the settings preserved in the baseline inference script. The three-shot condition uses three manually authored demonstrations, including one no-call example; they were not sampled from the training split. No claim is made that these demonstrations balance dialects or domains.

Prompt and generation reproducibility. The original inference script contains the system prompt

Dialect	Released	Final
MSA	825	660
Egyptian	104	175
Gulf	83	128
Levantine	102	128
Maghrebi	11	34
Total	**1,125**	**1,125**

Table 11: Test row counts before and after dialect relabeling. Final counts include positive and no-call rows; they are not necessarily the positive-only denominators for ArgEM.

Setting	Recorded value
Model alias	`gpt-4o`
Temperature	0
Output limit	`max_tokens=300`
Demonstrations	Zero, or three manually authored examples
Negative example	One in the three-shot condition
Retry setting	`max_retries=3`, exponential backoff
Parsing	Markdown-fence removal and regular-expression JSON fallback
Failure default	Abstention (`none`)

Table 12: Recoverable GPT-4o baseline settings. The alias is not pinned to an identifiable historical model snapshot.

and the three demonstrations, but an unpinned `gpt-4o` alias does not identify the exact historical API snapshot. Consequently, matching the prompt and decoding settings does not guarantee regeneration of the archived predictions. The three-shot result characterizes the recorded demonstration set; it is not evidence that few-shot prompting generally degrades performance.

The 270M baseline. The released AISA-AR-FunctionCall-Think model card identifies `google/gemma-3-270m` as the base model and describes LoRA adaptation with rank 64, three training epochs, and a cosine learning-rate scheduler.[4] These are model-card statements; the original complete training configuration was not recovered. They do not establish the missing optimizer, learning-rate, batch-size, seed, and checkpoint-selection details required for a complete retraining specification.

Archived random predictions. The random-baseline prediction file remains available for rescoring, but its generator was not recovered. Its reported FnAcc of 0.0418 should therefore not be described as the chance performance of uniform selection from four candidates. For a rule that always calls and samples uniformly from the four candidates,

$$\mathbb{E}[\text{FnAcc}] = \frac{997}{1125} \cdot \frac{1}{4} \approx 0.2216. \tag{8}$$

This expectation assumes one gold candidate on each positive row and no correct candidate on a no-call row. The historical random result is retained as an archived run, not a fully specified sampling algorithm.

Score reproduction. Rescoring the four archived baseline prediction files with the final gold and scorer reproduces their reported metrics. Rescoring the archived QMUL_AK predictions similarly reproduces FnAcc 0.9938, ArgEM 0.8796, Track A 0.9253, Track B 0.9380, and Track C 0.9075. This verifies the scoring of those predictions; it does not constitute fresh inference from the original models. Independent blind-test rescoring requires the exact final gold, prediction files, scorer, and normalizer revisions.

F Additional Evaluation Diagnostics

Participation and selected runs. Twenty-two teams submitted to the blind phase. One team's Track A and Track B files contained no parseable predictions and were recorded as invalid with zero scores, leaving 21 valid teams. The 17 valid entries in each ranked track share 13 teams; four teams appear only in Track A and four only in Track B. The submission record contains 73 entries. Each track selects the highest-scoring eligible run for each team using its own Overall score.

Analytical selection shortcuts. The first candidate is the gold tool on all 997 positive test rows, so always choosing that position yields FnAcc $997/1125 = 0.8862$. In the released inputs, `negative_category` is non-null on 125 rows, all negative under the final gold. Its precision as a no-call indicator is 100% and its recall is $125/128 = 97.66\%$. Predicting `none` when the field is non-null, and otherwise selecting the first candidate, therefore gives

$$\text{FnAcc}_{\text{shortcut}} = \frac{125 + 997}{1125} = 0.9973. \tag{9}$$

This analytical count matches the best reported participant FnAcc without interpreting the request. It is a diagnostic of the released inputs, not evidence that a particular participant used the rule. Neither shortcut supplies argument predictions.

[4] https://huggingface.co/TuwaiqAcademy/AISA-AR-FunctionCall-Think

Abstention error decomposition. For QMUL_AK, the seven function-label errors comprise six false calls on 128 negative rows and one missed call on 997 positive rows. Their rates are 4.69% and 0.10%, respectively. Among the 996 positive rows for which the system predicts a call, there are no wrong-tool errors. This decomposition concerns one archived system output, and the input shortcuts limit semantic conclusions from its high function-label accuracy.

Leading-system margins. Ṣaqr, Yalla, and QMUL_AK match 879, 878, and 877 argument dictionaries, respectively, out of 997 positive rows. Ṣaqr and Yalla have identical function-label accuracy; their net difference of one argument match contributes $0.60/997 = 0.000602$ to Track A and $0.50/997 = 0.000502$ to Track B, where both also have full trace compliance. A one-count difference does not mean that the systems disagree on only one instance. Without a paired analysis of their predictions, it also does not establish statistical equivalence or a significant performance difference.

Dialect-score sensitivity. In Track C, changing one argument outcome in dialect g changes the macro score by $0.12/N_{+,g}$ when function correctness is unchanged; changing one function-label outcome changes it by $0.08/N_g$ when argument correctness is unchanged. Here N_g is the total dialect count and $N_{+,g}$ its positive count. The two contributions add when both outcomes change. Small dialect subsets therefore give individual examples more influence. Total row counts alone are insufficient to compute argument-level sensitivity without the positive denominators. The reported diagnostic ordering is descriptive; no paired confidence intervals or significance tests are claimed.

Saudi Legal FC at AISA-ArabicFC: Disciplined Fine-Tuning and Gold-Free Post-Processing for Arabic Function Calling

Abdullah Almohammedi
Independent Researcher, Rabigh, Saudi Arabia
ORCID: 0009-0001-0832-0995

Abstract

We describe the Saudi Legal FC submission to the AISA-ArabicFC shared task on Arabic function calling (Nacar et al., 2026a). Our system is a parameter-efficient fine-tune of Qwen2.5-7B-Instruct (Team, 2025) with LoRA (Hu et al., 2022), trained with completion-only loss masking. Beyond the model, our central contribution is methodological: we use written, falsifiable score predictions and a validated local scorer to gate submissions, with a post-processing safety net that uses no gold at inference. On the public development set our best configuration reaches Argument Exact-Match (ArgEM) 0.828 and function-name accuracy 1.0 (Overall-B 0.914) under the official v1.3 evaluator. Its weights were then lost; the blind submission comes from a reconstruction selected against that model's frozen predictions, and ranks 12th on Track B with Overall-B 0.8946. We also report two negative findings—one retraining run, one rejected hypothesis—and an artifact-identity failure our behavioral checks caught before submission.

1 Introduction

Function calling—the interface through which a language model selects and parameterizes an external tool—has become central to agentic systems, but the capability remains far less developed for Arabic, with its dialectal variation and morphological richness, than for English. The AISA-ArabicFC shared task (Nacar et al., 2026a) targets exactly this gap. Given an Arabic query in one of five dialects and a candidate set of tools, a system must (i) decide whether any tool applies (a binary call/no-call decision), (ii) select the correct function when one applies, and (iii) extract its arguments as structured key–value pairs. Track A scores function selection and argument extraction; Track B additionally requires an Arabic reasoning trace; Track C is a diagnostic ranking by the equal-weight macro-average of the organizers' per-dialect Overall score across the five dialects.

Two features of the task shaped our approach. First, the headline metric is Argument Exact-Match (ArgEM), a strict comparison of every predicted argument key and value; the organizers' baselines make clear that function selection is largely tractable while argument extraction is the open problem.[1] Second, the final ranking is determined not on the public development split but on a *blind* test set released only at the end of the competition. This is decisive: any gain that does not *transfer*—in particular, tuning that overfits the public split—is worthless. Our guiding question for every change was therefore not "does this raise the dev score?" but "will this transfer to the blind set?"

2 Task and Data

The AISA-ArabicFC dataset comprises Arabic queries across five dialect groups—Modern Standard Arabic (MSA), Levantine, Egyptian, Gulf, and Maghrebi—spanning eight service domains and a fixed inventory of structured tools (Nacar et al., 2026a). It follows the AISA architecture for agentic Arabic systems and its data-centric approach to reliable structured tool calling (Nacar et al., 2026c,b). Each instance presents the model with a user message and a candidate set of tools; the gold output is either a single tool call with its arguments, or an explicit no-call ("none") for negative instances. The public release provides a training split and a development split, with the blind test set released at the close of the competition. Training used 10,500 task positives plus 20,331 supplementary rows: 17,604 hash-deduplicated AISA-AR-FunctionCall positives and 2,727 dialect-balanced negatives from task/AISA-AR pools. Among the

[1] Under the released final scorer and gold, the organizers report AISA-Think at FnAcc 0.9813/ArgEM 0.6790 (Track A 0.8000) and prompted GPT-4o zero-shot at 0.9324/0.7442 (Track A 0.8195).

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1547–1551
October 28-29, 2026 ©2026 Association for Computational Linguistics

combined positives, 5,600 copy-echo rows contained a gold argument verbatim in the user text; 2,800 were duplicated for $1.5\times$ effective weight. Build records preserve the criterion/count but not which 2,800 were duplicated. No development or test labels entered training.

Scoring uses a weighted composite per track. Writing FnAcc for function-name accuracy (exact match of the predicted function name, or "none" for negatives, which also penalizes hallucinated calls), ArgEM for argument exact-match over positive instances, and $\mathrm{ThinkRate}$ for the presence of an Arabic reasoning trace, the two track scores are:

$$\mathrm{A} = 0.40\,\mathrm{FnAcc} + 0.60\,\mathrm{ArgEM}, \quad (1)$$

$$\mathrm{B} = 0.30\,\mathrm{FnAcc} + 0.50\,\mathrm{ArgEM} + 0.20\,\mathrm{ThinkRate}. \quad (2)$$

On the development set ArgEM carried the largest weight and was furthest from saturation, so our engineering effort was directed there once function selection had saturated.

Data and scorer evolution. The task resources evolved through data v1.4 during the campaign. The organizers first released canonicalized data (v1.1) with a normalizing evaluator. Version 1.2 recovered unspecified gold arguments from execution traces in roughly 3% of training instances. Version 1.3 hardened the evaluator toward substance over surface form, normalizing product names, specialties and category aliases; v1.4 applied the organizers' annotation policy. The v1.2 and v1.3 changes each raised our measured scores without any change to our system, indicating that part of the measured difficulty was evaluation strictness rather than model error. Our locally re-implemented scorer was validated across v1.1–v1.3 and matched the official leaderboard to the fourth decimal on all eight submissions we made across the three evaluator versions.

2.1 System

Our system fine-tunes Qwen2.5-7B-Instruct (Team, 2025) using Low-Rank Adaptation (Hu et al., 2022) on the attention and MLP projection matrices.[2] We retained the natural dialect distribution; rebalancing it is examined and rejected in §4.5.

[2]Rank 64, $\alpha = 128$, dropout 0.05; learning rate 2×10^{-4}, effective batch 16, max sequence length 2048, 3-epoch schedule, seed 42.

Completion-only loss masking. The single most consequential design choice was to mask the prompt tokens from the training loss, computing the loss only over the completion (the reasoning trace and the structured call). We implemented this with a token-level response template so that gradient signal concentrates entirely on the function-calling output rather than being diluted across the instruction text. An earlier configuration that trained without this masking failed to reliably learn argument mappings it had nonetheless seen thousands of times in training—most visibly the mapping from Arabic currency and language names to their canonical ISO codes. Completion-only loss coincided with learning these mappings (§4).

Early models hallucinated calls on negative instances. We addressed this in training (reasoned Arabic abstention rationales) and at inference (the gold-free safety net, §3).

3 Methodology: Measurement-First Engineering

The distinctive part of our approach is not a single architectural trick but a discipline for deciding what to ship. We describe its three components.

3.1 A validated local scorer

The official evaluation is run only through the leaderboard, which returns a single score per submission. To make local iteration possible—and, more importantly, to make our decisions *checkable*—we re-implemented the scoring pipeline locally from the published evaluation code, mirroring its normalization rules and updating them at each evaluator revision. We validated this re-implementation against the official leaderboard on all eight of our submissions and obtained agreement to the fourth decimal place on every one (§2). From that point we treated the local scorer as a certified instrument: we could compute a submission's official score before uploading it.

3.2 Falsifiable predictions

We adopted a rule that no submission would be uploaded without a written, falsifiable prediction of its official score. This had two effects. It forced us to articulate *why* we expected a change to help, and by how much; and it gave us an immediate signal when an instrument—rather than a model—was misbehaving. A corollary rule, which we state plainly because it saved us twice, is that *an impossible number is evidence of a broken instrument,*

not of a broken model. On one occasion a sweep reported a function-name accuracy of 0.083 for a model whose predecessor had scored above 0.99; rather than concluding the model had collapsed, we treated the number as impossible and traced it to a parser that did not recognize the model's output format. The model was intact; the measurement was not.

3.3 The gold-free safety net

Post-processing on a public development set is dangerous precisely because the gold labels are visible: a rule can "fix" a development error by quietly memorizing which instances are negative, and such a rule will not transfer to the blind test, where no labels exist. We therefore constrained ourselves to rules that use only inference-time information. Our primary *per-sample candidate veto* forces out-of-list tools to "none." It was active on the blind test, firing on 64/1,125 rows (5.69%); without counterfactual gold we assign no separate score gain. Secondary N2 used only the abstention signal from dev-only V24, a Quran/customs/umrah hybrid (V14 tool decisions; V20F arguments on 14 rows). N2 was **not used on the blind test**: V24 had no test predictions.

A training-only enumeration rule. For `termination_type`, a training-only 13-entry Arabic-to-English map kept forms with $\geq$ 95% label consistency and ≥ 3 occurrences; ambiguous forms were untouched. It produced zero correct-to-wrong development flips, changed five predictions, corrected four, and raised Overall-B from 0.910 to 0.914.

4 Experiments and Results

4.1 Development-set progression

Table 1 traces our progression. The safety net lifted FnAcc from 0.95 to 0.996 with unchanged ArgEM; completion-only masking then lifted ArgEM from 0.732 to 0.778 and FnAcc to 1.0 (Overall-B 0.889). Gains came from learning canonical argument conventions the unmasked model had missed.

4.2 Error analysis

A field-level analysis of residual argument errors identified a categorical field whose gold had been reduced under v1.1 to canonical enumerated values while its *training* values remained free-form, so the model was learning an obsolete mapping. Remaining errors span recoverable mappings, copy-from-source extraction, and irreducible cases (relative dates, strict identifiers).

Configuration	FnAcc	ArgEM	B
Under the v1.1 scorer			
Base fine-tune	0.9505	0.732	0.851
+ safety net	0.9963	0.732	0.865
+ completion masking	**1.000**	**0.778**	**0.889**
Same model, re-scored under v1.3			
Pre-enumeration model	1.000	0.820	0.910
+ enumeration rule	**1.000**	**0.828**	**0.914**

Table 1: Development progression for the lost champion (§5.1). Upper block: v1.1 ablation. Lower: the same frozen predictions under v1.3, before/after the enumeration rule (§3.3). Blocks are not comparable because v1.3 normalizes previously rejected surface forms. ThinkRate is 1.0; the blind submission used a reconstruction (§4.4).

4.3 A targeted retraining negative result

Motivated by the error analysis, we corrected the obsolete categorical field in the training data (a `termination_type` training-label remap, 663 rows to five canonical values) together with an erroneous year in date fields (731 replacements), holding the recipe otherwise fixed. Applying both fixes as post-processing to the champion's frozen predictions gave a ceiling of ArgEM 0.826; the retrained model instead reached 0.740, against the champion's 0.778 (Overall-B 0.867 against 0.889; all v1.1). The targeted field improved—its field-level failures fell from 23 to 19, with no regression there—but nineteen exact-match rows were lost overall, spread across unrelated fields such as `num_persons` ($1 \rightarrow 23$ failures) and `days` ($10 \rightarrow 23$). We ran this once, with a single seed, so we cannot separate the effect from run-to-run variance; we report it because the direction was opposite to our pre-specified prediction. We did not promote this model.

4.4 Blind-test results

The submitted system is not the model of Table 1, whose weights were lost before test (§5.1). Checkpoint 5000 (epoch 2.38) was selected on a frozen hand-stratified 20-row development fingerprint: eight negatives (four N1 blind spots), all five enum-sensitive `termination_type` rows, and seven ordinary positives; the full gate covered four dialects including Levantine.[3] It matched

[3] Gate IDs: 0–4, 10, 14, 20, 50, 55, 84, 100, 125, 140, 164, 177, 200, 223, 417, 500.

the lost champion on $17/20$ under the June parser. The submitted strict-superset parser preserved all old successes and recovered one Qwen-native `<tool_call>` row with no regression; under v1.3 gold, checkpoint/champion were jointly correct on $18/20$ versus $19/20$. Hence the blind score is not same-model dev–test transfer, and the ArgEM drop ($0.828 \rightarrow 0.7994$) cannot be cleanly split between reconstruction mismatch and distribution shift. On the organizers' final blind-test leaderboard it obtains FnAcc 0.9831, ArgEM 0.7994, ThinkRate 1.0: Overall-B 0.8946 and Overall-A 0.8729, ranking 12th on both tracks. On Track C it scores 0.8547 (rank 15; leader 0.9075): Gulf 0.913, MSA 0.884, Levantine 0.864, Egyptian 0.836, Maghrebi 0.776; the official gap, computed from unrounded dialect scores, is 0.136.

4.5 Dialect-balancing hypothesis (rejected)

Our largest development dialect deficit was Levantine (ArgEM 0.746 versus 0.824 for MSA, pre-enumeration under v1.3), yet Levantine was already over-represented in training (16.9% versus 13.4% of positive development instances). Of sixteen attributable failures, twelve followed the same enumeration/date patterns as MSA, three reflected inconsistent gold currency values, and one was a dialect-comprehension error. Downsampling therefore addressed no supported cause; targeted augmentation was not tested. This was a diagnosis, not an experiment. Blind Track C reverses the Levantine–Egyptian ordering (0.864 versus 0.836), but for a reconstructed model under a different metric, so it does not validate the development diagnosis. Maghrebi is lowest (0.776) on 11 instances and should be read with that denominator.

5 Discussion and Lessons

Frozen-output estimates are not forecasts. We estimated our experiment's gain by applying the fix to a *frozen* model's outputs. Such an estimate bounds what the mechanism repairs in existing predictions and says nothing about what retraining does elsewhere.

In our experiment, retraining was diffuse. The corrections improved the fields they addressed, yet the model regressed overall through small losses across unrelated fields. We cannot generalize from one run, but holding the training recipe otherwise fixed let us *detect* the regression rather than ship it.

5.1 Checksum-authenticated identity confusion

A final lesson concerns the integrity discipline itself. Re-running the archived champion on 20 development instances and diffing against its frozen predictions failed at 11/20: the archived file was a rejected checkpoint from a parallel run, stored under the champion's name since an archival step six weeks earlier. Its SHA-256 had verified throughout—every check was correct, and every one attested a file that was never the right one.

We call this *checksum-authenticated identity confusion*: a checksum establishes that bits are unchanged, not that the intended artifact was hashed. Detecting it requires either an independent record binding the training run to the stored file, or evidence that the artifact *behaves* as the intended one. We had the latter unintentionally: development predictions retained for re-scoring served as an *incidental behavioral fingerprint*, and became the criterion for selecting among the retrained checkpoints. Behavioral fingerprints are established for distinguishing between known models (Yax et al., 2025; Wu et al., 2025); our observation is narrower and operational: a team's archived predictions already constitute one, and consulting them before an irreversible action is a check that hash verification cannot substitute for. Here they selected the system we submitted (§4.4).

6 Conclusion

Best-development B is 0.914; reconstruction ranks 12th on B (0.8946) and 15th on C (0.8547). Negative results and identity failure reinforce: measure first; verify before shipping.

Acknowledgments. We thank AISA-ArabicFC for the shared-task dataset and AISA-Think baseline.

Limitations

The blind submission is not a clean same-model transfer measurement: the checkpoint selected for submission is not the model characterized in Table 1, and its agreement with the lost champion (18/20 versus 19/20 under the final v1.3 gold) means the drop between the development and blind ArgEM scores ($0.828 \rightarrow 0.7994$) cannot be cleanly attributed to reconstruction mismatch versus distribution shift (§4.4). The targeted-retraining negative result and the dialect-balancing diagnosis are each

based on a single run with a single seed, so neither the direction of the retraining regression nor the dialect diagnosis should be read as established beyond this run (§4.3, §4.5). We did not train a same-base control without LoRA, so the contribution of LoRA fine-tuning relative to the base model is not isolated. The two blocks of Table 1 are scored under different evaluator versions and are not directly comparable; part of the apparent improvement between them reflects evaluator changes rather than model changes (§2). Finally, the 2,800 duplicated rows in the training mixture were selected by an automated copy-echo criterion whose build records preserve the criterion and count but not the specific rows selected, so that step of data preparation is not exactly reproducible from the released description alone (§2).

Ethics Statement

This work uses the AISA-ArabicFC shared-task dataset as released by the organizers; we did not collect additional data or conduct human-subjects research. Our system is a research artifact evaluating Arabic function-calling reliability and carries no dual-use risk beyond that of any general-purpose tool-calling assistant. All experiments were run on the publicly released training and development splits, and the blind test set was scored only through the organizers' official leaderboard.

Abstract

We describe the Durham-Jazan submission to AISA-ArabicFC 2026, an Arabic function-calling task in which a system selects one tool from four candidates and fills its arguments, scored on tool choice (FnAcc) and on strict exact match of the whole argument dictionary (ArgEM). Across six QLoRA fine-tunes of ALLaM-7B and Qwen2.5-7B, trained on the provided data, negatives derived from it and 68 hand-written no-tool utterances, and run on one 16 GB GPU, we vote on each argument separately, then apply two deterministic rules estimated from training statistics. The system reaches ArgEM 0.824 on development under the final evaluator and 0.826 on the blind test, placing 9th of 17 in Track A, 8th of 17 in Track B and 11th of 21 in Track C. Our main findings concern the benchmark. The reference tool is listed first on every training and development row that calls one, in every data release. Shuffling the candidates at inference costs the voted system 0.202 FnAcc and 0.190 ArgEM, and retraining one adapter per base on permuted candidates removes the dependence with no loss of ArgEM. One post-processing rule contributes 0.028 ArgEM and is the only component whose gain separates from zero, the other targets a convention the final data release removed and is inert, and the largest effect we can measure comes from the benchmark's construction rather than from our modelling.

1 Introduction

Function calling underpins agentic language-model systems. It is the decision of whether a user request requires a tool call, which tool to invoke, and with what arguments. For English it is tracked by mature benchmarks such as BFCL (Yan et al., 2024), API-Bank (Li et al., 2023), and the suite released with ToolLLM (Qin et al., 2024). For Arabic, with its dialectal variation and diglossia, it has been measured far less often. The AISA-ArabicFC 2026 shared task (Nacar et al., 2026a), part of the wider AISA effort on agentic Arabic systems (Nacar et al., 2026b), addresses this with a single task over Modern Standard Arabic and four dialect groups. It is scored on tool selection (FnAcc) and on strict exact match of the predicted argument dictionary (ArgEM), with a reasoning-trace track (Track B) alongside the core track (Track A).

Team Durham-Jazan took part in both tracks. We fine-tune six LoRA (Hu et al., 2022) adapters with QLoRA (Dettmers et al., 2023) over two open 7B bases, ALLaM-7B (Bari et al., 2024) and Qwen2.5-7B (Qwen Team, 2024), combine them with a per-argument majority vote and a schema-derived enum-validity rule, and add two deterministic convention rules estimated from train-split statistics alone. Most of our remaining errors are failures of surface form rather than of comprehension, because the reference uses conventions the request underdetermines and, on the rows we fail, applies them inconsistently, so an answer right in substance can still score zero. We therefore measure the problem instead of modelling around it.

Shuffling the four candidates costs the system 0.202 FnAcc, since the reference tool is always listed first. We rank 9th of 17 in Track A, 8th of 17 in Track B and 11th of 21 in Track C. Our code, submitted predictions and data-use disclosure are released, with the adapters available on request.[1]

2 Background

Task setup. Figure 1 is one item end to end, from the labour-law domain. Each example gives an Arabic utterance, a context stating the current date and time, and four candidate schemas from a 27-tool registry over eight domains. The reference tool is not merely among the four. On all

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1552–1563
October 28-29, 2026 ©2026 Association for Computational Linguistics

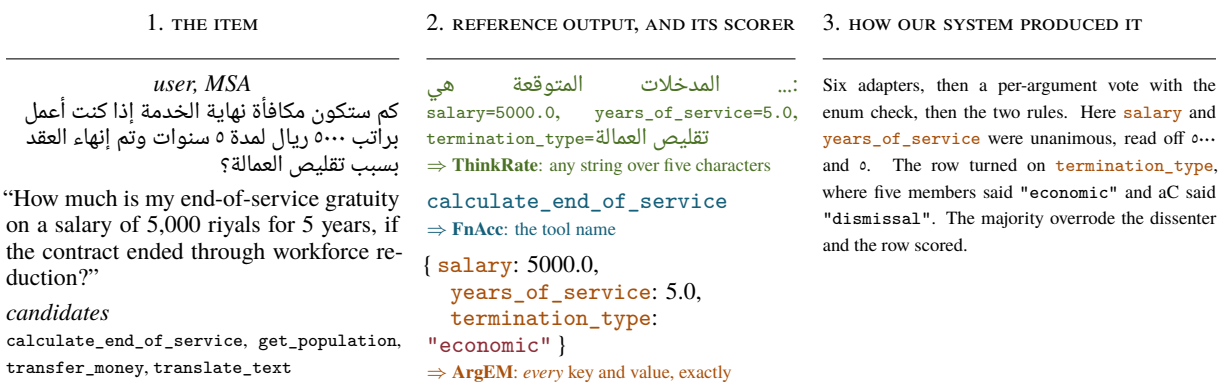

Figure 1: Development item 316, an end-of-service gratuity claim. Blue is the function name (FnAcc), orange the argument dictionary (ArgEM, all-or-nothing), green the trace (ThinkRate). The red value is the problem, and not because the mapping is wrong. The schema declares `Supported values: resignation, termination, retirement`, while the reference draws on eight values and uses one outside that list on 185 of 356 rows, with 300 of 491 for `calculate_zakat.type` and 38 of 40 for `search_quran.search_type`. A model obeying the schema it was given is scored wrong, which is why our enum-validity rule is inert.

11,000 training and development rows that call a tool it is the *first*, as the release stores them, in every release from v1.0 to v1.6 (Appendix E). The output is one tool with an argument dictionary, or `none`, plus an Arabic trace for Track B. FnAcc is exact-match tool selection over all rows. ArgEM is strict exact match of the whole normalised argument dictionary over rows whose reference calls a tool, not the full split. On development that denominator is 500 of the 545 rows, the other 45 calling no tool. On the blind split it is not published, so we cannot. The word normalised matters to our argument. The final normaliser forgives digits, orthography, list order and six closed value classes including currency, and since a July revision it also maps named days, relative terms and month names in date fields to one token, while an ISO date is compared exactly and is never reconciled with a natural-form date (Appendix C). ThinkRate is the share of rows carrying a trace, and the evaluator tests only that the string exceeds five characters, so despite the name it checks neither that the trace is Arabic nor that it relates to the call. Track A scores $0.4\,\text{FnAcc}+0.6\,\text{ArgEM}$ and Track B $0.3\,\text{FnAcc}+0.5\,\text{ArgEM}+0.2\,\text{ThinkRate}$, to which we sent the same files. Track C, published after the results and needing no separate submission, macro-averages per-dialect Track A scores and reports the max minus min *dialect gap*.

Data. 10,550 training, 545 development and 1,125 blind rows over MSA, Gulf, Egyptian, Levantine and Maghrebi. The blind split is MSA-heavy, 825 of 1,125 against 323 of 545. The data are template-generated and the reference is not consistent in the surface form it uses, a provenance that shapes Section 5.2. The reference was revised six times between 12 June and 23 July 2026, v1.1 to v1.6, and the scorer four times between 4 and 24 July. Section 4 states which pair each figure uses.

Related work. Function calling degrades outside English, the strongest model on MASSIVE-Agents falling from 57.4 to 36.1 AST accuracy between English and Arabic (Kulkarni et al., 2025). The closest Arabic-specific precedents are Ersoy et al. (2025), who study data strategies for Arabic tool calling and contribute training data and a tool-calling Fanar variant, and Kubrak et al. (2026), whose benchmark finds tool-calling accuracy dropping by five to ten points when models are prompted in Arabic. We pair ALLaM-7B, from the Arabic-focused line of Jais (Sengupta et al., 2023) and AceGPT (Huang et al., 2024), with the multilingual Qwen2.5-7B, reporting by dialect after NADI (Abdul-Mageed et al., 2024). Our analysis draws on the view that a single reference can misrepresent items with several acceptable realisations (Plank, 2022) and on what a benchmark score establishes (Bowman and Dahl, 2021; Sainz et al., 2023). Where Dehghani et al. (2021) show rankings moving with the choice of benchmark and Alzahrani et al. (2024) with small perturbations to its format, we measure what one benchmark's candidate order is worth.

3 System Overview

Fine-tunes. Six QLoRA adapters over 4-bit NF4 bases, three on ALLaM-7B and three on Qwen2.5-7B, with $\alpha = 2r$, dropout 0.05 and learning rate 2e-4 (Appendix A). The assistant target is `<think>`*trace*`</think>` followed by a JSON call (Appendix B), so Track B needs no separate procedure. We carry the trace of the member that won the tool vote, so on 24 rows it justifies a call whose values came from others. Reselecting traces to match the emitted dictionary would leave ThinkRate at 1.000, exactly as we scored, so the metric registers neither the defect nor its repair (Appendix C).

Negative augmentation. The train split is almost entirely positive and an unaugmented model almost never outputs `none` (FnAcc 0.932). We add candidate-swap negatives, real queries shown again with the gold tool removed from the candidate set, plus 68 no-action utterances we wrote by hand, each shown with six random candidate sets. FnAcc rises to 0.998 without costing a positive row.

Per-argument voting. The tool name is a majority over the six members. The argument dictionary is then decided *field by field*. Values are clustered by canonical form under the official normaliser, a key is kept when a majority holds it, and each kept key takes its most-supported value, with ties going to the earliest member in a fixed order. That order was fixed early and no longer tracks measured strength, though correcting it moves development ArgEM by one row, from 0.824 to 0.826. Combining structured output component by component is established in parser combination (Sagae and Lavie, 2006) and differs from self-consistency (Wang et al., 2023), which resamples one model. We have used cross-architecture majority voting before, for legal entailment (Alshehri et al., 2026), and the field-wise vote adapts it to structured arguments.

Field-wise combination is usually motivated by assembling an answer no member produced, which never happens here. Before the rules, the voted dictionary is identical to some member's on all 545 items, the gain coming from the 116 items on which the members disagree. The ensemble looks dispensable at $+0.002$ over the best single member, and that member with both rules reaches 0.822 against 0.824 for the vote, so with the rules applied the ensemble adds one row over its best member. A union oracle reaches 0.830, its 17-row headroom over the plain vote being argument rather than tool disagreements. An *enum-validity* rule then prefers a value appearing in the schema's `Supported values`, which changes no row's correctness on the six members we submitted.

Convention rules. Two deterministic rules, both estimated from the v1.4 train release alone and applied without reference to any development or test label. The *year rule* writes 2023 into a hotel or appointment date when the query states no year, since in that release the dated fields carried 2023 whatever the context date said, our models otherwise emitting context-consistent years that the metric penalised. Release v1.6 rewrote those fields to natural form without a year, so under the final evaluator the rule fires on 10 development rows and changes no score ($+0.000$, against $+0.004$ under the release we submitted against). The *omit rule* drops `recipient_iban` and `insurance_number` when the value is absent from the user text, since training keeps them only when stated ($+0.028$, alone or with the year rule). Appendix C gives the counts.

4 Experimental Setup

Data provenance. All six adapters were trained on the provided train split, negatives derived from it, and the 68 hand-written no-action utterances of Section 3, with no proprietary model, retrieval, external corpus or distillation in the submitted system, verified from training-log fingerprints in Appendix E. Only the inputs of the blind test were read and no development label entered training, though we did read the development negatives to decide which *categories* of no-action utterance to write.

Models and software. Transformers 5.5 (Wolf et al., 2020), PyTorch 2.6 for training and 2.10 for the blind run, PEFT 0.18, bitsandbytes 0.49, greedy decoding at batch 8. Scoring uses the official evaluator throughout, and local and leaderboard scores agreed exactly at every scored submission.

Evaluator provenance. Unless a figure is marked otherwise, every development number in this paper is scored with the final pinned evaluator: the leaderboard scorer at its last change, commit `30745ed0` of 24 July 2026, against data release

System	FnAcc	ArgEM	Ov.A	Ov.B
Random†	0.042	0.006	0.020	0.016

Table 1: Final official results. Ov.A and Ov.B are the Track A and Track B composite scores. †Official baselines on the blind test set (n=1,125), as re-scored by the organisers with the final evaluator for the overview paper. AISA-Think-270M is their fine-tuned FunctionGemma baseline (Nacar et al., 2026c), and GPT-4o produced no Track B trace. The pilot figures published on the portal during the campaign predate the normaliser and are not comparable. The top blind system is shown for reference. The development row is scored with the final evaluator (Section 4). Section 5.2 reports our submitted system at 0.796 FnAcc and 0.634 ArgEM once the candidate order is shuffled.

v1.6 of 23 July 2026, the pair the blind test was also scored with. The development leaderboard, and the version of this paper we submitted, used the scorer of 23 June and release v1.4. Appendix E gives the headline figures under both pairs and the released script that regenerates every development figure under either.

Compute. One RTX 4080 SUPER (16 GB) served all training and submitted inference, each fine-tune taking 2 to 5 hours and full blind inference about 1h50m, with the 32B comparison on one 80 GB GPU on Durham University's NCC cluster. The both-rules configuration was fixed as primary before the blind inputs were released (Appendices D and F).

5 Results

5.1 Official Results

Table 1 gives the official results and Table 3 what each component contributed. ArgEM moved from 0.824 to 0.826 across the two splits, so a system fixed before the blind data existed did not lose ground, and of the teams we can pair across the two splits on the development board's own figures, ours is the only one that rose, with the caveat that the board scored each development submission with the evaluator in force at the time and the blind test with the final one (Appendix D).

On Track C our per-dialect scores macro-average to 0.868 for 11th of 21, with a gap of 0.123 resting on a Maghrebi cell of 11 blind rows and not stable (Appendix G).

5.2 What the Scores Measure

Everything below is post hoc. The system of Section 3 was frozen before the blind inputs were released, and none of it altered our submitted predictions.

Competence against convention. On the 500 development positives the key set matches on 473 rows under the scorer's key handling, none of our 88 failing rows is a tool-selection error, and a date field is wrong on 29, most of them hotel stays where the v1.6 reference keeps the form the user wrote, *1 February*, and we emit a resolved ISO date (Appendix H).

Forgiving surface form on dates and currencies gives a *convention-relaxed* 0.884 against 0.824 strict, neither official, so convention does not explain the whole distance (Appendix H).

The ordering carries the tool decision. Keeping our system's decision of whether to call a tool but replacing its choice of which with "always take the first candidate" leaves development FnAcc at 0.998, success without reading the request being the signature of an annotation artefact (Gururangan et al., 2018). Shuffling the candidates and re-running inference settles which cue our models used. FnAcc falls to 0.796 and ArgEM to 0.634, drops of 0.202 and 0.190, against the 0.323 a positional system scores. The dependence is uneven. Our strongest member loses 0.064 and answers first on 28.3 per cent of rows, against the 26.2 per cent where the reference sits. Our rank-64 ALLaM member loses 0.650, answers first on 90.5 per cent, and lands on the positional baseline. Models carry option-order sensitivity even without fine-tuning (Pezeshkpour and Hruschka, 2024; Zheng et al., 2024). Ours saw that order in training, and retraining one adapter per base with the order permuted removes the drop at no cost in ArgEM (Appendix H), so the sensitivity measures what the benchmark taught rather than a defect of the models. FnAcc carries 0.4 of Track A, and for a system that reads the position, as ours did to varying degrees, a substantial share of that weight rewards the ordering rather than the ability it names.

6 Conclusion

We presented a field-wise vote over six QLoRA fine-tunes with two train-derived rules, which placed 9th of 17 in Track A. One train-derived rule contributes more than the ensemble, the other became inert when the final data release removed the convention it encoded, and the fixed candidate order substantially inflates FnAcc, confounding tool selection with a positional shortcut. Shuffling the four candidates before release would close that shortcut. For the two adapters we retrained, one per base, it cost nothing in ArgEM, and whether that holds for other systems is untested.

Limitations

Our headline deltas are small against the size of the splits. On 500 development positives one row is 0.002, and only the omit rule and the two rules together separate from zero under a paired test (Table 3). The ensemble's advantage over its best single member does not, and that comparison is in any case against a member chosen on the same split. The blind figure of 0.826 rests on a positive count the organisers do not publish. Working back from the published score gives roughly a thousand rows, on which the binomial standard error is about 0.012, so the 0.002 difference from our development score should be read as the absence of a fall rather than as a measured gain.

Our analysis of other teams is weaker still. We pair four systems across the two splits using published leaderboard figures, we did not see their systems, and we cannot attribute their regression to development fitting rather than to anything else. The direction is consistent across all four, and that is all we claim.

Both rules were estimated from the v1.4 train release. Evaluated against the final release the year rule is already inert, which is the transfer failure this caveat anticipated, and the omit rule's value may likewise not survive a later revision.

The convention-relaxed score of 0.884 is our own construction, not an official metric. It forgives surface form on currency and date fields as a class, which is coarser than forgiving only the cases where the reference is demonstrably inconsistent, so it is an upper estimate of what convention costs us. It is also coarser than the official normaliser, which aliases qualified currency names to ISO codes and, since 23 July, the bare ريال, درهم, جنيه and دولار to SAR, AED, EGP and USD, resolving a genuine ambiguity in favour of one reading, so a Moroccan درهم against a reference of MAD still fails (Appendix I).

We did not train on development labels, but we did read the development negatives to decide which categories of no-action utterance to write by hand. Our development function accuracy is therefore mildly optimistic, and only the blind figures are free of that.

Our candidate-order result has its own limits. That the reference tool is first on every row is a fact about the release, and the shuffled run shows our own members depended on it to different degrees. It does not show that other teams' systems did, since we have neither their models nor their predictions, and we do not claim it. We retrained only one adapter per base, not all six members, and the result speaks only for our own models.

Finally, the dialect gap is fragile on these data. Maghrebi is 11 of the 1,125 blind rows, so a single row moves that cell by about nine points, and any max-minus-min statistic over five cells inherits that noise.

Acknowledgments

We thank the AISA-ArabicFC organisers at Tuwaiq Academy for the dataset, the baseline systems and the evaluation scripts, and the anonymous reviewers for corrections that improved the paper. Some experiments in this work used Durham University's NCC cluster, maintained by the Department of Computer Science.

A Hyperparameters and Software

Bases: `ALLaM-AI/ALLaM-7B-Instruct-preview` and `Qwen/Qwen2.5-7B-Instruct`, 4-bit NF4 with double quantisation, bf16 compute. Members are listed in Table 2. LoRA on `q,k,v,o,gate,up,down_proj`, dropout 0.05, learning rate 2e-4, cosine schedule, warmup 0.03, `paged_adamw_8bit`, maximum sequence length 1024, per-device batch 1 with gradient accumulation 32 for the two members whose training command is preserved (`aC` and `qC`). The exact accumulation used for the four earlier members was not recorded, and we say so rather than assume it matched. Its practical effect is bounded by the spread between members, which is 0.020 ArgEM end to end, ten rows of 500, with the four unrecorded members spanning 0.774 to 0.790 inside it. The configuration was adopted from common QLoRA practice rather than searched on this task, with rank and epochs varied across members (Table 2) rather than tuned per member. Inference: greedy, `max_new_tokens` 256, batch 8. Adapters are LoRA deltas of about 80M trainable parameters, and 160M for the rank 64 member.

