Figure 4 visualises Re:CAP's internal cost-quality trade-off across the $E3$ ablation grid on MuSiQue. The recommended default ($N_q = 5$, $m = 50$, MAX_ITER= 3, gpt-4.1 pipeline) sits at the elbow of the Pareto front: spending 2× more (the $N_q = 10$ or top-$m = 100$ cells) buys +3–4 pp recall, while spending 3× less (the $N_q = 1$ cell) costs −10 pp. The front is monotone in recall up to ∼$1/q — no ablation simultaneously reduces cost and lifts recall. The chart is intra-Re:CAP: flat-retrieval baselines return ranked documents but produce no coverage audit, so they are not plotted on this axis; matched-budget recall comparisons appear in Table 2.

M.1 Gap-Q generator design (E3.1)

Table 19 reports the full 2 × 2 × 3 matrix (retriever × generator × dataset). The five-mechanism generator beats the $(Q{+}T)$-only ablation on hybrid by +1.1 pp on MuSiQue and +4.9 pp on HotPotQA; MultiHop-RAG is at ceiling. Two cells regress. The larger — MuSiQue with BM25 +

five-mechanism, -5.4 pp — is a retriever-coupling effect: tighter probes under-explore on a single-channel retriever, and the regression vanishes on hybrid. The smaller is MultiHop-RAG on hybrid (-1.0 pp), where the corpus is already at ceiling.

Dataset	BM25 QT	BM25 5m.	hyb. QT	**hyb. 5m.**
MuSiQue	0.888	0.834	0.890	**0.901**
HotPotQA	0.813	0.864	0.838	**0.888**
MultiHop-RAG	0.978	0.984	0.988	**0.978**

Table 19: Gap-Q generator ablation (E3.1): Re:CAP mean recall by retriever × gap-Q generator. *QT* = $(Q{+}T)$-only baseline; *5m.* = five-mechanism generator. Default in bold.

M.2 Per-lever leave-one-out (E3.1.2)

Table 20 attributes the five-mechanism generator's lift to each of its mechanisms via a 15-cell LOO sweep (5 levers × 3 bounded-evidence datasets, 100 q each on hybrid). Paired Δ is mean per-query (reference recall − leave-one-out recall) in pp; positive Δ means *dropping* the lever hurts. Cells with $|\Delta| > 0.42$ pp (the variance noise floor of §4.5) are bolded.

Lever	Mechanism	MuSiQue Δ	HotPotQA Δ	MultiHop Δ
A	entity ledger	**+8.58**	**+4.17**	**−1.47**
B	coverage topics	−0.42	**−2.06**	**−1.26**
C	probe roles	**−1.00**	**−1.03**	**−1.45**
D	anti-collapse	+0.33	**+1.55**	**−0.88**
E	failure memory	**+0.75**	0.00	**−0.48**

Table 20: Per-lever leave-one-out (E3.1.2). Paired Δ in pp; positive = lever helps recall. Lever A (entity-anchored gap-Q generation) accounts for nearly all of the five-mechanism generator's lift on the two bounded-evidence chain datasets; on near-ceiling MultiHop-RAG it mildly hurts because entities are already pinned by the question's surface form.

Decomposition: the five-mechanism generator is **one dominant anchoring mechanism plus four supporting refinements**. Lever A's $+8.58$ pp on MuSiQue and $+4.17$ pp on HotPotQA recover the entirety of the five-mechanism generator's hybrid-cell lift from Table 19. On MultiHop-RAG, dropping A *raises* recall by 1.47 pp at near-ceiling reference: the entity-ledger prompt over-constrains when the question itself names the relevant entities ("between article X and article Y…").

M.3 Number of gap questions (E3.2), expansion depth (E3.3), iteration depth (E3.4)

We swept each of the three primary hyperparameters individually on the MuSiQue M_0 slice (100 q, hybrid, five-mechanism generator, other defaults held). All three curves confirm the default Re:CAP config sits at the cost-recall knee.

E3.2 N_q**.** Recall climbs monotonically: $0.802 \rightarrow 0.883 \rightarrow 0.901 \rightarrow 0.936$ for $N_q \in \{1, 3, 5, 10\}$ at per-query cost $\$0.19/0.46/0.59/1.01$. $N_q = 10$ buys $+3.5$ pp paired over the default $N_q = 5$ at $+71\%$ cost.

E3.3 expansion top-m**.** Recall $0.875 \rightarrow 0.901 \rightarrow 0.938$ at cost $\$0.25/0.59/1.25$ for $m \in \{20, 50, 100\}$. $m = 100$ buys $+3.7$ pp at $+113\%$ cost.

E3.4 MAX_ITER. Iter = 1 drops 4.0 pp paired (outside the noise floor); iter $\in \{2, 3, 5\}$ are within ± 2 pp of each other with iter = 2 nominally best (-0.83 pp vs. ref, roughly $2\times$ the 0.42 pp variance noise floor of §4.5 and roughly five times smaller than the iter = 1 drop). Mean iterations actually run is $1.00/1.75/1.79/1.91$ respectively (anti-collapse termination dominates for ≥ 2), so on the public benchmarks reported here MAX_ITER > 3 buys neither recall nor convergence depth. We default to 3 for headroom: on internal production traffic with broader, more open-ended queries we observe occasional cases where the loop still surfaces novel topics at iter = 3 that iter = 2 misses, suggesting the public benchmarks under-sample the regime where deeper iteration helps.

M.4 Pipeline-model swap (E3.5) and generator-vs-judge cost decomposition (E3.6)

Swapping every *pipeline* component (generator, judge, topic extractor, reconciler) from GPT-4.1 to GPT-4.1-mini on HotPotQA drops recall by 0.51 pp paired ($0.888 \rightarrow 0.884$, on the edge of the 0.42 pp noise floor) while cutting per-query cost from $\$0.586$ to $\$0.128$ (-78%). The reader (GPT-5.2) is held fixed. Pipeline LLM quality is largely interchangeable against a stronger reader, and this is the largest cost lift available in the ablation grid.

To attribute the $E3.5$ saving, $E3.6$ isolates each component on the same HotPotQA slice with reader/extractor/reconciler held at GPT-4.1. (i) Generator = mini, judge = 4.1: recall 0.884 (paired $\Delta = +0.51$ pp), cost $\$0.537$/q ($-8\%$). (ii) Generator = 4.1, judge = mini: recall 0.867 (paired $\Delta = +2.06$ pp, outside the noise band), cost $\$0.145$/q ($-75\%$). The judge dominates both cost and quality; the generator is interchangeable across model tiers. This is the direct empirical attribution behind the $\sim$97%-judge claim in Table 4 and behind the recommendation to keep the judge at GPT-4.1 unless the deployment can tolerate ~ 2 pp recall in exchange for the additional $\sim 70\%$ cost

saving.

Ablation	Sweep
E3.1 Generator design	$(Q{+}T)$ / 5m.
E3.2 Num. gap-Qs	1 / 3 / 5 / 10
E3.3 Expansion top-m	20 / 50 / 100
E3.4 Iterations	1 / 2 / 3 / 5
E3.5 Pipeline model	4.1-m / 4.1
E3.6 Cross-model gen./judge	same / cross

Table 21: Ablation summary: the parameter sweeps reported across §M. Per-cell numbers are in the corresponding subsection.

N Component Validation and Generality

N.1 Cross-dataset generality (E5.2)

Table 22 reports the default configuration applied identically across four datasets with no per-dataset tuning.

Dataset	n	Recall	Δ vs. N_q	$\lvert G\rvert$	Iters
MuSiQue	100	**0.901**	**+0.291**	3.6	1.79
HotPotQA	98	**0.888**	**+0.061**	2.3	1.4
MultiHop-RAG	98	**0.978**	**+0.030**	9.7	1.0–1.3
TREC-COVID†	50	0.221	$+0.023$	36.9	2.6

Table 22: Cross-dataset generality (E5.2): default config applied with no per-dataset tuning. Δ is vs. flat BM25 at matched-N_q; $\lvert G\rvert$ is mean Re:CAP gap count per query.

N.2 Judge ceiling and gap-Q quality from gold labels

Judge ceiling. The primary component-level question is how often the LLM judge rejects a candidate that the gold qrels mark relevant. Across all 86 loss queries and 20,146 missing-gold documents (§O, Table 23), 1.4% of missing gold reached the candidate pool but was rejected by the judge; on the bounded-evidence primaries (HotPotQA, MuSiQue, MultiHop-RAG) the rate is 4.7% (3/64). The judge is therefore an empirically tight upper bound on the audit in the regime Re:CAP is designed for: $> 95\%$ of missing-gold losses are upstream of judging. This is consistent with LLM-as-judge studies on narrow relevance tasks (Faggioli et al., 2023; Thomas et al., 2024; Upadhyay et al., 2024a,b), while respecting cautions against replacing full human qrels with LLM labels (Soboroff, 2025).

Gap-Q quality (extrinsic). We evaluate gap-Q quality by the most direct operational signal: whether the questions recover gold the host retriever missed. Three converging pieces of evidence. (i) *Diversity:* mean pairwise LLM-embedding cosine 0.599 across batches on the MuSiQue 100-query anchor (target ≤ 0.7; max $0.758 \leq 0.85$). (ii) *Role coverage:* the five-role taxonomy enforces ≥ 3 of 5 probe roles per batch. (iii) *Causal contribution:* the per-lever LOO sweep (§M, Table 20) attributes $+8.58$ pp on MuSiQue and $+4.17$ pp on HotPotQA to the entity-anchored gap-Q lever alone — the main recall lift *is* the gap-Q quality measurement under the audit's own objective.

N.3 Human-evaluation protocol on ensemble-unreachable gap documents

This appendix expands the body §5 human evaluation: sample design and item-and-rubric protocol. Verdict counts are reported in Table 6 in the body.

Sample. $n = 123$ items from the deployed default (hybrid retrieval + five-mechanism generator). TREC-COVID: $n = 100$ stratified-random sample from the 1,034 ensemble-unreachable docs in the 50-query run, target 2 docs/query covering all 50 queries with ≥ 1 ensemble-unreachable doc. MuSiQue: census of all $n = 23$ ensemble-unreachable docs from the 100-query run. HotPotQA is omitted (4 ensemble-unreachable docs, insufficient for per-doc inference); MultiHop-RAG is omitted (0, corpus saturates); MS MARCO is omitted (BM25-only setup; no ensemble defined).

Item and rubric. Per item the annotator sees the query, the baseline reader's answer generated from the deployed default's D_0 alone, and the candidate document text (truncated at $\sim$500 words). Blinded to: which baseline(s) miss the document, qrels status, dataset name. Binary rubric: *new_info* if the document contains a substantive query-relevant fact not in the baseline answer (a new entity, a numeric or temporal anchor, a correction, an unambiguating clarification); *covered* if the relevant content is substantively present in the baseline answer. All sampled docs are gold-relevant by construction (NIST TREC pool / MuSiQue dataset authors), so the rubric does *not* adjudicate relevance, only informational novelty.

Worked example. Figure 5 shows one annotation item from the TREC-COVID slice. The deployed default's D_0 (hybrid top-10) yields an A_0 on paediatric COVID-19 outcomes. Re:CAP's gap-question generator produces an iteration-3 constraint-relaxed probe *"What are the health outcomes for children who contract viral respiratory infections, including but not limited to COVID-19?"*; expanded retrieval on this probe surfaces the candidate *"Laboratory Findings of COVID-19 In-*

fection are Conflicting in Different Age Groups. . . ", which adds paediatric-specific lab markers (CRP, WBC, procalcitonin) absent from A_0. The candidate is qrels-positive yet missed by all three flat top-500 retrievers (BM25, dense, hybrid). Re:CAP's own novelty judge marks it REDUNDANT (collapsing the paediatric lab pattern into a coarser parent topic — the sub-mechanism over-aggregation failure mode of App. O); all three blinded annotators independently rate it *new_info*.

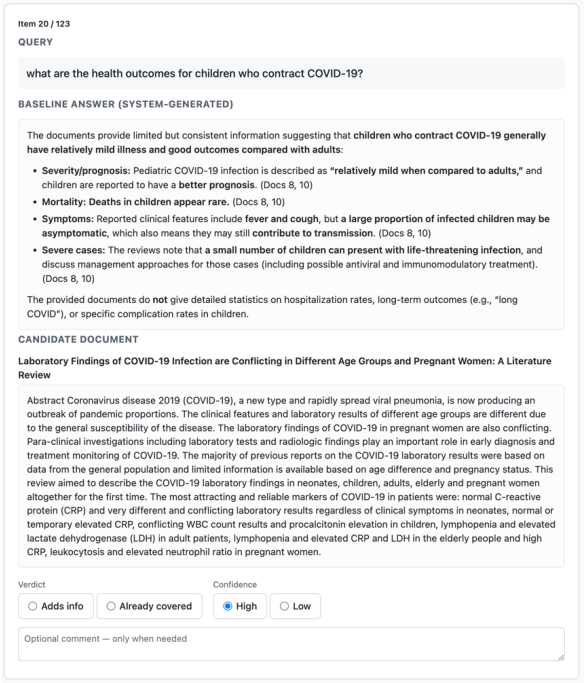

Figure 5: Annotation item TC-098 (`trec_covid__47__qo3p62m4`) as shown to annotator A1. Top: query and D_0-only baseline answer. Bottom: candidate document surfaced by Re:CAP's iteration-3 constraint-relaxed gap-question (text in main prose). All three annotators (blinded to retriever, judge verdict, and dataset) selected *new_info*, while the loop's own novelty judge had marked the document REDUNDANT.

O Failure-Mode Analysis

We classified 86 *loss queries* (where Re:CAP cumulative recall fell below the matched-N_q flat-retrieval floor) across four datasets and 20,146 missing-gold documents. Tables 23 and 24 report the breakdown. The aggregate 98.6% no-surface / 1.4% judge-rejected split is dominated by TREC-COVID, which contributes 20,082 of 20,146 missing-gold documents.

Two-regime interpretation. On bounded-evidence (HotPotQA, MuSiQue, MultiHop-RAG; $n_{\text{loss}} = 43$, 64 missing docs) the dominant failure modes are early convergence (41/43), gap-Q off-topic from bridge-entity erasure (19/43), and low topic yield (30/43) — all addressable on the generator side. On pooled-graded (TREC-COVID, $n_{\text{loss}} = 43$, 20,082 missing docs) the dominant failures are judge-rejected (39/43) compounded by iteration cap (24/43); both are structural consequences of binary-novelty judging applied to pooled-graded relevance with ∼493 rel docs/query at a ∼378-doc budget.

Targeted-recovery replay. We replayed the 33 unique bounded-evidence loss queries under the deployed default (hybrid + five-mechanism generator). 22/33 (67%) flipped from loss to tie or win; mean Δrecall +0.260 per query. Per dataset: MuSiQue-BM25 7/11 ($\Delta = +0.197$), HotPotQA-BM25 11/18 ($\Delta = +0.278$), MultiHop-RAG 4/4 ($\Delta = +0.354$). The residual ∼33% are largely cases where the entity ledger anchors on a hallucinated entity from A_0.

Dataset	n_{loss}	Miss.	% Judge	% No-surf.
HotPotQA (BM25)	18	26	0.0%	100.0%
MuSiQue (BM25)	11	17	5.9%	94.1%
MuSiQue (hybrid)	10	15	6.7%	93.3%
MultiHop-RAG	4	6	16.7%	83.3%
TREC-COVID	43	20 082	1.4%	98.6%
Overall	**86**	**20 146**	**1.4%**	**98.6%**
AND only	**43**	**64**	**4.7%**	**95.3%**

Table 23: Missing-gold attribution per dataset. *Judge* = surfaced as candidate but judge-rejected; *No-surf.* = never reached the candidate pool. The AND-only aggregate (95.3% no-surface) is the relevant number for the primary operational regime.

Dataset	n_l	EConv	OffT	ICap	Jdg	LowY	WkD
HotPot (BM25)	18	18	6	0	0	15	10
MuSiQue (BM25)	11	11	4	0	1	6	4
MuSiQue (hyb.)	10	9	5	0	1	6	3
MHopRAG	4	3	4	1	1	3	2
TREC-COVID	43	1	0	24	39	0	0
Overall	**86**	**42**	**19**	**25**	**42**	**30**	**19**

Table 24: Failure-mode tags per dataset (non-exclusive). *EConv* = early convergence; *OffT* = gap-Q off-topic; *ICap* = iteration cap hit; *Jdg* = judge-rejected gold; *LowY* = low topic yield; *WkD* = D_0 recall = 0.

O.1 Qualitative success examples

Three worked examples in which Re:CAP recovers gold that flat BM25 top-500 never reaches. Each is a run from §4.1; gap-Qs and topic labels are verbatim from the iteration trace.

(i) Hedged-answer disambiguation (HotPotQA, hybrid). Query. *"Kiley Dean was a back-up singer for what famous singer, who was also known as the Queen of Pop?"* **Cell.** `hotpotqa-hybrid`, D_0 recall = 0.50 (*Britney Spears* returned but not the *Queen of Pop* bridge), matched-N_q flat = 0.50,

flat-500 = 0.50; Re:CAP recall = 1.00 in 1 iteration. A_0 **excerpt.** "*Kiley Dean sang back-up for Britney Spears and Madonna . . . but they do not state which of these singers was also known as the Queen of Pop.*" **Unreachable gold (flat-500).** `142056` (*Madonna* biographical article). **Recovering gap-Q.** *"Which singer is widely recognized as the Queen of Pop in music history?"* **Topic assigned.** "*Madonna is referred to as the 'Queen of Pop'*". **Interpretation.** The entity ledger pinned both candidates (*Britney Spears*, *Madonna*) but a single concept-anchored probe on the ambiguous *Queen of Pop* role surfaces the disambiguating article that flat retrieval ranks below the top-500.

(ii) Triangulated multi-hop (MuSiQue, hybrid). Query. *"What county is the city that shares a border with the state capital of the state where Purrysburg is located?"* **Cell.** `musique-hybrid`, D_0 recall = 0.25 (only *Purrysburg* retrieved), matched-N_q flat = 0.00, flat-500 leaves 4 of 4 supporting paragraphs unreachable; Re:CAP recall = 1.00 in 2 iterations. A_0 **excerpt.** "*The documents don't provide enough information to determine this. Doc 2 says Purrysburg is in South Carolina, but none of the documents state South Carolina's state capital. . .*" **Unreachable gold.** `mq_charleston_south_carolina_9f68ae`, `mq_forest_acres_south_carolina_35cf43`, `mq_wwnq_9c37a4`, `mq_purrysburg_south_carolina_254ff0`. **Iter-1 gap-Qs.** *Geographical location of South Carolina state capital Columbia; Which cities share borders with Columbia, South Carolina; County jurisdiction of West Columbia, South Carolina*. **Topics assigned.** "*Location and county of Forest Acres, South Carolina*"; "*Geography and location of Forest Acres, South Carolina*". **Interpretation.** A canonical Re:CAP success: the loop triangulates Purrysburg → South Carolina → Columbia → Forest Acres in two iterations even though the initial answer admits insufficient context — the multi-hop pattern flat retrieval cannot resolve in a single pass.

(iii) Cold-start bridge entity (HotPotQA, hybrid). Query. *"What is the nationality of the film director responsible for a 2008 American science fantasy film based on a novel by Jeanne DuPrau?"* **Cell.** `hotpotqa-hybrid`, D_0 recall = 0.00 (neither film nor director retrieved), matched-N_q flat = 0.50, flat-500 misses the gold biography; Re:CAP recall = 1.00 in 1 iteration. A_0 **excerpt.** "*The documents provided do not identify the specific 2008 American science fantasy film based on a novel by Jeanne DuPrau, nor do they give the director's nationality . . .*" **Unreachable gold.** `6167253` (*Gil Kenan* biography). **Recovering gap-Qs.** *Director of City of Ember 2008 science fantasy film; Citizenship of Gil Kenan filmmaker*. **Topic assigned.** "*Nationality and biography of Gil Kenan, director of City of Ember*". **Interpretation.** The reader's "insufficient context" answer is recovered into the topic registry; the gap-Q generator extracts the DuPrau anchor, names the film (*City of Ember*), pivots to the director, and the judge promotes the biography to a new topic — the path flat retrieval cannot construct.

O.2 Qualitative failure examples

Three worked examples illustrating the three dominant bounded vs pooled-graded failure modes.

(i) Bridge-entity erasure (MuSiQue, hybrid). Query. *"A line with Williamsburg, Main Street and another station are in a state that's next to an ocean. When did that ocean start to open up?"* **Cell.** `musique-hybrid`, recall = 0.50 (matched-N_q flat = 0.75, flat-500 = 0.75), D_0 recall = 0, 2 iterations, 7 topics, 361 candidates judged. **Gold never surfaced.** `Newport News, Virginia`; `Virginia` (the bridge state). **Sample gap-Qs.** *Geological history of Atlantic seafloor formation near New York*; *Earliest rifting events of Pangaea affecting eastern North America*; *Age of Atlantic Ocean crust adjacent to Brooklyn shoreline*. **Diagnosis.** The bridge entity *Virginia* is required to link *Williamsburg* to *Atlantic Ocean*, but neither D_0 nor A_0 surface it (the loop guesses *New York*/*Brooklyn* instead), so the entity ledger never anchors a gap-Q on *Virginia*. Dominant *OffT* + *WkD* pattern on the BM25 cells of MuSiQue.

(ii) Hallucinated anchor (HotPotQA, BM25). Query. *"What is the nationality of the star of The Monster who was also in Swordswallers and Thin Men and The Savages?"* **Cell.** `hotpotqa-bm25`, recall = 0.00 (matched-N_q flat = 0.50, flat-500 = 0.50), D_0 recall = 0, 1 iteration, 1 topic, 0 NEWTOPIC verdicts, 137 candidates judged. **Gold never surfaced.** `Zoe Kazan`; `The Monster (2016 film)` (the correct bridge). **Sample gap-Qs.** *Which country is Toma Caragiu from, the actor in The Monster, Swordswallers and Thin Men, and The Savages?*; *What is the citizenship of Toma Caragiu . . .*; *Where was Toma Caragiu . . . born?* **Diagnosis.** The reader hallucinated *"Toma Caragiu"*

as the star in A_0 (Caragiu is a real Romanian actor but was not in any of the listed films); the entity ledger pinned on this fabricated name and every gap-Q probed around the wrong person. The judge had no opportunity to recover *Zoe Kazan* because she was never returned as a candidate.

(iii) Pooled-graded saturation (TREC-COVID, BM25 + $(Q{+}T)$-only). Query. *"What is the mechanism of inflammatory response and pathogenesis of COVID-19 cases?"* **Cell.** `trec-covid` `topic 38`, recall $= 0.02$ (matched-N_q flat $=$ 0.12, flat-500 $= 0.19$), D_0 recall $= 0.01$, 1 iteration (non-converged), 50 topics (cap), 125 NEWTOPIC verdicts, 249 candidates judged. Gold pool size: $\sim$1,000+ partially-relevant documents. **Gold judged-but-rejected (SUBTOPIC).** `17`β`-Estradiol. . .` folded under "Estradiol and sex hormone modulation of COVID-19 inflammation"; `Why is SARS-CoV-2 infection more severe in obese men?. . .` folded under "Gut-lung axis…". **Sample gap-Qs.** *Role of viral spike protein in triggering lung epithelial cell injury*; *Interaction between SARS-CoV-2 and ACE2 receptor leading to tissue damage*; *Contribution of neutrophil extracellular traps to COVID-19 lung pathology*. **Diagnosis.** The gap-Qs are genuinely on-topic and the loop produces $>$ 100 NEWTOPIC verdicts within the topic cap, but the corpus has thousands of partially relevant documents and most gold is never surfaced. The judge over-aggregates novel sub-mechanisms into existing topics — a structural mismatch between binary-novelty judging and pooled-graded relevance.

P Future Work

- *Robust entity grounding* — cross-check ledger entities against D_0 before anchoring; downgrade anchors to soft preferences when D_0 confidence is low. Targets the residual $\sim$33% of unrecovered bounded-evidence loss queries.
- *Judge-cost reduction* (highest engineering leverage per §4.5): batch judging across multiple candidates per LLM call; a lightweight cross-encoder pre-filter dropping 70–80% of candidates; topic-aware short-circuit when the matched topic is already saturated.
- *Multi-paraphrase gap-Qs per topic*: a queued lever for the remaining *OffT* failures the entity ledger does not catch.
- *Online gap discovery* as a production monitoring tool, and the per-query gap-topic list as a human-readable audit artifact that names the retriever's blind spots.
- *Multilingual extension* and *graph-structured topic registry* (replacing the flat list with a depth-3 rooted DAG, enabling multi-resolution metrics and graph-merge deduplication).
- *Gaps as training signal*: discovered gaps as hard negatives for retriever fine-tuning — closing the loop from evaluation back to improvement.
- *Gap inventory as synthetic qrels for retriever benchmarking*: each $(Q, \text{gap-Q}, \text{judged-novel doc})$ triple is a relevance label produced without human annotation. The unreachable-gold result (§4.1, Table 2: 9–29% of recovered gold is absent from flat BM25 top-500 on the bounded-evidence primaries, rising to 48% on TREC-COVID) shows these labels contain documents that strong flat baselines cannot surface, suggesting the inventory can serve as a low-cost evaluation set for comparing alternative — including inference-optimised — retrievers without re-running the full audit.

Q Prompt Templates

Every prompt used by the Re:CAP loop is reproduced below with the structured-output schema it is sent with, generated directly from the pipeline's definitions so that the listings cannot diverge from the code that runs. The schemas constrain the label set the model may return and are therefore part of the specification: a template alone does not determine the reported behaviour. The information-equivalence judge of §L is included for completeness; it belongs to that controlled experiment rather than the loop. Two presentation-only changes were applied: long lines are hard-wrapped, and non-ASCII glyphs are transliterated (`[+]` for a check mark, `[-]` for a ballot X, `->` for a right arrow, `-` for an em dash). Prompt wording is otherwise unmodified. Prompts use `{placeholder}` substitution; temperature and model settings are in Table 9.

The five probe roles tagged by the gap-question generator are:

- *entity-anchored* — probe centred on a named entity from L;

Topic extraction (Step 1) (1 of 2)

```
# Topic Extraction

Identify the distinct information facets present in the answer below.

## Input

**Query:** {query}

**Answer:**
{answer}

## Instructions

List every distinct piece of information this answer provides in response to the query.
A "topic" is a specific facet of information that helps answer the query.

- If the answer states it cannot answer, has no information, or is empty/unhelpful -> return an
  empty list.
- Only extract topics for **actual information provided**, not meta-statements about lack of
  information.
- Do **not** invent topics -- only extract what the answer actually contains.
```

Topic extraction (Step 1) (2 of 2)

```
## Granularity rules

- A topic is an **information facet** (a type of information), not a single data point or
  instance.
- **Paragraph test:** each topic should warrant its own distinct paragraph. If two topics would
  produce overlapping paragraphs, merge them.
- If the answer lists multiple instances of the same type (e.g. several countries, people,
  events), group them into **one** topic describing the category.
  - [+] `Countries that have won the FIFA World Cup`
  - [-] `Brazil won 5 times` + `Germany won 4 times` + `Italy won 4 times`
- Target: **1-5 topics** for a typical answer. More than 8 almost certainly means
  over-enumeration.

## Output format

Each topic: a short descriptive label (7-12 words) describing what information is provided.
```

Topic extraction (Step 1) — response schema

Enforced response schema — the model is constrained to return exactly these fields:

```
topics: list[str]
    List of distinct topic labels extracted from the answer. Each label is a short phrase
    (5-15 words) describing a specific piece of information. Empty list if the answer
    contains no useful information.
```

- *concept-anchored* — probe centred on an abstract noun phrase rather than a specific entity;
- *constraint-relaxed* — drops a constraint of Q to broaden retrieval;
- *constraint-tightened* — adds a constraint to narrow it;
- *inverse-negation* — probes for contradictory or counterexample evidence.

Entity-ledger initialisation (Step 1b)

```
Extract LITERAL anchor strings from the query and the answer below.
These anchors will be used to ground follow-up search queries -- every
extracted anchor must appear VERBATIM in the source text (not a
paraphrase, not a normalisation).

ORIGINAL QUERY: {query}

INITIAL ANSWER:
{answer}

Two output lists:

1. QUERY ANCHORS -- literal named entities from the QUERY only.
   Include: people, organisations, locations, titles of works, dates,
   version numbers, named events. Do NOT include common nouns or
   generic concepts.

2. ANSWER ANCHORS -- literal named entities or numerical/temporal anchors
   from the ANSWER that are NOT already in the query. These are the
   *bridge* anchors -- the names the query did not mention but the
   answer discovered. They are typically the most valuable for finding
   missing evidence.

Rules:
- Each anchor must be a short literal substring of the source text.
  Use exact capitalisation and spelling as in the source.
- Do not include the same anchor in both lists -- query anchors take
  precedence.
- Skip anchors that are too generic to be useful for retrieval
  (e.g. "year", "country", "person").
- It is fine for either list to be empty.
- Target 1-6 anchors per list.
```

Entity-ledger initialisation (Step 1b) — response schema

Enforced response schema — the model is constrained to return exactly these fields:

```
query_anchors: list[str]
    Named entities (people, organisations, locations, works, dates) extracted verbatim from
    the ORIGINAL QUERY. Each anchor is a short literal string that should appear in gap
    questions.
answer_anchors: list[str]
    Named entities or numerical/temporal anchors extracted verbatim from the ANSWER A_0 that
    are NOT already in query_anchors. These are the bridge entities -- the items the query
    did not mention but the answer discovered.
```

Doc–topic reconciliation (Step 2) (1 of 2)

```
# Document-Topic Reconciliation

Reconcile retrieved documents against a list of known topics.

## Input

**Query:** {query}

**Known topics:**
{topic_list}

**Retrieved documents:**
{documents}

## Process (for each document)

### Step 1 -- Entity check
Is this document about the **same entity/subject** as the query? If not -> `OFF_TOPIC`.

### Step 2 -- Novelty check (only if same entity)
Compare the document's information against the known topics list.
- Covers the same ground as an existing topic (even with different details) -> `REDUNDANT` --
  cite the topic number(s).
- Provides a genuinely **new** type of information -> `NEW_TOPIC` -- provide a short label (7-12
  words).
```

Doc–topic reconciliation (Step 2) (2 of 2)

```
## Granularity rules

- A "topic" is an **information facet** (a type/category of information), not a single data
  point, instance, or example.
- **Paragraph test:** would this topic warrant its own distinct paragraph that does not overlap
  with any existing topic? If not -> `REDUNDANT`.
- Another instance of a category already in the topic list -> `REDUNDANT`, not new.
  - Example: "Countries that won the World Cup" exists -> a document about a specific country's
    win is `REDUNDANT`.
- Sub-topics must represent a genuinely **different dimension**, not just deeper detail of the
  same dimension.
- When in doubt -> `REDUNDANT`. Prefer fewer, higher-quality topics over many overlapping ones.

## Classification labels

| Label | When to use |
|---|---|
| `OFF_TOPIC` | Not about the same entity, or not relevant |
| `REDUNDANT` | Covers same ground as known topics -- cite topic number(s) |
| `NEW_TOPIC` | Genuinely new information facet -- provide a 7-12 word label |
```

Doc–topic reconciliation (Step 2) — response schema

Enforced response schema — the model is constrained to return exactly these fields:

```
documents: list[DocReconciliationEntry]
    One entry per document, in the same order as the input.

DocReconciliationEntry:
  doc_number: int
      1-based document number.
  entity_match: bool
      True if the document is about the same entity/subject as the query.
  maps_to: list[int]
      Topic numbers from the known list that this document covers.
  classification: REDUNDANT | NEW_TOPIC | SUB_TOPIC | OFF_TOPIC
      Classification of this document.
  new_topic_label: str | None
      If NEW_TOPIC or SUB_TOPIC: the label for the new topic. Otherwise null.
  parent_topic: str | None
      If SUB_TOPIC: the parent topic label or number. Otherwise null.
```

OFF_TOPIC here is the reconciler's name for the outcome the novelty judge calls IRRELEVANT; the two steps use different labels for the same decision and both count as non-novel.

Gap-probing question generation (Step 3) (1 of 2)

```
### Task

You are generating SEARCH QUERIES that will be used to retrieve documents
likely to answer the ORIGINAL QUERY below. The goal is to surface
documents that the original query phrasing has NOT yet retrieved.

ORIGINAL QUERY: {query}

--- ENTITY LEDGER ---
These are LITERAL anchor strings extracted from the query and the current
answer. The "answer anchors" in particular are bridge entities that the
initial query did not mention but that subsequent retrieval should
target.

{entity_ledger}

--- TOPICS WITH COVERAGE STRENGTH ---
Each topic shows its current evidence count. Topics marked (weak) have
little supporting evidence and should be prioritised. Topics marked
(strong) are well-covered already -- do not over-probe them.

{topic_list_with_coverage}

--- PREVIOUS GAP QUESTIONS THAT YIELDED NO NEW TOPICS ---
Do NOT repeat or paraphrase any of these. Generate questions that probe
DIFFERENT retrieval directions.

{failed_gap_questions}

--- PROBE ROLES (your batch must be diverse) ---
Every question must declare exactly one role. Across the batch the roles
MUST vary -- do not pick the same role + same anchor twice.
```

Gap-probing question generation (Step 3) (2 of 2)

```
- entity-anchored:      Pivot on a named entity from the LEDGER and ask
                        a different question about it. The literal
                        anchor string MUST appear verbatim in the
                        question. Use this when bridge entities matter.
- concept-anchored:     A query about a concept or mechanism in the
                        answer (no named entity). Use when the gap is
                        conceptual.
- constraint-relaxed:   The original query with ONE specific constraint
                        (date, location, qualifier) REMOVED. Use to
                        widen retrieval.
- constraint-tightened: The original query with ONE specific anchor from
                        the LEDGER ADDED. The anchor MUST appear
                        verbatim. Use to narrow retrieval onto a
                        specific entity.
- inverse-negation:     Ask the inverse / counter perspective (e.g.
                        "What does NOT support ...", "What contradicts
                        the claim that ..."). Use sparingly -- at most one
                        per batch.

--- HARD RULES ---

1. Generate EXACTLY {num_questions} questions.
2. Each question must seek information that helps answer the ORIGINAL
   query.
3. For roles `entity-anchored` and `constraint-tightened`: the `anchor`
   field MUST be one of the literal anchors from the ENTITY LEDGER, and
   it MUST appear verbatim inside the question text.
4. Roles MUST NOT all be the same. Across the batch, use at least 3
   different roles when {num_questions} >= 4.
5. If a topic has `(weak: 0 docs)` or `(weak: 1 doc)`, set
   `targets_topic_id` to that topic's id on at least one question
   (when possible without contradicting the diversity rule).
6. Do not repeat or paraphrase anything in the FAILED GAP QUESTIONS list.
```

Gap-probing question generation (Step 3) — response schema

Enforced response schema — the model is constrained to return exactly these fields:

```
questions: list[RoleTaggedGapQuestion]
    Gap questions for this iteration. Each must declare its role + (if applicable) the
    literal anchor. Roles MUST vary across the batch -- repeating the same role with the
    same anchor is invalid.

RoleTaggedGapQuestion:
  role: entity-anchored | concept-anchored | constraint-relaxed | constraint-tightened |
  inverse-negation
      The structural probe role of this question. Must vary across the batch to enforce
      retrieval-space diversity.
  anchor: str | None
      If role is entity-anchored or constraint-tightened: the literal anchor string from
      the entity ledger that this question uses. MUST appear verbatim inside the question
      text. Null otherwise.
  targets_topic_id: int | None
      If this question is designed to probe a specific topic id from the topic list
      (typically a weakly-evidenced one), the topic id. Null if the question is
      broad/exploratory.
  question: str
      The complete gap question used as a retrieval query.
```

Query reformulation (Step 4)

Generate alternative phrasings of a gap question to improve retrieval coverage. Invocations per query: `1_per_gap_question`.

```
# Query Reformulation

Generate alternative phrasings of a search query to improve retrieval coverage.

**Original query:** {original_query}
**Gap question:** {gap_question}

## Instructions

Generate exactly **{num_reformulations}** alternative phrasings of the gap question that might
retrieve different relevant documents. Each reformulation should:

- Use different vocabulary while preserving the intent
- Be distinct enough from the others to explore diverse retrieval paths
```

Enforced response schema — the model is constrained to return exactly these fields:

```
reformulations: list[str]
    List of reformulated query strings.
```

Novelty judge (Step 5) (1 of 2)

```
# Document Evaluation -- Gap Judge

> Context: This is an academic information retrieval evaluation. The document may reference
sensitive historical events, conflicts, or social issues. Classify objectively without endorsing
any viewpoint.

Evaluate whether a candidate document contains novel, relevant information for answering a
query.

## Input

**Original query:** {query}

**Topics already found:**
{topic_list}

**Original answer (for reference):**
{answer}

**Candidate document:**
{document}

## Process

### Step 1 -- Relevance check
- Is this document about the **same entity/subject** as the query?
- Does it contain information that **directly helps answer** the query?
- If no to either -> `IRRELEVANT`.
```

Novelty judge (Step 5) (2 of 2)

```
### Step 2 -- Novelty check (only if relevant)
Compare the document's information against the topics already found.
- Covers the same ground as an existing topic (even with different details) -> `REDUNDANT` --
  cite the existing topic number.
- Provides a genuinely **new** type of information -> proceed to Step 3.

### Step 3 -- Topic labelling (only if novel)
Create a short label (7-12 words) for the new information facet.

## Granularity rules

- A "topic" is an **information facet** (a type/category of information), not a single data
  point, instance, or example.
- **Paragraph test:** would this topic warrant its own distinct paragraph that does not overlap
  with any existing topic? If not -> `REDUNDANT`.
- Another instance of a category already in the topic list -> `REDUNDANT`, not new.
  - Example: "Results of Steelers vs Ravens games" exists -> a document about a specific game
    result is `REDUNDANT`.
  - Example: "Countries that won the World Cup" exists -> a document about a specific country's
    win is `REDUNDANT`.
- Sub-topics must represent a genuinely **different dimension**, not just deeper detail of the
  same dimension.
  - [+] New: Parent "Hugo Weaving as V" -> "Production challenges with mask acting" (different
    dimension)
  - [-] Redundant: Parent "Sauron created the One Ring" -> "One Ring forged in Mount Doom" (same
    dimension, more detail)
- When in doubt -> `REDUNDANT`. Prefer fewer, higher-quality topics over many overlapping ones.
```

Novelty judge (Step 5) — response schema

Enforced response schema — the model is constrained to return exactly these fields:

```
verdict: NEW_TOPIC | SUB_TOPIC | REDUNDANT | IRRELEVANT | CONTRADICTORY
    The classification verdict for this document.
topic_label: str | None
    If NEW_TOPIC or SUB_TOPIC: a short descriptive label (5-15 words) for the new
    information facet. Otherwise null.
parent_topic: str | None
    If SUB_TOPIC: the parent topic label or number. Otherwise null.
existing_topics_covered: list[int]
    Topic numbers from the known list that this document also covers.
reason: str
    One sentence explaining the verdict.
```

The enum admits a fifth label, `CONTRADICTORY`, outside the four-way taxonomy used throughout: it fired once in 149,063 production verdicts and counts as non-novel wherever verdicts are collapsed.

Topic deduplication (Step 5b)

```
# Topic Deduplication

Deduplicate newly discovered information topics against the existing list.

## Input

**Existing known topics (already confirmed):**
{existing_topic_list}

**Newly discovered topics (need deduplication):**
{new_topic_labels}

## Instructions

1. **Cluster** new topic labels that are semantically equivalent (same concept, different
   wording).
2. **Merge instances** of the same category (e.g. "India's World Cup wins" and "Australia's
   World Cup wins" -> "Cricket World Cup winning countries").
3. For each cluster, pick the **best single label** as the canonical representative. Prefer
   category-level labels over instance-level ones.
4. **Check overlap:** if any cluster is semantically equivalent to an already-known topic, mark
   `overlaps_existing=true` and provide the existing topic ID number.

## Rules

- Merge labels that are instances/examples of the same information category into **one** cluster
  with a category-level label.
- A new label overlaps an existing topic if it describes another instance of the same category,
  or adds only minor detail to what that topic already covers.
- Only keep a new label as genuinely new if it represents a qualitatively **different** type of
  information (would warrant its own distinct paragraph).
- If a new label adds specificity or a new angle to an existing topic, it is **not** an overlap
  -- keep it as a genuine new topic.
```

Topic deduplication (Step 5b) — response schema

Enforced response schema — the model is constrained to return exactly these fields:

```
clusters: list[TopicCluster]
    Clusters of semantically equivalent new topic labels. Each cluster becomes one topic.
    Labels that overlap with existing topics should have overlaps_existing=True.

TopicCluster:
  canonical_label: str
      The best single label representing this cluster of topics.
  merged_labels: list[str]
      All original labels that belong to this cluster (including the canonical).
  overlaps_existing: bool
      True if this cluster is semantically equivalent to an already-known topic.
  existing_topic_id: int | None
      If overlaps_existing=True, the ID of the existing topic it overlaps with.
```

Reader (answer generation)

Generate an answer from retrieved documents. Invocations per query: 1.

```
# Answer Generation

Answer the question using **only** the documents provided. Do not use prior knowledge or any
information not contained in the documents.

## Documents

{documents}

## Question

{query}

## Instructions

- Base your answer solely on evidence in the documents above.
- If the documents don't contain sufficient information, say so explicitly.
```

Information-equivalence judge (E2.2 only)

Used only for the controlled gold-deletion experiment (Appendix L); not part of the deployed Re:CAP loop.

```
REMOVED:    {gold passage that was excluded}
CANDIDATE:  {doc surfaced by gap probing}

Does CANDIDATE contain the same core facts as
REMOVED? Output YES / PARTIAL / NO + reason.
```

FinDialogLens: Event Extraction over Multi-Party Dialogue for Missed-Trade Identification in Financial Chatrooms

Chin-Lun Fu Hong Ni Behrouz Madahian
Machine Learning Center of Excellence, JPMorgan Chase & Co.
{chin-lun.fu,hong.ni,behrouz.madahian}@jpmchase.com

Abstract

Multi-party financial chatrooms are vital for sales-and-trading professionals, but their complexity makes manual recovery of missed trades infeasible: each *Request for Quote* (RFQ) is an event whose final price and trade outcome appear many messages after the *RFQ-trigger message* (the inquiry message), interleaved with concurrent RFQs from other participants. We cast this as **event extraction (EE) over multi-party dialogue** and present **FinDialogLens**, a hybrid LLM pipeline in which compact fine-tuned classifiers act as inference-time scaffolds: they detect RFQ-triggers and price/trade outcome metadata, an RFQ-Level Module segments per-event RFQ windows, and a Trade Engine fills argument roles. With GPT-4o, FinDialogLens reaches 92.1% and 94.3% accuracy on final price and trade outcome, respectively, outperforming full-chatroom CoT prompting methods; fine-tuned open-source LLMs with as few as 3B parameters achieve comparable performance with modest in-domain data. To make the LLM-based solution practical at scale, a difficulty-aware router balances cost and accuracy by allocating RFQs between a low-cost rule-based engine and the higher-performing LLM-powered Trade Engine, cutting LLM calls by 85% on final price while recovering half of the accuracy gap to FinDialogLens (GPT-4o), saving over $300/day at our 70,000-RFQ/day scale.

1 Introduction

Financial institutions communicate with their clients at scale over multi-party chatrooms, where a single day routinely carries hundreds of messages and tens of distinct trade negotiations posted concurrently. A typical interaction begins when a client reaches out with a *Request for Quote* (RFQ), e.g., "*can I get a price quote on 5Y XYZ?*"; a sales representative responds with a quote (e.g.,"*75 / 76*"), and the client either agrees (e.g.,"*mine*") or walks away (e.g.,"*away, thanks*"). The inquiry, the final agreed price, and the trade outcome together form the structured record of the business event. In practice, RFQ negotiations are interleaved, asynchronous, and noisy: quotes, requotes, and trade outcomes may be separated by minutes, mixed with parallel client negotiations, and obscured by irrelevant market updates or chitchat. Consequently, identifying the trigger, quotes, and final outcome for a given RFQ requires linking distant, non-adjacent messages across substantial irrelevant context.

Executed trades are logged automatically by systems, but *missed* trades, namely inquiries that did not result in execution, are not, leaving sales desks unable to measure quote competitiveness or prioritize follow-up. At production volumes of tens of thousands of RFQs per day, manual recovery of missed-trade records from chat is infeasible.

We cast this problem as **event extraction over multi-party dialogue**, an application of EE to a setting where each RFQ is an event whose *trigger* is the inquiry message, and whose argument roles, the final price and the trade outcome, are filled by content from downstream messages that often appear many minutes later and are interleaved with unrelated concurrent RFQs from other participants. This combination of long-range argument scattering and multi-party interleaving is not the setting that existing EE recipes target: sentence-level methods (Doddington et al., 2004; Li et al., 2013; Chen et al., 2015) are bounded to a single sentence, while document-level methods (Ebner et al., 2020; Li et al., 2021; Zheng et al., 2019) assume coherent single-author text. Table 1 summarizes why other prior EE systems are not directly comparable.

Our framework, **FinDialogLens** (Figure 1), is a hybrid LLM pipeline with three modules. The *Message-Level Module* runs compact RoBERTa-base (Liu et al., 2019) classifiers fine-tuned on in-domain data to produce metadata for RFQ-trigger messages, price mentions, and trade outcome cues; these predictions act as *inference-time scaffolds* for

EMNLP 2026 Industry Track, pages 2566–2581
October 24-29, 2026 ©2026 Association for Computational Linguistics

the downstream LLM, supplying domain-specific signals that general-purpose LLMs lack on raw chat (Yu et al., 2023). The *RFQ-Level Module* segments the chatroom into per-event RFQ windows, one for each detected RFQ-trigger message, using a temporal heuristic. The *Trade Engine* performs LLM-based argument role filling over each RFQ window using GPT-4o (OpenAI et al., 2024) or a fine-tuned open-source LLM. To make the LLM-based solution practical at production scale, a *difficulty-aware router* predicts per-event difficulty and assigns easier RFQ windows[1] to a low-cost rule-based weak engine while escalating harder windows to the LLM-powered Trade Engine. Our contributions are as follows.

- We cast missed-trade identification as **event extraction (EE) over multi-party dialogue**, a setting in which arguments are unanchored, spread across non-adjacent turns, and interleaved with concurrent RFQ events. We show that direct off-the-shelf LLM prompting over full chatrooms performs poorly on this task.
- We show that **per-event RFQ windowing combined with compact specialized classifiers as inference-time scaffolds substantially improves GPT-4o over full-chatroom CoT prompting** for multi-party dialogue EE. The resulting pipeline, **FinDialogLens**, uses these classifiers as inference-time scaffolds for LLM extraction and achieves 92.1% and 94.3% accuracy for final price and trade outcome extraction.
- We propose a **difficulty-aware router** supervised by the per-event correctness of a rule-based weak engine. For final price, routing around 15% of RFQs to the LLM-powered Trade Engine (an 85% reduction in LLM calls) recovers half of the accuracy gap between the weak engine and FinDialogLens (GPT-4o), saving over $300/day at our 70,000-RFQ/day scale.

2 Related Work

Event extraction and financial NLP. Event extraction (EE) has progressed from sentence-level formulations on ACE (Doddington et al., 2004) to document-level argument linking (Ebner et al., 2020; Li et al., 2021; Zheng et al., 2019) and generative or instruction-tuned methods (Lu et al., 2021; Hsu et al., 2022; Wang et al., 2023; Sainz et al., 2024). Financial NLP (Li et al., 2024b; Nie et al., 2024; Chen et al., 2024) applies structured information extraction (IE) primarily to news and filings (e.g. Doc2EDAG (Zheng et al., 2019), FinRED (Sharma et al., 2023)); conversational financial data receives little attention. Dialogue disentanglement (Kummerfeld et al., 2019; Li et al., 2024a) handles multi-party input but targets thread separation rather than event extraction. Our setting requires four structural properties simultaneously: multi-party input, arguments that span multiple turns, explicit per-event triggers, and structured event records as output.

Method family	Multi-party	Cross-turn	Trigger-anchored	Event record
Sentence EE	×	×	✓	✓
Doc-level EE	×	✓	×	✓
Dialogue disent.	✓	✓	–	×
Ours	✓	✓	✓	✓

Table 1: Structural axes along which existing EE method families differ from our application setting.

3 Methodology

3.1 Problem Setting

A chatroom $C = (m_1, \ldots, m_N)$ is a time-ordered sequence of messages, each tagged with an author identifier. We model each RFQ as a typed event anchored by a single *RFQ-trigger message* and associated with two argument roles: *final price* and *trade outcome*. Throughout, an RFQ-trigger message refers to the message that initiates an RFQ. The goal is to recover the set of K RFQ events present in C,

$$E = \{e_j\}_{j=1}^{K}, \quad e_j = (m_j^{\text{trig}}, p_j, o_j), \qquad (1)$$

where $m_j^{\text{trig}} \in C$ is the RFQ-trigger message that anchors the event, p_j is the final price, represented as a string lifted from the dialogue or NONE if no price applies, and $o_j \in \{\text{Hit}, \text{Miss}, \text{Unknown}\}$ is the trade outcome.[2] Evidence for the two argument roles may appear well after m_j^{trig} and can be inter-

[1] Here, "easier" denotes RFQ windows that follow typical conversational patterns and can be addressed reliably using heuristic rules.

[2] HIT: the client agreed to trade; MISS: the client explicitly declined (e.g. "away"); UNKNOWN: no client response was observed within the context window. UNKNOWN is operationally distinct from MISS because sales follow-up decisions differ in the two cases.

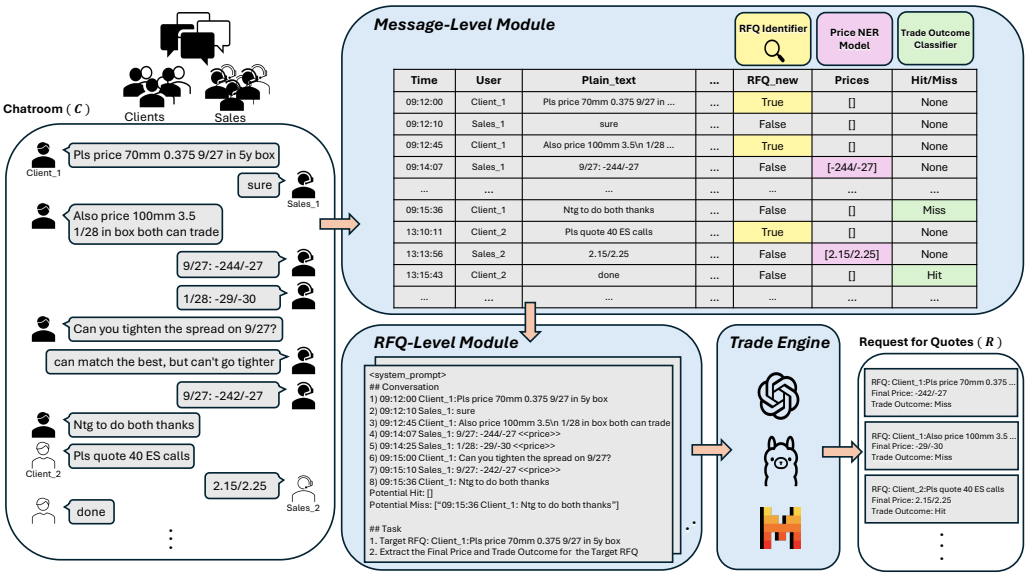

Figure 1: Overview of the FinDialogLens pipeline for event extraction over multi-party dialogue. The Message-Level Module produces message-level metadata through RFQ-trigger detection, trade outcome classification, and price NER. The RFQ-Level Module uses these predictions to segment per-event RFQ windows from the chatroom. The Trade Engine performs LLM-based argument role filling over each RFQ window.

leaved with messages from other concurrent RFQ events.

3.2 Message-Level Module

The Message-Level Module produces message-level metadata that serves as inference-time scaffolding for RFQ windowing and argument role filling. Inspired by recent work (Yu et al., 2023) showing that fine-tuning compact models like RoBERTa with sufficient data can outperform larger LLM-based models in specialized tasks, we fine-tune three RoBERTa-base models on in-domain data. The *RFQ Identifier* is a binary trigger detector that predicts whether each $m_i \in C$ initiates an RFQ event. The *Trade Outcome Classifier* assigns each message a label in $\{\text{Hit}, \text{Miss}, \text{None}\}$, highlighting messages that may express trade outcomes. A *Price NER Model* extracts price entities from each message. The resulting metadata annotations are attached to each m_i and consumed by the RFQ-Level Module and the Trade Engine.[3]

3.3 RFQ-Level Module

A typical daily chatroom C may contain hundreds of messages and numerous RFQs, with multiple clients and sales representatives negotiating prices for different products while also exchanging unrelated market updates and informal chatter. Processing the full chatroom context is therefore both inefficient and potentially unreliable, as long-context LLMs may underutilize relevant evidence when it is buried within lengthy inputs, a phenomenon commonly described as the "lost-in-the-middle" effect (Liu et al., 2024). To address this, the RFQ-Level Module constructs an *RFQ window* for each detected RFQ-trigger message. Each RFQ window is a temporally bounded, per-event context anchored at the trigger and passed to the Trade Engine for argument role filling. We denote the window for trigger m_j^{trig} as w_j.

For each trigger m_j^{trig} flagged by the RFQ Identifier, we collect the trigger message and its subsequent messages in C until either a 20-minute time gap or a 25-message cap is reached.[4] The message-level metadata is interleaved with the raw text inside w_j using special tokens (Figure 7). The module outputs the set of RFQ windows $W = \{w_j\}$, one for each trigger detected by the RFQ Identifier.

3.4 Trade Engine

Given a per-event RFQ window $w_j \in W$ anchored at trigger message m_j^{trig}, the Trade Engine predicts the remaining argument roles: the final price p_j and trade outcome o_j. The full event record is then assembled as $e_j = (m_j^{\text{trig}}, p_j, o_j)$.

The Trade Engine is LLM-powered. It prompts

[3]Training details are reported in Appendix B.1.

[4]Thresholds were chosen on the evaluation split; the resulting window covers the gold final price and trade outcome for over 96% of RFQ events.