B Prompt Format

Training and inference build the input identically. The system prompt is in Arabic and carries an instruction block, the four candidate schemas serialised as JSON, and a line stating the context date. The user message is the utterance verbatim. The assistant target is `<think>`*trace*`</think>` followed by a single JSON line of the form `{"name": t, "arguments": {...}}`, with `{"name": "none", "arguments": {}}` when no tool applies. Argument values are serialised with `ensure_ascii=False` so the model imitates the reference's exact rendering, floats as `5000.0` and

Arabic strings unescaped. The exact template is `src/aisa/prompt.py` in the released repository.

C The Combiner

Let M be the six members and canon$(\cdot)$ the official normaliser. For one item:

1. Each $m \in M$ emits a tool t_m and a dictionary A_m.
2. $t^\star$ is the tool with most votes among $\{t_m\}$, ties broken by the fixed member order.
3. Let $M^\star = \{m : t_m = t^\star\}$. A key k is kept if it appears in A_m for at least half of $M^\star$, so with six agreeing members a three-against-three split on a key keeps it.
4. For each kept k, group the values $\{A_m[k] : m \in M^\star, k \in A_m\}$ by canon, take the largest group, and emit that group's value from the earliest member in the fixed order. Ties between groups are broken the same way.
5. If a schema lists `Supported values` for k, restrict to the groups whose value is a member of that list and take the largest of those, if any.
6. Apply the year rule, then the omit rule.

The final normaliser folds Arabic-Indic and ASCII digits, strips diacritics and normalises alef and ta-marbuta, equates number words with numerals, compares list values as sets, strips optional arguments per tool, aliases six closed value classes (country, city, currency, language, zakat type and search type) together with product names, specialties and categories, and in date fields maps named days, relative terms and month names across Arabic and English to one token, so الجمعة and `Friday` are one string to the scorer. An ISO date is compared exactly and a natural-form date is never reconciled with a resolved one, so `2023-02-01` and 1 فبراير stay distinct. Bare ريال, درهم, جنيه and دولار have been aliased to SAR, AED, EGP and USD since 23 July 2026, while bare دينار and ليرة are not. The scorer we submitted against, of 23 June 2026, had none of the date handling and none of the bare-currency aliases.

The members agree outright on 429 of the 545 development items. The enum-validity rule was worth $+0.002$ on an earlier seven-member ensemble and we keep it only because it cannot prefer a value the schema forbids.

Because the trace is carried from the member that won the tool vote, it can contradict the emitted dictionary. Reselecting it from a member whose dictionary matches the vote removes the mismatch on all but the 21 rows where the convention rules leave a dictionary no member held, so the defect is structural to post-editing rather than to voting alone. Removing it entirely would require the trace and the call to be decoded together against the final dictionary rather than assembled from separate members, which a field-wise combiner cannot do by construction. We found this after the blind phase closed.

The year rule rests on the v1.4 train release, where 666 of the 816 ISO-formatted `search_hotels` date fields carried 2023, as did all 48 ISO-formatted `book_doctor_appointment` dates. Release v1.6 rewrote those fields to natural form: of 1,095 non-empty hotel date fields only 76 still carry a year, 70 of them 2023, and 6 of 520 appointment dates, all 2023, so on the final release the rule is inert (Table 3). The omit rule rests on `recipient_iban` being kept 278 times and `insurance_number` 397 times. Once Arabic-Indic digits are folded to ASCII, the value is present in the user text in every case and there are no counter-examples. Our implementation compares raw strings without folding digits. On development that alters the fired set on one row and changes no score, though folding is the safer implementation and we would adopt it.

The year rule fires on `search_hotels.check_in`, `search_hotels.check_out` and `book_doctor_appointment.date`. It rewrites a predicted year to 2023 when that year is not already 2023 and does not appear in the user text. The omit rule deletes `recipient_iban` or `insurance_number` when the predicted value is not a substring of the user text. Both tests are plain substring matches on the raw strings.

D Blind-Phase Protocol

Following van Miltenburg et al. (2021) we fixed the both-rules configuration as primary before the blind inputs were released, using the remaining slots for the rule ablation of Appendix F rather than for further tuning. Development-fitted gains did not transfer for the four teams we can pair across the two splits. All four fell while ours rose from 0.824 to 0.826, and the two furthest above the eventual blind range fell furthest, 0.932 to 0.869 and 0.886 to 0.708. With four paired systems and no sight of their methods this is a direction rather than

tag	base	r	ep	release	ArgEM	order drop
v10	ALLaM-7B	32	2	v1.1	0.782	−0.233
v12	ALLaM-7B	64	2	v1.1	0.776	−0.650
v7b	Qwen2.5-7B	32	2	v1.1	0.790	−0.154
v7	Qwen2.5-7B	32	1	v1.1	0.774	−0.328
aC	ALLaM-7B	32	1	v1.3	0.774	−0.160
qC	Qwen2.5-7B	32	1	v1.3	0.794	−0.064

Table 2: The six members. $\alpha = 2r$ throughout. Members differ by base, rank, epochs and data release. We did not vary the seed. ArgEM is measured on the 500 development positives under the final evaluator (Section 4), and order drop is the member's FnAcc loss when the four candidates are shuffled at inference (Appendix H).

an effect estimate. It is also confounded by the evaluator: the development board scored each submission with the scorer and release in force when it was made, and the blind test used the final pair, so part of any movement may be the evaluator rather than the system. For our own system the two evaluators differ by 0.002 on development. The comparison therefore says something about our system and nothing firm about the others.

E Reproduction and Provenance

`bash scripts/run_blind.sh <test.jsonl> <out.jsonl>` regenerates the blind submission deterministically from the six adapters. The same command on the development split reproduced our submitted development scores exactly under the scorer of 23 June with release v1.4, the pair the development leaderboard used: ArgEM 0.822 / Overall A 0.8925 / Overall B 0.9104. The same development file scores 0.824 / 0.8937 / 0.9114 under the final evaluator. Under that earlier pair the shuffled-order run scored 0.636 ArgEM, a drop of 0.186 over 96 rows lost and 3 gained, which the submitted version misreported as 0.184. Between the two pairs, 22 rows we had right become wrong, every one through the v1.6 relabelling of hotel dates and destination countries, and 23 rows we had wrong become right, 21 of them through the scorer's date and currency aliases. `scripts/rescore_final_evaluator.py` in the released repository regenerates every development figure in this paper under either pair from the released prediction files, and `scripts/audit_candidate_order.py` checks the position of the reference tool on any release of the dataset, as the release stores the candidate schemas and as they are rendered into the prompt. The reference is first on 10,500 of 10,500 training and 500 of 500 development positives in all seven releases from v1.0 to v1.6. Tokenised-count fingerprints from the training logs (11,284 for the v11-era members, 12,369 for the v1.3-clean members) uniquely identify the training file of every member as the provided train split plus the derived and hand-written negatives. The parent corpus, the larger collection the shared-task splits were drawn from, contributed nothing to the submitted system, verified by rebuilding the combiner's tool registry three ways (from the parent, from the shared-task train split, and from the blind rows' own schemas) and finding all three byte-identical.

Leakage audit. Of the 500 development positives, 26 occur verbatim in the train split and 292 have a train twin at or above 0.8 character similarity, candidates retrieved by character n-gram tf-idf and the top ten rescored exactly. On its own that figure says little. Applying the identical procedure to 500 training queries against the rest of the training split, each query left out of its own comparison, gives 304 twins at the same threshold and a median best-twin similarity of 0.820 against 0.816 for development. The development split is therefore no closer to the training split than the training split is to itself. The corpus is redundant by construction and the splits are not differentially leaky, so the informative quantity is the transfer rather than the overlap. A 1-nearest-neighbour predictor over all 10.5k train rows scores only 0.40 per argument and 0.23 exact match under the evaluator of the submitted version, because the twin carries re-randomised fills. Near-duplicate overlap is known to inflate scores where the answers carry over (Lewis et al., 2021), which here they do not, and n-gram decontamination would call these splits clean (Yang et al., 2023). On the blind split 5.2 per cent of queries are verbatim in train, matching development before de-duplication.

Both split-comparison diagnostics are reproduced by `scripts/blind_determinacy.py` in the released repository, and both run on model outputs and inputs alone, so neither requires the blind gold labels. Unanimity is computed over the 1,003 blind rows on which a majority of *our members* call a tool, against the 500 gold positives on development. These are not the same quantity, since the blind positives are not published, so the comparison is approximate. The submitted file con-

tains 1,004 calls, the extra row being one where the members split three against three. Twin similarity uses the same difflib character ratio as the original audit, retrieving candidates by character n-gram tf-idf and scoring the top ten exactly.

F Blind Submission Variants

Development, n=500	ArgEM	95% CI	p
best member (qC)	0.794		
weakest (v7, aC)	0.774		
vote + enum	0.796	$[-.014, +.018]$	1.00
+ year rule	0.796	$[.000, .000]$	1.00
+ omit rule	0.824	$[+.014, +.042]$	$<.001$
+ both (V1)	**0.824**	$[+.014, +.042]$	$<.001$

Table 3: What each component contributed, on the 500 development positives under the final evaluator. Intervals are 2,000-sample paired bootstrap and p values are exact McNemar. The vote row is tested against the best single member, and each rule row against the vote. The ordering is the point. The omit rule is worth $+0.028$ and is the only component that separates from zero. The year rule changes the outcome of no row under release v1.6 (it was $+0.004$ under v1.4), and the ensemble's $+0.002$ over the best single member does not separate from zero.

We prepared the four rule variants of Table 3. The task permitted three submissions per track, of which only the best-scoring file is ranked. V1 (both rules) was pre-registered as primary and submitted to both tracks, with the remaining slots used for the other variants. All four files carry 1,125 rows, ThinkRate 1.0, no out-of-candidate tools and 121 `none` rows. On the blind inputs the year rule fired on 17 rows (all `search_hotels`) and the omit rule on 36 rows, and the pairwise differences between the four files range from 17 to 53 rows. The remaining headroom is of the same kind as the rules themselves. Our models emit `termination_type` on 8 development rows where the reference omits the field, so a third rule of the same family would be worth $+0.016$, eight times what the ensemble contributes.

G Track C in Detail

The gap is not a stable quantity. Bootstrapped development intervals for every non-MSA cell overlap the MSA interval, and a max minus min over five cells is dominated by the smallest.

Development ArgEM by dialect with 95% bootstrap intervals over 2,000 resamples: MSA $0.855\,[0.813, 0.896]$ on 289 rows, Gulf $0.833\,[0.750, 0.917]$ on 72, Egyptian $0.742\,[0.636, 0.848]$ on 66, Levantine $0.776\,[0.672, 0.866]$ on 67, and Maghrebi $0.667\,[0.333, 1.000]$ on 6. No non-MSA interval is disjoint from the MSA interval.

Under the final evaluator the hotel date pair leads the failing fields in every dialect. Beneath it Levantine keeps `country`, Egyptian list-valued `items`, and MSA `termination_type`. On the blind split the organisers' per-dialect Overall scores are 0.911 MSA, 0.901 Gulf, 0.883 Levantine, 0.856 Egyptian and 0.788 Maghrebi, macro-averaging 0.868 for 11th of 21 with a gap of 0.123. These are the organisers' published figures. They cannot be recombined into the Track A row of Table 1 without the per-dialect row and positive counts, since FnAcc is computed over all rows and ArgEM over positive rows only, and those counts are not published. Balance looked like our clearest edge on development, where our ArgEM gap of 0.080 was the smallest on that board as the evaluator then in force scored it, and it only partly survived. Under the final evaluator the same development gap is 0.188, the six-row Maghrebi cell having lost one row. Our blind gap is narrower than the 0.136 and 0.140 of the two highest-scoring systems but wider than five others, and the system with the smallest gap of all placed third in Track A. Balance and accuracy were not in tension, and our narrow development gap was not the advantage we had taken it for. Maghrebi is 11 of the 1,125 blind rows, so one row moves that cell nine points.

H Further Analyses and Negative Results

All figures below are measured on the development set against V1, the configuration we fixed before the blind phase. The diagnostics come first, and the closing paragraph reports approaches that did not help.

Candidate order. Re-running inference on the development split with the four candidates shuffled, everything else held fixed, costs the voted system 0.202 FnAcc and 0.190 ArgEM. Per member the loss runs -0.064 (`qC`), -0.154 (`v7b`), -0.160 (`aC`), -0.233 (`v10`), -0.328 (`v7`) and -0.650 (`v12`). The last answers with the first candidate on 90.5 per cent of rows, against the 26.2 per cent where the reference sits, and its shuffled FnAcc of 0.349 lands close to the 0.323 a purely positional system scores. Retraining one adapter per base on the same data with the candidate order permuted

(seed 20260816, all else per the released recipe) removes the dependence. Shuffled-order FnAcc rises from 0.839 to 0.985 for ALLaM and from 0.936 to 0.996 for Qwen, at a canonical-order cost of 0.017 and 0.006, with no loss of ArgEM, and both retrained adapters answer with the first candidate at the rate the reference sits there. The dependence is therefore a property of how the release orders its candidates rather than of the models, and shuffling before release would remove it. Grouped by base among the submitted members, ALLaM appears twice as exposed as Qwen, -0.347 against -0.182, but that gap is carried entirely by `v12`, which is also the only member at rank 64, so base and rank are confounded, and three members per base are too few to separate them. Excluding it the two bases are indistinguishable at -0.196 and -0.182. The system loses 97 ArgEM rows and gains 2. Of the 97, 88 are rows whose tool flipped and 9 are rows that kept the tool but lost an argument, so the effect falls predominantly on tool selection.

Where the residual sits. All six members are wrong on 85 of the 500 positives, and 71 of our 88 errors fall on such rows. An oracle allowed to pick the best member on every row would reach 0.830 against 0.824 for the vote, so most of what we get wrong is beyond any combiner. None of the 88 is a tool-selection error. Counting fields rather than rows, a field failing when it is missing on one side or its values do not match under the normaliser, the date family gives 54 instances over 29 rows, `check_in` and `check_out` 25 each and always on the same hotel row, and `date` 4. The rest is a thin tail: `termination_type` 9, of which 8 are a key the reference deleted, `destination_country` 8, all a key the reference deleted, `items` 7, `procedure` 6, `country` 6, and `medication_name` 5.

Surface form. In release v1.6 the `date` field alone takes 111 surface values in three scripts, which the final normaliser reduces to 59, and the whole date family 427, reduced to 309. What the normaliser does not do is reconcile a natural-form date with a resolved one, and resolving both sides to a calendar date before comparison, as Ersoy et al. (2025) do, would remove our largest class of errors. Worked examples are in Appendix I.

Scale. A Qwen2.5-32B QLoRA reaches ArgEM 0.786, against 0.824 for the six-member vote and 0.794 for the best single member. Family and recipe were held fixed, which is what makes it a controlled comparison, but it also means the rank, learning rate and batch size were those chosen for a 7B model and nothing was searched at 32B. We report it as one point under our own recipe and draw no conclusion about scale on this task, beyond noting that exact-match metrics penalise semantically correct output differing in surface form (Zhong et al., 2020). The official baselines, rescored by the organisers with the final evaluator, put prompted GPT-4o at 0.744 ArgEM zero-shot above the fine-tuned FunctionGemma-270M (Gemma Team, 2025; Nacar et al., 2026c) at 0.679 on the blind test, the reverse of the order the pilot figures on the portal had shown, and that pair confounds tuning with scale in any case.

Nine further approaches. The deltas in this paragraph were measured while the system was being built, under the scorer and release then current, v1.1 to v1.4, so they are comparable with each other but not with the figures above. A canonicaliser learned from train, which changes no development row, the residue being plausible variation rather than correctable error (Plank, 2022). Dialectal paraphrase augmentation -0.014. Ensemble self-distillation, no gain over the vote and about 26 hours to label. Canonical-output supervision -0.05. Cross-lingual co-training -0.014. Combiner weight tuning, where the in-sample gain does not survive held-out folds. A train-pool kNN argument fallback, negative because the fills are re-randomised. Retrieval-augmented few-shot prompting, 0.796 to 0.742. Adding the parent corpus the splits were drawn from, -0.046, since its label conventions differ from the shared task's. A learned verifier over member disagreements, where the recoverable cases are dominated by contradictory gold so no verifier wins both sides.

I Qualitative Examples

All examples are development rows. Translations are ours. Our only development tool-selection error falls on a negative row, so it is not among the 88 argument failures above. It is item 509, ليش الجو في الخليج حار أكثر من لبنان؟ ("Why is the weather in the Gulf hotter than in Lebanon?"), where the reference is `none`, three of the six members call `get_weather` anyway, and the resulting three-against-three tie is resolved in their favour by the member order.

Canonicalisation, learned. For ممكن تترجم ده للألماني؟ أنا مشغول جدا النهاردة (Egyptian: "Can you translate this to German? I am very busy today"), the system predicts `translate_text{target_language: "de", text: "أنا مشغول جدا النهاردة"}`, correctly ISO-coding the language and extracting the span to be translated rather than the request boilerplate.

The convention tax, illustrated. These are gold and prediction pairs from the 30 convention-tax cases under the final evaluator, in which both forms are valid. Twenty-five are hotel stays where the reference keeps the form the user wrote, as in من 1 فبراير إلى 10 فبراير ("from 1 February to 10 February"), against which our resolved `2023-02-01` fails because an ISO date is compared exactly. The direction flips between rows: for يوم الأربعاء ("on Wednesday") the reference is the resolved `2023-10-11` and our الأربعاء fails. The remainder are forms outside the alias table, نهار الجمعة against الجمعة for Friday, the Egyptian spelling الحد الجاي against الأحد الجاي for next Sunday, and a Moroccan درهم against a reference of `MAD`, which the normaliser reads as AED. Under the scorer we submitted against, الجمعة against `Friday` and الأسبوع الجاي against `next week` were also among the cases, and the year rule targeted references such as `2023-02-01` against our `2024-02-01`, a generator stamp the v1.6 release removed.

Wajeh at AISA-ArabicFC: A Non-LLM Classical ML and Retrieval Pipeline for Arabic Function Calling

Abdullah Rashed Aldosari **Nader Hajed Shehri**
University of Bisha, Saudi Arabia
444800030@ub.edu.sa 443801387@ub.edu.sa

Abstract

We describe **NABIQ**, the system submitted by team Wajeh (واجه) to Tracks A and B of the AISA-ArabicFC shared task on Arabic function calling (Nacar et al., 2026a). NABIQ contains no large language model, no neural network of any kind, no external API and no GPU. It is a CPU-based pipeline of classical ML, retrieval and rule-based repair: a TF-IDF router, a per-tool nearest-argument retriever over train, span extractors with train-mined gazetteers, and a no-call detector. Its core mechanism is an *evidence gate*: a candidate value may replace a prediction only if it is a normalised substring of the utterance, a member of a closed canonical map, or a date whose tokens occur in the text. On the blind test the frozen system scored Overall A 0.7904 (rank 16) and Overall B 0.8282 (rank 15) at ThinkRate 1.0000. We keep five evaluation levels distinct because the submitted system drops 0.21 ArgEM from development to test. A rehearsal on 545 held-out training rows, run before the blind release, tracked our official Overall A far better than the tuned development estimate (composite error 0.0033 against 0.1724, cancelling larger FnAcc and ArgEM errors); that contrast, not the components, is our result.

1 Introduction

Function calling is the interface at which a language model stops describing an action and performs one. AISA-ArabicFC (Nacar et al., 2026a) is the first shared task to benchmark this capability in Arabic: given an utterance in one of five dialects (MSA, Gulf, Egyptian, Levantine, Maghrebi) and a candidate set from a 27-tool registry over eight service domains, a system must decide whether a call is required, select the tool, and emit its arguments as JSON. Track B adds an Arabic reasoning trace. Arguments are the harder sub-task: on the shared task's final evaluator the strongest published baselines reach argument exact match (ArgEM) of 0.744 (GPT-4o, zero-shot) and 0.679 (a fine-tuned 270M model, AISA-AR-FunctionCall-Think), each well below its own function-selection accuracy (Nacar et al., 2026a,b).

Our entry was deliberately contrarian. Instead of fine-tuning a generative model, we asked how far a non-neural, rule-governed system can go when, in the layers where the gate applies, a predicted value must satisfy explicit textual or canonical evidence criteria. NABIQ uses no LLM, no inference API, no PyTorch and no GPU; its only learned components are a TF-IDF representation and a logistic-regression classifier from `scikit-learn` (Pedregosa et al., 2011). It runs locally on CPU and is auditable line by line. That is what the evaluation and governance layers of the AISA reference architecture (Nacar et al., 2026c) ask of an agent whose calls must be explained after the fact.

We report three findings. First, evidence-gated extraction is competitive with learned decoding on argument accuracy: our blind-test ArgEM of 0.7081, from a system with no neural model, is on a par with a fine-tuned 270M model (0.679) and few-shot GPT-4o (0.699) on the final evaluator, below zero-shot GPT-4o (0.744); on Track B our perfect think coverage lifts us above the fine-tuned baseline (0.8282 against 0.8074). Second, the negative class is where routing performance breaks down. Our development FnAcc reached 1.0000, although that estimate was affected by the `negative_category` proxy in the no-call detector as well as by later rule-based no-call handling, and test FnAcc was 0.9138. Third, a zero-regression acceptance protocol is a weaker guarantee than it appears: 21 sequential accepts on the same 500 examples yielded a system that ranked high on development and 16th on the blind set, and a rehearsal on held-out training rows anticipated that outcome. We also report three engineering observations: nondeterminism from unordered iteration, an acceptance suite whose coverage did not

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1564–1573
October 28-29, 2026 ©2026 Association for Computational Linguistics

reach the rule that later failed the validator, and a label proxy in the input that reaches the no-call detector's feature string. Code and the frozen submission package: https://github.com/tgfdru/nabiq-arabicfc.

2 Background

Task setup. Each instance provides a developer message carrying the candidate tool schemas and an Arabic user message. A Track A prediction is a JSON line with `id`, `tool_called` (a tool name or `"none"`) and `arguments`; Track B adds `think`. For كم تبلغ الجمارك على حقيبة يد قيمتها 500 ريال في الإمارات؟ ("How much is customs on a handbag worth 500 riyals in the UAE?") the gold call is `calculate_customs` with `category` = حقيبة يد, `destination_country` = الإمارات and `product_value` = 500.0. The gold call omits `currency` although a currency word is present, a per-tool convention we recovered from the training split.

Data and metrics. We used only the released splits: 10,550 training rows and 545 development rows, of which 500 require a call and 45 are negative. Twenty tools appear in development gold; the other seven occur only as distractors. Among the 500 call-required development rows the dialects are MSA 289, Gulf 72, Levantine 67, Egyptian 66 and Maghrebi 6. Overall A weights FnAcc/ArgEM $0.40/0.60$; Overall B weights FnAcc/ArgEM/ThinkRate $0.30/0.50/0.20$; ArgEM requires all key-value pairs to match under the official normaliser. We entered Tracks A and B; Track C is a dialect breakdown of the same predictions.

Relation to prior work. Tool use is normally learned: models are trained to emit calls (Schick et al., 2023) or tuned against API registries (Patil et al., 2024), with structural validity imposed at decode time by grammar-constrained decoding (Geng et al., 2023). The task baseline takes the first route, a LoRA-tuned Gemma 3 (270M) (Nacar et al., 2026b). Ours is orthogonal: same supervision source, but the learned decoder is replaced by retrieval plus gated extraction, so structural validity holds by construction rather than by constraint. Predictions trace to a span in the utterance, a convention mined from train, or a retrieved neighbour's value; only the first two are textual or canonical evidence, and not every emission passes the shipped gate (Appendix B).

3 System Overview

NABIQ is a chain of pure functions over the tuple $(tool, arguments, user\_text, developer\_context)$; no stage reads a row identifier or gold.

P1: Arabic normalisation. A normalised projection unifies Alef and Hamza variants, final Ya / Alef-maqsura and Ta-marbuta, strips diacritics and tatweel, and maps Eastern-Arabic digits (٠١٢٣٤٥٦٧٨٩) to Western. This absorbs orthographic and dialectal variation (جدة/جده, الاسبوع/الأسبوع) with no learned representation. Matching uses this view; emitted values are verbatim spans.

P2: Routing and the negative class. Character n-gram TF-IDF features (Spärck Jones, 1972; Pedregosa et al., 2011), computed within word boundaries, are fitted on the 10,550 training utterances. A multi-class logistic regression ranks tools and we take its highest-probability label that appears in the row's candidate set. A separate binary detector handles the negative class, where routing actually fails: past-completion statements (قارنت أسعار الجوالات وقررت آخذ سامسونج, "I compared phone prices and decided on Samsung"), capability questions and out-of-scope requests. It raised development FnAcc from 0.9706 to 1.0000. Its feature text also concatenates `negative_category`, which §5 shows to be a label proxy. The concatenation sits in the feature builder rather than in any decision rule, and §5 measures what it contributes.

P3: Argument extraction. Per tool we mine the training split for the expected key set and the canonical form of each value: ISO-3 currency codes, ISO-2 language codes, English enums such as `resignation`/`end_of_contract`, ISO dates, and Arabic-verbatim country and category names. Values come from a per-tool TF-IDF cosine nearest-argument retriever, which supplies the key set and a starting value from the most similar training utterance; from direct span extraction (regexes plus closed train-mined gazetteers for cities, specialties, procedures, months and number words); and from canonical maps.

P4: Guards. A *schema guard* drops keys absent from the tool schema and coerces types. A *per-tool evidence guard* then removes optional arguments whose support is missing from the text: it

covers the five tools where speculative filling cost us most, dropping `guests` without a quantity word, `doctor_name` without a title, and so on. It is not general, and Limitations says what that leaves open.

P5: Repair layers and acceptance. Extraction alone reached ArgEM ≈ 0.53. The rest of the development gain came from successive generations of narrow repair rules, each simulated *independently* on all 500 positive cases and admitted only on a win with *exactly zero* regressions. Twenty-one rules were accepted, 13 in the first repair stage and 8 in the second. Further candidates were rejected under the same test; our records do not support an exact rejected total, and Appendix D lists the main ones with win and regression counts.

P6: The evidence gate. A non-oracle selector runs after the repair layers. A candidate value replaces the base prediction only if it is (i) a normalised substring of the user text, (ii) a member of a closed canonical map (specialty, procedure, currency code, or one of ten transliterated names themselves present in the text), (iii) an ISO date whose day and month tokens both occur in the text, or (iv) a *removal* of an unsupported argument. Numerics require digits or Arabic number words.

P7: Track B. The trace comes deterministically from the Track A prediction via a parameterised Arabic template: one sentence naming the tool and enumerating the extracted `key=value` pairs, or a fixed out-of-scope sentence for `none`. Track B reuses Track A's tool and arguments byte-for-byte and adds only `think`, so reasoning-action consistency holds by construction; ThinkRate was 1.0000 on every run.

4 Experimental Setup

Train and development splits only: no external corpora, no pretrained model, no fine-tuning, no GPU. All development figures use the 545-row development split as released for the final development phase, and all training uses the 10,550-row training split from the same release. L1 figures are the official leaderboard's; L2 and L3 are scored by our own re-implementation of the metric, which we label v1.2 throughout and distinguish from the official scorer. Development gold was used solely for offline scoring and the zero-regression diagnostics; it is never read at prediction time, and the blind runner refuses any input path whose filename contains `gold`, `answer` or `label`. The environment is Python 3.13.13 with `scikit-learn` 1.9.0, `numpy` 2.5.1, `scipy` 1.18.0 and `pandas` 3.0.5, run locally on CPU; pins ship with the reproducibility package (Appendix A). Our local scorer reimplements the metric with a v1.2 "fair" normalisation (digit systems, orthographic variants, currency and language aliases, order-independent lists); on generations 12–13 the official scorer was 0.000–0.004 more lenient.

Determinism. Post-submission forensic testing identified a Python hash-order dependency in tied candidate selection: tie-breaking iterated unordered containers and so inherited the interpreter's hash order, so two runs in fresh processes could differ on a few rows. A pipeline with "no random seed" is not automatically deterministic; unordered iteration is a silent seed. Rerunning the archived package on the development-as-blind input under two different hash seeds changes 5 of 545 rows, all of them gazetteer tie-breaks between orthographic variants of the same city; repeating a run at a fixed seed is identical. We therefore report the archived package as reproducible *only* under a pinned `PYTHONHASHSEED`, and we do not claim that the submitted fallback was byte-identical across fresh processes. Sorting the affected traversals is the fix this diagnosis implies; it is not present in the archived package (Appendix A).

5 Results and Analysis

Levels of number. Table 1 keeps them apart: **L1** the official development leaderboard, **L2** a local ablation on the 500 positive development rows, **L3** the acceptance run on a development-as-blind input, **L3b** a rehearsal on held-out training rows, **L4** the blind test.

Official results. On the $1{,}125$-row blind test NABIQ obtained FnAcc $1028/1125 = 0.9138$, ArgEM 0.7081 and ThinkRate 1.0000, giving Overall A 0.7904 (rank 16) and Overall B 0.8282 (rank 15). Both official submission files, Track A and Track B, were produced by the fallback runner `run_nabiq_blind.py`; the primary `v15rx` runner was prepared but not submitted (see below). Track B reuses Track A's predictions unchanged. The winner scored Overall B 0.9400, and 0.087 of that 0.112 gap is ArgEM. We do not attach a significance claim to the ranking: separating neighbour-

Configuration	FnAcc	ArgEM	Ovr. A
L1. Official development leaderboard			
v8	1.0000	0.7820	0.8692
v13	1.0000	0.8860	0.9316
L2. Local ablation (500 pos., v1.2 scorer)			
v13 base	1.0000	0.8820	0.9292
+stage1 (repairs)	1.0000	0.9140	0.9484
+stage2 (toolpacks)	1.0000	**0.9380**	0.9628
L3. Acceptance run (dev-as-blind, 545 rows)			
v15rx primary	1.0000	0.9380	0.9628
fallback (submitted)	1.0000	0.9200	0.9520
L3b. Pseudo-blind rehearsal (545 held-out rows)			
v14 chain, seed 13	0.9963	0.6476	0.7871
L4. *Official blind test* (1,125 rows)			
fallback, Track A	0.9138	0.7081	**0.7904**

Table 1: Levels of evaluation. L2 and L3 reuse the 500 development cases the rules were selected on. L3b is a rehearsal on data the system never saw, run before the blind release; it predicts L4's *Overall A* to 0.0033, while the development estimate is off by 0.1724. This agreement is composite: L3b overestimates FnAcc by 0.0825 and underestimates ArgEM by 0.0605, and the 0.40/0.60 weighting cancels most of both (see text). A further L2 stage scored 0.9360 and was not kept; L3 strict ArgEM is 0.9160 / 0.8960.

System	FnAcc	ArgEM	Ovr. A	Ovr. B
GPT-4o, zero-shot	0.9324	**0.7442**	**0.8195**	—
270M fine-tuned	**0.9813**	0.6790	0.8000	0.8074
GPT-4o, 3-shot	0.8676	0.6991	0.7665	—
NABIQ (ours)	0.9138	0.7081	0.7904	**0.8282**
Random selection	0.0418	0.0060	0.0203	0.0155

Table 2: Blind test, re-scored by the organisers with the final argument normaliser (Nacar et al., 2026a). The pre-normaliser figures circulated during the campaign are not comparable and are not used here.

ing systems evaluated on the same instances would require a paired test, which we did not run.

Comparison with the baselines. Table 2 places NABIQ against the organisers' baselines, all re-scored with the released argument normaliser on the final gold so the figures are comparable. With no neural component NABIQ is on a par with the fine-tuned 270M model and few-shot GPT-4o on ArgEM and Overall A, below zero-shot GPT-4o, and ahead of the fine-tuned baseline on Overall B. The organisers' table does not report a ThinkRate column, so we compare Overall B directly and do not infer one.

What transferred. Argument extraction. The parts responsible are grounded in *train*: normalisation, train-mined canonical forms and key-set conventions, and the evidence gate, whose criterion is a property of the language, not of a 500-example sample. Generations 1–6, before any development-derived rule, already reached ArgEM 0.756 on development.

What did not. Function selection. FnAcc fell from 1.0000 on development to 0.9138 on test, below the function-selection accuracy of the published baselines in Table 2. The no-call detector's feature string concatenates `negative_category`, which is null for all 10,500 positive training rows and populated for all 50 negative ones, and which the organisers have confirmed is *nulled in the blind test*: the detector saw the label on both splits it was developed against and nothing at test time. Five-fold cross-validation on train, at the shipped threshold, gives no-call recall 0.9600 with the field and 0.5400 without it. Rerunning the whole frozen chain with the field blanked in train and input costs 0.0294 FnAcc and 0.0177 Overall A on development. That magnitude is about a third of the development-to-test FnAcc difference and about a tenth of our 0.1724 development-estimate error, but it is a development counterfactual and the remainder cannot be attributed to any single cause (Appendix C).

Evidence-gate conformance. Under the P6 criterion, which admits a numeric supported by digits *or* an Arabic number word, 907 of 988 emitted development values conform (91.8%); a surface-only diagnostic that credits digits but not number words gives 862 (87.2%). Of the 81 non-conforming values, 48 are relative dates resolved to ISO and 21 are retrieval-introduced strings absent from the utterance (2.1% of all values). Those 21 are what the gate does not reach: it governs candidate *replacements* and a subset of tools, so a first-pass retrieved value can survive without textual support (Appendix B).

The gap, measured in advance. The submitted fallback fell from ArgEM 0.9200 on the development-as-blind acceptance run (L3) to 0.7081 on test, a like-for-like drop of 0.2119; the primary v15RX configuration reached 0.9380 on development but was not the system evaluated at test. This pattern is consistent with adaptive development-set selection pressure, and the evidence predates the blind release. Two weeks out we carved 545 rows from train, stripped their gold, refitted every component on the remaining

10,005 rows and ran the frozen runner (L3b). It scored Overall A 0.7871 against an official 0.7904, an error of 0.0033, versus 0.1724 for our development estimate and 0.1412 for the last official leaderboard entry. This composite agreement is partly cancellation: L3b overestimated FnAcc (0.9963 against 0.9138, $+0.0825$) and underestimated ArgEM (0.6476 against 0.7081, -0.0605), and the $0.40/0.60$ weighting nets these to -0.0033, so it bounds the aggregate, not each component. It still anticipated the direction and scale of a drop the development leaderboard did not: four further seeds put held-out ArgEM between 0.6155 and 0.6685. The acceptance protocol looked strict but was applied 21 times to the *same* 500 examples: generations 1–6 encode train conventions, generations 7–14 encode development conventions, and only the first kind survived.

Acceptance coverage and the validator. For the blind run we prepared v15RX, the frozen chain plus two guarded rules, one re-extracting `recipient_iban` after an explicit account marker (the G2 rule). A post-run handoff record, written two days before the phase closed, states that the primary outputs were rejected because of invalid `recipient_iban` values and that the fallback outputs were the files uploaded for both tracks, having passed the validator with no errors or warnings. That record is our evidence for the rejection; the primary blind outputs themselves were not retained, so we could not re-run the validator on them to reconstruct the failure independently.

Two engineering failures interacted. The first is a contract mismatch: G2's token pattern admits a purely numeric token of six or more digits, whereas the validator requires an IBAN-like value, so the rule could emit values the contract rejects. The second is a path-coverage gap in acceptance, which measured the run (row count, validator verdict, Track A/B agreement) but not whether each new rule was exercised. Rerunning G2 over the 545-row development-as-blind acceptance input produces *zero* insertions across the 24 predicted `transfer_money` rows, so the acceptance suite never executed the G2 insertion path and the contract mismatch stayed hidden until the blind run. Neither failure alone would have been sufficient: a rule whose output the validator accepts would have survived poor coverage, and full coverage would have surfaced the mismatch. A useful acceptance criterion is per-rule: each new rule should fire on $\geq k$ rows with every emitted value checked against the validator contract. The configuration change cost 0.9380 vs. 0.9200 ArgEM at L3.

A label proxy in the input. The rows carry `negative_category`, which reaches the no-call detector's feature string. Appendix C measures its contribution and what follows for benchmark design.

Dialect robustness (Track C). Official per-dialect Overall: MSA 0.797, Gulf 0.798, Egyptian 0.798, Levantine 0.791, Maghrebi 0.647, a macro-average of 0.7661 and a gap of 0.151. Four dialects sit within 0.007; the entire gap is Maghrebi. Our L2 gap of 0.074 had suggested that surface spans confer dialect robustness, but Maghrebi is six development rows there, and the gazetteers come from a distribution in which it is 1.3% of the data.

Error analysis. Before the final generation 59 development cases were wrong, dominated by date (27) and span (20) errors; stage 2 fixed 28 with zero regressions. Most survivors coincide with a date-format variation we measured in the development gold for `search_hotels`, which alternates between ISO, verbatim Arabic and `DD-MM` for equivalent expressions (Appendix D). We report this as an observation about those development rows and about our own residual errors, not as a claim about the benchmark's ceiling or about the task overall.

6 Conclusion

NABIQ reaches ArgEM 0.7081 and Overall B 0.8282 with no LLM and no GPU, and the evidence gate is the transferable idea: where it applies, a candidate value must satisfy explicit textual or canonical evidence criteria. It does not apply to every emitted value, and Appendix B bounds the shortfall. The methodological result is cheaper than any architecture: for NABIQ, a rehearsal on held-out training rows produced a substantially closer estimate of the final aggregate than the repeatedly tuned development estimate (0.0033 against 0.1724 on Overall A), even though its FnAcc and ArgEM estimates were each off by more. This is a single-system result; it suggests that held-out rehearsals are worth running in similar shared-task settings, where a development split doubles as the tuning split.

Limitations and Future Work

The rule-selection protocol would be better served by a held-out split. Reserving 150 development cases and requiring every candidate rule to be non-negative there, as well as zero-regression on the remaining 350, trades live-leaderboard position for a less biased estimate, and the trade is the incentive such a board creates. The next system should be hybrid: a small fine-tuned model as the proposal distribution (Nacar et al., 2026b), especially for the call/no-call decision, with the evidence gate kept as the acceptance test: the shape AISA's governance layers (Nacar et al., 2026c) would ask for regardless.

The evidence gate is narrower in our code than the principle it implements. It governs candidate *replacements*, and the per-tool guard covers five of the twenty tools that appear in gold, so a value supplied by the nearest-argument retriever from a different training row can survive into a prediction without occurring in the user's text. The hallucination-resistance claim should therefore be read as scoped to the layers described in P4 and P6 rather than to every emitted value. Appendix B quantifies the shortfall on development: 2.1% of emitted values are strings absent from the utterance. Two limitations attach to that figure. It is development-only, because blind gold is not released, so we cannot report the same quantity for the test set. And it is a surface diagnostic rather than a measurement of the shipped gate, since it does not credit numerics supported by Arabic number words. Extending the gate to cover every first-pass emission, and measuring conformance directly against the shipped criterion, both remain future work.

As submitted, our extractors are per-tool and closed: adding a tool requires writing gazetteers and span rules for it, so the approach does not scale to an open registry the way a fine-tuned decoder does. The no-call detector is sensitive to unseen phrasing once the `negative_category` signal is absent, so its development figures reflect that signal as well as the model. All L2 and L3 numbers are computed on the same 500 development cases used for rule selection and are therefore optimistic. Our held-out estimates come from rehearsals carved out of train (L3b), which share train's gold conventions and contain almost no negative rows, so they bound argument extraction well and say nothing about no-call detection. We report no multiple-run variance on the blind test, and that absence is a limit of our evidence rather than a property of the system: the official score comes from the single submitted fallback output for each track, blind gold was never available to us for repeated evaluation, our repeated-run diagnostics use held-out-train rehearsal seeds rather than the blind split, and the archived code can itself vary across fresh processes through the documented hash-order dependency. The blind Track C breakdown shows the cost concretely: Maghrebi Overall is 0.647 against ≈ 0.79 for the other four dialects, and closing that gap needs training signal the released split barely contains.

Ethical Considerations

We collected no new data. All work uses the organisers' released splits. Two licences apply and we keep them distinct. Our own code is released under the MIT licence. The one data artefact we redistribute is a processed form of the organisers' training split, which is a derivative of the AISA-ArabicFC dataset and remains governed by that dataset's upstream licence, Apache 2.0, with attribution; we do not relicense it.

The corpus contains person names and bank-account-like strings as argument values for tools such as `transfer_money`. We treated these as task data and made no attempt to link them to real individuals; readers reusing the release should note that argument values, not only utterances, can carry person-like strings.