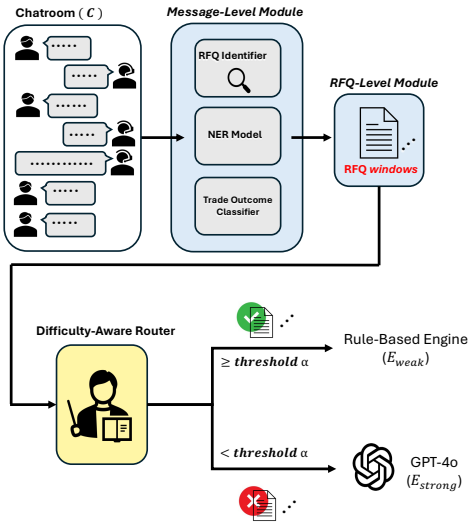

Figure 2: Difficulty-Aware Router. For each RFQ event, the router assigns easier cases to rule-based engine and escalates harder cases to the LLM-powered engine.

an LLM with the metadata-augmented RFQ window w_j under a unified template (Figure 9), then parses the structured response into (p_j, o_j). The LLM is instructed to identify the final price when applicable and determine the trade outcome from the dialogue evidence. We instantiate the Trade Engine with two LLM families:

1. **Proprietary**: GPT-4o.
2. **Open-source**: Mistral-7B-Instruct (Jiang et al., 2023), Llama-3-8B-Instruct (Grattafiori et al., 2024), Phi-3-mini-4k-instruct (Abdin et al., 2024), and Flan-T5-XL (Chung et al., 2022).

Throughout, "FinDialogLens (M)" denotes the full pipeline using model M as the LLM-powered Trade Engine.

3.5 Difficulty-Aware Router

Although the LLM-powered Trade Engine achieves strong performance, using it for every RFQ window incurs avoidable cost and latency. Some windows exhibit empirical structural patterns, such as nearby evidence, predictable reply behavior, or explicit product and outcome references, that a rule-based weak engine E_{weak} can exploit reliably. As shown in Figure 2, we therefore introduce a *difficulty-aware router* that sends lower-ambiguity RFQ windows to E_{weak} and reserves the LLM-powered strong engine E_{strong} for more ambiguous cases.

We train the router to estimate the reliability of the weak engine, $P_\theta(\text{Correct} \mid w)$, using labels obtained by running the weak engine on labeled RFQ windows. At inference time, a threshold α controls the cost–accuracy trade-off:

$$R^\alpha(w) = \begin{cases} E_{\text{weak}}, & P_\theta(\text{Correct} \mid w) \geq \alpha, \\ E_{\text{strong}}, & \text{otherwise.} \end{cases} \quad (2)$$

We instantiate P_θ with RoBERTa-base, Mistral-7B-Instruct, and Flan-T5-XL.

4 Experiments

4.1 Experiment Setup

4.1.1 Data Overview

We annotate 47,362 messages from two years of financial conversations (2023–2024), covering 8,343 RFQs in total. The data is partitioned into three non-overlapping splits: 37,245 messages / 7,082 RFQs for training, 1,147 messages / 295 RFQs for evaluation, and 8,970 messages / 966 RFQs for testing. The splits are time-based rather than uniformly sampled: we hold out a contiguous June–July 2024 window, the most recent period in our annotated data, as the test set. The training and evaluation sets are drawn from the remaining 2023–2024 data, with no RFQ or message overlap across splits.

This setup mimics the production setting, where models are trained on historical labeled data and evaluated on new incoming conversations. The training split is used to train the Message-Level Module, Trade Engine, and difficulty-aware router, while the evaluation split is used for prompt and hyperparameter selection. All reported results are on the test split. To protect sensitive financial communications, strict privacy protocols are enforced to prevent data leakage or unauthorized access.[5]

4.1.2 Baselines

We compare FinDialogLens against both non-LLM and LLM-based baselines. As a non-LLM baseline, we implement a Rule-based Engine that uses the same message-level metadata produced by the Message-Level Module and links predicted prices and trade outcomes to RFQ events through predefined heuristics based on conversation characteristics. As LLM-based baselines, we evaluate end-to-end Chain-of-Thought

[5]Further details on data privacy, annotation guidelines, and training details are provided in Appendix A and Appendix B.

Method	w/ Metadata	Input Context		Trade Engine	Final Price	Trade Outcome	
		Whole Day	RFQ Windows		Acc	Acc	F1
Rule-based Engine	✓	✓		Rule-based	77.1	90.3	90.7

Table 2: Comparison of final price and trade outcome extraction performance across the Rule-based Engine, full-chatroom CoT prompting baselines, and FinDialogLens. "w/ Metadata" indicates whether the input context is augmented with predicted RFQ-trigger, price, and trade-outcome tags from the Message-Level Module. "Input Context" specifies whether the model consumes the full daily chatroom or per-event RFQ windows produced by the RFQ-Level Module.

(CoT) prompting (Wei et al., 2022) with GPT-4o (`gpt-4o-2024-05-13`). We run CoT prompting on the full daily chatroom under four configurations: {zero-shot, few-shot (3 examples)} × {with metadata, without metadata}. In the metadata setting, the full chatroom is augmented with the Message-Level Module's predicted RFQ-trigger, price, and trade-outcome tags using the same special tokens as FinDialogLens (Figure 7). The CoT prompt templates are shown in Figure 8.

4.1.3 Evaluation Protocol and Metrics

We evaluate FinDialogLens with a trigger-anchored event extraction protocol. The RFQ-trigger message defines the identity of an RFQ event, while final price and trade outcome are arguments whose correctness is defined relative to that anchor. At inference time, FinDialogLens runs end-to-end from raw chatroom messages: it detects RFQ triggers and metadata, constructs one RFQ window for each detected trigger, and predicts the final-price and trade-outcome arguments. Gold triggers are not provided as input.

For scoring, predicted RFQ events are aligned to reference events by their trigger message, and argument accuracy is computed on the aligned events. RFQ-trigger detection is evaluated separately through the RFQ Identifier in the Message-Level Module, with precision, recall, and F1 reported in Table 3; this separates event-anchor discovery from cross-turn argument linking. Final price is evaluated by exact-match accuracy with no normalization or post-processing; trade outcome is evaluated as a three-way classification over Hit, Miss, and Unknown using accuracy and F1.

To assess the difficulty-aware router, we follow RouteLLM (Ong et al., 2025) and report Performance Gap Recovery (PGR) and Call-Performance Threshold (CPT):

$$PGR(R^{\alpha}) = \frac{r(R^{\alpha}) - r(E_{\text{weak}})}{r(E_{\text{strong}}) - r(E_{\text{weak}})}, \quad (3)$$

where E_{weak} is the rule-based weak engine, E_{strong} is the LLM-powered Trade Engine with GPT-4o, and $r(\cdot)$ is response quality measured by accuracy. CPT($x\%$) is the minimum percentage of RFQ windows routed to E_{strong} needed to achieve PGR $= x\%$.

4.2 Results

We evaluate FinDialogLens along three dimensions aligned with our main claims: (1) whether message-level metadata and per-event RFQ windowing improve LLM-based role filling over full-chatroom CoT prompting; (2) whether fine-tuned open-source LLMs can approach proprietary LLM performance within the FinDialogLens pipeline; and (3) whether the difficulty-aware router can reduce LLM usage while preserving extraction accuracy. As a prerequisite, we verify that the Message-Level Module provides reliable metadata scaffolds for downstream windowing and role filling. The three specialized RoBERTa-base classifiers achieve F1 scores of 0.97, 0.95, and 0.93 for the RFQ Identifier, Trade Outcome Classifier, and Price NER model, respectively; per-model precision and recall are reported in Table 3.

4.2.1 Effect of Message-Level Metadata and Per-Event Windowing

Table 2 compares FinDialogLens with the Rule-based Engine and full-chatroom CoT-prompting

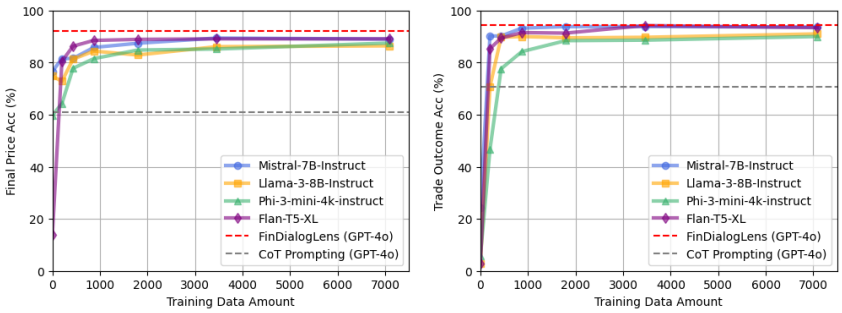

Figure 3: Accuracy of fine-tuned open-source LLMs on final price and trade outcome extraction as training-set size varies. Dashed lines mark FinDialogLens (GPT-4o) and zero-shot CoT Prompting (GPT-4o) baseline.

Model	Precision	Recall	F1
RFQ Identifier	0.97	0.97	0.97
Trade Outcome Classifier	0.96	0.93	0.95
Price NER Model	0.91	0.95	0.93

Table 3: Performance of the Message-Level Module, including the RFQ Identifier, Trade Outcome Classifier, and Price NER Model.

baselines. The "w/ Metadata" column denotes whether the input is augmented with predicted RFQ-trigger, price, and trade-outcome tags produced by the Message-Level Module. The CoT-prompting baselines apply GPT-4o to the full daily chatroom, whereas FinDialogLens first segments the chatroom into RFQ-specific windows and then performs role filling within each window. The main table reports one run for each method: GPT-4o-based methods use decoding with temperature set to 0, and fine-tuned open-source LLMs use greedy decoding. Because hosted API models can still exhibit residual nondeterminism even with temperature set to 0, Appendix C reports five-run mean and standard deviation for GPT-4o-based methods.

Message-level metadata substantially improves both the Rule-Based Engine and full-chatroom CoT prompting methods. For the Rule-Based Engine, message-level metadata enables final price and trade outcome accuracies of 77.1% and 90.3%, respectively. This improvement is largely due to the strong performance of the Message-Level Module, which helps the Rule-Based Engine link the correct final price and trade outcome to each detected RFQ trigger. However, the rule-based approach still struggles when multiple RFQs occur within a very short time span.

In the few-shot CoT setting, adding metadata increases final price accuracy from 64.4% to 79.2% and trade outcome accuracy from 70.5% to 87.0%, corresponding to gains of 14.8 and 16.5 points, respectively. Similar improvements appear in the zero-shot setting, where metadata improves final price accuracy by 13.0 points and trade outcome accuracy by 20.4 points. These results show that compact message-level classifiers provide useful domain-specific signals for LLM-based extraction from noisy financial dialogue.

Per-event RFQ windowing provides a second, complementary gain. Compared with the strongest metadata-augmented CoT baseline, FinDialogLens (GPT-4o) improves final price accuracy from 79.2% to 92.1% and trade outcome accuracy from 87.0% to 94.3%, yielding gains of 12.9 and 7.3 points, respectively. This suggests that isolating each RFQ into a focused context window reduces cross-event interference and makes argument role filling easier for the LLM.

Overall, message-level metadata and per-event windowing jointly drive FinDialogLens's improvement. Metadata provides compact domain-specific signals, while per-event windowing focuses the LLM on the relevant RFQ context for role filling. Together, these components allow FinDialogLens to achieve the best overall performance among all compared methods, with 92.1% final price accuracy and 94.3% trade outcome accuracy.

4.2.2 Open-source vs. Proprietary LLMs

Figure 3 shows that fine-tuned open-source LLMs in FinDialogLens improve rapidly on both final price and trade outcome extraction as the amount of in-domain training data increases, with performance plateauing after about 1,000 examples. With the full training set, all four open-source LLMs outperform GPT-4o CoT prompting baselines in Table 2. For instance, Flan-T5-XL achieves 91.7% final price accuracy and 92.8% trade outcome accuracy. These results show that modest in-domain

Router Type	Final Price		Trade Outcome	
	CPT (50%)	CPT (80%)	CPT (50%)	CPT (80%)
Random	49.2%	81.3%	52.1%	75.8%
RoBERTa-base	**14.9%**	32.4%	29.5%	62.6%
Mistral-7B-Instruct	16.4%	31.8%	26.7%	36.3%
Flan-T5-XL	16.1%	**29.9%**	**25.1%**	**32.8%**

Table 4: Call-Performance Threshold (CPT) for different router types. CPT is the fraction of RFQ windows routed to the LLM-powered Trade Engine required to recover a target percentage of the gap between the rule-based weak engine and FinDialogLens (GPT-4o). Bold indicates the best (lowest) value per column.

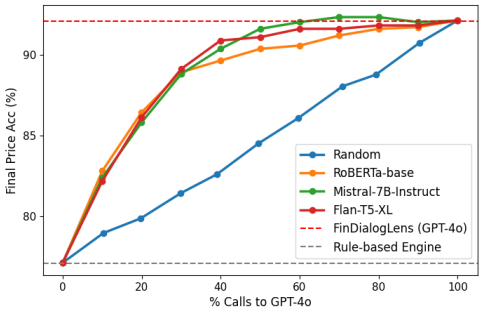

Figure 4: Performance of routers under various budget constraints (α).

supervision enables open-source LLMs with as few as 3B parameters to approach proprietary-model performance within the FinDialogLens pipeline.

4.2.3 Difficulty-Aware Router

The difficulty-aware router assigns each RFQ window to either the rule-based weak engine or the LLM-powered Trade Engine. The weak engine achieves 77.1% final price accuracy and 90.3% trade outcome accuracy on the test set, compared with 92.1% and 94.3% for FinDialogLens (GPT-4o), respectively. We evaluate routing by how efficiently it recovers this performance gap while reducing LLM calls, using both CPT and threshold-based analyses to measure the trade-off between accuracy and LLM usage.

Table 4 reports the Call-Performance Thresholds (CPT) for four routing strategies. Lower CPT indicates greater efficiency: fewer RFQ windows need to be routed to the LLM-powered Trade Engine to achieve a target PGR. Fine-tuned routers substantially outperform the Random baseline. For final price, RoBERTa-base reaches 50% PGR while routing only 14.9% of RFQ windows to the LLM-powered Trade Engine, and Flan-T5-XL reaches 80% PGR with 29.9%. For trade outcome, Flan-T5-XL requires only 25.1% and 32.8% of RFQ windows to reach 50% and 80% PGR, respectively.

Figure 4 shows the effect of varying α, which adjusts the fraction of RFQ windows routed to the LLM-powered engine. Fine-tuned routers outperform the Random router in final price accuracy as the LLM call fraction decreases. Notably, they achieve performance close to running the LLM-powered engine on every RFQ window while routing only 40% of RFQ windows to it, indicating their effectiveness in assigning easier RFQ windows to the rule-based engine. Among the fine-tuned models, performance is similar, with no single model consistently superior.

Detailed routing-quality, cost, and latency analyses are in Appendix F. In our production setting of over 70,000 RFQs/day, routing 14.9% of RFQ windows to the LLM-powered Trade Engine for final price extraction recovers half of the accuracy gap between the weak engine and FinDialogLens (GPT-4o), saving over $300/day in API spend.

5 Conclusion

We present **FinDialogLens**, a hybrid LLM pipeline for event extraction over multi-party dialogue, applied to missed-trade identification in financial chatrooms. Compact message-level classifiers provide inference-time metadata scaffolds, the RFQ-Level Module segments per-event RFQ windows, and the LLM-powered Trade Engine predicts the final price and trade outcome for each recovered RFQ. With GPT-4o, FinDialogLens reaches 92.1% and 94.3% accuracy on final price and trade outcome, outperforming full-chatroom CoT prompting; fine-tuned open-source LLMs with as few as 3B parameters achieve comparable performance with modest in-domain data. A difficulty-aware router further reduces cost by assigning easier RFQs to a rule-based weak engine and escalating harder RFQs to the LLM-powered Trade Engine, cutting LLM calls by 85% on final price while recovering half of the accuracy gap to FinDialogLens (GPT-4o), saving over $300/day at our 70,000-RFQ/day scale.

Limitations

FinDialogLens provides a reusable framework for missed-trade identification in financial multi-party dialogue, a setting that has received limited attention in prior event extraction research. While the framework is designed to generalize beyond a single deployment environment, several components require adaptation before being applied to new institutions, asset classes, or communication settings.

First, FinDialogLens depends on high-performing compact models to generate message-level metadata, including RFQ-trigger labels, price mentions, and trade outcome cues. These signals are central to the pipeline: they guide RFQ window construction and provide inference-time scaffolding that helps the downstream LLM focus on relevant evidence. However, training reliable compact models requires labeled in-domain data, and their utility may decrease when annotations are scarce or when communication styles and product conventions shift. Second, the RFQ-Level Module currently constructs per-event RFQ windows using fixed temporal and message-count thresholds. Although these thresholds provide strong coverage in our setting, negotiation dynamics can vary substantially across desks, clients, and asset classes; some RFQs resolve immediately, while others unfold over longer intervals with clarification, requoting, or follow-up. Adaptive boundary detection conditioned on dialogue structure, participant behavior, and product-specific patterns could improve portability. Third, our difficulty-aware router is tailored to our deployment setting, where the primary decision is whether to use a low-cost rule-based engine or escalate to an LLM-powered Trade Engine. This binary design captures the cost–accuracy trade-off most relevant to our use case, but other deployments may require multi-way, cost-aware, or task-specific routing across multiple model tiers, specialist engines, latency constraints, or risk-based escalation policies.

Finally, due to client and regulatory confidentiality, the underlying conversations cannot be publicly released, limiting direct external replication on the original corpus. To partially mitigate this limitation, we provide annotation guidelines, dataset statistics, model architectures, training configurations, hyperparameters, and evaluation protocols to support reproduction on comparable proprietary financial dialogue datasets.

Ethics Statement

This research is driven by the goal of enhancing operational efficiency in financial markets through the automated analysis of unstructured communication channels, such as chatrooms and instant messaging platforms. The proposed framework, FinDialogLens, is designed to support financial professionals in identifying missed trading opportunities and improving decision-making, while complementing, rather than replacing, human expertise and judgment.

The financial data and conversational content analyzed in this study are highly sensitive and managed in accordance with strict industry governance and privacy protocols. All experiments were conducted using anonymized, internally governed datasets, with user identities replaced by generic identifiers to ensure privacy. No personal or client-identifying information was collected, stored, or utilized at any stage. Access to both data and model outputs is strictly restricted to authorized personnel, and all data handling complies with relevant regulatory and organizational standards.

The sample dialogues presented in this paper do not represent the opinions or positions of the authors or their organizations. We are committed to maintaining the highest standards of data privacy, security, and research integrity throughout this work.

A Data Privacy, Annotation Guidelines, and Statistics

Privacy: To ensure the privacy and confidentiality of conversations used in our framework, we implemented dedicated anonymization measures. Specifically, user names within the conversations are replaced with generic identifiers such as "Client_" and "Sales_," effectively safeguarding individual identities.

Annotation Guidelines: To ensure the accuracy and reliability of our human-labeled data, we adopted a rigorous annotation protocol involving two professional annotators, each of whom independently reviewed every message and Request for Quote (RFQ). For message-level annotation, both annotators labeled the RFQ-triggering message, trade outcome classification, and price information associated with each message. For RFQ-level annotation, each annotator independently assigned the final price and trading outcome for each RFQ, with outcomes categorized as Hit, Miss, or Unknown.

To maintain annotation quality, we excluded cases falling into either of the following categories: (1) *Annotator-disagreement cases*: cases in which both annotators were able to assign labels based on the chat context, but their labels differed. (2) *Unresolvable cases*: cases in which the gold final price or trade outcome could not be determined from the chatroom alone because the negotiation moved to other communication channels, such as phone or email.

The fraction of cases discarded due to direct annotator disagreement was very small, accounting for less than 1% of the data. Because our annotators are professionals with domain experience, most labels were consistent across annotators. Separately, approximately 1% of RFQs were marked as unresolvable because the raw chatroom data did not contain sufficient information to determine the gold final price or trade outcome.

We provide several examples of these unresolvable cases below. In these examples, XYZ and ABC are placeholders used to mask product or security identifiers for confidentiality reasons.

Examples of Unresolvable Cases. Below are examples of RFQs that were marked as unresolvable.

Difficulty	Count	Percentage
Easy: 1 RFQ in window	598	61.9%
Hard: ≥2 RFQs in window	368	38.1%
Total	966	100.0%

Table 5: Distribution of test RFQs by the number of gold RFQ-trigger messages in the RFQ window. Hard cases correspond to interleaved RFQ windows containing two or more RFQs.

In these cases, the final price or trade outcome cannot be determined from the chat text alone because the negotiation moved to another communication channel. Therefore, we exclude these cases as out of scope.

Phone

```
<user_1>: Could you please price
XYZ?
<user_2>: sure
<user_2>: -16.5 / -15
<user_1>: calling you
<user_2>: ok
```

Email

```
<user_1>: Please price XYZ
<user_2>: can u send an email
<user_2>: resending email confirm
<user_1>: email sent
```

Statistics of Challenging Interleaved RFQs. To quantify the prevalence of challenging interleaved RFQs in the test set, we categorize each test RFQ according to the number of gold RFQ-trigger messages appearing within its RFQ window. In total, 368 out of 966 RFQs, corresponding to 38.1% of the test set, occur in windows containing two or more gold RFQ-trigger messages. These cases represent the type of interleaved RFQ scenarios illustrated in Figure 5, where multiple RFQs appear in close proximity and a model may incorrectly associate a price or trading outcome with the wrong RFQ.

B Training Details of FinDialogLens

All experiments are conducted with a fixed random seed of 42 and, where applicable, a temperature setting of 0. Model training is performed on a machine equipped with 4 NVIDIA A10G GPUs.

B.1 Message-Level Module

Inspired by recent work (Yu et al., 2023) demonstrating that fine-tuning compact models such as RoBERTa with sufficient data can outperform larger models like GPT-4 in specialized tasks, we fine-tune three RoBERTa-base models within the Message-Level module to generate more sophisticated financial outputs for each message. Formally, for each message $m_i \in C$:

- **RFQ Identifier**: Determines whether a message m_i constitutes a Request for Quote (RFQ). We define a binary function:

$$y_i^{\text{RFQ}} = f_{\text{RFQ}}(m_i) \in \{\text{True}, \text{False}\} \quad (4)$$

  where $y_i^{\text{RFQ}} = True$ indicates that m_i is identified as an RFQ message.

- **Trade Outcome Classifier**: Determines whether a message m_i indicates a trade outcome as either "Hit", "Miss", or "None." We define:

$$y_i^{\text{trade}} = f_{\text{trade}}(m_i) \in \{\text{Hit}, \text{Miss}, \text{None}\} \quad (5)$$

- **Price NER Model**: Identifies and extracts the price entity from the message content. We define:

$$y_i^{\text{price}} = f_{\text{NER}}(m_i) \quad (6)$$

  where y_i^{price} is the list of extracted price values from m_i.

The predictions y_i^{RFQ}, y_i^{trade}, and y_i^{price} are stored as metadata for each message m_i and are utilized in the subsequent module of our framework. The precision, recall, and F1 scores for these models are reported in Table 3.

B.2 Trade Engine

For the GPT-4o engine, we use "gpt-4o-2024-05-13" API version. We fine-tune four open-source LLMs as Trade Engines: (1) Mistral-7B-Instruct, (2) Llama-3-8B-Instruct, (3) Phi-3-mini-4k-instruct, and (4) Flan-T5-XL. The unified prompt template for all LLMs is shown in Figure 9. The training configuration is as follows:

1. Batch_size = 2
2. Gradient_accumulation_steps = 16
3. LoRAConfig = (lora_alpha = 16, lora_dropout = 0.1, r = 64)
4. Optimizer: AdamW

5. Epochs and learning rates (vary by training dataset size):

#Train	#Epoch	Learning rate
200	10	5e-5
435	10	5e-5
870	10	5e-5
1790	20	5e-5
3455	20	5e-5
7082	20	5e-5

B.3 Difficulty-Aware Router

In this section, we elaborate on the training details for three types of routers:

a) **Encoder-only Classifier**: RoBERTa-base is fully fine-tuned for this classifier. A classification layer is applied to the <s> token embedding to determine the class label L. The model is trained using cross-entropy loss, optimizing the parameters to accurately classify each input context window based on the provided labels.

b) **Decoder-only Classifier**: Mistral-7B-Instruct is fine-tuned using a prompt template to generate a single token, either "Yes" or "No." A "Yes" indicates that the rule-based engine is correct on the input context window, while a "No" indicates incorrectness. The probability of correctness is computed using a softmax over "Yes" and "No," with "Yes" corresponding to $P_\theta(\text{Correct} \mid w)$.

c) **Encoder-Decoder Classifier**: Flan-T5-XL is fine-tuned for this classifier under the same training and inference pipeline as the Decoder-only Classifier, with both encoder and decoder used to process the input context window and emit a single token, either "Yes" or "No".

Below are the training configurations:
RoBERTa-base:

1. Epoch = 5
2. Learning_rate = 2e-5
3. Batch_size = 32
4. Gradient_accumulation_steps = 8
5. Optimizer: AdamW

1) 10:35:27 <Client_1>: Hi please price <prod_A>
2) 10:35:38 <Client_2>: Could you please price <prod_B>
3) 10:35:38 <Sales_1>: See
4) 10:35:42 <Sales_2>: ok
5) 10:36:06 <Sales_2>: 75 76
6) 10:37:04 <Client_2>: Hold off pls brl di
7) 10:37:14 <Sales_2>: sure.
8) 10:39:31 <Client_2>: Could you please price <prod_C>
9) 10:39:36 <Sales_3>: ok
10) 10:39:50 <Sales_3>: 21?
11) 10:40:23 <Client_2>: 21 start / 21 rolls
12) 10:40:26 <Client_2>: srry
13) 10:40:28 <Sales_3>: pricing
14) 10:41:12 <Sales_2>: 44 47
15) 10:42:38 <Client_2>: Away
16) 10:43:03 <Client_1>: away

7. Optimizer: AdamW

C Multi-Run Evaluation for GPT-4o-Based Methods

For GPT-4o-based methods, we use temperature-0 decoding. Although this setting is near-greedy, API-side nondeterminism can still introduce small run-to-run variation. We therefore run each GPT-4o-based setting five times and report the mean and standard deviation in Table 8.

D Error Analysis

We conducted error analysis of FinDialogLens (GPT-4o) on the test data and found that most edge cases occurred when multiple RFQs were requested within a short time period. In these complex scenarios, the LLM occasionally failed to correctly identify which response message corresponded to which RFQ.

Router Type	Final Price		Trade Outcome	
	CPT (50%)	CPT (80%)	CPT (50%)	CPT (80%)
Random	$2.66	$4.39	$2.81	$4.09
RoBERTa-base	**$0.80**	$1.75	$1.59	$3.38
Mistral-7B-Instruct	$0.89	$1.72	$1.44	$1.96
Flan-T5-XL	$0.87	**$1.61**	**$1.36**	**$1.77**

Table 6: Cost analysis of different router types for final price and trade outcome under CPT (50%) and CPT (80%). Reported values are USD per 1,000 RFQs; processing 1,000 RFQs with GPT-4o costs approximately $5.40.

Router Type	Final Price		Trade Outcome	
	CPT (50%)	CPT (80%)	CPT (50%)	CPT (80%)
Random	717.8	1186.2	760.1	1105.9
RoBERTa-base	**217.4**	427.7	430.4	913.3
Mistral-7B-Instruct	239.3	464.0	389.6	529.6
Flan-T5-XL	234.9	**436.2**	**366.2**	**478.6**

Table 7: Latency analysis of different router types for final price and trade outcome under CPT (50%) and CPT (80%). Reported values are total LLM API latency (seconds) for the full test set; processing the full test set with GPT-4o alone takes approximately 1,459 seconds.

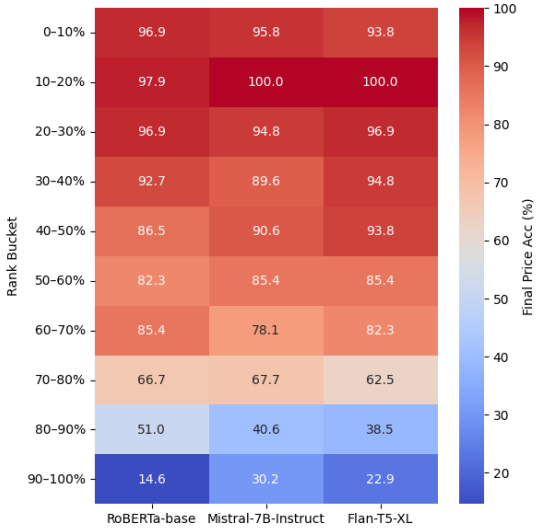

Figure 6: Accuracy of the rule-based engine on per-event RFQ windows grouped into deciles by router logit ranking.

For example, in Figure 5, the target RFQ is the first message of the conversation, where <Client_1> requests a price for <prod_A>. Shortly after, <Client_2> submits a second RFQ for <prod_B> (message 2), and both RFQs receive prompt replies from <Sales_1> and <Sales_2>, respectively. Notably, <Sales_1> does not provide any price for the target RFQ, while <Sales_2> offers a price of "75 76" in message 5, which corresponds to the second RFQ. Eventually, <Client_1> replies "away" in message 16, indicating the target RFQ was a missed trade. In this scenario, the LLM correctly identifies the target RFQ as a missed trade based on message 16, but incorrectly links the price "75 76" from message 5 to the target RFQ. The correct final price for the target RFQ should be NONE.

E Ablation Study on Metadata Error Propagation

To quantify the impact of metadata errors and the extent to which they propagate to the downstream RFQ-level prediction task, we conduct an additional ablation study. In this study, we replace the predicted message-level price and trade-outcome metadata with human-annotated gold labels, while keeping GPT-4o as the Trade Engine. This allows us to compare the original pipeline, which uses predicted metadata, against an oracle setting in which the downstream Trade Engine receives gold message-level metadata.

The results suggest that error propagation from the message-level metadata module is limited. Replacing predicted metadata with gold metadata changes final price accuracy only marginally, from 92.1% to 91.9%, while improving trade outcome accuracy from 94.3% to 95.9% and trade outcome F1 from 94.5% to 95.7%. These results indicate that the downstream Trade Engine is relatively robust to the remaining errors produced by the high-

Method	w/ Metadata	Input Context		Trade Engine	Final Price	Trade Outcome	
		Whole Day	RFQ Windows		Acc	Acc	F1
CoT Prompting		✓		GPT-4o (Zero-shot)	$62.2_{\pm 0.95}$	$66.7_{\pm 0.94}$	$76.7_{\pm 0.37}$
		✓		GPT-4o (Few-shot)	$66.1_{\pm 2.17}$	$67.5_{\pm 2.47}$	$77.2_{\pm 2.09}$
	✓	✓		GPT-4o (Zero-shot)	$76.4_{\pm 1.73}$	$84.4_{\pm 1.32}$	$89.7_{\pm 1.40}$
	✓	✓		GPT-4o (Few-shot)	$79.2_{\pm 0.59}$	$85.2_{\pm 0.81}$	$90.3_{\pm 0.93}$
FinDialogLens	✓		✓	GPT-4o	$\mathbf{91.8}_{\pm 0.42}$	$\mathbf{93.4}_{\pm 0.27}$	$\mathbf{93.5}_{\pm 0.38}$

Table 8: Multi-run results for GPT-4o-based methods. We report mean accuracy/F1 over five runs, with standard deviation in subscript. All GPT-4o runs use temperature-0 decoding.

Method	Final Price	Trade Outcome	
	Acc	Acc	F1
FinDialogLens (GPT-4o)	92.1	94.3	94.5
FinDialogLens (GPT-4o) + oracle message-level metadata	91.9	95.9	95.7

Table 9: Ablation study on metadata error propagation. We compare the original FinDialogLens pipeline using predicted message-level metadata with an oracle setting that replaces predicted metadata with gold message-level labels.

performing Message-Level Module.

F Difficulty-Aware Router Analysis

F.1 Routing Quality

To further assess routing quality, we ranked all RFQ windows by their router logits and partitioned them into ten equal-sized bins. We then evaluated the accuracy of the rule-based engine within each bin to analyze the relationship between router confidence and routing effectiveness. As shown in Figure 6, the top-ranked bins (0–10%, 10–20%, 20–30%) achieved outstanding performance, with final price prediction accuracy ranging from 95% to 100%. In contrast, the lowest-ranked bin (90–100%) exhibited a markedly lower accuracy of just 14.6% in the RoBERTa-base router. These findings indicate that our fine-tuned routers are highly effective at identifying which RFQ events are most appropriate for rule-based processing.

F.2 Cost and Latency

We provide a detailed analysis of cost and latency for the routing experiments. The average cost per RFQ using GPT-4o is $0.0054, with an average of 1,024.4 input tokens and 18.5 output tokens per RFQ. As shown in Table 6, processing over 70,000 RFQs per day with the RoBERTa-base router results in daily savings exceeding $300, while maintaining approximately 85% accuracy for final price extraction.

For latency, the average response time for a single GPT-4o API call is 1.51 seconds per RFQ event. In our latency experiments, we measured the total processing time by sequentially submitting one RFQ event at a time, without batching or parallelization. The total latency for processing the entire test set with GPT-4o is approximately 1,459 seconds.

Table 7 reports total LLM API latency (in seconds) for the different router types under CPT(50%) and CPT(80%). Fine-tuned routers such as RoBERTa-base and Flan-T5-XL substantially reduce overall latency compared with the Random baseline. Under CPT(50%), the RoBERTa-base router reduces total latency for final-price extraction to 217.4 seconds, compared with 717.8 seconds for the Random router. Flan-T5-XL achieves 234.9 seconds under CPT(50%) for final price and 366.2 seconds for trade outcome, both well below the Random router's 760.1 seconds. These reductions support the practicality of our framework in deployment.

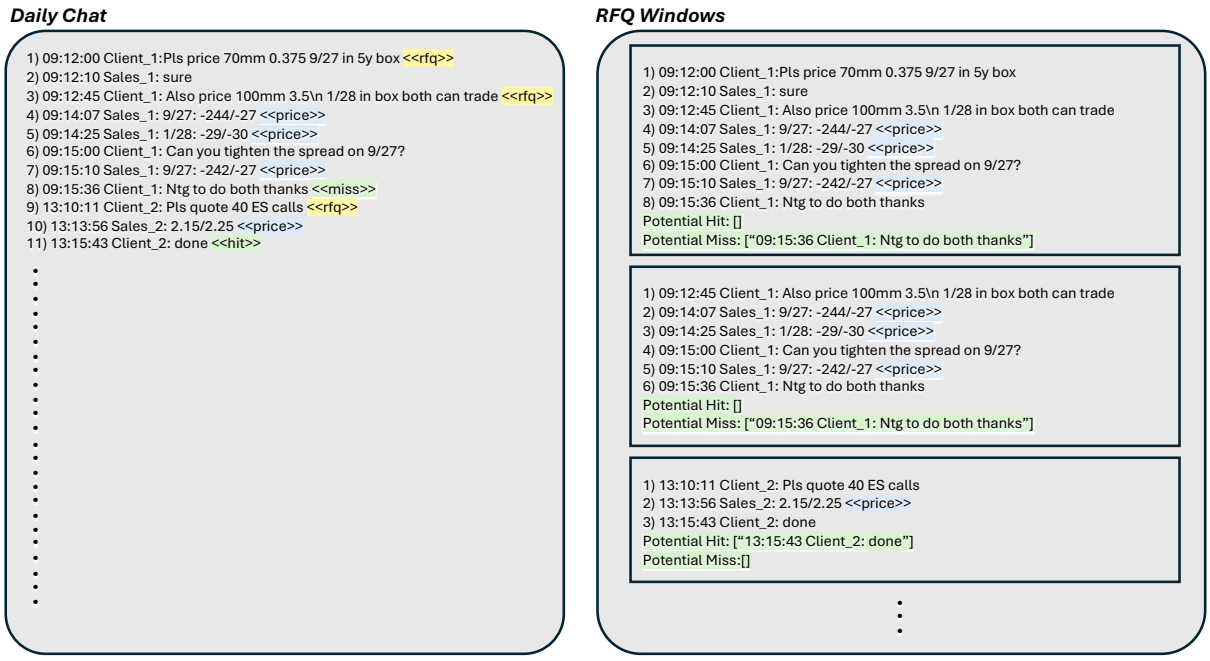

Figure 7: Examples of the two types of **Input Context**: full daily chatroom and per-event RFQ window, supplied to the Trade Engine. Message-level metadata from the Message-Level Module is interleaved with the dialogue text using special tokens (≪rfq≫, ≪hit≫, ≪miss≫, ≪price≫). CoT prompting baselines consume the full daily chatroom; FinDialogLens consumes per-event RFQ windows produced by the RFQ-Level Module.

Abstract

Legal documents frequently contain heterogeneous references to judicial precedents, making automated Precedent Reference Extraction (PRE) challenging for legal AI systems. Existing approaches rely heavily on LLM-based pipelines, which are often effective but also incur recurring prompting costs in high-volume production workloads and struggle with tracing extracted entities back to their character offsets in the source text. In light of these issues, we present *Notarius*, a domain-specific and production-ready hybrid framework that decomposes PRE into two stages: Overlapped NER Feature Extraction (ONFE), which extracts fine-grained precedent features, and Precedent Feature Aggregation (PFA), which reconstructs complete references for downstream applications. Our implementation integrates the Unified NER method W^{2}NER with domain-specific heuristics. We evaluate *Notarius* at both feature and reference levels on a collection of judicial decisions and compare it in production against an LLM-based pipeline. *Notarius* achieves higher extraction quality, eliminates recurring LLM API costs for PRE, and provides span-level offset traceability. The system currently powers precedent extraction on Jusbrasil, demonstrating that discriminative, domain-specialized NER architectures remain valuable for cost-effective, high-precision legal information extraction in the LLM era.

1 Introduction

In modern legal systems, precedents consist of collections of past judicial decisions, interpretations, and rulings issued by courts. They play a central role in promoting legal stability and predictability, enabling judges and legal practitioners to resolve new cases by drawing on established judicial understanding. In this work, we address the problem of accurately extracting precedent references, a task we refer to as *Precedent Reference Extraction* (PRE), in legal documents from the Brazilian civil-law system, which constitutes the primary domain served by Jusbrasil[1].

Effective PRE is essential for downstream applications such as legal search, precedent resolution, and automated document analysis. While PRE can be framed as a Named Entity Recognition (NER) task, directly extracting precedent references is challenging due to the absence of uniform citation standards and the diversity of judicial acts that may constitute a precedent, including court rulings, settled case law, and binding summaries (Correia et al., 2022; Mentzingen et al., 2025). As a result, precedent citation strings, which act as the primary reference unit in legal documents by encompassing multiple features necessary for uniquely identifying a precedent, are written in a wide variety of reference formats, as illustrated in Figure 1.

Another challenge in PRE is information fragmentation, which leads to discontinuous NER (Dai et al., 2020; Yan et al., 2021; Li et al., 2022), where a single reference is spread across non-contiguous spans. As seen in Figure 1, the first reference contains all features required for unique precedent identification within (overlapping) the citation string, whereas the second includes only the *CLASS* and *NUMBER*, with the *COURT*, *VENUE*, and *STATE* appearing earlier in the sentence. Traditional flat NER models cannot resolve overlapped or discontinuous entities, and regex-based approaches become overly complex to design and maintain for such structures. Modern Unified NER methods can detect these types of entities, but they remain impractical for large-scale PRE due to the high cost and complexity of annotating discontinuous

[1]Jusbrasil is a major legal-technology (legaltech) platform, reporting more than 30 million users and reaching approximately 80% of the country's lawyers. Although built around judicial and legal information, the majority of its traffic originates from ordinary citizens outside the legal profession, positioning it as a mass-market gateway to legal content rather than a strictly professional tool.

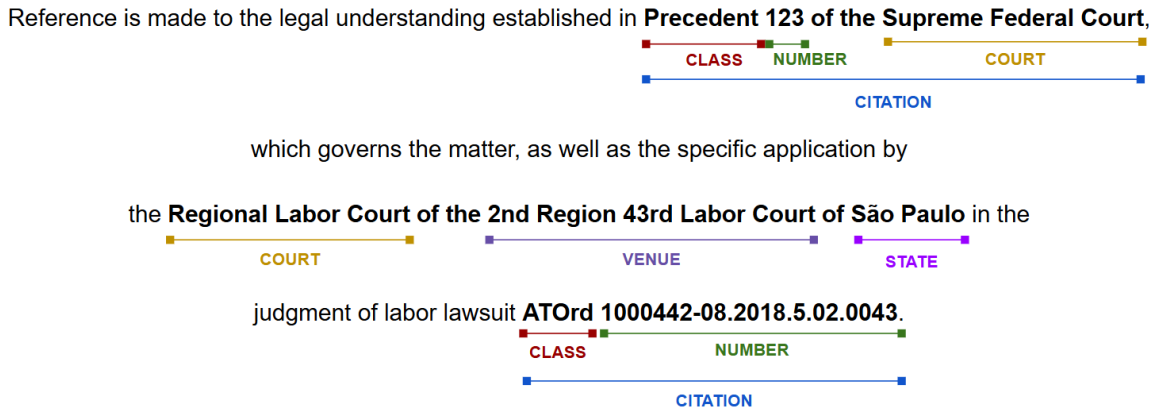

Figure 1: Snippet of a translated Brazilian judicial decision illustrating two precedent references in distinct formats along with their respective features.

spans. While LLM-based NER was initially explored within Jusbrasil and proved effective at capturing these overlapped and fragmented entities, empirical long-term deployment revealed some structural and financial bottlenecks. First, because company applications run continuously across high volumes of documents, the variable token costs of generative prompting create an unsustainable financial overhead compared to local discriminative models (Zschache and Hartwig, 2026; Alaswad et al., 2026). Second, reliably recovering exact character-level offsets from generative LLM outputs remains challenging (Wang et al., 2025; Zhan et al., 2026). This limitation was also observed during the deployment of our previous LLM-based pipeline, where generated extractions could not consistently be mapped to their exact spans in the source document. Such span-level traceability is a functional requirement within the company ecosystem: downstream applications rely on exact starting and ending character offsets for entity linking, automatic text highlighting, and dynamic hyperlinking.

In this paper, we propose a practical and scalable alternative for PRE called *Notarius*, a hybrid framework that decomposes PRE into two specialized steps: Overlapped NER Feature Extraction (ONFE) and Precedent Feature Aggregation (PFA). The ONFE module identifies fine-grained entities that encode features of the same precedents. These extracted entities are then processed and properly aggregated by the PFA module, reconstructing a complete representation of each precedent reference, suitable for downstream legal applications. We experiment with an implementation of *Notarius* that integrates a state-of-the-art open-source Unified NER method, W^{2}NER (Li et al., 2022), within the ONFE module, and domain-specific heuristics within the PFA module.

We evaluated *Notarius* using two strategies. First, in the development stage, we measured the ONFE module's feature extraction quality and conducted a qualitative expert assessment to verify the accuracy and completeness of the final extracted references on a collection of judicial decisions. Second, we assessed robustness in a production environment, where experts continuously reviewed outputs from real-world documents. This approach allowed us to identify edge cases that may not appear in curated datasets and to benchmark *Notarius* against the previous LLM-based pipeline in terms of reference-level quality, cost, and span-level offset traceability.

Our contributions are summarized as follows: i) We formalize PRE as a feature-binding problem and introduce *Notarius*, a cost-effective, domain-aware approach to PRE that reconstructs full precedent references through sequential feature extraction and aggregation; ii) We present key insights derived from a full-scale industrial migration from a generative LLM pipeline to a local deployment of *Notarius* combining a state-of-the-art NER model with domain-specific heuristics, enabling span-level offset traceability and eliminating continuous prompting overhead; iii) We validate *Notarius* through two complementary evaluations: a post-training qualitative assessment conducted by legal experts on a curated dataset of Brazilian judicial decisions, and continuous expert-driven monitoring of the system in production using real user documents.

2 Related Work

2.1 Legal NER and Precedent Extraction

Initial research in Brazilian Portuguese Legal NER focused primarily on identifying broad legal and universal entities. The foundational LeNER-Br dataset (Luz de Araujo et al., 2018) maps specific legal entity types, including precedents, across judicial decisions. However, its annotation scheme is strictly restricted to flat entities. Similarly, the Ulysses project (Câmara dos Deputados, 2018) significantly expanded available domain resources by introducing the UlyssesNER-Br (Albuquerque et al., 2022) and UlyssesLegalNER-Br (Albuquerque et al., 2026) corpora, built upon several types of legal documents. However, they also restrict annotation to flat entities, effectively not handling the overlapped or fragmented nature of precedent citations. Furthermore, a more granular perspective was introduced by Correia et al. (2022), which breaks down legal and precedent citations from documents from the Brazilian Supreme Federal Court (STF) into constituent parts. While this corpus is one of the few legal datasets to incorporate overlapping structures, its scope remains narrow, limited to the STF domain, and it stops short of the feature aggregation needed to map fragmented precedent components back to unique, resolvable entities.

More broadly, existing Legal NER and precedent extraction work has focused on either identifying precedents as flat entities or extracting their fine-grained components and, to the best of our knowledge, the reconstruction of complete precedent references from such fragmented features has not been directly addressed. Consequently, these approaches solve a different extraction problem and are not directly comparable baselines for PRE as formulated in this work.

2.2 Unified NER Methods

The limitations of traditional flat extraction have driven the development of diverse unified NER methods. Generative methods, such as BART-NER (Yan et al., 2021), recast entity extraction as a sequence-to-sequence problem. Among discriminative approaches, T2-NER (Huang et al., 2023) utilizes a two-stage entity-relation extraction setup, whereas W^{2}NER (Li et al., 2022) formulates entity recognition as a word-word relation classification task. While these supervised architectures show high structural accuracy, their reliance on large annotated datasets is a current bottleneck due to the cost and complexity of annotating overlapped and discontinuous entities.

LLM-based unified NER methods, such as PromptNER (Ashok and Lipton, 2023), leverage zero or few-shot prompting to extract complex entity lists dynamically. While these prompt-based generative methods are able to handle overlapping and discontinuous text without local training, their long-term deployment in commercial environments reveals significant trade-offs. As mentioned in section 1, generative LLMs introduce recurring per-token API costs and fail to achieve the span-level offset traceability required by downstream structural applications. This makes highly optimized, non-LLM architectures a superior alternative for stable, localized feature extraction.

In summary, current literature presents a challenging dilemma for deployment-ready PRE. On one hand, supervised unified NER methods are constrained by a lack of publicly available, annotated datasets mapping fragmented precedent references, as described in subsection 2.1. On the other hand, adopting generative LLM-based methods to circumvent this data dependency introduces structural problems in production, namely recurring token-based financial overhead and a fundamental inability to provide exact span-level offset traceability.

3 The *Notarius* Framework

In this section we introduce *Notarius*, a novel PRE method developed to address the gaps identified in current literature, namely the lack of publicly available annotated legal datasets for fragmented precedent references, and the structural and financial limitations of LLM-based methods.

3.1 Overview

Notarius operates as a sequential pipeline. As illustrated in Figure 2, the process begins with raw legal text, which is first processed by the Overlapped NER Feature Extraction (ONFE) module. ONFE extracts the precedent citation strings together with overlapped and neighboring entities that encode additional features of the same precedent. These extracted elements are then passed to the Precedent Feature Aggregation (PFA) module, which clusters and consolidates related entities into structured precedent references.

3.2 Overlapped NER Feature Extraction (ONFE)

Since traditional flat NER models typically assume that entity spans are disjoint (Dai et al., 2020; Yan et al., 2021; Li et al., 2022), their applicability to PRE is limited, because precedent references frequently contain overlapped and discontinuous entities, as discussed in section 1. Our ONFE module partially addresses this limitation by incorporating Overlapped NER methods, which can identify both flat and overlapped entities. Consequently, the module can extract fine-grained entities that encode specific precedent features, together with the citation string. In the example presented in Figure 2, the ONFE module extracts the citation string and additional features of two different references from the input text. At this stage, however, ONFE does not determine which features belong to which specific reference, an essential step in documents that contain multiple, potentially interleaved precedent references.

3.3 Precedent Feature Aggregation (PFA)

If a citation string already contains all the information required to uniquely reference a precedent, no additional processing would be necessary, in principle. In practice, however, real-world legal texts often present this information in fragmented (discontinuous) ways that make it difficult for the ONFE module to recover a complete reference, even when all required features are present in the document. This challenge is amplified in industrial settings, where we cannot assume perfect citation string extraction accuracy or consistent authoring conventions.

The PFA module addresses both issues by performing feature aggregation over the entities extracted by the ONFE module, acting as a logical aggregation layer that resolves spatial and semantic ambiguity. The aggregation process is guided by a feature-binding framework that analyzes contextual proximity and structural dependencies between extracted citation strings and their associated precedent features. Based on these signals, PFA maps each feature to the correct precedent and consolidates them into a single structured reference, as illustrated in Figure 2. The process by which these heuristics were derived, from an analysis of expert-annotated citation patterns to iterative refinement on production errors, is detailed in subsection 4.2.

Although this feature-binding process is related to traditional Relation Extraction (RE), the two differ in their objectives. RE typically predicts predefined semantic relations between entities, whereas PFA determines which heterogeneous precedent features belong to the same reference and aggregates them into a complete representation. Thus, we formulate PFA as a feature-binding problem rather than a semantic relation classification task.

4 Experimental Setup

4.1 Corpus and Annotation

Our corpus consists of 548 public Brazilian judicial decisions, reflecting diverse legal writing styles. Preprocessing involved HTML cleaning, text normalization, and tokenization using spaCy's Brazilian Portuguese large model, *pt_core_news_lg*. To manage document length, we applied dynamic segmentation (100–150 tokens with 10–15 token overlap), yielding 6,874 chunks. We reduced this to 2,180 chunks by removing those without annotated entities and partitioned the remainder into training, development, and test sets.

Legal experts followed a standardized annotation protocol, labeling nine entity types essential for uniquely identifying precedents: *CITATION*, *CLASS*, *NUMBER*, *STATE*, *RAPPORTEUR*, *DATE*, *VENUE*, *PUB_LOC* (Publishing Location), and *COURT*. Due to operational constraints, each expert annotated a distinct subset of documents; thus, inter-annotator agreement was not measured.

Preliminary analysis revealed significant underrepresentation of some entity types, as shown in Table 1. To mitigate the risk of reduced recall for minority labels due to this imbalance, we employed an LLM-based data augmentation strategy on the training split only. Synthetic but legally coherent samples were generated to increase the frequency of such labels while preserving domain consistency. Specific prompt engineering details cannot be disclosed due to internal policies. Development and test splits remained unchanged to ensure fair evaluation.

4.2 *Notarius* Configuration

We implemented the ONFE module in an industrial setting by incorporating W^{2}NER (Li et al., 2022), a state-of-the-art Unified NER method, which is particularly suitable for PRE as it handles the extraction of flat and overlapped entities within a single architecture. We trained the model for 30 epochs, selecting the best-epoch model using the develop-

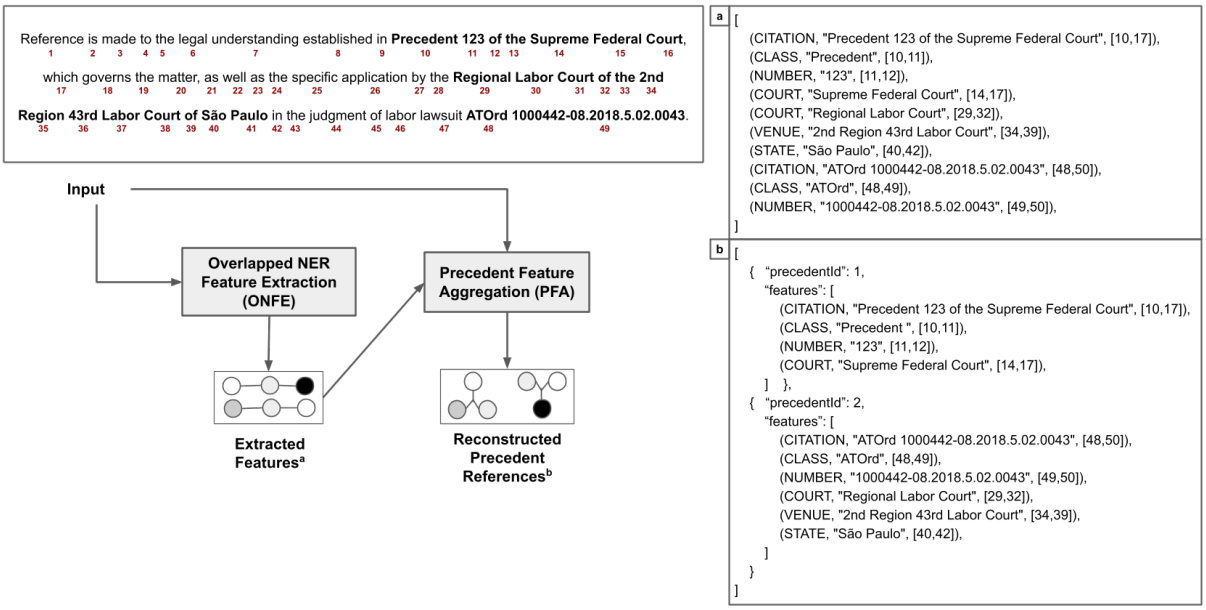

Figure 2: *Notarius* workflow.

ment split. To isolate the impact of data augmentation, we established two configurations under identical hyperparameters: a baseline model trained on the original distribution and an augmented model trained on the augmented training split described in subsection 4.1.

For the PFA module, we designed a set of domain-specific heuristics that operate as a deterministic aggregation layer over the entities extracted by the ONFE module. These heuristics are designed to group the extracted features on the basis of their textual proximity to form candidate citations. To this end, we conducted an analysis of the expert-annotated data, which allowed us to segment citations into the following patterns: i) distant and isolated citations (all citations in Figure 2); ii) nearby and isolated citations (e.g., "...[Theme 465 of the STF] and [Precedent 123 of the TST]."); iii) agglutinated citations (e.g., "...did not incur direct and literal violation of [Themes 123, 456, and 789 of the STJ]"); and iv) nearby agglutinated citations (e.g., "[Themes 123, 456, and 789 of the STJ] and [Summaries 123 and 456 of the STF]"). These patterns also illustrate why textual proximity alone is insufficient for feature aggregation. Precedent features may occur non-contiguously or be interleaved with features associated with neighboring references, particularly in fragmented and agglutinated citation structures. Consequently, assigning each extracted feature to the nearest citation span may incorrectly bind features across adjacent precedents or split features belonging to the same precedent. PFA therefore combines proximity with the structural dependencies captured by these citation patterns when reconstructing complete references. These patterns have guided the design of the heuristics that group the extracted labels according to their position in the text and expand the length of the obtained citation by looking at the other extracted labels in its neighborhood. We refined the heuristics iteratively, using errors observed in production to expose edge cases and citation styles absent from the curated corpus. Internal policies prevent further disclosure of the detailed rule logic and weights.