Dialect representation is the clearest fairness concern our numbers speak to. NABIQ performed substantially worse on the Maghrebi blind subset than on the other four dialect subsets: Overall 0.647 against ≈ 0.79. The development set contains only six call-required Maghrebi rows, and Maghrebi is 1.3% of the corpus, so our development-side evidence for this dialect is thin and the blind subset is the stronger signal. We read this as a representation concern about a system whose gazetteers and conventions are mined from this distribution, and as a reason not to report a single aggregate score alone. We do not extrapolate from these benchmark subsets to how the system would serve Maghrebi speakers in deployment.

The tool registry spans banking, government and health services, so an argument-level error is not cosmetic: a wrong `recipient_iban`

or `iqama` number has consequences outside the benchmark. The evidence gate reduces one class of that risk by refusing to emit values absent from the user's text, but it does not address the other direction, and our blind FnAcc of 0.9138 means the system still calls a tool on some utterances that ask for none. Neither this system nor its successor should be deployed on such tools without a confirmation step under human control.

Acknowledgments

We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, the baseline model, and the evaluation framework for this shared task, and for their responsiveness throughout the evaluation period. We also thank the anonymous reviewers for their comments.

A Configuration and Reproducibility

Nothing in NABIQ is trained by gradient descent, so there is no learning rate, batch size or epoch count. The complete set of fitted-model settings is:

- **Router.** `TfidfVectorizer` with `analyzer="char_wb"`, `ngram_range=(3,5)`, `min_df=2`, `max_features=120000`, feeding `LogisticRegression` with `solver="lbfgs"`, `max_iter=2000`, `class_weight= "balanced"`. Input text concatenates the user utterance, the dialect tag, and the name, description and parameter names of every candidate tool.

- **No-call detector.** Same vectoriser and classifier settings. Decision threshold 0.60 on the predicted probability of the call class. Its input text additionally concatenates `negative_category` (Appendix C).
- **Per-tool argument retriever.** One `TfidfVectorizer` per tool with `analyzer="char_wb"`, `ngram_range=(2,5)`, `min_df=1`, `max_features=80000`; cosine similarity, top-1 neighbour.

Tokenisation. We use no morphological segmenter: neither Farasa (Abdelali et al., 2016) nor CAMeL Tools (Obeid et al., 2020), and no model tokeniser. Character n-grams are computed directly on the normalised string by `scikit-learn`, which is why the P1 normalisation carries the load that a segmenter would carry elsewhere. We do not handle Arabizi or Latin-script code-switching; neither appears in the released splits.

Hardware and runtime. The system was executed locally on CPU, with no GPU and no external inference API. We did not preserve a run log recording core count or wall-clock time, so we make no exact historical runtime claim.

Which figures come from which run. The official leaderboard result corresponds to the single submitted fallback output for each track: Track A and Track B were both submitted from the fallback runner. A primary v15RX candidate was also generated locally on the blind input, but it was not submitted after failing validation, so the blind input was executed locally more than once even though only one output per track was scored officially. We did not receive repeated official evaluations. Development and development-as-blind figures come from reruns of the archived package, which reproduce at a fixed hash seed. The held-out rehearsal figures come from five pseudo-blind seeds used as a diagnostic; these are rehearsals on data carved from train, not repeated blind evaluations.

Package and determinism. The submission package contains the two approved runners, the mandatory validator, the pinned environment and the released training file used for routing, retrieval and convention mining. It contains no gold, answer or label file of any kind, and no notebooks or caches. Predictions are produced by `python src/run_nabiq_blind.py --input data/blind/test.jsonl --track-a A.jsonl --track-b B.jsonl`, followed by `src/validate_submission_files.py`, which checks row count, identifier uniqueness, field types, absence of `think` in Track A, and agreement between Tracks A and B on `id`, `tool_called` and `arguments`. The package is MD5-frozen and contains no sampling and no explicit seed. Its one source of run-to-run variation is the hash-order dependency described in Section 5: ties in the gazetteer-mining and candidate-collection paths are broken by iteration order over unordered containers. Measured on the development-as-blind input, two runs under different values of `PYTHONHASHSEED` differ on 5 of 545 rows, while two runs at the same value are identical. Reproducing our numbers therefore requires pinning `PYTHONHASHSEED`; we distinguish this archived package from the configuration that produced the official submission, which carried the same dependency and for which we make no byte-determinism claim.

B Direct Surface Grounding (Diagnostic)

This appendix reports a diagnostic, not a measurement of the shipped evidence gate. The two differ deliberately, and we state the difference rather than reconcile it by adjusting the number.

We measure on the 545 development rows using the frozen v14 Track A submission (`nabiq_v14_pc.jsonl`, MD5 `fa764e6d…`), so the figure is reproducible from that artifact. The measurement script accompanies this paper's supplementary package. Blind gold is not released, so this is a development-only measurement.

We report two quantities. **P6 conformance** applies the shipped criterion: a value conforms if, after the P1 normalisation, it is a substring of the user utterance, a member of one of the closed canonical maps (currency, language, Zakat type, termination type, Quran search type, country), an ISO date whose day and month tokens both appear, or a numeric supported by digits *or by an Arabic number word*. The **surface diagnostic** is the same test with the number-word clause removed, and is therefore a strict lower bound.

Of 988 emitted argument values, 907 conform to P6 (91.8%) and 862 (87.2%) are surface-grounded. The surface figure decomposes as 480 by substring, 142 by a canonical map, 234 by digits and 6 by date tokens; the further 45 that P6 admits are quantities

Tool	n	ArgEM	Tool	n	ArgEM
translate_text	26	1.000	convert_currency	24	0.917
check_iqama	25	1.000	order_food	24	0.917
check_traffic	24	1.000	check_insurance	27	0.889
check_visa	24	1.000	calculate_zakat	24	0.875
search_umrah	23	1.000	transfer_money	24	0.875
end_of_service	23	1.000	book_doctor	30	0.833
search_quran	24	0.958	compare_prices	24	0.833
get_air_quality	23	0.957	calculate_customs	24	0.833
search_medications	27	0.926	get_weather	29	0.828
get_qibla	25	0.920	search_hotels	26	0.731

Table 3: Per-tool ArgEM, development, v14, strict scoring; FnAcc is 1.000 for every tool, and the 45 none rows are all routed correctly. Tool names are abbreviated. search_hotels is weakest, matching the date-format inconsistency reported below.

written as Arabic cardinals, including dual forms such as شخصين for two and multiplier phrases such as نص مليون for 500,000.

The 81 values that do not conform to P6 are: 48 relative dates resolved to ISO from the developer context, 21 strings absent from the utterance (2.1% of all values), 8 quantities derived from a unit word rather than a number word (اسبوع yielding days = 7, which we do not count as a number word), and 4 numerics with no recoverable support.

That last group is the one the gate does not reach. As shipped it governs candidate *replacements* and a subset of tools, so a first-pass value taken from the nearest-argument retriever can survive without direct support; 2.1% bounds how often that happens on this development set. Extending the gate to every first-pass emission remains future work.

C The negative_category Leak

Each distributed row carries a negative_category field. In the released training split it is null for all 10,500 positive rows and populated for all 50 negative ones, with five values (general_knowledge, chitchat, opinion, ambiguous_underspecified, off_domain). It is therefore a perfect proxy for the call/no-call label. The organisers have since confirmed that the field is non-null exactly when requires_function is false across all 10,550 training rows and all 545 development rows, and that *it is nulled in the blind test*.

That asymmetry is the mechanism behind our largest development-to-test movement. A detector that consumes the field sees the label on both splits it was developed against and sees nothing at test time, so its development behaviour cannot transfer. We quantify the size of the effect below; it is smaller end to end than the detector-level comparison implies, because later rule-based no-call layers absorb much of the loss.

Our build_none_text helper concatenates this field into the string that the no-call detector vectorises, at training and at inference alike. We did not intend this and did not catch it before the freeze. The router, the nearest-argument retriever, the span extractors and both guards do not read the field; the no-call detector does.

To measure the effect we reran the shipped detector configuration post-submission, at the shipped threshold of 0.60, once with the field in the feature string and once with it blanked. Under five-fold cross-validation on train, no-call recall is 0.9600 (48/50) with the field and 0.5400 (27/50) without. Trained on train and evaluated on development, the same comparison gives 0.6222 against 0.5333.

The two numbers differ for an instructive reason. Train uses five negative categories; development uses eleven, six of which (past_tense_completed, feelings_experiences, meta_questions, about_domain_no_action, comparative_evaluation, hypothetical_conditional) never appear in train, so the memorised strings transfer to only about half of the development negatives. The leak therefore inflates the detector without being the whole explanation for development FnAcc of 1.0000, which the full chain reaches with later no-call layers as well. These are post-submission diagnostics and change no submitted prediction.

End-to-end ablation. The measurements above isolate the detector. To size the field's effect on the delivered system we reran the entire frozen chain twice on a development-as-blind input, once as shipped and once with negative_category

blanked in the training split *and* in the input, scoring both with our v1.2 scorer. The as-shipped arm reproduces the reported L3 fallback row exactly (FnAcc 1.0000, ArgEM 0.9200, Overall A 0.9520), which validates the replication.

	FnAcc	ArgEM	Ovr. A
As shipped	1.0000	0.9200	0.9520
Field blanked	0.9706	0.9100	0.9343
Difference	−0.0294	−0.0100	−0.0177

Table 4: End-to-end effect of blanking `negative_category` in both the training split and the input, on the frozen chain, development-as-blind, v1.2 scorer.

No-call recall over the 45 development negatives falls from $45/45$ to $35/45$; 16 rows change their tool decision and 6 positives are wrongly routed to `none`. The end-to-end cost is therefore much smaller than the detector-level comparison suggests, because later rule-based no-call layers recover most of what the detector loses.

This is a development-as-blind counterfactual, not an intervention on the blind test, so it sizes the field's contribution under that counterfactual rather than isolating a cause of the observed test result. Its magnitude, 0.0294 FnAcc, is roughly one third of the 0.0862 development-to-test FnAcc difference, and its 0.0177 on Overall A is roughly one tenth of the 0.1724 development-estimate error. The remaining difference cannot be uniquely attributed to a single cause; it is consistent with repeated development-set selection pressure, with the configuration difference between the tuned primary and the submitted fallback, and with distributional differences between the development and blind splits, and we do not attempt to apportion it among them.

The rerun used the shipped `scikit-learn` version, 1.9.0, under Python 3.11.15 rather than the originally recorded Python 3.13.13 environment. The as-shipped arm reproduces the recorded L3 fallback v1.2 figures exactly. Strict ArgEM differs from the archived 0.8960 by two rows; we cannot isolate whether that difference arises from the substitute runner's documented replay path, from the Python-version difference, or from their interaction, and we do not attribute it to any one of them.

Two recommendations follow for benchmark design. Removing `negative_category` from future releases, in train as well as in the blind file, closes the shortcut: the no-call decision carries 0.40 of the Track A composite, which is a large share to leave recoverable from a metadata field. More generally, a field can enter a system through a feature builder rather than through a decision rule, so an audit that inspects only the decision logic will not find it.

D Development Error Analysis

Per tool. Per-tool ArgEM for the v14 chain on the 545 development rows under our strict scorer, which gives overall FnAcc 1.0000 and ArgEM 0.9120. These are L2-level numbers on the split the rules were selected on, so read them as a map of where the extractors are weak, not as generalisation estimates. The blind gold is not released, so a per-tool breakdown at L4 is unavailable to us.

By error type. The 59 remaining development errors before the final generation, by type (a case may fall in several categories): wrong date 27, wrong span 20, wrong entity boundary 12, missing argument 8, extra argument 7, wrong number 4, wrong list 3. By argument key they concentrate in `check_in` and `check_out` (22 combined), followed by `specialty`, `medication_name` and `category`. Stage 2 of the final generation fixed 28 of the 59 with zero regressions.

Rejected rules. The main rejected candidates, with their (wins, regressions) on the 500 positive development cases: strip the definite article from `medication_name` (1, 11); `search_quran search_type=verse` for آية (1, 14); `calculate_zakat` type removal (1, 22); `get_weather days=1` for اليوم (4, 5); unconditional عملية strip from `procedure` (3, 8); Arabic-to-English name transliteration at large (2, 6); بعد غد canonicalisation (1, 1); and customs category Arabic-to-English maps, rejected on a training-majority check before simulation. A further candidate layer (the "G3" rule and a deletion gate) was rejected before the freeze and is absent from the submitted package.

PuDyDG at AISA-ArabicFC: Decomposed Fine-Tuning with Function-Centric Few-Shot Augmentation for Arabic Function Calling

Duy Dang Phu and Dang Van Thin
University of Information Technology, VNU-HCM, Ho Chi Minh City, Vietnam
Vietnam National University Ho Chi Minh City, Vietnam
24520010@gm.uit.edu.vn, thindv@uit.edu.vn

Abstract

Tool calling has become increasingly important for agentic systems, but remains challenging in multilingual settings, particularly for Arabic. We present our system for the AISA-ArabicFC shared task at ArabicNLP 2026. Our approach combines decomposed multi-task fine-tuning, function-centric few-shot augmentation, and hybrid schema-aware inference. On the development set, our system achieves a function-name accuracy of 1.000 and a normalized argument exact match of 0.858. On the blind test set, the released baseline re-scored with the final scorer obtains a Track A score of 0.8000, compared with 0.9111 for our submission. Our system achieves a function-name accuracy of 0.9973 and an argument exact match score of 0.8536 on this set, ranking seventh in Track A. Our solution is released in the GitHub repository[1].

1 Introduction

The rapid development of agentic systems has made tool use an important capability of large language models (LLMs). To interact reliably with external APIs, these models must identify the appropriate function and generate valid arguments from a user's request.

Despite recent progress in tool calling, existing evaluations remain predominantly English-centric, and recent work has only begun to systematically examine robustness under multilingual user interactions (Luo et al., 2026). Even when a model correctly understands the user's intent and selects the appropriate tool, its call may remain operationally invalid because the generated arguments violate language-invariant interface conventions. These findings motivate further study of Arabic tool calling, where systems must process linguistically diverse user requests while producing outputs that conform to rigid function schemas.

In this paper, we describe our system for the AISA-ArabicFC shared task at ArabicNLP 2026 (Nacar et al., 2026a). Starting from the task-provided `AISA-AR-FunctionCall-Think` model, we apply fine-tuning with a decomposition-based strategy. Although the system also generates the auxiliary reasoning trace evaluated in Track B, our system design and analysis primarily focus on the function-call fields evaluated in Track A. Each official training instance is reformulated into complementary objectives for tool-use decision, function-name prediction, argument extraction, function-call construction, and end-to-end response generation. At inference time, our hybrid pipeline combines function selection with argument extraction conditioned on the predicted function, followed by schema-aware post-processing. We further augment the argument-extraction objective with synthetic, function-centric Arabic requests generated from few-shot examples and the released function schemas. Our results suggest that task decomposition and targeted data augmentation are effective for improving Arabic function-calling performance, particularly argument extraction. Under the final scorer, the released baseline checkpoint obtains FnAcc 0.9813, ArgEM 0.6790, and a Track A score of 0.8000 on the blind test set, compared with 0.9973, 0.8536, and 0.9111, respectively, for our submission. On the official test leaderboard, our submission under the team name *PuDyDG* ranked seventh with a Track A score of 0.9111, FnAcc of 0.9973, and ArgEM of 0.8536 in Track A; the same submission ranked sixth in Track B.

2 Background

2.1 Problem Definition

Each AISA-ArabicFC instance presents an Arabic request, temporal context, and four candidate tools, each specified by a function name, description, and JSON parameter schema (Nacar et al.,

[1] https://github.com/phud774/PuDyDG-AISA-ArabicNLP

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1574–1579
October 28-29, 2026 ©2026 Association for Computational Linguistics

2026a). The Track A output is a pair (f, a): a candidate function name and a schema-compliant JSON argument object. For example, a request meaning "convert 5,000 Egyptian pounds to Kuwaiti dinars" maps to `convert_currency` with `amount=5000`, `from_currency=EGP`, and `to_currency=KWD`; a no-call request maps to $(\texttt{none}, \{\})$. Track A combines exact function-name accuracy (FNACC), including `none`, and argument exact match (ARGEM) after official value normalization as $0.40\,\text{FNACC} + 0.60\,\text{ARGEM}$. Tracks B and C additionally assess reasoning-trace generation and cross-dialect robustness, respectively.

2.2 Data and Evaluation

The official release contains 10,550 training instances (10,500 call/50 no-call), 545 development instances (500/45), and 1,125 blind test requests. Its task-oriented assistant queries span Modern Standard, Gulf, Egyptian, Levantine, and Maghrebi Arabic and eight service domains: healthcare, finance, government, Islamic services, travel, weather, e-commerce, and utilities. The registry contains 27 tools, including 20 target tools and seven distractors (Nacar et al., 2026a).

We use the full training split for adaptation and the development split only for validation. Synthetic examples use only positive training instances and released function schemas; development and test requests are excluded. We select 500 of 1,500 validated generations with seed 42. On development and the blind test set, we report FNACC, normalized ARGEM, and their official weighted score.

2.3 Related Work

Prior work has studied tool-use training and evaluation at increasing scales. Toolformer learns to invoke external APIs from demonstrations (Schick et al., 2023), while API-Bank and ToolLLM extend tool-use evaluation and instruction tuning to broader collections of APIs (Li et al., 2023; Qin et al., 2024). BFCL further evaluates function selection, argument construction, abstention, and multi-turn tool use (Patil et al., 2025). However, multilingual evaluations reveal substantial performance disparities across languages (Kulkarni et al., 2025). Models may select the correct function while still producing invalid arguments because user-language expressions do not conform to schema-defined fields and value conventions (Luo et al., 2026).

Recent work has begun to address Arabic tool calling. Arabic and bilingual instruction tuning improve tool-use decisions and argument generation, although cross-lingual transfer alone remains insufficient (Ersoy et al., 2025). Arabic adaptations of BFCL also report lower accuracy for Arabic queries, particularly in complex calling settings (Kubrak et al., 2025). Within the AISA framework (Nacar et al., 2026c), dataset auditing, schema repair, tool-aware prompting, and dialect-diverse fine-tuning have been shown to reduce structural errors (Nacar et al., 2026b). Our system complements these approaches by decomposing function calling into specialized training objectives, conditioning argument extraction on the selected schema, and applying function-centric Arabic augmentation specifically to the argument-extraction objective.

3 System Overview

Our system LoRA-adapts one model with five training views covering tool-use decision, function selection, argument extraction, call construction, and end-to-end generation. We add 500 function-centric examples for argument extraction and oversample no-tool cases. At inference, function selection and schema-conditioned extraction are combined with deterministic post-processing and a guarded end-to-end fallback.

3.1 Decomposed Multi-task Fine-tuning

Let an official training instance be $(x, \mathcal{F}, y)$, where x is the Arabic request, $\mathcal{F}$ contains four candidate schemas, and y is either a call (f, a) or a no-tool response. The *tool-use decision* view predicts a Boolean value; *function selection* predicts $f \in \mathcal{F}$ or `none`; and *argument extraction* predicts a JSON object conditioned on the gold function. For positive instances, *function-call construction* reproduces the structured call without `<think>`, whereas the *end-to-end* view retains the original reasoning span and call format.

A short Arabic instruction identifies each view. Candidate schemas, temporal context, and the user request are otherwise retained, except for argument extraction: we replace all candidates with a compact description of the gold schema, including types, required fields, and enumerated values. Its target contains only non-empty, evaluator-relevant arguments. Across views, the model is instructed to emit only values stated or directly inferable from the request and to omit missing values rather than invent defaults.

Examples are weighted through repetition before shuffling. Argument-extraction and end-to-end views are repeated twice, and every no-tool view receives an additional factor of 20. This prioritizes the more heavily scored argument objective while preserving a strong abstention signal.

3.2 Function-centric Few-shot Augmentation

Argument extraction must map varied Arabic expressions to rigid, language-invariant fields. We therefore group positive training instances by gold function and generate additional examples on a balanced function schedule. Each prompt contains five distinct same-function request–argument demonstrations, the compact schema, and the dialect and temporal context of an official template. The generator returns a new Arabic request and its JSON arguments.

We reject empty or duplicate examples, undeclared keys, missing required fields, invalid enumerated values, and values removed by the schema sanitizer; numeric and Boolean values are normalized when possible. Invalid candidates are retried with the validation error. Accepted examples are used only for argument extraction, avoiding synthetic supervision for selection, abstention, or reasoning traces.

3.3 Hybrid Schema-aware Inference

All inference passes use the same adapted model with greedy decoding. The selection pass emits one candidate function or `none`; only recognized names and no-tool markers are accepted. If parsing fails, a valid function from the independently generated end-to-end response is used, otherwise the system returns `none`. For Track B, the auxiliary reasoning trace is produced by the independently decoded end-to-end pass, which was trained on the original reasoning-span-and-call format. Its `<think>` span supplies the submitted trace when available; the final function name and arguments continue to be produced by the hybrid selection-and-extraction pipeline described below.

For $\hat{f} \neq \texttt{none}$, a second pass removes all candidate declarations and inserts only the schema of $\hat{f}$, then requests one JSON argument object. We parse the first balanced object as JSON, with a conservative literal parser for minor quoting errors. If parsing fails, the end-to-end arguments are used only when their function agrees with $\hat{f}$. For $\hat{f} = \texttt{none}$, extraction is skipped.

Finally, schema-aware post-processing removes undeclared, empty, and officially ignored fields, normalizes Arabic-Indic digits, casts numeric and Boolean values, and preserves identifier-like strings with leading zeros. The resulting $(\hat{f}, \hat{a})$ is the Track A prediction.

4 Experimental Setup

Baseline. We report the official development results originally published by the organizers for `AISA-AR-FunctionCall-Think 270M`, without retraining or reevaluating the checkpoint. The originally published development baseline used a pre-normalization evaluator and is therefore not used for direct comparison with our development results. For a like-for-like comparison, the organizers re-scored the same baseline checkpoint on the 1,125-instance blind test set with the released final scorer. It obtained FNACC 0.9813, ARGEM 0.6790, Track A 0.8000, and Track B 0.8074.

4.1 Training Configuration

We initialize the system from the task-provided `AISA-AR-FunctionCall-Think` checkpoint. LoRA is applied to all attention projections and the gate, up, and down MLP projections, with rank 64, scaling factor 128, and dropout 0.05.

Training runs for one epoch with a 2,048-token sequence limit. We use fused AdamW with a peak learning rate of 10^{-4}, cosine decay, 3% warm-up, and weight decay 0.01. A per-device batch size of 6 with eight gradient-accumulation steps gives an effective batch size of 48. Training uses BF16, gradient checkpointing, seed 42, and target-only loss.

4.2 Augmentation and Decoding Configuration

For each synthetic generation slot, we sample five distinct same-function demonstrations and query `Llama-3.3-70B-Instruct` at temperature 0.9. Invalid candidates are retried with the validation error, up to three attempts. At inference, maximum generation lengths are 24 tokens for selection, 160 for argument extraction, and 256 for end-to-end generation.

4.3 Reproducibility

The original training and inference run was performed on a temporary single-GPU Vast.ai instance. Seed 42 was fixed, but deterministic PyTorch/CUDA algorithms were not enforced, and

Table 1: Development-set single-run results. Batch configurations denote per-device batch size × gradient-accumulation steps.

Configuration	FnAcc	ArgEM
Decomposition		
Decomposed (4×8)	1.000	0.780
Training configuration		
+ separate argument model	1.000	0.744
Decomposed (6×8)	1.000	0.788
Decomposed (12×8)	1.000	0.786
Function-centric augmentation		
Decomposed (6×8; 0 augmented)	1.000	0.788
+ 250 augmented examples	1.000	0.844
+ 500 augmented examples (full)	1.000	**0.858**
+ 750 augmented examples	1.000	0.844
Training-only objective ablation		
− function-call construction view	1.000	0.856
− tool-use decision view	1.000	0.842

synthetic generation is stochastic; retraining or regenerating the data is therefore not expected to be byte-identical. We release the exact augmentation pool, adapter, tokenizer, configuration, and prediction artifacts. Inference from the released checkpoint on an NVIDIA RTX PRO 5000 reproduced the submitted prediction file byte for byte. Separately, the organizers independently evaluated the released reproduction run and obtained a Track A score of 0.9105, compared with the published submission score of 0.9111. This small difference is consistent with the disclosed sampling and training non-determinism.

5 Results

5.1 Development Results and Ablations

Among our single-run experiments in Table 1, the shared multi-task model reaches 0.788, compared with 0.744 for the separate argument model. The 6×8 configuration also gives the highest observed score among the tested batch settings, although its 0.002 difference from the 12×8 configuration corresponds to only one of the 500 positive development examples.

Adding 500 function-centric examples gives the highest observed ARGEM, 0.858, while both 250 and 750 examples obtain 0.844. These results are not monotonic and come from one run per configuration; the apparent peak at 500 examples may therefore lie within run-to-run variation rather than establish a reliable optimum.

The training-only objective ablations leave FNACC at 1.000 but yield ARGEM scores of 0.856 without function-call construction and 0.842 without tool-use decision. Relative to the full result of 0.858, these differences correspond to approximately one and eight positive development examples, respectively. They suggest beneficial multi-task transfer, but should not be interpreted as statistically robust without repeated runs. Neither objective adds an inference stage. All of our configurations in Table 1 are single training runs using seed 42, and no variance estimates are available.

5.2 Development-set Argument Error Analysis

We further inspect the released development predictions associated with an ARGEM of 0.844. This post-hoc analysis is distinct from the best development run (0.858) in Table 1. Among the 500 positive development instances, 78 have an argument mismatch under the official evaluator. In 55 cases (70.5%), the predicted and gold objects contain the same keys but differ in at least one value. Manual inspection reveals three main causes: span-boundary mismatches in free-text and list fields, semantic substitutions or hallucinated values, and a smaller number of ambiguous or inconsistent gold annotations. Thus, argument-value prediction, rather than field selection or output parsing, remains the main source of residual error.

Among well-represented dialects, mismatch rates range from 12.8% for MSA to 22.4% for Levantine, with Gulf (16.7%) and Egyptian (18.2%) between them. Maghrebi reaches 33.3%, but has only six positive examples. These figures suggest a dialect effect, although the smallest groups require cautious interpretation.

5.3 Official Test Results

Our submission under the team name *PuDyDG* ranked seventh in Track A, achieving a score of 0.9111, with FNACC of 0.9973 and ARGEM of 0.8536. Under the same released final scorer, the baseline checkpoint obtains FNACC 0.9813, ARGEM 0.6790, and Track A 0.8000 on the blind test set, providing a like-for-like comparison.

For Track B, which additionally evaluates the reasoning trace, our submission ranked sixth. The trace is supplied by the end-to-end generation pass trained on the original response format containing the `<think>` span. This pass is separate from the selection and schema-conditioned argument-extraction passes used to construct the final function call.

6 Limitations

Our study has four main limitations. First, each development configuration was trained only once with seed 42, and no variance estimates are available. Because the positive development subset contains only 500 instances, several observed differences correspond to only a handful of examples and may not be statistically robust.

Second, although 500 augmented examples produced the highest observed development ARGEM, the augmentation-size experiments were single runs. The difference between 500 and 750 examples may therefore reflect run-to-run variation rather than establish 500 examples as a reliable optimum.

Third, exact retraining reproducibility is limited. Synthetic examples were generated through stochastic sampling, and deterministic PyTorch/CUDA algorithms were not enforced. We release the exact augmentation pool, adapter, tokenizer, configuration, and predictions, which supports exact inference from the released checkpoint, but retraining or regenerating the augmentation data may produce different results.

Finally, our analysis primarily focuses on Track A. Although our submission ranked sixth in Track B and the reasoning trace is generated by the end-to-end pass, we do not provide a detailed quantitative or manual analysis of trace quality. Further work should examine the faithfulness, consistency, and contribution of these traces independently of function-call accuracy.

7 Conclusion

In this paper, we presented our system for the AISA-ArabicFC shared task at ArabicNLP 2026. The system combines decomposed multi-task fine-tuning, function-centric few-shot augmentation, and hybrid schema-aware inference. On the development set, our system achieved a normalized argument exact match of 0.858 while maintaining perfect function selection. On the blind test set under the final scorer, our system achieved Track A 0.9111 and ARGEM 0.8536, compared with 0.8000 and 0.6790, respectively, for the rescored baseline checkpoint. Our system ranked seventh in Track A and sixth in Track B, where the end-to-end generation view supplied the auxiliary reasoning trace. Because the development configurations were each evaluated with a single seed, small differences among them should be interpreted cautiously.

Our error analysis suggests that argument-value prediction remains the main bottleneck, particularly for free-text spans and list-valued fields, where span-boundary mismatches, semantic substitutions, and hallucinated values are common. Performance also varies across dialects, although results for dialects with few examples should be interpreted cautiously.

8 Acknowledgments

This research was supported by The VNUHCM University of Information Technology's Scientific Research Support Fund.

We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, the baseline model, and the evaluation framework for this shared task.

QMUL_AK at AISA-ArabicFC: Schema-Constrained Function Calling with ALLaM

Ali Khairallah **Arkaitz Zubiaga**
Queen Mary University of London
a.m.khairallah@qmul.ac.uk a.zubiaga@qmul.ac.uk

Abstract

We describe the QMUL_AK submission to AISA-ArabicFC 2026. The system adapts the Arabic-English ALLaM-7B-Instruct model to function calling with low-rank adaptation (LoRA). It combines an Arabic schema-aware prompt, dialect and no-call resampling, a token-weighted training objective, and deterministic validation of generated calls against the candidate tool schema. The same output supports Track A function calling and Track B reasoning-augmented calling. Training uses only the official task data. On the development set, the system achieves 0.9982 function accuracy and 0.8920 argument exact match, corresponding to overall A and B scores of 0.9345 and 0.9454. On the blind test set, the system reaches overall A and B scores of 0.9253 and 0.9380, ranking 3rd on both submission tracks and 1st of 21 teams on the Track C dialect-robustness diagnostic with a macro-averaged score of 0.9075 and the smallest dialect gap in the shared task (0.077). The results show that function selection is nearly saturated, while argument extraction remains the main source of error.

1 Introduction

AISA-ArabicFC evaluates whether a system can decide when an Arabic request requires a tool, select a function from a supplied candidate set, and return its arguments as structured JSON (Nacar et al., 2026a). It covers Arabic in Modern Standard Arabic (MSA) and four regional dialect groups across practical service domains. The task is connected to the AISA reference architecture (Nacar et al., 2026c) and to a recent data-centric work on reliable Arabic function calling (Nacar et al., 2026b).

Our submission uses ALLaM-7B-Instruct, an Arabic-English autoregressive model (Bari et al., 2025), rather than a larger general-purpose one. We fine-tune it with LoRA (Hu et al., 2022) and keep the base weights in `bfloat16`. Three design choices address the main difficulties of the task: an Arabic schema-aware prompt that places the candidate functions, their argument names, and types directly in the input; a resampling scheme that offsets the imbalance of no-call and minority-dialect examples; and a deterministic validation step that removes malformed or out-of-schema fields before submission. The rest of this paper describes the methodology implemented by our system and analyses the results achieved, which placed third on both submission tracks and first on the dialect-robustness diagnostic.

Code, the submitted adapter, and reproduction instructions are available at `https://github.com/alikhairallah/AISA-ArabicFC`.

2 Data

The shared task provides 10,550 training, 545 development, and 1,125 blind test examples (Nacar et al., 2026a). Each example contains a user request in MSA or one of four regional dialect groups (Gulf, Levantine, Egyptian, and Maghrebi), a developer message carrying date and time, and a candidate set of four tool schemas drawn from a registry of 27 functions. Each schema declares a function name, an Arabic description and typed argument definitions. Of the 27 registry functions, 20 appear as gold calls; the remaining seven occur only as distractors in the candidate sets and are never correct. The reference output is a single call naming one of the 20 callable functions together with an argument dictionary or `none` when no tool applies. Arguments are heterogeneous, with identifiers and free-text spans copied from the request, numeric quantities, closed-class codes such as ISO currency and language identifiers, and comma-separated lists. Table 1 shows one example with its reference call. No-call examples are rare in training (50 of 10,550, 0.5%) but frequent

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1580–1584
October 28-29, 2026 ©2026 Association for Computational Linguistics

in development (45 of 545, 8.3%), which motivates the resampling scheme in Section 3. Every example additionally carries a dialect label, which we use for the analysis in Section 5.

Request (AR)	الجو في الدوحة بعد ثلاث أيام؟
Translation	"The weather in Doha in three days?"
Gold	`{"tool_called": "get_weather", "arguments": {"city": "الدوحة", "days": 3.0}}`

Table 1: A training example. The city الدوحة ("Doha") is copied verbatim into the argument, while ثلاث ("three") is written as a word in the request and must be emitted as the number 3.0.

3 System

Schema-aware prompting. Each example contains a user request, a developer instruction, and a set of candidate tools. We convert every sample into a compact Arabic description containing the function name, description, argument names, types, and argument descriptions. These descriptions are appended to the original developer message. A final Arabic instruction requires a short `<think>` segment followed by one JSON object with the keys `tool_called` and `arguments`. It also states that only information explicitly present in the request may be extracted. No-call cases must use `none` with an empty argument object. The resulting system and user messages are rendered with ALLaM's native chat template.

This representation makes the output contract part of every training and inference instance. It also avoids maintaining a fixed global tool inventory: the model sees only the functions that are supplied for that row.

Model adaptation. We fine-tune ALLaM using LoRA modules applied to the query, key, value, and output attention projections, as well as the gate and feed-forward projections in each transformer block. The pretrained model remains frozen while only the LoRA parameters are optimised.

Training objectives. Training uses token-level causal cross-entropy over the generated completion. Prompt tokens are excluded from the loss, while JSON function-call tokens receive a weight of 1.0 and reasoning tokens inside the `<think>` segment receive a lower weight of 0.3. This assigns greater importance to the exact function name and argument structure while retaining the reasoning format required for Track B.

Data balancing. The training split is heavily imbalanced: only 50 of the 10,550 examples are no-call, and the dialects are unevenly represented. We correct both by replicating no-call examples and by duplicating every example according to a dialect weight (3 for Maghrebi, 2 for Levantine and Egyptian, and 1 for Gulf and MSA), so scarce cases are seen more often. For the submitted model we combine the train and development splits (11,095 examples) and resample the no-call examples to match the no-call share produced by the development-phase resampling, approximately 11%, which keeps the total divisible by the batch size. This gives 16,308 training samples. Development-phase configuration applies the resampling to the training split only, totalling 15,583 examples, of which 1,740 are no-call. Table 2 shows the distribution before and after resampling.

	Train	Dev	Test	Train∪Dev resampled
MSA	6,151	323	825	7,550
Levantine	1,784	75	102	4,150
Egyptian	1,283	66	104	2,759
Gulf	1,190	75	83	1,405
Maghrebi	142	6	11	444
Total	10,550	545	1,125	16,308
no-call	50	45	—	1,820

Table 2: Dataset composition by dialect. The final column is the training distribution of the submitted model, obtained by resampling train ∪ dev (11,095 examples) to 16,308. No-call is a subset of each column; test gold was not released. No-call prevalence shifts from 0.5% in train to 8.3% in dev, which motivates the resampling in Section 3.

3.1 Output validation

We extract the first valid JSON object after the optional reasoning segment and validate it against the candidate functions provided for the input. Predictions that select an unavailable function are mapped to a no-call output. For a valid function, we retain only arguments declared in its schema and remove null, empty, non-finite, and out-of-enumeration values. Values are not checked against the declared primitive type. This step enforces the required output format without selecting another function or constructing new argument values.

After validation, we replace the model's free-form reasoning with a short deterministic Arabic

statement associated with the validated function, including a corresponding statement for no-call predictions. This ensures that the submitted trace is non-empty and consistent with the final action, but it also means ThinkRate is satisfied by construction rather than by model reasoning: the reported Track B scores measure trace presence, not faithfulness. The procedure does not change the predicted function or its arguments.

4 Experimental setup

Data protocol. Development experiments use the official training split for adaptation and the 545-row development split for evaluation. All development results and ablations reported here come from models trained on the official training split alone and evaluated on the held-out split. During the blind test, the produced checkpoint was retrained separately on the union of train and development, so the development figures are not held-out measurements of the checkpoint scored on the blind test set. After fixing the prompt, sampling strategy, and training configuration, we retrained the submitted model on the union of the training and development splits and generated predictions for the 1,125 blind test examples. The test split is not used for model or configuration selection. We use no external function-calling data, test labels, or labelled resources that overlap with the task data. The organisers verified top submissions for reproducibility and fairness. Gold test labels were not released, so all reported test-set scores are the official leaderboard scores, including the per-dialect breakdown published for Track C.

Evaluation. We report function accuracy (FnAcc), argument exact match over positive examples (ArgEM), and reasoning presence rate (ThinkRate). The official track scores, denoted A and B, are computed as:

$$\mathrm{A} = 0.4\,\mathrm{FnAcc} + 0.6\,\mathrm{ArgEM},$$
$$\mathrm{B} = 0.3\,\mathrm{FnAcc} + 0.5\,\mathrm{ArgEM} + 0.2\,\mathrm{ThinkRate}.$$

Implementation. Table 3 lists the full training and inference configuration. We retain ALLaM frozen base parameters in `bfloat16`, while the trainable LoRA parameters remain in `float32` (no quantization is applied). Experiments use PyTorch 2.11, Transformers 4.46.3, PEFT 0.19.1, and torchao 0.17.0 on a single-GPU Google Colab G4 runtime. The system does not use torchao quantization; the version is pinned for reproducibility purposes, as PEFT's optional torchao availability probe is incompatible with the package preinstalled on Colab. Training the final model for two epochs takes approximately 65–75 minutes.

Setting	Value
LoRA rank / α / dropout	16 / 32 / 0.05
Epochs / batch size	2 / 12
No-call oversampling factor	30
Maximum sequence length	2,048 tokens
Optimizer / learning rate	AdamW / 10^{-4}
Learning-rate schedule	Cosine, 5% warm-up
Gradient clipping	1.0
Decoding	Greedy, 320 new tokens
Random seed	42

Table 3: Training and inference configuration of the submitted system.

5 Results and Analysis

Overall results. Table 4 reports development and blind-test scores. The system predicts the correct function for 544 of the 545 development examples. Argument objects are exactly correct for 446 of the 500 positive examples, leaving 54 argument errors but only one function error. The main performance bottleneck is therefore argument extraction rather than deciding whether to call a tool or selecting the appropriate function. Since ArgEM is evaluated over the complete argument object, a single missing, additional, or incorrectly normalised value makes the entire prediction incorrect. All results in this paper come from single runs at seed 42; we do not report variance across seeds.

Split	FnAcc	ArgEM	Overall A	Overall B
Development	0.9982	0.8920	0.9345	0.9454
Test	0.9938	0.8796	0.9253	0.9380

Table 4: Development and official blind-test results, computed with the official scorer. ThinkRate is 1.0000 on both splits. QMUL_AK ranked 3rd on both submission tracks.

Dialect breakdown. Argument extraction on the development set also varies across dialect. The system obtains an ArgEM of 0.9273 for MSA (268/289), 0.8889 for Gulf (64/72), 0.8485 for Egyptian (56/66), 0.8060 for Levantine (54/67), and 0.6667 for Maghrebi (4/6). The Maghrebi result is based on only six positive examples and is

therefore not a stable estimate. Nevertheless, the gap between MSA and the larger Egyptian and Levantine subsets indicates that robust dialectal argument extraction remains an open challenge.

Generalisation from development to test. Our Overall A score falls by 0.009 between development (0.9345) and blind test (0.9253), and Overall B by 0.007 (0.9454 to 0.9380). Function accuracy falls by 0.004 and argument exact match by 0.012, so argument extraction remains the bottleneck on unseen data.

Dialect robustness on the test set. Track C macro-averages the per-dialect overall score with equal weight per dialect and reports the gap between a system's best and worst dialect. Our system ranks 1st of 21 teams with a macro score of 0.9075, scoring 0.935 on MSA, 0.932 Egyptian, 0.915 Gulf, 0.897 Levantine, and 0.859 Maghrebi. Both the Maghrebi score and the gap of 0.077 are the best recorded in the shared task. An ablation on the development split (Table 5) shows that removing dialect resampling lowers overall ArgEM by 1.0 point but raises Maghrebi from 0.6667 to 0.8333 and Levantine from 0.8060 to 0.8358. With six Maghrebi positives in development these are one- and two-example differences, so the development split cannot resolve the per-dialect contribution either way.