4.3 Evaluation Protocol

The evaluation framework mirrors the two-stage architecture of *Notarius*, assessing performance at two complementary levels. First, the **Feature-Level Evaluation** computes the F1-score of the ONFE module (baseline and augmented models) on the test set. Second, the **Reference-Level Evaluation** assesses whether *Notarius* extracts practically usable precedent references. Two legal experts (with a third for tie-breaking) manually inspected extracted references from 94 new documents outside the annotated corpus by answering: "Is the information in this reference sufficient to uniquely identify the cited precedent?" Responses were restricted to binary labels ("Yes" or "No"), and experts also recorded the ground-truth (actual) precedents. We then compute Precision (P), Recall

	Train	Aug. Train	Dev	Test	Feature-level (F1) Base	Aug.	Δ

5 Results

5.1 Feature-Level Evaluation

Table 1 reports the F1-scores for each feature entity type in the test set, for both the baseline and augmented models. A key observation is that both models achieved lower F1-scores for the *CITATION* label (0.57 and 0.56) than all other precedent features. This difference is expected because *CITATION* represents heterogeneous and frequently overlapping composite spans that may combine multiple legal elements into a single reference, whereas the remaining feature entities typically correspond to more localized and semantically homogeneous spans. This finding further supports the architectural decision to decompose PRE into sequential stages of feature extraction and aggregation. Furthermore, LLM-based data augmentation did not improve overall micro/macro average F1 (stagnant at 0.71 and 0.75). At the entity level, higher F1-scores were observed after augmentation for *STATE* (+0.05), *DATE* (+0.04), and *COURT* (+0.05). However, these per-class differences are descriptive and should be interpreted cautiously given the limited number of evaluation instances for these entity types and that no statistical significance testing was performed.

5.2 Reference-Level Evaluation

Table 2 summarizes the manual inspection by legal experts. *Notarius* achieved a reference-level F1-score of 0.89, substantially higher than the F1-score obtained for the *CITATION* label alone. Although these scores correspond to different evaluation levels and do not constitute a controlled ablation of PFA, the result is consistent with the motivation for feature aggregation: citation spans alone may not contain all the information required to recover a complete precedent reference. By binding complementary extracted features, PFA can reconstruct references even when the citation string is missed or only partially extracted, provided that sufficient identifying information is available. Common invalid references include: (1) partial misses in com-

pound references (e.g., "SUMMARIES 362 and 382 from TST"), where the system binds features to only one precedent; and (2) insufficient metadata (e.g., "STF, on 13.11.2014"), which lacks other required features.

6 Deployment and Industrial Impact

In production at Jusbrasil, *Notarius* replaced a pure LLM-based pipeline. During the production evaluation, both systems were evaluated on the same set of production documents, over the same evaluation timeframe, and using the Reference-Level Evaluation protocol described in subsection 4.3. Under this controlled comparison, *Notarius* achieved an F1-score of 0.92, compared with 0.89 for the legacy LLM pipeline. The legacy pipeline used few-shot prompting with ChatGPT-4o (snapshot gpt-4o-2024-08-06) to extract precedent references from the input text. The complete prompting strategy cannot be disclosed due to company intellectual property policies. Importantly, the LLM baseline F1-score of 0.89 reported here is independent of the identically valued 0.89 F1-score reported for *Notarius* in subsection 5.2, which was obtained from a separate evaluation on the 94 documents outside the annotated corpus described in subsection 4.3.

The two systems also differ fundamentally in their operational cost structure. The LLM baseline incurs a recurring API cost for every processed document, determined by the number of input and output tokens and the public API pricing of ChatGPT. Consequently, its API cost scales with the volume of processed documents. *Notarius*, in contrast, runs a smaller discriminative model on in-house infrastructure and incurs no per-document third-party API cost. Its operational cost instead consists of local inference and maintenance overhead, which is amortized over the production workload. At production scale, replacing recurring per-document API charges with local inference substantially reduces operational expenditure. Absolute production costs cannot be reported due to company confidentiality policies. Importantly, this cost difference is independent of extraction quality: the higher F1-score achieved by *Notarius* does not itself account for the reduction in operational costs. The two systems differ both in predictive performance and in deployment architecture. Moreover, although *Notarius* requires an upfront investment in data annotation and model development, these costs do not recur for every processed document, whereas the LLM baseline continues to incur token-based API charges throughout inference.

Beyond efficiency, the discriminative architecture of *Notarius* enables direct span matching through entity offsets, unlike generative methods, allowing full traceability between each extraction and its source text, which supports downstream tasks such as automated text highlighting and dynamic hyperlinking. *Notarius* also produces consistent outputs for identical inputs, ensuring determinism and reproducibility, which are critical for legal auditability.

7 Conclusion

We presented *Notarius*, a hybrid framework for Precedent Reference Extraction designed to address the financial and structural limitations of generative models in continuous production environments by decomposing the task into sequential stages of feature extraction (ONFE) and aggregation (PFA). Our implementation using W^2NER and domain-specific heuristics achieved an F1-score of 0.89 in a manual legal expert evaluation, extracting accurate references even when precedent features are dispersed and citation strings are fragmented. The industrial deployment of *Notarius* demonstrates that shifting from an LLM-based method to a local, discriminative alternative eliminates recurring third-party API costs while providing the span-level offset traceability required by downstream applications. More broadly, this work suggests that hybrid discriminative pipelines remain essential for high-precision structured extraction tasks even in the era of large generative models.

Limitations

While *Notarius* demonstrates high precision and significant operational efficiency in a production environment, some limitations should be considered when evaluating our pipeline. First, due to resource constraints in the industrial deployment timeline, each legal expert annotated a distinct, non-overlapping subset of the document corpus. Consequently, inter-annotator agreement was not measured, meaning that, while the experts followed a highly standardized and rigorous protocol, we could not statistically quantify the level of subjective bias or annotation drift across different annotators.

Additionally, the PFA module relies on a deterministic layer of heuristics tailored to internal corporate IP guidelines. Because these specific rule structures are proprietary to Jusbrasil and cannot be fully disclosed, the system is only partially reproducible by the research community, though the underlying sequential architecture remains generally applicable. A further limitation is the absence of a controlled comparison between PFA and simpler aggregation strategies. We did not retain gold feature-to-precedent assignments that would permit automatic evaluation of alternative aggregation methods. Moreover, our reference-level evaluation requires legal experts to assess whether each reconstructed reference uniquely identifies the cited precedent, and the expert annotation capacity required to evaluate the outputs of alternative aggregators is no longer available. Consequently, we cannot quantify how much PFA improves over simpler aggregation strategies, such as assigning each feature to the nearest citation span.

Furthermore, our evaluation and implementation are strictly bounded by the structural patterns and highly specific citation formatting of judicial decisions in the Brazilian civil-law system. Therefore, generalization of this framework to common-law jurisdictions, other languages, or other legal document types, such as legislative acts, government regulations, or contracts remains unexplored and would likely require further analysis at both the ONFE and PFA levels. We leave cross-jurisdictional, cross-language and cross-document-type evaluations to future work. Moreover, our evaluation design relies entirely on a binary judgment by legal experts regarding whether a reference contains sufficient metadata to uniquely identify a precedent, an approach that does not entirely capture granular nuances in extraction quality. Additionally, production monitoring was conducted exclusively within a single platform of Jusbrasil, meaning the robust performance reported may reflect the specific document distribution and user base of this environment rather than the entire universe of legal applications.

Finally, latency and throughput were not systematically measured during the production comparison and therefore cannot be reported retrospectively. Consequently, our operational comparison focuses on extraction quality and the structural difference in deployment costs rather than runtime performance.

Ethics Statement

Our work adheres to rigorous ethical standards regarding data privacy and the deployment of legal AI tools. The underlying corpus consists exclusively of public Brazilian judicial decisions that are accessible under national transparency laws. However, because Brazilian legal documents frequently contain raw Personally Identifiable Information (PII), the industrial production pipeline at Jusbrasil strictly implements internal data protection policies and sanitization routines to ensure compliance with data privacy regulations. To maintain complete evaluation integrity, our LLM-based data augmentation strategy was confined to the training split, while the development and test partitions remained entirely unaltered to prevent any synthetic bias from distorting our reported performance. Additionally, *Notarius* is engineered purely as an assistive legal research utility rather than an automated decision-making tool. Finally, the pipeline ensures auditability through *Notarius*'s span-level offset traceability, facilitating the verification and validation of all extracted source spans before they are used in downstream applications.

Abstract

Conversational assistants can blend retrieval, action selection, escalation, and wording in one model path, or separate those roles. We report a production migration of a conversational assistant for customer support at a large accommodation marketplace (millions of conversations per month, 11 languages, 10-second P90). Dynamic Response (DR) replaces a single Qwen3-235B-A22B blended responder with a bounded ReAct orchestrator over typed tools plus a smaller generator that writes from a backend-validated context contract. Because the migration also changed prompts, alignment, and serving, we attribute each effect to its cause and claim as architecture effects only those measured on identical replayed turns: typed entity selection moves the reservation selector to a precision-first operating point (precision 8.3% to 89.1% at recall 75.2% to 67.3%), and typed action IDs with a membership check remove observed structured-action hallucination (2.14% to 0.0%). A low-ramp A/B test reproduces the replay escalation reductions: hard-escalation responses fall 5.60% to 3.08% and soft-escalation responses 9.56% to 2.49% while production handoff volume holds roughly steady, and self-solve is directional (+5.1 points, 95% CI $[-2, +12]$). Serving optimizations cut orchestrator P90 from 3.87s to 2.24s on a GPU footprint reduced by roughly one-third, and self-hosting reduces estimated annual model-serving cost by more than an order of magnitude (Appendix F).

1 Introduction

Conversational assistants built on LLMs increasingly act as first-line customer-support agents. In our setting, the assistant answers policy questions, selects structured cancellation and refund flows, asks clarifying questions, and routes to humans when automation should stop. Each turn must fit a 10-second P90 end-to-end budget, including translation across 11 languages. The central systems problem is that support turns require both *decision making* and *wording*. A single blended responder can retrieve context, select entities or actions, decide whether to clarify or escalate, and write the reply, but these responsibilities fail differently. Wrong entity cards, unsupported action language, or premature human handoff become hard to localize when routing and prose are produced in one generation path. Dynamic Response (DR) separates those roles. A large orchestrator plans, calls typed tools, and owns routing, action, and escalation decisions; a smaller generator writes the user-facing reply from a backend-validated context contract. We focus on systems design: fixed production release checks localize regressions and gate rollout, while scoring-instrument construction, offline-to-online calibration, and launch-decision methodology are companion evaluation work. Because the migration changed architecture, prompts, alignment, and serving together, we attribute each reported effect to its cause and claim as architecture effects only those measured on identical replayed turns (Table 4); the remaining results are system-migration outcomes. We make four contributions. Unlike a RAG workflow with an API wrapper, DR structures and logs intermediate decisions, constrains generation to orchestrator decisions and retrieved evidence, and uses role-specific model sizes. The transferable principle is to make high-consequence decisions explicit, backend-validated typed tools and keep wording downstream and constrained. Concretely: (1) **production decomposition**, a typed context contract that separates orchestration from final prose; (2) a **tool-mediated runtime** with bounded RxeAct planning, typed schemas, boundary guardrails, and conservative fallback; (3) a **serving recipe**, a self-hosted open-weight MoE on vLLM with tensor-parallel serving, FlashInfer, EAGLE-3 speculative decoding, and a latency-fit layout; and (4) **operational lessons** on context handoff, tool false positives, soft escalation,

EMNLP 2026 Industry Track, pages 2591–2607

and open-weight cost and control trade-offs.

2 Background and Problem Setting

2.1 Task

When a guest or host starts support, the assistant must understand the request, retrieve user state (reservation, listing, payment, account), retrieve policy and help-center evidence, and choose among structured action cards, clarification, informational answers, and human routing. Many turns require cross-source reasoning: a cancellation may depend on reservation dates, listing policy, payment state, and regional rules. The system must also support translation, avoid unsupported actions, keep references traceable, and preserve human handoff; these constraints make architecture as important as base-model choice.

2.2 Monolithic Blending Baseline

The predecessor used the same Qwen3-235B-A22B-class model as a monolithic responder. Backend services preassembled candidate help or policy snippets, user-state variables, and renderable structured-action candidates. A single blended model path then chose the response strategy, decided whether to present an action or escalate, and wrote the user-facing reply; backend rules validated renderability, blocked unsupported outputs, and provided conservative fallback. This design was simple and avoided a second model call, but it entangled *what to do* with *what to say*: wrong actions, unsupported handoff language, or wrong entity references all appeared in one generation trace, hard to assign to retrieval, routing, or wording. Adding tools also enlarged the blended prompt, since every capability had to be exposed to the path that produced final prose. DR keeps the same large-model reasoning capacity for planning while making routing, tool use, and final wording separately observable and controllable. A stronger monolithic system with constrained decoding or structured JSON output would enforce syntactic validity, but routing and prose would still share one generation trace — a wrong entity, handoff phrase, or action could not be individually localized, gated, or rolled back — and role-specific model sizing would remain unavailable.

2.3 Related Work

DR combines ideas from RAG, tool-using agents, and LLM serving. RAG (Lewis et al., 2020) grounds generation in retrieved evidence, but single-pass RAG-style support systems can still couple evidence selection, action choice, escalation, and final wording. Building on chain-of-thought prompting (Wei et al., 2022), ReAct (Yao et al., 2023) interleaves reasoning and acting, which maps naturally to support resolution as tool calls plus observations, and tool-augmented LLMs (Schick et al., 2023; Qin et al., 2024) study how models select and use external tools. Serving efficiency also matters because orchestration must fit a production latency budget: mixture-of-experts models (Shazeer et al., 2017), grouped-query attention (Ainslie et al., 2023), vLLM (Kwon et al., 2023), and speculative decoding (Leviathan et al., 2023; Chen et al., 2023) make large routing models practical to serve. Agent frameworks such as AutoGen (Wu et al., 2023), LangGraph (LangChain, 2024), Smolagents (Hugging Face, 2025), and CrewAI (CrewAI, Inc., 2024) provide useful orchestration abstractions, but our deployment required backend-enforced control over routing, guardrail placement, logging, context handoff, and fallback behavior. Closest to our setting are recent LLM customer-support agents: benchmarks for resolving real e-commerce issues (Wang et al., 2025) and for asking clarifying questions in conversational product search (Ye et al., 2025a), and deployed systems built around continuous-improvement data flywheels (Zhao et al., 2025) and incremental summarization with agent feedback (Wu et al., 2025). These target task performance, data loops, and assistance features, and typically evaluate a single end-to-end policy. DR instead makes high-consequence decisions typed, backend-validated tool calls and reports the migration with explicit effect attribution on identical replayed turns; the evaluation methodology behind our release gates is companion work.

3 Dynamic Response Architecture

3.1 Design Principles and Runtime

DR follows three design rules. **Separate routing from wording:** the orchestrator chooses tools, actions, and escalation; the generator writes the reply without overriding those decisions. **Retrieve on demand:** the orchestrator requests only the context the turn needs and passes a curated state to the generator. **Make control flow observable:** each orchestration step is logged as a structured event, so failures can be localized and guardrails attached

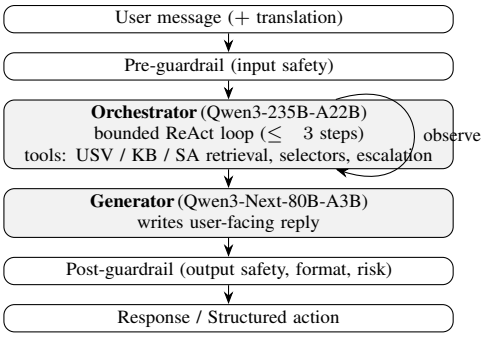

Figure 1: DR runtime. The large orchestrator plans and calls tools in a bounded ReAct loop; the smaller generator writes from the typed contract. Guardrails wrap input, tool use, and output.

at the right boundary. Figure 1 shows the runtime. After input safety checks and translation, the orchestrator enters a bounded ReAct loop capped at three steps. It may call retrieval tools, selector tools, the escalation tool, or response generation; tool observations are appended to orchestration state. Once response generation is selected, the generator receives the typed context contract and writes the final reply. Post-generation checks validate formatting, references, unsupported actions, and safety-sensitive output before delivery.

3.2 Model Roles

The orchestrator is a fine-tuned open-weight MoE model, Qwen3-235B-A22B (Qwen Team, 2025), with 235B total and 22B active parameters. It is the same large-model class used by the monolithic baseline, but DR restricts it to structured tool-call decisions, terminal actions, and fallback conditions rather than user-facing prose. The generator is Qwen3-Next-80B-A3B, selected because final responses are longer and must fit the latency budget. It writes from the contract in Section 4 and cannot select a new action, call retrieval, or initiate escalation.

3.3 Tool Registry

The orchestrator uses a typed registry (full schema in Appendix C, Table 13). Each entry defines schema, eligibility, logging fields, and guardrail hooks. User-facing tools change the customer experience; internal tools retrieve context or constrain the action space. Tool outputs are small typed objects when possible, letting the backend validate IDs, reason codes, and source membership before generation.

3.4 Two-Phase Deployment

DR shipped in two stages, both retaining fallback to the previous path to separate migration risks. Stage 1 used one orchestrator call over pre-fetched context, preserving much of the backend while validating structured routing; unlike Monolithic, it invoked a separate generator instead of writing final prose. Stage 2 introduced the full tool-mediated loop, letting the orchestrator decide which retrieval tools to call, whether entity selection is needed, whether a structured action applies, and when generation should run. The architecture-local wins reported below come from Stage 2's typed decisions; Stage 1 mainly validated structured routing and the handoff, and a per-stage ablation is out of scope.

4 Context Contract, Guardrails, and Fallback

4.1 Context Contract

The handoff between orchestrator and generator is a product interface, not a prompt detail. The forward contract passes task state, eligible tools, retrieved sources, user-state variables, policy constraints, locale, and prior observations. The return contract contains response text, source references, an optional orchestrator-selected action-card reference, and rendering fields; full fields are in Appendix A. Two constraints are central. First, the generator may reference only tools, sources, and user-state keys present in the contract, and post-generation checks enforce this closure. Second, the handoff includes the orchestration state needed for coherence, not only cited snippets: cited-only handoff was shorter but lost context such as why an action was unavailable.

4.2 Guardrails and Fallback

DR places guardrails before orchestration, inside the ReAct loop, and after generation. Pre-checks classify input safety and eligibility; mid-stream checks validate tool schema, eligibility, and consistency with prior state; post-checks validate references, action-card IDs, format, and risk-sensitive phrasing. If the orchestrator exceeds the iteration limit, emits an invalid tool call, or receives inconsistent observations, DR falls back to conservative generation over available context. Fallback cannot invent actions or bypass safety routing; every fallback logs its trigger, separating infrastructure failures (timeout, malformed tool results) from pol-

icy failures (no eligible action, ambiguous state), which require different owners.

5 Model and Serving Choices

5.1 Open-Weight Serving

The orchestrator and generator are self-hosted on vLLM (Kwon et al., 2023). Open weights let us align models to policy with full-parameter preference optimization (Appendix E), keep pre-production and production settings identical, tune serving to our traffic shape, and run large shadow tests; the alignment recipe is described in Appendix E, and reward calibration to production self-solve is out of scope. At our volume and decoding settings, self-hosting reduced estimated annual model-serving cost by more than an order of magnitude relative to a proprietary-API baseline. These are order-of-magnitude internal estimates that compare self-hosted hardware and power against API list price and exclude engineering and on-call labor; the claim we stand behind is a greater-than-tenfold reduction in serving cost at our scale, not a precise ratio (illustrative dollar estimates and basis in Appendix F).

5.2 Inference-Engine Tuning

The orchestrator runs deterministic decoding on H100 GPUs, where latency rather than throughput was the binding constraint. Switching from tensor-plus-expert parallelism to tensor-parallel-only serving (Shoeybi et al., 2019), enabling asynchronous scheduling, and using FlashInfer kernels (Ye et al., 2025b) reduced P90 from 3.87s to 2.24s while shrinking the GPU footprint by roughly one-third. Orchestrator-only serving latency across operating points is reported in Appendix D (Table 20), and the end-to-end latency distribution by stage is reported in Table 9. EAGLE-3 speculative decoding (Li et al., 2025) is being validated as a serving-only optimization toward a further-reduced operating point (Table 20), and orchestrator and generator capacity are co-located behind the stable contract; details are in Appendix D.

6 Controlled Comparison and Launch Process

We evaluate DR as an architecture migration, with evidence from zero-exposure shadow replay, a low-ramp online A/B experiment, and targeted human and risk review, all under fixed production release checks.

What we attribute to architecture. The migration changed the architecture, generator placement, prompt and tool schemas, alignment, and serving stack. The high-level decision-model class remained Qwen3-235B-A22B-class in both systems: Monolithic used it as a blended final responder, while DR uses it as the orchestrator. We therefore separate *architecture-local* effects, which correspond to typed selector, action, and escalation decisions, from *model and alignment* and serving effects, which would also benefit a single-call system. Table 4 (Appendix B) states this mapping. We do not claim a pure architecture-only ablation; readers should treat the end-to-end comparison as a production migration, with component replay used to localize the main behavior changes.

Evaluation scope. Table 5 (Appendix B) maps evidence to claims: replay localizes component failures on identical turns, human and risk review gates broadening, and A/B measures real-user outcomes under identical eligibility. We claim only architecture-local behavior, release-gated response quality, low-ramp online outcomes, and serving cost and latency; fitting self-solve utility, assigning evaluator roles, certifying judges, and calibrating offline scores to online SSR are companion-evaluation questions. Fixed launch gates were: bad-response rate $\leq 1\%$, correctness $\geq 90\%$, groundedness $\geq 75\%$, structured-action FPP $\leq 7\%$, structured-action recall $\geq 60\%$, and end-to-end P90 ≤ 10s. Correctness and groundedness in Table 1 come from fixed production release-check judges (Zheng et al., 2023) on a calibrated $\approx$1k-turn set. Each judge is certified against expert-adjudicated human labels before use (the problem-solution judge reaches ICC 0.88 and AUC 0.84 against a 0.75 human baseline). These scores interpret the architecture comparison and are not treated as powered significance tests.

6.1 Shadow Replay

We replayed production requests through both systems while serving only Monolithic responses. Fixed user behavior plus logged inputs, tool decisions, and outputs lets us localize failures to orchestration, tool selection, or final wording.

Response quality and risk. Table 1 shows that DR remains within production release thresholds while shifting the error profile. Orchestrator-decided metrics (selector, escalation, and reference checks) and generator-realized metrics (correct-

Metric	DR Orch.	DR Gen.	Monolithic

Escalation correctness (↑)	**97.3**	n/a	96.3

Table 1: Turn-level quality on a fixed shadow window ($n \approx 1{,}000$ turns). **DR Orch.** reports metrics decided by the orchestrator (reference checks, selector, escalation); **DR Gen.** reports metrics realized in the generator's final wording; "n/a" marks a non-applicable role. Arrows give the preferred direction; bold marks the better arm. †*Shadow-window logic correctness* compares final wording on identical replayed turns and is a different instrument from *core correctness (alignment effect)* in Table 4.

ness, groundedness, style) are reported in separate columns, so each win or regression is attributed to the role that produced it. The main architecture wins are zero observed structured-action hallucinations and lower user-role confusion; the main regressions are generator-side USV attribution, style and tone, and repetition. USV errors mix strict citation mismatch with genuine gap filling, so we are moving from per-sentence to per-key attribution to separate those cases (Appendix B). Style and repetition regressions are treated as generator headroom rather than evidence against the split, because upstream decision quality improves (Appendices C.7 and C.6). The structured-action hallucination claim is scoped to structured-action references only, and the 0.0% is the delivered rate: the generator can reference only actions present in the contract, the backend independently blocks any spurious action ID before delivery, and blocked attempts are logged separately.

Entity selection. The selector shifts to a precision-first operating point (full precision and recall in Appendix B, Table 6). Monolithic favored recall and surfaced many wrong entity cards; DR makes entity choice an explicit typed orchestrator decision. The design goal of the precision-first point is that a selector miss should not surface a wrong entity card, which would be misinformation. On the shadow slice where the Monolithic arm surfaced an entity but the DR selector returned null ($n = 6{,}945$ turns), that goal largely holds: DR renders a wrong entity in only 1.01% of these turns (Monolithic 0.20% on the same turns), so a miss rarely produces entity-level misinformation. The cost is elsewhere in resolution quality. On this slice DR gives an entity-free answer judged correct in 47.75% of turns, asks a clarifying question in 1.43%, and escalates in 3.87%; the remaining turns give entity-free answers not judged fully correct. This slice is a known weakness: picker correctness here (about 48%) is well below the selector's overall operating point, and raising miss-slice resolution is ongoing work. Precision is also enforced structurally: the backend rejects any rendered card whose ID the orchestrator did not select.

Structured-action selection. DR exposes the precision and recall trade-off in the orchestrator prompt (Appendix B, Table 10). We distinguish the F1 frontier from the shipped point: one configuration reaches Monolithic-level F1 but exceeds the false-positive gate, while the deployed configuration sacrifices a small amount of F1 to satisfy the false-positive and recall gates. Thus the shipped claim is gate compliance; the parity claim refers only to the achievable frontier.

Escalation behavior. Treating escalation as a tool gives a clearer control point than allowing handoff phrases to appear in final prose. DR reduces avoidable soft escalation, while replay shows that nearly all Monolithic hard escalations remain hard-escalated, so the reduction is not simply suppressed routing. Per-risk-category risk prevalence on the same replayed traffic is reported in Appendix B, Table 7, so the escalation reduction can be checked against risk exposure rather than taken on faith.

6.2 Human Review and Risk Monitoring

Pre-broadening review covered 1,173 DR conversations and 2,335 dual-labeled judgments from 28 annotators. One development snapshot passed correctness and groundedness checks but failed an internal risk gate, blocking broadening. We include this as release-process evidence, not as a launch-ready result. Error modes appear in Appendix B. We also compared Monolithic and DR on false promise, medical-records, tax, ID-verification, and refund risks. Review found no statistically reliable increase, though this is monitoring evidence rather than proof of equivalence (Table 7). In internal red-team exercises (Perez et al., 2022; Ganguli et al., 2022), DR introduced no qualitatively new

attack surface: of the issues identified in manual red-teaming of DR, all that were retested (24 of 24, across 123 attempts by six testers) reproduced at least once on the Monolithic production system, and in automated adversarial template scans DR's pass rate matched or exceeded Monolithic's on all three primary templates after iterative remediation. Findings follow standard remediation.

6.3 Online A/B (Low Ramp)

We then ran a low-ramp online A/B test under identical eligibility, randomized at the user level. We report the 5% ramp stage at its final day (2026-03-05), by which point 1,328 control and 1,346 treatment users had enrolled; escalation rates are computed at the turn level over all turns from enrolled users, using the same escalation definitions and counting logic in both arms: hard escalation is a user-initiated escalation not triggered by a guardrail, over total turns, and soft escalation is an offer to connect the user to a human. The escalation reductions observed in replay reproduce online: hard escalation falls from 5.60% to 3.08% (95% CI on the change $[-4.1, -0.9]$ points) and soft escalation from 9.56% to 2.49% (95% CI $[-8.1, -5.8]$ points). Both rates classify responses on evaluated turns; the production human-handoff rate on the same cohort held roughly steady (8.56% to 8.20%), so the reduction reflects fewer escalation-framed responses, not fewer human handoffs — itself evidence against under-escalation. Self-solve moves directionally (+5.1 points, 95% CI $[-2, +12]$) but is not significant at this ramp; contact-rate effects are likewise directional. At the fuller ramp (Table 8) the session-level self-solve gain is smaller but well powered; we treat the low-ramp estimate as directional and escalation behavior, not self-solve, as the supported online result. Per-language and per-tier hard/soft escalation splits are in Appendix B, Table 8; windows and denominators differ from the low-ramp rates above (see caption), though the wider window reproduces the reductions (English soft escalation 9.43% to 2.03%). Tier 2 languages carried no assistant traffic during the experiment.

7 Production Rollout and Operations

DR rolled out in stages: zero-exposure replay while the previous system served responses; low-traffic canary with immediate fallback; expansion by region and language; and retained rollback to the previous system during migration. Because the orchestrator, generator, tool calls, and post-generation checks are logged separately, operators can localize failures to a boundary and roll back only the affected component. Operations follow a weekly release train: tool or policy changes update the registry and prompt contracts first, and model updates stage behind the same interface, so generator swaps do not change the orchestrator and prompt updates do not change the backend renderer. Training and monitoring data is de-identified and excludes opt-out users.

8 Lessons Learned

The handoff is the architecture. Decomposition only works when the boundary between orchestrator and generator is explicit. Early prototypes treated the handoff as a prompt string, making failures hard to localize; the typed contract made the boundary inspectable and gave guardrails concrete objects to validate. **High-impact decisions should be explicit tools.** Escalation, entity selection, and action-card rendering are too consequential to leave to final prose: a single-call model can say "an agent can help" without making a routing decision, or surface a wrong entity card when clarification would be safer. DR makes these orchestrator tool decisions; the generator may explain the selected path but cannot create a new escalation or action through wording alone. **Role separation changes the optimization target.** Because the generator no longer performs global planning, it can be smaller, provided the contract carries the evidence needed for grounded wording and prevents action changes. Open weights made the split practical: self-hosting let us tune parallelism, kernels, speculative decoding, and placement while keeping the previous system as a large-scale fallback during migration.

9 Conclusion

We presented Dynamic Response, a two-model agentic architecture for production conversational assistants: a large orchestrator plans and calls tools, and a smaller generator writes the final reply. Self-hosted open-weight MoE models and serving optimizations fit a 10-second P90 multilingual budget with observable, modular control flow. The added complexity pays off when the handoff contract, guardrails, and serving stack are first-class parts of the architecture.

Limitations

DR was built for one support domain with mature tools, stable policy sources, and a human-support fallback. Decomposition is most likely to pay off when high-consequence typed decisions must be logged, validated, and rolled back, when the latency budget can absorb a second model call, and when tools and policy are mature; it helps less when tools are sparse, when policy changes faster than the contract and registry can be maintained, or when wrong decisions carry little risk. It also has a real operational price: a second serving stack and release train, and version coordination across the tool registry, orchestrator prompts, and backend validators. The second model call adds operational complexity even though serving optimizations keep latency within budget. Cost and latency figures reflect our hardware, traffic, and decoding settings.

Reproducibility. The paper releases the reusable interfaces (the context-contract schemas and invariants, the tool-registry schema, and the release-evidence framework); the shadow sets, judge prompts, and labeled data are proprietary and cannot be released. This paper reports release-process evidence needed to interpret the architecture, but omits the companion methodology used to construct evaluator roles, certify LLM judges, calibrate offline scores to online outcomes, or select prompt and model variants. The online A/B evidence is low-ramp migration evidence; self-solve and contact effects are directional at the low ramp, while the fuller-ramp session-level self-solve gain is smaller but powered (Table 8). Because DR was evaluated as a production migration, the comparison should not be read as a pure causal ablation of architecture alone.

Ethical Considerations

The system processes customer-support conversations. Data used for training, debugging, and monitoring is de-identified, opt-out users are excluded before training use, and log access is restricted; human annotators reviewed only de-identified conversations. Pre-, mid-, and post-generation guardrails reduce harmful, discriminatory, privacy-violating, or policy-violating outputs. Human escalation remains available, and safety-sensitive topics can be routed automatically. We also monitor under-escalation because reducing escalations is only desirable when automation remains appropriate; escalation is a typed tool with reason codes, so under-escalation is monitorable per risk category and per language in production. Table 7 reports per-category risk prevalence, Table 8 per-language escalation, and Appendix B the per-category detection performance and layered controls that bound under-escalation. Together with the steady production handoff rate (Section 6.3), these breakdowns let a reader check that the escalation reduction does not come from under-escalation. Cost and infrastructure figures are illustrative estimates, not audited financial statements or actuals.

A Context-Contract Specification

The forward contract restricts what the generator can see and reference; the return contract restricts what it can send back to the backend. The tables use the full page width because field descriptions are part of the interface specification. The contract enforces four invariants. First, reference closure: every article ID, structured action, and user-state key in the return object must be a member of the forward object. Second, role separation: the generator may explain an action but may not choose a different action path. Third, replayability: the forward object plus tool observations is sufficient to reconstruct why the user-facing response was allowed. Fourth, localization safety: locale is carried as data, while translation and rendering stay in backend services rather than being delegated to free-form model text. These invariants are checked by backend code, not by trusting the model to follow natural-language instructions alone.

B Additional Error and Component Analysis

This appendix expands process evidence from Section 6; example conversations are synthetic. Table 5 summarizes which instrument supports which claim, and Table 4 attributes each main gain to its cause.

Per-category under-escalation controls. Under-escalation is bounded by layered controls rather than by orchestrator discretion alone. First, safety-sensitive content is detected by dedicated per-category guardrail models (safety, jailbreak, inappropriate content) and routed deterministically to humans, independent of the orchestrator decision. The safety detector's offline evaluation against human labels at deployment measured policy recall of 89.3% at 29.5% precision (perceived recall 80.0% at 49.8% precision): a deliberately recall-first operating point that trades false positives for coverage of policy-relevant safety content, so detector misses — the per-category under-escalation channel — are the minority case by design. Jailbreak and inappropriate-content guardrails run on the same independent routing path and are threshold-calibrated on production traffic against judge-labeled samples; their operating points are security-sensitive and not disclosed. Second, the user can request human escalation at any turn, and user-initiated handoff volume held roughly steady across the migration (Section 6.3), so the response-level escalation reduction did not suppress user-initiated handoffs. Third, a post-interaction outreach program reviews flagged conversations and follows up after the fact, so a missed live escalation is not a terminal failure. Production prevalence of these categories is low (well under 0.1% of turns for all but general safety topics), so per-category under-escalation rates carry wide confidence intervals and are monitored operationally rather than estimated from the shadow window.

Structured-action selection. Table 10 reports precision, recall, F1, and false-positive proportion across routing-prompt iterations. DR reaches F1 parity while making the operating point explicit.

Human-review error taxonomy.

Soft-escalation buckets. Of the Monolithic soft escalations that DR resolves without escalation (approximately 3% of total traffic), Table 12 shows the scenario mix used for policy review.

Field	Type	Description
task_state	enum	Orchestrator objective: answer_informational, present_action_card, ask_clarifying, escalate, or fallback.
available_tools	list	Structured actions and tools eligible for this turn; the generator may reference only these members.
rag_context	list	Retrieved KB or policy passages with source_id, title, and snippet.
contextual_ variables	map	User-state variables such as reservation, listing, payment, and account state, keyed for citation.
prior_decisions	list	Earlier tool calls and observations in the bounded ReAct loop.
policy_constraints	list	Policy and risk constraints the reply must respect.
locale	string	User language and region for tone and translation.

Table 2: Forward context contract: fields the orchestrator passes to the generator.

Field	Type	Description
response_text	string	User-facing reply, pre-translation.
resolution_path	enum	Canonical support path selected by the orchestrator.
cited_article_ids	list	KB/policy IDs used by the reply; the backend verifies membership in rag_context.
cited_cv_keys	list	User-state-variable keys referenced; verified against contextual_variables.
action_card_ref	optional	Echo of the orchestrator-selected structured action to render; rejected if absent from available_tools or inconsistent with the orchestrator decision.
contextual_information	map	Renderable fields such as dates, amounts, and names.
handoff_status	enum	Backend status for normal generation, clarification, fallback, or escalation explanation.

Table 3: Return context contract: fields the generator returns to the backend.

Generator user-state-variable attribution. The elevated generator-side USV attribution error in Table 1 comes from strict attribution and genuine gap filling. In the first case, a reply may correctly summarize multiple variables but cite only one key; in the second, the generator states a value absent from the contract. We are moving from per-sentence to per-key attribution to separate these cases. Gap filling is also structurally bounded: post-generation checks reject any user-state key outside the contract, so the residual exposure is wrong values for legitimate keys, which per-key attribution measures directly.

Illustrative failures. Ambiguous requests such as "I need to change my trip" can trigger the wrong policy instead of a clarifying question. Safety-sensitive check-in and access issues can also require escalation even when a help article exists. Both cases are handled as routing-policy updates rather than generator-only fixes.

C Component Design and Optimization Details

This appendix details design choices behind DR. It reports operational component checks, not a new measurement methodology; scoring-instrument construction and production-outcome validation remain out of scope. The intent is to document the interfaces and choices a reader would need to reproduce the decomposition: what the planner can choose, what context it receives, how routing prompts were isolated, and why the smaller generator was acceptable. Throughout, **L** denotes Qwen3-235B-A22B for orchestration and **S** denotes Qwen3-Next-80B-A3B for generation.

C.1 Architectural decomposition

Monolithic fixed much of the turn flow inside a single blended model path over preassembled context. DR instead lets the orchestrator choose response generation, escalation, reservation and listing selectors, structured-action retrieval, help-content retrieval, and user-state-variable retrieval. The generator receives the selected path through the contract and cannot choose a different action. This exposes separately tunable surfaces: tool schemas, selector context, routing prompts, generator prompts, fallback behavior, and model placement. The registry is versioned with the prompts: when a tool schema changes, both the orchestrator prompt and backend validator are advanced together, then shadowed be-

Effect	Source	Attributable to
Selector precision 8.3 to 89.1%	explicit selector tool	architecture
SA hallucination 2.14 to 0%	typed action IDs + check	architecture
Soft-escalation responses -74%	escalation as a tool	architecture
Core correctness (alignment effect) 0.825 to 0.93	self-host + alignment	model and alignment
P90 -42%, GPU footprint -33%	inference-engine tuning	serving

Table 4: Attribution of the main gains. Architecture-local effects are measured on identical replayed turns; model, alignment, and serving effects would also benefit a single-call system. *Core correctness (alignment effect)* is the self-hosting-plus-alignment gain on one instrument (0.825 pre-alignment baseline to 0.93 aligned model); it is a different measurement from *shadow-window logic correctness* in Table 1, where both arms already use the aligned self-hosted models.

Evidence	Unit / source	Use in this paper
Shadow replay	Turn; fixed replay traffic	Compare systems without exposure and localize component failures.
Tool-decision checks	Tool call; labeled slices	Measure selector, structured-action, and escalation decisions.
Human/risk review	Conversation; dual labels	Gate broadening and identify risk modes.
Online A/B	User/session; low-ramp RCT	Check escalation, contact, and self-solve trends; report confidence where powered.
Serving logs	Request	Verify latency budget and GPU footprint.

Table 5: Release evidence for the architecture comparison. Instrument construction, judge certification, and offline-to-online calibration are not contributions.

	Reservation		Listing	
System	Prec.	Rec.	Prec.	Rec.
Monolithic	8.3	75.2	9.0	87.7
DR (no selector ctx)	82.1	45.6	66.8	48.9
DR (+ ctx, v2)	87.5	58.5	71.7	55.2
DR (+ ctx, v3)	**89.1**	67.3	**73.3**	58.5

Table 6: Selector precision and recall (%, approximately 1k shadow samples).

	Risk prevalence, % [95% CI]	
Risk category	Monolithic	DR
Cancellation / refund	7.6 [6.7, 8.7]	8.4 [7.3, 9.6]
General	4.0 [3.3, 4.8]	4.1 [3.3, 4.9]
False promise	1.2 [0.8, 1.7]	1.2 [0.8, 1.7]
Tax	1.0 [0.7, 1.4]	0.9 [0.6, 1.4]
Medical records	0.0 [0.0, 0.2]	0.1 [0.0, 0.3]

Table 7: Per-risk-category risk prevalence on identical shadow traffic (Monolithic n=2,795 turns; DR n=2,318 responses: prevalence is computed among responses because a subset of replayed turns routed to typed non-response actions such as entity pickers, which would otherwise bias the comparison downward). Flags come from five risk classifiers calibrated against subject-matter-expert labels, built as a three-stage hierarchical pipeline (category filter, sub-skill filter, focused per-pattern scoring with policy-encoded prompts). No category shows a statistically significant difference between the systems (all 95% CIs overlap). ID-verification and other safety-sensitive contact reasons are routed deterministically to humans, independent of the model's decision (Section 6.2).

Tier	Escalation	n_C	n_T	Control	Treatment	Δ (pp)	p	95% CI (pp)

FR	soft	154	179	9.74%	2.79%	-6.95	0.008	$[-12.22, -1.68]$
Overall	hard	8,926	9,073	5.23%	2.82%	-2.41	1.8×10^{-16}	$[-2.98, -1.84]$
Overall	soft	8,926	9,073	9.41%	2.03%	-7.38	2.1×10^{-101}	$[-8.05, -6.71]$

Table 8: Per-language-tier hard and soft escalation: turn-level response classifications on evaluated turns over 2026-03-05 to 2026-03-12, the widest window in which both arms served non-shadow traffic. Δ is treatment minus control in points. English and Tier 1 confidence intervals overlap on both metrics, indicating no language-tier interaction. Within Tier 1, both single-language soft-escalation reductions are significant, while the single-language hard-escalation deltas are directional at these sample sizes (their CIs cross zero); ES turn counts are derived as Tier 1 minus FR, since Portuguese carried no assistant traffic in this window, and the ES/FR confidence intervals are computed with the same unpooled two-proportion method as the tier rows. Tier 2 (DE, IT, RU, JA, KO, TH, ZH) was routed to the legacy bot during the experiment and carried no assistant traffic in either arm; the 11 languages in the abstract describe the deployed platform, not this experiment's eligible population. Session-level results over the full experiment window (2026-02-24 to 2026-04-14; $n \approx 139$K engaged sessions per arm, a different denominator) show the same consistency: self-solve $+1.77$ points for English and $+1.80$ for Tier 1, combined escalation -1.68 and -1.77 (all $p < 10^{-8}$), and end-to-end P90 latency improves from 9.43s to 7.34s for English and 10.08s to 8.25s for Tier 1, though Tier 1 remains slower than English in both arms. Tier-level differences are not driven by language routing: the language-identification guardrail exceeds 99% weighted accuracy on human-labeled production data.

Stage	P50	P90	P99
Translation	0.043	0.059	0.792
Orchestration (incl. tools)	2.772	4.151	7.404
Generation	0.926	1.325	1.695
Guardrails + rendering	0.734	1.460	2.292
End-to-end	4.787	6.539	10.386

Table 9: End-to-end latency distribution by stage (seconds), DR arm on live traffic over the stabilized tail 2026-03-02 to 2026-03-05 ($n = 4{,}155$ turns). Percentiles are computed over per-turn stage sums, not as sums of per-stage percentiles, so the stage rows need not add to the end-to-end row; the unattributed residual is at most 0.39s at P99. The orchestration stage spans the full bounded ReAct loop, including tool executions and up to three model calls, so it exceeds the single-call orchestrator serving latency in Table 20. End-to-end P90 (6.539s) is within the 10s release gate, and orchestration is the dominant stage (about 58% of the median turn).

System / prompt	P	R	F1	FPP
Monolithic (prod)	80.7	75.2	77.9	6.6
DR (v1)	82.5	70.5	76.0	**5.5**
DR (v2)	77.9	77.4	77.7	8.0

Table 10: Structured-action precision, recall, F1, and false-positive proportion (%). DR reaches F1 parity; the routing prompt sets the operating point.

Error mode	Share	Denominator
Intent classification	34.8%	all errors
Missed escalation trigger	30.4%	all errors
Hallucination (gap-filling)	55.0%	groundedness errors

Table 11: Top error modes from human review. Shares use different denominators and are not a mutually exclusive partition.

Scenario	Share
Technical error	29.3%
Booking modification / cancellation	17.0%
Check-in / access	12.9%
Payment / billing	12.2%
Unresponsive host	8.8%
Other (long tail)	19.8%

Table 12: Scenario mix of soft escalations resolved by DR without escalation. "Other" is the residual after the named buckets.

fore user exposure. Table 13 lists the full registry referenced in Section 3.

C.2 Selector context implementation

The selector input contains the set of candidate reservation or listing IDs, whether an ID is currently active in the conversation, whether it came from the user message, profile state, itinerary state, or a previous tool observation, and a short natural-language mention span when one exists. The selector can return a concrete ID, a `null` decision when no entity is needed, or a clarification request when multiple entities remain plausible. This schema moved entity choice out of final prose: the generator no longer has to infer a reservation from wording, and the backend can reject any rendered card whose ID was not selected by the orchestrator.

C.3 Planner model selection

The orchestrator must produce short but high-impact routing decisions. We compared candidate planners on action-card selection against the same human-labeled set (Table 14). Among untuned candidate planners, GPT-4o had the strongest initial F1, but **L** was already deployed, self-hosted, and adaptable in house; we selected **L** and closed the gap through routing-prompt iteration.

C.4 Action-card routing prompt

After selecting **L**, we tuned the action-card routing prompt. The first DR prompt raised recall but over-fired; adding selector context raised recall further; later instructions reduced over-firing while preserving most recall (Table 15).

C.5 Help-content routing

The help-content path uses a stage-aware primary-source rule: "why" or "can I" queries prefer policy or overview articles, while "how" or "what do I do" queries prefer procedural articles. Encoding this at routing time keeps source choice separate from wording and improves labeled help-content selection (Table 16). The generator then explains the selected source rather than searching again, which prevents late-stage source drift.

C.6 Generator model selection

The generator must leave latency headroom for orchestration, retrieval, guardrails, and translation. We compared the larger **L**, the smaller **S**, and frontier APIs on a production-shaped synthetic set (Table 17). Claude 4 Opus was infeasible on latency in this setup. We chose **S** because it met release thresholds at lower P90 and about half the serving footprint of **L**. Selecting a smaller model for the narrower generation role is consistent with model compression and on-policy distillation results (Hinton et al., 2015; Agarwal et al., 2024); here we use an existing open-weight model aligned to policy (Appendix E) rather than distilling our own.

C.7 Generator prompt and residual headroom

With **S** selected, we compared a reduced-context per-solution prompt with a merged full-context prompt. The reduced prompt is attractive because it passes only the action-card, help-content, or contextual-variable slice selected by the orchestrator. The merged prompt is operationally simpler: it always passes the same schema and lets the generator decide how much of the allowed context to mention. The core quality scores were close, so we chose the merged prompt because one schema removes per-path branching, shortens replies, and slightly improves style, tone, and repetition behavior (Table 18). Table 19 shows the residual gap between **S** and larger **L**. We treat it as future generator headroom, not evidence against the split, because the architecture gains come from better upstream decisions.

D Serving Model Detail

Speculative decoding and co-location. EAGLE-3 speculative decoding is being validated as a serving-only optimization for a further-reduced footprint target (Table 20). The draft model fuses low, middle, and high verifier-layer hidden states to predict the next three tokens; under standard speculative verification, accepted outputs preserve the verifier distribution. We train the draft on production-shaped traces, warm-start from a public Qwen3-235B speculator checkpoint, and validate on shadow traffic so the optimization changes serving rather than behavior. We co-locate orchestrator and generator capacity so the two share one availability envelope; future generator swaps leave the orchestrator interface unchanged because the contract is stable. Table 20 reports orchestrator-only serving latency across operating points, expanding the headline figures in Section 5. Footprints are stated relative to the pre-optimization baseline. Table 21 summarizes orchestrator candidates from a serving and controllability perspective: active

Tool class	Visibility	Output to orchestrator	Architectural purpose
USV retrieval	Internal	User-state variables under stable keys	Provides reservation, listing, payment, and account state without exposing the full user record.
KB retrieval	Internal	Ranked policy/help snippets with source IDs	Grounds informational answers and constrains citation targets.
Structured-action retrieval	Internal	Eligible action-card subset	Limits actions to cards renderable for this user and turn.
Reservation/listing selectors	Internal or user-facing	Selected entity ID or null decision	Prevents the generator from guessing the referenced entity.
Escalation	User-facing	Hard-route decision and reason code	Makes human routing an explicit action, not generated phrasing.
Response generation	User-facing	Final response from generator	Runs only after task state and context are fixed.
Fallback generation	User-facing	Conservative response over available context	Handles ReAct iteration limit or invalid orchestration state.

Table 13: Orchestrator tool registry. Each tool has a typed schema, eligibility constraints, and logging fields.

Planner model (initial prompt)	Precision	Recall	F1	FPP
Production prompt on **L** (reference)	0.807	0.752	0.779	0.066
GPT-4o	0.782	0.760	0.771	0.077
In-house Qwen3-235B-A22B (**L**)	0.701	0.714	0.707	0.111
Vanilla Qwen3-235B (base)	0.728	0.497	0.591	0.068
Vanilla Qwen3-235B (instruct)	0.693	0.705	0.699	0.114

Table 14: Planner model comparison for action-card selection against the same human-labeled set. FPP denotes false-positive proportion.

parameters, latency under our stack, and whether the model allows in-house adaptation. We selected Qwen3-235B-A22B not because it was the highest-quality model on every slice, but because it gave the best joint operating point: low served latency in our stack, self-hosted control, and a path to future in-house adaptation without changing the tool interface.

E Alignment Data and Reward Abstraction

This appendix gives a minimal description of the alignment stage used after model selection. We intentionally keep implementation details abstract because this paper focuses on the deployed orchestrator and generator interface, not on a full evaluation or reward-calibration study.

E.1 Alignment data

We construct alignment examples from de-identified production and simulated support cases after removing opt-out traffic. Cases are sampled to cover both successful and unsuccessful interactions. For each input, the current policy produces multiple candidate responses under the same conversation state, retrieved context, and available actions. This creates within-input comparisons that isolate response-policy behavior while holding the orchestrator inputs fixed. The resulting candidates are scored by task rewards and converted into the training format required by the chosen post-training method, following the RLHF lineage (Ouyang et al., 2022; Schulman et al., 2017). Pairwise methods use higher-scoring and lower-scoring responses as preference pairs (Rafailov et al., 2023; Hong et al., 2024), while relative-reward methods use the candidate set to compute group-level advantages (Shao et al., 2024; Zheng et al., 2025).

E.2 Reward abstraction

We use two reward families. A quality-centered reward scores whether the response is correct, grounded, clear, and compliant with the prompt. A reference-aware reward additionally checks whether the response covers a likely solution and uses supporting knowledge-base or action-card evidence consistently. The second family is intended to discourage safe but under-resolving answers, such as generic policy summaries or clarification-only responses when enough evidence exists to provide a conditional next step. To reduce leakage between training and evaluation, reward scoring is separated from final offline evaluation. Before serving, the selected checkpoint is frozen and evaluated through the same deployment checks as other candidate updates. The serving interface is unchanged: the orchestrator still supplies conversation state, retrieved context, and available actions, while only the generator policy is replaced.

F Serving-Cost Estimate

The $6M and $200K figures are order-of-magnitude internal estimates for annual model-serving cost at our volume and decoding settings,

Planner prompt	Response-tool rate	Precision	Recall	F1	FPP
Production prompt (reference)	n/a	0.807	0.752	0.779	0.066
DR V1.0	93.8%	0.712	0.831	0.767	0.122
DR V1.1 + picker context	97.6%	0.695	0.863	0.770	0.138
DR V1.2.4 + picker context	97.0%	0.752	0.816	0.783	0.098

Table 15: Action-card routing against the human golden label, planner on **L**. Later prompt iterations explored the F1 and false-positive trade-off; Appendix B identifies the gate-compliant deployed point.

System	Precision	Recall	F1
Monolithic reference	32.32%	75.44%	34.15%
DR + routing-prompt tuning	37.25%	85.32%	41.39%

Table 16: Help-content selection against ground-truth labels on approximately 800 samples.

provided for illustration only; they are estimates, not audited financials or actuals. We state the basis so readers can rescale to their own.

Proprietary-API baseline. Estimated from annual generated-plus-prompt token volume across orchestration and generation at production traffic, and the blended list price of the proprietary API considered. For rescaling: the orchestrator processes roughly 8,000 prompt and 200 completion tokens per model call (up to three calls per turn), and annual turn volume is on the order of 10^7.

Self-hosted. Estimated as amortised hardware plus power for the production footprint (the orchestrator at its current production operating point plus co-located generator capacity), at our measured utilisation over a standard amortisation period. It *excludes* engineering and on-call labor, model-development cost, and shared-platform overhead; including loaded labor would raise the self-hosted figure but not by enough to close an order-of-magnitude gap.

Scope of the estimate. The comparison is therefore self-hosted hardware cost against API list price. The takeaway we stand behind is a greater-than-tenfold reduction in *serving* cost at our scale, not a precise ratio. The figures move with traffic, hardware generation, utilisation, and API pricing.

Generation model	Serving footprint	P90 latency	Correctness	Groundedness
L: Qwen3-235B-A22B	2×	6.29 s	93.3%	86.6%
S: Qwen3-Next-80B-A3B (deployed)	1× (reference)	5.45 s	92.1%	83.1%
GPT-4.1 (API)	n/a	4.76 s	94.4%	89.4%
Claude 4 Opus (API)	n/a	17.81 s	94.8%	87.2%

Table 17: Generator candidates on a production-shaped synthetic set: serving footprint (relative to the deployed configuration), model-only P90 latency, and release-check scores. Latency is measured under model-selection settings and is not directly comparable to the production generation-stage latency in Table 9.

Generator prompt	Resolution	Groundedness	Correctness	Repeat-instr. ↓	Words	Style/tone
Reduced-context (per-solution)	0.84	0.84	0.91	0.24	109	0.65
Full-context (merged, deployed)	0.81	0.83	0.92	0.21	61	0.71

Table 18: Generator prompting regimes on **S** over a shared shadow-traffic set of approximately 455 samples. Scores are in $[0, 1]$ except word count; lower is better for repeated instruction.

Generation model	Resolution	Groundedness	Correctness	Words	Style/tone
S: deployed full-context generator	0.81	0.83	0.92	61	0.71
L: larger in-house model	0.86	0.85	0.94	131	0.68
Δ (**S** − **L**)	−0.05	−0.02	−0.02	−70	+0.03

Table 19: Deployed generator **S** versus larger in-house **L** on a shared shadow-traffic set. Δ is **S** minus **L**.

Config	P90	P95	P99	GPU Δ
Baseline	3.87	4.53	5.95	n/a
Opt. 1	2.24	2.61	3.43	-33%
Opt. 2	2.60	3.02	3.87	-56%
Opt. 3	2.66	3.16	4.07	-67%

Table 20: Orchestrator serving latency in seconds and GPU-footprint reduction relative to the pre-optimization baseline. Opt. 1 is the current production operating point; Opt. 2 is the rollout target for speculative decoding.

Model	Act. prm	P50 (s)	P90 (s)	Control
Claude Opus 4.5	n/a	3.19	4.41	API only
GPT-4.1	n/a	1.86	2.42	API only
Gemini 3 Pro	n/a	12.12	26.11	API only
Gemini 3 Flash	n/a	2.25	3.16	API only
Claude Haiku 4.5	n/a	3.15	4.41	API only
Kimi 2.5	32B	5.46	8.73	open-weight path
Qwen3-235B-A22B (ours)	22B	1.56	1.96	self-hosted

Table 21: Orchestrator model options from a serving and controllability perspective. Latency is measured on the model-selection benchmark under internal settings and is not directly comparable to the production orchestrator latency in Table 20. Proprietary models are API-served, while Qwen3 is self-hosted.