Component ablation. Table 5 removes one component at a time, training on the training split alone and evaluating on the held-out development split. Every removal costs accuracy, so the full configuration is the best of the four. Token weighting is the largest lever, costing 2.0 ArgEM points when reasoning tokens are given full weight, and it is the only controlled comparison in the table: it leaves the training frame unchanged at 15,583 rows and 2,596 optimiser updates. Removing dialect weights costs 1.0 ArgEM, and removing no-call oversampling costs 0.6, but both also shrink the training frame, so part of each gap may reflect fewer updates rather than the component itself.

Contribution of the validation layer. Table 6 compares the model's parsed output with the validated output over the same generations. Validation changes 1 of the 545 development rows and removes a single argument field. It raises FnAcc from 0.9963 to 0.9982 and leaves ArgEM unchanged at 0.8920, worth 0.0007 Overall A. The model selects a function outside the candidate set on one row, which is mapped to none; the gold for that row is also none, and no row with a gold call is ever mapped away, so the mapping discarded nothing recoverable. There are no parse failures.

Configuration	Rows	FnAcc	ArgEM	Overall B
Full system	15,583	0.9982	0.8920	0.9454
– dialect weights	12,000	0.9890	0.8820	0.9377
– no-call $\times 30$	13,901	0.9853	0.8860	0.9386
– token weighting	15,583	0.9963	0.8720	0.9349

Table 5: Component removal on the held-out development split, training on the training split only at seed 42. Removing a resampling component shrinks the training frame and so the number of optimiser updates (2,596, 2,000 and 2,316 respectively); only the token-weighting row is directly comparable to the full system. Token weighting is the largest single contributor to ArgEM.

Output	FnAcc	ArgEM	Overall A	Overall B
Parsed only	0.9963	0.8920	0.9337	0.9449
Validated	0.9982	0.8920	0.9345	0.9454

Table 6: Effect of validation on the development split, scored over the same generations with an identical deterministic trace.

6 Conclusion

In this paper, we present the QMUL_AK system for Arabic function calling we implemented as part of the AISA-ArabicFC shared task, based on LoRA adaptation of ALLaM with schema-aware prompting, imbalance-aware sampling, and constrained output validation. Development results show that function selection is highly reliable, while exact argument extraction accounts for almost all remaining errors. In the test phase we ranked 3rd on Tracks A and B and 1st of 21 teams on the Track C dialect-robustness diagnostic. Future work should therefore focus on dialect-robust value extraction and normalisation methods that generalise beyond development-specific patterns.

Limitations

All results come from single runs at seed 42, so component effects cannot be separated from run-to-run variance. Removing a resampling component also changes the number of optimiser updates, so only the token-weighting ablation is a controlled comparison. We evaluate on one tool registry and do not test transfer.

Acknowledgements

We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, the baseline model, and the evaluation framework for this shared task.

Abstract

We describe Abjad's submission to the AISA-ArabicFC shared task (Track B), which targets Arabic function calling with explicit natural-language reasoning prior to the structured call. Rather than fine-tuning, our system builds a robust inference pipeline around the organizers' baseline model, AISA-AR-FunctionCall-Think, diagnosing and fixing two pipeline-level bugs that were silently depressing scores during development. On the shared task's 545-example development set, rescored with the organizers' own official evaluator (`normalize.py`/`eval_lib.py`), our submitted system reaches a function-name accuracy of 96.15%, an argument exact-match of 43.80%, and an official Track B score of 0.6825.

Beyond the original submission, we report a post-submission diagnostic finding: 117 of 500 positive predictions had a correct predicted function but a completely empty structured argument dictionary, and for 79 of these the model's own `<think>` span already stated every required gold value verbatim (an oracle upper bound, not an achieved result). Guided by this finding, we built a deterministic, schema-aware, gold-free repair that recovers such values only when they are unambiguously stated, together with a second, smaller schema-validity cleanup step; together they raise development-set ArgEM from 0.438 to 0.582 (+0.144) and Track B from 0.6825 to 0.7545 (+0.072), with zero observed regressions and no model weight updates, additional training data, or gold labels used at repair time. We present this as a diagnostic and pipeline-reliability contribution specific to our own submission: a substantial, measurable component of the argument-understanding gap observed in *our* development-set predictions from this baseline model is attributable to fixable output-serialization issues in our inference pipeline rather than semantic or reasoning failures, though genuine semantic errors remain and are characterized as the target for future modeling work. We do not claim this finding generalizes to other teams' pipelines or to the baseline model's behavior under different inference settings.

1 Introduction

Function calling, the ability of a language model to translate a natural-language request into a structured call to an external tool with correctly typed arguments, is an increasingly central capability for deploying language models in real applications. The AISA-ArabicFC shared task (Tuwaiq Academy AISA-ArabicFC Organizing Team, 2026) evaluates this capability specifically in Arabic, covering both Modern Standard Arabic and dialectal variation, using a baseline model that produces an explicit `<think>` reasoning span before emitting its function call.

This paper describes the system submitted by team Abjad: not a novel model or training procedure, but a carefully debugged inference pipeline built around the organizers' baseline model, together with a targeted error analysis. We identified and fixed two issues that silently corrupted our results during development: a stale checkpoint file that caused our generation loop to skip re-running samples, and an injected "anti-hallucination" reminder string that degraded the model's output format.

For this camera-ready version we additionally rescored our submitted, unmodified predictions using the organizers' *actual, released* scoring implementation (`normalize.py`/`eval_lib.py`) rather than the local reimplementation used at submission time, and conducted a further round of diagnostic analysis. We show that our original submission's low argument exact-match score is driven substantially by a pipeline-level structured-output failure — the model's reasoning trace routinely already contains the correct argument values, but the emit-

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1585–1591
October 28-29, 2026 ©2026 Association for Computational Linguistics

ted structured arguments are empty — rather than purely by argument-value misunderstanding, and we designed a deterministic, gold-free repair for this failure mode. Throughout this paper, we distinguish the *original submitted system* (rescored with the official evaluator) from *post-submission diagnostic experiments*: the latter are not a resubmitted or re-ranked competition entry.

Our contribution is therefore: (1) rescoring our submission with the actual official evaluator; (2) the discovery, via reproducible measurement rather than manual sampling, that a specific structured-output serialization failure accounts for a measurable share of the original argument-extraction gap; (3) a deterministic, gold-free repair pipeline that recovers a substantial portion of these serialization-related errors without any model weight changes; and (4) a grounded characterization of the errors that remain, which we argue are the genuine targets for future fine-tuning or decoding-level work.

The paper proceeds as follows: Section 2 covers task and dataset background; Section 3 describes our system and post-submission repair steps; Section 4 the experimental setup; Section 5 results and error analysis; Section 6 concludes.

2 Background

Task setup. Given a natural-language user request in Arabic, the system must produce a `<think>` reasoning span followed by either a structured function call or an explicit no-call decision. Two distinct correctness conditions are scored separately (Section 4): whether the predicted *tool name* matches gold, and whether the predicted *argument values* match gold under the organizers' normalization rules; the latter is not conditioned on the former.

Dataset and track. We use the `TuwaiqAcademy/AISA-ArabicFC` dataset released by the organizers: Arabic (MSA and dialectal) user utterances paired with gold tool calls from a fixed API-style function schema. The development split, on which all results here are computed, contains 545 examples (500 positive, 45 negative/`none`); we independently re-verified this split against the organizers' public Hugging Face release for this camera-ready version, confirming row counts and id alignment with our stored predictions. We participate in Track B, which additionally requires and scores the explicit `<think>` span (Section 4); we do not submit to Track A.

Related work and novelty. Tool use extends language models beyond text generation to structured, typed calls against APIs (Qu et al., 2024); most existing work is English-centric, and Ersoy et al. (2025) show that Arabic-specific tuning meaningfully affects tool-calling performance. Arabic function calling adds challenges beyond general Arabic NLP: dialectal variation, script normalization (digits, diacritics), and mapping Arabic-script mentions to standardized codes (ISO currency/language codes). AISA-ArabicFC (Tuwaiq Academy, 2026) is, to our knowledge, among the first shared tasks to combine these directly, using a baseline model, AISA-AR-FunctionCall-Think (Nacar et al., 2026), that couples function calling with explicit chain-of-thought. Unlike prior work reporting aggregate accuracy, our contribution is a diagnostic separating tool-selection from argument-normalization failures, plus pipeline-level lessons (Section 3) reusable regardless of fine-tuning.

3 System Overview

3.1 Base Model and Decoding

Our system uses the organizers' baseline model, `TuwaiqAcademy/AISA-AR-FunctionCall-Think`, loaded via the Hugging Face `transformers` library (Wolf et al., 2020). We run inference in float32 precision rather than float16, which we found necessary to avoid numerical instability (NaN outputs) during generation. We use greedy decoding (`do_sample=False`) with a repetition penalty of 1.1 and a generation budget of 300 new tokens, applied to the model's native chat template (`<start_of_turn>model`). A well-formed generation consists of a `<think>...</think>` reasoning span followed by either a structured call or an explicit indication that no tool applies.

3.2 Pipeline Debugging

We built our inference and evaluation pipeline from scratch on the provided train/dev splits. Two issues, visible only through direct inspection of raw model outputs rather than aggregate metrics, silently depressed our measured scores during development: (1) **stale checkpointing** — our generation loop resumed from a checkpoint file, but a stale checkpoint from an earlier, buggy run was silently treated as complete, causing later evaluations to score outdated predictions; and (2) a **prompt-injected anti-**

hallucination instruction — a reminder string telling the model not to invent unmentioned arguments interfered with its learned output format, reducing well-formed generations, and was removed after we compared raw outputs with and without it.

3.3 No Fine-Tuning

Our submitted system uses the baseline model's original weights, without parameter updates; we frame our contribution as diagnostic rather than leaderboard-optimized. Sections 3.5–3.6 describe post-submission, gold-free repairs for the structured-output failures identified in Section 5; genuine semantic errors are left as future work.

3.4 Output Parsing

We implemented a regex-based parser that extracts the `<think>` span and function call from raw output, typecasting argument values (number/string) per the tool's parameter schema before comparison against gold. This is the parser used to produce the originally submitted predictions.

3.5 Post-Submission Parser Repair

After submission, we investigated the composition of our system's argument exact-match failures using the organizers' officially released dev-set gold labels and scorer (Section 4). We found that 117 of the 500 positive-class predictions had a non-`none` predicted function but a completely empty structured `arguments` dictionary, despite the model's own `<think>` span routinely already stating the correct argument values in `key=value` form. This indicates a failure downstream of the model's reasoning — in how that reasoning was serialized into the structured call — rather than a reasoning failure itself.

We built a deterministic, schema-aware repair script that recovers arguments from `think` only when: (1) the predicted function is not `none`; (2) the structured `arguments` dictionary is empty; (3) the `think` span is non-empty; and (4) `think` contains an explicit, unambiguous `key=value`/`key: value` association for a key in the *predicted* function's own schema. Extraction uses only the predicted function name, the model's own `think` text, and tool schema metadata — **no gold labels, no hard-coded row identifiers**, and the predicted function name and `think` text are never altered. Ambiguous or non-schema-valid values are left unfilled rather than invented; the repair recovers only information the model had already stated explicitly.

3.6 Post-Submission Schema Cleanup

As a second, independent post-submission step, we inspected predicted argument *keys* against the predicted function's own declared schema and found a small number of predictions with keys that do not exist at all in that schema. We apply one general, deterministic, schema-derived (not gold-derived) rule: drop any predicted argument key not declared in the predicted function's own schema, regardless of whether the dropped key agrees or disagrees with gold.

We additionally apply a general safety guard: this cleanup is never applied if it would reduce a non-empty argument dictionary to completely empty, since gold arguments for scored examples are never empty, so emptying a prediction can only hurt or be neutral. This guard proved necessary because the official scorer's ArgEM check is independent of function-name correctness (Section 4): without it, a coincidental correct-argument match on a wrong-function prediction could be broken by cleanup that empties its argument dictionary.

4 Experimental Setup

Data and tools. We use the official train/development splits of `TuwaiqAcademy/AISA-ArabicFC`. All results here are on the 545-example development split (500 positive, 45 `none`); we lacked access to the blind test split.

Evaluator (revised). At submission time, we evaluated locally using our own reimplementation of the organizers' published scoring rules. For this camera-ready version, **all** dev-set numbers reported in this paper — including for the originally submitted, unmodified predictions — were recomputed using the organizers' actual released scoring implementation (`normalize.py`/`eval_lib.py`, obtained from the shared task's official Hugging Face Space). This changes some figures relative to the accepted submission (Section 5.1), since the official normalizer implements a broader set of closed-class aliases and a per-function `OPTIONAL_IGNORE` argument list that our earlier local reimplementation did not cover in full.

Metrics (corrected). Function-name accuracy (FnAcc) is computed over all development examples, including negative (`none`) ones. Argument exact-match (ArgEM) is computed only

over the 500 positive examples. We previously stated that ArgEM is forced to 0 whenever the predicted function name does not match gold; **this described our own earlier local reimplementation, not the organizers' actual evaluator**, whose `eval_lib.py` checks argument-dictionary equality independently of function-name correctness. Think-tag presence rate (ThinkRate) is the fraction of examples with a non-empty `<think>` span. The two official composite scores are unchanged: $\text{Overall}_A = 0.40\,FnAcc + 0.60\,ArgEM$
$Overall_B = 0.30\,FnAcc + 0.50\,ArgEM + 0.20\,ThinkRate$ with Overall_B the official ranking metric for Track B. All results in this paper, original and post-submission alike, are computed on the 545-row **development** split; the organizers' corrected baseline figures (Section 5.1) are reported on a separate **1,125-row blind test** split and are not numerically comparable to the development-set results here.

5 Results

5.1 Official Metrics

Table 1 summarizes results on the 545-row development split, recomputed with the organizers' official scorer.

The parser/serialization repair contributes $+0.132$ ArgEM and $+0.066$ Track B over the original submitted predictions; the schema-cleanup step contributes a further $+0.012$ ArgEM and $+0.006$ Track B; the total gain is $+0.144$ ArgEM and $+0.072$ Track B, with **zero regressions** at either stage — no previously argument-exact-match-correct example was broken, function-name predictions and `think` spans are identical across all three rows, and FnAcc/ThinkRate are unchanged throughout. The repaired-variant scores (0.7485, 0.7545) are post-submission development-set analysis figures, not a competition submission or leaderboard score. The organizers' corrected blind-test baselines (e.g., AISA-AR-FunctionCall-Think 270M: Track B 0.8074) are measured on the separate 1,125-row split described in Section 4 and are omitted from Table 1 accordingly.

5.2 Design-Decision Impact

Since we do not fine-tune the baseline model, we report no training-configuration ablations. The one pre-submission comparison available is the qualitative pipeline debugging in Section 3.2: inspection with and without the anti-hallucination reminder showed a clear drop in well-formed generations with it present, motivating its removal, though we did not re-quantify this with matched full-set scores (see Limitations).

5.3 Error Analysis

We replace our earlier manual-sample-based error characterization with measured, reproducible counts obtained by comparing predictions against the organizers' real development-set gold labels.

Diagnostic / oracle analysis. Of the 500 positive-class original submitted predictions, 117 had a non-`none` predicted function but a completely empty structured `arguments` dictionary. All 117 of these had the correct predicted function name and genuinely required arguments according to gold. Of these 117, 79 (67.5%) had every required gold argument value already present verbatim in the model's own `<think>` text, and 108 (92.3%) had at least one gold value present verbatim. **These 79 and 108 counts are oracle diagnostic observations** — they use gold labels purely to measure what could in principle be recovered from the existing `think` text, and they are *not* achieved corrections.

Actual gold-free implemented repair. The deterministic, schema-aware repair described in Section 3.5 — which uses no gold labels — modified the structured arguments of 114 predictions and made 66 additional positive examples argument-exact-match-correct, with zero regressions. The gap between the 79-row oracle upper bound and the 66 achieved corrections reflects the repair's deliberately conservative extraction criteria: it declines to fill a value whenever the `think` text's key/value association is not unambiguous under schema-restricted, literal pattern matching, in order to avoid inventing or guessing values.

ThinkRate composition. The official ThinkRate metric (0.8752) reflects 68 of the 545 development examples with a completely empty `<think>` span. Of these 68, 59 (86.8%) coincide with examples where the model itself predicted `none` (i.e., the model's own decision was that no tool call applies, and it did not additionally produce a reasoning trace for that decision); the remaining 9 (13.2%) are positive-class predictions — a non-`none` predicted function — with an empty `<think>` span

System	FnAcc	ArgEM	ThinkRate	Track A	Track B	ΔB
Original submitted predictions	0.9615	0.4380	0.8752	0.6474	0.6825	—
+ Parser/serialization repair	0.9615	0.5700	0.8752	0.7266	0.7485	+0.0660
+ Schema cleanup	0.9615	0.5820	0.8752	0.7338	0.7545	+0.0720 (total)

Table 1: Development-set results. All rows are computed on the *same* 545-example development split (500 positive, 45 negative) using the organizers' actual released `normalize.py`/`eval_lib.py`. The "Parser/serialization repair" and "Schema cleanup" rows are **post-submission camera-ready diagnostic experiments**, not part of the original competition submission and not a resubmitted or re-ranked leaderboard entry. ΔB is the change in Track B relative to the original submitted predictions.

despite a call being made. The shortfall from a perfect ThinkRate is therefore concentrated in `none`-decision cases rather than spread evenly across the dataset, and only a small minority (9/545, 1.65%) reflects missing reasoning alongside an actual function call.

Remaining errors after repair. After both post-submission repair steps, the dominant remaining failure groups are, in descending order of frequency: semantic/content value mismatches where the predicted and gold values differ even after the official normalizer's canonicalization; extra or missing schema-valid arguments, where the model over- or under-specifies arguments relative to gold despite both being valid for the predicted tool's schema; a smaller number of wrong function-name predictions; and a small number of fields — most notably `termination_type` — that the organizers' own published normalizer explicitly declines to canonicalize due to a large number of uncontrolled surface variants. We do not report exact post-final counts for these categories beyond what has been directly recomputed against the schema-cleanup predictions (Table 1).

Normalization finding. As a further post-submission diagnostic, we tested whether rewriting predicted argument *values* into their canonical surface form (e.g., mapping a spelled-out currency name to its ISO code) using the organizers' own published alias tables would improve scores beyond the repairs above. It did not: canonical value rewriting produced no additional ArgEM improvement, because the official scorer already applies the identical canonicalization function symmetrically to both the prediction and the gold answer at scoring time. This finding is specific to *additional pre-scoring canonical rewriting under this evaluator*; it does not imply that normalization in general is unhelpful, only that re-applying the same normalization the scorer already performs is redundant. The one genuine gain available from key-level (not value-level) cleanup — dropping schema-invalid argument keys — is already captured in Table 1.

6 Conclusion

We presented Abjad's submission to AISA-ArabicFC Track B together with a post-submission diagnostic analysis. Rescored with the organizers' official scorer, our submitted system reaches 96.15% function-name accuracy and 43.80% argument exact-match (Track B 0.6825). A substantial, measurable component of this gap is attributable to a pipeline-level structured-output failure rather than a failure of task comprehension: a deterministic, schema-aware, gold-free repair, together with a smaller schema-cleanup step, raises development-set ArgEM to 0.582 and Track B to 0.7545 (+0.144 ArgEM / +0.072 Track B), with zero regressions and no changes to model weights or training data. Canonical value rewriting alone yields no further gain, since the official scorer already applies the same canonicalization symmetrically. What remains — genuine value disagreements, function-selection errors, and organizer-acknowledged uncanonicalized fields — is increasingly model-level, and we identify constrained generation, prompt/decoding changes, or targeted fine-tuning on these residual error types as the appropriate next steps.

Limitations

Our originally submitted results used a local reimplementation of the organizers' published scoring rules rather than their released scorer; the camera-ready numbers in this paper (Table 1, all rows) instead use the organizers' actual `normalize.py`/`eval_lib.py`. All system results reported in this paper — for both the original submission and the post-submission repaired variants — are **development-set** results; final competition rankings are determined by the organizers on a

separate, held-out blind test split, to which we did not have access, and none of the numbers in this paper should be interpreted as revised leaderboard or test-set performance. The post-submission parser-repair and schema-cleanup variants (Sections 3.5–3.6, 5.1) were developed and evaluated entirely after our competition submission, using only the development split; we did not have blind test labels available to evaluate these repairs on held-out data, and we caution that iterative diagnostic development and evaluation on the same development split, however conservative, carries some risk of overestimating how well a fix would generalize relative to a genuinely held-out evaluation. The parser repair is fundamentally limited by what is recoverable from the model's own generated `think` text: it can only recover an argument value when the model's reasoning already states that value in an explicit, schema-matched, unambiguous form; it cannot correct cases where the model's reasoning itself is silent on or wrong about the required value. This work was conducted by a three-person team with limited compute. The stale-checkpoint and anti-hallucination-reminder fixes described in Section 3.2 were identified and validated during development via direct qualitative inspection of raw model outputs, comparing generations with and without each change on a small set of examples; this was sufficient to establish that each change was necessary to obtain well-formed output, but we did not preserve a matched, full-development-set quantitative comparison (with-bug vs. without-bug) under a single evaluator, so we cannot report a numerical before/after score for these two pre-submission fixes, unlike the post-submission repairs in Table 1, which are fully quantified.

Ethics Statement

This work uses the organizers' publicly released AISA-ArabicFC benchmark and baseline model as provided for the shared task; we did not collect, annotate, or release any new human-subject data. Our analysis is restricted to examining system outputs (model predictions and the released development-set inputs/gold labels) for the purpose of pipeline debugging and error characterization, and we do not make claims about the dataset's provenance, licensing terms, or content properties beyond what the organizers have documented. We report deterministic, rule-based post-processing methods only. No additional model training or human annotation was conducted for these experiments, and generative AI tools were not used to generate the reported experimental results.

Generative AI disclosure. Generative AI tools were used during the camera-ready preparation to assist with language editing, manuscript restructuring, and code review/debugging. All scientific claims, experimental procedures, reported results, and final manuscript content were reviewed and verified by the authors, who take full responsibility for the paper.

Acknowledgments

We thank the AISA-ArabicFC organizers (Tuwaiq Academy) for organizing the shared task and for publicly releasing the `TuwaiqAcademy/AISA-ArabicFC` benchmark dataset, the `AISA-AR-FunctionCall-Think` baseline model, and the official scoring and argument-normalization implementation (`normalize.py`/`eval_lib.py`), all of which this paper's camera-ready analysis relies on directly.

A Normalization and Scoring Details

For replicability, we summarize the value-normalization rules applied before comparing predicted and gold argument values, based on the organizers' actual released `normalize.py`:

- **Digits & number words.** Arabic-Indic and Persian digits map to Western digits; common Arabic number words map to their digit equivalents.
- **Orthographic normalization.** Diacritics/tatweel are stripped; alef variants unify to bare alef; alef-maqsura and ta-marbuta are normalized; hamza seats are simplified; whitespace is collapsed.
- **Closed-vocabulary aliasing.** Countries, cities, currencies, languages, zakat asset types, and Quran search types map to canonical forms via lookup tables covering both Arabic and English/ISO surface forms. One field, `termination_type`, is explicitly *not* semantically aliased by the organizers due to a large number of uncontrolled surface variants, pending an organizer-approved canonical mapping.
- **Identifier and list fields.** Identifier-like fields (ID/IBAN/ passport/iqama/phone numbers, etc.) compare as normalized strings, preserving leading zeros; a small set of fields (`items`, `country`, `destination_country`) compare as unordered sets after splitting on common separators.
- **Optional/ignored arguments.** For a small, per-function set of arguments (`OPTIONAL_IGNORE` in the official implementation) that are declared in a tool's schema but never required by any gold answer, the argument is dropped from both prediction and gold before comparison.

Correction to the previously reported metric description. We previously stated that argument exact-match (ArgEM) for an example is "forced to 0 whenever the predicted function name does not match gold." This described our own local reimplementation used at submission time, not the organizers' actual evaluator. In the official `eval_lib.py`, ArgEM for a positive example is computed by directly comparing the (normalized) predicted and gold argument dictionaries, independently of whether the predicted function name is correct. We flag this correction for reproducibility; it does not materially change our headline findings, since function-name accuracy is uniformly high (96.15%) across all reported systems in this paper.

Siraj at AISA-ArabicFC: Selective Argument Repair and the Limits of Post-Editing in Arabic Function Calling

Abstract

We describe Siraj's Track B submission to AISA-ArabicFC. A QLoRA-tuned ALLaM-7B is followed by a separately trained argument repairer whose edits pass a type-restricted acceptance filter, then by one deterministic year rule. On the blind test set (1,125 rows) it scores 0.8245 ArgEM and 0.9101 Track B, 10th of 17 systems; the post-editing stage is worth about one example on test against four on development, a difference smaller than we can distinguish from single-seed run-to-run variation. Every rule that error inspection suggested was adjudicated on out-of-fold training predictions, scored with the task's own published matcher, before it could touch development predictions; all five were rejected, one of them breaking 168 more rows than it fixed. Two development-time conclusions did not survive: the top three systems finished 5.5 to 5.7 ArgEM points ahead, so our error rate was not a task-level ceiling, and a later dataset revision lowers our development ArgEM from 0.850 to 0.8080 and neutralises our strongest rule. Post-editing rules fitted to gold conventions can inherit changes in those conventions.

1 Introduction

Arabic function calling requires selecting a tool and filling its arguments from an utterance in Modern Standard Arabic or a dialect. AISA-ArabicFC (Nacar et al., 2026a,c) scores arguments all-or-nothing (ArgEM) after a published deterministic matcher, so one mis-formatted field invalidates an otherwise correct call. After fine-tuning the residual errors look systematic—wrong year, extra qualifier, transliteration instead of Arabic—suggesting some may be amenable to post-editing. We report how that intuition was tested and where it failed: a three-stage pipeline and its measured effect (§3, §5); a gate that adjudicates candidate rules on out-of-fold training predictions (§4, §6); and a post-hoc analysis of what the standings and a post-evaluation dataset revision reveal about our own measurements (§7).

2 Task, Metric, and a Moving Target

Track B scores $0.30 \cdot \text{FnAcc} + 0.50 \cdot \text{ArgEM} + 0.20 \cdot \text{ThinkRate}$: tool-name accuracy over all rows, exact match of the argument dictionary over positive rows, and the fraction of rows containing the required reasoning trace. The data (Tuwaiq Academy, 2026a; Nacar et al., 2026b) comprise 10,550 training rows (10,500 positive), 545 development and 1,125 blind test rows, each offering four candidate tool schemas from a registry of 27 (20 appear as gold calls, seven only as distractors) and one of five dialect labels. A Track B system returns an Arabic `<think>` trace, then the selected tool and its arguments as JSON, or no call.

The organisers publish `normalize.py`, the matcher used for scoring; we re-implemented it locally and, on the release then current, reproduced the official scores of three submissions exactly. It was revised twice during development: one unchanged prediction file, submitted twice under different system names, returned 0.826 and later 0.850. A concurrent data change cannot be ruled out, so we do not attribute that to the matcher alone. Gold values recorded in our development-time error analyses differ from the current public release: values that were ISO dates now appear as natural Arabic dates. We cannot date that revision from public artefacts. All development figures below are recomputed against the current release; development-time figures are marked as such.

3 System

Figure 1 shows how the pipeline components interact.

Task model. We fine-tune `ALLaM-7B-Instruct-preview` (ALLaM-AI) with QLoRA (Dettmers et al., 2023) (r=32,

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1592–1596
October 28-29, 2026 ©2026 Association for Computational Linguistics

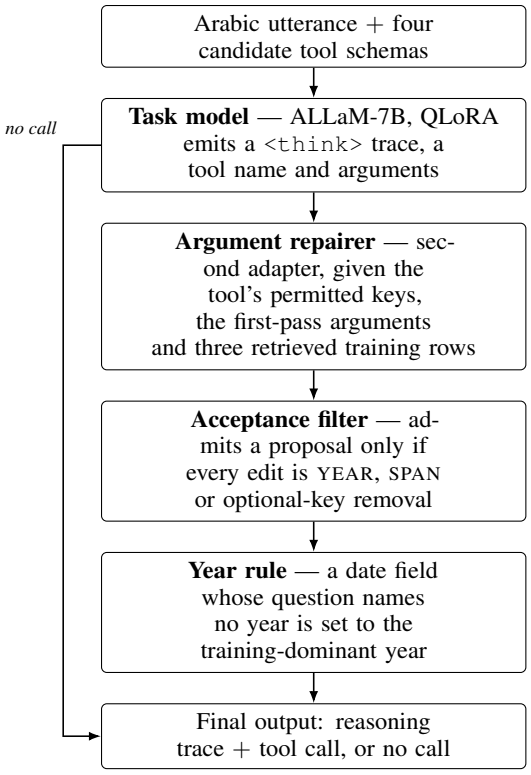

Figure 1: Siraj pipeline. The task model runs on every row; the repairer and the filter run only on rows where a tool was predicted, and the filter falls back to the first-pass arguments whenever a proposal is rejected. The year rule is applied last and is independent of the repairer.

α=64, dropout 0.05, all seven projection matrices, 4-bit NF4, bf16). The split holds only 50 no-call rows, so we hand-wrote 72 more Arabic no-call utterances over six categories—completed past actions, feelings, questions about the assistant, domain commentary, comparative questions, hypotheticals—each with a fixed rationale and grafted onto a copy of a real negative row to keep the tool inventory realistic. The 122 negatives are oversampled ninefold: 11,598 examples, 9.5% no-call. Rows without a reasoning trace receive a template sentence as the supervised target, so part of that supervision is generated. Sequences truncate at 1,280 tokens and the loss covers the full sequence. Training runs 3 epochs (2,175 steps) at learning rate 1×10^{-4}, cosine after 150 warmup steps, paged AdamW 8-bit, effective batch 16, seed 42; loss falls from 1.06 to 0.10. Checkpoint handling touches development twice: training restores the best of four checkpoints by evaluation loss on 100 shuffled development rows, and we then re-score all four with the official matcher.

Argument repairer. A second adapter (r=16, α=32, same modules) maps the question, the tool, its permitted argument keys, the first-pass arguments and three retrieved training examples to corrected arguments; retrieval is character 3-gram Jaccard over training questions of the same tool. Its loss, unlike the task model's, is masked to the target JSON; it trains 2 epochs at learning rate 7×10^{-5}, same optimiser, batch and seed. Pairs come from out-of-fold inference—the training split is halved, a model is trained on each half and predicts on the other, already-correct pairs kept as identity targets—and from corrupting training gold on a 30% sample: year, short prefix, list delimiter, field deletion, or an unused optional field.

Acceptance filter. Unfiltered, the repairer changes 47 development rows: 13 fixes, 12 breaks and 22 changes that alter no outcome. Per edit type the net effect is +3 for SPAN, +1 for REWRITE, 0 for YEAR and for optional-key removal, −1 for key addition and −2 for LANG-FLIP. The primary system admits only YEAR, SPAN and optional-key removal: each can be checked against an explicit structural relation—the same string with the year replaced, one value a substring of the other, or a key that training gold marks optional—whereas REWRITE is the residual class in which any value may replace any other, so admitting it means trusting the repairer wholesale. A proposal is further required to add only keys in the tool schema, remove only keys optional in training gold, and change at most two fields. A wide variant repairs field by field, also admitting REWRITE, and a LANG-FLIP only when it moves toward the training language policy for that field ($\geq$ 70% majority over $\geq$ 10 observations).

Deterministic rule. Date-bearing training gold carries the year 2023 in 78 of 84 cases (92.9%) while prompt dates are randomised. When a predicted date carries a year and the question mentions neither a year nor a next-year expression, we set it to 2023. This was our largest development-time gain; under the current release it is neutral (§7).

4 Validating Rules on Training Data

Development errors suggest rules; adopting them on that evidence fits a 545-row sample. Every rule error inspection suggested was therefore adjudicated on training data first: applied to the 4,000 out-of-fold predictions built for the repairer, counting

	ArgEM	Overall B	FnAcc
Development (n=545), current release			
Model alone	0.8000	0.8994	0.9982
+ repairer, wide	0.8080	0.9034	0.9982
+ repairer, primary	**0.8080**	**0.9034**	0.9982
Blind test (n=1,125), official			
Siraj (rank 10 of 17)	0.8245	0.9101	0.9929
Best system (rank 1)	0.8816	0.9400	0.9973

Table 1: ThinkRate is 1.0000 throughout. Development figures are recomputed with the current matcher and data release; test figures are the organisers' (Tuwaiq Academy, 2026b).

fixed against broken rows with the official matcher, admitted only if it fixed at least twice as many rows as it broke. Five went through this gate and all five failed (Table 2), none near the threshold—the closest still broke almost three times as many rows as it fixed. The year rule did not come from this route: it follows from a frequency in training gold, not from a hypothesis about observed errors.

5 Results

The pipeline adds +0.0080 ArgEM on development (Table 1), four of the 500 positive rows—not a fully held-out estimate, since acceptance thresholds were tuned on development and checkpoint selection touched it. On the release used during the evaluation, the model-alone and primary-pipeline files scored 0.838 and 0.850 respectively. On ArgEM alone we place 12th rather than 10th: two systems with higher ArgEM rank below us on the weighted score because of weaker function accuracy.

Variant comparison. FnAcc and ThinkRate are identical across our three submissions, so differences are entirely in ArgEM: primary filter 0.9101 Overall B, model alone 0.9097, wide filter 0.9096. Since ArgEM carries weight 0.50 and the other two components are constant, each ArgEM difference is twice the Overall B difference: the primary filter is worth about +0.0008 ArgEM over the model alone, roughly one positive test row, and the wide filter differs from it by less than one example at the reported precision.

Dialect. Development ArgEM is 0.841 MSA, 0.806 Gulf, 0.791 Levantine, 0.712 Egyptian, 0.500 Maghrebi over buckets of 323, 75, 75, 66 and 6 rows; post-editing widens the max−min gap from 0.174 to 0.341, both dominated by the six-row Maghrebi bucket where one example moves ArgEM by at least 0.167. The diagnostic track reports per-dialect *Overall* B on test, a different quantity on twice the data: 0.906 MSA, 0.922 Gulf, 0.852 Egyptian, 0.883 Levantine, 0.788 Maghrebi; macro 0.8703, 10th of 21, gap 0.134 over eleven Maghrebi rows (Tuwaiq Academy, 2026b). Gulf exceeds MSA there, so the development reading that our system favours MSA does not survive. Egyptian also trails the other nine systems with published per-dialect figures, 0.852 against 0.891–0.935. We draw no conclusion from the Maghrebi cell in either split: at six development and eleven test rows it is too small to separate a property of the system from sampling, and both max−min gaps we report are determined by it.

6 What Did Not Work

Each rule below was measured on training or out-of-fold data with the official matcher current at the time of the experiment.

Surface-form rules. Gold values are often verbatim spans of the question—city 98%, procedure and medication 93%, restaurant 92%, product 89%, category 85%, but date 56%, items 27%, currency 24%, source and target 4% and 3%—so snapping to the nearest span looks compelling, but performs poorly. So does rewriting ISO dates into the question's surface form, which would corrupt 442 rows whose gold is itself ISO, and emitting `search_type` from an explicit cue, since the gold convention omits that field far more often than the cue suggests.

Country rules. Mapping a predicted city to its country for `compare_prices` is unsafe: 21 training gold values are themselves cities. Reducing a multi-country prediction to the first mentioned country matches gold in 50 of 64 ambiguous rows, but 86 of 484 gold values are genuinely multi-country, so we did not judge the rule reliable enough to adopt.

Closed vocabularies and a learned presence gate. Snapping to closed vocabularies never triggered: only seven (tool, field) pairs have at most 25 values over at least 30 observations (eight under the current release), and the model never erred orthographically on them. A per-field TF-IDF and logistic-regression presence classifier, calibrated out-of-fold to at least 98.5% precision, left two usable gates that removed no field.

Rejected rule	fixed	broke
Verbatim-span snapping	32	200
`search_type` cue rule	8	110
Date-format harmonisation	104	442
`get_weather` days rule	9	25
Dialectal date snapping	0	2

Table 2: Rules rejected by the validation gate, on training or out-of-fold data.

7 Post-hoc Analysis

Comparison with higher-ranked systems. We concluded during development that the residual errors were annotation-convention noise and therefore irreducible. Three systems reached 0.88 ArgEM on test, 5.5 to 5.7 points above us, which shows our error rate was not a task-level ceiling—though not that they corrected the rows we missed. Our own evidence supports only the narrower claim: given this backbone and fine-tune, the remaining errors were not reducible by any deterministic rule we tested.

Sensitivity to gold conventions. Re-scoring our unchanged submissions against the current release drops development ArgEM from 0.850 to 0.8080, and the year rule—our largest development-time gain—becomes neutral (0 fixed, 0 broken, 6 rows changed): the revision replaced ISO gold dates with natural Arabic ones while our predictions stayed ISO. A rule estimated from gold conventions is only as stable as those conventions; validating on training data reduces the risk of over-fitting to a development sample, but not the risk of a change in the annotation standard.

Residual error analysis. The primary system leaves 96 erroneous development rows. Twenty-five (26%) carry a `check_in` or `check_out` mismatch, contributing 50 field-level mismatches; in 46 of those the prediction and gold name the same day and month, the prediction an ISO date carrying a year and the gold an Arabic day-and-month expression without one (row 17: `2023-02-10` against a gold reading "the tenth of February"). None names a different date, and four resisted automatic parsing. The next largest field counts run from 8 (`procedure`, `items`) to 4 (`product_name`, `category`, `date`), covering paraphrases, list separators, name transliterations, bare versus qualified currency words and definite-article presence. The residue therefore contains one sizeable date-representation mismatch plus a long tail of convention variance—not, as we had concluded, irreducible annotation noise throughout.

Test-set effect size. The repairer and filter are worth +0.0080 ArgEM on development (four of 500 positive rows) and about +0.0008 on test (one row). The sign is the same on both, but a one-row difference over a single run is not evidence of reliable transfer. Ranks 8–10 are separated by 0.0008 Overall B, so these neighbouring ranks do not support strong claims about relative method quality.

8 Conclusion

An Arabic-specialised 7B backbone with QLoRA, an out-of-fold-trained argument repairer, a precision-oriented acceptance filter and one deterministic rule reach 0.8245 ArgEM on the blind test set: 10th of 17 Track B systems on the weighted score, 12th on ArgEM alone. The restrictive filter beat the bare model there by about one example, against four on development—too small, from a single run, to call reliable transfer. Adjudicating candidate rules on training data with the official matcher kept five plausible rules out of the final system, one of which would have broken 168 more rows than it fixed. The caution is twofold: that discipline bounds only the post-editing layer and is no substitute for investing in the generator, and rules fitted to gold conventions can inherit changes in those conventions. That suggests a scope condition worth testing: a repairer of this kind should be most useful where annotation conventions are settled, and least useful on a benchmark still under revision.

Limitations

Each reported configuration was trained once at seed 42; we did not repeat training across seeds, so effects of the size we report—one to four rows—cannot be separated from run-to-run variation, and the 545-row development split and 4,000 out-of-fold predictions may fail to detect a small true effect. Our conclusions are conditional on this system configuration: systems 5.5 to 5.7 ArgEM points ahead show that our error rate was not a task-level ceiling. Two components depend on development data—the per-edit-type acceptance thresholds, mitigated but not eliminated by operating over six coarse edit classes, and best-checkpoint selection on evaluation loss over 100 development rows.

Development figures are recomputed against the current public release, which differs from the one used during the evaluation; test figures are the organisers' and cannot be independently recomputed, since test gold is not released. Per-dialect gaps are unstable for the Maghrebi bucket: six development rows, eleven on test. Finally, the system was assessed only as a scoring task: an argument error costing one point here—a wrong recipient or amount—would carry real consequences in a live tool.

Ethics and Data Statement

Gradient updates used the provided training split together with the 72 no-call utterances we wrote ourselves (§3); no external corpora were used and no gold labels retrieved from external sources. We did not independently audit the organiser-provided corpus for personal or offensive content. The base model and the data were used under the terms their providers publish; we have re-distributed neither, and any adapters we release will carry terms compatible with the base model's licence. Development data influenced model and hyper-parameter selection but never gradient updates. We make available to the organisers the two LoRA adapters, an audit script that recomputes every development figure here, and a reproduction notebook pinned to `torch` 2.2.2, `transformers` 4.44.2, `peft` 0.12.0 and `bitsandbytes` 0.43.1. A clean-directory rerun on the same GPU model (NVIDIA A100-SXM4-80GB; roughly 20 GPU-hours for the project) regenerated all three submitted files bit-identically, with matching SHA-256 digests over 1,125 rows each.

Acknowledgements

We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, the baseline model, and the evaluation framework for this shared task.

The authors used an AI assistant to draft and revise this text from their own experiment logs, run outputs and configuration files, and to write parts of the analysis code. All experiments, results, methodological choices and claims are the authors' own.

ArgTune at AISA-ArabicFC: A Modular Pipeline for Arabic Function Calling

Sabah Baothman
Independent Researcher, Saudi Arabia
sabah.a.baothman@gmail.com

Abstract

We present ArgTune, a modular pipeline for Arabic function calling developed for the AISA-ArabicFC shared task. ArgTune separates tool selection from argument extraction using three LoRA-fine-tuned AISA-AR-FunctionCall-Think (270M) models: a tool-selection model, a general argument model, and a specialist model for seven challenging tools, allowing each model to focus on a more specific task. Targeted augmentation, data balancing, and query-grounded post-processing further address difficult argument cases. On the official test set, ArgTune achieved 0.9964 FnAcc, 0.8506 ArgEM, and an overall score of 0.9089, ranking 8th. The results highlight the remaining difficulty of exact argument extraction despite highly accurate tool selection.

1 Introduction

Function calling enables language models to interact with external tools by selecting a function and generating its arguments. This capability is central to agentic AI systems such as the broader AISA framework (Nacar et al., 2026c). In Arabic, function calling is particularly challenging due to dialectal and linguistic variation alongside strict structured-output requirements. The AISA-ArabicFC shared task evaluates these capabilities in Arabic (Nacar et al., 2026a).

Our experiments revealed a clear gap between tool selection and exact argument extraction. This motivated ArgTune, a modular pipeline that separates the two tasks and uses specialized argument extraction for difficult tools. Targeted augmentation, data balancing, and lightweight query-grounded post-processing were used to address recurring errors.

On the official test set, ArgTune achieved 0.9964 FnAcc, 0.8506 ArgEM, and an overall score of 0.9089, ranking 8th. The remaining gap between the two metrics identifies exact argument extraction as the main challenge.

Code and models are available at https://github.com/SabahBaothman/ArgTune.

2 Background

AISA-ArabicFC is a shared task on Arabic function calling for agentic AI systems. Given an Arabic user request and a set of available tools, the system must select the appropriate function and generate its arguments in a structured format (Nacar et al., 2026a). Table 1 shows an example from the development set.

Field	Example
Query	أريد تحويل 1500 ريال سعودي إلى دولار أمريكي.
Tool	convert_currency
Arguments	amount=1500, from=SAR, to=USD

Table 1: Example Arabic function-calling instance.

We participated in Track A (Core), which requires generating the function call (function name and its argument values) directly from the user request. The dataset contains 10,550 training and 545 development instances, covering five Arabic varieties: Modern Standard Arabic (MSA), Levantine, Egyptian, Gulf, and Maghrebi. Each request is paired with tool definitions and a structured target function call.

Our system builds on AISA-AR-FunctionCall-Think, the 270M-parameter model provided with the shared task. The model is based on Gemma 3 and was developed for Arabic structured tool calling using a data-centric fine-tuning approach (Nacar et al., 2026b). Prior work on function calling has shown that high-quality and diverse training data can improve reliability (Liu et al., 2025), while Arabic tool-calling studies report persistent performance challenges across different query forms (Kubrak et al., 2026). ArgTune uses a modular architecture to improve model focus by separating

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1597–1602
October 28-29, 2026 ©2026 Association for Computational Linguistics

tool selection from argument extraction and assigning seven challenging tools to a specialist argument model. To improve data quality and coverage, we also use targeted augmentation and balancing for difficult and underrepresented cases.

3 System Overview

ArgTune follows a modular architecture that decomposes Arabic function calling into distinct stages for tool selection and argument extraction. Given an input query, the system first applies preprocessing before passing the query to a dedicated tool-selection model. The predicted tool then determines which argument-extraction model is used: a specialist model handles seven challenging tools, while a general model covers the remaining tools. Finally, lightweight query-grounded post-processing rules are applied to improve the consistency of the extracted arguments and produce the final function call. Figure 1 illustrates the overall ArgTune workflow.

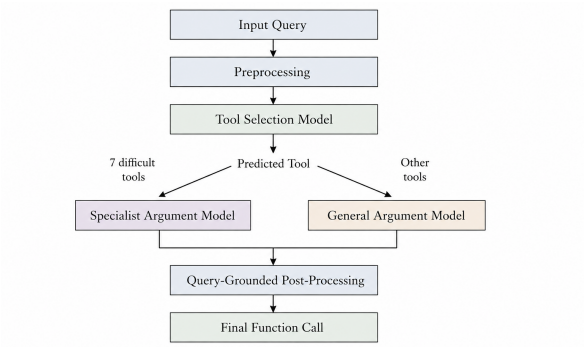

Figure 1: Overview of the ArgTune modular architecture.

3.1 Preprocessing

Before training, we reviewed the training examples and cleaned cases with inconsistent or noisy labels. Empty argument values were removed, and examples where the labeled arguments were not supported by the user query were either corrected when the intended value was clear or excluded from training.

Cleaning was performed separately for the argument models. For the general argument model, 50 original rows were excluded and four retained hotel examples had their guest-count labels corrected. For the specialist model, 133 rows were excluded: 6 from book_doctor_appointment, 32 from calculate_end_of_service, 85 from compare_prices, 5 from transfer_money, and 5 from calculate_customs. These removals mainly involved unsupported dates, ambiguous or inconsistent argument labels, and values not supported by the user query.

3.2 Tool Selection

The first stage of ArgTune is responsible for selecting the appropriate tool for each user query. We use a dedicated LoRA-fine-tuned AISA-AR-FunctionCall-Think model for this stage, allowing tool selection to be handled independently from argument extraction.

Most tools were already identified reliably by the base model. We therefore focused the additional training data on the remaining difficult cases rather than augmenting all tools equally. We added 30 targeted examples for translate_text and transfer_money, with 15 examples for each tool and variation across Arabic dialects. These examples were added once without oversampling, increasing the tool-selection training set from 10,550 to 10,580 examples. The selected tool is then used to route the query to the appropriate argument-extraction model.

3.3 Argument Extraction

After tool selection, ArgTune uses a separate model to extract the arguments required by the predicted tool. During our experiments, argument extraction was more challenging than tool selection, especially for tools with multiple or closely related argument fields. Instead of using a single argument model for all tools, we divided this stage into a general model and a specialist model.

The specialist model handles seven tools that showed more difficult argument-extraction patterns: order_food, book_doctor_appointment, check_insurance_coverage, compare_prices, calculate_customs, transfer_money, and calculate_end_of_service. The general model handles the remaining tools. Both models are LoRA-fine-tuned from AISA-AR-FunctionCall-Think and receive the user query together with the tool selected in the previous stage.

Training for both argument models was supported by targeted augmentation and selective oversampling. For the general model, we added 264 unique examples: 151 for search_hotels, 22 for get_weather, 12 for search_medications, 3 for search_quran, 36 for calculate_zakat, and 40 for convert_currency. The first 188 targeted examples were used three times each, while the re-

maining 76 examples were added once. We also duplicated 37 search_quran training examples to improve the balance of the search_type argument. This produced 7,441 training examples, including 6,764 cleaned original examples and 677 augmented or oversampled examples.

For the specialist model, we added 52 unique targeted examples: 26 for transfer_money, 6 each for calculate_end_of_service, calculate_customs, and check_insurance_coverage, 5 for compare_prices, and 3 for book_doctor_appointment. No new examples were added for order_food. After cleaning, the 3,553 original specialist examples were combined with the targeted examples and balanced across tools. Tools were initially oversampled toward 622 examples, with at most three occurrences of each source row. End-of-service termination values were further balanced, and selected targeted examples received between four and nine total training exposures. The final specialist training set contained 4,707 examples.

Model	Unique Aug.	Added Exp.	Final Train
Tool selection	30	30	10,580
General args.	264	677	7,441
Specialist args.	52	1,154	4,707

Table 2: Training augmentation and oversampling by model. In total, 346 unique targeted examples were added.

3.4 Query-Grounded Post-processing

After argument extraction, we apply a fixed set of lightweight, tool-specific post-processing rules. The rules use explicit evidence from the user query to remove unsupported arguments, recover explicitly stated values, and normalize recurring formatting inconsistencies. They modify only the predicted arguments and do not change the selected tool. Table 3 lists the complete set of rules used in the final pipeline. A final schema-level cleanup removes empty values and arguments that are not valid for the selected tool. On the development set, the rules modified 24 of the 545 predictions.

Tool	Post-processing rule
order_food	Remove the Arabic "restaurant" prefix from restaurant names.
calculate_customs	Remove the Arabic "device" prefix from product categories.
calculate_end_of_service	Map explicit termination cues to the corresponding schema value; remove ambiguous values.
transfer_money	Normalize IBANs by removing spaces and trailing .0.
calculate_zakat	Remove invalid weight-unit currencies and normalize crop to crops.
search_umrah_packages	Remove departure_date when no date is stated.
translate_text	Recover quoted text, clean quotation artifacts, and normalize the target language.
check_visa_status	Remove visa_number when no numeric identifier is stated.
search_hotels	Recover explicit guests and dates; remove unsupported guest or date arguments.
get_weather	Normalize days from explicit temporal expressions and remove invalid values.
get_qibla_direction	Remove the Arabic "city" prefix from city names.
convert_currency	Recover amounts from supported Arabic written-number expressions.
All tools	Remove empty values and arguments outside the selected tool schema.

Table 3: Query-grounded post-processing rules used in the final pipeline.

4 Experimental Setup

We used the training and development splits provided by the AISA-ArabicFC shared task (Nacar et al., 2026a). The training split was used for fine-tuning, the development split for model development and error analysis, and the blind test set was reserved for official evaluation. Training data were cleaned, augmented, and selectively oversampled as described in the System Overview. No external training data or generation APIs were used.

All three models were initialized from AISA-AR-FunctionCall-Think (270M) and fine-tuned with LoRA for one epoch using a batch size of 1. The tool-selection model used rank 8 with a learning rate of 2×10^{-5}; the general argument model used rank 8 with 1×10^{-4}; and the specialist model used rank 16 with 1×10^{-4}. Experiments were conducted on NVIDIA T4 GPUs using PyTorch 2.10.0, Transformers 5.15.0, Datasets 5.0.1, Accelerate 1.14.0, and PEFT 0.20.0; library URLs are provided in Appendix A.

Evaluation follows the official Track A metrics. FnAcc measures whether the correct function is selected, while ArgEM requires an exact match between the predicted and gold argument sets.

For development reporting, ArgEM is computed over the 500 positive function-calling examples only; the 45 negative examples are excluded from the ArgEM denominator.

The overall score combines both metrics as

$0.4\,\text{FnAcc} + 0.6\,\text{ArgEM}$.

5 Results

ArgTune achieved an overall score of 90.89% on the official test set, with FnAcc of 99.64% and ArgEM of 85.06%, ranking 8th in the shared task. On the development set, FnAcc reached 100.00% while ArgEM was 81.40%, resulting in an overall score of 88.84%. After correction, development ArgEM was lower than the blind test ArgEM by 3.66 percentage points, despite using development observations to guide augmentation and post-processing. Table 4 summarizes the development and official test results.

Split	FnAcc	ArgEM	Overall
Dev	100.00	81.40	88.84
Test	99.64	85.06	90.89

Table 4: ArgTune results on the development and official test sets (%).

5.1 Component Analysis

We analyze the main development steps that led from the initial single-model configuration to the final ArgTune pipeline. All comparisons in this section are based on the development split.

Single Model: Our initial configuration used a single model to predict the complete function call. It achieved 98.17% FnAcc but only 46.60% ArgEM, resulting in an overall score of 67.23%. The large gap showed that most remaining errors came from argument extraction rather than tool selection.

Task Separation: Based on this observation, we separated tool selection from argument extraction and trained a dedicated model for each task. Allowing the argument model to focus only on extracting argument values increased ArgEM from 46.60% to 52.60% on the development set. However, further tuning produced limited and inconsistent gains across individual tools.

Argument Specialization: Error analysis showed that argument mistakes were concentrated in seven tools. We also observed that changes intended to improve these tools could improve some while degrading others. We therefore separated argument extraction into a general model for the remaining tools and a specialist model for these seven difficult tools. This specialization increased ArgEM to 72.00% and formed the final three-model architecture of ArgTune. The large gain indicates that isolating the difficult tools allowed the specialist model to focus on their more challenging argument patterns without interfering with the remaining tools.

Targeted Augmentation: After establishing the three-model pipeline, targeted augmentation was applied to the remaining difficult cases rather than increasing the data uniformly. Additional examples and selective oversampling were introduced separately for tool selection and argument extraction. With targeted augmentation, the three-model pipeline reached 100.00% FnAcc and 79.60% ArgEM on the development set.

Query-Grounded Post-Processing: Finally, lightweight rules were applied to recurring argument errors that could be resolved directly from the user query. The rules mainly removed unsupported values and recovered or normalized explicitly stated arguments. Post-processing changed ArgEM from 79.60% to 81.40%, producing the final development score reported in Table 5.

Configuration	FnAcc	ArgEM	Overall
Single model	98.17	46.60	67.23
Task separation	98.17	52.60	70.83
Argument specialization	98.17	72.00	82.47
+ Targeted augmentation	100.00	79.60	87.76
+ Post-processing	100.00	81.40	88.84

Table 5: ArgTune development performance across system stages (%).

5.2 Error Analysis

Error analysis was performed on the full development split, which contains 545 examples: 500 positive function-calling examples and 45 negative examples. Among the 500 positive examples, 93 remained incorrect after the final query-grounded post-processing stage. In all 93 cases, the predicted tool was correct, indicating that the remaining errors were entirely due to argument extraction. We identified three main error types: incorrect argument values, missing arguments, and extra unsupported arguments. Table 6 summarizes their percentages and provides an example of each type.

Error Type	Count	%	Example
Wrong value	81	87.1	AED predicted as MAD.
Missing argument	10	10.8	days=1 missing from a "weather" query.
Extra argument	4	4.3	destination_country added to a customs query.

Table 6: Error types among the 93 remaining incorrect positive development examples; an example may contain multiple error types.

We further examined how these errors were distributed across tools. Table 7 shows the tools accounting for the largest shares of the 93 residual errors.

Tool	Errors	% of Errors
book_doctor_appointment	13	14.0
compare_prices	13	14.0
transfer_money	11	11.8
order_food	9	9.7
search_medications	7	7.5
calculate_customs	7	7.5

Table 7: Tools with the largest shares of the 93 residual argument errors on the positive development set.

Although specialization improved ArgEM, most of the tools with the largest remaining error counts were still specialist tools. This suggests that these tools remain particularly difficult for exact argument extraction.

Overall, the analysis shows that the main remaining challenge is not selecting the correct tool, but extracting the exact argument values required by the reference. Future improvements should therefore focus on more precise value extraction and schema-consistent argument generation.

5.3 Dialect Robustness

We additionally analyze ArgTune using the Track C dialect-robustness diagnostics provided by the shared-task organizers. Track C macro-averages the per-dialect Overall scores across MSA, Gulf, Egyptian, Levantine, and Maghrebi with equal weight. Table 8 reports ArgTune's per-dialect performance. The Maghrebi score of 0.735 and the resulting 0.184 dialect gap are based on only 11 test examples. Although this was the widest dialect gap among the top ten systems, the small sample size means that the result should be interpreted with caution.

Macro	MSA	Gulf	Egy	Lev	Maghrebi	Gap
0.8754	0.920	0.918	0.918	0.886	0.735	0.184

Table 8: ArgTune Track C dialect-robustness results.

Performance was similar across MSA, Gulf, and Egyptian, but lower for Maghrebi, resulting in a dialect gap of 0.184.

6 Conclusion

We presented ArgTune, a modular pipeline for Arabic function calling that separates tool selection from argument extraction and uses specialized modeling for difficult tools. ArgTune achieved an official test score of 0.9089, ranking 8th, with highly accurate tool selection while exact argument extraction remained the main challenge. Targeted augmentation and query-grounded post-processing further improved difficult cases. Future work will focus on improving argument extraction while reducing reliance on manually defined post-processing rules.

Limitations

While ArgTune achieved strong results, there remain several opportunities for further improvement. The targeted augmentation and query-grounded post-processing were designed around recurring patterns observed during development, and future work could explore broader augmentation strategies to improve coverage of less common query forms. In addition, although specialization substantially improved argument extraction, some of the more challenging specialist tools still show room for further accuracy gains. Finally, the Maghrebi test subset contains only 11 examples, so additional evaluation on a larger sample would provide a more reliable assessment of performance for this dialect.

Acknowledgments

We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, the baseline model, and the evaluation framework for this shared task.

Abstract

Arabic function calling requires models to identify appropriate tools and reproduce arguments in the exact representation expected by evaluators. This is challenging due to dialectal variation, lexical alternatives, and surface-form normalization. We present a hybrid system based on Qwen2.5-7B-Instruct adapted with 4-bit QLoRA, followed by conservative deterministic post-processing. The neural model generates flexible tool calls, while a lightweight deterministic layer parses, validates, and casts the output to improve compliance with the exact-match evaluation format. On the official blind evaluation, our system obtains 93.24% Function Accuracy and 58.38% Argument Exact Match (Track A: 72.32%, Track B: 71.37%). Error analysis indicates that many remaining failures arise from argument-surface mismatches rather than function-selection errors, supporting a design where generative modeling handles semantics while deterministic processing controls exact realization.

1 Introduction

Function calling enables language models to interact with external tools by generating structured function names and arguments (Schick et al., 2023; Patil et al., 2025). Rather than generating only natural-language responses, a model must identify whether a tool should be invoked, select the appropriate function, and populate its arguments according to a predefined schema. This capability is increasingly important for practical AI systems because reliable tool invocation forms a bridge between natural-language interfaces and executable software.

Arabic function calling introduces challenges such as regional dialects, spelling variations, and Latin-script transliterations (Nacar et al., 2026b). Under strict exact-match evaluation, a model can infer the correct semantic argument but receive zero credit if its surface form differs from the reference. The AISA-ArabicFC shared task provides a benchmark for this problem (Nacar et al., 2026a).

Our approach combines parameter-efficient adaptation of an instruction-tuned language model with a deterministic post-processing pipeline. The central design principle is separation of responsibilities. The neural model is responsible for interpreting the Arabic request and proposing the function call, while deterministic processing is responsible for producing a representation that satisfies the output contract. We deliberately use conservative repairs: the post-processing layer enforces schema compliance without inventing unsupported arguments. The primary finding of our submission is the substantial gap between function selection reliability and exact argument realization. This work builds upon recent efforts toward unified agentic architectures and reliable Arabic tool calling (Nacar et al., 2026c,b). To support reproducibility and future research, our complete source code and processing pipelines are publicly available at https://github.com/Sarahalo204/Optimal_AISA-ArabicFC.

2 Background

2.1 Task Setup and Dataset

The task frames function calling as structured prediction. Given an Arabic request and candidate schemas, the system outputs a JSON tool invocation. For example, consider the request:

أريد تحويل 1200 ريال سعودي إلى حساب
أحمد في البنك الأهلي

A corresponding structured prediction can be represented as:

```
{
  "tool_called": "transfer_money",
  "arguments": {
    "amount": 1200,
```

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1603–1607
October 28-29, 2026 ©2026 Association for Computational Linguistics

```
    "recipient_name": "Ahmed"
  }
}
```

This example illustrates an important property of the task. The Arabic request contains "أحمد", whereas the reference argument may use the Latin-script form "Ahmed". Both expressions refer to the same person, but under exact argument matching they are different strings. Consequently, the task involves two linked decisions: selecting the correct function and realizing its arguments in the expected surface form.

The task evaluates Function Accuracy (FnAcc) and Argument Exact Match (ArgEM). We utilize the official AISA-ArabicFC dataset (Nacar et al., 2026a), constructing a deterministic internal split (Train/Tune/Lockbox) to prevent public-development overfitting. Our team participated in all three evaluation tracks (Track A, B, and C).

2.2 Related Work

Research on tool use has progressed from action-oriented prompting to systems that explicitly connect language models with external tools. ReAct demonstrated the usefulness of interleaving reasoning and actions (Yao et al., 2023), while Toolformer investigated how language models can learn when and how to invoke external tools (Schick et al., 2023). Function calling has also motivated dedicated evaluation frameworks such as the Berkeley Function Calling Leaderboard (BFCL) (Patil et al., 2025), which provides a dedicated benchmark for evaluating function-calling capabilities and structured tool invocation.

Recent AISA work has proposed a unified architecture for agentic AI systems, while subsequent work has specifically investigated reliable Arabic tool calling (Nacar et al., 2026c,b). Our work complements generative fine-tuning by showing that deterministic post-processing can improve exact-match surface realization.

3 System Overview

3.1 Architecture

Our system follows a two-stage hybrid pipeline, illustrated in Figure 1.

The neural generator interprets the request, while the deterministic optimizer enforces the structured representation.

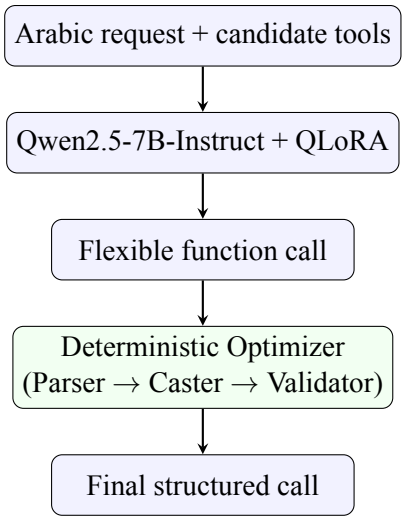

Figure 1: Overview of our Generative-Optimizer pipeline.

3.2 Neural Generator (QLoRA)

We use Qwen2.5-7B-Instruct (Qwen et al., 2024) as the base model. Rather than relying on constrained decoding, we trained the model to output flexible, easily parsable text:

```
TOOL_CALL(order_food,
meal="Kabsa")
```

The model was adapted using 4-bit QLoRA (Dettmers et al., 2023; Mangrulkar et al., 2022), optimizing the standard supervised fine-tuning objective. For Track B evaluation, the model responded to the track-specific prompt by generating a free-form reasoning trace (rationale) prior to outputting the structured tool call. Our deterministic Regex Parser isolated the tool call from this preceding text, allowing the official evaluator to compute the ThinkRate.

3.3 Deterministic Optimizer

The optimizer contains three components that process the neural output:

- **Regex Parser:** Extracts the function name and arguments, safely ignoring conversational hallucinations.
- **Schema Caster:** Dynamically checks generated values against the expected schema, casting types (e.g., strings to integers) when supported.
- **Validator and Normalizer:** Applies deterministic checks, removes Arabic diacritics (Tashkeel), and applies task-supported temporal mappings (e.g., anchoring dates to 2023).

This conservative repair strategy prevents the optimizer from introducing values that are not supported by the defined repair rules.

4 Experimental Setup

4.1 Data Protocol and Metrics

The official training dataset of 10,550 instances was internally split using a strict 80/10/10 ratio to create the Train (8,440), Tune (1,055), and Lockbox (1,055) partitions using seed 20260618 (Table 1). The public development set was only used post-freeze. To maintain strict evaluation integrity, we did not retrain the final model on the full 10,550 split prior to submission. The shared task evaluates systems across three tracks. Track A (Core) computes the Overall score as $0.40 \cdot \text{FnAcc} + 0.60 \cdot \text{ArgEM}$. Track B (Reasoning) includes the reasoning-trace rate, computed as $0.30 \cdot \text{FnAcc} + 0.50 \cdot \text{ArgEM} + 0.20 \cdot \text{ThinkRate}$. Track C (Dialect Robustness) measures the macro-average of per-dialect Overall scores (MSA, Gulf, Egyptian, Levantine, and Maghrebi).

Split	Size	Role
Train	8,440	Model training
Tune	1,055	Configuration selection
Lockbox	1,055	Internal confirmation

Table 1: Internal development splits.

4.2 Training Configuration

We fine-tuned the model for 3 epochs using a learning rate of 2×10^{-4} on a single NVIDIA A100 (40GB) GPU. Table 2 outlines the exact configuration used for the QLoRA adapter. No external instruction-tuning dataset was used. We utilized the following libraries for adaptation: `transformers` (v4.45.2), `peft` (v0.13.2), `bitsandbytes` (v0.44.1), `trl` (v0.11.3), and `torch` (v2.5.0). During inference, we applied greedy decoding (temperature=0.0, top_p=1.0) to maximize output determinism.

Parameter	Value
Base model	Qwen2.5-7B-Instruct
Adaptation	4-bit QLoRA
LoRA rank	16
LoRA alpha	32
LoRA dropout	0.05
Target modules	`q_proj`, `v_proj`
Epochs	3
Learning rate	2×10^{-4}
Max sequence length	512
Batch size	8
Gradient accumulation	2
Seed	20260618
Objective	Full LM

Table 2: Selected training configuration.

5 Results

5.1 Official Results

Table 3 reports our official blind-test results. The system achieved 93.24% Function Accuracy (FnAcc) and 58.38% Argument Exact Match (ArgEM). For Track B, the system achieved a ThinkRate of 71.02%. For Track C, the system obtained a Macro score of 0.6950 with a gap of 0.128 across dialects. The submitted leaderboard record places our system at **Rank 17** globally. Notably, we observed a substantial performance degradation in ArgEM between our internal lockbox (81.53%) and the official blind set (58.38%). We hypothesize that this gap may reflect differences between the internal development setting and the official blind evaluation, including possible differences in schema coverage and dialectal variation. However, as we did not conduct a controlled raw-model comparison on the blind set, this attribution to schema and dialect shift remains explicitly untested. The gap between FnAcc and ArgEM indicates that, for our system, function selection was substantially more reliable than exact argument realization.

Track	Rank	Overall	FnAcc	ArgEM	Additional Metric
Track A	17	0.7232	0.9324	0.5838	–
Track B	17	0.7137	0.9324	0.5838	0.7102 (ThinkRate)
Track C	21	0.6950	–	–	0.128 (Dialect Gap)

Table 3: Official blind-test results across all three tracks.

5.2 Internal Ablation

Table 4 shows that our default conservative ruleset (`accepted`) provided a marginal but stable improvement in ArgEM (from 81.34% to 81.53%) on the lockbox. Although the deterministic layer's quantitative contribution to ArgEM is modest, it provides a rule-based mechanism for enforcing schema compliance within the supported repair rules. Indeed, a more aggressive ruleset (`surface_v2`) degraded ArgEM on the lockbox, reinforcing the necessity of conservative post-processing.

Configuration	FnAcc	ArgEM	Track A
G0 raw	0.9991	0.8134	0.8877
G0 + accepted	1.0000	0.8153	0.8892
G0 + `surface_v2`	1.0000	0.8077	0.8846

Table 4: Internal lockbox ablation results.

5.3 Error Analysis

Post-submission analysis of the development references identified several recurring error categories:

- **Lexical and Surface Mismatch (22 cases, 35%):** Predictions like "طبيب الأطفال" failed against references like "طب الأطفال".
- **Temporal Representation (18 cases, 28%):** A recurring failure involved converting Arabic expressions into normalized English/ISO formats (e.g., "بكرة" vs `"tomorrow"`).
- **Unwanted Inference (14 cases, 22%):** The model occasionally hallucinated default values for optional arguments that the reference deliberately omitted.
- **List Serialization (9 cases, 15%):** Minor formatting differences in array structures, such as comma spacing or conjunction preservation, caused strict ArgEM failures.

6 Conclusion

Our hybrid Arabic function-calling system successfully separates semantic generation from exact surface realization. While our hybrid system achieves highly reliable function selection (93.24%), the strictness of Argument Exact Match (58.38%) highlights the challenges our system encountered in handling transliteration, lexical variants, and temporal normalization. Future work should focus on schema-aware normalization mechanisms that bridge this realization gap.

7 Limitations

Our hybrid approach relies on a deterministic post-processing pipeline whose coverage is limited by the rules defined for the observed schemas and data. Consequently, the system may struggle to generalize to entirely novel API schemas or dialectal variations that are not covered by the implemented normalization rules. In addition, because the post-processing strategy is intentionally conservative, semantically correct but lexically distinct arguments, such as unseen synonyms or complex transliterations, may remain unresolved without explicit rules. This limitation can reduce Argument Exact Match even when the generated function and the underlying argument meaning are correct.

Acknowledgments

We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, the baseline model, and the evaluation framework for this shared task. We also thank Zakariya H. for his valuable assistance, helpful feedback, and support.

A Low-Level Replication Details

This appendix provides low-level replication details not essential to the main concepts of the paper, ensuring full reproducibility.

Dataset and Evaluator: The experiments are tied to the following revisions:

- Dataset: `1a5e5f8a9eeadd996118a8a86f72c4285047a00e`
- Evaluator: `f73d1f95d2ccd3219e01cf2aa68173018acd9e0d`

The internal deterministic split utilizes seed `20260618`.

Models and Hyperparameters: The selected run is `G0-qwen2.5-7b-qlora-3ep`. We utilized the `paged_adamw_32bit` optimizer. The components are:

- Base model: `Qwen/Qwen2.5-7B-Instruct` (revision `a09a35458c702b33eeacc393d103063234e8bc28`)
- Adapter: `arabic-aisa/arabicfc-7b` (revision `57aa2ab514e8fca42a5643df3fec8b0157b5437d`)

Ruleset Selection and Validation: The default `accepted` ruleset contains only narrowly supported rules derived from the training data and schema. The `surface_v2` ruleset was retained separately because it produced stronger public-development results but lower internal lockbox performance, which informed our conservative final selection. All configuration hashes, adapter revisions, and post-processing rule hashes are recorded in our project manifests.

Yalla at AISA-ArabicFC: Argument-Focused Fine-Tuning and Per-Argument Ensembling for Arabic Function Calling

Manish Joshi
Independent Researcher
manishinuae@gmail.com

Abstract

We describe the Team Yalla submission to the AISA-ArabicFC shared task on Arabic function calling, which ranked second in both tracks (0.9273 Track A, 0.9395 Track B), within 0.0006 of the winning system. The headline metric, exact argument match (ARGEM), is unforgiving: a single wrong surface form loses the whole example. The provided targets bury the scored object inside a rationale: the tool name and argument dictionary are only 30.3% of the target characters. We trained on the 30.3%, which is our largest single gain (+0.020 ARGEM in a matched comparison). A matched follow-up shows that reasoning need not be removed entirely: emitting it after the arguments trails the JSON-only target by only 0.008 ARGEM. We add a reinforcement-learning stage that uses the official scorer as the reward, and combine three deliberately diverse fine-tunes with a per-argument majority vote, which repairs individual argument slots rather than choosing whole predictions. Every member is a LoRA fine-tune of a public 4B or 7B Qwen model trained on the official split alone, with no distillation and no external data. We note that two of the three voting members emit no rationale, so our Track B `think` field is attached after prediction from a separate reasoning-trained model whose predicted call for that row is identical: it is a post-hoc explanation, not the computation that produced the arguments. We report the experiments that failed alongside those that worked.

1 Introduction

Function calling asks a model to map a natural-language request onto a typed API call: decide whether any of the candidate tools applies, select one, and extract its arguments as JSON (Patil et al., 2023; Qin et al., 2024). The AISA-ArabicFC shared task (Nacar et al., 2026a) poses this problem for Arabic, including dialectal Arabic, with a deliberately strict headline metric: ARGEM counts an example only if the predicted argument dictionary matches the gold dictionary *exactly* after normalization. There is no partial credit; copying a name verbatim where the gold transliterates it, or resolving a relative date that the gold keeps as the uttered phrase, scores zero for the example.

Tool selection saturates quickly under fine-tuning (our final test FNACC is 0.9973, three errors in 1,125 rows), so what is left to win is argument surface forms. That is where the whole budget went.[1] We contribute four things. An **argument-focused objective** strips the reasoning field from the supervised target so that all of the loss lands on the scored JSON, worth +0.020 ARGEM in a matched pair and our largest single lever. A **placement analysis** shows most of that gain survives without giving up a per-example rationale: emitting it after the arguments costs only 0.008 (Section 4). A **GRPO stage** (Shao et al., 2024) takes its reward from the official normalizer's own exact-match check rather than a proxy (Section 5). A **per-argument vote** lets three diverse fine-tunes assemble a correct dictionary from models that are each wrong somewhere (Section 3). We also report what did not work. Two caveats apply throughout: the final ensemble was selected on the development set, and most ablations are single runs.

2 Task and Data

Each example provides an Arabic query and four candidate tool schemas; the system outputs `tool_called`, a candidate name or `none`, and `arguments`. The data and the surrounding agentic framework are described by Nacar et al. (2026b) and Nacar et al. (2026c). Track B additionally requires a non-empty Arabic reasoning field (`think`). Track A is scored as $0.4\,\text{FNACC} + 0.6\,\text{ARGEM}$ and Track B as $0.3\,\text{FNACC} + 0.5\,\text{ARGEM} +$

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1608–1613
October 28-29, 2026 ©2026 Association for Computational Linguistics

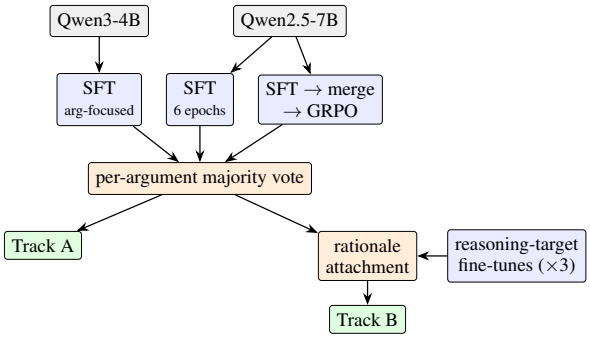

Figure 1: System overview. Three diverse LoRA fine-tunes vote per argument key. Because two members emit no rationale, the Track B `think` field is attached after prediction from a reasoning-trained model whose prediction for that row is identical; arguments are never modified by this step.

0.2 THINKRATE. The data comprise 10,550 training (50 negative), 545 development (45 negative), and 1,125 blind test examples across Modern Standard Arabic and Gulf, Levantine, Egyptian, and Maghrebi dialects. For experiments that needed a second held-out set we carved 1,007 rows out of the training split, leaving 9,543 for training; we refer to this as the validation split, and no model trained on the remaining 9,543 rows ever saw it. Annotation policy dictates that arguments are included only when explicitly stated by the user, and revised gold conventions keep many values verbatim as uttered (e.g. a relative date is kept as the phrase, not resolved to ISO format), which makes surface-form fidelity, rather than semantic correctness, the binding constraint.

3 System

Figure 1 shows the pipeline. All members are LoRA fine-tunes (Hu et al., 2022) (r=32 or 64, α=2r) of public Qwen bases (Qwen Team, 2024, 2025), trained on the official training split only and decoded greedily with vLLM (Kwon et al., 2023). The three voting members are chosen for diversity along every axis we could vary cheaply: base family and size (Qwen3-4B vs. Qwen2.5-7B), training length (3 vs. 6 epochs), and objective (supervised only vs. an added RL stage).

Per-argument vote. For each example, the plurality tool is selected first; among the members selecting that tool, each argument key is included if at least half of them (rounded up) produced it, and its plurality value is used. Voting per key instead of per prediction lets the ensemble build a fully correct dictionary from members that each err on different slots, which is what an all-or-nothing metric rewards. Value ties are resolved by member order, making order part of the recipe (Appendix B).

Track B rationale. Two of the three voting members are trained with the argument-focused objective and so emit no rationale, and we therefore had to supply the `think` field separately. We held this step to two rules. First, every rationale is produced by one of our own reasoning-trained fine-tunes. Second, a rationale is reused for a row only when that model's predicted tool and arguments are *identical* to what we submit, so it can never describe a call we do not make; this covers 97.7% of rows, and the remaining 2.3% receive a row-specific description derived from the submitted call itself. The step never modifies `tool_called` or `arguments`. We record per-row provenance for all 1,125 rows and release it with a verifier script. The procedure produces a distinct rationale for each example. It is a post-hoc explanation, not the reasoning that produced the arguments. Section 4 measures what a single model doing both would cost.

4 Argument-Focused Training

The distributed targets have the form <think> rationale </think> JSON. ARGEM is decided entirely by the serialized call $z = \{\texttt{tool\_called}, \texttt{arguments}\}$, so that is what we supervise. Standard fine-tuning with assistant-only loss instead minimizes cross-entropy over the full target $y = [r; z]$, a rationale r followed by z, of which z is only 30.3% of the characters. Our change is confined to the target: we keep the prompt masking and drop r,

$$\mathcal{L}(\theta) = -\sum_{t=1}^{|z|} \log p_\theta(z_t \mid x,\, z_{<t})\,, \qquad (1)$$

so that every supervised token belongs to the scored object $z = \{\texttt{tool\_called}, \texttt{arguments}\}$. Architecture, data, and decoding are untouched.

Table 1 shows the effect in matched pairs; training details are in Table 5 (Appendix A). Removing the rationale from the target is worth +0.020 ARGEM on the development set. This result, however, conflates two changes: (i) the loss budget shifts entirely to scored tokens, and (ii) at inference the argument tokens are no longer conditioned on a sampled reasoning prefix, removing a source of

Target format	Split	ARGEM
reasoning → JSON	dev	0.8440
JSON only (arg-focused)	dev	**0.8640**
JSON only (arg-focused)	val	**0.8352**
JSON → reasoning	val	0.8272

Table 1: Target-format ablation. Each pair is matched (Qwen3-4B, LoRA r=32, 3 epochs, identical training rows); the two pairs use different data subsets and evaluation splits, so they are comparable within, not across, pairs. Single runs.

drift between what the model says and what it extracts. Chain-of-thought prompting and sampling-based aggregation (Wei et al., 2022; Wang et al., 2023) improve reasoning-heavy tasks, but the interaction between generated rationales and strict structured output is less settled, which is what motivates the following ablation. To probe this we trained a third arm whose target is a single JSON object with the rationale as its *final* field: arguments are generated first, then the explanation. Putting the rationale last costs only 0.008 ARGEM against the JSON-only target (0.8272 vs. 0.8352 on our validation split), and still yields a genuine per-example rationale. Rationale-first and rationale-last were never compared in a single fully matched three-arm experiment, so we cannot cleanly separate the conditioning explanation from the loss-dilution one. The pair we do have does show that, on this task, most of the benefit is available without giving up a per-example rationale.

5 Scorer-in-the-Loop RL

Greedy decoding often misses surface forms that the model can produce: on development data an oracle over eight samples reached roughly 0.92 ARGEM against 0.85 for greedy. We therefore add a GRPO stage (Shao et al., 2024): the supervised LoRA is merged into the base weights, since a second adapter cannot be trained cleanly on top of a first, and a fresh LoRA is trained as the policy. For each prompt we sample G=8 completions at temperature 1.0 and score each with

$$r(y) = \begin{cases} 1 & \text{exact} \\ s(y) & \text{otherwise,} \end{cases} \qquad (2)$$

where *exact* means the tool is correct and the arguments match under the *official* scorer's comparison, and the shaping term $s(y) = 0.3\mathbb{1}[\text{tool}] + 0.1\mathbb{1}[\text{JSON}] + 0.1\mathbb{1}[\text{rationale}]$ gives partial credit.

Member	dev ARGEM
SFT, arg-focused, Qwen3-4B	0.8640
SFT, 6 epochs, Qwen2.5-7B	0.8420
SFT+GRPO, Qwen2.5-7B	0.8640
Per-argument ensemble	**0.8780**

Table 2: The submitted ensemble against its members on the development set. The vote beats its best member while containing the weakest.