Tool-Making and Self-Evolving LLM Agents in Low-Latency Systems

Abstract

Production LLM agents often waste latency and reliability by regenerating code for the same procedural steps on every request. We replace this inference-time coding loop with an agentic tool-making pipeline that compiles repeated SOP steps into validated, versioned tools before deployment. The tool-maker grounds synthesis in the live environment as it collects execution traces, observes backend schemas and values, generates candidate tools, and repairs them against labeled cases. At runtime, the production agent calls these tools directly and falls back to code generation only when needed. We deploy the approach in a Fulfillment Center alarm-triage system, where an agent diagnoses alarms against a 44-node SOP over heterogeneous metric backends. In production, tool calls reduce p50 latency by 42%. On 1,500 historical alarms, they reduce end-to-end error rate by up to 53% by suppressing run-to-run variance in repeated steps. Because tools return compact structured verdicts, they also enable a simpler direct-call architecture, reducing p50 latency by a further 62% in a controlled ablation. Versioned tools also improve auditability and expose specification gaps and upstream data drift. Our results show that agents that build and maintain their own tool libraries, a key element of self-evolving agents, can make industrial LLM systems faster, more reliable, and easier to operate.

1 Introduction

LLM coding agents are becoming a practical interface to complex software and operational systems. Instead of a fixed API or hand-written automation per task, these agents read natural-language instructions, write and execute code, and iterate until they produce an answer or action. This flexibility has enabled deployments in on-call incident triage (Chen et al., 2024b; Wang et al., 2024b), workflow-guided operations (Ye et al., 2025), and general code-based tool use (Wang et al., 2024a). In industry settings, many procedures are documented as standard operating procedures (SOPs), while the data needed to execute them resides in metric stores, logs, dashboards, and ticketing systems.

This flexibility, however, creates an efficiency and reliability bottleneck. In the prevailing CodeAct-style paradigm (Wang et al., 2024a), the agent generates and executes fresh code for each request at inference time. When the same workflow is repeated against a stable backend, the agent re-interprets the same instruction, rediscovers the same schema, and regenerates similar code, raising latency, cost, and run-to-run variance. Prior benchmarks show agents still struggle with workflow-guided tasks (Nandi et al., 2025; Wang et al., 2025b; Riddell et al., 2026), and even SOP-enhanced multi-agent systems leave a substantial accuracy gap on operational diagnostics (Pei et al., 2025). In our setting, most latency and correctness errors are caused by translating underspecified SOP text into a concrete query against a production metric backend.

This has motivated a shift from inference-time coding agents to self-evolving agents: systems that improve their own action space over time by constructing reusable tools, skills, or programs before they are needed in production. Recent work explores task-conditioned tool synthesis (Cai et al., 2024; Yuan et al., 2024; Wang et al., 2024c), closed-loop construction driven by feedback (Wang et al., 2023; Wölflein et al., 2025), reusable workflow induction from demonstrations (Wang et al., 2024d), and the translation of operational documents such as company policies and troubleshooting guides into tools (Zwerdling et al., 2025; Mao et al., 2026). The key idea is to amortize cost by identifying procedural steps executed repeatedly and compiling them into deterministic tools, which are then invoked cheaply and consistently at runtime.

We study this approach in a production agent at a Fulfillment Center (FC), where SOPs prescribe how alarms on robotic induct, conveyance,

EMNLP 2026 Industry Track, pages 2608–2624
October 24-29, 2026 ©2026 Association for Computational Linguistics

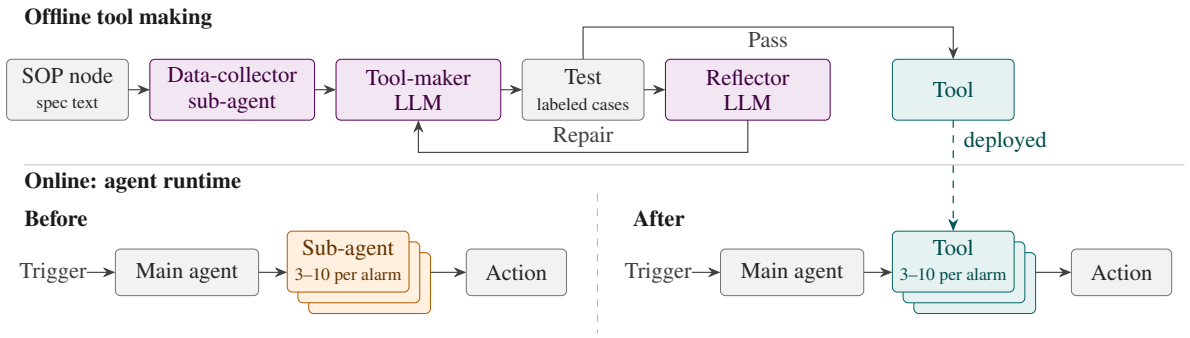

Figure 1: Offline (top), each SOP node is compiled into a tool: a data-collector sub-agent runs against MCP, producing a trace; a tool-maker LLM writes a candidate from it; and a reflector–tool-maker loop repairs the candidate against labeled cases. Online (bottom), the baseline sub-agent writes fresh MCP-querying code per node over 10–20 LLM turns, whereas our agent calls the compiled tools inline, one call per node.

and sortation subsystems are diagnosed and acted upon. These SOPs branch on thresholds from heterogeneous metric backends and select interventions from low-cost flow reallocations to high-cost staffing changes, ticket escalations, and equipment standbys. Latency and correctness are tightly coupled: failures cascade across subsystems within minutes, while an expensive action taken against the wrong cause is difficult to reverse. Manual execution by floor operators is slow under concurrent alarms and error-prone given the number of metrics, schemas, and conditional branches.

We report the design and production deployment of an agentic tool-making pipeline for this setting, triaging outbound dock alarms against a written SOP. The system has two modes (Figure 1). At build time, a tool-maker constructs a library of per-SOP-step tools against the production environment, observing schemas and execution traces and validating candidates against labeled cases rather than relying on SOP text alone. At inference time, the agent invokes these tools per alarm, falling back to code generation only when a tool is unavailable or fails. This preserves the flexibility of coding agents while moving repeated, latency-sensitive work into a reusable and auditable tool library.

We make two main contributions: an agentic tool-making pipeline that compiles repeated SOP steps into validated tools, and its integration into a deployed alarm-triage agent, where it cuts p50 latency by 42%, enables an architectural redesign that cuts it a further 62% in a controlled ablation, and reduces the end-to-end error rate by up to 53%. We also report three findings. The data-collection trace and test-repair loop are both necessary. Residual errors then concentrate on underspecified SOP steps, where targeted fixes raise pass@1 from 94.5% to 99.9%. Versioned tools with stable inputs and outputs reveal pre-existing upstream inconsistencies that run-to-run variation otherwise hides. Our results suggest that agents that compile their own experience into reusable tools are a practical path for bringing coding-agent flexibility to latency-sensitive industrial workflows.

2 Production Setting and Task

An outbound dock is the final operation in a fulfillment center, where packages are sorted and loaded before they leave for downstream logistics. The dock is tightly coupled: a degraded subsystem backs up the operations feeding it and cascades across the dock within minutes, amplifying a localized fault into an outsized delay that threatens delivery commitments. The agent triages alarms such as robotic stations idling due to upstream conveyance blockages, or producing elevated error rates from camera, sensor, label, or packaging defects.

The agent follows an SOP encoded as a decision tree of 44 decision nodes and 19 action nodes. Decision nodes are of three kinds. Observations test whether a metric crosses an alert threshold and serve as alarm entry points, root causes identify the underlying failure, and constraints gate the most expensive actions. Actions range from cheap (process alerts, flow reallocation) to costly (equipment shutdown, staffing changes). Each node specifies which data to query and how to process it.

The agent evaluates observations to localize the failure, reaches candidate root causes, and executes the action. Before shutting down a robot with a faulty suction cup, for example, constraint nodes verify that the shutdown is either safe (remaining capacity covers the item flow) or unavoidable (the error rate makes operation worse).

3 Method

We build on the hierarchical multi-agent architecture of Eluna (Liu et al., 2026b) where a main agent traverses the decision tree and delegates each evaluated node to a CodeAct-style sub-agent (Wang et al., 2024a) via a free-text question. The sub-agent generates and executes code that queries metrics through MCP (Model Context Protocol), iterating until it returns a free-text answer, which the main agent parses into a verdict (true/false/no data) to inform subsequent traversal. Delegation keeps the multi-turn data-processing context within the sub-agent, and sub-agent calls within a decision-tree layer run in parallel. Per alarm, the agent evaluates 3–10 nodes, and the sub-agent loop can exceed 100 LLM turns in the most complex cases.

The dominant per-alarm cost in this architecture is the sub-agent's loop, as most of its turns translate the same SOP text into the same MCP queries against an unchanging interface. We replace this loop with per-node tools, each a build-time compilation of the loop for one node into a single deterministic call that returns the verdict directly at inference. Tools are model-agnostic and regenerable independently of agent fine-tuning.

3.1 Tool-Making Pipeline

SOPs are authored by humans, and the SOP text omits execution details that a human reader would resolve from domain knowledge or by inspecting the data, such as field names, datatypes, null handling, and boundary-case conventions. These omissions cause persistent failures when a tool-maker is given only the SOP text. The pipeline closes the gap with two grounding mechanisms (Figure 1, top): a *data-collection trace* of real execution against the live schema, and a *test–repair loop* that corrects each candidate against labeled cases. Each tool is a function with a uniform signature mapping a (warehouse, timestamp, context) input to the node's verdict (true, false, or no data) and supporting detail. The context carries site-specific parameters and verdicts from parent nodes. Each node has a labeled training set, consisting of (input, verdict) pairs from an offline labeler whose logic was specified by subject-matter experts (Appendix B discusses the labeling).

The pipeline has three model components, shown left-to-right in Figure 1. The *data-collector sub-agent* is the baseline CodeAct sub-agent serving as the inference-time fallback, with access to the production MCP. For each node, it is run on three sampled training cases balanced across verdict labels, writing and executing query code and iterating to a final verdict that is graded against the case label. The resulting trace, passed to the tool-maker, contains the query code, the MCP responses and observed schema (field names, datatypes, value ranges), and the graded verdict, supplying the execution details the SOP omits.

The *tool-maker LLM* produces a candidate tool conditioned on the SOP node text, the node's position in the decision tree (its parent and child nodes), and the data-collector's traces. The candidate is then tested against the full labeled training set, and disagreements are passed to the test–repair loop. The *reflector LLM* writes a short diagnosis of the failures, after which the tool-maker does a rewrite conditioned on the diagnosis and the disagreements. The reflector receives the failing (input, expected, predicted) triples and the previous candidate, and the tool-maker receives the same and the reflector's diagnosis. The loop runs for a budget of three rounds and terminates early once a candidate passes the full training set. The candidate with the highest training-set pass rate is deployed. Appendix E shows an example from a generated tool.

At inference, tools are used in one of two configurations: the main agent delegates a node to a sub-agent that calls the node's tool, or the main agent calls the tool directly (Figure 1, bottom). Each tool returns the verdict, the observed value, the threshold, and a textual explanation. "No data" is reserved for missing metrics, and exceptions trigger fallback to the CodeAct sub-agent of the baseline. Only the affected node reverts to baseline latency and accuracy. The remaining nodes continue using their tools.

3.2 Agent Fine-Tuning

Production latency constraints cap the deployed alarm-triage agent at a small model size, and small off-the-shelf models fail to follow the SOP reliably. We therefore distill a larger teacher into the small student model: the teacher generates trajectories on the alarm-triage task, rejection sampling retains only those whose extracted observations, root causes, and actions all match ground truth (Yuan et al., 2023), and the student is fine-tuned on them with LoRA (Hu et al., 2022). To keep the student robust when tools are missing or fail, the teacher generates trajectories under varied tool availability: in 75% of trajectories, the generated

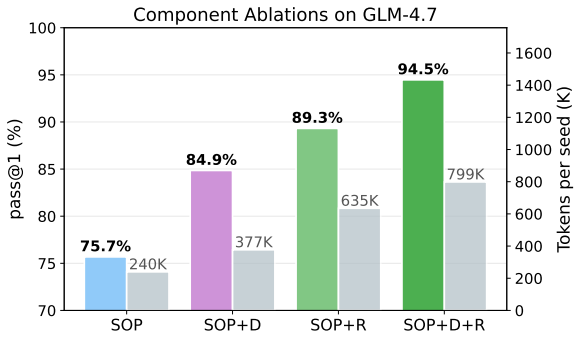

Figure 2: Per-node pass@1 (left) and generation cost in tokens (right) for each ablation configuration on GLM-4.7. +D adds the data-collection trace (Section 3.1); +R adds the test-repair loop. Only the deployed configuration (SOP+D+R) exceeds 90% pass@1.

Tool Maker	SOP	+D	+R	+D+R
GLM-4.7	75.7	84.9	89.3	**94.5**
GLM-5	76.8	83.4	88.0	93.6
Qwen3 235B	74.2	71.6	79.9	81.1
GLM-4.7 Flash	56.4	60.4	58.7	65.8

Table 1: Per-node pass@1 (%) by tool-maker and configuration. +D adds the data-collection trace; +R adds the test-repair loop. The deployed SOP+D+R column is in bold, with GLM-4.7 deployed. Confidence intervals and significance tests are in Table 9.

tools are available but 25% of tools are randomly disabled per trajectory, and in the remaining 25% all node tools are removed so the teacher falls back to the sub-agent for every node.

4 Tool-Making Experiments

4.1 Experimental Setup

Data. The pipeline is evaluated on 44 decision nodes. Each node has a labeled training set used by the pipeline and a separate held-out evaluation set. Per-node case counts range from 100 to 200, totaling 8,011 training cases and 8,022 evaluation cases. Data labels are evenly distributed.

Models. We compare the following four models as the tool-making agent (Section 3.1): GLM-4.7 (Zeng et al., 2025), GLM-5 (Zeng et al., 2026), Qwen3 235B (Yang et al., 2025), and GLM-4.7 Flash (Zeng et al., 2025). We use Claude Opus 4.6 for additional ablations (Anthropic, 2026) to prevent model capacity from confounding the comparison. When reflection is used, the reflector LLM is the same as the tool-maker LLM. The deployed alarm-triage agent uses a separately fine-tuned model (Section 3.2).

Evaluation. We evaluate the build-time pipeline by per-node pass@1: the probability that one full execution of the pipeline produces a tool that passes the held-out evaluation set for that node, where a tool passes only if it returns the correct verdict on every case in the set. Pass@1 is averaged across the 44 decision nodes. Confidence intervals and significance tests are reported in Appendix G.

4.2 Main Results

Figure 2 shows the per-node pass@1 and generation cost of each configuration on GLM-4.7, and Table 1 reports pass@1 for all four tool-makers. The full configuration adds the data-collection trace (+D) and the test-repair loop (+R) to the SOP text, reaching 94.5% pass@1 on GLM-4.7 and 93.6% on GLM-5. Both components are necessary: removing the repair loop reduces pass@1 by 9.6pp and removing the trace by 5.2pp, and only the full SOP+D+R configuration exceeds 90%. The two strong tool-makers, GLM-4.7 and GLM-5, behave alike, with the trace and the repair loop each adding a significant gain, whereas the weaker Qwen3 235B and GLM-4.7 Flash gain less and do not improve monotonically. We deploy GLM-4.7, which attains the highest pass@1 of the four. The appendices report further results (Appendix C). Repair compute cannot substitute for the trace, whose components each contribute a gain, and reflection-based repair outperforms repairing from raw failures only when the trace is present. The pipeline also approaches the full-data ceiling from a handful of labeled cases per node, with a label-free variant within a few points (Appendix D).

Across the 30 GLM-4.7 pipeline runs, each generated library contains 39–43 tools that pass their full held-out sets (median and mode: 42 of 44), and 38 of the 44 nodes succeed in all 30 runs. Failures are concentrated in three nodes, which succeed in 19, 3, and 0 of the 30 runs, respectively. When they fail, each misses only one to three fixed edge cases out of roughly 200. Thus, although these tools fail the strict pass@1 criterion, they remain correct on the overwhelming majority of their cases, which allows us to deploy them. The deployed library was produced by a single pipeline run under this configuration and contains 42 of 44 tools that pass all held-out cases.

4.3 Specification Quality as the Bottleneck

At this 94.5% ceiling, four of the 44 nodes account for almost all remaining errors. Three have edge

Configuration	pass@1
Original SOP, original data	94.5
Original SOP, augmented data	96.6
Clarified SOP, augmented data	**99.9**

Table 2: Effect of targeted specification and data improvements on the four residual nodes (Opus). Augmentation adds labeled cases for the edge-case nodes.

cases (negative denominators, null MCP values) that neither the SOP nor the training labels cover, so no failing case reaches the repair loop. The fourth has an ambiguous averaging window that the repair loop overfits away from the SOP (Appendix E). Two undeployed Opus runs confirm the cause: augmenting the training data raises pass@1 to 96.6%, and clarifying the ambiguous SOP raises it to 99.9% (Table 2). The headline 94.5% pass@1 in Section 4.2 is unaffected.

5 Agent Experiments and Deployment

The deployed alarm-triage agent uses small language models to meet production latency targets and calls the GLM-4.7-generated tool library from Section 4. We report runs with two such models (Qwen3 32B (Yang et al., 2025) and GLM-4.5-Air (Zeng et al., 2025)), while the tool-making pipeline (Section 3.1) runs offline with stronger models, paying their reasoning cost once per tool and amortizing it across every production call. We evaluate end-to-end correctness on 1,500 historical alarm scenarios with ground-truth observations, root causes, and actions, and latency from production. The evaluation alarms are separated from the fine-tuning trajectories (Section 3.2) by a temporal split and are disjoint from the cases used for tool generation. Non-deployed configurations are evaluated by offline ablation. Before a candidate agent is promoted to production, it runs in shadow: it executes on live alarms in parallel with the production agent without affecting outcomes, and discrepancies between the two are reviewed by humans. Since deployment, our tools have been invoked across over 5,000 production alarms.

5.1 Latency

Table 3 reports production p50 and p99 latency across three configurations. Replacing the sub-agent's CodeAct loop with tool calls cuts per-alarm production p50 by 42% on Qwen3 32B under the original two-tier sub-agent architecture (rows 1–2). The same comparison reduces per-alarm output tokens by 58% (14,998 to 6,225) and sub-agent turns by 45% (33.7 to 18.7). A per-component breakdown (Appendix F) shows the reduction is dominated by an 80% fall in sub-agent code-generation tokens, with main-agent tokens also falling.

Model	Configuration	p50	p99
Qwen3 32B	Sub-agent writes code	100	100
Qwen3 32B	Sub-agent calls tools	58	59
GLM-4.5-Air	Main-agent direct calls	26	29

Table 3: Production p50/p99 latency, relative to the no-tools sub-agent baseline (set to 100, lower is better). Rows 1 and 2 differ only in whether the agent uses tools. Row 3 changes both the architecture (direct calls) and the model (GLM-4.5-Air). A controlled ablation isolates the architecture-only effect, a 62% p50 reduction (Section 5.1).

	No tools	Sub-agent	Main-agent
Qwen3 32B	97.2	98.2^{**}	—
GLM-4.5-Air	98.3	99.2^{***}	99.3^{***}

Table 4: End-to-end agent accuracy (%, $N{=}1,500$). "No tools": the sub-agent writes MCP code, fine-tuned without tools. "Sub-agent" and "Main-agent" both use generated tools, the latter called directly by the main agent. Significance vs. no-tools baseline: $^{**}p < 0.01$, $^{***}p < 0.001$ (Tables 12–14).

Because tool outputs are small (a few tokens), reading them inline costs little, so the main agent can call tools without a sub-agent, removing the original rationale for the sub-agent layer (Section 3). This direct-call configuration's p50 is a further 55% below row 2, but it also runs GLM-4.5-Air, confounding the two effects. To isolate the architecture, we run an offline ablation that holds the model and inference framework fixed (GLM-4.5-Air, three seeds, 1,500 alarms): direct calls alone reduce p50 by 62% and p99 by 30% relative to the sub-agent architecture.

5.2 End-to-End Agent Evaluation

Table 4 reports end-to-end agent accuracy on the 1,500 historical alarms across the same three configurations. Tools reduce the error rate from 2.8% to 1.8% on Qwen3 32B and from 1.7% to 0.8% on GLM-4.5-Air, relative reductions of 36% and 53%. Manual inspection of trajectories on which the sub-agent and tool configurations disagree reveals two recurring sub-agent failure modes. First, it deviates from the SOP, using a similar but different metric or aggregating where the SOP specifies

a per-entity check. Second, it reaches the correct conclusion but reports it incorrectly to the main agent. Deterministic tools eliminate both.

The agent is fine-tuned on a mixture of trajectories with and without tools (Section 3.2) so that it can fall back to manual reasoning when a tool is unavailable. When the Qwen3 32B agent fine-tuned with tools is evaluated with tools disabled, its action accuracy (97.4%) and overall accuracy (96.9%) are statistically indistinguishable from the 97.4% and 97.2% obtained without tools, so mixed-trajectory fine-tuning preserves the fallback.

6 Discussion and Production Insights

Tools transfer across agents and models with a one-time generation cost. The library generated by GLM-4.7 serves both the Qwen3 32B and GLM-4.5-Air agents without regenerating any tool. Generating the full 44-node library is a one-time cost of 800K tokens (Figure 2).

Parameterized tools cover a family of deployments. A generated tool generalizes across deployments when the quantities that vary between them are tool inputs. In our case these are numeric thresholds, which differ across physical sites with alarm preferences and baseline robot error rates. Each tool resolves them from a runtime parameter store, so one library can serve multiple sites.

Logging tool outputs makes upstream data and environment inconsistencies visible. Because a tool returns the same value on the same input, its logs reveal environment issues that run-to-run variation in generated code hides. Every invocation logs the tool version, inputs, and outputs, and a monitoring agent reviews these logs in batch, surfacing drift that no single trajectory would reveal. A flagged tool is corrected by rerunning the generate-test-repair loop and promoting a new version once it passes the held-out set and manual review. Because the agent is decoupled from any specific tool version, deploying or reverting a fix is a configuration change requiring no retraining, and no rollback has been needed since deployment.

This mechanism has revealed three pre-existing inconsistencies in the upstream environment. First, one field differed in type between the offline and production MCPs. Generated code silently adapted, whereas the tool raised a reproducible exception that localized the issue. Second, a node's MCP reported cumulative events while the SOP referred to currently active ones: the tool passed offline evaluation, and the monitoring agent flagged the resulting high positive rate in production. Third, an endpoint silently changed its return format from percentages (75) to decimals (0.75), which the monitoring agent caught from the shifted value distribution.

7 Related Work

Tool use and tool-making. Early LLM tool use focused on calling fixed APIs (Schick et al., 2023; Patil et al., 2024). A parallel line gave agents an action space of executable code (Gao et al., 2023; Yao et al., 2022; Wang et al., 2024a). A more recent line of work has the agent construct its own tools. These include methods that synthesize tools from task descriptions or datasets (Cai et al., 2024; Qian et al., 2023; Yuan et al., 2024; Wang et al., 2024c) and agents that iteratively generate and refine tools through repeated execution and testing (Wang et al., 2023; Zheng et al., 2025; Wölflein et al., 2025). Operational documents can also be transformed into tools (Zwerdling et al., 2025; Mao et al., 2026; Ye et al., 2025). Recent research confirms that prompting-based agents fail to follow SOPs reliably when evaluated against the original SOP code as a verifier (Li et al., 2025; Nandi et al., 2025), with recurring failure modes including route blindness and calculation errors (Wang et al., 2025b). Recent industrial deployments include frameworks for alert triage and root cause analysis in production systems (Liu et al., 2026a; Bharadwaj and Tu, 2026). The closest peer work for SOP-to-code is Pei et al. (2025), but it is only evaluated on a benchmark. We contribute to this line of work by compiling SOPs into tools validated against labeled production cases.

Iterative refinement and data grounding. Our work is closely related to the execution-feedback refinement family (Chen et al., 2024a; Zhang et al., 2023; Zhong et al., 2024; Ridnik et al., 2024). Olausson et al. (2024) conclude that the success of self-repair depends on the feedback. Our finding that the pipeline plateaus without environmental grounding is consistent with this. The text-to-SQL literature also finds that schema alone hits a ceiling and grounding in database values is required (Li et al., 2023; Wang et al., 2025a; Cao et al., 2026). Our findings on the importance of specification quality for tool generation echo what has been reported earlier in the code and SQL generation literature (Wretblad et al., 2024; Jin et al., 2026).

8 Conclusion

We show that repeated inference-time code generation can be optimized for production LLM agents. By compiling SOP nodes into environment-grounded, validated, and versioned tools, our system moves recurring procedural work out of the latency-critical path while preserving fallback flexibility for failures. In a deployed fulfillment-center alarm-triage agent, this reduces latency and improves end-to-end accuracy.

The broader contribution is an operating pattern, a step toward self-evolving industrial agents: the agent maintains the implementation of its action space, building, testing, and repairing tools offline rather than improvising code on every request. The action space itself, defined by the SOP, and tool promotion remain human decisions. Once grounded tools are in place, the limiting factor becomes the quality of the underlying SOP specification instead of the agent's ability to rediscover schemas or rewrite boilerplate. This makes agent behavior faster, more consistent, and more auditable, suggesting a practical route to reliable low-latency LLM systems in operational workflows.

Limitations

Our agentic tool-making loop has been deployed on one application, outbound dock alarm triage. Generalization to other application domains, such as free-form runbooks, is not established. The setting nonetheless shares properties with typical agentic workflows: a written procedure that the agent must follow and that is executed against a stable backend, and latency or auditability constraints that make inference-time code generation less appealing as an alternative.

The improvement loop retains human oversight for production safety. It already automates parts of the cycle, such as drift detection and candidate tool generation, but we cannot yet guarantee that every failure would be caught without human review, so fully automating it remains open. Clarifying an underspecified SOP is inherently a human task, because the SOP encodes the author's intent for how the procedure should behave. Creating a new tool still benefits from labeled cases. Our label-free configuration trails the labeled ceiling by less than 3pp, and a fully label-free pipeline would remove the need for hand-labeled cases when adding new nodes.

Appendix

A Experimental Setup

Seeds. Per-node pass@1 results in Section 4 use 30 independent generation runs per configuration, except the SOP column in Table 1 and the augmented-data row in Table 2, which use 10. End-to-end agent accuracy in Section 5 uses 3 seeds per configuration on the same 1,500 alarm scenarios.

Inference framework. The deployed agent (Qwen3 32B and GLM-4.5-Air) runs on vLLM (Kwon et al., 2023) for both offline benchmarks and production. The open-weight tool-makers (GLM-4.7, Qwen3 235B, GLM-4.7 Flash) likewise run on vLLM. GLM-5 and the Claude ablations are served via Amazon Bedrock.

Hardware. Inference, both offline benchmarks and production, runs on a single 8×H100 instance. Fine-tuning runs on 64 H100s for Qwen3 32B and 128 H100s for GLM-4.5-Air.

Latency measurement. For competitive reasons we cannot disclose absolute production latencies. Hence, Table 3 reports figures normalized to the no-tools sub-agent baseline.

Fine-tuning. We follow the training procedure of Liu et al. (2026b). We distill GLM-4.7 (Zeng et al., 2025) into the two deployed students, Qwen3 32B and GLM-4.5-Air. A teacher trajectory is retained only when its extracted observations, root causes, and actions all match the ground-truth labels. This filter accepts approximately 92% of trajectories (93% on the with-tools slice with dropout, 4,171/4,500, and 91% on the no-tools slice, 1,358/1,500). The same filter applied to the no-tools baseline accepts 91% of trajectories (6,786/7,500), so tool availability also raises the teacher's own accuracy. Students are fine-tuned with LoRA (Hu et al., 2022) using MS-SWIFT (Zhao et al., 2024), with rank and α of 256 and learning rate 2×10^{-4} for Qwen3 32B and 32 and 1×10^{-4} for GLM-4.5-Air. Both train at batch size 64 with a 5% linear warmup and cosine decay to zero, on 64 and 128 H100 GPUs respectively. The with-tools fine-tunes use one epoch, while the no-tools baseline fine-tunes use two epochs (Liu et al., 2026b). After the training, we merge the LoRA adapters so inference carries no added overhead.

B Ground-Truth Labeling

The pipeline consumes labeled (input, verdict) cases per node (Section 3.1). Human annotations could provide these labels directly, and only a few labels are needed: pass@1 reaches 91.8% from five labeled cases per node, and the label-free variant reaches 91.6% with none (Appendices C and D). However, we lacked the annotator capacity to label all the training and evaluation cases used in our experiments, so we produced labels programmatically. Subject-matter experts provide step-by-step guidance for each node's logic. We implement this logic, verify the implementation with them, and run the resulting offline labeler over the historical cases.

The labeler is not itself deployable as a production tool. It is written against dashboard data logged into a data lake of historical snapshots, whereas production tools query live MCPs with different schemas. Historical snapshots are complete, whereas live MCP data may arrive incomplete or with gaps (nulls, missing rows, partial windows), so the tools must be robust to varying patterns of missing data. Production tools also retrieve per-site thresholds from the runtime parameter store and return the observed value, threshold, and explanation alongside the verdict. The pipeline's task is to synthesize implementations that meet this production contract and reproduce the reference verdicts. We expect the pipeline's advantage over hand-written tools to lie less in the initial implementation than in maintenance: the upstream inconsistencies in Section 6 were corrected by rerunning the pipeline, whereas hand-maintained tools would consume engineering time with every environment change, and this cost scales with the size of the tool library.

C Further Method Ablations

C.1 Impact of Repair Loop

The deployed pipeline's repair loop uses single-path reflection, where the model produces a brief diagnosis of the failures and writes a corrected tool after each test round. This is repeated for three rounds. We compare this strategy against two alternatives: no reflection (the model repairs from failures alone without a separate diagnosis step), and multi-hypothesis branching. In multi-hypothesis branching, three independent diagnoses are generated per round. Each is tried as a separate repair branch and we keep the lowest-failure branch.

Figure 3 shows that reflection and branching reach similar performance at similar total cost (556K tokens for reflection at 10 rounds, 597K for branching at 4 rounds). Branching reaches the ceiling in fewer rounds because it explores three diagnoses in parallel each round. No-reflection plateaus around 92.5% because additional rounds repeat the same diagnostic errors.

C.2 Impact of the Data-Collection Trace

The two intermediate conditions in Table 5 each prepend only a part of the trace to the tool-maker's prompt: the schema metadata observed by the sub-agent (column names, dtypes, row counts), or the sub-agent's verdict graded against the labeled answer.

Schema metadata adds $+1.8$pp and grading the sub-agent's verdict adds $+1.7$pp, whereas the full trace adds another $+1.2$pp by showing the tool-maker working code. This is a form of execution-grounded feedback that prior work has identified as a significant contributor to repair quality (Olausson et al., 2024).

Two concrete failure modes illustrate the gain.

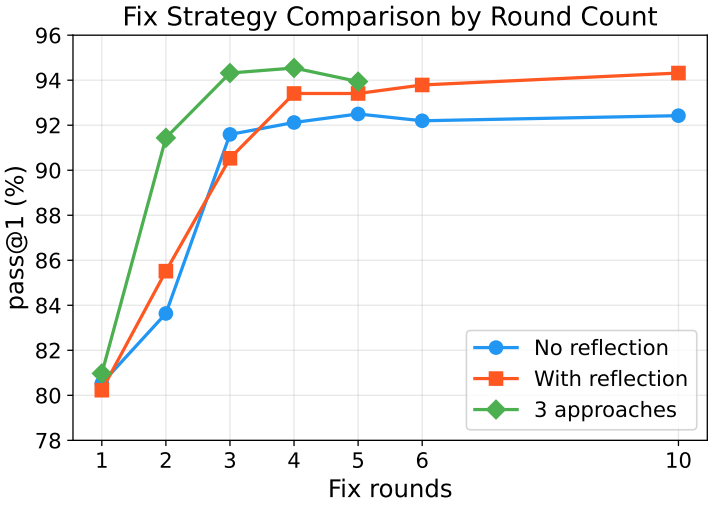

Figure 3: pass@1 across repair rounds for each repair strategy, without the data-collection trace (SOP+R, Opus). No-reflection plateaus around 92.5%, while reflection peaks at 94.3% by round 10 but underperforms no-reflection at low round counts. Multi-hypothesis branching reaches 94.3% by round 3 at roughly 3× the per-round cost.

Trace content	pass@1	Prompt content
No trace	91.6	SOP only
Metadata only	93.4	Cols, shapes, rows
Grading only	93.3	Determination, label
Full trace	94.5	Code, MCP, grading

Table 5: Trace-content ablation (Opus, three repair rounds). Each component contributes a consistent gain. Confidence intervals are in Table 10.

Including the grading corrects semantic biases that are underspecified by the SOP. One tool should return true on zero violations, and models consistently emit a `count > 0` guard. When the sub-agent makes the same error on a sampled case, the trace shows the sub-agent's verdict marked incorrect, and the tool-maker drops the guard in subsequent generations. Including the code can help prevent boundary bugs. Zero-shot tool-maker code often rounds the outcome before comparing to the threshold, whereas the sub-agent's code does not exhibit this failure mode.

C.3 Interaction Between the Repair Loop and the Trace

Table 6 reports each repair-loop strategy at three repair rounds, the deployed budget, with and without the data-collection trace. The main finding is that the trace yields the largest gain under reflection (+4.0pp). At three rounds without the trace, reflection underperforms no-reflection (90.5% vs. 91.6%), though reflection eventually catches up as shown in Appendix C.1. The mechanism is that the trace's working code and graded verdict ground the diagnosis step in concrete failure modes, so reflection no longer expends repair rounds on incorrect hypotheses. No-reflection benefits less (91.6% to 92.8%, +1.2pp) because without an explicit diagnosis step, it does not fully exploit the information in the trace. Branching is essentially unchanged (94.3% to 94.4%). With three independent diagnoses, branching explores enough alternatives to converge even without the data-collection trace. With the trace, reflection (94.5%, 395K tokens) and branching (94.4%, 496K tokens) reach the same accuracy, but reflection costs 20% fewer tokens, so the deployed pipeline uses reflection.

C.4 Data Efficiency

Each new SOP node requires labeled training cases to generate its tool. Hence, a practical pipeline must reach high pass@1 from few labels. With grounding, pass@1 reaches 91.8% at $N{=}5$ training cases per node, within 3pp of the full-set ceiling (Figure 4). Removing labels entirely is also feasible. We investigate a label-free tool-maker that uses judge-filtered pseudo-labels and multi-candidate voting instead of the labeled repair-loop test cases.

Strategy (3 rounds)	No trace	Data + grading	Δ
No reflection	91.6	92.8	+1.2
With reflection	90.5	94.5	+4.0
Three hypotheses	94.3	94.4	+0.1

Table 6: Interaction between data grounding and repair strategy (Opus, 3 rounds). pass@1 (%). Confidence intervals and t-tests are in Table 11.

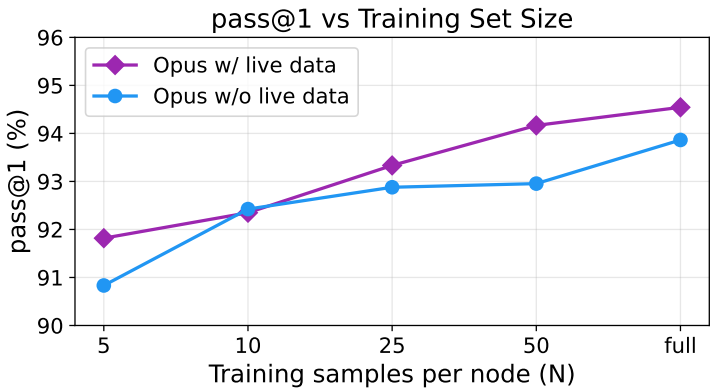

Figure 4: pass@1 vs. training-set size, with and without data grounding (Opus).

This configuration reaches 91.6% pass@1, also within 3pp of the labeled ceiling (Appendix D).

C.5 Token Scaling

We perform two follow-ups to the main-text GLM-4.7 ablation (Figure 2). First, we investigate whether GLM-4.7 repair-only catches up to the deployed configuration at higher token budgets. Second, we report the same ablation on a stronger tool-maker, Opus 4.6.

SOP+R does not scale with tokens on GLM-4.7. Table 7 compares the best SOP+R configuration we ran against a higher-budget SOP+R configuration that explores three repair branches per round. Despite spending 55% more tokens, branching reduces pass@1 from 89.3% to 87.0%. The cheapest SOP+D+R configuration (1 sample, 3-round repair) reaches 91.2% at 596K tokens, which is fewer tokens than the best SOP+R point. The deployed SOP+D+R configuration in the main text reaches 94.5% at 799K. No SOP+R configuration we ran exceeds 89.3%.

Opus 4.6 component ablation. Figure 5 repeats the Figure 2 ablation on Opus 4.6. The repair loop alone reaches 94.3% pass@1 at 556K tokens with 10 rounds. The deployed configuration reaches comparable accuracy (94.5%) at 395K tokens, a 29% token reduction. The trace helps Opus reach the ceiling at lower cost, but the ceiling is unchanged.

D Label-Free Generation

We investigate how to replace the labeled repair loop with a pipeline that combines voting and LLM judges. For each tool, K independent sub-agents each investigate one sampled unlabeled case. An LLM judge filters out traces that are not consistent with the SOP. From the surviving traces, we generate N independent candidates, and execute each candidate against the K sampled cases. We then assign a pseudo-label for each case by majority vote across the surviving traces and the N candidate outputs, and iterate a repair loop for R rounds. Each round, every candidate is executed on the K investigated cases. Candidates that agree with all current pseudo-labels and pass a code-review judge (an LLM that inspects the candidate tool's code for consistency with the SOP) are carried forward unchanged. The remaining candidates see their disagreement cases as failure feedback, write a short diagnosis, and regenerate. After all N candidates have either regenerated or been carried forward, the pseudo-labels for each case are recomputed by majority vote over the updated candidate outputs and the judge-passing sub-agent determinations. The final candidate is selected by counting how many of the K investigated cases each candidate matches the pseudo-label on. Ties are broken first by the code-review judge, then by code length.

Configuration	Tokens (K)	pass@1
SOP+R, 4 rounds	635	89.3
SOP+R, 3 rounds × 3 branches	982	87.0
SOP+D+R, 1 sample, 3 rounds	596	91.2
SOP+D+R, 3 samples, 3 rounds	799	94.5

Table 7: GLM-4.7 SOP+R configurations at higher token budgets, paired with two SOP+D+R configurations for reference. +D adds the data-collection trace; +R adds the test-repair loop. Per-seed tokens are means over 30 seeds (10 for the 3-branches row).

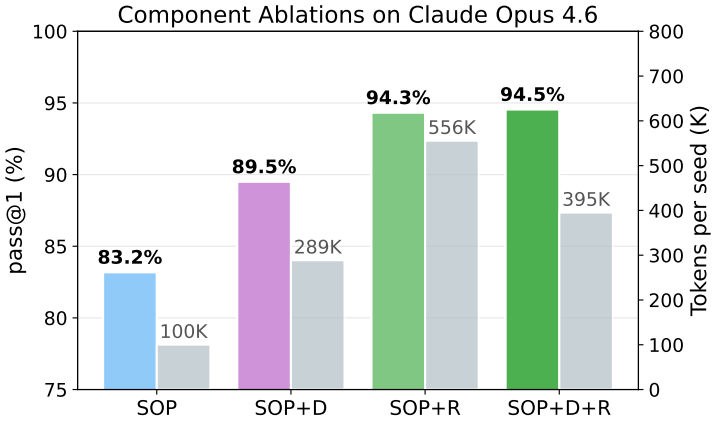

Figure 5: Per-node pass@1 (left bars) and generation cost in tokens per seed (right bars) for each ablation configuration on Claude Opus 4.6. The deployed configuration matches the repair-only ceiling within seed variance at 29% fewer tokens.

The headline configuration is GLM-4.7 as the tool-maker, Claude Sonnet 4.5 as the trace judge, and Claude Opus 4.7 as the reflector agent, with $K{=}3$, $N{=}10$, and $R{=}5$. The reflector here is Opus 4.7 due to model availability at the time of this experiment. We do not attribute the result to the newer model. This reaches 91.6% pass@1 (cf. the 94.5% labeled ceiling). The most significant component is voting across N candidates: $N{=}1$ loses 8.6pp. Other ablations (removing the repair loop, reducing to $K{=}1$, skipping the code-review judge) each cost 2.1–3.4pp. Once we clarify the specification as in Section 4.3, Opus 4.7 without labels reaches 99.1% pass@1.

E The Repair Loop Unlearns Correct Code

The fourth residual node in Section 4.3 is a precondition for a downstaffing action: downstaffing only proceeds if the collector belt is sufficiently empty. The SOP requires, for each quadrant, a 5-minute average leading up to that quadrant's most recent timestamp, with no rows older than 10 minutes included. The round-0 candidate below is mostly correct, but uses $>$ instead of the SOP's $\geq$ at the start boundary, which produces 6 test failures in round 1. The round-2 candidate replaces the 5-minute averaging logic with a simple average over the full 10-minute window, which produces fewer test failures, but no longer matches the SOP.

```
# Round 0: per-quadrant 5-minute window
# (uses > instead of the SOP's implied >=)
fresh = df[
    (df['five_minute_interval'] >= start_time) &
    (df['five_minute_interval'] <= current_time)
]
for q, col in quadrants.items():
    q_data = fresh[fresh[col].notna()]
    analysis_time = q_data['five_minute_interval'].max()
    five_min_start = max(analysis_time - timedelta(
      minutes=5), start_time)
    subset = q_data[
        (q_data['five_minute_interval'] >
      five_min_start) &
        (q_data['five_minute_interval'] <= analysis_time
      )
    ]
    avgs[q] = subset[col].mean()

# Round 2: 5-minute window collapsed to the
# full 10-minute window per quadrant
fresh = df[
    (df['five_minute_interval'] >= start_time) &
    (df['five_minute_interval'] <= current_time)
]
for q, col in quadrants.items():
    avgs[q] = fresh[col].dropna().mean()

# Both rounds: thresholding and outcome (unchanged)
north_avg = (avgs['NW'] + avgs['NE']) / 2
south_avg = (avgs['SW'] + avgs['SE']) / 2
holds = (north_avg <= north_threshold and
         south_avg <= south_threshold)
```

F Per-Component Output-Token Breakdown

Section 5 reports a 58% reduction in per-alarm output tokens with tools. Table 8 gives a breakdown by agent role (main vs. sub-agent) and by content type (reasoning, prose text, code blocks). The main contributor to the reduction is sub-agent code generation (-80%), which is expected when per-invocation code generation is replaced with tool calls. The sub-agent also needs to reason less, as calling the tool is simpler than writing the code. The main agent's tokens also fall (-16%), as reading a structured verdict is cheaper than parsing the sub-agent's free-text answer. The 20% of sub-agent code tokens that remain consist mostly of the tool calls themselves, which appear as code blocks under the CodeAct-style execution model, and the agent's programmatic to-do list.

Component	With tools	No tools	Δ
Main: thinking	1,118	1,349	-17%
Main: text	391	436	-10%
Main: code	202	259	-22%
Main total	**1,711**	**2,044**	$\mathbf{-16\%}$
Sub: thinking	2,013	4,144	-51%
Sub: text	1,035	1,358	-24%
Sub: code	1,466	7,452	-80%
Sub total	**4,514**	**12,954**	$\mathbf{-65\%}$
Total	**6,225**	**14,998**	$\mathbf{-58\%}$

Table 8: Per-trace output-token breakdown by agent role and content type, per-alarm production means (Qwen3 32B).

G Confidence Intervals and Significance Tests

Point estimates reported elsewhere in the paper are repeated here with 95% confidence intervals (mean $\pm 1.96\times$ SE over per-seed pass@1 scores) and corresponding significance tests.

Per-seed pass@1 with confidence intervals. Tables 9, 10, and 11 give the build-time pipeline results from Section 4 and Appendix C with 95% CIs and paired t-tests over 30 seeds (10 for the SOP column).

Significance of end-to-end correctness (Table 4). For each model, we run three seeds with tools and three seeds without tools, and we evaluate each seed on the same 1,500 tasks. To compute confidence intervals and p-values, we aggregate at the task level because we cannot treat the 4,500 (task, seed) pairs as independent. We average the three seed-level results per task, and we resample tasks with replacement. The reported 95% CIs are the 2.5th and 97.5th percentiles of the resampled accuracy difference (with tools minus without tools) over $n_{\text{boot}} = 5{,}000$ bootstrap iterations. The reported p-value is the fraction of bootstrap iterations in which the resampled accuracy difference was zero or had the opposite sign to the observed delta, multiplied by two for the two-sided test.

Improvements in overall accuracy are significant for both agent models in the sub-agent architecture (Tables 12 and 13) and persist when the main agent calls tools directly (Table 14). Qwen3 32B's gains come primarily from improved root-cause and action accuracy, whereas GLM-4.5-Air analyzes observations more accurately.

Significance of repair loop and trace contributions. For the two best models, GLM-4.7 and GLM-5, all three pairwise comparisons are significant ($p < 10^{-4}$). The deployed configuration (SOP+D+R) is significantly better than either single-component ablation, and both components contribute. On Qwen3 235B, SOP+D+R is not significantly better than SOP+R alone. Manual inspection of regressions shows that Qwen3 235B incorrectly infers schema details from the data-collection trace (wrong tool selection, wrong column types, missing columns), producing tools that crash or return "No data" on inputs the SOP-only configuration handles correctly. On GLM-4.7 Flash, the smaller tool-maker fails to productively use the repair loop without the trace to ground the repairs. The performance of SOP+D+R exceeds that of SOP+R and SOP+D, and neither component alone matches the gain of the combined configuration.

Significance of specification interventions. Both interventions, clarifying the SOP and augmenting the training data, are individually significant (Table 16).

	SOP	SOP+D	SOP+R	SOP+D+R
GLM-4.7	75.7 [74.5, 76.8]	84.9 [83.5, 86.2]	89.3 [87.8, 90.8]	94.5 [93.8, 95.1]
GLM-5	76.8 [75.4, 78.3]	83.4 [82.0, 84.8]	88.0 [87.0, 89.0]	93.6 [92.8, 94.3]
Qwen3 235B	74.2 [72.3, 76.2]	71.6 [70.2, 72.9]	79.9 [78.9, 80.9]	81.1 [79.9, 82.2]
GLM-4.7 Flash	56.4 [54.4, 58.5]	60.4 [59.2, 61.6]	58.7 [57.7, 59.8]	65.8 [64.3, 67.3]

Table 9: Component ablations of the deployed pipeline with 95% CIs (pass@1, %), corresponding to the point estimates in Table 1. +D adds the data-collection trace (Section 3.1); +R adds the test-repair loop. SOP+D+R is the deployed configuration. Differences between SOP+D+R and the SOP+D and SOP+R ablations are statistically significant on GLM-4.7, GLM-5, and GLM-4.7 Flash (significance tests in Table 15).

Abstract

We present PLSQLBENCH, to our knowledge the first benchmark for evaluating whether LLMs can write executable PL/SQL programs, with correctness measured through execution-based tests. Existing LLM evaluations largely target general-purpose code generation or declarative text-to-SQL, leaving procedural database programming underexplored. PLSQLBENCH contains 2,865 instances: 2,594 single-turn tasks and 271 multi-turn conversations spanning 978 turns. The benchmark combines complex schema-grounded tasks over enterprise-style Spider 2 databases, simpler schema-grounded tasks derived from Spider, and MBPP-derived procedural problems, covering varying levels of database grounding and procedural complexity. Experiments with eight LLMs reveal recurring difficulties in schema grounding, PL/SQL dialect fidelity, procedural control flow, exception handling, and cross-turn consistency. Tool-augmented LLM agents improve performance on several schema-grounded evaluations, although substantial gaps remain. These results highlight procedural database-programming capabilities not directly assessed by conventional code-generation or text-to-SQL benchmarks. Our code is available at https://github.com/oracle-samples/plsqlbench.

1 Introduction

Enterprise database development often requires procedural database programming: creating reusable database-resident programs that combine SQL with procedural constructs such as variables, control flow, loops, cursors, and error handling. In production systems, these programs validate records, enforce business rules, log failures, coordinate transactions, and run scheduled maintenance tasks. Procedural programming over databases is supported across relational and cloud data platforms through procedural SQL dialects, including GoogleSQL scripting in BigQuery, PL/pgSQL in PostgreSQL, Snowflake Scripting in Snowflake, Transact-SQL in SQL Server, and PL/SQL in Oracle Database (Google Cloud, 2026; The PostgreSQL Global Development Group, 2026; Snowflake Inc., 2026; Microsoft, 2026; Oracle, 2026a).

However, current benchmarks for AI-assisted database development remain centered on either general-purpose programming or standalone declarative SQL. General code-generation benchmarks such as HumanEval, MBPP, MBPP+, and MultiPL-E primarily evaluate programming in languages such as Python, Java, and C++ (Chen et al., 2021; Austin et al., 2021; Cassano et al., 2022; Liu et al., 2024). Text-to-SQL benchmarks such as Spider, BIRD, and Spider 2.0 focus on generating standalone declarative queries over relational schemas (Yu et al., 2018; Li et al., 2023; Lei et al., 2025). Even recent interactive database benchmarks such as Bird-Interact (Huo et al., 2025) remain centered on SQL querying rather than executable procedural database programs. As a result, the ability of AI systems to generate, modify, debug, and repair procedural database programs remains underexplored.

To study this setting concretely, we introduce PLSQLBENCH, a benchmark for evaluating LLM systems on executable procedural database programming in PL/SQL. In this work, we focus on PL/SQL, an executable procedural SQL dialect with support for stored procedures, functions, packages, cursors and exceptions. Oracle Database is currently ranked first in the DB-Engines popularity ranking of database management systems (DB-Engines, 2026), making PL/SQL a practically relevant testbed for evaluating AI systems on executable procedural database programs. Figure 1 illustrates the benchmark design through a representative workflow: a user asks a system to write a reusable procedure for reporting top-selling products, then iteratively extends it with date-range fil-

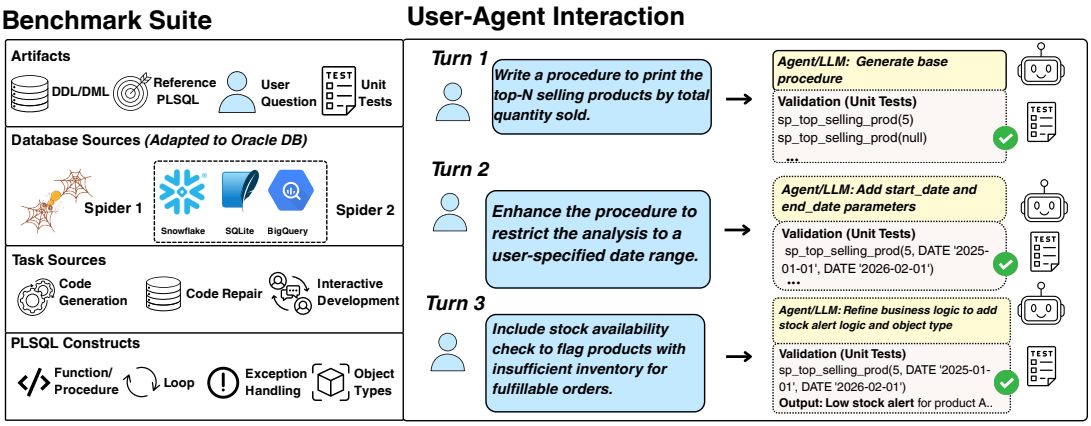

Figure 1: Representative multi-turn, schema-grounded workflow in PLSQLBENCH, illustrated with a Spider2-style database task. It contains both single-turn tasks and multi-turn interactive workflows requiring generation, modification, debugging, validation, and repair of executable PL/SQL programs. The benchmark also includes single-turn Spider-PLSQL and MBPP-derived function-generation tasks, which are not shown.

tering and low-stock alerts. PLSQLBENCH combines PL/SQL artifacts, database schemas, development tasks, and executable tests to evaluate whether LLM systems can generate, modify, debug, and repair procedural programs while preserving conversational context.

Our contributions are threefold:

1. We introduce PLSQLBENCH, to our knowledge the first benchmark specifically designed to evaluate LLM systems on executable procedural database programming in PL/SQL. It combines complex schema-grounded tasks over enterprise-style Spider 2 databases, simpler schema-grounded tasks derived from Spider, and MBPP-derived procedural problems, covering varying levels of database grounding and procedural complexity. Unlike conventional text-to-SQL benchmarks that emphasize standalone declarative queries, PLSQLBENCH evaluates executable procedural programs involving control flow, schema-grounded logic, and exception handling, in both single-turn and multi-turn development settings.

2. We design an execution-based evaluation protocol for procedural database workflows, combining strict and partial-credit metrics for single-turn tasks with dynamic multi-turn evaluation under accumulated conversation context.

3. We benchmark eight proprietary and open-weight LLMs, together with tool-augmented database agents, revealing persistent challenges in schema use, PL/SQL dialect fidelity, procedural reasoning, exception handling, and cross-turn consistency.

2 Related Work

Code-generation benchmarks. General code-generation benchmarks such as HumanEval and MBPP evaluate whether models can synthesize short programs from natural-language specifications, often using unit tests for execution-based scoring (Chen et al., 2021; Austin et al., 2021). MultiPL-E and MXEVAL extend this evaluation across multiple programming languages (Cassano et al., 2022; Athiwaratkun et al., 2023). Recent benchmarks broaden coverage to contamination-resistant evaluation, complex library use, and repository-level software engineering through LiveCodeBench, BigCodeBench, and SWE-bench (Jain et al., 2025; Zhuo et al., 2025; Jimenez et al., 2024). However, these benchmarks focus on general-purpose coding tasks, not executable database programs whose correctness depends on schemas, persistent objects, transactions, and procedural runtime behavior.

Text-to-SQL and database interaction. Text-to-SQL benchmarks have evolved from cross-domain query generation to more realistic enterprise database workflows. Spider evaluates complex schema-grounded SQL generation, while BIRD, BEAVER, and Spider 2.0 scale this setting to larger databases, enterprise-style schemas, and workflow-level tasks such as Spider2-DBT (Yu

et al., 2018; Li et al., 2023; Chen et al., 2024; Lei et al., 2025). Conversational and interactive benchmarks, including SParC, CoSQL, and BIRD-INTERACT, study context-dependent querying, clarification, and execution feedback (Yu et al., 2019b,a; Huo et al., 2025), and BIRD-CRITIC targets SQL issue debugging (Li et al., 2025). Despite this progress, these benchmarks remain centered on SQL-based tasks. PLSQLBENCH instead evaluates procedural database programming, where models must write executable PL/SQL programs that combine procedural logic with SQL over database schemas.