	FNACC	ARGEM	Overall	Rank
Dev (Track A)	1.0000	0.8780	0.9268	–
Test (Track A)	0.9973	0.8806	0.9273	2
Test (Track B)	0.9973	0.8806	0.9395	2

Table 3: Final results. The winning systems scored 0.9279 (A) and 0.9400 (B); the gap to first place is roughly one test example's contribution.

Rewards are standardized within the group to obtain advantages, so no value network is needed. Rewarding the real metric matters: the normalizer defines equivalence classes (digit systems, boolean forms, list separators) that a generic string reward would miss, and the shaping term supplies gradient on near misses. In single runs GRPO moved ARGEM from 0.860 to 0.864 at 7B, the member we use, from 0.854 to 0.866 at 3B, and left 4B unchanged; these differences are small, unreplicated, and do not establish a scale trend. The stage earns its place less through that margin than by contributing a model whose errors differ from its supervised siblings, though we did not run a leave-one-out ensemble to confirm it.

6 Results

Table 2 sets the ensemble against its members: +0.014 over the best of them on development data, while containing the weakest. That margin is measured on the split the ensemble was selected on, and should be read as optimistic. The vote can nonetheless assemble a dictionary that no single member produced. Table 3 shows the final scores: second place in both tracks, 0.0006 and 0.0005 behind the winner. Three call/no-call errors cost us 0.0011 on Track A, more than that margin: a task where FNACC looks solved was still decided by FNACC. Test ARGEM (0.8806) and development ARGEM (0.8780) differ by 0.0026, which is well inside the variation we measure between reruns and does not by itself demonstrate generalization; what it shows is that no collapse occurred between the two splits. The winning combination was the best

of 2,508 member-subset and voting-rule combinations evaluated on 545 development examples, so its +0.014 margin over the best single member is an optimistic estimate, and we did not score individual members on the blind test. A useful control: a variant trained on train+dev reached 0.9260 development ARGEM, but a controlled pair showed +0.076 of that to be memorization, and on the blind test it did not beat the ensemble described here. The train-only ensemble remained our best system.

Dialect	n	n_+	FNACC	ARGEM
MSA	323	289	1.0000	0.9135
Gulf	75	72	1.0000	0.8750
Levantine	75	67	1.0000	0.7761
Egyptian	66	66	1.0000	0.8182
Maghrebi	6	6	1.0000	1.0000

Table 4: Per-dialect development results for the submitted ensemble (official scorer breakdown). FNACC is computed over all n rows and ARGEM over the n_+ positive rows only. The Maghrebi cell has six examples and should not be interpreted.

Dialects. We made no dialect-specific design choices; all members are trained uniformly on the mixed-dialect data. Table 4 reports the official per-dialect breakdown of our ensemble on the development set. Tool selection is uniform across dialects, but ARGEM is not: Modern Standard Arabic reaches 0.9135 while Levantine trails at 0.7761, and the official dialect-gap metric is 0.2239 (inflated by the six-example Maghrebi cell). Since FNACC shows no gap, the disparity lies in argument extraction and value rendering, not in tool selection. Where our three ensemble models disagree with each other, the disagreements are of exactly this kind: a date written with Arabic-Indic digits against the same date in ASCII digits, a dialectal time expression kept verbatim against its Modern Standard Arabic or English equivalent, a noun with and without the definite article *al-*, and two spellings of the same word that differ only in a diacritic. Each is a single character-level choice that the metric treats as a total loss. On Levantine the weakest member overall (0.8420) becomes the strongest (0.8060 vs. 0.7612 and 0.7463). We did not plan for that, but it is exactly the kind of disagreement the per-argument vote exists to cash in. The organizers' robustness ranking, a macro-average of per-dialect Overall, places us fifth with the widest maximum-minus-minimum gap, 0.140: among the five ranked teams we are first on Modern Standard Arabic and on Levantine, last on Gulf, and joint-last on Maghrebi. The width comes from the floor, not the ceiling, since our best dialect is 0.011 above the leading team's best while our worst is 0.053 below theirs. Which dialect is weakest is less clear, as Levantine is our worst on development data and our joint-best on test; we claim only that the spread is real and unaddressed. Closing it, for instance with dialect-balanced or dialect-augmented training, is the largest remaining gain we can identify.

What did not work. Measured and discarded: retrieval-augmented prompting at inference (-0.020 ARGEM), frontier-model distillation, deterministic post-processing, higher LoRA rank, longer SFT, longer or repeated RL, a binary RL reward, and adding the arguments-first model to the ensemble (its errors correlate with the supervised members').

Reproducibility. Decoding is greedy, but batched GPU inference is not bit-deterministic, so a rerun does not reproduce a submission file exactly. Three independent end-to-end reruns of our pipeline agreed with the submitted file on 99.0 to 99.5% of rows, and with each other over the same range, so the submitted file is an ordinary sample of this process rather than an outlier; tool selection matched on 100% of rows in every run. The organizers independently verified our submission from the weights and scripts we supplied, which we release publicly: code and training scripts at https://github.com/mcjoshi/ArabicFC, adapters and the merged base at https://huggingface.co/mojo28/aisa-arabicfc-ens-v3.

7 Conclusion

We never found a change of scale or architecture that mattered as much as where the training signal lands. Deleting the rationale from the target was worth more (+0.020) than an entire RL stage. The arguments-first ablation suggests systems can keep genuine rationales at a modest cost (0.008 ARGEM) by emitting them after the answer, a simple recipe for tasks where reasoning is wanted but strict output fidelity is scored.

Limitations

Most ablations are single training runs; the key comparison in Table 1 is matched but unreplicated,

and differences of 0.008 to 0.020 ARGEM correspond to roughly 8 to 10 examples. The final ensemble was the best of 2,508 candidates on the 545-example development set, and we did not score individual members on the blind test, so its margin over a single model is optimistic. The Track B rationale is a post-hoc explanation attached after prediction, and ensembling triples inference cost. Two omissions cost us more than any technique gained. Negative examples are 0.5% of training but 8.3% of development data, and three call/no-call errors on the test set were worth 0.0011 on Track A, more than the 0.0006 that separated us from first place. Bringing every dialect to the Modern Standard Arabic level would add roughly 0.037 ARGEM, though that rests on development cells as small as six examples. Finally, batched GPU inference is not bit-deterministic, so re-running our pipeline reproduces 99.0 to 99.5% of the submitted rows rather than all of them.

Acknowledgments

We thank the AISA-ArabicFC organizers for a well-run task, for the open scorer that made scorer-in-the-loop training possible, and for their reproducibility verification.

A Training and Decoding Details

The rank-64 member is the 6-epoch Qwen2.5-7B fine-tune; all other members use rank 32. The GRPO stage samples roughly 1,600 prompts from

the training split (4 prompts per optimizer step for 400 steps, 8 completions each).

B The Per-Argument Vote

Given member predictions $\{(t_m, a_m)\}_{m=1}^{n}$ for one example: (1) the final tool t^* is the plurality of $\{t_m\}$; if t^* is none, the arguments are empty; (2) otherwise, restrict to the members with $t_m = t^*$, and include argument key k if and only if at least half of them (rounded up) produce k; (3) the value for k is the plurality value among those members. Ties in steps (1) and (3) are resolved by member order, which therefore forms part of the recipe; we use the submitted order (arg-focused 4B, 6-epoch 7B, GRPO 7B).

Abstract

We describe Ṣaqr, ranked first on both scored tracks of the AISA-ArabicFC shared task on Arabic function calling, scoring 0.9279 on Track A and 0.9400 on Track B over a 1,125-instance blind test set. The system is deliberately plain: one Qwen3-4B model with LoRA, two epochs, provided data only. Our contribution is not the system but an accounting of where score comes from. We find that scale helped only up to a point in our single-run, cross-family comparison, and that the remaining gains came instead from inference-time decisions worth +0.0063 Overall A and +0.0223 Overall B (Appendix A) with no retraining. prefilling the reasoning trace so the model cannot skip it, and parsing arguments against the declared schema . We also report two properties of the data that bound any system's score: abstention is decidable from prompt structure without reading the query, and the gold annotation is self-inconsistent on precisely the slots that separate strong systems.

1 Introduction

Tool calling: mapping a request onto a structured function invocation, is the interface through which language models act rather than merely answer. Reasoning and planning pay off only once they become a correct call to the right tool with the right arguments (Patil et al., 2025). It is also the standard fix for hallucination and arithmetic error, offloading those to a database or calculator (Zhuang et al., 2023). For Arabic it is not yet routine: the best model scores 57% in English but only ~36% in Arabic on a 52-language benchmark (Kulkarni et al., 2025). The gap is not just training data, multilingual models still produce malformed Arabic calls, and English-learned skill transfers poorly (Ersoy et al., 2025). Systems must also handle dialectal/orthographic variation and arguments that may stay Arabic or canonicalise to English/ISO codes. AISA-ArabicFC (Nacar et al., 2026a) is the first shared task testing this across MSA and four dialects over 27 tools, extending (Nacar et al., 2026b) within (Nacar et al., 2026c).

It was sufficient to keep our winning system simple[1]: one open 4B model, LoRA on the provided split, no chat-template re-rendering, no ensembling, no unmeasured post-processing, each component beats its own absence before entering the pipeline. We rank first on Track A and Track B, third on the Track C diagnostic. Two findings:

1. **Scale helps, then stops.** In single, uncontrolled runs across model families, Overall A rises from Gemma-3 (270M, 1B) to Gemma-4 E2B and Qwen3-4B, then drops at Gemma-4 E4B (§5.2). We read this as a trend, not a controlled scaling law: the E4B point is one run and may be unfavourable (Limitations).
2. **Inference-time decisions were the last lever.** <think> prefill plus schema-typed parsing add +0.0063 Overall A and +0.0223 Overall B (§3.3).

2 Background

2.1 Task Setup

Given an Arabic dialect (MSA or Gulf/Egyptian/Levantine/Maghrebi) and four candidate schemas from a 27-tool registry (20 gold, seven distractor-only), a system outputs the correct function with typed key-value arguments, or the literal none. E.g., ابغى احجز عند دكتور اسنان يوم الاحد الساعة خمسة العصر maps to **book_doctor_appointment (specialty="Dentistry", day="Sunday", time="17:00")**. Two scored tracks: **Track A** (call+args, Eq. (1)) and **Track B** (call+args plus an Arabic **<think>** trace, Eq. (2)); see Appendix A. **Track C** (Cross-Dialect Robustness) is an automatic diagnostic, not a submission: per-dialect FnAcc/ArgEM with the max−min gap across dialects.

and BFCL (Patil et al., 2025) are standard but English-only; BFCL-V3 audits show 71.5% of entries contain schema/trajectory errors (Chen et al., 2026), and GRANITE-FUNCTIONCALLING (Abdelaziz et al., 2024) likewise. Under paraphrase and toolkit expansion, SOTA models degrade sharply, 70–90% of errors from argument-value mismatches (Rabinovich and Anaby-Tavor, 2025) — motivating our schema-typed post-processing and dev-grader checkpoint selection.

Multilingual and Arabic tool calling. MASSIVE-Agents (Kulkarni et al., 2025) covers 52 languages but shows a severe low-resource cliff. Ersoy et al. (2025) translate Glaive/xLAM for Fanar; native data beats translated for argument accuracy. Nacar et al. (2026b) introduce AISA-AR-FunctionCall, underlying AISA-ArabicFC, cutting parse failures from 87% to under 1% via full fine-tuning of a 270M FunctionGemma. We instead LoRA-adapt Qwen3-4B and report a call-only vs. reasoning-primed comparison not previously reported for Arabic function calling.

3 System Overview

Our system is a single pipeline: `unsloth/Qwen3-4B-Instruct-2507` (Qwen Team, 2025), LoRA-fine-tuned directly on the shared task's **AISA-ArabicFC**[2] (Nacar et al., 2026b), This model was selected empirically: we fine-tuned and evaluated a sequence of candidate base models on dev before settling on it (Table 2). We use no additional labelled data; the only external resources are the base models' pretrained weights, the Unsloth kernels, and the official grader (§4). Figure 1 shows the pipeline.

3.1 Training Phase

We trained and scored several base models on dev (Table 2) — and kept the one with the highest Overall A. Qwen3-4B was the final choice, and the checkpoint sweep below (§3.2) operates only on it.

Training uses the dataset's own DSL `text` field verbatim (tool declarations, user turn, **<think>**+call target) — calls use a bespoke serialisation, **<start_function_call>call:*name*{*k*:<escape>*v*<escape>}<end_function_call>**, with string arguments escape-wrapped and numeric arguments bare — only stripping a leading **<bos>** — no chat-template re-rendering. Since Gemma-style markers are plain multi-token text to the Qwen3 `transformers`-based (Wolf et al., 2020) tokenizer, we mask the SFT loss by locating the last token-id span of the response marker rather than by string search, keeping only the **<think>**+call span in the loss.

3.2 Checkpoint selection

Once Qwen3-4B was fixed as the base model, every saved checkpoint of its fine-tune is scored raw (no pre-/post-processing) on dev with the official grader; the checkpoint with the highest resulting Overall A is carried into test inference. This isolates checkpoint quality from anything the inference pipeline could add.

3.3 Inference Phase

Only after the checkpoint is frozen do we layer on three inference-time components. Their combined effect on dev is +0.0063 Overall A and +0.0223 Overall B (Table 2, last two Qwen3-4B rows).

Think priming. We append `\n<think>\n` to each prompt so the model's first generated token continues an already-open reasoning block rather than deciding whether to open one. Without this, the model occasionally skips reasoning entirely, dropping ThinkRate below 1.0; with it, ThinkRate reaches 1.0000 on both dev and test. Since Track B weights ThinkRate at 0.20 (Eq. (2)), this single change accounts for the majority of the Overall B gain.

Schema-typed argument parsing. A naive parser that applies `int()` when no decimal point is present destroys leading zeros on identifier fields: gold `00112233` becomes `112233` and can never match. Our parser instead reads each tool's declared parameter types from the schema at inference time and casts accordingly: fields declared as STRING, along with a fixed set of twelve identifier fields[3], are kept as strings verbatim. NUMBER and INTEGER fields are cast via `float()` after translating any Arabic-Indic digits (٠–٩) to Western digits. Untyped values fall back to the naive heuristic. On the blind test set, this parser altered 191 of 1,125 argument sets relative to the naive baseline, the vast majority being identifier fields whose leading zeros were preserved.

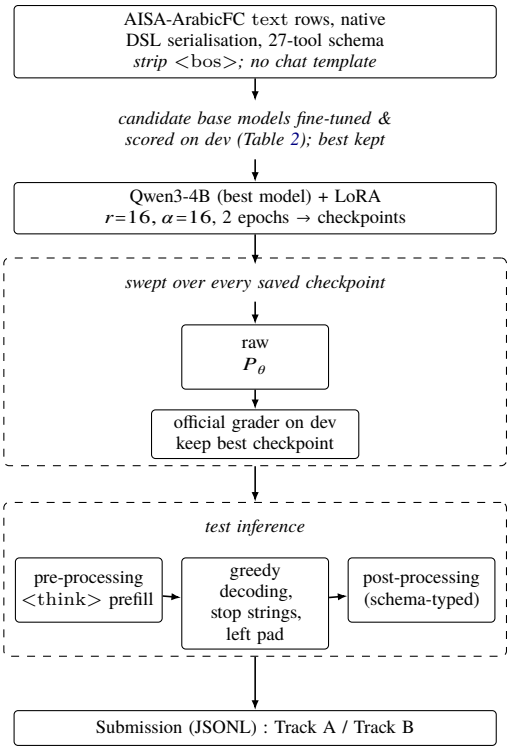

Figure 1: Pipeline.

Greedy decoding with structural stops. Generation uses greedy decoding (do_sample=False), a cap of 300 new tokens, and stop strings on <end_function_call> and <end_of_turn>. Padding and truncation are both set to left: right-truncation would cut the trailing <start_of_turn>model marker that separates prompt from generation.

4 Experimental Setup

4.1 Data Preparation

All three splits share the same preprocessing — only the leading <bos> literal stripped, no chat-template re-rendering (§3.1) — but are consumed differently: training tokenizes and masks the full text field, while dev/test generation uses only the prompt prefix up to and including <start_of_turn>model (tool declarations + user turn), obtained by splitting each row's text on that marker. Sequences truncate at max_seq_length = 2048 (max observed on dev: 944 tokens).Test is blind and scored once.

4.2 Training Configuration

We used base model unsloth/Qwen3-4B-Instruct-2507, LoRA (r=16, α=16, dropout 0) on the attention and MLP projections, 2 epochs (1,320 steps) at effective batch size 16, learning rate 2e−4 with a cosine schedule and 20 warm-up steps, AdamW-8bit optimizer, and hardware acceleration through Google Colab with A100 GPU via Unsloth[4] (Unsloth AI, 2024). Track A/B share one checkpoint and generation, differing only in whether think is included in the JSONL record.

4.3 Evaluation Metrics

Official metrics: FnAcc, ArgEM (grader-normalized names/dates/ currencies/numerals/lists), ThinkRate, Overall A/B, per-dialect FnAcc/ArgEM, and accuracy gaps (gap_fnacc, gap_argem). Grader fetched at run time from the shared task's HF Space[5] and called unmodified; implementation details in the grader itself, not reproduced here for space.

5 Results

5.1 Official results

Our system was evaluated on both development and test sets, achieving the following results:

Split	O_A	O_B	FnAcc	ArgEM	Think	$\text{Macro}_{\text{dial}}$
Dev	0.9316	0.9430	1.0000	0.8860	1.0000	0.9201
Test	0.9279	0.9400	0.9973	0.8816	1.0000	0.8994

Table 1: Dev vs. official blind test. O_A/O_B=Overall A/B; $\text{Macro}_{\text{dial}}$=macro-avg. per-dialect Overall.

We rank **1st on Track A** , **1st on Track B** , and **3rd on the Track C** . so with ThinkRate and FnAcc pinned at 1.0000, **ArgEM is the only lever left**: one more correct row is worth $0.6/n_+ \approx$ 0.0006 Overall A.

Test FnAcc (0.9973) is a hair below dev's 1.0000 : a handful of function-selection misses appear only on the blind set, while ArgEM held nearly flat (Δ=−0.0044), so the checkpoint selected on dev generalised with minimal loss.

5.2 Ablations

Scale helps until it does not. Table 2 shows the full trajectory. Overall A rises monotonically across Gemma3 270M → 1B → Gemma4 E2B → Qwen3-4B The exception is instructive: Gemma4 E4B, the largest model we trained, scored below E2B at roughly twice the compute. This

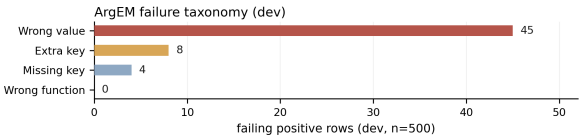

Figure 2: ArgEM failure taxonomy, dev split.

can be consistent with the ceiling being set by data quality rather than capacity.

Model chosen but the gains don't stop. The inference pre / post-processing (§3.3) move Qwen3-4B from raw 0.9253/0.9207 to 0.9316/0.9430 Overall A/B on dev +0.0063/+0.0223 improvement with no retraining.

5.3 Error Analysis (dev split)

FnAcc is 1.0000 on all 545 dev rows in every dialect , so all remaining error lives in args_match: of 500 positive rows, 57 fail ArgEM, split **wrong_value** 45 (79%), **extra_key** 8 (14%), **missing_key** 4 (7%), **wrong_function** 0 (Figure 2). Errors concentrate in three tools with free-text, boundary-sensitive arguments: compare_prices (42%), calculate_customs (38%), order_food (33%) while the fourteen tools whose sole argument is a verbatim ID or city are error-free. Two failure modes recur: **span-boundary** disagreement, where gold itself is inconsistent ("قارن لي أسعار جهاز آيفون في مصر والسعودية" takes country=مصر, while a near-identical query elsewhere takes both countries), and **list-serialisation** drift, e.g. gold شيش طاووق وكوكاكولا vs. predicted شيش طاووق, كوكاكولا for order_food.items — model and annotation disagree whether و ("and") or a comma delimits a list, and gold uses both conventions elsewhere. These read as un-normalised targets more than model failures. canonicalising training targets is the most promising next step (§6).

Abstention is structurally signalled. A no-call instance is identifiable directly from the text column: it contains no <start_function_declaration> marker, while every positive renders four. The classes separate perfectly on the labelled splits (train 50 negatives vs. 10,500 positives; dev 45 vs. 500), and the blind test partitions the same way (125 of 1,125 rows carry no declaration). Abstention is therefore decidable from prompt structure without reading the query.

5.4 Cross-Dialect Robustness (Track C)

We post the best MSA, Egyptian, and Levantine score of the top three teams, but the widest spread (gap=0.136 vs. 0.077/0.093 for 1st/2nd), driven by Maghrebi (0.806), is why we place 3rd despite leading on three of five dialects. Maghrebi is just 1.3% of the corpus and the weakest dialect for all, pointing to data scarcity rather than a pipeline-specific flaw; on dev this appears as one miss in six rows, consistent with sample-size noise.

5.5 The annotation ceiling

Part of the residual error is unrecoverable. Three development queries state that employment ended by contract expiry: وسبب الفصل إنهاء عقد (38), مع إنهاء عقد (63), and النوع إنهاء عقد (243). Yet gold records termination_type=end_of_contract for the first and omits the field for the other two; across the 23 instances of that tool it is present in 15. The weather tool's days=1 default is mandated in the prompt but appears in only four of nine development instances. There's no single choice that gets both right. We also observed instances labelled MSA whose queries are plainly Egyptian.

The top two teams have identical FnAcc (0.9973) and ThinkRate (1.0000), so their entire margin is ArgEM: 0.0006 Overall A and 0.0005 Overall B, the weight of a single argument row ($0.6/n_+$ and $0.5/n_+$ with $n_+ = 997$). These argument slots are exactly the inconsistent-gold tools of §5.3, so the gold annotation is self-inconsistent on the very slots that separate the top systems.

6 Conclusion

We presented Ṣaqr, a deliberately plain system for Arabic function calling: a single LoRA-adapted

Qwen3-4B trained for two epochs on the provided data only. It ranks 1st on Tracks A and B, and 3rd on Track C. Our accounting of where the score comes from yields three points: scale helps only up to a point (§5.2); the final gains came from inference-time pre- and post-processing, with no retraining; and, with FnAcc and ThinkRate saturated, the residual error is entirely argument-level, confined to tools whose gold annotation is itself inconsistent which bounds any system. Future work takes three directions. First, a larger adapter: r=32 rather than the submitted r=16, which we could not afford to evaluate. Second, ensembling several checkpoints or base models, which we excluded by design (§5.3). Third, targeted data augmentation for Maghrebi, our weakest dialect and just 1.3% of the corpus, generated for every tool. (§5.4).

Limitations

All training ran on a single Google Colab A100 under a constrained GPU budget, which fixed our search space more than our findings did: one LoRA configuration (r=16, α=16), two epochs, and a single run per base model, with no seed replication and no hyper-parameter sweep. Differences between nearby configurations are therefore single-run point estimates — the E4B result in particular may reflect an unfavourable run rather than a property of the model. With more compute we would train longer, sweep the adapter settings, and repeat each configuration across seeds. Our error analysis is likewise confined to the 545-row development split, since test labels are withheld.

Acknowledgments

We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, the baseline model, and the evaluation framework for this shared task.

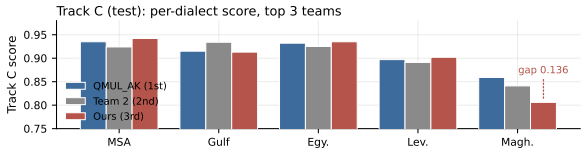

Figure 4: Track C (test), per-dialect score for the top 3 teams.(§5.4).

token-id sequence, and set labels to the ignore index up to and including it; assert no instance yields an empty answer span. No chat template is applied anywhere.

Gold value conventions. Verified without exception over all 10,500 positive training instances: schema STRING yields a string (16,514 values); NUMBER (2,983) and INTEGER (1,313) yield floats retaining the fractional zero. No gold value is ever an array. Arabic-Indic digits occur only inside string-typed values, including dates and identifiers, never in numeric fields.

Identifier fields kept as strings by our parser and compared as strings by the scorer: account_number, iban, id_number, insurance_number, iqama_number, national_id, passport_number, phone, phone_number, recipient_iban, reference_number, visa_number. The scorer additionally strips fourteen tool-scoped optional parameters from both sides before comparison; all remaining keys are compared under strict set equality.

Thakaa at AISA-ArabicFC: Convention-Aligned Prompting and the Limits of Argument Exact Match in Arabic Function Calling

{h.alqaeril, m.alamr, aldahlawi}@thakaait.net

Abstract

Argument exact-match (ArgEM) dominates the AISA-ArabicFC score. Under one prompt, a base `gemma-4-12B-it` reaches 0.9853 FnAcc but only 0.6940 ArgEM on dev, suggesting that argument convention rather than tool selection is the binding constraint. Fine-tuning on the provided train split raises ArgEM to 0.8880 while FnAcc increases only from 0.9853 to 0.9945, yet the model still fails 8.4% of the 10,500 positive training rows. Across rules, retrieval, prompting, selection, reranking, and fusion, dev-selected gains did not consistently transfer beyond development; smaller gains from other tested interventions remain unresolved. Explicit convention cards add 7.5 ArgEM points on a dev-selected 228-row subset for an unconfigured model, but give no measurable gain to the already configured pipeline. A scorer-equivalent gold answer occurs in a 20-sample pool for 34/56 (60.7%) rows missed by the raw fine-tune, but our selectors cannot exploit it. Our official prompt-only `gemma-4-31B-it` submission placed 6th of 17 on Track A, 5th of 17 on Track B, and 4th of 21 on Track C. The 12B fine-tune used for analysis was developed first but inadvertently omitted from the blind-test submission, so it has no official test score.

1 Introduction

Function calling asks a model to map a natural-language request onto a structured API call: choose the correct tool from a catalog, or abstain, and fill that tool's arguments. AISA-ArabicFC (Nacar et al., 2026a) poses this problem in Arabic across five dialect families (MSA, Gulf, Egyptian, Levantine, and Maghrebi) and eight service domains. Arabic adds representation load to the argument-filling half, and not where one might expect: the official normaliser already absorbs Arabic-Indic digits and hamza and alef spelling, so those cost nothing under this scorer. In our residual audit, the recurring mismatches are that list items take a comma or the clitic waw, which attaches to the following word; the definite article and generic head nouns are optional on entity values; and values may be written in Arabic or English. We treat this as systematic human label variation rather than random noise (Plank, 2022).

Function accuracy (FnAcc) scores the predicted tool over all rows, so hallucinated and missed calls are both penalised; argument exact-match (ArgEM) compares the whole argument dictionary on positive rows under a published normaliser. Track A ranks by $0.40 \cdot \text{FnAcc} + 0.60 \cdot \text{ArgEM}$, Track B reweights to $0.30 \cdot \text{FnAcc} + 0.50 \cdot \text{ArgEM} + 0.20 \cdot \text{ThinkRate}$, the fraction of rows carrying a reasoning trace, and Track C macro-averages per-dialect Overall A. Our strategy was deliberately simple: one model, no ensembling, no external data, and a few post-processing rules validated on the provided splits.

The dominant gap in this tested setup is argument convention rather than tool selection: under the identical prompt the base model already picks the right tool on 0.9853 of dev rows but matches only 0.6940 of argument dictionaries, and fine-tuning moves arguments while leaving tool choice essentially unchanged. Post-processing adds 0.2 points, and no rule we tested transfers from train to dev. We also report two distinct operational failures. During pre-submission evaluation, our chat endpoint appended a closed, empty reasoning channel; the fine-tune met an unseen prefix, skipped the trace it was trained to emit, and lost 3.8 ArgEM with no error raised. Separately, although we developed the 12B fine-tune before the 31B prompt-only pipeline, we inadvertently omitted it from the blind-test submission.

Two systems appear here and only one was scored. Table 1 and all official numbers are from the submitted prompt-only `gemma-4-31B-it`; Tables 2 and 5 and the residual analysis use a 12B

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1621–1634
October 28-29, 2026 ©2026 Association for Computational Linguistics

fine-tune developed first but omitted from blind-test submission, **except for the convention-card row in Table 5, which evaluates the configured 31B pipeline**. The 12B train, dev, and OOD measurements are not official test results. Re-running the submitted pipeline reproduces 983/1,125 scored calls; its prompt was not version-controlled at submission time and the remote serving state is unrecoverable. Appendix A documents what can and cannot be reconstructed.

The 12B LoRA is publicly available.

2 Background

Task setup. Each instance gives an Arabic query and four candidate tools with JSON schemas; the system outputs a tool name and argument dictionary, or `none`. The Levantine query بدي فندق بالدوحة من ١٨ ل ٢٢ نوفمبر (*biddi funduq bi-l-Dawha min 18 la-22 nufimbir*, 'I want a hotel in Doha from 18 to 22 November') maps to `search_hotels` with `check_in` = 18 نوفمبر and `check_out` = 22 نوفمبر ('18 November', '22 November'): the month is written once and distributed to both endpoints. The digit conversion is free; the month distribution is not.

Data and scoring. The data covers 27 tools over 8 domains, with 10,550 train, 545 dev and 1,125 blind test rows; seven catalog tools are never gold in the released splits and act as distractors. We infer, rather than directly observe, 128 negatives among the 1,125 test rows (11.4%) and therefore 997 positives, the ArgEM denominator; Appendix A reconstructs these counts from the published per-team scores. Negatives are 8.3% of dev and 0.5% of train. ArgEM is computed by an open normaliser that equates different writings of one answer: Arabic-Indic digits, orthographic variants, number words, set-valued fields and alias tables. We entered Tracks A and B; Track C is automatic.

Track	Weighting	FnAcc	ArgEM	Rank
A	0.40/0.60	0.9893	0.8676	**6/17**
B	0.30/0.50/0.20	0.9893	0.8676	**5/17**
C	macro per-dialect	n/a	n/a	**4/21**

Table 1: Official blind-test results for **the 31B prompt-only system**, the strongest of our three submitted `gemma-4-31B-it` variants ($n = 1{,}125$; leaderboard entry *Thaka*). Overall is 0.9163 on Track A, 0.9306 on Track B with ThinkRate 1.000, and 0.8978 on Track C, the macro-average of per-dialect Overall A. The ThinkRate of 1.000 includes traces reconstructed after decoding on rows that emitted none (Section 3), so it measures the presence of a trace and not its consistency with the call.

Relation to prior work. The task follows the AISA reference architecture (Nacar et al., 2026b) and the data-centric fine-tuning methodology behind its baseline (Nacar et al., 2026c). Prior benchmarks such as Gorilla (Patil et al., 2024) and ToolLLM (Qin et al., 2024) are English, and BFCL (Yan et al., 2024) relaxes argument comparison, matching syntax trees and accepting more than one gold value per field. Our results motivate evaluating the second option in a future task edition, without establishing its effect on leaderboard scores. Multilingual coverage has often been reached by translating English data (Chen et al., 2025). The closest independent precedent is Ersoy et al. (2025), whose Arabic error analysis attributes 50.2% of argument errors to paraphrase variance, a semantically correct value in the wrong surface form. Three mechanisms here are ours too: a structured reasoning template rather than free-form chain of thought (Wei et al., 2022; Dang et al., 2025), an Arabic trace before the call (Nacar et al., 2026c; Wei et al., 2026), and repeated-query weighting, related to hard-pattern oversampling (Hao et al., 2025) but not selected by a controlled difficulty score. Our abstention failure is the one Lin et al. (2024) predict, that tuning for function selection degrades irrelevance detection unless negatives are supplied explicitly (Wu et al., 2026). Prior work also trains granular sub-tasks jointly (Abdelaziz et al., 2024), which we do not. Our contribution is a quantitative account of how far annotation convention limits ArgEM under this evaluation protocol, together with the negative results that support it.

3 System Overview

The submitted system. Every leaderboard number here comes from a prompt-only pipeline over `google/gemma-4-31B-it` (Gemma Team, 2026), weights unchanged: greedy decoding under the convention-stating prompt described below, up to four exemplars retrieved per query from the public gold (train and dev for the test run; train alone for every dev number, so no dev query retrieves itself), one per candidate tool and only where the query overlaps it, so the mean is 3.2 and not every query gets four, then eight deter-

ministic post-processing stages, defined in Appendix A: six convention rules, `rare_key_drop`, and `value_canon`. One named rule is score-neutral; the candidate guard used by the fine-tune was not in this pipeline, although it would change no submitted call. Track B traces were completed after decoding: 47 of the 138 abstentions emitted none and received a fixed Arabic sentence, which is why ThinkRate is 1.000 rather than the 0.9582 the decode alone gives (Appendix A).

We entered three variants of this 31B prompt-only pipeline. This paper describes the 31B prompt-only system, the strongest official variant. The earlier 12B fine-tune was inadvertently omitted; the serving defect described in Limitations independently depressed its pre-submission dev measurement.

The fine-tune analysed here. Before developing the submitted 31B pipeline, we fine-tuned `google/gemma-4-12B-it` (Gemma Team, 2026). We did not fine-tune the 31B, which we could reach only as a remote inference endpoint, with LoRA (Hu et al., 2022) over a bfloat16 rather than a quantised base (Dettmers et al., 2023), taking loss on the response tokens only; the training stack is Unsloth (Han et al., 2023) over TRL (von Werra et al., 2020). The system prompt is written in English, carries Arabic terminology and worked examples, and states the annotation conventions explicitly, including schema corrections found by auditing gold (for example `calculate_zakat.type` takes `cash`/`trade`/`shares` rather than the schema's wording). The model emits an Arabic `<think>` trace then a JSON call, or `<no_tool_call>`.

Five deterministic steps follow the fine-tune's decode. (1) Candidate guard: a predicted tool absent from the row's candidate list, or naming one of the seven never-gold distractors, cannot score, so the row abstains. It was worth +0.4 points of FnAcc on the fine-tune's original decode and leaves the corrected decode at 0.9945. (2) Three convention rules, each gated net-positive on train and dev at submission time on the decode our serving defect had corrupted (Limitations). `natural_date` rewrites ISO dates into the natural `<day> <month>` form gold usually uses and strips zero-padded days (no gold date takes the natural form with one, though 84 gold dates are full ISO, and the comparator distinguishes the forms). `customs_origin_not_target` drops `destination_country` when the query marks that country as origin, and `drop_ungrounded_ids` drops identifiers absent from the query. Three further steps drop keys the scorer ignores per tool, fix numerals, currency, punctuation and argument types, and attach the Arabic think text of the model, reconstructed from the final call on rows producing none, which gives ThinkRate 1.000.

After the test phase closed we derived five further rules (dev ArgEM 0.8900 to 0.9020 on the corrected decode). They are part of neither system as evaluated and are reported separately throughout.

4 Experimental Setup

We trained on the provided train split only. The mixture has 12,306 rows over 10,090 unique queries, including 2,216 repeated-query copies inherited from earlier mixture construction rather than a controlled difficulty sampler; the full distribution is in Appendix A. Only 11 copies are negative, so the negative rate remains 0.50%. A row survives only if its rendered query occurs in the provided splits, and the builder aborts if any kept query is test-only, so the guarantee rests on raw query text rather than row identifiers. Every row maps into official train. Test gold was never released. Appendix A gives hyperparameters, software versions and the reproduction procedure. We use the organizers' published scorer unmodified.

Additional resources (post-hoc only). Beyond the provided splits we use one external corpus (Haroon, 2024), strictly for post-competition analysis (Section 5.2). It was not used for training, model selection, rule gating, or any submitted prediction, and not to reconstruct gold for test items; queries overlapping the blind test (1,393 rows) or the provided splits (12,262) were removed before sampling.

5 Results

Table 1 gives the official blind-test results.

Which system these numbers describe. They come from the prompt-only `gemma-4-31B-it` pipeline of Section 3. The fine-tune analysed below was developed earlier but inadvertently omitted from the blind-test submission; it therefore has no official test score.

Leaderboard context. The Track A gap to first is 0.0116 (9 FnAcc and 14 ArgEM rows). Track C

is much less stable: its adjudicated labels contain 34 Maghrebi and 660 MSA rows, so one Maghrebi *FnAcc* error has 19.4 times the weight of one MSA FnAcc error. ArgEM leverage additionally depends on the per-dialect positive counts (Appendix B). Ranking is context here, not evidence for the argument-convention claim.

5.1 The residual on seen and held-out public data

The finished 12B system reaches FnAcc 0.9999 and ArgEM 0.9164 on all 10,550 training rows, versus 0.8880 ArgEM on held-out dev. This does not prove the target unlearnable: only 34 of 878 failures have contradictory duplicate-query gold, so most could be memorised by a larger fit. Under our tested configurations, improvements on training do not transfer to dev; Appendix C quantifies this system-specific result.

Is the residual reachable? Sampling 20 completions per dev positive at temperature 1.0, an answer equivalent to gold under the official `args_match` comparator appears in the pool for 34 of the 56 failing dev rows (60.7%, 95% Wilson CI $[0.48, 0.72]$), and an oracle over it scores 0.9560 on dev and 0.9680 on train. This is scorer equivalence, not byte-identical string equality.

No selector we tested exploits this pool: 289/500 rows have twenty identical samples, while a selector on the rest must win 34 failures without losing 162 greedy holds. Oracle@k can also exploit conflicting gold for identical queries, so we treat it as a diagnostic upper bound rather than an attainable selector result (Appendix C).

5.2 Ablation

Fine-tuning moves arguments far more than tool selection. The three shipped rules add one dev row once correctly served ($0.8880 \rightarrow 0.8900$); the five post-deadline rules add six ($0.8900 \rightarrow 0.9020$) and were never submitted. The fine-tune transfers to the independent annotation ($+14.5$ ArgEM, $+2.1$ FnAcc), whereas convention rules lose 2.0 points there; this is agreement, not correctness (Appendix D). Dev-gated rules also reverse on train: the five later rules fix/break 6/0 dev rows ($p = .031$) but 3/13 train rows ($p = .021$); the three shipped rules yield $+0.20$ dev and -0.04 train.

Table 2: Ablation of the **`gemma-4-12B-it` fine-tune**; ‡ is the 31B on dev with train-only retrieval. OOD is argument agreement on 571 independently annotated rows, not accuracy. † is post-deadline; Ov.A $= 0.40$ FnAcc$+0.60$ ArgEM. One run; sub-point effects are not separated from run variance.

5.3 Error analysis (dev, 500 positives)

After the later rules, 49/500 dev positives fail: 11 key-set errors and 38 value mismatches. Gold uses both forms in the largest classes: `get_weather.days` is valued on 535 rows and null on 114, while `order_food.items` is comma-joined on 344 and waw-joined on 126 (125 under a stricter token-initial regex). The comparator splits an attached waw only before a definite noun, so the same separator can be free or fatal. The organisers confirmed this asymmetry and corrected a future release (Appendix C). Our public-split measurements use the public scorer; the official scoring revision is unconfirmed. Also, 30 byte-identical (tool, query) groups carry comparator-distinct gold (76 rows); Appendix C shows that this self-conflict alone bounds little.

Table 5 inventories interventions against this residual. Its positive held-out entries were not significant under the reported paired tests, so smaller gains remain unresolved. A permitted, post-deadline synthetic-negative diagnostic, never submitted, improves train ArgEM by 1.20 points ($p = 6.0\times10^{-12}$) but moves dev by -0.40 ($p = .81$).

6 Conclusion

Positive held-out entries were not statistically significant under the reported paired tests; smaller gains remain unresolved. No tested selector exploited gold found in 20 samples, and multi-reference scoring remains untested. These are setting-specific results; the unsubmitted 12B has no blind-test score.

Limitations

Our conclusions about the limit are drawn from the train and dev splits, because blind-test gold was never released. What we can say about test rests on the published leaderboard aggregates, and our inference of the test negative count is a reconstruction from those aggregates rather than an observation.

Our dialect-level estimates are uncertain. We built no dialect-specific components, several per-dialect dev cells are small, and the participant-facing test file retains labels older than the final adjudicated labels. The organizers confirm that the official values reproduce under the corrected labels, but those row-level labels were not yet available to us; our per-dialect dev numbers are therefore diagnostic rather than predictive.

The 12B fine-tune was developed before the 31B prompt-only pipeline, but we inadvertently omitted it from the blind-test submission. This was an operational submission error, not a dev-based choice between the two systems. A separate serving defect, identified only after the deadline, affected its pre-submission measurement: the chat template appended a closed, empty reasoning channel, which suppressed the trace the fine-tune was trained to emit and depressed its score without raising an error. Neither issue changes the submitted 31B predictions or their official scores. Measurements involving the 12B in this paper use the corrected decode and are flagged where the defective and corrected decodes differ.

The external annotation we cross-check against is an independent labelling of overlapping queries, not a reference for the blind split, so it bounds annotation distance rather than correctness.

We did not implement the proposed field-level multi-reference comparator or rescore other teams. Competitor prediction files and adjudicated row-level test labels were unavailable, so we cannot establish its effect on Track A ordering; our quantified 0.40-point bound covers only byte-identical repeated queries on dev.

We evaluated a single fine-tuning run rather than multiple seeds, so run-to-run variance is not separated from the ablation effects we report, and rules gated on dev are not expected to transfer. ThinkRate measures the presence of a reasoning trace rather than its consistency with the emitted call, and some of our traces were reconstructed after the fact, so that score is not evidence of reasoning-action consistency.

Acknowledgments

We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, the baseline model, and the evaluation framework for this shared task. Releasing the scorer openly is what made the analysis in this paper possible.

A Reproducibility Inventory

Table 3 states, for each system in the paper, what data it saw, how it was adapted and how it was decoded.

Licensing. The LoRA adapter is released under the Apache License 2.0. It is a derivative of `gemma-4-12B-it` and is therefore additionally governed by the Gemma Terms of Use; the provided splits are released by the organisers under Apache 2.0.

Repeated-query weighting. The 12,306-row training mixture contains 2,216 copies beyond the first occurrence of a query. Of 1,877 repeated queries, 1,756 occur twice and 121 at least three times. The largest extra-copy concentrations are `get_qibla_direction` (331), `get_weather` (190), and `get_air_quality` (162). This is an inherited weighting, not a controlled hard-example sampler.

Blind-test denominator. Test gold was not released, so we infer the ArgEM denominator from the published scores. Requiring one integer denominator to reproduce all 17 Track A ArgEM values uniquely gives 997 in the range 900–1,125; FnAcc uniquely gives 1,125. We therefore infer 997 positives and 128 negatives rather than treating those counts as directly observed.

Hyperparameters. LoRA rank 64, α 128, dropout 0.05, rsLoRA scaling (Kalajdzievski, 2023), applied to all linear layers of the language tower (attention and MLP; vision layers frozen), giving 262M trainable parameters, 2.15% of the 12.2B total. Three epochs, 1,155 optimizer steps (385 per epoch), per-device batch 1 with gradient accumulation 16 over two GPUs for an effective batch of 32, peak learning rate 5×10^{-5}, cosine schedule with 10% warmup, weight decay 0.01, gradient clipping at 1.0, 8-bit AdamW (Dettmers et al., 2022), NEFTune (Jain et al., 2024) disabled, seed 42, bfloat16, maximum sequence length 4096 at training (the longest mixture row is 4,005 tokens, so no row is truncated) and 6144 at inference. Loss at the final logged step is 0.0035; the mean over the whole run, as the trainer reports it, is 0.2245. Training took 37.5 hours on 2×NVIDIA RTX A6000 (48 GB).

Inference. vLLM 0.27.1 (Kwon et al., 2023), `--max-model-len 6144`, `--gpu-memory-utilization 0.80`, greedy decoding, seed 13, `max_tokens` 768. Output is byte-identical across reruns on fixed hardware and configuration. Decode through `/v1/completions` with the prompt rendered exactly as in training, or set

System	data use	training or retrieval	inference and post-processing
31B, submitted	provided train and dev; no test, no external data	`gemma-4-31B-it`, weights unchanged; up to 4 exemplars per query, one per candidate tool, from train+dev for the test run and train alone for dev measurement; on test the counts are 1/2/3/4 on 17/174/503/431 rows (mean 3.20, four on 38.3%)	greedy, temperature 0; no candidate guard; six convention rules (`procedure_strip`, `medication_strip`, `customs_currency`, `quran_search_type`, `zakat_type_canon`, `termination_canon`), then `rare_key_drop` and `value_canon`; the later trace-filling script was not recovered
12B, developed first; unsubmitted	provided train only; mixture of 12,306 rows over 10,090 unique queries, 0 dev-only and 0 test-only	`gemma-4-12B-it` LoRA rank 64, α 128, 3 epochs, 1,155 steps, seed 42, bf16, 37.5 h on 2×A6000	vLLM 0.27.1, greedy, seed 13, `max_tokens` 768; decode in the training format; candidate guard; three convention rules

Table 3: The two systems and their status. The 12B fine-tune was developed first but inadvertently omitted from the blind-test submission; only the 31B has an official test score. The 12B carries the train, dev, and OOD analyses.

`enable_thinking` to true in the request's `chat_template_kwargs`: without one of the two, Gemma-4's chat template appends a closed, empty reasoning channel, the model skips the trace it was trained to emit, and ArgEM falls by 3.8 points with no error raised. The defect affects fine-tuned checkpoints only. Our officially scored file was produced by the prompt-only pipeline, which never had a training format to mismatch, so the leaderboard figures are unaffected by it; what the defect cost was 3.8 points in the 12B's pre-submission dev measurement, not any part of the score of the 31B system we submitted.

Gemma-4's native tool protocol. We tested whether our bespoke format costs anything against the protocol Google trained in, serving the base model with `--tool-call-parser gemma4`, `--reasoning-parser gemma4` and `--enable-auto-tool-choice` so that calls arrive already parsed. On dev it is worse on both axes: FnAcc 0.8330 and ArgEM 0.5400 with thinking disabled, 0.7486 and 0.4760 with it enabled, against FnAcc 0.9853 and ArgEM 0.6940 for the same base model under our prompt and JSON format. The comparison is not like-for-like, since both the input rendering and the output grammar differ. It shows only that this native-protocol configuration is not a cheaper route to our reported performance; it does not isolate input format from output grammar or prove that formatting cannot contribute to the argument gap.

train ($n = 10{,}550$)	FnAcc	ArgEM
31B, prompt-only	0.9930	0.8132
12B, fine-tuned	0.9999	**0.9164**

Table 4: Both systems scored on the full training split.

31B against 12B, measured. Only the 31B was scored on blind test, but the main-paper dev comparison and every other split we can measure put the 12B fine-tune ahead of the 31B prompt-only pipeline:

The 31B dev figure uses a train-only retrieval pool; with dev in the pool it reaches 0.8640. On the 1,000 test queries the external annotation covers — a different sample from the 571 dialect-balanced OOD rows in Table 2 — the 31B agrees with that annotation on 0.9860 of tool names and 0.6130 of argument dictionaries and the 12B on 0.9940 and 0.6300, so the 12B had the higher agreement with that annotation. This is not an official test score and does not establish a test advantage. The 12B advantage is 2.6 points of dev ArgEM, 10.3 of train, and 1.7 of external argument agreement, against a model 2.6 times its size. The 12B was inadvertently omitted; only the 31B was submitted.

Abstention, and what fine-tuning changed. Dev FnAcc is 0.9853 for the base model and 0.9945 for the fine-tune, but the errors behind those two numbers are disjoint in kind. All 8 of the base model's are missed calls on positive rows and none are false calls; all 3 of the fine-tune's are false calls on negative rows and none are missed. Fine-tuning did not leave tool selection untouched: it moved the failure from under-calling to over-calling, which is what Lin et al. (2024) predict when a model is tuned for selection on a mixture carrying almost no negatives (0.50% of train, against 8.3% of dev). We did not pursue a negatives-augmented fine-tune before the submission deadline. The post-deadline diagnostic in Appendix C tests that lever; on the blind test the FnAcc component of our gap to first place is 9 rows.

Rules on the scored system. The submitted pipeline applied six convention rules of its own, recorded in the producer log:

`procedure_strip`	`quran_search_type`
`medication_strip`	`zakat_type_canon`
`customs_currency`	`termination_canon`

They are disjoint from the three the fine-tune ships, so Table 2 does not describe the scored file's post-processing. The two `strip` rules remove generic procedure or medication heads; `customs_currency` removes customs currency; `quran_search_type` infers a search mode but is score-neutral; `zakat_type_canon` and `termination_canon` map Arabic labels to the gold enums. Then `rare_key_drop` removes scored keys with train emit-rate below 0.02, and `value_canon` applies tool- and field-specific currency, article, head-noun, and procedure-prefix canonicalisation. Our retained implementation records the executable definitions and their order.

Serving the scored system. The prompt-only pipeline that produced the submitted file ran against `gemma-4-31B-it` served in Docker (`vllm/vllm-openai:gemma4`) with tensor parallelism over four GPUs, `--gpu-memory-utilization 0.95` and `--trust-remote-code`. The weights were bind-mounted from local disk to `/gemma-4-31b`, so vLLM advertised that path as the model id; this is the string our logs record, and it is why we cannot attest a Hugging Face revision for the run. `--max-model-len` was not set, so the model default of 32,768 applied. The longest prompt the pipeline builds is 7,081 tokens, and with `max_tokens` 768 the largest request is 7,849, so an 8,192-token window would also have sufficed. The server was additionally started with Gemma-4's native tool-call and reasoning parsers enabled; the pipeline does not use them, parsing the model's JSON output itself. Decoding was greedy, temperature 0, one sample per row, with the anchor date fixed to 2023-10-15.

Reproduction. We ran separate reproduction checks for the two systems. The fine-tune's corrected development prediction file rebuilds byte-exactly from its archived raw outputs. The prompt-only pipeline does not: `run_test.sh` writes `submission_test.jsonl`, whose tool name and argument dictionary match the scored test-split file `predictions/submission_test_v1.jsonl` on 983 of 1,125 rows (87.4%). As a same-era control on the released dev split, we compare `predictions/dev_control_rerun.jsonl` with `predictions/dev_trainonly.jsonl`. Their scored call fields match on 541/545 rows (99.3%) with no function-name differences; byte-identical JSONL rows, including the trace text, number 435/545. The remaining reproduction gap cannot be uniquely attributed to generation or to the unpreserved finalization step described below; we verified that all documented post-processing still runs. The prompt file was not under version control at submission time, but the producer log records a system prompt of 15,677 characters and the recovered file has exactly that length; this evidence supports, but cannot prove byte-for-byte, that its content is unchanged. What we cannot restore is the serving state. The endpoint was remote, served the weights from a local path rather than a released revision, and recycled repeatedly during the window in which we tried to measure it, so we cannot attest a model revision for the original run. We report the scored file itself as the artifact of record.

One further gap, found while preparing this version. The submitted file was written in two steps: the producer script on 28 July, then a finalize step on 29 July that filled the missing Track B traces described in Section 3. That second script was never committed and we could not recover it; its input was also deleted. Its only effect we can still observe is the trace filling, which we can reconstruct exactly because both canned sentences survive in the prediction files, but because its input is gone we can-

not rule out that it also touched tools or arguments. Our reproduction implementation regenerates the eight documented post-processing stages and not that step. On the dev split, `predictions/dev_trainonly.jsonl` therefore reports ThinkRate 0.9633; this is not a like-for-like comparison with the 1.000 reported by the finalized test-split submission.

Software. Training ran on Unsloth 2026.6.9 (Han et al., 2023) over TRL 0.24.0 (von Werra et al., 2020), Transformers 5.10.2 (Wolf et al., 2020), PEFT 0.19.1 (Mangrulkar et al., 2022), Accelerate 1.14.0 (Gugger et al., 2022), bitsandbytes 0.49.2 (Dettmers et al., 2022) (8-bit optimizer), Datasets 4.3.0 (Lhoest et al., 2021) and PyTorch 2.10.0 (Paszke et al., 2019). Serving used vLLM 0.27.1 (Kwon et al., 2023); Transformers below 5.10.2 fails to load the base architecture. Figures use Matplotlib (Hunter, 2007). The scorer files are the organizers' own, verified by checksum.

B Track C: Adjudicated Labels and Small-Cell Leverage

Track C macro-averages the five per-dialect Overall A values. After our query, the organizers confirmed that the official scorer used a corrected, adjudicated dialect assignment with these *total-instance* counts: MSA 660, Egyptian 175, Gulf 128, Levantine 128, and Maghrebi 34 (sum 1,125). The participant-facing `test.parquet` retained an earlier annotation — its dialect column has 825 MSA and 11 Maghrebi rows — and must not be used to recompute Track C. The organizers state that the published leaderboard reproduces under the adjudicated labels and will release them with the task artifacts.

The distinction between total and positive counts matters. If n_d and p_d are a dialect's total and positive counts, a correction affecting only FnAcc moves Track C by $0.2(0.4/n_d)$, while an ArgEM-only correction moves it by $0.2(0.6/p_d)$. Thus a Maghrebi FnAcc error has exactly $660/34 = 19.4$ times the weight of an MSA FnAcc error, but the corresponding ArgEM ratio cannot be computed without the adjudicated positive counts. For a positive Maghrebi row whose function and arguments both flip from wrong to right, the movement is $0.2(0.4/34 + 0.6/p_{\text{Magh}}) \geq 0.0059$, because $p_{\text{Magh}} \leq 34$.

The top five Track C systems span only 0.0118, and our 0.8978 fourth-place score lies within that band. The small Maghrebi cell can therefore change close ordering with very few joint errors. The program committee independently audited this point, concluded that closely placed ordering is not statistically identified, and plans confidence intervals or a larger cell in a future edition. We do not have adjudicated row-level labels or competitor predictions, so we do not claim a paired re-ranking analysis.

Our public-split measurements reinforce only the uncertainty, not a test-set claim. Maghrebi is last on train (ArgEM 0.8310, $n = 142$) but mid-pack on dev, where $n = 6$ gives a Wilson interval of $[0.44, 0.97]$. Our system's FnAcc spread is 1.33 points on dev and 0.02 on train. These diagnostics do not determine its behaviour under the adjudicated blind-test labels.

Table 5: Exploratory intervention search against the ArgEM residual, **primarily on the `gemma-4-12B-it` fine-tune**. The rows are heterogeneous in split, subset and search procedure and are an inventory of what we tried, not a controlled ablation. Δ is against greedy on the 500 dev positives (one row = 0.0020); p is exact McNemar over discordant pairs. Positive entries were not statistically significant under the reported paired tests; smaller gains remain unresolved. Dashes mark best-of searches, where one paired test would ignore selection over many configurations. † The convention-card row evaluates the configured `gemma-4-31B-it` pipeline; all other rows use the 12B fine-tune. * On a 4,000-row train sample.

C The Residual: Where It Sits and Why Our Tested Rules Did Not Remove It

We classified every failing positive row on both public splits. A row fails either because the tool name is wrong, because the key set differs from gold (KEY-SET), or because every key matches but at least one value does not (VALUE). The pattern be-

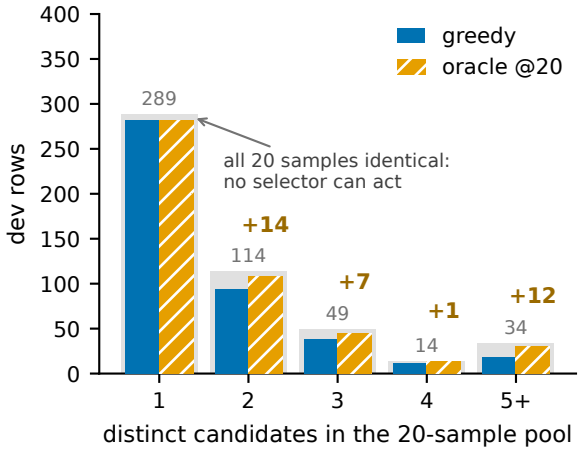

Figure 1: Where the oracle headroom lives for the **`gemma-4-12B-it` fine-tune**. Dev positives ($n = 500$) grouped by how many string-distinct argument dictionaries the 20-sample pool contains; the grey backdrop is the number of rows in each group. Under the scorer's own `args_match` equivalence the first group is larger still, 370 of 500, so the selectability problem below is if anything understated here. On 289 rows all twenty samples agree, so no selector can act, and greedy is already correct on 282 of them. The whole 34-row gap between greedy (0.8880) and oracle (0.9560) sits in the 211 rows with two or more distinct candidates.

low is an instance of human label variation (Plank, 2022): the disagreement is systematic and tied to annotator convention, not random error.

split	failures	VALUE	KEY-SET
train ($n = 10{,}500$)	878	614	264
dev ($n = 500$)	56	44	12

Table 6: Failing positive rows by error type, `gemma-4-12B-it` fine-tune.

Value disagreements are 70% of the train residual and 79% of dev. A correct tool and key set do not alone distinguish convention mismatch from semantic extraction error; in the classes we audited by hand below, what differs is the surface convention rather than the entity referred to. The largest classes are ones where the gold uses both conventions. On train the biggest are `items` (86), `medication_name` (84), `restaurant` (67), `country` (63) and the two `search_hotels` dates (121 combined). The pattern repeats on dev at a twentieth of the scale.

These 70% and 79% figures are the share of our residual assigned to the broad VALUE class, not the share adjudicated as paraphrase variance. They are therefore not directly comparable with the 50.2% paraphrase-variance rate of Ersoy et al. (2025); the two studies support the same qualitative mechanism but use different denominators and taxonomies.

Four kinds account for nearly all of it. A list separator: we write مشويات, مياه معدنية (*mashawiyat, miyah ma'daniyya*, 'grills, mineral water') where gold writes مشويات ومياه معدنية (the same items joined by waw). A definite article, in both directions: we write الباراسيتامول (*al-barasitamul*) for gold باراسيتامول (*barasitamul*, 'paracetamol'), and بروفين (*brufin*) for gold البروفين (*al-brufin*, 'ibuprofen'). A generic head noun, also in both directions: where the query supplies it, gold usually strips it in `restaurant` (kept on 96 of 413 rows) and `medication_name` (32 of 481) but usually keeps it in `procedure` (380 of 531), so the convention inverts between fields. And the language of the value itself, where we answer in Arabic and gold in English, or the reverse.

Self-conflict does not explain this system's residual. A deterministic system maps identical inputs to one output, so self-conflicting gold bounds a perfect system at the largest gold class per identical-query group. Conditioned on the full query that bound is 1.0000 on dev and 0.9971 on train, so self-conflict forbids almost nothing and a ceiling argument resting on it alone would not survive. We can bound what repairing it would buy: of the 76 rows in the 30 self-conflicting groups, only 2 are dev positives, so a multi-reference scorer that accepted every gold observed for a byte-identical (tool, query) pair would move dev ArgEM by at most 0.40 points. That is a bound on this narrow construction only, not on the broader multi-reference gold we recommend, which would also admit alternative surface forms per field. In the features and interventions we tested, we did not identify a convention predictor that transfers to dev. Fitting the majority convention per (tool, field, entity, candidate-set) on train and applying it to dev moves ArgEM from 0.8880 to 0.8800, three rows fixed against seven broken; an entity-agnostic prior reaches 0.8820. The model is already the better-informed predictor: it matches gold exactly on 0.861 of `order_food.restaurant` and 0.848 of `medication_name`, well above the majority-convention rate a surface rule could reach, so such a rule can only overwrite a better decision with a worse one. The fixes-against-breaks table below is

the direct evidence.

Duplicate-query conflicts complicate Oracle@*k*. On the 684 training rows whose query is exactly duplicated elsewhere, gold agrees with its own majority on 0.9561, so no deterministic function of the input can beat that rate on those rows. Separately, Oracle@20 reaches 0.9680 over all training positives. Because the denominators differ and we did not measure Oracle@20 on the 684-row duplicate-query subset, these figures do not establish how much of the all-train oracle gain is unattainable. They show only that, where identical queries carry conflicting gold, a per-row oracle may benefit from choosing different samples for inputs that a deterministic system must map to one answer.

The tested deterministic rules do not remove it. We simulated the obvious deterministic repairs on the train split, applying each to every row of the affected field and counting rows fixed against rows broken. Every one is net-negative:

field	transform	fixes	breaks	net
`items`	comma → waw	42	284	−242
`med_name`	drop ال	30	131	−101
`med_name`	add ال	19	335	−316
`restaurant`	add مطعم	28	319	−291
`restaurant`	drop مطعم	7	52	−45
`category`	drop ال	1	33	−32

Table 7: Deterministic field repairs simulated on train: every candidate is net-negative.

The comparator explains why this field is the worst. It splits list values on a comma, but splits an attached waw only when the word after it begins with the definite article. So مصر والإمارات (*Misr wa-l-Imarat*, 'Egypt and the UAE') matches its comma form while مشويات ومياه معدنية (*mashawiyat wa-miyah ma'daniyya*) does not: the separator is score-free when the following conjunct is definite and fatal when it is not.

Confirmed upstream; not yet in the public scorer revision used here. We reported this asymmetry and the `get_weather.days` inconsistency to the organisers, with two further items: that ArgEM is scored independently of function correctness, so a row abstained on with empty gold arguments still earns argument credit, and that open-vocabulary fields such as `restaurant` and `procedure` admit no Arabic-to-canonical equivalence. The organisers confirmed the comparator asymmetry and replied that it was corrected by broadening the conjunction rule to split an attached waw before any Arabic word, and the second by treating `days` as non-scored for `get_weather`, and that the other two are candidates for a later revision. The public Space itself remained at commit `c43abee` when we re-checked it on 4 September 2026, with `normalize.py` unchanged. Our public-split measurements use that public revision. We have not confirmed which scorer revision produced the official leaderboard results, which we report as returned by the organisers. The confirmed correction is not included in our public-split measurements.

In our comparisons, stating the conventions outright helps only in the following dev-selected setting. We ran the 31B pipeline with per-tool cards that give, for every candidate tool and field, the value form, the emit rate and gold examples mined from train. Against the bare prompt on 228 dev positives the cards are worth $+7.5$ points of ArgEM, 18 rows fixed against 1 broken ($p = 10^{-4}$). Like every configuration in this paper, the cards were selected on development, so this figure carries the same caveat as the rules in Section 5.2: dev-gated gains here did not transfer, and the subset is 228 positives rather than the 500 used elsewhere. Added on top of the shipped configuration, which already retrieves up to four gold exemplars per query, the same cards move 6 rows and break 5 on all 500 dev positives, a net of one row at $p = 1.00$. Four real examples already carry the conventions the cards spell out; adding the cards to the configured 31B pipeline yielded no statistically significant additional dev gain.

Our tested nearest-example transfer does not help either; this result does not bound few-shot prompting in general. Transferring the convention from the most lexically similar same-tool training row scores 0.62 on `items` and 0.75 on `restaurant` against global-majority rates of 0.76 and 0.92, because the nearest neighbour often carries the other convention. In this system's training residual, concentration by domain is stronger than by dialect. By official domain the train ArgEM runs from 0.9942 on Government to 0.7618 on E-commerce, and E-commerce and Healthcare alone hold 467 of the 878 failures; the dialect spread inside a domain is a

third of that. Conditioning on dialect also does not help in this diagnostic. Fitting the majority convention per dialect on train and applying it to dev matches the global majority exactly on `items`, `medication_name` and `restaurant` (no change on any of the 72 rows), because every dialect shares the same majority form. An oracle allowed to pick the best convention per dialect *on dev itself* gains two rows in total. Conditioning on the query does not rescue them. The obvious hypothesis is that gold copies the surface form of the query. It does not: on `order_food.items` the query's separator predicts gold's on 0.283 of rows against 0.672 for always writing a comma, and on `order_food.restaurant` 0.462 against 0.815 for always dropping the head noun. Only `medication_name` favours copying as a feature (0.871 against 0.704), and applied as a rule on train it fixes 20 rows and breaks 41 ($p = 0.010$). The arithmetic explains the failure of these particular transforms. The system is already correct on 75–90% of each field, and gold uses both conventions, so a blanket transform trades a large correct majority for a small incorrect minority. A rule can only win where its conditioning evidence predicts the held-out convention; our tested rules did not.

Three rows of Table 5 deserve comment. Reverse scoring, $\log P(\text{query} \mid \text{args})$, is the only orthogonal signal we found; it fixes 15 rows no other method reaches but breaks 41, and a reranker given it as a feature learns a weight of -0.072, i.e. it ignores it. Gold-vocabulary snapping scores $+38$ rows on train and -47 on dev: the lexicon is built from train gold, so evaluating it on train reads the labels. And optimising directly against the scorer's normaliser, the natural analogue of adversarial metric attacks (Jon and Bojar, 2024), costs 24 rows, because `value_match` is a hard indicator with no partial credit to climb; the same property that makes ArgEM discrete made this tested metric-aware transform ineffective.

Method choice is also constrained by power. With 500 dev positives at ArgEM ≈ 0.89, exact McNemar conditions only on discordant pairs, so a run of six fixes against no breaks already reaches $p = 0.031$ two-sided (0.016 one-sided); no method in Table 5 delivered a run that one-sided. Three interventions looked positive on dev and reversed under replication: a logprob selector at $+1.65$pp on 182 rows fell to $+0.20$pp on 500; `min_p` sampling swung 8 rows across three seeds; and the critic above moved from $+0.80$pp on dev to -2.88pp on 4,000 train rows.

Post-deadline: negative augmentation separates fit from generalisation. Everything in this paragraph is **post-deadline, was never submitted, and is not part of the official system**: the added negatives are synthetic, generated by `gemma-4-31B-it` rather than drawn from the released splits. Synthetic augmentation was allowed by the task; this provenance statement distinguishes the diagnostic from our official entry, which used only the provided data. We report it because it measures directly what the rest of this appendix argues from the failure of other interventions. The mixture is the paper's, plus about 1,019 synthetic no-call rows (13,325 rows, 8.1% negative against 0.50%); the recipe is otherwise unchanged and the comparison is matched at every epoch.

epoch 3	train ArgEM	dev ArgEM	train − dev
no synth. neg.	0.9115	**0.8900**	+2.15
+ negatives	**0.9235**	0.8860	+3.75

Table 8: Negative augmentation: a post-deadline diagnostic using a task-permitted synthetic-negative mixture; never submitted.

On the full 10,550 training rows the augmented run fixes 232 and breaks 106, $+1.20$ points at exact McNemar $p = 6.0\times10^{-12}$. On dev it fixes 8 and breaks 10, -0.40 points at $p = 0.81$. A method that moves training ArgEM about as decisively as this data allows moves held-out ArgEM by nothing and widens the train–dev gap from 2.15 to 3.75 points. Thus this particular augmentation learns additional training conventions without a corresponding dev gain; it does not establish a task-wide ceiling or impossibility result.

The abstention result is smaller than it first looks and we state it as such. Negatives fix 10 FnAcc rows against 0 at epoch 2 ($p = 0.0020$), but by epoch 3 the margin is 5 against 1 ($p = 0.22$) and the original-mixture arm has caught up on its own from 61 negatives. The augmented arm reached fewer FnAcc errors earlier by epoch count, but its final advantage was not statistically significant: epoch 2 with augmentation (1 FnAcc error) already beats epoch 3 without it (6). Two caveats. The baseline arm here is a matched re-run for this experiment, not the fine-tune of Table 2: it reaches 0.9890 FnAcc against that model's 0.9945, so the comparison is internal to this appendix and neither arm should be read against 0.8880. Both arms are scored on raw decodes, and this is one run

per arm, so sub-point differences are not separated from run-to-run variance. Finally, this augmentation changes the training data, not model capacity: it improved training ArgEM without a statistically significant dev improvement, and higher-rank or longer-training experiments remain untested.

D External Annotation Cross-Check

We checked whether a separately released Arabic function-calling corpus (Haroon, 2024) could stand in for the blind test gold. It cannot, and the reason is instructive.

Measured on the 11,000 rows where both resources label the same query, and scored with the official comparator, the two annotations agree perfectly on the function name (11,000/11,000) and on only 0.7056 of argument dictionaries. The disagreement concentrates in a few tools, and splits them cleanly into two groups (Table 9). The tools that disagree are those whose arguments are dates, money and free-text lists, which is where the conventions of these two annotation resources diverge most.

We report this as evidence that argument conventions differ sharply between independent annotations of the same task. We did not use it to estimate a test score: it is an independent annotation of overlapping queries, not a reference for the blind split, and the tools on which it diverges most are exactly the ones that carry our own residual.

tool	agreement
agree ≥ 0.95	
`check_traffic_violations`	0.998
`translate_text`	0.997
`search_quran`	0.996

Abstract

Reliable function calling is challenging for Arabic due to dialectal variation and limited task-specific resources. We present **Makeen**, a data-centric approach for the AISA-ArabicFC shared-task, and extend it with span extraction and confidence-gated routing. The best post-submission variant achieves 83.20% argument exact match and 91.11% Track B on development data under held-out (cross-validated) routing, while the submitted model achieves 82.65% argument exact match and 91.06% Track B on the blind test set, ranking 9th in Task B. We also release two Arabic tool-use datasets and show that external-tool augmentation improves unseen-tool argument exact match from 44.49% to 66.53%. These results highlight the importance of data quality, argument grounding, and tool-level generalization for Arabic function calling.

1 Introduction

Function calling refers to the capability of a large language model (LLM) to access predefined external functions and transform natural-language instructions into structured requests (Wang et al., 2026). Reliable function calling requires a precise understanding of user intent and accurate extraction of function arguments. For Arabic-language systems, this process is further complicated by orthographic variation (Darwish et al., 2021), limited Arabic function-calling resources (Ersoy et al., 2025), and the diversity of Arabic dialects (Nacar et al., 2026b).

We present **Makeen**, our system for Arabic function calling. The submitted system is a generator fine-tuned on filtered data and enhanced tool declarations (§4). We extend it with extractive hints and confidence-gated routing (§3), and report both stages. Our main contributions are:

- A hybrid system pairing a label-semantic span extractor with a hint-grounded generator.
- Confidence-gated per-argument routing between the two components.
- **Public release of Arabic function-calling resources** addressing the scarcity of publicly available Arabic data: translations of two English datasets with tool declarations and reasoning traces, providing 5,758 examples across 1,442 distinct tools. [1] [2]
- A study of generalization to unseen tools (§4.5), evaluating systems both on the shared-task dev split of 27 tools and on an unseen-tool split held out from the translated data.

2 Background

2.1 Task And Data

The AISA-ArabicFC shared-task (Nacar et al., 2026a) requires mapping an Arabic utterance onto a single tool call. Each instance presents four candidate declarations, sampled from an inventory of 27 tools across eight real-world domains: at most one is correct, the remainder being distractors, and a system either selects that tool and predicts its arguments or abstains with `none` (Figure 1, Appendix A). This work addresses Track B, which additionally requires an Arabic `<think>` reasoning trace and is scored

$$0.3\,\textsc{FnAcc} + 0.5\,\textsc{ArgEM} + 0.2\,\textsc{ThinkRate} \quad (1)$$

with ArgEM satisfied only by an exact match over all arguments. The released AISA-ArabicFC data (Nacar et al., 2026b,c,a) cover five Arabic dialects, comprising 10,550 training, 545 development and 1,125 blind test instances.

2.2 Related Work

Arabic function-calling resources remain comparatively limited, particularly for dialectal and multilingual settings. Ersoy et al. (Ersoy et al., 2025) studied data strategies and instruction tuning for Arabic tool calling and showed the value of translating and adapting English tool-use datasets. More recently, AISA-ArabicFc introduced a larger Arabic function-calling resource with dataset auditing, schema normalization, and tool-aware fine-tuning (Nacar et al., 2026c). We build on this line of work in a shared-task setting with noisy supervision, refined tool declarations, and explicit evaluation of generalization to held-out tools. Our approach further uses a hybrid generative-extractive architecture to improve exact argument matching.

3 System Overview

Given an Arabic utterance q and candidate tool declarations $\mathcal{T}$, Makeen predicts a tool $\hat{y} \in \mathcal{T} \cup \{\texttt{none}\}$ and an argument map $\hat{a}$. The submitted system, $\text{Makeen}_{\text{Base}}$, is a generator fine-tuned on the filtered and enhanced shared-task data. We then extend it in two stages: first, $\text{Makeen}_{\text{+Hint}}$ augments the generator with a label-semantic extractor E that supplies structured hints; second, confidence-gated routing combines the generator and extractor outputs at inference time. The complete Makeen pipeline is shown in Figure 7(Appendix J).

The two components are complementary: the extractor preserves surface-grounded values exactly, while the generator can normalize values or infer arguments that are not explicitly expressed in the utterance. Routing exploits this complementarity by selectively replacing generated arguments with confident extracted values.

3.1 Label-Semantic Extractor

E is a bi-encoder initialised from `multilingual-e5-base` (Wang et al., 2024; Conneau et al., 2020); bi-encoders have been applied to Arabic span extraction before, notably for named-entity recognition (Hussein et al., 2023). Following label-semantic tagging (Ma et al., 2022), tools and arguments are represented by their natural-language descriptions rather than class indices, so declarations unseen in training remain scorable; candidates are re-sampled per example. The utterance is encoded *once* with offset mapping retained: mean-pooling all token states gives e_q, and mean-pooling those overlapping word w_i gives a contextual e_{w_i}, so one pass serves both objectives.

Tool scores $s(t) = e_q^\top e_t/\tau$ are read against a no-call score $s_\varnothing = e_q^\top e_\varnothing/\tau$, at the training temperature $\tau = 0.05$: E calls no tool when $\max_t s(t) < \theta$ or $s_\varnothing > \max_t s(t)$, with $\theta = 3.0$ throughout. Words are scored against the selected tool's arguments, $S_{i,p} = e_{w_i}^\top e_p/\tau$, and decoded by *exclusive assignment*

$$\pi(i) = \arg\max_p S_{i,p}, \quad \text{kept iff } S_{i,\pi(i)} > \theta, \quad (2)$$

so each word is claimed by at most one argument. A value is the concatenation of its words, and $c_p = \max_{i:\pi(i)=p} S_{i,p}$ is the confidence the router consumes. Training sums InfoNCE over the in-batch candidates including NONE (van den Oord et al., 2018) with a per-word binary cross-entropy against each argument's gold span, positives up-weighted by $n_{\text{neg}}/n_{\text{pos}}$ to offset the outside-label imbalance.

3.2 Hint-Grounded Generation

The generator is Qwen3.5-4B (Yang et al., 2025) adapted with LoRA (Hu et al., 2021). For $\text{Makeen}_{\text{+Hint}}$, the extractor output is serialized into a three-line Arabic hint block appended to the user turn:

```
الأداة المتوقعة: check_traffic_violations
المُستخرج: id_number=1122334455
يحتاج استنتاج: plate_number
```

giving the predicted tool, the arguments already grounded in surface text, and those still to be inferred; negatives carry الأداة المتوقعة: `none`. The third line makes the block a *plan* rather than an answer. Hints are injected identically at training and test time. Training hints are perturbed (§4) so that the generator learns to tolerate and repair extractor errors. The block is therefore part of the supervision and not of the prompt alone: the generator reads and repairs it only because every training example carries one, the same lever that installs new Arabic capabilities in a pretrained speech model (Mattar et al., 2025). Thus, $\text{Makeen}_{\text{Base}}$ and $\text{Makeen}_{\text{+Hint}}$ use the same generator architecture and optimization setup; they differ only in whether the extractor-derived hint is provided as an additional supervised input.

3.3 Confidence-gated Routing

R therefore arbitrates per argument (Algorithm 1). It is gated on *tool agreement*: components disagreeing on the tool have incomparable argument spaces.

A *policy* names the set of routed fields $\mathcal{F}$, and for each $f \in \mathcal{F}$ a confidence threshold θ_f and a mode m_f: REPLACE overwrites a value the generator produced, while PRESENCE lets a confident extraction decide whether the key appears at all. Closed-class spans (country, city, currency, category, …) are first snapped to the value set enumerated from train gold; every field outside $\mathcal{F}$ passes through unchanged. Policies are fitted by greedy forward selection over (field, mode, threshold) on end-to-end ARGEM; details are provided in Appendix B.

4 Experimental Setup

Our experiments proceed in four stages: data curation and tool-declaration refinement, model training, inference-time routing, and generalization to external tools. We first construct quality-controlled training data and refine tool declarations, then train the generator and extractor, apply inference-time routing, while additional translated tools extend the training inventory for evaluating generalization beyond the shared-task setting.

4.1 Data Curation And Tool-Declaration Refinement

We apply LLM-based verification to the 10,550 AISA-ArabicFC training examples, retaining 7,748 high-confidence instances. We then fine-tune an initial Qwen3.5-4B model and use argument-level error analysis to identify ambiguities in the tool declarations. This motivates *Tool-v2*, which refines affected declarations while preserving their original semantics. Detailed filtering criteria, error analysis, and declaration changes are provided in Appendices F and H.

4.2 Generator Training

For all Makeen variants, we fine-tune `Qwen3.5-4B` (Qwen Team, 2026a) with LLaMA-Factory (Zheng et al., 2024), using LoRA and reasoning-trace supervision on the filtered, Tool-v2-enhanced data. Complete optimization and model settings are given in Appendix E.

4.3 Label-Semantic Extractor Setup

The label-semantic extractor E is initialized from `multilingual-e5-base` and fine-tuned on the shared-task training split using the tool and argument descriptions as semantic labels. At inference time, it produces the selected tool, extracted argument values, and per-argument confidence scores c_p. Word-level extraction is decoded at $\theta = 3.0$. The extractor is trained independently of the two generator variants and is shared by $\text{Makeen}_{\text{Base}}$ and $\text{Makeen}_{\text{+Hint}}$.

4.4 Confidence-Gated Routing

Routing is applied at inference time: the output of each Makeen variant is combined with the corresponding extractor output using Algorithm 1. Before routing, closed-class extracted values are snapped at $\sigma = 0.84$ against a value vocabulary derived from training gold. Routing policies are fitted by greedy selection and scored by cross-validation. Additionally, policies are fitted independently for $\text{Makeen}_{\text{Base}}$ and $\text{Makeen}_{\text{+Hint}}$; the resulting policies are listed in Appendix C.

4.5 Generalization To External Tools

An additional experiment was conducted to evaluate generalization beyond the 27 shared-task tools by augmenting training with Arabic translations of Hermes Tool Use Reasoning (interstellarninja, 2025) and Glaive [3]. We translate tool declarations and examples with `Qwen3.6-27B` (Qwen Team, 2026b), retain only single-tool-call examples to match the shared-task setting and generate Arabic reasoning traces for Glaive. To test generalization to unseen tools, we construct a held-out split using lexical grouping, BGE-M3 (Chen et al., 2025) semantic isolation, and an LLM-based cross-pool leakage audit. The resulting split contains 236 examples spanning 126 tools, while the translated training portion contains 5,522 examples across 1,316 tools (Table 6). Detailed construction and leakage-control procedures are provided in Appendix I.

5 Results

Table 1 shows the progression from the zero-shot **Qwen3.5-4B** baseline to the submitted and post-submission **Makeen** variants. Fine-tuning on the filtered and enhanced data, $\text{Makeen}_{\text{Base}}$, increases ARGEM from 51.00% to 81.20% and raises FNACC to 99.63%. Adding extractive hints in $\text{Makeen}_{\text{+Hint}}$ yields a further 1.40-point improvement in ARGEM, accompanied by a 1.28-point decrease in FNACC. Routing offers a further margin in principle for $\text{Makeen}_{\text{Base}}$ and $\text{Makeen}_{\text{+Hint}}$ respectively: under a perfect policy the extractor recovers 7.40 and 5.00 points. Held out by cross-validation, rout-

4*	$\text{Makeen}_{\text{+Hint}}$	w/	w/ oracle	*87.60* (+5.00)	98.35	100.0	*93.31*
			w/ CV	**83.20** (+0.60)	98.35	100.0	**91.11**
			w/ train	82.60 (+0.00)	98.35	100.0	90.80

Table 1: Results on the AISA-ArabicFC development split (545 examples: 500 positive and 45 negative). All values are percentages; ↑ denotes higher is better. Row 0 is the zero-shot Qwen3.5-4B baseline, row 1 is the submitted system, and rows marked * are post-submission experiments. The best result per column is boldfaced.