Enterprise workflow benchmarks. Enterprise-oriented benchmarks increasingly move beyond isolated prompts to realistic agent settings, including web-based workplace tasks, simulated software-company environments, and retrieval over heterogeneous enterprise artifacts (Boisvert et al., 2024; Xu et al., 2025; Choubey et al., 2025). These benchmarks capture enterprise interaction and information access, but they do not evaluate executable procedural database programming. PLSQLBENCH addresses this gap by evaluating read-only PL/SQL generation in both single-turn and multi-turn settings. Its tasks span complex schema-grounded scenarios over enterprise-style databases, simpler schema-grounded database tasks, and MBPP-derived procedural problems, enabling evaluation across varying levels of database grounding and procedural complexity.

3 Dataset Construction and Curation

3.1 Benchmark Composition

We construct PLSQLBENCH from three source families: Spider 2.0 Lite, Spider 1.0, and MBPP/MBPP+, forming five subsets: Spider2-ST, Spider2-MT, Spider-PLSQL, MBPP-PLSQL, and MBPP+-PLSQL. Spider2-ST and Spider2-MT contain new PL/SQL tasks curated over Oracle-normalized Spider 2.0 Lite schemas; Spider-PLSQL retains the original Spider questions and uses gold-SQL result sets for execution-based evaluation; and MBPP-PLSQL and MBPP+-PLSQL adapt short programming problems and their tests to PL/SQL. These subsets cover varying levels of database grounding, schema complexity, and procedural reasoning.

The PLSQLBENCH construction pipeline comprises source normalization and schema setup, question generation and prompt construction, reference PL/SQL curation, unit-test generation, and quality control. Dataset-specific construction and evaluation procedures are described in the corresponding appendices, with representative examples in Appendix C.3.

Overall, PLSQLBENCH contains 2,865 instances: 2,594 single-turn tasks and 271 multi-turn conversations spanning 978 turns. Table 1 summarizes the subset-level statistics. For safe and repeatable execution, benchmark tasks do not require modifying persistent data through inserts, updates, or deletes, avoiding destructive side effects across runs.

Spider2-ST and Spider2-MT are the primary enterprise-style, schema-grounded subsets, using Spider 2.0 Lite databases ported to the Oracle dialect (see Appendix A.2). Spider2-ST contains 407 development and 103 test tasks. Spider2-MT contains 208 development and 63 test complete conversations, spanning 750 and 228 turns, respectively. Detailed turn, difficulty, and reasoning-type distributions are provided in Appendix C.

Spider-PLSQL contains 970 tasks over Spider 1.0 databases ported to the Oracle dialect (Oracle Corporation, 2025). MBPP-PLSQL and MBPP+-PLSQL contain 806 and 308 tasks, respectively. These subsets adapt the original programming problems and Python unit tests into executable PL/SQL function-generation tasks. They do not require persistent database tables, although some tasks require Oracle object or collection types to represent structured inputs, providing a complementary evaluation of procedural reasoning with less database grounding than the Spider-derived subsets.

3.2 Source Normalization and Schema Setup

For schema-grounded tasks, each prompt includes the database context needed to write and execute the requested PL/SQL program, including table definitions, column names, types, and any additional objects referenced by the task. Across the benchmark, source tasks are adapted differently depending on the dataset: MBPP and MBPP+ tasks are mapped to PL/SQL functions or procedures that do not require persistent database tables, with Oracle types provided when needed; Spider 1.0 retains its original natural-language questions and Oracle schemas while prompting for PL/SQL with SQL-output-compatible formatting; and Spider 2.0 Lite tasks are curated directly over Oracle-dialect schemas prepared for PL/SQL evaluation. The

Benchmark	Inst.	#DB	#Test (Avg.)
Spider2-ST-dev	407	26	4.9
Spider2-ST-test	103	8	4.7
Spider2-MT-dev	208	26	13.7
Spider2-MT-test	63	7	13.0
Spider-PLSQL	970	20	1.0
MBPP-PLSQL†	806	–	3.0
MBPP+-PLSQL†	308	–	91.7
PLSQLBench (Overall)	**2,865**	**54**	

† MBPP-derived function-generation tasks do not require persistent database tables, although some use Oracle object or collection types.
For Spider2-MT, an instance denotes a complete conversation, and the test average counts executable tests across all turns.

Table 1: Dataset statistics for PLSQLBENCH. Inst. denotes the number of single-turn tasks or multi-turn conversations, #DB the number of distinct databases, and #Test (Avg.) the average number of executable unit tests per instance.

dataset-specific normalization and curation procedures are described in Appendices A.2, A.4, and A.5.

3.3 Spider 2.0 Question Generation and Prompt Construction

For Spider2-ST and Spider2-MT, we construct natural-language prompts for three task families: PL/SQL code generation, schema-grounded code repair, and interactive development. Code generation asks models to synthesize new PL/SQL artifacts from a specification; code repair asks them to correct faulty or incomplete code with respect to the schema and expected behavior; and interactive development uses multi-turn requests that extend, modify, debug, or repair earlier code while preserving prior context. Prompt construction follows the metadata-driven curation protocol in Appendix A.3. The system prompt used for generation can be found in Appendix D.

3.4 Execution-Based Evaluation

For Spider2-ST and Spider2-MT, each task contains an executable reference PL/SQL answer and one or more test scripts, but the expected test outputs are not stored in advance. We first execute the tests against the reference answer and capture the resulting outputs. We then execute the same tests against the generated answer and compare its outputs with the captured reference outputs. For Spider2-MT, we use rollout evaluation: reference and generated answers are executed in turn order in separate clean states, so each later turn observes the state established by earlier turns in the same sequence, without mixing generated and reference answers.

For MBPP-PLSQL and MBPP+-PLSQL, we retain the original programming problems and "translate" their Python unit tests into self-contained executable PL/SQL test blocks (using a rule-based approach). The translated tests encode the test inputs and expected outputs directly in PL/SQL and execute entirely in Oracle against the generated PL/SQL function. No Python code or canonical Python solution is executed during evaluation. The rule-based unit-test conversion and its validation are described in Appendix A.5.

For Spider-PLSQL, we execute the original Spider 1.0 gold SQL query and use its result set as the expected output. The model is instructed to emit one line per row, with field values separated by commas, so that the generated PL/SQL output can be compared directly with the gold SQL result. Thus, Spider-PLSQL does not use reference PL/SQL solutions. Appendix D provides a sample Spider-PLSQL prompt illustrating this output-format requirement. Because generated PL/SQL may emit fields in a different order from the columns selected by the gold query, we compare its output against a bounded set of permutations of the gold result-set columns.

3.5 Quality Control

We apply multi-stage quality control to Spider2-ST and Spider2-MT to ensure that each curated example is clear, schema-consistent, executable, and properly annotated. Each instance is checked for prompt-answer alignment, table and column accuracy, PL/SQL syntax and execution correctness, test-case validity, metadata consistency, and required PL/SQL feature coverage. For multi-turn examples, we additionally verify that later turns preserve prior intent while introducing realistic incremental changes. Examples with ambiguous prompts, schema mismatches, non-executable reference code, invalid tests, incomplete metadata, or inconsistent cross-turn state are revised or removed. Further details of the review pipeline and quality dimensions are provided in Appendix A.

The separate quality-control and validation procedures for MBPP-PLSQL and MBPP+-PLSQL are described in Appendix A.5.

Model	Development				Test		
	MBPP	Spider-PLSQL	Spider2-ST	Spider2-MT	MBPP+	Spider2-ST	Spider2-MT

Table 2: Main PLSQLBENCH results. All values are Mean Test Pass@1 (%). Best results in each column are shown in bold.

4 Experiments

4.1 Experimental Setting

Model and Hardware Setup. We evaluate eight proprietary and open-weight models: Gemma-4-31B, Llama-4-Maverick, Claude-Opus-4.8, Gemini-2.5-Flash-Lite, Grok-4.3, GPT-5.4-Mini, GPT-5.4, and GPT-5.6-Sol.

We also evaluate two Codex CLI-based database agents with GPT-5.4-Mini and GPT-5.6-Sol backbones using medium reasoning. The agents use the Oracle SQL and PL/SQL skills (Oracle, 2026b,c) together with a database tool to inspect the target schema, execute PL/SQL, diagnose database errors, and revise the program before returning a final answer. Direct generation does not use database interaction. Prompts, hyperparameters, and hardware details are provided in Appendices D and E.

Data Split. For Spider2-ST and Spider2-MT, we construct approximately 80/20 development and private test splits at the database level, assigning all tasks from the same database to the same partition. The resulting test sets are therefore fully held out and database-disjoint from development data. Spider-PLSQL, derived from Spider 1.0, and MBPP-PLSQL serve only as diagnostic evaluation sets and are not used for training. MBPP+-PLSQL is the stricter test evaluation for the MBPP-derived tasks: it shares problem descriptions with MBPP-PLSQL but uses expanded translated PL/SQL unit tests that are withheld from the evaluated systems and used only for scoring. Accordingly, we report MBPP+-PLSQL, Spider2-ST-test, and Spider2-MT-test separately because they differ in database grounding and interaction structure.

4.2 Evaluation Metrics

We evaluate generated PL/SQL using execution-based unit tests, following prior code-generation benchmarks (Chen et al., 2021; Austin et al., 2021). For a single-turn task with n unit tests, of which p pass, **Mean Test Pass@1** assigns the task a score of p/n, providing partial credit for partially correct programs. **Suite Pass@1** instead assigns a score of one only when all n tests pass, and zero otherwise. We first compute these scores within each task and then average across tasks, so tasks with more unit tests do not receive greater weight.

For multi-turn tasks, each turn is evaluated using the accumulated conversation history, including the model-generated PL/SQL from previous turns. A turn is considered solved only when all of its unit tests pass. **Turn Suite Pass@1** measures the average fraction of fully solved turns within a conversation, whereas **Episode Pass@1** requires every turn in the conversation to be solved. Multi-turn Mean Test Pass@1 first computes the fraction of tests passed within each conversation and then averages across conversations, giving each conversation equal weight. Formal definitions are provided in Appendix B.

4.3 Experimental Results

Table 2 reports the main PLSQLBENCH results using Mean Test Pass@1. Tables 4 and 5 report complementary strict results for the single-turn and multi-turn evaluations, respectively, across both development and test splits. We highlight the following findings.

Proprietary models lead most benchmarks, while strong open-weight models remain competitive. Table 2 shows that GPT-5.4 achieves

		Development		Test		
Backbone	**Setting**	**Spider2-ST**	**Spider2-MT**	**MBPP+**	**Spider2-ST**	**Spider2-MT**
GPT-5.4-Mini	Direct	63.14	61.29	38.96	70.90	65.94
	Codex DB Agent	**75.36**	**70.21**	**45.13**	**77.80**	**75.72**
GPT-5.6-Sol	Direct	61.77	64.69	**46.75**	71.57	66.81
	Codex DB Agent	**77.53**	**73.94**	46.10	**83.56**	**81.29**

Table 3: Direct generation versus Codex DB Agent with medium reasoning, measured by Mean Test Pass@1 (%). Bold marks the better setting per backbone.

Tool-augmented agents					
GPT-5.4-Mini + Codex DB Agent	–	–	56.51	45.13	64.08
GPT-5.6-Sol + Codex DB Agent	–	–	**60.93**	46.10	**74.76**

Table 4: Single-turn Suite Pass@1 (%). Codex DB Agent uses medium reasoning; bold denotes the best result in each column and – indicates unavailable evaluations.

the highest scores on both Spider2 variants across the development and test sets, including 79.47% on Spider2-ST and 73.19% on Spider2-MT at test time. Leadership varies across task families, however: GPT-5.6-Sol performs best on MBPP, while Claude-Opus-4.8 leads on Spider-PLSQL and MBPP+. Among the open-weight models, Gemma-4-31B outperforms Llama-4-Maverick on every reported benchmark and exceeds several proprietary models on multiple tasks. These results show that no single model dominates across all procedural database settings. Moreover, the best MBPP+ result remains below 50%, and the leading Spider2 test scores remain below 80%, indicating substantial headroom in procedural database programming.

Tool-augmented agents substantially improve database-grounded PL/SQL generation. Across Tables 3, 4, and 5, Codex DB Agent improves every Spider2 result for both backbones. On the test sets, Mean Test Pass@1 increases by 6.9–9.8 points for GPT-5.4-Mini and 12.0–14.5 points for GPT-5.6-Sol, with GPT-5.6-Sol showing consistently larger gains. The improvements also persist under strict correctness: Spider2-ST Suite Pass@1 increases by 1.9 and 9.7 points, while Spider2-MT Episode Pass@1 increases by 4.8 and 19.1 points. The largest gain is observed for GPT-5.6-Sol on multi-turn episodes, where database interaction helps maintain correctness across successive modifications. In contrast, MBPP+ changes by $+6.2$ and -0.7 points, suggesting that the benefits of database interaction are primarily concentrated in schema-grounded tasks rather than less database-grounded procedural programming.

Strict correctness remains limited, especially in multi-turn settings. Table 4 reports single-turn Suite Pass@1, which requires all unit tests for a task to pass. Among direct-generation models, Claude-Opus-4.8 leads MBPP+ at 47.73%, while GPT-5.4 leads Spider2-ST at 68.93%. Tool augmentation raises the best Spider2-ST Suite Pass@1 to 74.76% with GPT-5.6-Sol, whereas all MBPP+ Suite Pass@1 results remain below 50%. The bottleneck is larger in multi-turn settings (Table 5), where GPT-5.4 achieves 33.33% Episode Pass@1 despite reaching 59.21% Turn Suite Pass@1. The strongest tool-augmented agent improves these scores to 41.27% and 64.91%, respectively, but still completes fewer than half of the conversations without error. These gaps show that errors compound across successive modifications, making end-to-end multi-turn PL/SQL development and repair particularly challenging.

Model	Episode Pass@1		Turn Suite Pass@1	
	Dev	Test	Dev	Test
Open-weight models				
Llama-4-Maverick	17.31	15.87	36.93	39.47
Gemma-4-31B	26.44	30.16	50.53	54.39
Proprietary models				
Gemini-2.5-Flash-Lite	15.38	19.05	35.07	42.98
Grok-4.3	23.56	28.57	48.13	51.75
GPT-5.4-Mini	24.04	23.81	46.93	50.88
GPT-5.4	27.88	33.33	52.53	59.21
GPT-5.6-Sol	23.56	22.22	47.20	50.00
Claude-Opus-4.8	26.92	28.57	50.80	52.63
Tool-augmented agents				
GPT-5.4-Mini + Codex DB Agent	28.37	28.57	51.33	56.14
GPT-5.6-Sol + Codex DB Agent	**33.17**	**41.27**	**55.87**	**64.91**

Table 5: Spider2-MT strict multi-turn results (%). Episode Pass@1 requires every turn in a conversation to pass all unit tests, while Turn Suite Pass@1 measures suite-level success at the individual-turn level. Codex DB Agent uses medium reasoning; bold denotes the best result in each column.

4.4 Error Analysis

We analyze PLSQLBENCH failures across three capabilities: implementing the requested behavior, generating valid PL/SQL, and preserving the expected database interface. Appendices C.4 and C.5 describe the annotation protocol and provide representative examples.

Wrong procedure logic or output. The largest failure class (11,015; 82.5%) consists of procedures that compile or partially execute but produce incorrect results, including 9,953 output mismatches and 1,062 runtime failures. Common errors involve filters, lookup keys, joins, ordering, aggregation, formatting, and edge cases. In MBPP-style tasks, models often miss boundary cases or return incorrectly formatted values; in schema-grounded tasks, they may retrieve the wrong rows, aggregate at the wrong level, or return values in the wrong order. Thus, syntactically plausible procedures frequently fail to implement the intended semantics.

Invalid or incomplete PL/SQL artifacts. The second largest category consists of invalid or incomplete generated code, covering 1,777 failures (13.3%). This includes 943 syntax or parser failures and 834 invalid compiled objects that fail when invoked by the test harness. Typical problems include incomplete procedure bodies, unclosed SQL or PL/SQL blocks, incorrect declarations, and non-executable explanatory text. These failures prevent meaningful semantic comparison and show that reliable PL/SQL artifact construction remains challenging.

Interface, signature, or schema grounding errors. A smaller but important class of failures involves mismatches between the generated artifact and the expected database interface. These account for 566 failures (4.2%). Typical errors include missing expected entry points, wrong parameter signatures, missing package members, invalid object names, and incorrect column or identifier references. Spider2-MT accounts for 525 of these 566 failures (92.8%), suggesting that multi-turn settings make it harder for models to preserve interface contracts and schema grounding across edits.

5 Conclusion

We presented PLSQLBENCH, to our knowledge the first benchmark for evaluating LLM systems on executable procedural database programming in PL/SQL across varying levels of database grounding and procedural complexity. PLSQLBENCH combines schema-grounded and procedural tasks, execution-based tests, and single-turn and multi-turn workflows, capturing capabilities not directly measured by conventional code-generation or text-to-SQL benchmarks. Results show substantial headroom: the best direct-generation results reach 79.47% on Spider2-ST, 73.19% on Spider2-MT, and 47.73% on MBPP+ under Mean Test Pass@1. Tool augmentation improves the Spider2 results to 83.56% and 81.29%, respectively, but the strongest agent still solves only 41.27% of complete multi-turn test conversations (metric Episode Pass@1). Error analysis reveals recurring failures in procedural semantics, PL/SQL artifact construction, and interface or schema grounding. These findings motivate systems that more reliably validate generated artifacts, preserve database contracts across revisions, and reason over executable database semantics and PL/SQL dialect constraints.

Limitations

PLSQLBENCH covers only a subset of real-world database development. Production systems often involve larger schemas, legacy dependencies, performance constraints, permission boundaries, and deployment requirements that are not fully captured by the benchmark.

PLSQLBENCH currently supports only read-only PL/SQL programs. This omits important write-oriented workflows, but keeps execution-based evaluation reproducible by running each prediction against the same fixed database state. Extending the benchmark to updatable PL/SQL is challenging because DML may be interleaved with DDL, commits, rollbacks, and session-level side effects that are difficult to isolate or undo. We leave this direction to future work.

As with any execution-based benchmark, correctness is bounded by test coverage: passing all tests does not guarantee that a program is correct under all inputs.

PLSQLBENCH does not provide a large benchmark-specific training set and is intended for test-only evaluation. Thus, results should be interpreted as a measure of models' ability to generalize to its schemas, task formats, and test cases, rather than their ability to adapt through benchmark-specific tuning.

Ethical Considerations

PLSQLBENCH is intended to evaluate the reliability of language models for procedural database programming, not to encourage unsupervised deployment of model-generated database code. Because PL/SQL programs can encode business logic and interact with database state, incorrect generations may lead to wrong reports, broken interfaces, or unsafe operational behavior if used directly in production. We therefore evaluate models in isolated benchmark schemas with database-backed tests and focus on read-only tasks that avoid persistent data modifications. The benchmark is constructed from public, curated, or synthetic sources and does not include private customer data or production database contents. Some tasks and prompts are produced or converted with LLM assistance, which may introduce artifacts or distributional biases; we mitigate this through human review, schema-consistency checks, compilation and execution validation, and test-based quality control. Results should be used to understand model limitations and guide safer AI-assisted database development, with human review, access controls, and production testing remaining necessary for real deployments.

A Details on Data Curation and Quality Control

A.1 Metadata-Guided Curation

Each PL/SQL task is initialized with prepopulated metadata specifying the source dataset, database, target PL/SQL constructs, reasoning types, difficulty level, and number of turns. Developers are instructed to follow these metadata fields when writing prompts, reference PL/SQL, tests, and annotations. In particular, they must ensure that the reference answer matches the user request, compiles and runs under the provided Oracle-dialect DDL/DML, uses the required constructs, and maintains turn-to-turn consistency for multi-turn examples. Metadata fields such as `tables_required`, `columns_required`, `reasoning_types`, and `plsql_constructs` are checked for accuracy and completeness.

A.2 Spider 2 Normalization to Oracle Dialect

Spider 2.0 Lite databases were normalized to Oracle DB before PL/SQL task construction and execution. Since the source databases are adapted from heterogeneous SQL dialects, including SQLite, Snowflake, and BigQuery, we applied a normalization pipeline that converts source DDL/DML into Oracle-compatible schema and data artifacts.

Identifier normalization. We normalized table, column, and schema identifiers to satisfy Oracle naming rules. Identifiers longer than Oracle's 128-character limit were truncated. Names containing spaces, hyphens, dots, or other special characters were rewritten using underscores to produce safe, unquoted Oracle identifiers. Identifiers beginning with digits or underscores were prefixed with valid alphabetic prefixes, such as `C_` for columns and `S_` for schemas. We also prefixed identifiers that conflict with Oracle reserved words to prevent invalid-identifier and invalid-table-name errors during schema creation.

Type normalization. We converted source-specific data types to Oracle-compatible types. For example, SQLite- and MySQL-style types such as `INT`, `BIGINT`, `FLOAT`, and `DATETIME` were mapped to Oracle types such as `NUMBER(38)`, `NUMBER`, `TIMESTAMP`, `VARCHAR2`, `CLOB`, `BLOB`, `CHAR(1)`, and `DATE`.

Literal and value normalization. We normalized data literals to avoid Oracle loading and execu-

tion errors. Date and timestamp values appearing in ISO-8601 format, U.S. date format, or bare date format were converted to valid Oracle date or timestamp literals using `DATE`, `TIMESTAMP`, `TO_DATE`, or `TO_TIMESTAMP`. MySQL-style backslash-escaped quotes were rewritten using Oracle's single-quote escaping convention. MySQL-style `NULL` values were converted to Oracle `NULL`. Oversized string literals exceeding Oracle's `VARCHAR2` literal limit were split into chunks and concatenated using `TO_CLOB`. Invalid numeric values such as `Infinity`, `-Inf`, and `NaN` were replaced with `NULL` to prevent numeric conversion errors.

BigQuery-specific normalization. For Spider 2.0 Lite databases originating from BigQuery, we additionally handled values that do not have direct Oracle equivalents. In particular, BigQuery `GEOGRAPHY` values exported as coordinate tuples were detected and replaced with `NULL`, since these values cannot be loaded directly into standard Oracle numeric columns without a spatial-type conversion layer.

Overall, this normalization step ensures that Spider 2.0 Lite schemas and data can be instantiated consistently in Oracle DB and used for executable PL/SQL code generation, code repair, and interactive development tasks.

A.3 Task Curation Methodology

Each task in the benchmark is created from preassigned metadata fields that control the source, scope, and expected PL/SQL behavior. These fields specify the source dataset, target database, difficulty level, number of turns, required PL/SQL constructs, and reasoning types. Example constructs include functions, procedures, packages, cursors, exception handling, object types, dynamic SQL, and other procedural database features. Example reasoning types include data retrieval, validation, debugging, control flow, aggregation, object-oriented design, exception handling, and state-aware procedural logic.

Metadata-guided prompt construction. Annotators write natural-language task prompts that satisfy all assigned metadata fields. Prompts are required to reflect realistic PL/SQL workflows, such as reporting, auditing, validation, debugging, business-rule enforcement, and database-grounded procedural processing. Tasks may require models to reason about data-processing logic, but their target behavior does not require persistent modifications to database state. For schema-grounded tasks, prompts must align with the assigned database and use the relevant tables and columns. For MBPP-derived tasks, prompts are paired with PL/SQL-compatible inputs, outputs, and Oracle types when needed.

Task families. The benchmark contains three task families. In code generation tasks, the model generates a new PL/SQL function, procedure, package, or related program unit from a natural-language specification. In code repair tasks, the model is given incorrect, incomplete, or failing PL/SQL code and must repair it while preserving the intended behavior. In interactive development tasks, the model receives a sequence of user requests over multiple turns. Later turns may add new requirements, modify business logic, introduce debugging feedback, or ask for repairs, and the model must preserve context from earlier turns.

Difficulty assignment. Task difficulty is assigned according to schema complexity, PL/SQL construct coverage, reasoning requirements, and interaction structure. Simple tasks use limited schema context and basic PL/SQL constructs. Intermediate tasks involve richer schema access, joins, aggregation, loops, cursors or exception handling. Advanced tasks combine multiple tables, complex business logic, object types, dynamic SQL, package-level structure, exception handling, or explicit debugging and cross-object requirements. Multi-turn tasks are additionally scored by whether the interaction requires state tracking, consistent naming, incremental modification, or repair of earlier code.

Reference solutions and tests. Each task is paired with a reference PL/SQL solution and executable validation tests. Reference solutions must match the prompt exactly, compile in Oracle DB, and run against the task schema. Tests must be deterministic and runnable without modification. For multi-turn tasks, the reference solution and tests are updated consistently across turns so that later requirements do not contradict or silently break earlier behavior.

Coverage tracking. During curation, we track the source dataset, database, required tables, required columns, reasoning types, PL/SQL constructs, difficulty level, and turn count. These annotations are used to balance benchmark coverage

Quality Dimension	Check
Prompt–answer alignment	Required PL/SQL features, such as procedures, cursors, exceptions, object types, or dynamic SQL.
Metadata accuracy	Required tables/columns, difficulty, reasoning types, and PL/SQL features are correct.
Syntax and compilation	Reference PL/SQL compiles in the target Oracle environment.
Execution correctness	Program output matches the expected result.
Test-case validity	Tests run without modification and validate the reference answer.
Idiomatic PL/SQL	Code is readable, maintainable, Oracle-dialect compliant, and avoids anti-patterns.
Feature coverage	Required PL/SQL features, such as procedures, cursors, exceptions, or dynamic SQL are present.
Safety	Tasks avoid unsafe operations and unsupported SQL syntax.
Multi-turn coherence	Later turns preserve prior context while adding realistic changes.
Format validity	JSON and code fields follow the required format.
Enterprise relevance	Prompt reflects realistic PL/SQL workflows such as validation, reporting, debugging, or maintenance.

Table 6: Quality dimensions used in PLSQLBENCH review.

across schemas, task types, PL/SQL features, and reasoning categories, and they enable fine-grained model error analysis after evaluation.

A.4 Spider 1.0 Adaptation

For Spider-PLSQL, we adapt the Oracle-converted release of Spider 1.0 (Oracle Corporation, 2025), which provides the original natural-language questions together with corresponding SQL queries in Oracle syntax. We retain the original questions and use the Oracle SQL result set as the reference for execution accuracy. We instruct the model to format PL/SQL output so that it can be compared directly with the textual gold-SQL results, using `DBMS_OUTPUT.PUT_LINE` with one result row per line and comma-separated field values. These additional output-format instructions are shown in Figure 2.

A.5 MBPP and MBPP+ Python-to-PL/SQL Conversion

The Mostly Basic Programming Problems (MBPP) dataset has 974 short Python programming assignments designed to be solvable by entry-level programmers and cover programming fundamentals, such as numeric, list, and string manipulations, along with standard library functionality. (Austin et al., 2021). Each assignment requests to create a short Python function from a text description. Correctness of the implementation is verified using unit tests.

However, Liu et al. (2023) showed that a small number of unit tests can fail to detect a substantial fraction of incorrect implementations. To address this issue, they introduced HumanEval+, an enhanced version of HumanEval (Chen et al., 2021) with approximately $80\times$ more unit tests, and observed decreases in pass rates by 9.3–28.9%. Liu et al. (2024) subsequently introduced MBPP+, a subset of MBPP with a substantially expanded set of unit tests.

We took MBPP and MBPP+ and "translated" them into PL/SQL. The resulting PL/SQL functions do not require persistent database tables; the conversion focuses on function signatures, inputs, expected outputs, and any Oracle object or collection types needed to represent structured inputs. We, nevertheless, believe it still provides a useful indication of the model's PL/SQL coding abilities.

This conversion was fully rule-based and automatic:

- We ingested MBPP-style test case definitions and analyzed them with Python's AST parser to extract assertions of the form `assert candidate(<args>) == <expected>` (see Figure 3 for an example).[1]
- The converter then located each `candidate(...)` call and extracted its literal arguments and expected return value. Using these extracted test cases, it attempted to infer the function's argument types and return type. The converter rejected test cases containing non-literal or unsafe expressions, as well as tasks for which it could not infer argument types that were consistent across all unit tests.
- Using the inferred signature, the tool emitted a PL/SQL function scaffold with the exact argument and return types, along with a generated unit-test block that calls the function and asserts equality on each case.
- The converter also generated the necessary Oracle collection types (e.g., `CREATE TYPE ... AS TABLE OF ...`) once per unique element type to ensure the function can accept array-like inputs.
- We carried out an Oracle-backed replay validation of the converted benchmark records. For

[1] For MBPP+ we used a slightly different but similar in spirit approach.

```
Output requirements:
- Produce result rows only with DBMS_OUTPUT.PUT_LINE; do not use RETURN, OUT parameters, ref cursors,
↪  OPEN ... FOR, PIPE ROW, SELECT output, table writes, or any other output channel as the final
↪  answer.
- Print no headers, labels, trailers, summaries, or explanatory text.
- Print exactly one output line per result row.
- For multi-column rows, separate fields only with commas; do not use spaces, tabs, pipes, semicolons,
↪  or JSON/list formatting as delimiters.
- For single-column rows, print only the value.
- Format DATE values as YYYY-MM-DD.
- Format TIMESTAMP values as YYYY-MM-DD HH24:MI:SS.
- Print string field values exactly as text without surrounding single quotes or double quotes.
```

Figure 2: Output-format instructions for Spider-PLSQL.

```
def check(candidate):
        assert candidate([[1, 2, 3], [4, 8, 2], [1, 5, 3]], 2, 2) == 8
        assert candidate([[2, 3, 4], [5, 9, 3], [2, 6, 4]], 2, 2) == 12
        assert candidate([[3, 4, 5], [6, 10, 4], [3, 7, 5]], 2, 2) == 16
```

Figure 3: A sample MBPP-style test suite.

each converted problem, we constructed a replay PL/SQL function that maps the converted test inputs to the corresponding expected outputs and executed the generated PL/SQL unit-test block against this function. This check verifies that the generated PL/SQL test harness is itself executable and that, for every retained record, there exists at least one PL/SQL function that can satisfy the emitted tests.

In the final validation pass, 806 out of 823 candidate MBPP records and 308 out of 323 candidate MBPP+ records passed these checks.

While MXEval (Athiwaratkun et al., 2023) explored a similar high-level approach to constructing multilingual code-generation benchmarks, our work differs in several important respects. In particular, we target PL/SQL language, which is not supported by MXEval. Furthermore, we introduce a different translation pipeline and evaluation methodology. MXEval relies on a rule-based conversion framework for translating prompts and test cases, supplemented by manual expert review of selected languages to identify issues and iteratively improve the conversion procedure. In contrast, our conversion pipeline was applied as a fixed rule-based procedure, without iterative manual refinement of the translated benchmark. We then relied on automated replay-based validation, discarding cases for which a valid PL/SQL replay function could not be constructed or could not pass the translated test harness.

```
CREATE OR REPLACE FUNCTION
    count_first_elements(
  p1 IN CLOB_NTT
) RETURN NUMBER
AS
BEGIN
  IF p1 IS NULL OR p1.COUNT = 0 THEN
    RETURN 0;
  END IF;

  RETURN p1.COUNT - 1;
END;
```

Figure 4: A sample MBPP+ shortcut function generated by a model with Python unit-tests in the prompt.

To further corroborate the correctness of the Python-to-PL/SQL translation and evaluation harness, we carried out two tests. In the first test, we generated PL/SQL solutions from prompts containing the Python canonical solution and all available unit-test examples (using GPT-5.5). This experiment was intended to establish a lower bound on the number of converted problems for which the model can generate a valid PL/SQL implementation that passes the translated tests when given sufficient information about the intended computation. We did it only for MBPP+, because on MBPP the best models already achieve nearly-perfect accuracy.

Because the Python unit tests were visible, a model could potentially pass them using a shortcut rather than implementing the intended function. Figure 4 shows such an MBPP+ example. Thus,

we carried out two checks to ensure that shortcut or replay solutions are rare.

- First, we compared generated-function lengths across prompt conditions. The hinted and no-hint solutions were similar in length for MBPP+, with no evidence that exposing reference solutions or unit tests caused generations to collapse into short lookup-style implementations.
- Second, we manually reviewed paired generations produced with no hints and with the maximum available hints. We inspected 50 sampled MBPP+ records. Apart from one identified case in which the model appeared to exploit a shortcut, the inspected hinted generations appeared to be bona-fide implementations of the requested functions rather than replay tables or test-specific shortcuts.

Dataset	Prompt condition	Pass rate
MBPP+	No hints	45.1%
MBPP+	Canonical solution	56.8%
MBPP+	Canonical solution + 20% tests	68.8%
MBPP+	Canonical solution + 100% tests	87.3%

Table 7: PL/SQL pass rates for MBPP+ under different prompt conditions.

The corresponding pass rates provide the diagnostic lower-bound signal that motivated these experiments. According to Table 7, providing progressively more information about the intended Python computation substantially increased the fraction of translated problems for which the model could generate a passing PL/SQL implementation.

As a second benchmark-validation check, we compared generated PL/SQL functions with the original Python canonical solutions. For each supported record, we evaluated the generated Oracle function on the converted inputs and the Python reference solution on the corresponding Python inputs, normalized known representation differences, and compared the outputs. To maximize the number of informative comparisons, the PL/SQL functions were generated using the hinted prompts described above.

The PL/SQL outputs matched the Python-reference checks for 96.8% of output-comparable MBPP records and 89.7% of MBPP+ records. At the pass/fail level, agreement was 96.7% for MBPP and 91.6% for MBPP+, increasing to 98.7% and 96.6%, respectively, when only conclusive comparisons were considered (compatibility of a small fraction of outputs could not be verified). Note that perfect agreement is not expected because Python-to-PL/SQL comparison is itself heuristic, especially for complex or nested types whose representations do not map exactly between the two languages. We therefore use this comparison as a strong sanity check rather than as a proof of exact semantic equivalence.

Taken together, the replay validation, Python–PL/SQL behavioral cross-checks, and hinted-generation analysis collectively provide evidence that the retained MBPP and MBPP+ tasks form a reliable benchmark surface for evaluating PL/SQL coding ability with limited database grounding.

A.6 Spider 2.0 Quality Control Pipeline

Quality control combines automatic checks, human review, post-processing, and LLM-as-judge review. Automatic review is applied before submission and checks all examples for formatting, metadata completeness, prompt-reference alignment, schema references, compilation, execution, and test validity. Human reviewers then inspect examples for semantic correctness, idiomatic PL/SQL, realistic developer intent, and recurring annotation issues. A post-processing pipeline checks each delivery file for SQL compilation, test execution, reasoning-type labels, construct labels, and under- or over-claimed table and column names. Finally, an LLM-as-judge pass evaluates dimensions such as specification alignment, control-flow correctness, data handling, edge cases, and PL/SQL quality.

A.7 Quality Dimensions

Table 6 summarizes the primary quality dimensions used during review.

B Metric Definitions

All metrics are computed from execution-based unit tests using a single generated PL/SQL program per task or turn (*Pass@1*). A compilation error, runtime error, or failure to create the required database object is treated as passing zero tests for the affected task or turn. Since tasks may contain different numbers of unit tests, we compute test-level partial credit within each task or episode first, then average across tasks or episodes.

Single-turn metrics. For a single-turn task i, let n_i be the number of unit tests and let p_i be the

number of tests passed by the generated program. We define the task-level test pass rate as:

$$\mathrm{TestPass}_i = \frac{p_i}{n_i}.$$

The strict suite-level score is:

$$\mathrm{SuitePass}_i = \begin{cases} 1 & \text{if } p_i = n_i, \\ 0 & \text{otherwise.} \end{cases}$$

For a set of single-turn tasks $\mathcal{S}$, we report:

$$\mathrm{MeanTestPass@1} = \frac{1}{|\mathcal{S}|} \sum_{i \in \mathcal{S}} \mathrm{TestPass}_i,$$

$$\mathrm{SuitePass@1} = \frac{1}{|\mathcal{S}|} \sum_{i \in \mathcal{S}} \mathrm{SuitePass}_i.$$

Thus, Mean Test Pass@1 gives each task equal weight after normalizing by its number of unit tests. For example, if one task passes 2 of 3 tests and another passes 1 of 3 tests, then $\mathrm{MeanTestPass@1} = ((2/3) + (1/3))/2 = 1/2$.

Multi-turn metrics. For a multi-turn episode e, let m_e be the number of turns. At turn t, let $n_{e,t}$ be the number of unit tests and let $p_{e,t}$ be the number of tests passed. We first define whether each turn is fully solved:

$$\mathrm{TurnSolved}_{e,t} = \begin{cases} 1 & \text{if } p_{e,t} = n_{e,t}, \\ 0 & \text{otherwise.} \end{cases}$$

Episode Pass requires every turn to be fully solved:

$$\mathrm{EpisodePass}_e = \begin{cases} 1 & \text{if } \sum_{t=1}^{m_e} \mathrm{TurnSolved}_{e,t} = m_e, \\ 0 & \text{otherwise.} \end{cases}$$

Turn Suite Pass measures the fraction of turns that are fully solved:

$$\mathrm{TurnSuitePass}_e = \frac{1}{m_e} \sum_{t=1}^{m_e} \mathrm{TurnSolved}_{e,t}.$$

Mean Test Pass gives partial credit across all tests in an episode:

$$\mathrm{EpisodeTestPass}_e = \frac{\sum_{t=1}^{m_e} p_{e,t}}{\sum_{t=1}^{m_e} n_{e,t}}.$$

For a set of multi-turn episodes $\mathcal{E}$, we report:

$$\mathrm{MeanTestPass@1} = \frac{1}{|\mathcal{E}|} \sum_{e \in \mathcal{E}} \mathrm{EpisodeTestPass}_e,$$

$$\mathrm{EpisodePass@1} = \frac{1}{|\mathcal{E}|} \sum_{e \in \mathcal{E}} \mathrm{EpisodePass}_e,$$

$$\mathrm{TurnSuitePass@1} = \frac{1}{|\mathcal{E}|} \sum_{e \in \mathcal{E}} \mathrm{TurnSuitePass}_e.$$

Thus, each episode contributes equally to the final multi-turn benchmark score, even when episodes contain different numbers of unit tests. For example, for one row of data, in a three-turn episode with six total tests, if the model fully solves two turns and passes 5 of 6 tests overall, then $\mathrm{EpisodePass} = 0$, $\mathrm{TurnSuitePass} = 2/3$, and $\mathrm{EpisodeTestPass} = 5/6$.

C Dataset Statistics Details

C.1 Turn Distribution of Spider2-MT

Spider2-MT contains 271 complete multi-turn conversations spanning 978 turns across the development and test partitions. Each conversation contains three to five turns. Three-turn conversations form the largest group, with 155 conversations (57.2%), followed by 67 four-turn conversations (24.7%) and 49 five-turn conversations (18.1%). The development partition contains 208 conversations and 750 turns, while the test partition contains 63 conversations and 228 turns.

	Dev		Test		All	
Turns	Conv.	Turns	Conv.	Turns	Conv.	Turns
3	117	351	38	114	155	465
4	56	224	11	44	67	268
5	35	175	14	70	49	245
Total	208	750	63	228	271	978

Table 8: Turn-length distribution of Spider2-MT conversations in PLSQLBENCH.

C.2 Reasoning Type and Difficulty Distribution on Spider2

We further characterize the Spider2-ST and Spider2-MT splits by difficulty and reasoning type. Difficulty labels are assigned according to the procedural and database reasoning required by each task. *Simple* tasks typically involve a single retrieval or straightforward control-flow pattern over a small number of tables, with limited state or exception behavior. *Intermediate* tasks combine multiple procedural requirements, such as joins, aggregation, cursor iteration, validation logic, or structured exception handling. *Advanced* tasks require more complex PL/SQL program construction, such as packages, multi-step stateful logic, dynamic SQL, object-oriented types, bulk processing, or coordinated behavior across turns in a multi-turn conversation.

Difficulty	**ST Dev**	**ST Test**	**MT Dev**	**MT Test**
Simple	229 (56.3)	65 (63.1)	459 (61.2)	134 (58.8)
Intermediate	169 (41.5)	37 (35.9)	254 (33.9)	66 (28.9)
Advanced	9 (2.2)	1 (1.0)	37 (4.9)	28 (12.3)

Table 9: Difficulty distribution for Spider2-ST and Spider2-MT dev/test splits. Parenthesized values are percentages within each split; Spider2-MT counts are over turns.

	Spider2-ST		**Spider2-MT**	
Reasoning Type	**Dev**	**Test**	**Dev**	**Test**
Exception Handling	407 (100.0)	103 (100.0)	750 (100.0)	226 (99.1)
Data Retrieval	407 (100.0)	103 (100.0)	746 (99.5)	227 (99.6)
Control Flow	398 (97.8)	102 (99.0)	716 (95.5)	221 (96.9)
Debugging	336 (82.6)	81 (78.6)	665 (88.7)	210 (92.1)
Iterative Processing	283 (69.5)	66 (64.1)	436 (58.1)	143 (62.7)
Aggregation	162 (39.8)	38 (36.9)	330 (44.0)	116 (50.9)
Structural/Type Reasoning	111 (27.3)	27 (26.2)	268 (35.7)	89 (39.0)
Validation	108 (26.5)	26 (25.2)	183 (24.4)	57 (25.0)
Cursors	101 (24.8)	20 (19.4)	142 (18.9)	67 (29.4)
Decision Logic	60 (14.7)	10 (9.7)	107 (14.3)	40 (17.5)

Table 10: Top-10 reasoning types across Spider2 splits, ranked by MT-dev frequency. Cells report count (%); annotations are multi-label, and MT counts are turn-level.

C.3 Representative Benchmark Instances

We provide one representative instance from each major PLSQLBENCH subset. These examples illustrate the range of artifacts required by the benchmark: schema-grounded single-turn program units, MBPP-derived function generation without persistent database tables, and multi-turn procedure revision.

Spider2-ST. The Spider2-ST subset contains enterprise-style schema-grounded PL/SQL tasks. The following instance asks for a reusable function with anchored database behavior and explicit exception handling.

Spider2-ST single-turn example

Instance: `spider2_single_turn_2`
Database: `city_legislation`

Task. Design and implement a reusable PL/SQL function named `sf_get_city_population` that retrieves the population information for a given city.

Requirements.

- Function name: `sf_get_city_population`
- Parameter: `p_city_name IN VARCHAR2`
- Return value: `VARCHAR2` population text
- Match city names case-insensitively.
- Return `City name cannot be NULL` for NULL input.
- Return `City not found` for `NO_DATA_FOUND`.
- Return `Duplicate city records found` for `TOO_MANY_ROWS`.

- Return `Unexpected error occurred` for other failures.

Example tests.

```
SELECT sf_get_city_population('Atlanta')
    FROM DUAL;
SELECT sf_get_city_population(NULL) FROM
    DUAL;
```

MBPP-PLSQL. The MBPP-PLSQL subset converts MBPP programming tasks into PL/SQL function-generation tasks. These tasks do not require persistent database tables; instead, they provide the necessary PL/SQL types and unit tests.

MBPP-PLSQL function generation example

Instance: `MBPP/1`

Task. Complete the Oracle PL/SQL function `min_cost`.

Original Python specification. Write a function to find the minimum cost path to reach `(m, n)` from `(0, 0)` for the given cost matrix `cost[][]`.

Examples.

```
min_cost([[1, 2, 3], [4, 8, 2], [1, 5, 3]],
    2, 2) -> 8
min_cost([[2, 3, 4], [5, 9, 3], [2, 6, 4]],
    2, 2) -> 12
min_cost([[3, 4, 5], [6, 10, 4], [3, 7, 5]],
     2, 2) -> 16
```

Provided PL/SQL collection types.

```
CREATE TYPE NUMBER_NTT AS TABLE OF NUMBER;
CREATE TYPE NUMBER_NTT_NTT AS TABLE OF
    NUMBER_NTT;
```

Function signature.

```
CREATE OR REPLACE FUNCTION min_cost(
  p1 IN NUMBER_NTT_NTT,
  p2 IN NUMBER,
  p3 IN NUMBER
) RETURN NUMBER
```

Spider2-MT. The Spider2-MT subset evaluates whether models can revise and extend prior PL/SQL artifacts across turns. The following conversation shows a three-turn revision sequence over the same stored procedure.

Spider2-MT multi-turn example

Conversation: `plsql-multiturn-0002`
Database: `stacking`
Complexity: advanced
Source dataset: Spider 2.0 Lite
Turns: 3

Shared procedure interface.

```
SP_GET_MODEL_PERFORMANCE(
  p_model    IN VARCHAR2,
  p_analysis IN VARCHAR2
)
```

Turn 1: create the procedure.
User request. Create `SP_GET_MODEL_PERFORMANCE` to retrieve and print the latest test score for a model and analysis from `STACKING.MODEL_SCORE`.

Relevant columns.

```
STACKING.MODEL_SCORE:
  MODEL, VERSION, NAME, TEST_SCORE, STEP
```

Required behavior.

- Match `MODEL` and `NAME` case-insensitively with `LOWER(...)`.
- Select the latest row using `ORDER BY VERSION DESC, STEP DESC` and `ROWNUM = 1`.
- Print `Model: <p_model> | Score: <lv_score>`.
- Handle `NO_DATA_FOUND` with a `DBMS_OUTPUT` message.
- Handle unexpected failures with `Unexpected error occurred`.

Representative tests.

```
EXEC SP_GET_MODEL_PERFORMANCE('RFCE', '
    Diabetes');
-- Expected: Model: RFCE | Score: 1

EXEC SP_GET_MODEL_PERFORMANCE('Unknown Model
    ', 'analysis_999');
-- Expected: Record not found for Model:
    Unknown Model in Analysis: analysis_999

EXEC SP_GET_MODEL_PERFORMANCE('RFCE', 'Pain'
    );
-- Expected: Record not found for Model:
    RFCE in Analysis: Pain

EXEC SP_GET_MODEL_PERFORMANCE(NULL, NULL);
-- Expected: Record not found for Model:  in
     Analysis:
```

Turn 2: modify the decision logic.

Conversation dependency. The model must preserve the procedure name, parameters, score lookup, version ordering, and exception behavior from Turn 1, then replace the output logic with threshold-based branching.

User request. Update SP_GET_MODEL_PERFORMANCE to evaluate the retrieved score against a 0.7 threshold and print distinct success or warning messages.

Added behavior.

```
If lv_score >= 0.7:
  Success: Model <p_model> passed with score
     <lv_score>

If lv_score < 0.7:
  Warning: Model <p_model> failed to meet
     the 0.7 threshold.
```

Representative tests.

```
EXEC SP_GET_MODEL_PERFORMANCE('Stack', '
    Pumpkin Seeds');
-- Expected: Success: Model Stack passed
    with score 1

EXEC SP_GET_MODEL_PERFORMANCE('MLPC1', 'iris
    ');
-- Expected: Warning: Model MLPC1 failed to
    meet the 0.7 threshold.

EXEC SP_GET_MODEL_PERFORMANCE('Unknown Model
    ', 'analysis_999');
-- Expected: Record not found for Model:
    Unknown Model in Analysis: analysis_999

EXEC SP_GET_MODEL_PERFORMANCE(NULL, NULL);
-- Expected: Record not found for Model:  in
     Analysis:
```

Turn 3: add a join and object-oriented formatting.

Conversation dependency. The model must preserve the Turn 2 threshold behavior while extending the procedure with a join to STACKING.PROBLEM and introducing object-oriented formatting through a SQL object type and type body.

User request. Update SP_GET_MODEL_PERFORMANCE to join STACKING.MODEL_SCORE and STACKING.PROBLEM on NAME, fetch the problem TYPE, include lv_type in all outputs, and implement MODEL_PERFORMANCE_OT plus its type body.

New artifacts.

- CREATE OR REPLACE TYPE MODEL_PERFORMANCE_OT AS OBJECT (...)
- CREATE OR REPLACE TYPE BODY MODEL_PERFORMANCE_OT
- CREATE OR REPLACE PROCEDURE SP_GET_MODEL_PERFORMANCE

Additional schema elements.

```
STACKING.PROBLEM:
  NAME, TYPE
```

Added PL/SQL constructs.

```
CREATE OR REPLACE TYPE
CREATE OR REPLACE TYPE BODY
MEMBER FUNCTION
INNER JOIN
NVL
TO_CHAR
TOO_MANY_ROWS exception handling
```

Representative tests.

```
EXEC SP_GET_MODEL_PERFORMANCE('ABC', 'water
    quality');
-- Expected: Model: ABC | Analysis: water
    quality | Type: classification | Score:
    1

EXEC SP_GET_MODEL_PERFORMANCE('GPRQ', '
    concrete');
-- Expected: Threshold failed for regression
     model: GPRQ

EXEC SP_GET_MODEL_PERFORMANCE('XGBoost', '
    non_existent_analysis');
-- Expected: Record not found for Model:
    XGBoost in Analysis:
    non_existent_analysis

EXEC SP_GET_MODEL_PERFORMANCE(NULL, NULL);
-- Expected: Record not found for Model:  in
     Analysis:
```

Why this is multi-turn. Each later turn relies on the earlier procedure interface and lookup semantics, then asks the model to modify selected parts of the program while preserving previously established behavior.

C.4 Error Analysis Protocol

We perform error analysis over the execution-level evaluation logs produced by the PL/SQL harness. Each evaluated single-turn instance, and each turn in a multi-turn conversation, is treated as one analysis unit. We first exclude `reference_error` rows, which correspond to reference-solution or harness execution failures rather than model-attributable failures. For the remaining rows, we separate passed executions from model failures and assign each failure to a coarse category using the row status, Oracle diagnostics, skipped-execution reasons, and expected-versus-actual outputs.

Our taxonomy contains three major model-attributable failure categories. First, *wrong procedure logic or output* covers generated PL/SQL that compiles or executes but produces incorrect observable behavior, including incorrect procedural control flow, exception handling, state updates, output ordering, formatting required by the task, or query results. Second, *invalid or incomplete PL/SQL artifacts* covers malformed, incomplete, or non-executable program units, including syntax errors, truncated procedures, invalid compiled objects, explanatory text emitted instead of code, and generated SQL skipped by the safety checker. Third, *interface, signature, or schema grounding errors* covers failures where the generated artifact does not match the expected database-facing contract, such as missing entry points, wrong parameter signatures, missing package members, invalid object names, or incorrect table/column references.

We use Oracle diagnostics as evidence for assigning failures to these categories. For example, `PLS-00905` indicates that a generated program unit compiled into an invalid object, `PLS-00201` often indicates a missing expected entry point, `PLS-00306` indicates a wrong number or type of arguments, and `ORA-00904` or `ORA-00942` indicate schema or identifier grounding failures. Output mismatches without Oracle exceptions are inspected through expected-versus-actual outputs.

For multi-turn data, failures are analyzed at the turn level while retaining the conversation identifier. This lets us identify failures that arise after accumulated conversational context. We report aggregate counts by error category, dataset, and model. We then manually inspect representative examples for each major category. During manual inspection, we avoid examples that are primarily artifacts of brittle exact-string evaluation, such as harmless date-format differences, and instead select cases where the generated PL/SQL exhibits a clear procedural, artifact-construction, or interface-grounding failure.

C.5 Representative Error Examples

Figures 5–7 provide representative examples from the three error categories discussed in Section 4.4. We include compact execution evidence rather than full traces to show how each failure is identified from the generated artifact and unit-test outcome.

Error Category: Wrong procedure logic or output.

Example. Dataset: `Spider2-MT`; Model: `GPT-5.4`; Instance: `plsql-multiturn-0053_q01`; Tests passed: `0/3`.

Task. The user asks for a reusable reporting procedure, `sp_report_team_appearances`, that summarizes a team's lineup usage for a given season. The procedure takes `p_team_id` and `p_year` as inputs, prints up to 15 players ordered by total games, and handles `NO_DATA_FOUND` by printing:

```
No appearances found for given team and
year
```

Generated behavior. The generated procedure compiles and contains a cursor loop over aggregated appearance records. However, it only prints player rows inside the loop. If the cursor returns no rows, it raises `NO_DATA_FOUND` after the loop and jumps directly to the exception handler:

```
IF v_row_count = 0 THEN RAISE
    NO_DATA_FOUND; END IF;
```

As a result, the generated procedure prints only the exception message for empty-result cases.

Reference behavior. The reference procedure treats the routine as a report. It prints report header lines before iterating through the cursor:

```
TEAM=<team_id> YEAR=<year>

PLAYER_ID TOTAL_G TOTAL_GS
```

Only after producing these report headers does it raise `NO_DATA_FOUND` when no player rows are found. Thus, even in an empty-result case, the expected observable output includes both the report context and the exception message.

Failure signal. For the test case `p_team_id = NYA` and `p_year = 2000`, the expected output is:

```
TEAM=NYA YEAR=2000

PLAYER_ID TOTAL_G TOTAL_GS

No appearances found for given team and
year
```

The generated procedure instead outputs only:

```
No appearances found for given team and
year
```

The same pattern occurs for all three tests. No compile-time or runtime exception is recorded; the failure is an output mismatch.

Why this is an error. This is a PL/SQL-specific control-flow and side-effect failure. The model does not simply

choose the wrong SQL filter or produce a syntax error. Instead, it changes the observable behavior of the stored procedure by placing report output inside a path that is skipped when the cursor is empty. In procedural database programming, DBMS_OUTPUT calls are part of the program's external behavior, and exception handling must preserve the required side effects. This example shows that even compiling PL/SQL can fail when models mishandle the ordering of cursor iteration, output emission, and exception control flow.

Figure 5: Representative wrong-procedure-logic failure. The generated procedure compiles, but raises NO_DATA_FOUND before emitting the required report headers, so the observable DBMS_OUTPUT behavior does not match the reference.

Error Category: Invalid or incomplete PL/SQL artifact.

Example. Dataset: Spider; Model: GPT-5.4; Instance: spider_237; Tests passed: 0/1.

Task. The user asks for PL/SQL code that prints the titles of all cartoons on the TV channel whose series name is Sky Radio, with no output header. The task is solvable from the provided schema by joining TVSHOW.TV_CHANNEL with TVSHOW.CARTOON and printing the matching titles.

Failure signal. Instead of returning an executable PL/SQL block, the model outputs:

```
INVALID\_REQUEST
```

The expected output contains two titles:

```
The Rise of the Blue Beetle!

Return of the Fearsome Fangs!
```

The actual output is empty. Evaluation fails before semantic comparison because the harness attempts to execute INVALID_REQUEST as SQL:

```
ORA-00900: invalid SQL statement
```

Why this is an error. This is an artifact-construction failure. The model rejects or fails to instantiate a valid task and returns text that is not executable PL/SQL. The problem is not an incorrect filter or output row inside executable code, but the absence of a valid database artifact.

Figure 6: Representative invalid-artifact failure. The model returns INVALID_REQUEST for a solvable query, causing execution to fail before semantic comparison.

Error Category: Interface, signature, or schema grounding.

Example. Dataset: Spider2-MT-dev; Model: Gemini-2.5-Flash-Lite; Instance: plsql-multiturn-0739_q04; Tests passed: 0/4.

Task. The user asks for the package procedure PIZZA_RUNNER_UTIL.KPI_DASHBOARD, which accepts a runner ID and prints that runner's delivery KPIs.

Failure signal. The generated code defines the procedure only inside:

```
CREATE OR REPLACE PACKAGE BODY
MODERN\_DATA.PIZZA\_RUNNER\_UTIL
```

It does not create the required public package specification at the expected entry point. The harness invokes:

```
BEGIN
pizza\_runner\_util.kpi\_dashboard(1); END;
```

All four tests therefore fail before output comparison with:

```
PLS-00201: identifier
'PIZZA\_RUNNER\_UTIL.KPI\_DASHBOARD' must
be declared
```

Why this is an error. This is a contract-preservation failure. Although the generated package body contains plausible KPI logic, schema-qualifying the package and omitting its callable specification means that the required public procedure cannot be resolved by the benchmark harness.

Figure 7: Representative interface failure. The generated artifact creates only a schema-qualified package body, so the required public package procedure cannot be called.

D Prompts

D.1 Prompt for PL/SQL Code Generation

We follow the SQL-generation system-prompt structure of Liu et al. (2025) and Somayajula et al. (2026).

You are an expert database developer proficient in Oracle PL/SQL.
Goal. Generate executable Oracle PL/SQL that correctly satisfies the user request using only the provided schema context.
Background. PL/SQL is Oracle's procedural extension to SQL. It supports variables, control flow, exception handling, cursors, packages, object types, and dynamic SQL. Correct PL/SQL must be schema-grounded, Oracle-dialect compliant, and executable.
Input.

- **DDL context:** `{ddl}`
- **User request:** `{question}`

Instructions.

- Use only tables, columns, and database objects included in the DDL context.
- Prefer fully qualified names in `SCHEMA.TABLE` format when available.
- Generate Oracle-dialect PL/SQL only.
- Produce the requested artifact type, such as an anonymous block, procedure, function, package, package body, or related `CREATE OR REPLACE` statements.
- Include appropriate exception handling for data lookup or iterative processing.
- Do not include explanations, Markdown, or comments outside the code.

Output format.

- Return only executable PL/SQL text.
- Include the trailing `/` on a new line.
- If the request cannot be satisfied because required tables, columns, or database objects are missing, or because the task is logically impossible, return exactly `INVALID_REQUEST`.

Figure 8: Prompt for PL/SQL generation.

E Hyperparameters and Infrastructure

To support reproducibility, Tables 11 and 12 report the model, prompting, inference, schema, and infrastructure settings used in our PLSQLBENCH experiments.

Module	Setting	Value / Notes
Models	Evaluated models	Gemma-4-31B, Llama-4-Maverick, Claude-Opus-4.8, Gemini-2.5-Flash-Lite, Grok-4.3, GPT-5.4-Mini, GPT-5.4, and GPT-5.6-Sol.
Prompts	System prompt	Oracle PL/SQL program-unit generation prompt; see Appendix D.
	Prompt inputs	Natural-language request, schema DDL context, and task requirements.
	Multi-turn context	Each previous-turn question and generated answer is appended to the context for subsequent turns.
	Output format	Executable Oracle PL/SQL only, with a trailing `/` and no Markdown explanations.
Inference	Temperature	0.0
	Maximum output tokens	8192
	Context mode	Rollout context using previous model-generated responses as conversation history.
	Regeneration policy	Failed, empty, and retry-eligible cached generations are regenerated.

Table 11: Model, prompt, and inference settings for PLSQLBENCH.

Module	Setting	Value / Notes
Schema setup	Spider 2 DML population limit	For Spider 2, up to the first 10,000 JSONL-ordered rows per table are loaded. For the other datasets, the complete available schema data are used.
Infrastructure	Database	Oracle Autonomous Database 23ai.
	Database service	Serverless Autonomous Database.
	Execution environment	Oracle PL/SQL execution over benchmark schemas and test cases.
	Documentation	Oracle Autonomous Database documentation .

Table 12: Schema and infrastructure settings for PLSQLBENCH.

Frustratingly Easy Agentic RAG via Portable Skills: A Case Study in Customer Support

Istok Bako **Bonan Min** **Qihong (Tiffany) Shao** **Claire Cheng** **Yashar Mehdad**
Airbnb, Inc., USA

Abstract

Enterprise workflow automation typically requires retrieving a complete and accurate set of relevant information from large operational document corpora (SOPs, policy documents) given a specific scenario or request. In customer support (CS), for example, human specialists must determine the correct sequence of resolution steps for each case, a task that demands precise grounding in policy documentation. Meeting this bar in production typically requires complex document chunking, indexing, and retrieval pipelines, often layered with learned re-rankers, query rewriters, and bespoke agentic RAG infrastructure.

We report a deployment case study of a simpler alternative: a portable *skill* consisting of a natural-language instruction, lightweight tools (a retrieval API, format-checking scripts), and a corpus enriched with an LLM-generated *navigation layer*, which is a structured "Wikipedia-style" index over the underlying documents. This agentic RAG approach is straightforward to implement (1-2 engineer days), portable across capable agentic harnesses (e.g., Claude Code), and performs strongly on the challenging task of CS resolution workflow generation, achieving 99.2% procedural equivalence to human-approved ground truth and 83.3% evidence sufficiency. It is also roughly an order of magnitude slower per case than our deployed production assistant (∼90 s vs. ∼8–9 s), so we claim no latency advantage. Our claim is scoped to that setting: a mature, well-curated corpus, a latency-tolerant workflow, and human review of every case. There, the skill did the work of a complex RAG stack, and maintenance became a matter of editing text and data rather than retraining models.

1 Introduction

Customer Support (CS) aims to enhance the end-customer experience by making every interaction between customers and CS specialists smarter, faster, and more seamless. We develop AI solutions with LLM agents that empower CS specialists to work more efficiently, effectively, and intelligently.

Internal LLM agents (systems that read a work item and produce a structured artifact for a human operator) are increasingly common in enterprise settings. A representative instance is the *customer-service guidance agent*: it ingests a de-identified support case, from which identifiable customer personal information has been removed, (contact reason, internal CS-specialist notes, and the user–specialist transcript) and produces step-by-step guidance for a CS specialist, together with verbatim supporting evidence drawn from an operational knowledge base.

The default response is a production RAG stack: a fine-tuned or prompt-specialized generator, a multi-stage retrieval pipeline with learned re-rankers and query rewriters, and per-workflow heuristics. Such stacks deliver, but are expensive to build and, most painfully, hard to maintain as the knowledge base, contact-reason taxonomy, and user behavior drift: every task change implies a change to a model artifact or pipeline component.

We describe an alternative we have found effective in practice: the **skill-based paradigm**, building on the idea of portable, model-agnostic agent *skills* (Anthropic, 2025). A *skill* is a self-contained, declarative specification of an agentic task, comprising (i) a natural-language operating manual that defines the workflow, constraints, and output contract; (ii) a small set of deterministic scripts that the agent must call to read inputs, fetch corpus content, and write validated outputs; (iii) a configuration file pinning paths and parameters; and (iv) a structured corpus. The skill carries no model weights. It is executed by a general-purpose LLM agent harness (a coding-agent runtime with file access and tool use), which supplies the reasoning. Deploying the task means *authoring a skill*; maintaining it means *editing text and corpus*, not retraining.

EMNLP 2026 Industry Track, pages 2647–2661
October 24-29, 2026 ©2026 Association for Computational Linguistics

We instantiate it for CS guidance with a single retrieval tool: hybrid (BM25 + dense) search over a structured operational wiki of ~2,700 Markdown pages cross-referenced to source articles by stable identifiers, with no learned re-ranker, query rewriter, fine-tuning, or bespoke serving. The agent parses the case, runs a few queries, fetches source articles, drafts guidance, and extracts verbatim evidence, with deterministic scripts validating every step.

On **132 real CS cases** from deployed traffic, this skill produces guidance that an LLM judge rates as equivalent to human-approved ground truth on **99.2%** of cases, and supplies sufficient verbatim evidence to reconstruct the procedure on **83.3%**.

We are explicit about what is and is not new here. The *mechanism* (an instruction-conditioned agent that calls tools and a retriever) is not novel, and commercial agent frameworks already package instructions, tools, and retrieval together. Our contributions are an LLM-generated navigation layer, a deployment lens, and an evaluation, not a new agent algorithm:

- **An LLM-generated navigation layer** (our main contribution): generated automatically from the source articles, it combines three properties in one index: (i) intent indexing, where each page states what its workflow solves rather than its steps (Su et al., 2025); (ii) typed links to the underlying articles, a lightweight knowledge graph in the spirit of GraphRAG (Edge et al., 2024) but with no graph-construction step and no multi-hop traversal at query time; and (iii) merged entities that consolidate a procedure split across articles into a single page, eliminating the need for multi-hop retrieval. The novelty is not any single property but their automatic, jointly generated combination as a swappable retrieval substrate (Section 6.1).
- We frame the **skill** as a unit of *deployment and maintenance* whose load-bearing property is an *enforced trust boundary*: that every emitted snippet is a verbatim substring of its cited article is enforced by code rejecting nonconformant outputs, not by prompting, making the I/O contract auditable independently of the model, which is what distinguishes a "skill" from a system prompt with tools.
- We report a **deployment case study** in which the system is improved and maintained by editing prose and data rather than retraining, and quantify guidance quality on 132 real cases using a single hybrid retriever and no production retrieval engineering.
- A **two-metric evaluation** (procedural equivalence and evidence sufficiency) used as an *investment localizer*: the gap between them indicates whether the next improvement belongs in the agent or the corpus, and our failure inspection (Section 7) attributes the residual gap to corpus content rather than retrieval or generation failures.

2 Related Work

Our work builds on retrieval-augmented generation (Lewis et al., 2020; Karpukhin et al., 2020; Robertson and Zaragoza, 2009; Gao et al., 2024), agentic retrieval and tool use (Yao et al., 2023; Schick et al., 2023; Asai et al., 2024; Wang et al., 2024), the established split between answer and evidence quality in RAG evaluation (Es et al., 2024; Saad-Falcon et al., 2024), and LLM-as-judge evaluation (Zheng et al., 2023; Stureborg et al., 2024). The mechanism is standard; our contribution is the *deployment unit* (a script-enforced, model-agnostic skill) and the use of the procedural-equivalence/evidence-sufficiency split as an *investment localizer*, not the agent loop or the metrics themselves. Appendix A expands these connections. The navigation layer is a retrieve-over-summaries index, a shape it shares with RAPTOR's recursive abstractive summarization (Sarthi et al., 2024), document-summary indexes that search per-document summaries and dereference to the source text (Liu, 2023), and doc2query-style document expansion (Nogueira et al., 2019); Appendix A draws the comparison out, including with the closest work in this domain (Su et al., 2025). Our contribution is the deployment pattern, the maintainability evidence, and the code-enforced evidence contract, not a novel retrieval mechanism.

3 The Skill-Based Paradigm

We use *skill* to mean a portable, declarative package that fully specifies an agentic task for a general-purpose LLM agent harness, without embedding any task-specific model weights. A skill has four parts: an operating manual, a set of deterministic scripts, a configuration file that pins paths and parameters, and a structured corpus (Section 4). We describe the first two, which carry the design.

Operating manual. A natural-language document (in our case a single Markdown file, `SKILL.md`) that states the task, the step-by-step workflow, the hard constraints, and the output contract. It is read by the agent harness at the start of a session and functions as the agent's specification. Crucially it is prose, not code: it is edited by the operators who own the task, and version-controlled alongside the scripts and corpus.

Deterministic scripts. A small set of programs the agent must call rather than reason around: a case loader; a corpus reader returning article content by identifier; an output writer that validates against a schema and rejects non-conformant writes; and an evaluation runner. The scripts are the skill's *trust boundary*: they enforce in code, not by prompting, the constraint that "every emitted snippet is a verbatim substring of its cited source article", exact after Unicode-punctuation and whitespace normalization, which is the only leniency the shipped validator allows (Appendix D). During benchmarking the loader also strips the withheld ground-truth fields, an evaluation-integrity safeguard not present in deployment, where there is no reference.

Why this is a useful unit of deployment. Four properties follow: *portability* (the same skill runs unchanged on any capable harness; a model upgrade is just a harness change), *maintainability* (adapted by editing prose or data, not retraining), *auditability* (the deterministic scripts make the I/O contract enforceable independent of the model), and *separation of concerns* (retrieval, content access, generation, and validation are distinct, swappable components).

4 A Wiki-Backed Guidance Skill

4.1 Structured Corpus: Two Layers

The skill operates over an internal operational knowledge base exposed as two layers (Figure 1).

- A **wiki layer** of ~2,700 Markdown pages authored as topic-organized summaries. Each page ends with a list of stable identifiers (e.g. `art_NNN`) that point to the underlying source articles. This layer is the *navigation index*: it is what retrieval searches over.
- A **source-article layer** containing the 2,881 underlying operational articles. These are the primary truth source: all verbatim evidence the skill emits must be quoted from here, never from the wiki summaries.

This separates *finding* the right material from *quoting* authoritative content: retrieval lands on wiki pages, then dereferences their identifiers to read source articles for evidence, and the navigation layer can be re-authored independently of the underlying articles.

What makes the navigation layer novel. The navigation pages are generated automatically from the source articles by an LLM (Karpathy, 2026) and combine three properties. Concretely, a single GPT-4.1 pass over the 2,881 source articles builds the layer via an update-or-create loop against a running page index, so merged entities and typed cross-links emerge with no separate clustering step (Appendix D). First, each states *what its workflow solves*, and what it does not, so queries match by intent, not procedural wording (Su et al., 2025). Second, each records typed links to the articles it draws on: a lightweight knowledge graph in the spirit of GraphRAG (Edge et al., 2024), but with no graph-construction or multi-hop traversal. Third, where a procedure is split across articles, a *merged entity* consolidates the pieces into one page, so a need that would otherwise require multi-hop retrieval is met by a single page, moving the difficulty from the retriever into one-time, LLM-authored content.

Navigation-layer quality. Because the layer is generated rather than curated, we audit it directly. An independent, stronger model judged every one of the 3,168 navigation-to-source links (the complete link set, not a sample) against the articles they cite: approximately 96% were relevant and source-supported, while roughly 4% were dangling, irrelevant, or insufficiently supported; the flagged links were corrected in a follow-up QA pass. A structural check confirms that all 2,881 source articles are referenced by at least one navigation page, so no source content is orphaned at the identifier level (Appendix D). The layer is navigational, not authoritative: a weak link costs recall, never evidence integrity, because every emitted span is dereferenced from a cited source article and re-checked at save time (Section 7).

4.2 Retrieval Tool

The only retrieval component is a single hybrid search tool over the wiki layer, combining BM25

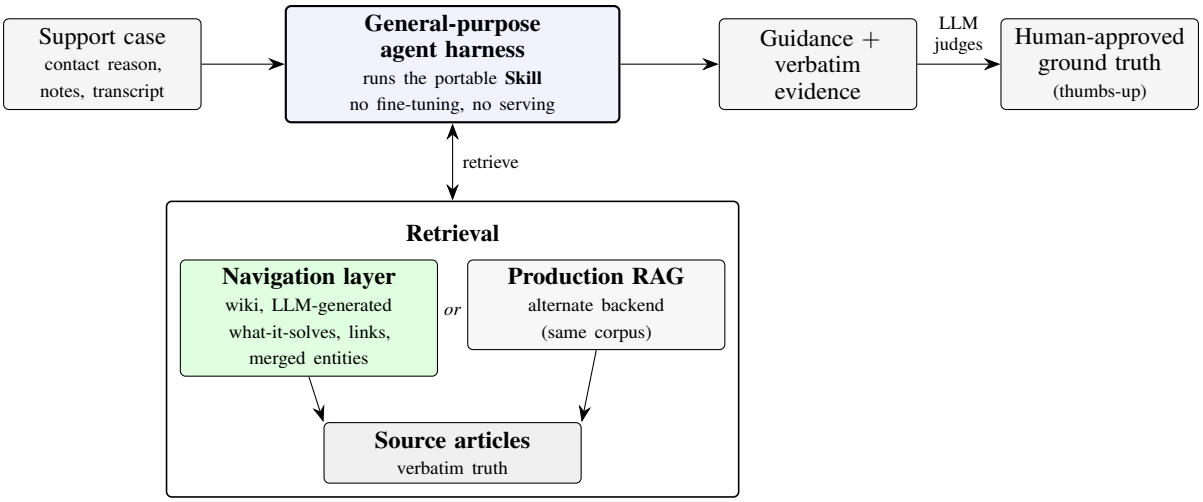

Figure 1: Overall architecture. A general-purpose agent harness runs the portable *skill* as a fixed loop. Its *Retrieval* component is swappable: the default LLM-generated wiki *navigation layer* or the organization's *production RAG* retriever, both surfacing the same *source articles* (the two conditions ran different loops; Section 6). A deterministic validator admits only verbatim snippets; outputs are scored against human-approved ground truth by GUIDANCE-MATCH and SNIPPETS-SUFFICIENT.

(Robertson and Zaragoza, 2009) with dense vector similarity (Karpukhin et al., 2020); it exposes keyword, hybrid, and direct-page fetch, with no learned re-ranker, query rewriter, or per-workflow heuristic. It is swappable: any retriever mapping a query to ranked wiki pages, and thence to source-article identifiers, satisfies the skill's contract.

4.3 Agent Loop

For each case the agent harness executes a fixed loop defined by the operating manual: it parses the case; issues three to five hybrid queries and aggregates the cited source-article identifiers; fetches the article bodies; drafts guidance; extracts up to k verbatim spans ($k = 15$); and validates and saves, with the writer re-checking every snippet against its cited article (Appendix D). Per case this is a median of roughly five queries and six fetches; the agent never sees prior outputs or the ground truth.

5 Evaluation

5.1 Cases and Inputs

We evaluate on a fixed benchmark of **132 real CS cases** sampled from deployed traffic. For each case, personally identifiable information is removed and the agent is then given the contact reason, the internal CS-specialist notes, and the user–specialist transcript. Each case carries a human-approved **ground-truth guidance document**: suggestions, steps, tips, and relevant articles a CS specialist reviewed and approved (thumbs-up) as correct. We use it as the validation reference. It is withheld from the agent at inference time and used only by the evaluation scripts.

Ground-truth provenance. The ground-truth guidance was approved (thumbs-up) by experienced CS specialists as part of the organization's existing quality-assurance process, before the agent existed; we reuse it rather than commissioning new annotations. We did not re-audit it; cases whose ground truth is itself debatable score as failures regardless of agent quality, biasing our numbers *downward*.

Why parametric knowledge cannot substitute for retrieval. The corpus is internal operational content: tool navigation, routing rules, and version-specific policy, none of it likely to be well represented in a general-purpose model's pretraining. More decisively, SNIPPETS-SUFFICIENT cannot be satisfied without retrieval *by construction*: a passing case requires verbatim substrings of internal articles, which the writer script enforces, so the agent must fetch them. The 83.3% is therefore itself evidence that retrieval is load-bearing, not a number a no-retrieval baseline could approach; Section 6.1 isolates the retrieval substrate and the layer's content organization separately.

5.2 Metrics

Each case is scored on two LLM judge metrics.

GUIDANCE-MATCH (procedural equivalence). The judge sees the agent's guidance and the ground-truth guidance and decides: *could a CS specialist use the candidate guidance to resolve this case equivalently to the ground truth?* The check tolerates paraphrase and additional adjacent procedures; it scores procedural outcome and semantic meaning, not surface text.

SNIPPETS-SUFFICIENT (evidence reconstruction). The judge sees the case, the ground-truth guidance, and the agent's verbatim snippets with their source-article identifiers, and decides: *could a CS specialist reconstruct guidance equivalent to the ground truth using only these snippets?* This is strictly harder: it requires the procedural text the ground truth cites to exist verbatim in one of the cited source articles.

Both metrics are evaluated by majority vote over **three independent judge invocations** (Zheng et al., 2023; Es et al., 2024). We observed non-trivial single-invocation disagreement, on the order of 15%, and higher on the harder SNIPPETS-SUFFICIENT metric than on GUIDANCE-MATCH (Stureborg et al., 2024). Majority-voting over three runs is what we report; we estimate residual instability at roughly ±2–3 percentage points, well below the 16-point gap between our two metrics.

Models and decoding. The guidance generator is Claude Opus 4.7, run in Claude Code with adaptive thinking (`xhigh`), provider-default temperature and top-p, and a 32,000-token output cap. The navigation-layer builder and the primary judge are both OpenAI GPT-4.1 at temperature 0, with top-p omitted and a 16,384-token completion cap; every judge decision is a majority vote over three independent calls. The dated snapshot behind the `gpt-4.1` alias was not pinned at run time and cannot be recovered retrospectively. Generator and judge are therefore from different vendors and model families, so the headline numbers are not a same-family self-evaluation. The judge sees the case, the ground-truth guidance, and the candidate guidance or its snippets, but never the navigation pages, so generated page text cannot leak into a judge decision. As supporting evidence for the judge design, an orthogonal internal effort separately calibrated a comparable GPT-4.1 judge across groundedness, completeness, policy alignment, and absence of redundancy.

Metric	Pass rate	95% CI
GUIDANCE-MATCH	99.2%	[95.8, 99.9]
SNIPPETS-SUFFICIENT	83.3%	[76.1, 88.7]

Table 1: Pass rates on the 132-case benchmark (131/132 and 110/132 cases), majority-voted over three independent judge invocations; 95% Wilson confidence intervals (Wilson, 1927).

6 Results

Table 1 reports the headline numbers: with a minimal retrieval layer and no model training, the skill reaches 99.2% procedural equivalence and 83.3% evidence sufficiency. SNIPPETS-SUFFICIENT is necessarily lower: over the *same* output it asks the strictly harder question, requiring the procedure to be reconstructable from the agent's verbatim spans, which holds only when the needed text exists quotably in the cited articles. The 16-point gap is thus cases with equivalent guidance that could not be fully grounded in quotable evidence, a shortfall we trace (Section 7) to missing corpus content, not retrieval or generation. Because GUIDANCE-MATCH is reference-based and evaluated without a no-retrieval baseline, part of the 99.2% may reflect generically-reasonable rather than case-specific guidance; we therefore treat SNIPPETS-SUFFICIENT, which retrieval provably gates (Section 5.1), as the more informative metric.

Head-to-head: two retrieval workflows. Because the retriever is meant to be swappable (Section 3), we swapped the hybrid wiki search for the organization's production RAG retrieval service over the same corpus, holding the corpus, the 132 cases, and the evaluation protocol fixed, but *not* the query and fetch budgets or the agent's behavior: the wiki condition ran the full agent loop, whereas the production-RAG condition used a scripted query–retrieve–compose pipeline, and ran the full 132-case benchmark (Table 2). Both backends reach near-ceiling procedural equivalence (99.2% vs. 96.2%), but the lightweight navigation layer is markedly stronger on the harder, retrieval-gated evidence metric (83.3% vs. 59.8%). The SNIPPETS-SUFFICIENT gap shows as non-overlapping 95% Wilson intervals (wiki $[76.1, 88.7]$ vs. production RAG $[51.3, 67.8]$); the GUIDANCE-MATCH intervals overlap ($[95.8, 99.9]$ vs. $[91.4, 98.4]$), consistent with the near-tie.

We read this as an end-to-end comparison of two operating points, not as evidence that the retrieval

Retrieval backend	Qry.	Src.	Guid.	Evid.
Wiki backend (ours)	5	6	99.2%	83.3%
Production RAG	5	10	96.2%	59.8%

Table 2: Full 132-case head-to-head with the retrieval backend swapped (same corpus, cases, and judge protocol; query and fetch budgets and agent behavior *not* held constant): GUIDANCE-MATCH and SNIPPETS-SUFFICIENT pass rates, with median retrieval queries (Qry.) and median distinct sources (Src.) per case. The two source measures are *not* directly comparable: the wiki figure counts source articles the agent fetched, whereas the production figure counts distinct sources represented in its emitted evidence, not service fetches. The production backend was the organization's deployed search service, called at its unified-search endpoint in the configuration used by the production assistant but driven by a scripted query–retrieve–compose harness rather than by the assistant itself; it retrieved before composition and so could not re-retrieve once composition had begun. Neither the service nor its index was tuned to these cases, and its internal retrieval depth, lexical/dense weighting, query rewriting, reranking, and index freshness are not exposed and cannot be characterized from the available artifacts.

representation alone explains the gap. Both backends search the *same* corpus, so the needed text is reachable by either; what differs is the workflow that surfaces it. The navigation layer states what each workflow solves and links to the exact underlying articles, and, because the layer is meant to be traversed, the agent can issue a targeted follow-up search once it identifies missing evidence. That re-retrieval is a property of the layer's design rather than a larger fixed budget: the production workflow completed retrieval before composition and so could not re-retrieve. Adding that behavior to the scripted baseline would require extending its orchestration; the skill expresses it in prose in the operating manual, within the agent-and-tool loop it already runs. Part of the evidence gap plausibly reflects this difference, but we do not claim the representation alone accounts for it, and the available artifacts cannot establish whether the gap survives at matched query and fetch effort (see Limitations).

6.1 Ablations

Because the navigation layer is the paper's main contribution, we isolate it in two ways on the same 132 cases, holding the skill, harness, model, judge protocol, and $k = 15$ fixed and varying one factor per arm (Table 3). We score on SNIPPETS-SUFFICIENT, the retrieval-gated metric;

Condition	SS	%	95% CI	Δ
Retrieval substrate (same navigation layer)				
Hybrid (default)	110/132	83.3	[76.1, 88.7]	–
BM25 only	103/132	78.0	[70.2, 84.2]	−5.3
Dense only	104/132	78.8	[71.1, 84.9]	−4.5
Content organization (same hybrid retriever)				
Full layer	110/132	83.3	[76.1, 88.7]	–
− merged entities	101/132	76.5	[68.6, 82.9]	−6.8
− intent summaries	104/132	78.8	[71.1, 84.9]	−4.5
− typed links	107/132	81.1	[73.5, 86.8]	−2.3
No layer (raw articles)	103/132	78.0	[70.2, 84.2]	−5.3

Table 3: Ablations on the same 132 cases, scored on SNIPPETS-SUFFICIENT (SS) with the skill, harness, model, judge protocol, and $k = 15$ held fixed. Pass counts are given as $k/132$ with the corresponding pass rate; both the rate and the interval are percentages. The typed-link arm weakens that field rather than removing it (Appendix C). Δ is the paired difference from the full system in percentage points; intervals are 95% Wilson. All ablated intervals overlap the full system's, so we read these as directional: exact paired McNemar tests separate no arm from the full system (Table 5).

GUIDANCE-MATCH is at ceiling and uninformative here.

Varying only the search method moves little: BM25 alone reaches 103/132 and dense alone 104/132, against 110/132 for hybrid. Varying the layer's *content organization* moves more. Removing merged-entity consolidation is the largest single drop (101/132), removing the intent summaries costs 104/132, weakening the typed links costs 107/132, and retrieving over the raw source articles with no navigation layer at all gives 103/132. Consolidation removed scores slightly *below* no layer at all, which we read as fragmentation: forcing one page per source article leaves the layer interposed between query and article while removing the property that made it worth traversing.

We report these as *directional*. Every ablated arm's Wilson interval overlaps the full system's, and exact paired McNemar tests (McNemar, 1947) over the per-case outcomes separate none of them from the full system at $n = 132$: the smallest p is 0.078, for removing merged entities, and the search-method arms are firmly null ($p = 0.21$ and $p = 0.26$). Per-arm discordant counts and p-values are in Appendix C. The pattern we take from this is narrow but useful for a practitioner: on this corpus the value lies in how the retrieval surface is organized rather than in the search algorithm applied to it, and no single property of the layer accounts for that on its own.

7 Analysis

The verbatim validator is the load-bearing guarantee. Every emitted snippet is checked at save time to be a verbatim substring of its cited article (modulo Unicode-punctuation normalization), and non-conformant writes are rejected, so the evidence contract is a property of the deterministic trust boundary (Section 3), not of model behavior. In the reported run, 99.7% of emitted snippets were byte-identical to their cited article before normalization and 100% satisfied the enforced, normalization-tolerant contract; the residual 0.3% differed only by a curly-versus-straight apostrophe. The denominator is the 1,769 snippets emitted across the 132 cases of that run; validator rejection and retry counts were not logged.

The gap is consistent with missing content, not retrieval or generation. We inspected the 22 cases that fail SNIPPETS-SUFFICIENT, a qualitative inspection by the authors, not an adjudicated annotation, so we report it as a supporting observation without per-category counts (Appendix B). The dominant pattern: the agent fetched relevant articles and its guidance is rated equivalent to ground truth, yet a specific procedural element the ground truth depends on is not present verbatim in those articles: a *corpus-content gap*, not a retrieval failure. Typically that element is an action (an internal cross-check, fallback step, tool-navigation path, or escalation target) known to experienced CS specialists but unwritten in any source article. As a concrete (synthetic) instance, a case may hinge on a fallback step, *"if the file-upload step fails, fall back to the email intake channel"*, that experienced specialists apply routinely but that is not written in the fetched articles (the guidance is equivalent, yet no verbatim snippet supports that step).

Closing gaps of this kind requires *authoring or extending source articles*, not improving retrieval, generation, or the skill; Appendix B gives synthetic illustrations of their shape.

The single guidance failure. Exactly one case fails GUIDANCE-MATCH (one of three judges accepted): a *wrong-state assumption*, where the case admits two procedural phases and the agent produced guidance for the wrong one because the input under-specified which applied. At $n = 1$ this is illustrative of a failure *mode*, not a meaningful rate; it suggests explicit case-state enumeration in the operating manual as a mitigation.

8 Discussion

Scope and generality. Maintainability is a *design property* of this factoring rather than a measured result: because no task competence is baked into model weights, adapting the task is an edit to prose or data rather than a retraining cycle. We do not claim production pipelines are obsolete: the skill says nothing about latency, cost-per-case, or robustness under load, it operates over a mature, well-curated corpus, and learned re-rankers may help more on noisier or younger corpora, where content gaps would shift the bottleneck to authoring. The evaluation design generalizes: any task with a verifiable ground-truth procedure and a citable corpus admits the split between procedural equivalence and evidence reconstruction, and the gap between them indicates whether the next investment belongs in the agent or the corpus. We reproduce the skill in Appendices D and E: operating manual, script interfaces, output schema, the validator that enforces the evidence contract, and the structure of the judge prompts, with no cases and no article text.

Maintaining the navigation layer. Because the layer is generated, it drifts as the source corpus changes. Maintenance is three steps, none of which touches a model: structural checks that surface broken or dangling references, an independent semantic audit that flags weakly supported links (Section 4), and removal or regeneration of the flagged pages after a corpus update. This is the sense in which the burden moves to text and data curation: it is a real burden, not an absent one.

Section 6.1 reports these ablations: the search method is within noise, while the layer's content organization is not.

9 Conclusion

We presented the skill-based paradigm for deploying internal LLM agents: a declarative, model-agnostic package of operating manual, deterministic scripts, configuration, and corpus, run by a general-purpose harness with no task-specific training. A wiki-backed instantiation for CS guidance, with a single hybrid retriever and no production retrieval engineering, reaches 99.2% guidance equivalence and 83.3% evidence sufficiency on 132 real cases. Maintaining it by editing text and data rather than retraining is our practical deployment lesson for mature operational corpora.

Backend	Search	Generation	Total
Wiki backend (ours)	~1 s	~89 s	~90 s
Production RAG	~5 s	~69 s	~74 s
Production assistant	~3–4 s	~4–5 s	~8–9 s

Table 4: Per-case latency (medians): retrieval/search vs. the multi-step generation/agentic loop. Search is negligible for the skill (served warm); the wiki backend runs more navigation steps during generation than the production-RAG backend. The deployed production assistant's ~8–9 s splits between retrieval (~3–4 s) and generation (~4–5 s).

Limitations

Scope of the study. Our study is a focused single-deployment case study, and we state results within that scope. The benchmark is 132 real cases over one mature, well-curated corpus; we expect the recipe to transfer best to similarly mature corpora, while younger or sparser ones may benefit more from additional retrieval engineering. All evidence here comes from one internal benchmark on one corpus; we make no cross-domain superiority claim, and a faithful port to a public procedural-support benchmark remains future work.

Evaluation. Quality is scored by LLM judges with majority voting over three runs (estimated residual uncertainty $\pm$2–3 points); human re-scoring and a second judge family are natural complements we leave to future work. The head-to-head compares two end-to-end operating points rather than two retrievers at matched effort: query and fetch budgets were not held constant, and the artifacts we retain cannot establish whether the evidence gap survives at matched navigation effort.

Scope of the contribution. Our claims concern the skill as a deployment unit rather than retriever internals: we show that a single hybrid retriever suffices and that retrieval is load-bearing (Section 7). Section 6.1 isolates the retrieval substrate and the layer's content organization, but at $n = 132$ those differences are directional rather than significant, and each property-level claim is limited to the specific operationalization we ablated; and because we optimize for maintainability rather than latency (Table 4), throughput-sensitive deployments would add standard batching, caching, or parallel fetch.

Ethical Considerations

The 132 cases involve real customer-support interactions and are subject to the organization's data-handling policies. No real case content, customer data, or personally identifying information is reproduced anywhere in this paper. The example strings in Section 7 are *synthetic*: they were written by the authors purely to illustrate the *shape* of a failure category, and do not reproduce any real procedure, article, customer utterance, or internal entity name. Quantitative results are reported only as aggregate pass rates and counts. The skill runs against internal infrastructure and does not transmit customer data to external systems. Its outputs are intended to assist human CS specialists, not to act autonomously on customer accounts; deploying such a skill in a fully autonomous setting would require safeguards beyond those discussed here.

A Extended Related Work

Retrieval-augmented generation. RAG (Lewis et al., 2020) with dense retrieval (Karpukhin et al., 2020) and BM25 (Robertson and Zaragoza, 2009) is standard practice; production stacks add learned re-rankers and query expansion (Gao et al., 2024). We instead use a single hybrid retriever as one swappable component, omitting that machinery to isolate what the corpus and a general-purpose harness deliver on their own.

Retrieve-over-summaries indexes. Retrieving over generated summaries and dereferencing to source text is an established pattern: RAPTOR clusters and recursively summarizes chunks into a tree and retrieves at a chosen level of abstraction (Sarthi et al., 2024); document-summary indexes retrieve documents by summary relevance and then return their underlying nodes (Liu, 2023); doc2query expands documents with predicted queries so that lexical retrieval matches how users ask (Nogueira et al., 2019). Our navigation layer differs in what the summary layer is *for*. It is authored to be navigated rather than to be a compressed substitute for the source: each page states what its workflow solves and what it does not, typed links name the articles it draws on, and a procedure split across articles is consolidated onto one page. Crucially, no summary is ever quoted: all verbatim evidence is dereferenced from the cited source articles and checked in code (Section 3), so the summary layer carries navigation risk but never evidence risk.

Knowledge representation for customer support. Closest to our setting, Su et al. (2025) restructure a customer-support knowledge base into an LLM-friendly representation and motivate indexing by what a workflow solves, which is the property our intent summaries adopt. We differ in two ways that matter for deployment rather than for retrieval quality: the source articles remain the sole evidence

authority, so the generated layer can be regenerated at will without touching what may be quoted; and the resulting contract is enforced by a validator rather than requested in a prompt, which is what makes the boundary auditable independently of the model.

Agentic retrieval and tool use. ReAct (Yao et al., 2023), tool-use frameworks (Schick et al., 2023), and self-reflective retrieval (Asai et al., 2024) interleave reasoning, retrieval, and tool calls (Wang et al., 2024). Our loop is a deliberately plain instance; the contribution is the *deployment* unit, not the loop: a declarative, model-agnostic skill whose hard constraints are script-enforced (Section 3).

RAG evaluation. Separating answer quality from evidence quality is established (Es et al., 2024; Saad-Falcon et al., 2024). Our two-metric design instantiates this split; the contribution is its use as an *investment localizer*, reading the gap to decide whether the next effort belongs in the agent or the corpus, with a failure analysis attributing the gap.

LLM-as-judge evaluation. We evaluate with LLM judges (Zheng et al., 2023), mitigating their variance (Stureborg et al., 2024) by majority-voting over three independent invocations.

B Failure Inspection

The inspection underlying Section 7 was qualitative. We examined the 22 cases failing SNIPPETS-SUFFICIENT and, for each, checked whether the articles the ground truth references had been fetched by the agent and whether the procedural element the ground truth depends on appeared verbatim in those articles. The inspection was performed by the authors, used only article identifiers and the presence or absence of verbatim spans, and examined no customer data.

We deliberately do not report an adjudicated per-category count: the inspection was not a multi-annotator annotation with an agreement statistic, and we present it only as a qualitative indication of where the residual gap lies.

A formal, independently labeled failure taxonomy is future work. All illustrative examples in this paper are synthetic (see Ethical Considerations); no real corpus or case strings are reproduced.

Synthetic illustrations of the shape of these gaps (no real procedure, article, or data): "re-confirm the adjustment amount against the counterparty's written agreement before issuing"; "if the file-upload step fails, fall back to the email intake channel"; "open the internal billing console, locate the transaction, copy its reference ID"; "route to the specialist queue when a safety flag is present."

C Ablation Details

All arms in Table 3 run over the same 132 cases with the skill, harness, generator, judge prompts, judge protocol (three-call majority vote), and $k = 15$ fixed; exactly one factor changes per arm. The retrieval-substrate arms reuse the navigation layer unchanged and vary only the search method. The content-organization arms rebuild the layer with one property removed: merged entities disabled by forcing one page per source article, intent summaries replaced by raw procedural text in the indexed field, and the typed links weakened rather than dropped: every page-to-source edge is preserved, but source identifiers are moved out of their inline and section-local positions into a single deduplicated page-level pool, so that arm tests local claim-to-source association rather than the presence of links. Because all arms share the same cases, the reported Δ is the mean paired difference from the full system.

Paired tests. Because each arm is scored on the same cases as the full system, the informative comparison is the discordance: how many cases pass under the full system but fail under the arm (b), and how many do the reverse (c). Table 5 reports both, with two-sided exact McNemar p-values (McNemar, 1947). We use the exact binomial form on the discordant pairs rather than the asymptotic χ^2 approximation, which is the appropriate choice at discordance counts of 19–23. No arm separates from the full system at the 0.05 level. Removing merged entities is the closest ($b = 15$, $c = 6$, $p = 0.078$), and the two search-method arms are furthest from significance despite discordance of 20–23 cases, which is what a genuine null looks like: the arms disagree on individual cases in both directions in roughly equal measure. We therefore report the deltas as directional and make no property-level causal claim.

Evidence-coverage correlate. As an uncontrolled observation, cases issuing a refinement query (for a sub-topic uncovered by the first round) or an entity-triggered query tended to have higher snippet coverage than single-query cases. We report this as a hypothesis, not a measured effect;

Arm	b	c	Exact p
BM25 only	15	8	0.210
Dense only	13	7	0.263
− intent summaries	14	8	0.286
− typed links	11	8	0.648
− merged entities	15	6	0.078
No layer	14	7	0.189

Table 5: Paired discordance against the full system on SNIPPETS-SUFFICIENT: b is cases the full system passes and the arm fails, c the reverse. p is the two-sided exact McNemar test. Each arm's net delta is $b - c$, matching Table 3.

notably, such behaviors are prose edits to the operating manual, needing no model or retriever change.

D Skill Scaffold

For reproducibility we reproduce the skill in this appendix and the next, with no cases, no article text, and no organization-specific names: the operating manual (`SKILL.md`); the four deterministic script interfaces below, with the output schema (`scripts/INTERFACES.md`); a runnable, data-free validator that enforces the schema and the verbatim-evidence constraint (`scripts/validate_output.py`); and a structural description of the evaluation-judge prompts, covering guidance correctness and evidence sufficiency. The validator takes an output file and a mapping from article identifier to article body, so it runs on any corpus.

Navigation-layer build. The navigation layer is generated by an incremental, index-aware ingestion loop driven by a single general-purpose LLM (GPT-4.1), one pass per source article. For each of the 2,881 articles the builder prompts the model with (i) a fixed page schema, (ii) the current `index.md` (the running list of pages already created, which serves as the wiki's memory), and (iii) the article text (id, title, source, content). The model identifies the article's topics, entities, and procedures; updates an existing page when topics overlap or creates a new one otherwise; emits the full Markdown page per the schema; and updates `index.md` and a `log.md`. Merged entities and the typed cross-links are emergent from this update-or-create loop rather than a separate clustering pass, and the loop retries failed articles until all are covered: fully automatic, with no human in the loop.

Navigation-layer audit. To check the generated layer we extracted every navigation-to-source link (3,168, the complete set rather than a sample) and asked an independent, stronger model than the builder to judge each link against the article it cites, scoring whether the cited article supports the procedure the linking page attributes to it. Approximately 96% passed; the roughly 4% that did not were dangling, irrelevant, or insufficiently supported, and are removed or regenerated as part of maintenance (Section 8). Separately, a structural pass confirmed that every one of the 2,881 source articles is referenced by at least one navigation page.

Operating manual (`SKILL.md`). A prose specification read at session start, stating the task; the six-step workflow (parse, retrieve, fetch, draft, extract evidence, validate-and-save; Section 4); the hard constraints (every emitted snippet must be a verbatim substring of its cited source article); and the output contract (a guidance document plus up to k source-tagged verbatim snippets).

Script interfaces.

- `load_case(id)` returns the case fields (contact reason, CS-specialist notes, transcript) and strips any reference/ground-truth fields.
- `retrieve(query)` returns ranked navigation pages and the source-article identifiers they cite.
- `get_article(id)` returns the raw source-article body.
- `save_output(guidance, snippets)` validates and writes the output, or rejects it (below).

Verbatim validator (enforced at save). For each emitted snippet s citing article a: normalize Unicode punctuation in s and in `get_article`(a), and accept only if s is a substring of a; any non-conformant snippet rejects the entire write. This pins emitted evidence to verbatim source text independent of the model.

Judge prompts. Two binary LLM-judge prompts, each majority-voted over three runs; Appendix E describes their structure. GUIDANCE-MATCH: given the candidate guidance and the ground truth, decide whether a CS specialist could use the candidate to resolve the case equivalently to the ground truth (tolerating paraphrase and

additional adjacent procedures). SNIPPETS-SUFFICIENT: given the case, the ground truth, and the candidate's verbatim snippets with source identifiers, decide whether a CS specialist could reconstruct guidance equivalent to the ground truth from those snippets alone.

E Skill Code and Judge Prompts

This appendix reproduces the skill in full: the operating manual, the tool interfaces and output schema, the validator that enforces the evidence contract, and the judge prompts used for evaluation. Everything needed to reimplement the method on another corpus is here; nothing is deferred to an external artifact. No cases, article text, or organization-specific names appear anywhere in it.

# Skill-based CS-guidance agent --
    reproducible scaffold (no data)

This is an anonymized scaffold for the
    skill-based customer-support
    guidance
agent described in the paper. It
    contains the **operating manual**,
    the
**deterministic script interfaces**,
    the **output validator** (the
    enforced
"trust boundary"), and the **LLM-judge
    prompts** -- but **no data, no
    corpus, and
no organization-specific names**. It is
    sufficient to reproduce the
    *method* on
any structured knowledge corpus.

## Contents
- `SKILL.md` -- the agent operating
    manual (workflow + constraints +
    output contract).
- `scripts/INTERFACES.md` -- the four
    deterministic script interfaces the
    agent calls.
- `scripts/validate_output.py` -- the
    output validator: schema +
    verbatim-evidence
  enforcement (the trust boundary).
    Runnable, data-free.
- `judge_prompts.md` -- the two
    evaluation-judge prompts (guidance
    correctness;
  evidence sufficiency) and the
    pairwise-preference prompt.

## The idea in one paragraph
A general-purpose LLM coding/agent
    harness is given (1) a
    natural-language
operating manual, (2) a few
    deterministic scripts that load
    inputs, search a
structured knowledge corpus, fetch
    source content, and write
    *validated*
outputs, and (3) the corpus itself
    organized as a navigation layer
    over source
articles. The agent composes
    step-by-step guidance plus verbatim
    supporting
snippets. A validator script enforces
    hard constraints (every snippet is a
verbatim substring of its cited source;
    ground truth is never read) -- so
correctness of the output contract does
    not depend on model goodwill.
```

E.2 `SKILL.md`: operating manual

```
---
name: cs-guidance-agent
description: Produce step-by-step
    customer-support guidance for a
    case, with verbatim supporting
    evidence drawn from a structured
    knowledge corpus, using a
    general-purpose agent harness (no
    bespoke retrieval pipeline). Then
    evaluate.
---

# CS Guidance Agent (anonymized
    operating manual)

Produce, for each support case, (a)
    step-by-step guidance for a human
    agent and
(b) up to 15 verbatim supporting
    snippets quoted from source
    articles. The
knowledge base has two layers:

- **Navigation layer** -- a structured,
    LLM-authored "wiki" of topic pages.
    Each
  page (i) states *what the underlying
    workflow solves* (not just its
    steps),
  (ii) lists the **source articles** it
    relates to, and (iii) may be a
    **merged
  entity** synthesizing several
    articles. Retrieval searches this
    layer; it is
  what makes "find the right material"
    easy.
- **Content layer** -- the underlying
    source articles. All verbatim
    snippets must
  be quoted from here, never from the
    navigation pages.

## Per-case workflow (identical
    regardless of retrieval backend)
1. **Load** the case via `load_case.py`
    (ground truth is stripped -- never
    seek it).
2. **Retrieve** candidates: run 3-5
    `retrieve.py "<query>" --case <id>`
    queries
```

```
   covering the primary workflow,
    sub-topics, and named entities.
3. **Fetch** full bodies of promising
    candidates via `get_article.py`.
4. **Compose** concise, case-specific
    step-by-step guidance.
5. **Extract** 10-14 snippets, each
    copied **verbatim** from a fetched
    article,
   tagged with its `source_article` id
    and a one-line `why`.
6. **Save** via `save_output.py`
    (validates schema + verbatim
    evidence; rejects
   non-conformant output).

## Hard constraints
- Never read the dataset directly; only
    `load_case.py`.
- Snippet text must be a verbatim
    substring of its cited article body.
- ≤ 15 snippets. Do not fabricate
    citations.
- Do not template guidance; compose per
    case from that case's retrieved
    content.

## Configuration
A single config pins corpus paths,
    output locations, the retrieval
    backend, and
parameters. Swapping the backend
    (navigation-layer vs
    direct-article) changes
only `retrieve.py`; the rest of the
    workflow is unchanged.
```

E.3 scripts/INTERFACES.md: tool contract and output schema

```
# Deterministic script interfaces (the
    skill's tool contract)

The agent calls exactly four
    deterministic scripts. They are the
    skill's trust
boundary and audit surface -- the agent
    reasons, but I/O constraints are
    enforced
by code.

## `load_case.py --idx N` (or `--id
    <case_id>`)
Loads one case, **stripping all
    ground-truth fields** before the
    agent sees it
(guidance, labels, timestamps). Emits
    only: `case_id`, `contact_reason`,
`contact_reason_path`, `case_notes`,
    `case_messages`, `n_messages`,
    `n_notes`.
→ Guarantees the agent can never read
    the answer it's evaluated against.

## `retrieve.py "<query>" [-n K]
    [--case <id>]`
The **swappable retrieval layer**.
    Returns a ranked list of candidate
    source
article IDs (+ short preview),
    regardless of backend. Two
    reference backends:
- **navigation layer** (recommended):
    hybrid (BM25+dense) search over a
  structured wiki whose pages cite
    source-article IDs; return those
    IDs.
- **direct**: search the source-article
    corpus directly.
Logs per-call latency. Swapping the
    backend changes only this script.

## `get_article.py --id <article_id>
    [--section H] [--summary]`
Reads full source-article content by ID
    from the corpus (the **content
    layer**).
The agent quotes verbatim from here.
    Logs per-call latency.

## `save_output.py --file out.json`
Validates against the output schema and
    **enforces that every snippet is a
verbatim substring of its cited source
    article** (see
    `validate_output.py`);
rejects non-conformant writes. Stamps
    per-case timing. This is the
    enforced
contract that makes outputs auditable
    independent of the model.

## Output schema
```json
{
  "case_id": "<id>", "guidance":
    "<markdown>",
  "snippets": [{"source_article":
    "art_NN", "source_title": "...",
                "text": "<verbatim
    substring of the cited article>",
    "why": "..."}],
  "n_snippets": <int matching
    len(snippets)>,
  "articles_consulted": ["art_NN", ...]
}
```
Constraints enforced: ≤15 snippets;
    every `text` verbatim in its cited
    article
(modulo unicode-punctuation/whitespace
    normalization); `source_article`
    matches
the id scheme; ground truth never
    loaded.
```

E.4 scripts/validate_output.py: the enforced trust boundary

```
#!/usr/bin/env python3
"""
validate_output.py -- the enforced "
    trust boundary" for a skill-based
    guidance
agent. Anonymized, data-free. Validates
    one agent output against the schema
    and
```

```
enforces that every emitted snippet is a
     verbatim substring of its cited
    source
article. Rejects non-conformant writes.
    This is what makes the output
    contract
auditable independently of the model.

Usage:
    python3 validate_output.py --file
    out.json --articles articles.json
where articles.json maps {article_id:
    full_text} for the cited sources.
"""
import argparse, json, re, sys

    args = ap.parse_args()
    output = json.load(open(args.file))
    articles = json.load(open(args.
    articles))
    errs = validate(output, articles)
    if errs:
        print("VALIDATION FAILED:", file
    =sys.stderr)
        for e in errs:
            print("  -", e, file=sys.
    stderr)
        sys.exit(1)
    print("OK: output conforms to schema
     and all snippets are verbatim.",
    file=sys.stderr)

if __name__ == "__main__":
    main()
```

E.5 Judge-prompt structure

We give each judge as a schematic: the slots it is filled with, the order of the reasoning it is asked to perform, and the terminal output the scoring code parses. Both are frozen for a run and majority-voted over three independent calls.