	Shared-task dev				Unseen-tool dev			
Training data	ArgEM ↑	FnAcc ↑	ThinkRate ↑	Track B ↑	ArgEM ↑	FnAcc ↑	ThinkRate ↑	Track B ↑
None (zero-shot baseline)	51.00	95.78	22.75	58.78	44.49†	98.73	21.19	56.10
Enhanced shared-task data	**81.20**	**99.63**	**100.0**	**90.49**	44.49†	**100.0**	**100.0**	72.24
+ external tools	78.00	96.33	99.63	87.83	**66.53**	**100.0**	**100.0**	**83.26**

Table 2: Effect of translated external-tool augmentation on in-distribution and unseen-tool generalization. $\text{Makeen}_{\text{Base}}$ is fine-tuned on the enhanced shared-task data, while $\text{Makeen}_{\text{+Aug}}$ additionally uses translated external tools; both are evaluated without routing. Results are reported on the AISA-ArabicFC development split and the unseen-tool development split described in Appendix I. The zero-shot Qwen3.5-4B baseline is included for reference and matches Table 1. †Equal as measured: $44.49 = 44.49$.

ing captures only 0.40 and 0.60 of that margin, and choosing the routed arguments from training statistics alone, with nothing tuned on dev, 0.20 and 0.00. **$\text{Makeen}_{\text{Base}}$** configuration was used for the final submission; the hint and routing variants were evaluated post-submission. On the blind test set, the submitted system achieves 82.65% ArgEM, 99.11% FnAcc, and 91.06% Track B, placing our system **9th in Task B**.

Table 2 reveals a clear specialization–generalization trade-off. Training only on the enhanced data, $\text{Makeen}_{\text{Base}}$, gives the strongest performance on the development split, whereas adding translated external tools in $\text{Makeen}_{\text{+Aug}}$ substantially improves performance on unseen tools. In particular, external augmentation increases unseen-tool ArgEM from 44.49% to 66.53% (+22.04 points) and Track B from 72.24% to 83.26% (+11.02 points). The cost on shared-task dev is 2.66 Track B points: ArgEM $81.20 \rightarrow 78.00$ and FnAcc $99.63 \rightarrow 96.33$.

6 Conclusion

We presented **Makeen**, a data-centric approach to Arabic function calling that combines improved supervision with targeted inference-time grounding. Our experiments show that higher-quality training data and tool-declaration refinement substantially strengthen function-calling performance, while semantic extraction and confidence-gated routing improve argument prediction. The oracle results, which provide an upper bound on routing performance, reveal a substantial gap with the observed gains, suggesting room for improvement in routing policy selection and motivating this as a direction for future work. We also investigated generalization to unseen tools and found that translated external tool resources improve transfer, while introducing a trade-off in performance on the shared-task distribution.

These findings highlight the need to balance in-distribution performance with broader tool-level generalization and better understand and optimize this trade-off. The released resources provide a basis for continued research on Arabic function calling, particularly in tool-level generalization and transfer across tool distributions.

Acknowledgments

We gratefully acknowledge Knights Lab at Alexandria University for providing the infrastructure that made the experiments in this work possible.

A Example Task Instance

Figure 1 shows an example instance from the development split, as described in §2.1.

TOOLS
- `search_umrah_packages(departure_city, departure_date, duration_days, hotel_rating, num_persons)`
- `search_hotels(check_in, check_out, city, guests, stars)`
- `search_quran(query, search_type, surah_number)`
- `transfer_money(amount, bank_name, currency, recipient_iban, recipient_name)`

USER

أبي أحجز باقة عمرة من الرياض لسبعة أشخاص

GOLD

```
<think>
فهمت أنك ترغب في حجز باقة عمرة من الرياض لسبعة أشخاص. أداة "search_umrah_packages" هي الأنسب لأن
لديها القدرة على البحث عن باقات العمرة المتاحة. المدخلات المتوقعة هي: departure_city=الرياض
و num_persons=7.
</think>
function_call:search_umrah_packages{
  departure_city: الرياض,
  num_persons:7}
```

Figure 1: A Gulf-dialect instance from the development split, showing the four candidate declarations offered to the system, the utterance, and the gold output, all reproduced verbatim. Each declaration is abridged for space to its argument names and the tool's Arabic description, and the string delimiters of the raw serialisation are elided. The value الرياض is copied from the utterance, whereas لسبعة must be normalised to 7; the three remaining tools are distractors, `search_hotels` a close one.

B Confidence-gated Routing Details

Algorithm 1 gives the complete confidence-gated routing procedure. Routing is applied only when the generator and extractor agree on the tool; otherwise, the generator output is returned unchanged. A routed argument is substituted only when its extracted value meets the policy's confidence threshold θ_f. Closed-class spans are snapped using the policy's snapping threshold σ, and any argument not listed in the policy is passed through exactly as the generator produced it. REPLACE overwrites a value the generator already produced; PRESENCE lets a confident extraction decide both whether the key appears and what it holds.

Algorithm 1 Confidence-gated routing

Require: (y_G, a_G), (y_E, a_E, c), policy $(\mathcal{F}, \theta_f, m_f, \sigma)$
if $y_G = \texttt{none}$ **or** $y_G \neq y_E$ **then return** (y_G, a_G)
end if
$a_E \leftarrow \textsc{Snap}(a_E, \sigma)$
for $f \in \mathcal{F}$ **do**
  $ok \leftarrow f \in a_E \wedge c_f \geq \theta_f$
  if $m_f = \textsc{presence}$ **then**
    $a_G[f] \leftarrow a_E[f]$ **if** *ok* **else** drop f
  else if $f \in a_G \wedge ok$ **then**
    $a_G[f] \leftarrow a_E[f]$
  end if
end for
return (y_G, a_G)

Policies are fitted per model; their selected fields, modes, confidence thresholds, and snapping threshold are reported in Appendix C.

A dev example makes the mechanism concrete. For the request below, Makeen$_{\text{+Hint}}$ returns the restaurant name together with the noun مطعم ('restaurant'), whereas E marks the name alone:

	ابي اطلب من مطعم الفخامة، ابغى كبسة ودجاج مشوي
Makeen$_{+\text{Hint}}$	`restaurant` = مطعم الفخامة
E	`restaurant` = الفخامة $(c = 9.4)$
gold	`restaurant` = الفخامة

Both components agree on `order_food`, and `restaurant` is a routed field, so the extraction replaces the generated value and the row becomes an exact match. The same row's `items` argument is left untouched, since it is not a routed field.

C Routing Policies

Table 1 reports three ways of choosing a routing policy. This section gives each of them, using the confidence threshold θ_f and the REPLACE/PRESENCE modes defined in §B. In every case the snapping threshold is $\sigma = 0.84$.

C.1 Train-Derived Selection

No search on the development split. An argument is routed when its gold value is a verbatim span of the query in at least 95% of its *training* occurrences; all routed arguments use REPLACE with $\theta_f = 0$. The rule selects the same 13 arguments for both systems and gives the 0.20 and 0.00 margins.

argument	% direct	n	argument	% direct	n
`visa_number`	100.0	494	`text`	98.5	547
`insurance_number`	100.0	397	`city`	98.4	2802
`recipient_iban`	100.0	278	`years_of_service`	97.4	491
`id_number`	99.8	507	`product_value`	97.0	508
`query`	99.4	506	`destination_country`	95.8	481
`salary`	99.4	491	`departure_city`	95.1	473
`iqama_number`	99.1	529			

Table 3: Arguments selected from training statistics alone. *% direct* is the share of training occurrences whose gold value appears verbatim in the query; n is the number of occurrences.

C.2 Cross-Validated Fold Policies

Cross-validation fits one policy per fold, so the reported figure is not produced by a single policy: the five held-out fold predictions are stitched together and scored once.

Makeen$_{\text{Base}}$ out-of-fold 81.60 (+0.40)

		`query`	REPLACE	0.0
		`recipient_iban`	PRESENCE	5.0
		`restaurant`	REPLACE	0.0

Table 4: Per-fold routing policies. Folds are stratified by gold tool; *fit/test* gives the number of rows the policy was fitted on and scored on. The selected set varies from fold to fold – `city` and `medication_name` appear in every fold, while `country`, `type` and `bank_name` appear in some only – and thresholds move with it, which is why no single policy stands behind the cross-validated figure.

D Translation Prompts

Prompts used to translate the data of §4.5: Figure 2 for a tool declaration and Figure 3 for a sample, given its already-translated declaration as context; Figure 4 replaces rule 2 of the sample prompt for Glaive.

```
You are a precise dataset translator for a tool-calling (function-calling) dataset.
Translate ONLY the human-readable text of the given tool DECLARATION from English
into Arabic.

Rules:
1. Keep "name" UNCHANGED (it is an API identifier).
2. Keep every parameter KEY UNCHANGED (they are API identifiers).
3. Keep all "type" values UNCHANGED.
4. Translate the "description" fields (the tool description and each parameter
   description) into natural Arabic.
   - If a description embeds enum/identifier tokens (e.g. "Supported values:
     driving, walking, transit"), keep those tokens UNCHANGED and translate only
     the surrounding words.
5. Preserve the JSON structure exactly (same keys, same nesting).
6. Output ONLY the translated declaration as a single valid JSON object, no
   markdown, no commentary.

Do not justify or explain your response. Only deliver your response in the JSON.

INPUT:
{<tool declaration>}

OUTPUT JSON:
```

Figure 2: Declaration prompt.

```
You are a precise dataset translator for a tool-calling (function-calling) dataset.
Translate the given fields from English into Arabic.
The tool declaration is ALREADY translated and provided under
"translated_declaration_context" only as context. Do NOT translate it and do NOT
output it.

Follow these rules EXACTLY:
1. Translate "human" (the user query) into natural Arabic. You have to
   translate everything, including names.
2. Translate "think" (the reasoning) into natural Arabic.
   - Make the translated version shorter.
3. For "tool_call":
   - Keep "name" UNCHANGED (it is an API identifier).
   - Keep every argument KEY UNCHANGED (they are API identifiers).
   - For each argument VALUE:
     * If the value is natural-language text taken from the user query, translate
       it so that the translated value is an EXACT substring of your translated
       "human" field, copy the same wording verbatim, do NOT rephrase, do NOT add
       or drop words. Alignment must be exact.
4. Output ONLY a single valid JSON object, no markdown, no commentary, with keys:
   "human", "think", "tool_call".
   "tool_call" must be a nested object with "name" and "arguments" (arguments as
   a nested dict).

Do not justify or explain your response. Only deliver your response in the JSON.

INPUT:
{
  "human": "<user query>",
  "think": "<reasoning>",
  "tool_call": {"name": "<tool>", "arguments": {...}},
  "translated_declaration_context": {<declaration already translated>}
}

OUTPUT JSON:
```

Figure 3: Sample prompt (Hermes).

Training parameter	Value
Base model	`Qwen/Qwen3.5-4B`
Framework	LLaMA-Factory
Fine-tuning	LoRA
Template	`qwen3_5`
Attention	FlashAttention-2
Learning rate	1×10^{-4}
Epochs	3
Per-device batch size	16
Gradient accumulation	2
Warmup ratio	0.03
Quantization	4-bit
LoRA rank	16
LoRA α	32
LoRA dropout	0.05
enable_reasoning	True

Table 5: Fine-tuning configuration.

Split	Samples	Tools
Training		
AISA-ArabicFC, Tool-v2-enhanced	7,748	27
Hermes + Glaive, translated	5,522	1,316
all	13,270	1,337
Development, unseen tools		
Hermes + Glaive, translated	236	126

Table 6: MAKEEN$_{+\text{AUG}}$ data. *Samples* counts examples after filtering, *Tools* distinct declared tools; the total counts shared function names once. train $\cap$ dev $= \emptyset$.

```
2. For "think" (the reasoning):
   - GENERATE long, natural Arabic "think" that reasons about which tool to
     call and why, based on the "human" query, the "tool_call", and the provided
     translated declaration context. Keep it concise (2-3 sentences). Do NOT leave
     it empty.
```

Figure 4: Rule replacing rule 2 of Figure 3 for Glaive, whose examples carry no reasoning trace.

E Training Configuration

We fine-tune `Qwen/Qwen3.5-4B` (Qwen Team, 2026a) using LLaMA-Factory (Zheng et al., 2024). Preliminary evaluation on the AISA-ArabicFC data indicated that the base model already exhibited basic function-calling ability, motivating task-specific adaptation to the dataset's tool declarations and annotation conventions. The complete training configuration is summarized in Table 5.

For the additional generalization experiment of Section 4.5, the shared-task training pool is augmented with translated external tools to train MAKEEN$_{+\text{AUG}}$, and a held-out unseen-tool development split is used for evaluation. Table 6 reports the size of each.

Training used NVIDIA RTX PRO 6000 and RTX 4090 GPUs with 97GB and 24GB memory, respectively.

F Data Quality Control

F.1 Overview

AISA-ArabicFC data was subjected to strict LLM-based quality control. The evaluator assessed each annotation against the available system prompt, user request, and tool declaration. Rejected cases were subsequently inspected to recover valid examples that had been conservatively rejected.

Of the 10,550 initial examples, 6,391 were accepted by the LLM-based evaluator. Manual inspection of rejected cases recovered valid examples, yielding a final pool of 7,748 examples. The resulting dataset is therefore treated as high-confidence rather than error-free, with filtering prioritizing supervision quality and consistency over dataset size.

Group	Error type	Description
Function selection	`wrong_function`	A different tool is selected from the one required by the request.
	`no_function_needed`	A tool is called although the request does not require one.
Argument extraction	`missing_parameter`	A required argument is omitted.
	`extra_parameter`	An unnecessary argument is added.
	`hallucinated_value`	A value not supported by the system prompt or user request is introduced.
	`wrong_parameter_name`	The argument name does not match the tool declaration.
	`wrong_parameter_type`	The argument type violates the tool declaration.
	`wrong_argument_value`	The extracted value does not match the intended annotation.
Representation	`translated_parameter`	A user-provided value is unnecessarily translated.
	`rephrased_parameter`	The user's wording or representation is unnecessarily changed.
	`unsupported_assumption`	Information not established by the input is inferred or assumed.
Schema/supervision	`invalid_format`	The function call does not follow the required call format.
	`schema_violation`	The annotation violates a schema constraint not captured by a more specific error category.
	`ambiguous_request`	The input does not provide sufficient information for a unique decision.
	`multiple_errors`	Multiple substantive errors are present and no single primary error adequately characterizes the annotation.

Table 7: Error taxonomy used by the LLM-based evaluator for training-data quality control and function-calling error analysis.

F.2 Evaluation Criteria And Error Taxonomy

The LLM-based evaluator checks five complementary dimensions: function selection, argument completeness, value fidelity, schema compliance, and function-call format. It returns a binary decision and, for rejected annotations, assigns one primary error reason. These reasons are grouped into function selection, argument extraction, representation, and schema/supervision categories, as summarized in Table 7. The complete evaluation prompt is provided in Appendix G.

F.3 Evaluator Models

The LLM-based evaluator was implemented using five LLMs accessed through NVIDIA NIM APIs (Saunders et al., 2024). Multiple evaluator models were used during large-scale filtering to reduce operational bottlenecks and API rate-limit constraints. The models were

- `nvidia/nemotron-3-ultra-550b-a55b`
- `z-ai/glm-5.1`
- `deepseek-ai/deepseek-v4-pro`
- `moonshotai/kimi-k2.6`
- `stepfun-ai/step-3.7-flash`

F.4 Representative Data-Annotation Errors

Table 8 presents representative errors identified in the training data annotations by the LLM-based evaluator. Each example includes only the context necessary to interpret the error, with the erroneous function call or argument highlighted alongside the assigned error category and diagnosis.

Error	Example
`hallucinated_value`	**System prompt:** YYYY-MM-DDTHH:MM:SS: 2024-07-23T09:23:15 التاريخ والوقت الحالي بصيغة اليوم هو الثلاثاء أنت نموذج يمكنه استدعاء الوظائف التالية **User:** عندي رحلة على بيروت، في فنادق مقترحة؟ `check_in = 2023-11-01` **Issue:** The date was neither provided by the user nor supported by the temporal context present in the system prompt.
`missing_parameter`	**User:** ازاي أحسب زكاة الذهب لو عندي 50 جرام؟ **Issue:** The reference annotation omitted the user-specified weight unit. `weight_unit = gram`
`no_function_needed`	**User:** متى يمكنني حجز موعد مع طبيب قلب في الرياض؟ The reference annotation calls: `book_doctor_appointment` **Issue:** The request asks when an appointment can be booked rather than asking to perform a booking.
`wrong_function`	**User:** ممكن أسأل عن دكاترة عيون في القاهرة؟ The reference annotation calls: `book_doctor_appointment` **Issue:** The request is a doctor-search or information request rather than an appointment-booking request.
`translated_parameter`	**User:** ممكن حجز مع دكتور نساء وتوليد في الزقازيق يوم الجمعة؟ **Issue:** The reference annotation translated the user-provided temporal value instead of preserving its original representation. `date = Friday`
`wrong_parameter_name`	**User:** كم نسبة الزكاة على الذهب عيار ٢٤ اذا عندي ٥٠٠ جرام؟ The reference annotation contains: `currency = gram` **Issue:** The annotation uses `currency`, whereas the tool declaration defines the argument as `weight_unit`. Argument names must exactly match the tool declaration; therefore, this is a `wrong_parameter_name` error.

Table 8: Representative training-annotation errors identified by the LLM-based evaluator. Each example shows the relevant user request and erroneous annotation, together with the assigned error category and diagnosis.

G Complete Filtering Prompt

For reproducibility, the evaluator prompt is provided below. The placeholders `{{tools}}`, `{{system_prompt}}`, `{{user_query}}`, and `{{function_call}}` are replaced with the corresponding example fields.

```
You are an expert evaluator of function-calling annotations.

Your task is to determine whether the provided function call is a perfect
annotation of the user's request.

Available tools:

{{ tools }}

Evaluation criteria:

1. The selected function is the single best choice among the available tools.
2. A function should only be called if the user's request actually requires one.
3. If no available tool should be called, any function call is incorrect.
4. Every required parameter is present.
5. No unnecessary or hallucinated parameters are included.
6. Every parameter value is exactly supported by the original system prompt or the
   user's request.
7. Missing information must not be invented or assumed.
8. Parameter names exactly match the selected tool's schema.
9. Parameter values have the correct types according to the tool schema.
10. The function call follows the required function-call format.
11. The function call fully conforms to the selected tool's schema.
12. Ignore insignificant differences in whitespace or formatting that do not
    affect the meaning or structure of the function call.
13. Parameter values must preserve the user's original wording unless the tool
    schema explicitly requires normalization (e.g., enum values, ISO dates, standardized
    formats).
14. Translating, paraphrasing, summarizing, correcting spelling, expanding
    abbreviations, or otherwise modifying a parameter value is considered an
    error unless explicitly required by the tool schema.

Decision rule:
- Return `label = 1` ONLY if every criterion is unquestionably satisfied.
- If there is any ambiguity, unsupported assumption, missing information,
  incorrect function, incorrect parameter, invalid extraction, schema violation,
  formatting violation, translation, paraphrasing, or uncertainty, return `label = 0`.

Reason codes:
If `label` is `0`, choose ONLY ONE primary reason from the following list:

[wrong_function, no_function_needed, missing_parameter, extra_parameter, translated_parameter,
rephrased_parameter, wrong_parameter_name, wrong_parameter_type, wrong_argument_value,
hallucinated_value, invalid_format, schema_violation, unsupported_assumption, ambiguous_request,
multiple_errors]

If `label` is `1`, use: correct

Output format:
Return ONLY valid JSON.

Correct annotation:
{ "label": 1, "reason": "correct"}

Incorrect annotation:
{ "label": 0, "reason": "<reason_code>"}

Do not output markdown.
Do not output explanations.
Do not output any additional text.

Original system prompt:

{{ system_prompt }}

Original user request:

{{ user_query }}

Function call format:

The function call is NOT JSON. It always follows this XML-like structure:
<tool_call><function=function_name><parameter=parameter_name>parameter_value</parameter>...</function></tool_call>

Evaluation notes:

- The function name is specified in the opening `<function=...>` tag.
- Each parameter is represented by a `<parameter=...>` tag.
- Parameter values are plain text between the opening and closing parameter tags.
- The order of parameters is not important unless explicitly required by the tool schema.
- Ignore insignificant whitespace and line breaks.
- Evaluate semantic correctness rather than exact formatting, provided the
  structure remains valid.
- Do not infer or guess missing information.
- Reject any function call containing unsupported, hallucinated, or incorrectly extracted values.
- Validate the function call against the provided tool schema, not against the example above.
```

```
Function call to evaluate:

{{ function_call }}

Result:
```

Figure 5: Full evaluation prompt used by the LLM-based evaluator to assess training annotations against the system prompt, user request, and tool declaration.

H Tool-Declaration Refinement And Data Consistency Analysis

We conducted an error analysis of function-calling predictions from an initial Qwen3.5-4B model fine-tuned on the pre-processed training data. The analysis focused on argument-level errors and identified recurring cases in which failures were associated with ambiguity, incompleteness, or insufficient specificity in the corresponding tool declarations.

Based on these observations, we introduced **Tool-v2** by refining affected tool declarations while preserving their original functionality and task semantics. The refinements target four recurring sources of ambiguity: (i) preservation of user-provided values, (ii) incomplete categorical value enumerations, (iii) ambiguity between semantically related arguments, and (iv) unclear extraction boundaries. The corresponding changes are illustrated in Sections H.1–H.4.

The analysis also revealed substantial variation in the surface-form representation of date arguments across the reference annotations. Because this variation is present in the annotations themselves, it cannot be resolved through tool-declaration refinement alone. We therefore retain date representation as a data-level ambiguity rather than imposing an arbitrary canonical format (Section H.5).

This data-level ambiguity is distinct from the Tool-v2 refinements, which modify only the tool descriptions provided to the model while preserving the underlying tool functionality and task semantics.

H.1 Preserving User-Provided Representations

A recurring error involved unnecessary transformation of values explicitly provided by the user, particularly names of cities and countries. To make the expected behavior unambiguous, the corresponding argument descriptions were revised to require preservation of the user's original representation.

Language preservation

Tool-v1		Tool-v2
اسم المدينة بالعربية	⟶	اسم المدينة بالعربية، وإذا أدخله المستخدم بلغة أخرى فاستخدمه كما هو
اسم الدولة بالعربية	⟶	اسم الدولة بالعربية، وإن ذكرها المستخدم بلغة أخرى فاستخدمها كما هي

Refinement: Explicitly preserve user-provided values rather than implicitly converting them to Arabic or English.

H.2 Completing Categorical Value Enumerations

Several tool declarations listed only a subset of the categorical values observed in the reference annotations. Such incomplete enumerations can make the declaration inconsistent with valid reference values and may reduce the model's ability to associate an argument with its supported value space. We therefore expanded the affected enumerations to include additional values supported by the data.

Categorical value coverage

Tool-v1	Tool-v2
`money, gold, silver, trade_goods, stocks`	`cash, gold, fitr, trade, crops, silver, general, livestock, realestate, shares, salary`
`resignation, termination, retirement`	`dismissal, resignation, end_of_contract, retirement, unfair_dismissal, economic, mutual_consent, disciplinary`
`text, topic, surah`	`text, topic, surah, tafseer, verse`

Refinement: Complete the enumeration using valid values supported by the training data, rather than restricting the model to an incomplete subset.

H.3 Clarifying Argument Semantics

Some errors involved confusion between arguments with closely related semantics. We therefore refined the affected descriptions to make the intended meaning and admissible value types explicit.

Argument semantics

Tool-v1	Tool-v2
`recipient_name`	
اسم المستفيد	اسم المستفيد. يجب أن يكون اسم شخص حقيقي وليس وصفا مثل "صديقي" أو "أخي"
`doctor_name`	
اسم الطبيب (اختياري)	اسم الطبيب ويجب أن يكون اسم شخص حقيقي (اختياري)
`product_value`	
قيمة المنتج	قيمة المنتج (سعره الإجمالي أو المبلغ المدفوع لشرائه)

Refinement: Disambiguate closely related concepts by explicitly stating what qualifies as a valid argument value.

H.4 Clarifying Extraction Boundaries

We also observed cases in which the predicted argument span contained information beyond the intended value. Where the reference annotations supported a consistent extraction rule, the corresponding descriptions were refined to state the required boundary explicitly.

	ArgEM↑	FnAcc↑	ThinkRate↑	Track B↑
$\text{Makeen}_{\text{Base}}$	76.60 → **81.20** (+4.60)	94.68 → **99.63** (+4.95)	100.0 → 100.0 (+0.00)	86.70 → **90.49** (+3.79)

Table 9: Effect of tool-description refinement on $\text{Makeen}_{\text{Base}}$. Each cell reports *Tool-v1* → *Tool-v2*, with the absolute change shown in parentheses. Tool-v1 uses the original shared-task tool descriptions, whereas Tool-v2 uses the refined descriptions.

Extraction boundaries

Tool-v1		Tool-v2
`items`		
قائمة الطعام	→	قائمة الطلب كاملة مع كل التفاصيل كما هي بدون اختصار أو حذف
`text`		
النص المراد ترجمته	→	النص المراد ترجمته فقط، يجب استخراج النص المطلوب للترجمة دون تضمين كامل الاستعلام

Refinement: Specify the intended argument span instead of leaving the extraction boundary implicit.

H.5 Date Representation Ambiguity

The same analysis revealed substantial variation in the surface form of date arguments such as `check_in` and `check_out`. Observed representations include ISO-formatted dates (`2024-11-10`), day–month expressions (١ مارس), Arabic-Indic numerals (٢٠ أكتوبر), and relative temporal expressions (بداية الشهر القادم).

Because these variations occur in the reference annotations themselves, they cannot be resolved through tool-declaration refinement alone. Imposing a canonical representation at the tool-declaration level without first resolving the underlying annotation inconsistency would introduce an additional assumption not supported by the data.

We therefore did not impose a canonical date format in Tool-v2. Instead, we treat date representation as a data-level ambiguity that should be resolved at the annotation level before a canonical representation is encoded in future tool specifications.

H.6 Empirical Impact Of Tool-Declaration Refinement

To quantify the effect of the tool-declaration refinements, we evaluated $\text{Makeen}_{\text{Base}}$ using two versions of the tool descriptions: (i) the original descriptions provided with the shared-task data (Tool-v1), and (ii) the refined descriptions introduced in Tool-v2. All other aspects of the system, including the model, training procedure, and evaluation setting, were kept unchanged.

As shown in Table 9, Tool-v2 yields consistent improvements in both function selection and argument extraction. In particular, ArgEM increases by 4.60 percentage points, while FnAcc increases by 4.95 percentage points. Because the comparison changes only the tool descriptions while keeping the model and evaluation setting fixed, these results provide evidence that improving the specificity and consistency of tool declarations can materially affect function-calling performance.

I Construction Of The Unseen-Tool Development Split

We construct the external-data train/dev split to evaluate generalization to functions that are not observed during training. The procedure operates over the combined inventory of shared-task and translated tools. First, we group functions using shared name tokens and exclude groups containing shared-task functions.

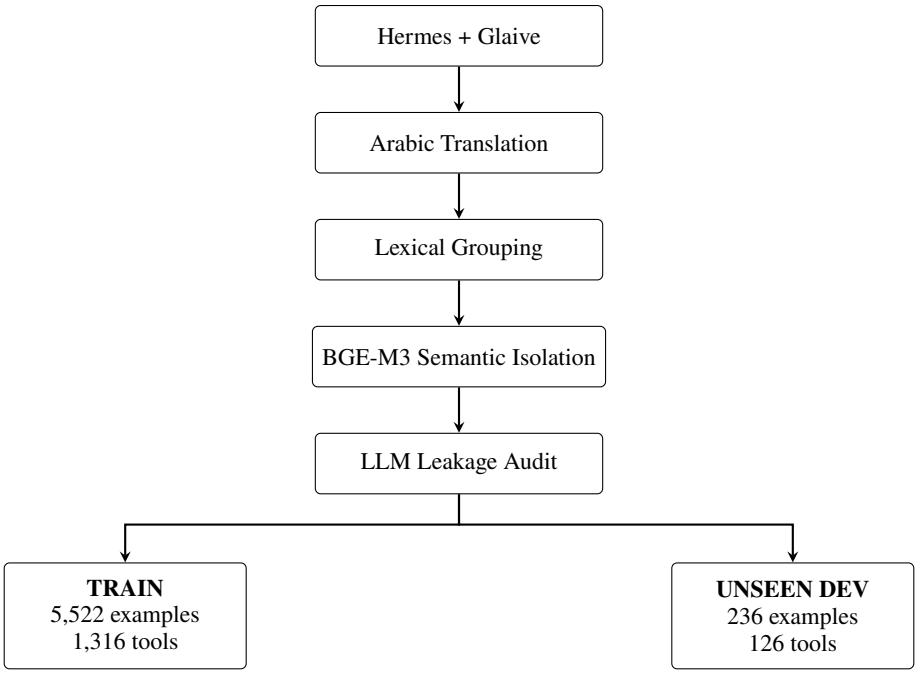

Figure 6: Construction of the external-tool training and unseen-tool development sets. Hermes and Glaive examples are translated into Arabic, grouped lexically, filtered using BGE-M3 semantic similarity to isolate tool groups, and subsequently audited with an LLM to reduce potential cross-split leakage. The final split is performed at the tool level, with 1,316 training tools and 126 unseen development tools.

These lexical groups serve only as candidate families for the subsequent semantic filtering. We then encode each tool using `BAAI/bge-m3` (Chen et al., 2025), representing the function name, description, and argument descriptions. A candidate held-out group is retained only when every function in the group has cosine similarity below 0.75 to every function outside the group in the combined tool inventory.
The resulting candidates are subjected to an exhaustive cross-pool semantic audit using GPT-5.6 Luna as an LLM judge. The judge receives the final TRAIN and DEV tool declarations as separate pools and identifies residual semantic overlap between the two inventories. We additionally verify function-level disjointness and candidate-pool separation before constructing the final examples. Each example is assigned according to its gold function, and candidate tools are drawn exclusively from the same split.
The final external-data training split contains $5{,}522$ examples spanning $1{,}316$ tools, while the held-out development split contains 236 examples spanning 126 tools. The shared-task development split is retained separately for evaluation on the original 27-tool inventory.

J Makeen Pipeline

Figure 7 illustrates the complete Makeen pipeline, from the generator and label-semantic extractor to hint construction and confidence-gated routing.

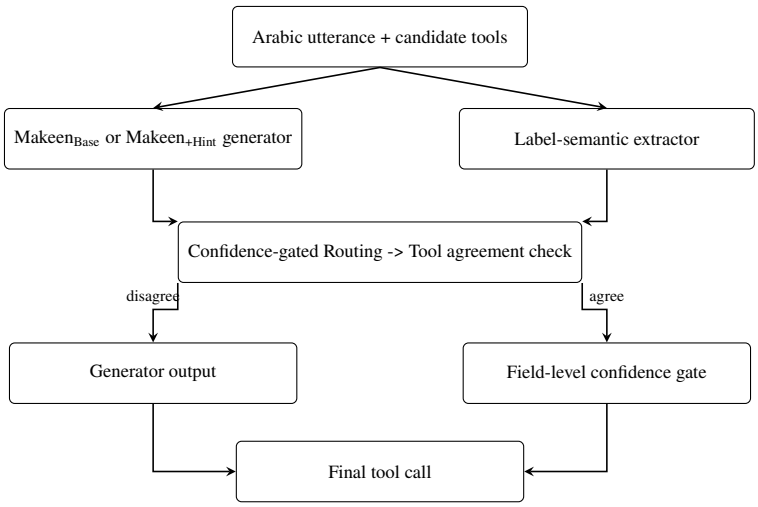

Figure 7: Overview of the Makeen pipeline. The submitted Makeen$_{\text{Base}}$ generator is extended with label-semantic extraction for Makeen$_{\text{+Hint}}$ and with confidence-gated routing at inference time.

Arabic Function Forge at AISA-ArabicFC: Copy, Don't Interpret Training-Free Arabic Function Calling

Anfal Alshehri
KAUST, Thuwal, Saudi Arabia

Jumanah Aljubayri
Tahakom, Riyadh, Saudi Arabia

Abstract

Arabic Function Forge is our submission to AISA-ArabicFC 2026. Our system is training-free: it uses a single off-the-shelf open-weights model, prompted once per request, with no parameter updates. It placed fifth on Track A, fourth on Track B, and sixth on Track C. Our central observation is that function selection is nearly saturated on this benchmark while argument extraction is not: we reach 0.9893 function accuracy but only 0.8686 argument exact match, so 94.9% of the remaining headroom lies in arguments. The dominant failure is not misunderstanding but over-interpretation: the model translates values, converts dates to ISO form, and adds fields the user never provided. Our system is designed to suppress this behaviour by preserving argument values as written. We further find that the dialect penalty is concentrated rather than graded, with most of the drop occurring on Maghrebi.

1 Introduction

With the recent advances in agentic workflows (Nacar et al., 2026c), function calling has become increasingly important. Function calling allows a language model to turn a natural language request into a structured call that invokes a function to do some job. This requires two main jobs: choosing the right function and extracting the right arguments for it. Both have to be correct. A call with the right function but the wrong arguments is still a failed call.

However, most current systems are developed and evaluated in English. The recent survey of agentic tool use (Hu et al., 2026) covers different approaches to function calling, but does not address language diversity or non-English evaluation. For Arabic, this matters because performance drops by 5–10% when models are prompted in Arabic, whether the tool descriptions are written in Arabic or English (Kubrak et al., 2026). Arabic also carries cultural and religious contexts that are not always captured by English-based systems (Al-Khalifa et al., 2025), and the problem becomes harder with dialects, where the value to extract is whatever the user actually wrote.

Most existing approaches solve function calling through some form of training. Toolformer (Schick et al., 2023) learns tool use self-supervised, ToolLLM (Qin et al., 2024) instruction-tunes over 16,000+ APIs, and Gorilla (Patil et al., 2024) uses fine-tuning for API calls. For Arabic, Nacar et al. (2026b) show that data-centric fine-tuning can reduce parse failures from 87% to under 1%. The problem is that these approaches depend on training, and changes to the available tools may require additional data or model updates. We instead take a training-free approach where tools are provided to the model at inference time.

Our system is based on three main decisions: (i) providing only the four candidate tools associated with each request rather than the full 27-tool registry; (ii) using the reference clock provided with each example to handle relative time expressions; and (iii) using an Arabic system prompt built from our development error analysis, with one main idea: copy the user's values as written instead of interpreting them.

Without any parameter updates, our system placed fifth on Track A, fourth on Track B, and sixth on Track C (Table 1). Our results show that function selection is close to saturated while argument extraction remains the main source of error. We also find that the dialect gap is not equal across Arabic varieties, but is concentrated mainly in Maghrebi. We analyse both findings in §4.

2 Related Work

Function calling is not a new problem. Before LLMs, a similar problem was studied as *intent detection* and *slot filling*: deciding what the user wants and extracting the values needed for that re-

Proceedings of The Fourth Arabic Natural Language Processing Conference (ArabicNLP 2026) - Volume 2 Shared Tasks, pages 1654–1657
October 28-29, 2026 ©2026 Association for Computational Linguistics

quest. This is closely related to choosing a function and filling its arguments. Weld et al. (2022) survey more than a decade of work on these tasks, while Chen et al. (2019) use BERT to jointly predict intents and slots. These systems, however, are built around a fixed schema, where adding new intents or slots can require new labelled data and retraining. MASSIVE (FitzGerald et al., 2023) extended this setting to 51 languages, including Saudi Arabic (`ar-SA`), but still uses a fixed inventory of 60 intents and 55 slots.

LLMs changed this by allowing tool schemas to be provided directly in the prompt. Hu et al. (2026) divide current approaches into prompting, supervised tool learning, and reward-driven tool learning; our system belongs to the first. Previous systems learn tool use through self-supervised learning (Schick et al., 2023), instruction tuning (Qin et al., 2024), or fine-tuning with retrieval (Patil et al., 2024). ToolkenGPT (Hao et al., 2023) keeps the language model frozen but learns an embedding for each tool. In contrast, our system requires no schema-specific parameter updates: a new tool is provided as a JSON schema at inference time.[1]

Function calling is commonly evaluated using API-Bank (Li et al., 2023) and BFCL (Patil et al., 2025). AISA-ArabicFC differs in that requests are Arabic and arguments are evaluated using strict key–value exact match. For Arabic, Kubrak et al. (2026) show that function-calling accuracy drops, while Nacar et al. (2026b) introduce the corpus underlying this shared task, described by Nacar et al. (2026a). These works establish that Arabic function calling degrades, but do not localise where argument extraction fails or separate extraction errors from dialect effects. This is the gap we study.

3 Methodology

We use the open-weights Qwen3.5-122B-A10B model (Qwen Team, 2026), served locally with vLLM (Kwon et al., 2023), without fine-tuning or retrieval. The labelled data are used only for error analysis and prompt design; no model parameters are updated.

For each AISA-ArabicFC request (Nacar et al., 2026a,b), AISA-ArabicFC provides four candidate tools in `tools_sampled`, which we pass directly to the model rather than the full 27-tool registry . Before inference, we sanitise the schemas by removing null properties and empty enums and updating the required fields. We also provide the reference clock included with each example so relative time expressions are resolved against the intended date rather than the current time.

The system prompt is written in Arabic and was built from our development error analysis. Its main instruction is to copy user values as written rather than translate, normalise, or infer them. We also add rules for the most common errors, including dates, the Arabic definite article, lists, optional fields, and tool-specific argument conventions.

We perform one generation per request with automatic tool selection, temperature 0.6, and Qwen thinking enabled. The function call is used for Track A and the Arabic reasoning from the same generation for Track B, with no second generation or translation step. Null and empty arguments are removed from the final call; no other post-processing is applied.

Track	FnAcc	ArgEM	Overall
A (5th)	0.9893	0.8686	**0.9169**
B (4th)	0.9893	0.8686	**0.9311**
C (6th)	—	—	**0.8847**

Table 1: Blind-test results and final leaderboard ranks. Track B has a ThinkRate of 1.0000, while Track C reports the macro average across five dialects.

4 Evaluation

We follow the official shared-task protocol (Nacar et al., 2026a) on 1,125 blind test examples, with no manual selection or modification of the predictions. Function Accuracy (FnAcc) measures correct function selection, while Argument Exact Match (ArgEM) requires the full argument dictionary to match exactly with no partial credit. Track A weights them as $0.40 \cdot \mathrm{FnAcc} + 0.60 \cdot \mathrm{ArgEM}$, Track B additionally evaluates the Arabic reasoning trace, and Track C evaluates dialect robustness.

The main remaining problem is argument extraction. FnAcc reaches 0.9893, while ArgEM is 0.8686. Under the Track A weighting, perfect function selection would improve Overall by only 0.0043, compared with 0.0788 for perfect argument extraction. This means that 94.9% of the remaining headroom lies in arguments. The dialect results also show that the degradation is not uniform: MSA and Egyptian score 0.933, Gulf

[1] Training-free is not cost-free. Serving a 122B-parameter Mixture-of-Experts model requires substantial GPU memory; our claim concerns maintenance as the tool registry changes, not total compute.

0.890, Levantine 0.880, and Maghrebi 0.788. The 0.145 best–worst gap is therefore mainly driven by Maghrebi, showing that the remaining dialect problem is concentrated rather than shared equally across Arabic varieties.

5 Conclusion

We presented a training-free approach for Arabic function calling using an open-weights model and prompt-based inference. Without fine-tuning, our system achieved an Overall score of 0.9169 on Track A, with 0.9893 function accuracy and 0.8686 argument exact match. This shows that the main remaining challenge is argument extraction rather than function selection. We also find that dialect degradation is concentrated mainly in Maghrebi. These results show that competitive Arabic function calling can be achieved without parameter updates.

Limitations

Although no model parameters are updated, our prompt was designed using labelled development data and therefore still uses supervision. Some prompt rules are also specific to the 27 tools and may not transfer directly to a new registry. Finally, our dialect results, particularly for Maghrebi, are based on a smaller portion of the data and should be interpreted with caution. Our results therefore show the potential of training-free function calling, rather than that it is more accurate than supervised approaches.

Acknowledgments

The authors declare that there is no conflict of interest. This work represents the authors' independent efforts and received no support or funding from any external organization. We thank Tuwaiq Academy and the AISA-ArabicFC organizers for providing the dataset, baseline model, and evaluation framework for this shared task.