```
JUDGE 1 - guidance correctness (binary)
 IN   {contact_reason}, {case_notes},
      {candidate_guidance}
      no reference guidance supplied
 ASK  does this guidance resolve the
      case: right procedures, right
      policies, nothing misleading?
 STEP 1) what does the case require?
      2) does the guidance address it?
      3) anything wrong or misleading?
      4) any critical step absent?
 OUT  reasoning, then last line:
      VERDICT <accept|reject>

JUDGE 2 - evidence sufficiency (binary)
 IN   {case}, {reference_guidance},
      {emitted_snippets}
 ASK  could a specialist rebuild
      guidance equivalent to the
      reference from these snippets
      alone?
 CAL  equivalent != identical
      ok: core procedures carried in
          other wording or articles
      not penalised: generic advice,
          minor tips, absent URLs
          where the tool is named
 STEP 1) list reference action points
      2) check each vs the snippets
      3) flag only missing CORE items
 OUT  reasoning, then last line:
      VERDICT <accept|reject>
```

Judge 1 receives no reference, so it scores standalone correctness rather than agreement with an approved answer. Judge 2's calibration block exists because the judge was otherwise prone to the three failure modes it names. The numbers in this paper come from Judges 1 and 2.

FlashTrie: A GPU-Accelerated Constrained Beam Search for Generative Retrieval

Abstract

Constrained decoding is essential in generative retrieval, where document identifiers generated directly from a query must exactly match a predefined library of valid IDs. At scale, decoding is often constrained using a trie with beam search but most implementations run on CPU. Limited parallelism then makes trie traversal and candidate validation a serving bottleneck as beam width grows.

We present **FlashTrie**, which addresses this limitation by optimizing constrained beam search on GPUs. It introduces an integer-aware succinct trie layout that uses bit compression to reduce memory footprint while keeping the full index in GPU high-bandwidth memory, reducing memory stalls, and a cooperative CUDA kernel that performs beam expansion, validation, and pruning entirely on-device without per-step host orchestration. GPU-native parallel primitives further replace CPU-style irregular lookup and heap maintenance, improving warp utilization and reducing divergence.

Together, these designs significantly reduce decoding latency and increase throughput while preserving retrieval quality. On a library of 800M valid identifiers, the bit-compressed layout stores the trie in 3.1 GB. With beam widths up to 1000, FlashTrie reduces mean trie-search latency to under 2 ms, achieving up to $24\times$ speedup over a highly optimized multi-threaded CPU baseline. These improvements enable FlashTrie to scale beam sizes by up to $5\times$ in latency-critical applications such as sponsored search. In a large-scale online A/B experiment on a commercial search engine, it delivers a statistically significant $+0.71\%$ revenue lift, enabling real-time constrained decoding at a scale previously impractical within our production serving budget.

A preprint of this work appeared as arXiv:2607.10044.

1 Introduction

Generative retrieval (Tay et al., 2022; Metzler et al., 2021) reframes document retrieval as a sequence-to-sequence task, mapping a query directly to an identifier (docID), replacing dual-encoder indexing (Karpukhin et al., 2020). This paradigm is attractive for large-scale search and recommendation systems because it can, in principle, avoid expensive retrieval pipelines while enabling compact end-to-end modeling. In practice, however, online serving is constrained by strict latency budgets, and the decoding procedure becomes the dominant bottleneck. Autoregressive (AR) (Sutskever et al., 2014) decoders are sequential and costly, while non-autoregressive (NAR) (Gu et al., 2018; Sun and Yang, 2020) decoders regain parallelism but their per-position independence frequently produces invalid identifiers, necessitating constrained decoding to restrict generation to valid outputs (Ziems et al., 2023; Pradeep et al., 2023). Constrained decoding is therefore not merely an implementation detail but a functional requirement of practical generative retrieval systems. However, enforcing these constraints efficiently over billion-scale retrieval inventories remains challenging. Existing search structures and validation mechanisms to guarantee valid outputs can introduce substantial overhead that dominates end-to-end serving latency.

Prior Work and Challenges. Generative retrieval produces document IDs (Tay et al., 2022), entity names (Cao et al., 2021), semantic IDs (Wang et al., 2022; Penha et al., 2025), or indexed substrings (Bevilacqua et al., 2022). Constraint enforcement has been implemented through trie-based prefix traversal for explicit identifier sets (Cao et al., 2021; Ye et al., 2025; Su et al., 2026), FM-index lookup (Bevilacqua et al., 2022), lexical beam search (Hokamp and Liu, 2017; Anderson et al., 2017), grammar-based token masking (Willard and Louf, 2023; Dong et al., 2025),

EMNLP 2026 Industry Track, pages 2662–2683
October 24-29, 2026 ©2026 Association for Computational Linguistics

and predicate-logic constraints (Lu et al., 2021).

Classical constraint indexes include compressed tries such as Patricia (Morrison, 1968), double-array tries (Aoe, 1989), minimal acyclic FSAs (Daciuk et al., 2000), and succinct structures such as MARISA (Yata, 2011), which combines Patricia compression with a LOUDS topology (Jacobson, 1989). While effective for static string collections and CPU traversal, these designs target character-level keys and map poorly to GPUs, leading to irregular accesses, warp divergence, and reduced hardware efficiency (Merrill et al., 2012).

Modern runtimes optimize GPU model execution (Wang et al., 2021; Dao et al., 2022; Kwon et al., 2023), but constraint enforcement often requires additional data structures and traversal logic outside the model's core computation. Recent systems accelerate it through structured generation (Willard and Louf, 2023; Dong et al., 2025), vectorized trie traversal (Su et al., 2026), or parallel prefix verification (Ye et al., 2025). Structured-generation frameworks compile symbolic grammars into token masks, whereas our setting requires explicit identifier inventories containing up to hundreds of millions of token sequences and sparse top-K prefix lookup. We also evaluate exact GPU hashing (Alcantara et al., 2011) as an alternative indexing strategy.

Complementary work accelerates parallel decoding (Zeng et al., 2024), scales NAR identifier vocabularies (Valluri et al., 2025), or optimizes recommendation inference (Lin et al., 2025). These methods modify model-side candidate generation rather than constraint-index traversal and could be combined with FlashTrie.

This motivates three key questions: *(i)* can succinct tries be adapted to token-level vocabularies without sacrificing space efficiency; *(ii)* can constrained beam search be executed entirely on GPU; and *(iii)* can such systems meet production latency constraints without degrading retrieval quality?

Our Contribution. We present **FlashTrie**, a GPU-native constrained decoding framework for generative retrieval that jointly optimizes constraint representation and decoding computation. Building on succinct tries, we redesign MARISA for integer-token vocabularies using a bit-compressed layout that reduces index size and keeps the constraint structure resident in GPU high-bandwidth memory (HBM). We further introduce GPU-friendly search and sort primitives- parallel trie child matching and heap-free beam selection, to replace pointer-heavy traversal and reduce divergence. Constrained beam search is executed fully on-device via a cooperative multi-step CUDA kernel that performs expansion, validation, and pruning without repeated kernel relaunch overhead across decoding steps. Two-level parallelism, beam-parallel and top-K-parallel execution, exploits hierarchical GPU concurrency, utilizing processing units called streaming multiprocessors (SMs) (NVIDIA Corporation, 2024, 2020) across the device and maintaining high occupancy across the device. FlashTrie scales constrained decoding to billion-scale constraint libraries on GPU, a regime previously feasible only in offline settings, while achieving up to 24× speedup over optimized CPU baselines and reducing trie-search latency to under 3 ms p95. In production A/B testing on a large-scale sponsored-search system, these latency gains enable a 3× wider beam within the same serving budget, which recovers more valid identifiers and yields a +0.71% revenue lift. Code is available at `flash-trie`.

2 Design and Implementation

We consider constrained decoding with a trie $\mathcal{T}$ over vocabulary $\mathcal{V}$. FlashTrie applies to both AR and NAR decoding; we focus on NAR in experiments because larger branching factors make constraint checking more expensive. At decoding step t the base model emits top-K candidates $(x_{t,i}, \ell_{t,i})$ with $\ell_{t,i} = \log p(x_{t,i} \mid x_{<t})$; trie-constrained beam search keeps the top-B valid prefixes under length-normalized log-probability (Wu et al., 2016) (Equation 2, Appendix F). For comparison, we use two CPU baselines built on the same LOUDS+tail/link trie skeleton (Yata, 2011) (Appendix B).

While prior work has primarily focused on trie representation and compression, our results suggest that lookup algorithms within a fixed trie layout can have an equally important impact on decoding performance. Accordingly, FlashTrie co-designs the constraint index, lookup procedure, and beam-search execution strategy for GPU architectures.

2.1 CPU Baselines: MARISA-Int and MARISA-Opt

MARISA-Int extends open-source MARISA (Yata, 2011) from character-level keys to 32-bit integer tokens and adds a minimal beam-search layer, while preserving the original build pipeline. It runs single-threaded on CPU.

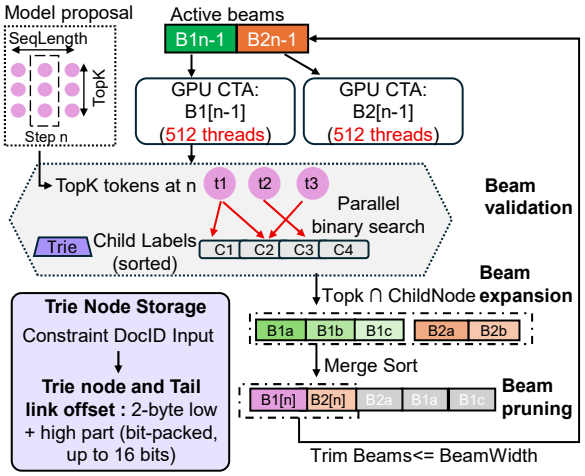

Figure 1: Overview of the FlashTrie pipeline. At each decoding step, active beam states are mapped to thread blocks (CTAs) and processed in parallel across the threads of a CTA for trie-based validation and beam expansion all executed on-device. (**Inset**) FlashTrie extends Narrow-LOUDS representation to integer tokens stored in compact structured arrays.

MARISA-Opt is a stronger CPU baseline: adds trie traversal with prefix-state caching, a multi-threaded worker pool, two-pointer merge between sorted proposals and child labels ($O(K+\Delta)$ per beam), and a bounded min-heap for top-B pruning ($O(C \log B)$). Design details and per-operation complexity are in Appendices C and D.

2.2 FlashTrie: GPU-Resident Constrained Beam Search

FlashTrie redesigns both the trie data structure and the decoding algorithm for GPU execution. The result is a GPU-resident constraint index that preserves succinct-trie space efficiency while reducing memory stalls and exposing hierarchical parallelism. We introduce each systems term below by what it does for decoding; Appendix A collects them for reference.

Narrow LOUDS for integer tokens A succinct trie represents tree topology as compact bit arrays with constant-time `rank`/`select` operations, allowing navigation through arithmetic on bit positions rather than pointer traversal; LOUDS (Jacobson, 1989) is the canonical encoding and FlashTrie introduces **Narrow-LOUDS**, a token-aware extension of the LOUDS trie. For constrained decoding, the resulting index is compact enough to reside entirely in GPU memory. Whereas published MARISA (Yata, 2011) targets 8-bit alphabets, Narrow-LOUDS supports 32-bit integer tokens by splitting both token labels and suffix indices into a 16-bit low part stored in the main array and a bit-packed high part materialized only when needed. This roughly halves the dominant array, enabling billion-scale libraries to fit in GPU HBM while improving memory locality by reducing amount of data fetched during traversal (Figure 1; Section 4.2).

Kernel Execution and Parallelism. FlashTrie executes all (T) decoding steps in one cooperative kernel, avoiding per-step host (CPU) launches and keeping intermediate states on the GPU. GPUs organize computation hierarchically into groups of threads called cooperative thread arrays (CTAs), which execute on SMs. FlashTrie maps this hierarchy onto beam search: queries in a batch are distributed across SMs. Each active beam is assigned to a 512-thread CTA, whose threads validate its (K) proposals in parallel using binary search over sorted trie children. After expansion, a grid-wide parallel selection retains the top-(B) hypotheses. This exposes (BK) child lookups per step while replacing the CPU baseline's sequential expansion and heap pruning.

At each decoding step, FlashTrie exposes two levels of parallelism. First, beam-parallel expansion: all B active hypotheses are expanded at once rather than one after another. Second, proposal-parallel validation within each beam: the K candidate tokens of each hypothesis are validated simultaneously via binary search over sorted trie children. The full T-step search executes in a single kernel launch (Algorithm 1), exposing BK independent child lookups per decoding step.

After expansion, FlashTrie replaces the CPU heap with an append-only candidate buffer and parallel top-B selection, eliminating lock contention and pointer chasing while keeping intermediate state on-device (Appendix E).

3 Experimental Setup

We evaluate on 13,000 retrieval requests from a production NAR model with a 2.2M-token vocabulary. Each request generates top-K proposals ($K \in \{100, \ldots, 1000\}$, beam width $= K$) over $T = 8$ decoding steps. The constraint trie is built with 800M keyword sequences and is resident on a single A100 80GB GPU paired with an AMD EPYC 7V13 host. For MARISA-Opt, we use 8 CPU workers to saturate the 8-core allocation; full hardware isolation details in Appendix F.

Algorithm 1 FLASHTRIE beam search. One persistent GPU kernel executes all T steps on device, exposing beam-parallel expansion and proposal-parallel validation. Kernel details: Appendix E.

Require: trie $\mathcal{T}$, initial state s_0, beam width B, length T, per-step LM proposals $\textsc{TopK}(s, K)$

$cur \leftarrow \{s_0\}$
for $t = 0$ **to** $T-1$ **do**
  $next \leftarrow \emptyset$
  for each $s \in cur$ **in parallel do**
    {(i) beam-parallel}
    $(\tau_{1:K}, \rho_{1:K}) \leftarrow \textsc{TopK}(s, K)$
    for $k = 1$ **to** K **in parallel do**
      {(ii) proposal-parallel}
      $u \leftarrow \textsc{ChildLookup}(\mathcal{T}, s.v, \tau_k)$
      {$O(\log \Delta)$ binary search}
      if $u \neq \perp$ **and** $s.\sigma + \rho_k > \theta_{\text{sent}}$ **then**
        append (s, u, ρ_k) to $next$
        {lock-free}
      end if
    end for
  end for
  barrier; $cur \leftarrow \textsc{Top-}B(next)$
  {on-device}
end for

return $\textsc{Backtrace}(cur)$

Table 1: Unconstrained NAR decoding with post-hoc filtering against the full 800M-identifier inventory; per-query means. Valid and Distinct are counts per query, Invalid is a rate. The Constrained column is definitional rather than measured: trie traversal returns the full beam and emits each identifier at most once, so its valid and distinct counts both equal K.

	Unconstrained + filter			Constrained
K	Invalid (%)	Valid (n)	Distinct (n)	IDs/query ($= K$)
100	80.8	19.2	18.3	100
600	87.0	78.1	69.2	600
1000	88.6	114.0	97.2	1000

We measure per-request latency (mean, p50/p90/p95/p99), throughput under batched serving ($b \in \{1, 4, 8\}$ queries), on-disk index size and wall-clock build time, and Precision@100/200 scored by a transformer teacher (Section 4.6). Latency timing spans the full request path (C++ entry to result return, including GPU stream synchronization). All timings average 10 passes over the full 13,000-request set after one warm-up discard. Details in Appendix F.

4 Results

4.1 Effectiveness of Constrained Decoding

To understand the role of constrained decoding at large identifier scales, we first measure the yield of unconstrained decoding followed by post-hoc filtering. We run this baseline on the same NAR top-K proposal grid used throughout the paper (T=8, $|\mathcal{V}|$≈2.2M) and validate decoded candidates against the full 800M-identifier inventory. Both methods share the same proposal distribution, scoring and length handling, differing only in whether the trie constrains expansion.

Table 1 shows that unconstrained decoding recovers only a small fraction of valid identifiers. At K=1000, it yields 114 valid candidates and 97.2 distinct identifiers per query after duplicate collapse, compared with 1000 identifiers returned by constrained traversal. Increasing beam width does not close this gap: valid yield falls from 19.2% at K=100 to 11.4% at K=1000, while duplicate rates increase from 4.7% to 14.7%. The invalid rate also grows sharply with identifier length, from 71% at length 2 to 94%, 98% and 99–100% at lengths 3, 4 and 5–8, biasing survivors toward short identifiers (Appendix G).

Post-hoc filtering also requires validating candidates against the same 800M-identifier inventory used during constrained decoding, but only after computation has already been spent on prefixes that would have been pruned earlier. We note that structured semantic identifiers have been observed to benefit less from constrained decoding (Penha et al., 2025). Our inventory instead consists of flat token sequences drawn from a much sparser combinatorial space, in which chance validity is correspondingly less likely.

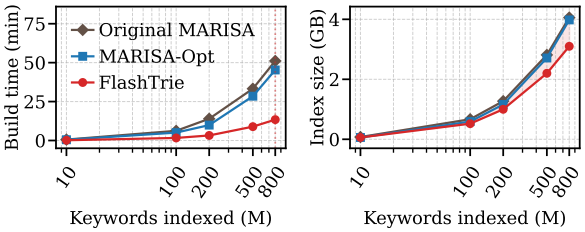

Figure 2: Trie construction scaling on 10M–800M keyword sequences, (**Left**) Build time, (**Right**) Size of constraint index. At 800M keys, FlashTrie builds in 13.4 min and uses 3.1 GB, versus 45.3 min / 4 GB for MARISA-Opt and 51.1 min / 4 GB for MARISA-Int.

4.2 Trie Build Time and Index Size

FlashTrie reduces both trie construction time and on-disk index size as the constraint set grows (Figure 2). Across 10M–800M sequences, the widening gap reflects a shift in the dominant cost: at small scales, fixed LOUDS and tail-construction over-

heads dominate (Appendix B), whereas at larger scales the per-edge link machinery and traversal bookkeeping become the bottleneck (Appendix D). MARISA-Int and MARISA-Opt remain close because they retain the same full-width node storage layout, while FlashTrie reduces per-node work by narrowing link offsets and splitting each 32-bit label into a compact base field plus packed high bits (Section 2.2). As the corpus grows, these savings compound, yielding increasingly larger gains in both build time and index size. Even at a large constraint index such as 800M, FlashTrie builds the trie 3.4× faster than MARISA-Opt while reducing index size by 22%. The resulting index occupies only 3.1 GB, allowing it to reside entirely in GPU HBM, eliminating host-device transfers during decoding and enabling deployment on resource-constrained GPUs like A100 MIG.

4.3 Latency Results

Next, we evaluate whether FlashTrie's GPU parallelism and fully GPU-resident constraint index maintain low trie-search latency as beam width increases. Figure 3 shows that latency grows slowly with beam width on GPU, remaining below 2 ms mean latency even at $K = 1000$. In contrast, MARISA-Opt exhibits substantially poorer scaling, with mean latency increasing from 9.03 ms to 46.30 ms over the same sweep. Consequently, FlashTrie achieves 16× - 24× mean speedup, with the performance gap widening as beam width increases. Slight latency dips near $K \approx 500$ and 800 arise from changes in the thread capacity of the on-device top-B sorter (Appendix E).

MARISA-Int (Section 2.1) is infeasible at billion-keyword scale (>3 h for a single K=1000 query on a 10-query subsample), so we adopt MARISA-Opt as the primary CPU comparator; full measurements are in Appendix J.

4.4 Runtime Breakdown

To profile decoding cost, we instrument the cooperative kernel and measure GPU runtime across four phases (Figure 1): beam expansion, validation, pruning and grid sync. Figure 4 (left) shows the dominant cost shifts with beam width: at K=100, expansion dominates (≈66%) as trie traversal is the bottleneck. As K grows, expansion remains inexpensive because parallel beams share upper trie nodes. In contrast, the number of surviving candidates scales with $B \times K$, increasing validation and pruning cost; at K=1000, validation becomes dominant (≈43% of total runtime). Pruning remains stable at 15–19%, while sync overhead stays small (≤ 6%, decreasing to 3.5%), confirming that the persistent kernel removes per-step host orchestration with negligible barrier overhead. Measurement details are in Appendix E.4.

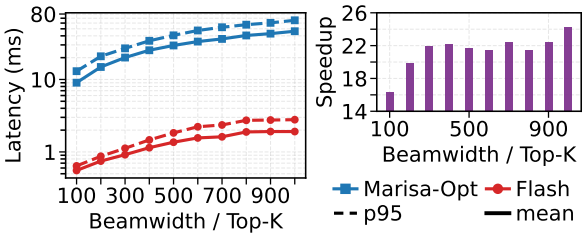

Figure 3: Per-request trie-search latency and GPU speedup vs. beam width K at b=1 ($|\mathcal{V}|$=2.2M, 800M-key trie). **(Left)** Mean (solid) and p95 (dashed) latency. CPU mean rises from 9.0 ms (K=100) to 46.3 ms (K=1000), with p95 65.5 ms and p99 76.7 ms at the top end. GPU mean stays sub-2 ms across the sweep (0.55–1.91 ms), with p95 ≤ 2.79 ms and p99 ≤ 3.31 ms. **(Right)** Mean GPU speedup climbs from 16× to 24×. Full per-percentile table: Appendix H.

4.5 Throughput Scaling with Batch Size

In Figure 4 (right), the throughput curves reflect different batching regimes. FlashTrie's throughput rises steeply from b=1 to b=8, peaking at 1,621 q/s for K=1000. This is 70× higher than MARISA-Opt at its own peak batch size. MARISA-Opt scales only modestly with batch size because its CPU thread pool is quickly saturated: once all workers are occupied, extra queries mostly queue (Section 2.1). FlashTrie benefits more from batching because each query is mapped to a GPU block with many threads, so larger batches better fill the device's execution resources.

4.6 Retrieval Quality

Table 2 shows that retrieval quality improves with beam width. P@100 increases from 0.53 at K=100 to 0.78 at K=1000, and P@200 increases from 0.52 to 0.69. Gains taper after $K \approx 700$, but the trend remains monotonic overall at the operating scale of interest. Because the underlying model is unchanged, these gains stem from exploring more candidate prefixes during search rather than improved modeling. A wider beam preserves plausible prefixes that would otherwise be pruned before their continuations are scored.

FlashTrie matches MARISA-Opt to within 0.001 across all settings, indicating that GPU execu-

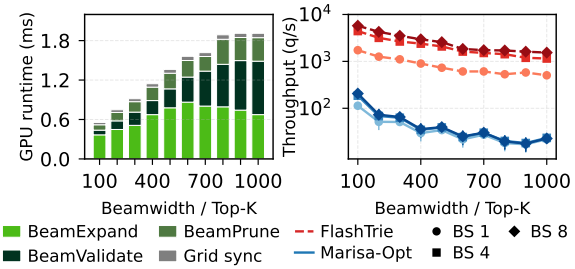

Figure 4: (**Left**) GPU runtime breakdown of FlashTrie's cooperative beam-search kernel vs. beam width K (b=1, averaged over 13,000 requests). As K grows, the bottleneck shifts from trie traversal (beam expansion) to candidate handling (beam validation). (**Right**) Throughput (mean q/s) vs. K, per batch size. FlashTrie peaks at b=8 for all K (6,623 q/s at K=100, 1,621 q/s at K=1000), while MARISA-Opt flattens earlier. At each system's own best batch size, FlashTrie delivers 32×–71× more throughput than MARISA-Opt.

Table 2: Retrieval precision at cutoffs 100 and 200 on the 13K-request dataset, scored by a Transformer cross-encoder (Mohankumar et al., 2023). MARISA-Opt and FlashTrie agree within 0.001 for every K (collapsed into one column). Prec@200 at K=100 equals Prec@100 due to a truncated denominator.

K	100	200	300	400	500	600	700	800	900	1000
P100	.53	.68	.72	.74	.75	.76	.77	.77	.78	.78
P200	.52	.46	.56	.61	.64	.65	.67	.66	.68	.69

tion remains in parity with the CPU implementation. More importantly, in latency-critical serving (e.g., sponsored search; Section 4.9), MARISA-Opt becomes impractical beyond roughly $K \geq 200$ as beam width grows. Thus, the quality gains from larger beam widths are operationally realizable only with FlashTrie, which keeps constrained decoding within tight online latency budgets where large-K MARISA-Opt cannot.

4.7 Ablations: Isolating Trie and Search-Algorithm Contributions

Section 4.3 combines three effects: execution substrate (CPU vs. GPU), trie-based constraint checking, and inner-loop child-search algorithm. Because a direct CPU MARISA implementation requires hundreds of seconds per request even at K=100 (Appendix J), we focus here on three GPU-resident ablations that isolate the latter two while sharing FlashTrie's cooperative kernel, scoring rules, thresholds, and length normalization.

Per-Position Token (PPT) performs depth-only filtering by intersecting top-K model tokens with a set of global tokens valid at depth t, then returns all matches regardless of beam prefix. Because this depth-level token set is shared, the matched set is computed once and reused across beams. Hash-map replaces Narrow-LOUDS with an exact hash table over trie transitions $(\text{state}, \text{token}) \rightarrow \text{child}$. Linear-probe keeps the LOUDS trie unchanged but swaps binary search for a shared-memory linear scan over child labels. Implementation details and the full per-K sweep are in Appendix K.

Table 3: Per-request latency (ms) for three GPU ablations vs. FlashTrie at b=1; p95 speedup is ablation p95/FlashTrie p95. PPT removes trie constraints; Hash-map replaces the succinct trie with an exact separate-chaining hash map over trie transitions; Linear-probe keeps the trie but replaces binary search with linear scan in the child range.

	PPT on GPU			**Hash-map on GPU**			**Linear-probe on GPU**		
K	Mean	p95	**Sp.**	Mean	p95	**Sp.**	Mean	p95	**Sp.**
100	0.57	0.79	1.2×	1.74	2.21	3.4×	110.2	134.1	209×
300	1.90	2.69	2.4×	3.14	5.15	4.6×	123.9	149.1	133×
500	3.54	5.20	2.8×	4.44	7.69	4.2×	128.6	155.7	85×
700	6.98	10.30	4.4×	5.39	9.54	4.0×	141.1	178.8	76×
900	9.73	14.36	5.2×	7.07	11.02	4.0×	151.2	194.3	71×
1000	11.28	16.65	6.0×	7.59	11.51	4.1×	154.3	198.7	71×

Table 3 yields three observations. (i) A permissive GPU baseline (PPT) is fast but not constraint-equivalent. (ii) An exact hash map over trie transitions is 3.4×–4.6× slower than FlashTrie, while consuming ≈31 GB versus 3.1 GB for Narrow-LOUDS (10×). Hence, the hash index does not fit the 10 GB A100 MIG slice that serves the production A/B test of Section 4.9, whereas FlashTrie does. Succinctness is thus not merely a space optimisation, it is what makes the index both cache-resident and deployable (Appendix K.2). (iii) Replacing binary search with a linear scan degrades p95 latency by 71×–209×, demonstrating that child-lookup design is a first-order determinant of decoding performance.

4.8 Public-Dataset Reproducibility

To reproduce the latency claim on public artifacts, we synthesise a parallel workload from NQ-Open queries (Kwiatkowski et al., 2019; Lee et al., 2019), the GENRE-KILT BART-large checkpoint (Cao et al., 2021; Lewis et al., 2020), and the ∼6M KILT Wikipedia titles (Petroni et al., 2021) as the constraint library. We sweep beam width $K \in \{100, 200, \ldots, 1000\}$ over all 3,600 NQ-Open validation queries (T=16 decoding positions) and measure per-request trie-search latency on the same

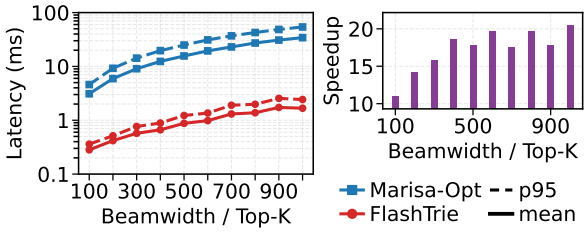

Figure 5: Latency on the NQ+GENRE public workload (3,600 queries, T=16, ∼6M-title trie) vs. beam width K. GPU mean latency rises from 0.28 ms (K=100) to 1.67 ms (K=1000); MARISA-Opt mean grows from 3.11 ms to 34.23 ms. Mean speedup: 11.0× to 20.5×.

hardware as Section 3.

Figure 5 shows that FlashTrie reproduces the internal-dataset speedup trend (Figure 3) on entirely public artifacts. The $p99$ speedup increases from 12.8× to 22.7×, indicating both lower and more predictable tail latency across the full K-sweep. A detailed noise-injection ablation studying the effect of cross-position incoherence (NAR-style proposal grids) is in Appendix L.

4.9 Online A/B Testing

We validate our offline findings with extensive online A/B testing on live traffic of a prominent commercial search engine. The goal is to determine whether the larger beam widths enabled by FlashTrie yield meaningful production gains in user engagement and revenue. The experiment runs for 16 consecutive days across multiple countries, with English and non-English results reported separately in Table 4.

Both arms deploy the same NAR generative retrieval model (Valluri et al., 2025) on an A100 MIG 10 GB slice. In control, production MARISA-Opt at B=200 is already near the online limit (≈25 ms p95; B>200 violates latency constraints). The treatment swaps MARISA-Opt trie stage for FlashTrie and uses the recovered latency headroom to increase beam width to B_{trt}=600, while keeping the model and downstream ranking stack unchanged. FlashTrie sustains B=600 at 15/17 ms (p50/p95), exploring 3× more candidates within the same serving budget.

The treatment produces statistically significant improvements in revenue (0.71% revenue lift), ad coverage, impressions, and clicks. Such gains are meaningful in a mature, heavily optimized production system. Revenue gains suggest the retrieved candidates correspond to higher-value matches, while defect rates, measured using offline relevance models, remain nonsignificant, indicating that the additional candidates are not of lower-quality.

Table 4: Online A/B test (Δ) on a commercial search engine for FlashTrie vs. CPU MARISA-Opt, reported by language segment. All metrics are statistically significant (α=0.05). See Appendix I for the full protocol.

Language	Revenue	Coverage	Impression	Clicks	Latency
English	+0.71%	+0.22%	+0.21%	+0.17%	−32%
Non-EN	+0.68%	+0.25%	+0.37%	+0.20%	−32%

Since the underlying model and its top-K proposals are unchanged, we attribute these gains to the 3× wider beam enabled by FlashTrie's latency reduction (−32%) that narrower beams discard. Hence, this improves retrieval quality (P@100 rises from 0.53 to 0.78; Section 4.6) and allows more relevant candidates to reach downstream ranking.

5 Discussion

FlashTrie exemplifies a broader accelerator-era pattern: data structures traditionally implemented on CPUs can become effective on GPUs when their access patterns are redesigned for parallel execution. Our central finding is that constrained decoding need not remain a CPU bottleneck. A static succinct trie can be made GPU-native when lookup and pruning are structured for batched execution and high device utilization. This reduces decoding latency even at wider beam widths, translating to lower end-to-end inference latency under strict serving constraints. This additional headroom is important because retrieval quality is often limited not only by the model but by how much of the constrained search space decoding can afford to explore. In our online deployment, FlashTrie translated wider beams into measurable gains in user engagement and revenue without degrading ad quality. It enabled retrieval-quality operating points that were previously unreachable under production latency budgets. The constraint mechanism itself is largely domain-agnostic, operating over arbitrary tokenized integer sequences via prefix-constrained child lookup. Our public GENRE experiment (Section 4.8) gives preliminary evidence that the approach transfers beyond ad keywords, reproducing the same qualitative trend with a different model, constraint trie, and an entity-linking task. Together, these findings suggest GPU-native constraint indexing is a promising direction for scaling constrained decoding in large-vocabulary generative retrieval.

Limitations

The current implementation requires the full constraint trie to reside within a single GPU's VRAM. At 800M keywords the trie occupies 3.1 GB on the A100 80 GB, leaving ample headroom for co-located weights; for larger libraries a natural extension is to shard subtrees across GPUs over NVLink/NVSwitch and aggregate candidates per step.

FlashTrie's batched scheduler allocates a fixed SM partition to each query (Section 4.5), avoiding cross-slot synchronisation but capping multi-query parallelism, dynamic or work-stealing alternatives that preserve persistent-kernel coherence are a natural next step.

All experiments use an NVIDIA A100 80 GB PCIe GPU. The persistent-kernel and cooperative-groups patterns are supported on all CUDA Compute Capability $\geq$ 7.0 devices, but quantitative characterisation on H100/B100 remains open.

Retrieval-ID and product-catalog settings remain architectural extensions that we have not evaluated empirically, and we regard them as promising future applications rather than validated deployment domains.

Appendix

A Glossary of Systems Terminology

FlashTrie sits between NLP decoding and GPU systems, so the paper uses vocabulary from both. The terms introduced inline in Section 2.2 are collected in Table 5 for reference; readers familiar with GPU programming can skip this section.

Table 5: Systems terminology used in the main text, defined by its role in constrained decoding.

Term	Role in constrained decoding
Succinct trie	Trie stored as a bit array near the information-theoretic minimum rather than as pointer-linked nodes; what shrinks the 800M-identifier index to 3.1 GB and makes it fit on the GPU
LOUDS, `rank/select`	The canonical succinct encoding (one bit per child slot in level order) and the two constant-time primitives that replace pointer dereferences, so a child move is arithmetic on bit positions (Appendix B)
HBM	The GPU's on-board DRAM; holding the whole trie there means a lookup never crosses PCIe to host memory
Kernel	One program launched from the CPU and run by many GPU threads; each launch has fixed overhead, so launching per decoding step is costly
Cooperative kernel	A kernel that synchronizes device-wide between phases, running all T steps in one launch with beam state on device
SM	Streaming multiprocessor, one of 108 execution units on an A100; the unit across which batched queries are distributed
CTA (thread block)	512 threads resident on one SM with shared on-chip memory; holds one active beam and validates its candidate tokens
Warp	32 threads executing in lockstep; the granularity at which divergence (threads branching apart, serialising each path) and coalescing (adjacent addresses served in one transaction) are decided
Occupancy	Fraction of thread slots actually resident; determines how much memory latency can be hidden
Beam-parallel / proposal-parallel	Expanding all B hypotheses at once, and checking all K proposals of a hypothesis at once (one per thread); at $B{=}K{=}1000$, up to 10^6 concurrent child lookups
MIG slice	Hardware-isolated 10 GB partition of an A100; the production serving unit, so a larger index cannot be deployed (Section 4.9)

B Trie Background: LOUDS with Tail/Link Compression

All three systems share the same LOUDS backbone (Yata (2011)): a $2n{+}1$-bit topology vector with constant-time `rank/select`, plus per-node `bases_` labels and `terminal_flags_`. What differs across systems is not the core topology but auxiliary build-time structures (Patricia/TAIL, link flags, and cache) and the search algorithm used on top of this layout (Table 6).

Patricia single-child compression and the TAIL buffer. Patricia compression folds maximal single-child chains into a head node plus an offset into `tail_`; link nodes store offsets, not labels. Without suffix sharing, this is usually a loss for wide labels. The net benefit depends on suffix deduplication, which can be summarized by:

$$\text{folded}(k, w, \alpha) \;\approx\; w + \alpha\, kw + O(\log |\texttt{tail_}|).$$

Folding beats expansion iff $\alpha\, kw + w < kw$, i.e.,

$$\boxed{\alpha \;<\; 1 - \tfrac{1}{k}\,.} \qquad (1)$$

In byte alphabets this criterion often holds; in wide 32-bit token alphabets suffix sharing is much weaker and the supporting metadata becomes relatively expensive. This is why MARISA-Opt disables Patricia/TAIL in our integer-token setting (Section 2.1). Recursive TAIL (`num_tries`) helps only when the same criterion holds at each level; we use `num_tries=1`.

The `link_flags_` bit-vector and `cache_`. `link_flags_` tags whether `bases_` holds a label or a TAIL offset; its rank index and high-bit arrays scale with the number of link nodes. When Patricia is disabled, these structures largely collapse. MARISA's optional `cache_` prefetch table speeds common top-of-trie transitions but adds build cost and index bytes. These component-level tradeoffs are summarized in Table 6; for full implementation details, see Yata (2011).

C CPU Baselines: Full Design Details and System Contrast

This appendix gives the full design description for the two CPU baselines summarised in Section 2.1 and the axis-by-axis contrast between all three systems (Table 6).

C.1 MARISA-Int

MARISA-Int extends the open-source MARISA codebase (Yata, 2011) with 32-bit integer-token sequences, reusing the original character-oriented storage layout and traversal routines without modifying the build pipeline. Since upstream MARISA provides only single-sequence operations (e.g., `lookup`, `predictive_search`), MARISA-Int adds a minimal beam-search layer. Each candidate is evaluated by repeatedly invoking these routines on the full prefix from the root, performing up to two root-to-node traversals per (beam, proposal) pair. No trie state is reused across steps, and pruning is implemented via `std::partial_sort` over a flat vector. The search is single-threaded, and all operations execute on the host CPU.

C.2 MARISA-Opt

MARISA-Opt builds on MARISA-Int while retaining the LOUDS-based trie layout and on-disk format, but introduces a set of implementation optimizations that make it a competitive CPU baseline. These include compact link-offset encoding, stateful traversal, multi-threaded execution, efficient per-beam expansion, and incremental top-B pruning (full per-operation derivations in Appendix D). Comparing FlashTrie against this optimized baseline ensures that performance gains reflect on-device parallelism rather than unoptimised CPU execution.

MARISA-Opt reduces index size by splitting link offsets across the per-node 32-bit slot and a secondary array, storing only the low-order 8 bits in the slot and packing the remaining bits compactly. The secondary array is allocated only when needed, avoiding unnecessary overhead. Token labels themselves remain in full in the per-node slot; only the link offsets are split. On CPU, MARISA-Opt does not narrow the per-node slot itself, the slot is still 32 bits, so at each link node 24 of those 32 bits are now unused padding.

For integer-token alphabets, MARISA-Opt further removes structures whose benefit is specific to byte-alphabet inputs (Appendix B). First, Patricia single-child link compression is disabled in the build path: every input token becomes its own LOUDS node, no link nodes are emitted, and the recursive trie-of-tails terminates after the first level regardless of the configured `num_tries`. As a consequence, `extras_`, the TAIL buffer, and the rank/select index over `link_flags_` are all empty in the on-disk index, and the link-offset split encoding described above is exercised only by character workloads. Second, the build-time prefetch cache table (`cache_`, used to amortize top-of-trie descents at lookup time) is skipped at construction and is absent from the on-disk index. Third, the in-process multikey quicksort over `Vector<Key>` is replaced by an external `sort -u -V` Unix pipeline that delivers unique, lexicographically ordered token sequences to the builder, so duplicate keys are removed before any trie work begins.

The combined effect is that on a 32-bit alphabet, where each TAIL token would still occupy 4 bytes and each TAIL reference would carry nontrivial `extras_` and `link_flags_` overhead, the bytes that Patricia compression would remove from `bases_` are smaller than the bytes its supporting structures would add. Disabling the compression therefore shrinks the on-disk index and shortens construction simultaneously; this is the dominant driver of MARISA-Opt's index-size and build-time advantage over MARISA-Int in Section 4.2.

Unlike MARISA-Int, which performs repeated root-to-node traversals at each decoding step, MARISA-Opt propagates trie state across beams. Each extension requires a single LOUDS navigation step from the cached node, making per-candidate cost independent of prefix length.

Work is parallelized across beams using a fixed-size CPU worker pool, while per-beam expansion is performed using a linear-time two-pointer merge between sorted proposals and sorted trie children. This reduces matching cost from $O(K\Delta)$ to $O(K+\Delta)$ with sequential memory ac-

cess. Threshold-based pruning is applied during expansion to discard low-probability candidates early.

Instead of end-of-step sorting, MARISA-Opt maintains a shared bounded min-heap of size B, reducing pruning cost from $O(C \log C)$ to $O(C \log B)$, where C is the number of candidates generated per step and B is the beam width, while keeping the top-B beams continuously updated.

C.3 Axis-by-Axis System Contrast

D CPU Trie Operations

The CPU trie operations used by MARISA-Int and MARISA-Opt are inherited from the MARISA framework and are not contributions of this work; we describe them in prose for completeness so that the GPU adaptations in Appendix E have a precise reference point.

Child enumeration. Locating the children of a node v is two rank/select operations on `louds_`. The position of v's first child within `louds_` is $\text{select}_0(v) + 1$, and the corresponding child node index is $\text{select}_0(v) + 1 - v - 1$ (subtracting the LOUDS header bits seen so far). The number of children Δ is the distance from that position to the next 0-bit; on CPU this is a sequential scan over `louds_`, and on GPU it is replaced by WARPNEXTUNSET (Appendix E). Labels of the Δ children sit contiguously at `bases_[base_node..base_node+`Δ`)` in sorted order.

FINDCHILD. Given a parent v and a target token τ, MARISA does a binary search over the Δ child labels. The only subtlety is that when a child u is a link node (`link_flags_`$[u] = 1$), its `bases_` slot holds a TAIL offset rather than a token, so the binary-search comparison must peek into `tail_` at that offset to recover the first label of the suffix; the comparison itself is then ordinary integer comparison. This costs one extra memory indirection per visited link node and is the reason TAIL traversal must read at most one tail byte per binary-search step rather than the entire suffix. Per-call cost is $O(\log \Delta)$ comparisons, each $O(1)$ amortized.

LOOKUP and predictive search. A whole-key lookup is L successive FINDCHILD calls followed by a check that the resulting node carries a terminal flag; the key identifier is then $\text{rank}_1(\texttt{terminal_flags_}, v) - 1$. Common prefix search and predictive search extend this loop with an additional in-order walk of the subtree rooted at the deepest matching node, paying $O(R)$ for R returned keys on top of the $O(L \log \Delta)$ descent. All of these operations execute serially on CPU and are the per-beam unit of work that FlashTrie's expansion kernel parallelises in Appendix E.

E GPU Implementation Details

FlashTrie replaces the serial FINDCHILD/LOOKUP loop of Appendix D with a cooperative-kernel pipeline that keeps the trie, the beam state, and the top-K output resident on the device for the entire query. This appendix documents the pieces that genuinely differ from the CPU baseline and are not adequately specified by prose alone: tail-suffix traversal, warp-cooperative LOUDS scanning, and large-B top-K selection. Bookkeeping aspects, memory residency, output serialization, and per-batch allocation, are described in prose since they involve no concurrency subtleties. Table 7 summarises per-operation time complexity for the GPU primitives used below alongside the CPU counterparts; the $1/P$ factor is the per-thread reduction the GPU contributes, with P=512 for per-CTA expansion and the full grid for sort passes.

Memory architecture. GPU memory is partitioned into three classes. The *static trie* (LOUDS bit-vectors, label arrays, tail buffer, rank/select indices) lives in CUDA Unified Memory and is prefetched on demand; this lets a single index back many concurrent search slots without per-slot duplication. *Per-batch search state*, three frontier arenas, a backtrace arena for parent pointers, and a beam-history buffer used during output reconstruction, is device-resident, allocated once at `init_tbs_gpu` time, and reused across requests so that no `cudaMalloc` appears on the hot path. *Per-request I/O* (input top-K tokens and log-probabilities, output beam sequences and normalised scores) is held in pinned host buffers paired with device mirrors, enabling asynchronous DMA that overlaps with kernel execution.

E.1 Tail Traversal

Beam expansion on the GPU runs in two passes per decoding step, both driven by the cooperative kernel in Algorithm 1. The first pass handles beams that are already *inside* a tail suffix (`s.in_link`): such a beam has exactly one valid continuation, the next token along the tail chain, so the work is to (i) read that token from `tail_` at `s.link_offset`, (ii)

Table 6: Design and implementation contrast across the three systems. All three share the LOUDS+tail/link trie skeleton (Appendix B); they differ in build-time storage choices and in where/how the beam search is executed. The *Improves* column tags whether each axis primarily affects search latency (LAT), build time (BUILD), or trie-on-disk size (SIZE). Per-operation time complexity is reported separately in Table 7. Background on Patricia single-child compression, the TAIL buffer, the `link_flags_` bit-vector, and the prefetch `cache_` table referenced in the rows below is given in Appendix B.

Aspect	MARISA-Int	MARISA-Opt	FlashTrie	Improves
`bases_` slot type	`Vector<UInt32>`, 4 B/entry	`Vector<UInt32>`, 4 B/entry	`Vector<UInt16>`, 2 B/entry	SIZE
Label storage at non-link nodes	full 32-bit token in `bases_`	full 32-bit token in `bases_`; label not split	low 16 bits in `bases_`; high bits in `extras_` via `split_label`	SIZE
Link-offset storage at link nodes	full pointer in `bases_`;	full pointer in `bases_`	low 16 bits in `bases_`; high bits packed in `link_extras_`;	SIZE
`num_tries` (trie-of-tails recursion depth)	1–7, default 1	1–7, default 1	1 only	BUILD SIZE
Recursive TAIL block (`tail_`)	built; tokens stored uncompressed as `uint32`, one offset entry per link node	empty (no link nodes produced, so the recursive `build_next_trie` returns immediately and `tail_` is never populated)	built; tokens stored as `uint32`, references compressed via bit-packed `link_extras_`	BUILD SIZE
`link_flags_` rank/select index	full bit-vector with rank/select over true link positions	identically zero across all nodes; rank/select index collapses to constant overhead	full bit-vector with rank/select over true link positions	SIZE
Build-time prefetch cache (`cache_` table)	built; size set by `cache_level`, persisted to disk to amortize top-of-trie descents at lookup time	skipped (`reserve_cache`, per-node `cache<T>`, and `fill_cache` all bypassed)	built	BUILD SIZE
Build-time key sort and dedup	in-process multikey quicksort over `Vector<Key>`; duplicate inputs not removed	in-process multikey quicksort over `Vector<Key>`; deduplication done outside	in-process multikey quicksort over `Vector<Key>`; deduplication done outside	BUILD
Beam-search residency	host RAM	host RAM	GPU HBM (CUDA Unified Memory, eager-prefetched)	LAT
Trie cursor primitive in beam search	`lookup` then `predictive_search` from root; up to two full root-to-node walks per candidate, no state carried across steps	`predictive_find_children`: one LOUDS step from a cached `node_id`	`extend_beam_binary_child_search`: one GPU LOUDS step; state in device buffers	LAT
Parallelism axis	none (single thread serialises both beams and proposals)	across parent beams (proposals serial within a beam)	across parent beams and across proposals within a beam	LAT
Workers / dispatch unit	1 CPU thread	8 `std::thread` workers; one parent beam per pool job	$\lfloor 108/b \rfloor$ CTAs $\times$ 512 threads/CTA per slot	LAT
Per-beam inner loop	linear scan over K proposals; trie re-walked per candidate	two-pointer merge between sorted child labels and sorted top-K proposals	one thread per proposal; parallel binary search against the sorted child-label array	LAT
Top-B pruning structure	`std::partial_sort` over a flat `std::vector` of beam states	mutex-protected `std::priority_queue` bounded heap	on-device block-merge-sort; registers/shared memory	LAT
Batched-call mechanism	sequential per query	shared FIFO of (query, beam) jobs across 8 workers; step barrier	b cooperative kernels on b CUDA streams; disjoint SM partitions; no cross-slot sync	LAT

Table 7: Per-operation time complexity. L = key length, Q = query length, R = result count, Δ = node out-degree, T = decoding steps, B = beam width, K = top-K proposals per step, P = GPU parallelism, BS = Beam Search.

Operation	Time
$\mathrm{rank}_1(i)$	$O(1)$
$\mathrm{select}_b(k)$	$O(1)$
WarpNextUnset	$O(\Delta/32)$
Lookup	$O(L \log \Delta)$
Common prefix search	$O(Q)$ total
Predictive search	$O(Q + R)$
MARISA-Opt BS	$O(T{\cdot}B{\cdot}(K + \Delta))$
FlashTrie BS	$O\left(T\frac{BK}{P} \log \Delta + T\frac{B \log B}{P}\right)$
MergeSort top-B	$O(B \log B/P)$

scan the top-K proposals for a match, (iii) apply token- and sentence-level log-prob thresholds, and (iv) emit the resulting beam either to `selected` (if the proposal closes the chain on a terminal node) or to `next`. Because the continuation is unique, no binary search is needed and each beam costs $O(K/P)$ work across the CTA's P threads; this is ExtendInLink in Algorithm 2.

The second pass handles beams sitting on ordinary LOUDS nodes. For each such beam the kernel first computes the child range $[base_node, base_node{+}\Delta)$ using select_0 and WarpNextUnset, then has each thread test one top-K proposal in parallel by binary-searching the sorted child labels. Each comparison transparently peeks into `tail_` when the visited child is a link node, exactly as in CPU FindChild. Surviv-

ing proposals become new beams that are routed to `selected` or `next` on the same terminal-/link-status rules as the first pass; this is EXTENDNODE in Algorithm 3. Splitting the work into two passes keeps the warps that are walking tail chains from interfering with the warps that are doing wider parallel child search, which keeps lane utilisation high in both modes.

Algorithm 2 ExtendInLink (device; one CTA per parent beam)

  if end **then**
    if $\text{is_terminal}(s'.v)$ **then**
      $selected.\text{push}(s')$
    end if
  else
    $next.\text{push}(s')$
  end if
  break
end for

E.2 Warp-Level LOUDS Navigation

The inner step of child enumeration, finding the next 0-bit in `louds_` starting from a given position, can span many 64-bit words when a node has high out-degree, and a sequential per-thread scan leaves 31 of the 32 lanes of a warp idle. FlashTrie uses a warp-ballot loop in which each lane checks one of the next 32 words simultaneously and the warp votes via `__ballot_sync`; the position of the first word containing a 0-bit is recovered by `ffs` on the ballot mask, and the final intra-word bit position by another `ffs` on the negated word. Asymptotically this turns the $O(\Delta)$ inner loop into $O(\Delta/32)$ memory accesses. Algorithm 4 gives the exact word-level masking and ballot pattern; the lane

Algorithm 3 ExtendNode (device; one CTA per parent beam)

Compute child range $[base_node,\ base_node + deg)$ via LOUDS select_0 and WARPNEXTUNSET()
if $deg = 0$ **then**
  return
end if
for $k = threadIdx.x$ **to** $K - 1$ **step** $blockDim.x$ **do**
  $\tau \leftarrow topk_id[k]$; $\rho \leftarrow topk_logp[k]$
  if $\rho \leq \theta_{\text{tok}}$ **or** $s.\sigma + \rho \leq \theta_{\text{sent}}$ **then**
    continue
  end if
  Binary-search sorted child labels in $[base_node,\ base_node + deg)$ for τ; peek into $tail$ when the visited child is a link node
  if not found **then**
    continue
  end if
  $s' \leftarrow$ BEAMSTATE($parent{=}s$, $token{=}\tau$); $s'.\sigma \leftarrow s.\sigma + \rho$; $s'.v \leftarrow$ matched child
  Route s' to $selected$ or $next$ per terminal- and link-status (same rules as Algorithm 2)
end for

arithmetic is what prose cannot specify precisely.

  return $w \cdot 64 + \text{ffs}(\sim word) - 1$
end if
$w \leftarrow w + 1$; $lane \leftarrow threadIdx.x \bmod 32$
repeat
  $ballot \leftarrow \text{ballot}((\sim B[w + lane]) \neq 0)$
  if $ballot = 0$ **then**
    $w \leftarrow w + 32$
  else
    $w \leftarrow w + \text{ffs}(ballot) - 1$; **break**
  end if
until false
return $w \cdot 64 + \text{ffs}(\sim B[w]) - 1$

E.3 Top-K Selection on the GPU

After expansion the candidate buffer `next` is trimmed to the top-B hypotheses by length-normalized score. FlashTrie switches between two implementations depending on B.

Block merge sort ($B \leq 1024$). For small B the entire selection fits in a small number of sort-blocks of size $2B$. Each CTA sorts one block in descending order of $\hat{\sigma}$ using CUB's `BlockMergeSort`, then the sorted blocks are combined by a tournament-merge tree in $\lceil \log_2(n/2B) \rceil$ rounds with a grid-wide barrier between rounds. After the final merge round the first B entries are the top-B beams. Total work is $O(n \log n/P)$ for the initial sort and $O(B \log(n/B)/P)$ for the merge rounds, with P the grid-wide thread count; see Algorithm 5.

Algorithm 5 BlockMergeSort Top-K (device; all blocks)

$remaining \leftarrow \lceil |cand|/(2B) \rceil$
{number of sort-blocks}
while $remaining \geq 1$ **do**
  {Phase 1: sort each block of $2B$ elements}
  for all block b assigned to this CTA **do**
    Load $2B/P$ elements per thread (pad with $-\infty$ if OOB)
    BLOCKMERGESORT($thread_data$) (descending by $\hat{\sigma}$)
    write back to $sort_state$
  end for
  if $remaining = 1$ **then**
    break
  end if
  $\mathrm{sync}(\mathcal{G})$
  {Phase 2: tournament merge}
  $remaining \leftarrow \lceil (remaining - 1)/2 \rceil + 1$
  $\mathrm{sync}(\mathcal{G})$
end while
{Phase 3: collect top-B entries into $cand[0 \ldots B-1]$}

Output serialization. The final `selected` buffer is descending-sorted by $\hat{\sigma}$ but the wire format expects ascending order, so GENERATERESULT writes the i-th selected beam into slot $n_o{-}1{-}i$ of the output arrays. Per-beam token sequences are reconstructed by walking the `beam_history` parent pointers in reverse, with a CUB `BlockScan` converting per-beam lengths into the end-offsets that index the flat `tokens` buffer. The on-wire layout for n_o beams totalling n_{tok} tokens is an 8-byte `num_beams` header followed by three contiguous arrays: $8n_o$ bytes of `logp_norm` (`float64`), $8n_o$ bytes of `sent_offset` (`uint64`), and $4n_{\text{tok}}$ bytes of `tokens` (`uint32`); sequence i occupies `tokens[sent_offset[`$i{-}1$`] : sent_offset[`i`]]`.

Per-batch GPU memory budget. A single search slot occupies roughly 320 MB of GPU memory, dominated by the persistent device-resident state: three frontier arrays at 56 MB each, a 56 MB beam history, six 8 MB sort-state arrays, a ∼128 MB device-side output buffer paired with pinned host memory, and a ∼12 MB input buffer similarly paired. Top-K scratch is small (3×0.5 MB) and the trie struct shell is a few hundred bytes; the trie arrays themselves live in Unified Memory and range from 50 to 500 MB depending on the constraint set, charged once across all slots rather than per-slot. A four-slot batch therefore uses ≈ 1.3 GB plus the trie, which fits comfortably alongside a generation-model weights footprint on a single 80 GB device.

E.4 Runtime Breakdown Methodology

Because beam search runs as a single persistent cooperative kernel (Section 2.2), we measure its internal phase breakdown with lightweight on-device instrumentation rather than separate kernel launches. Under a compile-time flag, a single grid-leader thread reads the GPU cycle counter (`clock64`) along its timeline. We time the *wall-clock span* of each phase region, bracketed by the grid barriers (`grid.sync`) that already separate the phases; because each region ends at a barrier, its span includes the slowest CTA, i.e. the phase's critical-path time across the grid rather than the leader's own work alone. Cycle counts are converted to milliseconds via the SM clock rate and averaged over the 13,000-request workload.

The four buckets map to kernel regions as follows. *Expansion* is the per-proposal binary search that locates a candidate token among a parent's children, including the dependent LOUDS/tail memory accesses at each search step (a single tail read for link-interior beams). *Validation* is per-candidate admission: the per-token and cumulative log-probability threshold tests, the terminal-node check, and the append into the candidate buffer. *Pruning* is the top-B selection (parallel mergesort) that enforces the beam width. *Sync* is the residual:

inter-phase grid barriers outside the work regions, frontier setup/save, result serialization, and buffer swaps. The expansion and validation regions are interleaved per proposal, so we report their combined wall span split by the leader thread's measured compute ratio; pruning and sync are measured directly. The four phases sum to total kernel time by construction.

We report *proportions* rather than absolute times: the instrumented build incurs mild register pressure that inflates absolute latency, so all latency numbers in Section 4.3 come from a separate, non-instrumented build. For reference, the measured mean per-phase times at $b{=}1$ range from 0.34/0.07/0.08/0.03 ms (expansion/validation/pruning/sync) at $K{=}100$ to 0.66/0.79/0.35/0.07 ms at $K{=}1000$, with total kernel time under 2 ms across the full sweep.

F Experimental Setup: Full Protocol

This appendix fills in the measurement details abbreviated in the main body's Experimental Setup (Section 3).

Deployment envelope. All systems run in one Docker container on 1× A100 80 GB with an AMD EPYC 7V13 host and 60 GB host RAM, NUMA-pinned to cores 0–7 of socket 0 via `numactl -cpunodebind=0 -membind=0 taskset -c 0-7`. The latency window is a C++ entry-point timer covering H2D, kernel, and D2H with stream synchronisation.

Comparability of the timing window. The CPU systems' timer closes when the search call returns; the FlashTrie timer closes after `cudaStreamSynchronize`. All three systems share the same C++ entry-point boundary and exclude only language-binding marshalling, so reported latencies are directly comparable. NUMA-pinning to a single socket also removes cross-socket traffic on the H2D path, so FlashTrie's speedup is reported under the same deployment-realistic envelope as the CPU baselines.

Length-normalised scoring. Beams are ranked by the Google-style length-normalised log-probability used in Section 2 (Wu et al., 2016):

$$s_{\text{norm}}(\mathbf{x}_{0:d}) = \Big(\sum_{j=0}^{d-1} \ell_{j,\sigma(j)}\Big) \cdot \Big(\frac{6}{5+d}\Big)^{\alpha}, \quad (2)$$

where α controls the normalisation strength and $\sigma(j)$ indexes the selected candidate at step j.

Per-request latency sampling. Each (K, b) configuration is benchmarked over the full 13,000-request dataset at batch size 1. One warm-up pass is discarded; FlashTrie additionally runs a short GPU warm-up before the measurement window opens. The next 10 passes are timed and pooled, producing 130,000 samples per configuration from which the mean and the 50th/90th/95th/99th percentiles are computed. The across-run standard deviation is reported as a variance bar in figures and as the $\pm$ value in Table 9.

Throughput sweep. For the throughput evaluation (Figure 4, Section 4) we sweep $b \in \{1, 4, 8\}$ at $K \in \{100, 300, 500, 700, 1000\}$. For each (K, b) the dataset is run as $\lceil 13000/b \rceil$ batched calls per pass, and per-pass throughput is total queries divided by total wall-clock duration measured with the same C++ entry-point timer window used for latency. One warm-up pass is discarded and four passes are timed; reported Θ is the mean over those four passes, with the across-pass standard deviation drawn as the error band in Figure 4.

Precision@K scoring. For the retrieval-quality evaluation (Section 4.6) each request's top-K trie-admitted output is scored by a transformer teacher model adapted from (Mohankumar et al., 2023) that takes the request and a candidate keyword sequence as input and returns a single relevance score. The teacher is identical across all three systems (MARISA-Opt, FlashTrie, and PPT) so that any precision differences are attributable to the candidate set, not to the scorer. Precision@$K{=}100$ and Precision@$K{=}200$ are reported as the macro-average over the 13,000 requests.

G Unconstrained Decoding with Post-Hoc Filtering

This appendix gives the protocol and the length breakdown behind the baseline of Section 4.1.

Protocol

The unconstrained path reuses the proposal grid of Section 3 unchanged: the same 13,000 requests, $T{=}8$ decoding positions, and a 2.2M-token vocabulary. It runs the identical beam search with the trie-validity test removed, so a beam may extend by any of its top-K proposals, while scoring, length normalisation and the log-prob thresholds stay fixed. Each decoded sequence is then looked up in the full 800M-identifier inventory, and a candidate counts

Table 8: Invalid rate of unconstrained NAR decoding by decoded identifier length, over the same 13,000-request set.

Identifier length	2	3	4	5–8
Invalid (%)	71	94	98	99–100

as valid only on an exact full-sequence match, the same criterion the trie enforces incrementally. *Valid* counts matching rows, *Distinct* counts unique identifiers after collapsing duplicates, and the invalid rate is one minus valid rows over K. All figures are per-query means over the request set.

Two properties of the comparison are worth making explicit. First, constrained traversal cannot emit a duplicate: a root-to-terminal trie path corresponds to exactly one identifier, so its valid and distinct counts coincide and both equal the beam width. Duplication is a cost borne only by the unconstrained path. Second, the unconstrained path is not cheaper per step in any way that offsets its shortfall. It performs the same expansion and the same top-B selection and merely omits the validity test, so the lower yield is not purchased with lower decode cost.

Invalid Rate by Identifier Length

Table 8 shows that validity decays steeply with identifier length. This is what per-position independence predicts: NAR positions are produced without conditioning on one another, and a candidate is valid only if all ℓ positions simultaneously agree on a single inventory entry, so the probability of validity falls off geometrically in ℓ.

The consequence for retrieval matters more than the rate itself. Because the surviving identifiers concentrate at lengths 2–3 while the inventory is dominated by longer sequences, post-hoc filtering does not simply return fewer identifiers, it returns a systematically biased subset of them. The shortfall in Table 1 therefore understates the loss in inventory coverage, and the bias cannot be removed by widening the beam, since a wider beam samples more densely from the same length-skewed distribution.

H Per-Percentile Latency Table

Table 9 gives the full per-percentile breakdown of the per-request trie-search latency reported in Figure 3: mean, p50, p90, p95 and p99 in milliseconds, for every beam width K, computed as the median across 10 runs of 13,000 queries each.

I Online A/B Test Protocol

This appendix gives the operational protocol of the production A/B test summarised in Section 4.9.

Sample-ratio-mismatch (SRM) check. A sample-ratio-mismatch check passed throughout the flight, confirming the realised treatment : control event ratio is consistent with the configured allocation after eligibility filtering. This rules out exposure-bias confounds before reading the metric lifts.

Latency-timing boundary. End-to-end latency is measured from request ingress at the retrieval service to emission of the final top-k candidate set, inclusive of trie traversal, beam expansion, scoring, and post-processing. Control and treatment share the entire ads downstream stack; they differ only in the retrieval-stage trie back-end and the beam configuration the back-end can sustain within the 30 ms end-to-end latency SLA.

Constraint library and back-end configurations. The production constraint library indexes hundreds of millions of docIDs. The control arm runs production CPU MARISA-Opt at B_{ctrl}=200, top-k=300, with a 3-thread pool matched to the per-worker MIG-slice CPU-core allocation.

Metric definitions. Columns of Table 4: *Revenue* is total advertiser revenue for the arm; *Coverage* is the fraction of queries for which a sponsored ad is shown; *Impression* is Impression Yield (IY), the expected value per impression opportunity; *Clicks* is total ad clicks; *Latency* is the end-to-end window defined above. The defect guardrails reported as nonsignificant in Section 4.9 are the Defect-ML classifier and Feedback-Based-Suppression (FBS) signals on Ads Selection.

J MARISA-Int Feasibility Measurements

MARISA-Int is included only as a feasibility check (not a primary performance baseline). At billion-key scale it is too slow for a full 13K sweep, so we report a fixed 10-query subsample (seed 42) and omit $K \geq 500$ after observing a single K=1000 query at 10,997 s (≈3.05 h).

Table 10 reports mean/p50/p90/p95 on the subsample. p99 is omitted at N=10. The large mean–median gap reflects high per-query variation in traversal depth and root branching.

Table 9: Per-request trie-search latency (ms), full percentile breakdown. Each cell is the median across 10 runs of 13,000 queries each. **Lower is better.**

	MARISA-Opt (CPU)					FlashTrie (GPU)				
K	Mean	p50	p90	p95	p99	Mean	p50	p90	p95	p99
100	9.0	8.9	11.8	13.0	15.1	0.6	0.5	0.6	0.6	0.7
200	14.9	14.4	19.2	20.9	23.6	0.7	0.7	0.8	0.9	0.9
300	20.1	19.8	25.2	26.9	30.0	0.9	0.9	1.1	1.1	1.2
400	25.3	25.1	32.2	34.2	38.3	1.1	1.1	1.4	1.5	1.6
500	29.5	29.3	38.2	40.6	45.4	1.4	1.4	1.7	1.8	2.0
600	33.4	33.0	44.2	47.4	53.9	1.6	1.5	2.0	2.2	2.6
700	36.3	35.9	48.8	52.6	60.4	1.6	1.6	2.2	2.4	2.8
800	40.5	38.4	52.7	57.0	66.5	1.9	1.8	2.5	2.7	3.2
900	42.9	40.6	55.9	60.5	70.5	1.9	1.9	2.5	2.8	3.3
1000	46.3	43.8	60.6	65.5	76.7	1.9	1.8	2.5	2.8	3.3

Table 10: MARISA-Int per-request latency on a fixed 10-query random subsample of the 13,000-request workload (seed 42, identical query indices across K).

	Latency (s)			
K	**Mean**	**p50**	**p90**	**p95**
100	394.5	37.6	1,049.7	1,809.4
200	764.6	492.0	2,392.3	2,597.4
300	1,498.9	947.7	4,333.6	5,134.4
400	2,028.9	1,329.3	4,789.9	6,391.6

Latency grows roughly linearly with K, consistent with MARISA-Int's serial per-beam execution model, and confirms it is unsuitable as a main comparator at this operating point (hence MARISA-Opt in Section 2.1).

K Ablations: Full Details

This appendix gives the construction, full per-K measurements, and analysis for the three GPU ablations of Section 4.7, together with two additional sequential variants that were measured but failed to scale. Together with the main-text comparison against MARISA-Opt, these results decompose the FlashTrie speedup into three contributions: GPU residency and kernel fusion (PPT vs. MARISA-Opt), the LOUDS-trie structure for path validity (FlashTrie vs. PPT and vs. the hash map), and binary search at the inner per-key loop (FlashTrie vs. the per-key linear probe).

Shared protocol. Every variant below runs in a cooperative kernel that is otherwise a clone of the FlashTrie kernel: the same grid-wide barrier per decoding step, the same 512-thread CTAs with one CTA per parent beam, the same proposal-parallel inner loop, and the same log-prob thresholds, length normalisation, append-only candidate buffer and on-device top-B selection. *Only the constraint lookup differs.* All variants are measured on the 13,000-request workload and the hardware of Appendix F at b=1 with beam width $= K$, using a 20-iteration GPU warm-up and one discarded warm-up pass followed by timed passes; percentiles are computed over the per-request wall-clock timings and averaged across passes. PPT and the per-key linear probe were measured at all ten beam widths, the hash map at every other K.

K.1 Per-Position Token (PPT)

For each decoding depth $d \in [0, T)$, we collect the set of all token IDs that appear at position d in any keyword of the constraint library and store them as a sorted, deduplicated array on the GPU. A flat (`valid_tokens, valid_offsets, valid_counts`) layout is used so that the depth-d alphabet is contiguous in device memory. At search time, for each beam at depth d, every top-K proposal token is tested against `valid_tokens`$[d]$ via a single `lower_bound` binary search; tokens that pass are admitted into the next beam, tokens that fail are pruned.

Formally, PPT admits a token $x_{t,i}$ at depth d iff $x_{t,i}$ appears at position d in some keyword; it does not require that the prefix $x_{0:d}$ extended by $x_{t,i}$ corresponds to a valid path in the constraint library. The candidate set produced by PPT is therefore a strict superset of the trie-valid set, and PPT performs strictly less work per step than FlashTrie. It is consequently not constraint-equivalent, and cannot answer whether a succinct trie is needed once the constraint index is GPU-resident.

K.2 Hash-Map Constraint Index

To answer that sharper question we replace the trie with an *exact* hash map over trie transitions and hold everything else fixed.

Index construction. Every transition of the LOUDS trie is materialised as one hash-map entry, keyed by the (state, token) pair that it consumes:

$$\mathrm{key}(s, x) \;=\; \big((s \ll 32) \mid x\big) + 1, \qquad (3)$$

where x is a 32-bit token id and s is a 32-bit state. A state is either a LOUDS node id or, for a position interior to a tail link, the link offset tagged with a high bit ($s = \texttt{0x80000000} \mid \mathit{offset}$), so a single map covers both the node-to-node and the in-link transitions that the trie kernel reaches through two separate code paths. The $+1$ keeps the key non-zero without disturbing the tag bit. Each entry stores the 64-bit key, the transition payload the kernel needs (child node id, link offset, and the `is_link`, `end_link` and `is_terminal` flags), and a chain successor index: 32 bytes in total, laid out as an array of structures in global memory.

Collisions are resolved by separate chaining, the layout of `std::unordered_map`: an array of bucket heads, each an index into a flat entry pool linked by a `next` field. The bucket count is the entry count rounded up to the next odd integer, giving a load factor of 1.0 and forcing a true integer modulo rather than a bit mask, and the hash is the identity modulo that bucket count. Because full 64-bit keys are stored and compared, the map is exact: it has no false positives and admits precisely the trie-valid candidate set, so the ablation is constraint-equivalent to FlashTrie by construction. The map is built on the host in a single trie traversal, serialised to a flat file, and uploaded to the device with one memory copy per array; there is no device-side build.

Kernel integration. Where FlashTrie binary searches the parent's sorted child labels in $\mathcal{O}(\log \Delta)$, the hash variant computes one modulo and walks the corresponding bucket chain. One probe is issued per (beam, proposal) pair, so a decoding step issues $B{\times}K$ probes, exactly the number of binary searches the trie kernel performs.

Memory footprint. A hash map stores one entry per transition and therefore cannot share structure between sibling or ancestor edges the way a trie does. The LOUDS bit-vector encodes the shape of the trie implicitly, so a node costs a handful of bits beyond its label, whereas the map must spell out every (state, token) pair explicitly and additionally pay for a bucket-head array and a per-entry chain pointer. On the 800M-keyword library the map holds 926,855,329 transitions over 790,943,908 trie nodes, which at 32 bytes per entry is 27.6 GiB of entry pool plus 3.5 GiB of bucket heads: ≈31 GB resident, against 3.1 GB for the Narrow-LOUDS index at the same scale (Section 4.2), a factor of 10.0. Beyond the deployment consequence noted in Section 4.7, the map would demand a full A100 80 GB, where it would still occupy ≈40% of HBM before any model weights or per-slot working memory (Appendix E).

K.3 Linear-Search Variants

Within the trie kernel itself, the per-parent child lookup is performed by a binary search over the parent's sorted child labels. To isolate the contribution of this algorithmic choice, as distinct from GPU residency, kernel fusion, and the LOUDS layout, we replaced the binary-search inner loop with three successively weaker variants. They differ only in how each parent beam locates the children whose labels appear in the top-K proposal set:

- **Two-pointer merge (vanilla MARISA port).** Faithful single-thread port of the CPU MARISA child-extension loop: one CTA per parent, one thread per CTA walks the parent's sorted children and the sorted top-K in lockstep, $O(\text{degree} + K)$ per parent. The remaining 511 threads of the CTA idle. Across-parent parallelism is preserved (one CTA per parent, many CTAs per SM), matching the CPU pattern of multi-threading across parents.

- **Per-child parallel linear scan.** Block-parallel baseline that distributes children across the CTA's threads: thread t handles children $t,\ t + \text{blockDim}, \ldots$ and for each assigned child performs an $O(K)$ linear scan through the top-K array to test membership. Per-parent work $O(\text{degree} \cdot K/\text{blockDim})$ in wall-clock, but every thread re-issues trie metadata loads (`select0`, `rank1`, label decode) for its assigned children with no sharing.

- **Per-key linear probe (FlashTrie inner loop with binary → linear).** Identical parallelisation to FlashTrie, one thread per top-K key, striding `blockDim`, but each thread linearly scans the parent's sorted children for its assigned key (with sorted-array early exit) instead of binary searching. To make this

Table 11: Full per-K sweep for PPT and the per-key linear probe (companion to Table 3). Speedup is ablation p95 divided by FlashTrie p95 at the same K. **Lower latency is better.**

	PPT			Linear-probe		
K	Mean	p95	**Sp.**	Mean	p95	**Sp.**
100	0.57	0.79	1.23×	110.2	134.1	209×
200	1.16	1.61	1.85×	119.6	144.2	166×
300	1.90	2.69	2.40×	123.9	149.1	133×
400	2.73	3.97	2.71×	126.8	152.8	104×
500	3.54	5.20	2.84×	128.6	155.7	85×
600	5.57	8.22	3.69×	135.5	169.3	76×
700	6.98	10.30	4.37×	141.1	178.8	76×
800	8.22	12.15	4.45×	145.6	186.3	68×
900	9.73	14.36	5.21×	151.2	194.3	71×
1000	11.28	16.65	5.98×	154.3	198.7	71×

competitive at all, the CTA cooperatively decodes each parent's child labels once into a shared-memory cache, after which all 512 threads scan the cache. Per-parent work $O(\text{degree} + K \cdot \text{degree}/\text{blockDim})$ in arithmetic, with all global-memory trie loads amortised across the topk loop.

Both fully sequential variants fail to scale to the full benchmark at production beam widths, and are reported only as a cautionary data point for naive GPU ports of the textbook MARISA traversal. The two-pointer merge, although algorithmically the lowest in arithmetic complexity per parent, uses only $1/512$ of each CTA's threads; the warm-up pass alone takes several minutes at $K{=}100$. The per-child parallel scan keeps every thread busy but pays with redundant per-thread re-decoding of child labels and an $O(K)$ inner scan per child, and a single 13K-query pass at $K{=}100$ failed to complete within seven hours. Only the per-key linear probe admits a meaningful comparison, since it shares FlashTrie's parallelisation scheme exactly and differs only in whether the inner per-key search over the cached children is binary or linear. Its full per-K sweep is given alongside PPT in Table 11.

K.4 Results

Table 11 gives the complete per-K sweep for PPT and the inner-loop linear probe. Hash-map mean and p95 values are already reported in Table 3; Table 12 provides its full percentile and throughput breakdown. Run-to-run variation for the hash variant is small: the standard deviation of the mean is ≤ 0.012 ms and of p95 is ≤ 0.032 ms at every K.

Table 12: Hash-map ablation, full percentile breakdown (ms) and throughput on the 13,000-request workload, $b{=}1$. Compare with the FlashTrie columns of Table 9. **Lower is better** for latency.

K	Mean	p50	p90	p95	p99	QPS
100	1.74	1.64	1.93	2.21	3.33	575.4
300	3.14	2.79	4.22	5.15	8.30	318.1
500	4.44	3.96	6.28	7.69	12.35	225.4
700	5.39	4.75	7.81	9.54	14.45	185.6
900	7.07	5.61	9.02	11.02	16.26	141.4
1000	7.59	5.86	9.44	11.51	16.90	131.8

K.5 Discussion

Why constant-time lookup loses on a GPU. Despite an expected $\mathcal{O}(1)$ lookup, and despite a load factor of 1.0 that makes the average chain a single hop, the hash variant is 3.1×–4.0× slower than FlashTrie in mean and 4.8×–5.1× slower at p99, and its throughput falls from 575 to 132 queries per second across the sweep. Three properties of the GPU memory system account for the gap. First, locality: the threads of a warp probe consecutive proposal tokens, whose keys differ only in the low 32 bits and therefore land in unrelated buckets, so one warp's probes touch as many distinct cache lines as it has active threads. FlashTrie's binary search instead walks a contiguous, sorted child range, and successive steps of the search hit lines that are already resident. Second, dependent loads: a bucket head is an index rather than a value, so even a one-hop lookup costs two serialised global accesses whose latency cannot be hidden when every thread misses simultaneously. Third, footprint: at ≈31 GB the entry pool exceeds the cache hierarchy by orders of magnitude, so nearly every probe reaches DRAM, whereas the 3.1 GB narrow-LOUDS arrays keep the upper trie levels, which every beam traverses at every query, resident in L2. The memory and latency disadvantages are thus two consequences of one cause: the map stores transitions individually instead of encoding them structurally.

This ablation therefore separates the value of the succinct layout from the value of GPU residency more cleanly than PPT does. The hash variant is GPU-resident, kernel-fused, constraint-exact, and asymptotically cheaper per lookup, and it still loses by roughly 4× in latency and an order of magnitude in memory. On a GPU, constant-time lookup is the wrong objective; coalesced access over a bounded footprint is the right one.

Why the hash map overtakes PPT at large K. The hash variant is slower than PPT below $K{=}700$ and faster above it (Table 3), which is expected rather than anomalous: PPT has the cheaper lookup of the two but is permissive, so it forwards a strict superset of the trie-valid candidates, and the validation and pruning stages that consume those candidates dominate runtime at large beam widths (Section 4.4). Past $K \approx 700$ the cost of PPT's larger candidate set outweighs its cheaper per-token test. The two ablations are therefore not ordered by lookup cost alone, and only the hash variant is constraint-equivalent to FlashTrie.

Why the inner search algorithm matters. At $K{=}100$ the per-key linear probe has a mean per-request latency of 110.2 ms against FlashTrie's 0.55 ms, indicating that binary search at the inner loop contributes a two-orders-of-magnitude factor on top of the GPU residency, kernel fusion, and shared-memory caching that it shares with FlashTrie. The two discarded variants illustrate a common failure mode of porting CPU succinct-trie code to the GPU. The CPU MARISA loop is fast because modern x86 cores are individually fast and MARISA-Opt multi-threads across parents. Both properties evaporate on the GPU: an SM's individual thread is far weaker than a CPU core, and the across-parents axis alone is not wide enough to amortise the trie metadata cost when each parent's inner loop is sequential. Only by holding the parallelisation scheme fixed and varying the inner-loop algorithm can the contribution of the search algorithm itself be measured cleanly, and that contribution is large.

L NQ + GENRE Workload Construction and Realistic-Threshold Analysis

The three components introduced in Section 4.8 are pinned for exact reproduction: NQ-Open validation (**3,600 questions**, free-form input matching serving shape), the public GENRE-KILT checkpoint (`facebook/genre-kilt`, BART-large with a $\sim$50k token vocabulary, ungated), and the deduplicated KILT Wikipedia titles ($\sim$6**M tokenized titles**, BART-tokenized so the model's emitted token IDs and the trie's edge labels share one ID space, avoiding train/serve vocabulary mismatch).

GENRE is autoregressive: a vanilla top-K beam roll-out produces a proposal grid where each position's top-K is conditioned on the previous-step argmax, so the grid is internally coherent and the trie does little admissibility filtering. To simulate the cross-position incoherence of production NAR grids, we use a two-stage pipeline.

Stage 1: AR top-K extraction. For each NQ-Open query we run GENRE over $T{=}16$ decoding positions, emitting at each position t the top-$K{=}600$ tokens with their log-softmax scores. The result is a per-query (T, K) grid of token IDs and log-probs, the same data shape FlashTrie and MARISA-Opt consume on internal traffic.

Stage 2: head + noise-tail replacement. For a chosen head size $r \in \{0, 9, 18, 150, 300, 600\}$ we keep the top-r AR-emitted tokens at each position (the "coherent head") and replace ranks $[r, K)$ with tokens sampled from the position-stratified marginal distribution of the trie corpus (the empirical frequency of each token at position t across all tokenized Wikipedia titles). Noise tokens inherit the AR model's tail log-probs at the occupied ranks so the resulting grid is indistinguishable from a real model emission to a downstream beam scorer. The knob r interpolates between $r{=}0$ (pure NAR-style proxy, maximum trie work) and $r{=}K$ (pure AR, minimum trie work).

Alternative noise designs (uniform-vocab, uniform-position alphabet, and history-conditioned sampling) were rejected because they either under-stress the trie or reintroduce AR coherence. Position-stratified marginal sampling preserves per-position plausibility while remaining cross-position independent. We keep AR tail log-probs to preserve realistic score decay under θ_{tok}, θ_{sent}, and length normalization.

All experiments use the deployment envelope of Appendix F. The constraint trie is built once over the tokenized KILT corpus and reused across all r. For the r-sweep, beam-score thresholds are set permissively ($\theta_{\text{tok}}{=}{-}20$, $\theta_{\text{sent}}{=}{-}200$, length-norm exponent 5.0) so that the trie's admissibility check, not the scorer, drives all pruning. Results are reported at $K{=}600$, which sits inside the beam-width range of the internal sweep (Figure 3) and has the densest r-grid in the released artifacts. The latency measurement protocol (Section 3) is reused verbatim.

GPU Overhead Floor

The GPU curve flattening in Table 13 is explained by a structural overhead floor (kernel launch, grid barriers, fixed top-B selection passes, and fixed-size H2D/D2H I/O). CPU has less fixed overhead, so its latency keeps scaling with reduced trie work

Table 13: Mean trie-search latency (ms) at K=600 on NQ+GENRE vs. head size r (r=0: NAR-style proxy, max trie work; r=600: GENRE verbatim). Speedup = CPU / GPU mean. **Lower latency, higher speedup are better.**

r	0	9	18	150	300	600
MARISA-Opt (ms)	41.2	40.5	40.2	37.6	33.7	20.4
FlashTrie (ms)	5.7	5.2	3.6	2.8	2.7	2.4
Speedup (CPU/GPU)	7.3	7.8	11.1	13.3	12.5	8.4

while GPU saturates once work drops below this floor.

Realistic-Threshold Operating Point

Table 13 uses permissive thresholds to stress trie work. Here we evaluate realistic production thresholds (Section 4.9), where scorer-side pruning is stronger under the same 30 ms SLA.

We keep all other NQ+GENRE settings fixed (3,600 queries, K=600, T=16, length norm 5.0, identical warmup) and use the deployed threshold pair. Table 14 reports mean latency and CPU/GPU speedup across the r sweep.

At realistic thresholds and worst-case r=0, MARISA-Opt drops from 41.19 ms (permissive) to 8.95 ms mean and FlashTrie from 5.66 ms to 1.54 ms, showing scorer-side pruning reduces absolute work for both systems. Relative advantage remains multi-×: 5.8× at r=0, typically 7.4–7.6× for $r \in \{9, 150, 300\}$ (Table 14).

Across the r sweep, CPU latency still tracks workload coherence, while GPU latency stays in a narrow band because fixed cooperative-kernel overhead dominates once useful trie work is small. This preserves FlashTrie's core value at production thresholds: lower and more stable latency under workload variance.

Retrieval Quality on NQ+GENRE

Sections 4.8 and the sweeps above establish the latency claim on public artifacts; here we check that constraint semantics are also preserved. Following KILT convention we report R@100 rather than P@k, because NQ-Open typically has a single gold title per query, which makes precision at a cutoff dominated by the cutoff itself rather than by retrieval behaviour.

MARISA-Opt and FlashTrie return *identical* results at every beam width (Table 15). This is the public-artifact counterpart of the internal agreement reported in Section 4.6 (Table 2), and it states

Table 14: Per-request mean trie-search latency (ms) at K=600 under realistic production thresholds on the NQ + GENRE public workload, across the head-size sweep $r \in \{0, 9, 18, 150, 300, 600\}$. MARISA-Opt is the CPU baseline (8 worker threads, NUMA-local pinning); FlashTrie is the GPU implementation on a single A100 80 GB. The **Speedup** column reports CPU mean / GPU mean per row. Compared to the permissive-threshold sweep in Table 13, score-driven pruning ahead of the trie reduces CPU mean latency by $\approx 5\times$ and GPU mean by $\approx$ 2–4×, while the relative CPU-to-GPU mean speedup remains multi-× throughout (3–8×). **Lower is better for latency; higher is better for speedup.**

r	MARISA-Opt	FlashTrie	Speedup
0	8.95	1.54	5.8×
9	8.61	1.13	7.6×
18	8.45	2.83	3.0×
150	7.22	0.95	7.6×
300	6.78	0.91	7.4×
600	6.70	1.40	4.8×

Table 15: Retrieval quality (R@100) on the NQ+GENRE public workload (3,600 NQ-Open validation queries, ∼6M-title KILT trie) vs. beam width K. The two systems agree exactly at every K, confirming that GPU execution is constraint-equivalent to the CPU baseline. **Higher is better.**

K	100	600	1000
MARISA-Opt (R@100)	0.5369	0.5805	0.6194
FlashTrie (R@100)	0.5369	0.5805	0.6194

the intended property directly: FlashTrie changes the cost of constrained beam search, not its semantics. Quality improves monotonically with beam width, from 0.5369 at K=100 to 0.5805 at K=600 and 0.6194 at K=1000, an absolute gain of 0.083 (+15% relative) across the sweep, matching the mechanism described in Section 4.6.

The improvement is smaller than at production scale, as expected: the ∼6M-title library and ∼50k BART vocabulary give far lower branching than the 800M-keyword, 2.2M-token production setting, so fewer plausible prefixes are lost to early pruning and there is correspondingly less search error for a wider beam to recover. The public workload therefore validates the latency and constraint-equivalence claims directly, while the magnitude of the quality gain remains scale-dependent.

WARP: Wasserstein-Aligned RAG for Population Opinions

Aman Singh Thakur* **Aditya Agrawal** **Alwarappan Nakkiran** **Alex Karlsson**

Amazon.com

Abstract

RAG systems are increasingly used to summarize what large collections of documents say. A user asks "What do people think about X?" and receives an answer that reads as consensus. But standard top-k retrieval ranks documents by query similarity, not by how faithfully they represent the population, so minority views quietly disappear. Existing fixes fall short. Diversity re-rankers like MMR and DPP spread retrieved documents apart, but with no target distribution to aim for. Calibration methods based on KL or JS divergence do target one, yet treat opinion bins as unordered: confusing strong positive with strong negative costs no more than an adjacent-bin miss.

We introduce WARP, a family of post-retrieval algorithms that calibrate retrieved evidence to the population's opinion distribution. WARP first recovers underrepresented opinions that cosine ranking may bury, then uses Wasserstein-1 distance to select documents whose sentiment-intensity distribution matches the population target, capturing the ordinal structure ignored by KL and JS divergence. We develop three variants for dense, sparse, and variable candidate pools, trading off calibration quality and speed. Across three review domains spanning 35K documents, 156 queries, and 26 entities, WARP's domain-matched variants reduce distributional error by at least 43% with sub-second latency. These gains carry through to generation: a five-judge LLM panel prefers WARP-generated answers in up to 86% of decided comparisons at k=5.

1 Introduction

Users used to browse reviews themselves - clicking through results, weighing contradictions, building a mental picture. Noisy, but transparent: you could see disagreement. RAG systems (Lewis et al., 2020) replace this with a single synthesized answer, but a new failure mode emerges. Standard top-k retrieval selects evidence by query similarity, without factoring spread of opinions in the corpus. Take a hotel where 60% of reviewers are satisfied and 40% complain about noise. Retrieval over-represents the majority because similarity scoring favors the dominant cluster. Every claim in the resulting summary traces to a real review, yet the user never learns that two in five guests had a bad experience. This leads to distributional distortion. A synthesized response from a skewed sample would read factual but would not present the whole picture.

For opinion queries, uncertainty is aleatoric: it reflects genuine disagreement. A faithful system must preserve the distribution without collapsing it. Agrawal et al. (2026) formalize this distinction; Nayeem and Rafiei (2025) build a scalable opinion summarization pipeline but do not optimize the retriever for distributional fidelity. **What's missing is the engineering: in a production stack with sub-second latency budgets, how do you select a small evidence set whose opinion distribution actually matches the population?**

A standard cosine retriever maximizes query similarity, producing relevant but homogeneous evidence - four glowing reviews when two would suffice. Diversity re-rankers (MMR (Carbonell and Goldstein, 1998), DPP (Kulesza and Taskar, 2012)) push back by maximizing pairwise spread, which helps until each sentiment bin has one representative; past that point they quietly revert to relevance ordering. KL and JS calibration (Steck, 2018; Dang and Croft, 2012) come closer by explicitly optimizing against a target distribution. But they remain categorical. Confusing "positive" with "negative" costs the same as confusing "positive" and "neutral". Opinions are ordinal and we need a metric which supports this.

Wasserstein-1 respects this ordering. Its closed-form CDF computation ($O(m)$ for m sentiment bins) makes per-candidate evaluation cheap enough

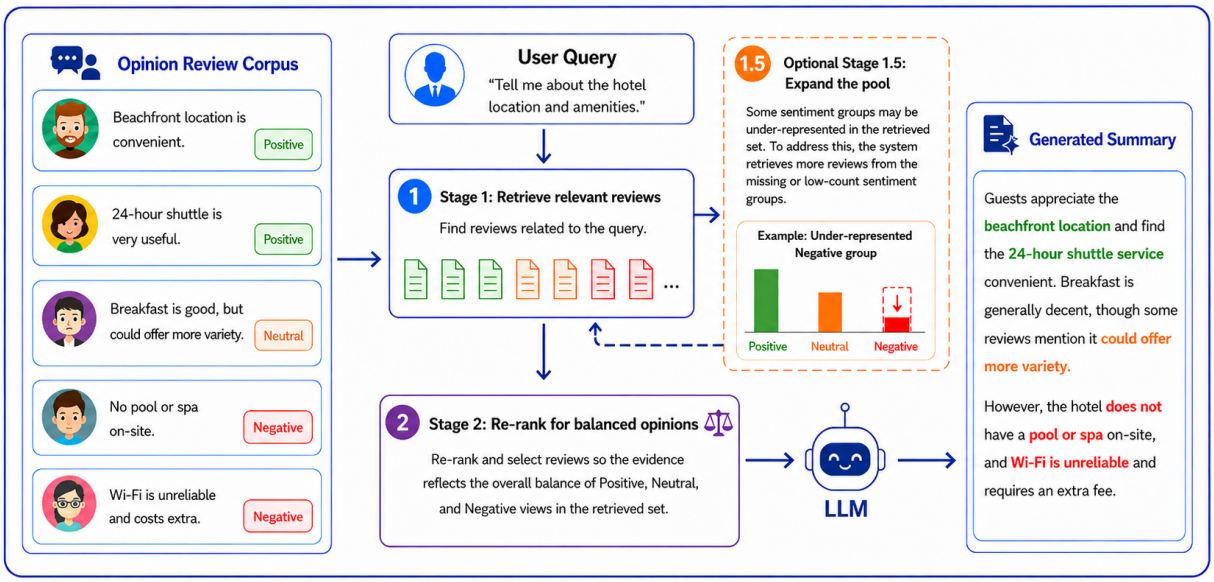

Figure 1: WARP pipeline. **Stage 1**: semantic retrieval returns a Top-N candidate pool. **Stage 1.5**: deficit-aware pool expansion recovers under-represented sentiment poles via re-retrieval (*Entity-Gated* or *Adaptive Expansion*; §3.3; self-bypasses when the pool is already balanced). **Stage 2**: W_1 re-ranking selects the final k documents whose empirical opinion distribution matches the population target P_{pop} (W_1 *Minimizer* for dense pools, W_1-*MMR* for sparse pools, or *WassRank OT* as a tuning-free fallback; §3.4). Pool density drives the variant choice (decision matrix in Table 3).

for runtime re-ranking without offline precomputation. We built WARP (Figure 1) around this in two stages. First, a deficit-aware pool expansion pass compares the retrieved distribution against the population target, identifies under-represented poles, and issues targeted re-retrievals only where gaps exist. Then a greedy re-ranker selects the final evidence set by minimizing W_1 distance to P_{pop}. The pipeline instantiates in three variants (Section 3.4): the Minimizer greedily selects from entity-matched candidates - effective for dense pools; for sparser conditions, W_1-MMR blends relevance with calibration, and WassRank OT solves the full slot-assignment as rectangular optimal transport requiring no per-domain tuning.

Our contributions:

1. **Pool expansion that recovers what cosine retrieval buries.** Entity-gated and adaptive re-retrieval recover under-represented opinions with near-complete entity coverage. Self-bypasses at zero cost when already balanced.

2. **W_1 re-rankers substantially reduce distributional error.** A greedy minimizer that matches opinion distribution for entity dense domains and the hybrid variants trade opinion diversity for relevance on sparse domains.

3. **Deployment characterization across 3 domains.** Pool density determines algorithm choice. All variants add under 310 ms re-ranking latency (p99) and generalize across labeling methods and index types.

2 Related Work

Retrieval diversity. MMR (Carbonell and Goldstein, 1998) penalizes redundancy via pairwise dissimilarity; DPP (Kulesza and Taskar, 2012) maximizes determinantal spread; xQuAD (Santos et al., 2010) diversifies over query intents. More recent variants-BQP (Lu and Sidiropoulos, 2026), AdaGReS (Peng et al., 2025), MUSS (Nguyen and Kan, 2026)-refine these ideas in various ways (see Wu et al. (2024) for a survey). However, diversity is the wrong objective here as the signal runs out, once every sentiment bin has one representative (5–7 selections).

Optimal transport (OT) in IR. Wasserstein distances (Peyré and Cuturi, 2019) have appeared in IR before-Word Mover's Distance (Kusner et al., 2015) for document similarity, WassRank (Yu et al., 2019) as a listwise training loss, OTExtSum (Tang et al., 2022) for extractive summarization, Wasserstein coresets (Claici et al., 2018) for data summarization. However, all these function at training time, over generic content. To our knowledge, none

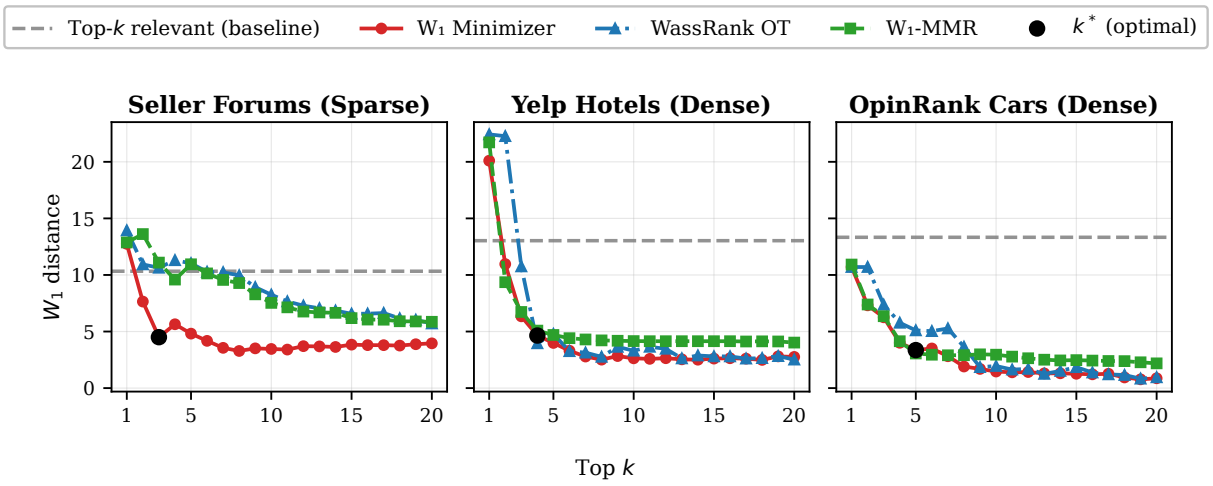

Figure 2: W_1 re-rankers (no re-retrieval): domain-matched variants reduce distributional error at least 43% vs. Top-k (gray dashed) — 43% Seller Forums (W_1-MMR), 80% Yelp (W_1 Minimizer), 69% OpinRank (W_1 Minimizer); see Table 1. Curves converge at k^*=3–5 documents (black dot; Appendix C.3) as most entities' opinion mass concentrates in 2–3 of 7 bins. N=200.

use Wasserstein as a *runtime* selection objective conditioned on an opinion distribution.

Opinion-aware retrieval. Agrawal et al. (2026) audit 30+ RAG benchmarks and find a striking gap: only one addresses opinion synthesis. They formalize the epistemic/aleatoric distinction - the posterior converges to the population distribution $P_{\text{pop}}(\theta)$ for opinion queries - and propose a three-term objective combining coverage (W_2), fidelity, and demographic fairness. However, their work is limited to 2 domains without practical retrieval strategies. Nayeem and Rafiei (2025) solve a different problem entirely: generating opinion highlights from thousands of reviews via retrieve-then-synthesize with AOS-triplet verification. Their retriever is standard semantic search without targeting distributional fidelity. We instantiate the Agrawal et al. (2026) coverage objective using W_1 instead of W_2 - its closed-form CDF difference enables $O(m)$ per-candidate evaluation at runtime - and test across three domains.

Calibrated selection and diversity methods. Calibrated recommendation via KL minimization (Steck, 2018) and proportional slot allocation (PM-2; Dang and Croft 2012) do address distributional fidelity across facets - but assume categorical labels. Fairness-aware ranking (Singh and Joachims, 2018; Zehlike et al., 2017; Oesterling et al., 2024) enforces demographic constraints without modeling ordinal opinion at all. On the sentiment side, Aktolga and Allan (2013) applies bias modes to retrieval, aspect-level summarization (Angelidis and Lapata, 2018; Jiang et al., 2023) diversifies across topical facets. The methods we surveyed all use categorical penalty structures that do not exploit ordinal distance between opinion bins. WARP addresses this gap: an ordinal W_1 ground cost applied at query time to opinion-distribution matching in RAG, drawing on the calibrated-selection tradition (Steck, 2018) and OT-in-ranking (Yu et al., 2019) while adapting both to a training-free runtime re-ranker across three review domains.

3 Methodology

Below we describe the experimental setup (Sections 3.1–3.2), pool expansion (Section 3.3), and W_1 re-ranking (Section 3.4) for stress-testing WARP.

3.1 Datasets

3 review corpora give us the spread we need across different domains:

- **Amazon Seller Forums**[1] (∼8K documents). Retrieved via Amazon Bedrock Knowledge Bases (Amazon Web Services, 2024b) with hybrid search.
- **Yelp Open Dataset** (Yelp, 2024) (∼14K hotel reviews). Retrieved via local FAISS (Johnson et al., 2019) + MiniLM-L6 (Wang et al., 2020; Reimers and Gurevych, 2019).

[1] https://sellercentral.amazon.com/seller-forums

- **OpinRank** (Ganesan and Zhai, 2012) ($\sim$13K automotive reviews). Retrieved via local FAISS + MiniLM-L6.

Entity selection follows Agrawal et al. (2026): LLM-based entity extraction, diversity filtering (Shannon entropy $H \geq 0.6$, minority sentiment $\geq 10\%$), then ranking by entropy.

We use six questions per entity (2 breadth, 2 polar, 2 segment; templates in Appendix A.2) which gives us 156 total queries, across all domains. Entity and sentiment-intensity labels come from a single LLM pass per document (prompt in Appendix A.3.1), mapped to a 7-bin ordinal scale $\mathcal{S} = \{-30, -20, -10, 0, +10, +20, +30\}$ (Table 4, Appendix A.1).

Full dataset statistics appear in Table 5 (Appendix A.1).

Defaults: N=200 candidate pool, k=20 output.

3.2 Baselines

Five baselines. Top-k is plain cosine-similarity retrieval. MMR (Carbonell and Goldstein, 1998) penalizes semantic redundancy (λ=0.5). DPP (Kulesza and Taskar, 2012) maximizes determinantal spread over 1D sentiment-intensity features. OpinionMMR penalizes opinion-bin distance rather than embedding distance. KL (JS) Minimizer implements Steck (2018)'s calibrated-recommendation objective with Jensen–Shannon divergence - identical to our W_1 Minimizer but with an order-agnostic metric (Appendix C.1).

Metrics. Distributional fidelity: Wasserstein-1 distance W_1 (lower is better). Entity relevance: Entity Match rate (EM%, hereafter EM; fraction of selected documents matching the queried entity, higher is better). We also report re-ranking latency in milliseconds. For generation evaluation, Cohen's κ (Cohen, 1960) measures inter-judge alignment.

3.3 Pool Expansion via Re-Retrieval

For entity sparse domains, the relevance-based retrieval step typically returns a substantial fraction of documents that do not discuss the queried entity - due to near-misses leaked in from other entities sharing the same index. We tackle this with two expansion strategies (full algorithms in Appendix B):

Entity-Gated Re-retrieval. Pass 1 pulls the standard top-N by relevance. Pass 2 then digs into the tail of the ranked list, fishing out documents that match the queried entity but fell below the cutoff, ranking them by opinion extremity (absolute sentiment-intensity score - strongly negative reviews surface before mild ones). The passes are merged and deduplicated.

Algorithm 1 W_1 Minimizer

Require: Pool C, entity e, target P_{pop}, output size k

$C_e \leftarrow \{d \in C : \text{entity}(d) = e\}$
$S \leftarrow \emptyset$
while $|S| < k$ **do**
  $d^* \leftarrow \arg\min_{d \in C_e \setminus S} W_1(\text{EmpDist}(S \cup \{d\}), P_{\text{pop}})$
    ties broken by relevance score $\downarrow$
  $S \leftarrow S \cup \{d^*\}$
end while
return S

Adaptive Expansion. We compare the pool's opinion breakdown against P_{pop}. If any bin is under-represented (pool fraction below threshold of the population fraction), a targeted retrieval fires for entity-matched documents in the deficit bin using pole-biased queries (Prompt A.3.4.1). If the pool already mirrors the target, nothing happens - zero overhead (Algorithm 3).

3.4 Wasserstein Re-Ranking Algorithms

Problem Formulation. For opinion queries, a faithful answer must reflect how viewpoints distribute along an ordinal axis - one where positions have a natural ordering and distances between them reflect severity of disagreement. The re-ranking objective follows directly: select k documents whose empirical distribution along this axis minimizes transport distance to the target distribution P_{pop}. We instantiate the axis as sentiment-intensity (SI), a 7-bin ordinal scale $\mathcal{S} = \{-30, -20, \ldots, +30\}$. At indexing time each document d receives an SI label; per entity e we derive $P_{\text{pop}}(s)$ as the corpus-observed fraction of documents for e in each bin, or as an externally-specified target (star ratings, survey-calibrated priors) when one is available — P_{pop} is an input to the re-ranker, not a claim about the true underlying population (§Limitations; tolerance to partial estimates in Section 4.4). Given a candidate pool C of N documents, pick $k \ll N$ into result set S minimizing:

$$W_1(P, Q) = \sum_{i=1}^{m-1} |\text{CDF}_P(s_i) - \text{CDF}_Q(s_i)| \cdot \Delta s \quad (1)$$

Table 1: Main results: Diversity baselines and calibrated methods vs WARP re-rankers. $W_1\downarrow$: distributional distance to the population opinion target. EM%↑: fraction of selected documents matching the queried entity. EG/AE = pool expansion strategies (Entity-Gated / Adaptive Expansion). N=200 candidates, k=20 output. Paired Wilcoxon vs. Top-k: $^{***}p<0.001$, $^{**}p<0.01$, $^{*}p<0.05$. Bold: best per column. †Shared FAISS index across all OpinRank entities (EM=82.9%); entity-specific indices give W_1=0.95 with 100% EM (Appendix F.3).

	Seller Forums		**Yelp Hotels**		**OpinRank Cars**		**Latency**
Method	$W_1\downarrow$	EM%	$W_1\downarrow$	EM%	$W_1\downarrow$	EM%	**(ms)**

where CDF is the cumulative distribution function, m=7 bins, and Δs=10 is the bin spacing. The ordinal structure matters: confusing $+30$ with -30 costs $W_1^{\max}$=60, while adjacent-bin errors cost only 10. Evaluation runs in $O(m)$ per candidate; we observe empirically that rank ordering is preserved under W_2 (Appendix C.4).

We implemented three variants that minimize this objective. They differ in how they cope with entity pool density and the relevance-calibration tradeoff:

W_1 Minimizer. Filter the pool to entity-matched candidates, then greedily add whichever document pulls the empirical distribution closest to P_{pop}, breaking ties by relevance score (Algorithm 1). Needs a dense pool where most candidates match the queried entity.

W_1-MMR. Built for sparse pools where entity-matched candidates alone cannot fill k slots. This variant works on the full candidate set - no entity filtering - and scores each candidate by blending retrieval relevance with the calibration gain it would contribute:

$$\text{score}(d) = \lambda \cdot \text{rel}(d) + (1-\lambda) \cdot \frac{\Delta W_1}{W_1^{\text{cur}}} \qquad (2)$$

$\text{rel}(d)$ is the original retrieval score, λ controls the relevance-calibration blend, and dividing by W_1^{cur} normalizes to percentage improvement so the calibration term does not vanish as the distribution tightens. Full algorithm in Appendix B.3.

WassRank OT. Instead of greedy selection, WassRank (Yu et al., 2019) solves the assignment globally: allocate k slots proportionally to P_{pop}, then find the minimum-cost candidate-to-slot bijection where cost blends normalized ordinal distance with a relevance penalty. This minimizes blended transport cost to a proportional discretization of P_{pop}, which empirically tracks W_1 (Appendix F.3). We solve the rectangular assignment (Crouse, 2016) in $O(k^2 \cdot N)$. Originally a listwise training loss; we repurpose it here as an inference-time re-ranker with no learned parameters and call it WassRank OT.

4 Results

Four questions drove our experiments: does it work, does the metric choice matter, do retrieval gains actually reach the user, and which variant belongs where? Sections 4.1–4.4 take them in order.

4.1 Main Results

In Table 1, the gains are large and consistent, concentrating on entities with the most skewed baseline distributions (per-entity breakdowns in Appendix C.5). Our domain-matched W_1 re-ranking algorithms (Section 3.4) cut distributional error (Equation 1) by at least 43% relative to Top-k — 43% on sparse Seller Forums (W_1-MMR), 80% on dense Yelp (W_1 Minimizer, rising to 89% with pool expansion), and 69% on OpinRank (W_1 Minimizer). Entity relevance tracks along: pairing Entity-Gated re-retrieval (Section 3.3) with W_1 Minimizer pushes Yelp EM% from 40.1% (Top-k baseline) to 99.2% (post-reranking). As a sanity check, 5% Gaussian perturbation of retrieval scores yields only 2–5% W_1 improvement, non-

significant. This confirms that the score structure drives these results and not the arbitrary reshuffling. (Appendix F.2)

4.2 The Ordinal Metric Makes a Measurable Difference

The metric matters. Swapping JS divergence for W_1 while keeping the same greedy loop and entity filtering cuts error by 8.7% on Yelp and 9.7% on OpinRank (Appendix C.1). JS penalizes a $+30 \leftrightarrow -30$ confusion no more than an adjacent-bin slip; W_1 charges six times more. Entity filtering alone accounts for 45.7% W_1 reduction on Yelp; W_1 Minimizer adds 62.6% beyond that, and on entity sparse domains, like Seller Forums, W_1-MMR adds 37.7% beyond the entity-filter baseline (Appendix C.2). We also stress-tested under noise: corrupting both SI labels and P_{pop} simultaneously, W_1 Minimizer never falls below Top-k even at 50% label error on dense pools, and still outperforms Top-k by 72% at 20% Dirichlet perturbation (Appendix F.1).

4.3 Retrieval Gains Propagate to Generation

Do retrieval gains actually reach users? We generated answers from each method's retrieved evidence (prompt in Appendix A.3.2) and ran blind pairwise comparisons against Top-k using a 5-judge LLM panel (Claude Sonnet 4 (Anthropic, 2025), Llama 3.3 70B (Meta, 2024), Mistral Large 3 (Mistral AI, 2025), Amazon Nova Pro (Amazon AGI, 2025), DeepSeek v3.2 (DeepSeek-AI, 2025)) with position control (Zheng et al., 2023) and 3/5 majority vote (Appendix G.1). All five judges from independent model families agree directionally at κ_d=0.61–1.00; the random baseline correctly shows no significance.

At k=5, calibration methods win 70–89% of decided comparisons (Table 2). At k=10 this drops to 73–88% (Table 20) as larger context lets the LLM average out distributional imbalance (Appendix G.1.3). A prompt ablation (Appendix G.1.4) disentangles two evaluation criteria: when judges assess *proportional accuracy* (does the answer reflect how common each view is?), W_1 Minimizer leads DPP by 8 pp and matches an oracle stratified-sampler within 1 pp (Table 21); under pure *viewpoint coverage* (does it mention all perspectives?), the gap narrows to parity. W_1's proportional advantage persists through generation, not just retrieval.

Table 2: Generation evaluation (k=5): 5-judge majority vote, position-controlled blind pairwise vs. Top-k (N=156 queries). Fair% = W/(W+L). Win% = W/N. All approaches significant at $p<0.001$ (sign test) except Random. k=10 in Appendix G.1.3.

Approach	W/L/T	Fair%	Win%
Random	16/36/104	31%	10%
MMR*	39/8/109	83%	25%
DPP*	54/7/95	**89%**	35%
WassRank OT*	66/28/62	70%	**42%**
W_1-MMR*	44/10/102	81%	28%
W_1 Minimizer*	51/8/97	**86%**	33%

Metric isolation. On sparse pools, W_1-MMR appears to lose to KL(JS)-MMR (Appendix C.1), but the comparison is confounded: KL(JS)-MMR selects 1.7–2× more entity-matched documents than W_1-MMR on Yelp and OpinRank. Once we control for EM%, the Minimizer comparison flips: W_1 wins on both domains (Appendix C.1), and a single-judge generation evaluation confirms the same direction, with W_1 Minimizer leading KL(JS) Minimizer by 7 pp Fair% cross-domain (Appendix G.2).

Two other patterns are worth noting. First, semantic-diversity baselines fade as k grows: MMR and OpinionMMR Fair% collapse to 29–33% at k=20, while distributional methods keep gaining (WassRank OT: 70%→73%→92% across $k\in\{5, 10, 20\}$; Appendix G.1.3). Second, DPP and W_1 optimize different targets — bin diversity vs. bin ratios — which happen to align at k=5 with 2–3 active bins but diverge at k=20. On OpinRank, near-uniform P_{pop} compresses ordinal distances, so the KL/W_1 gap narrows; the ordinal advantage is largest where distributions are skewed (Yelp, Seller Forums).

4.4 Deployment Characterization

Which algorithm to pick comes down to one number: entity match percentage (Table 3). Dense pools, where all retrieved documents discuss the query entity, are easy. When EM≥85%, W_1 Minimizer delivers 69–81% reduction, statistically indistinguishable from oracle stratified sampling. Entity-Gated re-retrieval pushes Yelp further (W_1: 2.76→1.52, EM%: 93.8→99.2); on OpinRank both expansion strategies detect no deficit and self-bypass. Sparse entity pools are a different story. On Seller Forums (Top-k baseline EM∼40%; W_1 Minimizer reaches ∼51% post-reranking), W_1-MMR scores all 200 candidates regardless of entity match,

Table 3: Deployment decision matrix. Pool density determines algorithm choice; all methods SLA-compliant (N=200, k=20, m=7 bins). $|C_e|$ = entity-matched candidates. Noise tolerance details in Appendix F.1.

Pool Condition	Method	ms	Complexity
Dense (EM≥85%)	W_1 Minimizer	9	$O(\|C_e\| \cdot k \cdot m)$
Sparse (baseline EM∼40%)	W_1-MMR	154	$O(N \cdot k \cdot m)$
Variable / unknown	EG + W_1 Min	13	$O(\|C_e\| \cdot k \cdot m)$

reaching 43% reduction while maintaining 81% generation propagation (Table 2). This outperforms WassRank OT (70%) despite comparable retrieval-side W_1, making W_1-MMR the preferred hybrid for sparse and variable pools. Re-ranking latency stays under 310 ms across the board; end-to-end depends on retrieval infrastructure (Appendix B.5). For dense pools N=100 suffices; W_1-MMR benefits from larger N on sparse pools (Appendix F.3).

An exact P_{pop} turns out to be unnecessary: fifty entity-matched documents preserve 74–98% of oracle improvement; smoothing with a domain prior (τ=50) matches the oracle's harm rate. Cold-start entities fall back to this prior while still beating Top-k (Appendix F.4). The pipeline runs unchanged across managed cloud vector stores and local FAISS indices.

4.5 Independent-Target Validation

A natural concern is circularity: our LLM-derived sentiment-intensity (SI) labels define both the population target P_{pop} used at inference and the W_1 metric applied to the retrieved evidence. If the labeler had systematic biases, calibrating and measuring against it could inflate the numbers. To rule this out, we cross-validate against Yelp's native 1–5 star ratings on all 13,533 reviews. Stars are ordinal, human-authored at review time, and participate in *no part* of the WARP pipeline — neither retrieval, nor re-ranking, nor the P_{pop} target. Mapped to the same 7-bin SI scale, star-derived and LLM-derived labels correlate at Spearman ρ=0.881 ($p<10^{-300}$) and Pearson r=0.908, with 81.3% same-valence agreement and MAE 7.2 SI units — less than one bin (Appendix E).

Correlation on individual labels is necessary but not sufficient; a labeler could still consistently mis-estimate the entity-level P_{pop}. We therefore recompute P_{pop} from star ratings alone for each of the 10 Yelp entities and evaluate WARP's retrievals against this fully independent target. Mean W_1 gap between star-derived and LLM-derived P_{pop}: 2.88 (Appendix Table 16). Triangle inequality then gives $W_1(\text{WARP}, \text{star-}P_{\text{pop}}) \leq 5.64$ and $W_1(\text{Top-}k, \text{star-}P_{\text{pop}}) \geq 10.72$, i.e., a worst-case reduction of at least 47.4% *against a target our labels never touched*. This complements the mislabel sensitivity study (Appendix F), where W_1 Minimizer never crosses the Top-k baseline on Yelp even at 50% label corruption, along with the FDR-corrected significance testing and entity-clustered bootstrap in Appendix D. The gains are not an artifact of the labeler or of any single evaluation protocol.

5 Conclusion

As enterprise document corpora grow, RAG systems have become the default interface between users and organizational knowledge, returning relevant evidence in sub-second re-ranking latencies. Yet when the underlying corpus is diverse and highly opinionated, relevance-ranked retrieval selects only for topical similarity; the retrieved set may not reflect population opinions proportionally, producing summaries that appear grounded but misrepresent the balance of views.

WARP closes this gap by re-ranking retrieved evidence against the target population distribution, requiring no model fine-tuning, no retriever changes, and no additional inference calls. The result is at least a 43% reduction in distributional distance to the population target (W_1), all within a 310 ms latency envelope suitable for production deployment.

Limitations

Offline evaluation under production constraints. All reported results come from offline experiments, engineered to satisfy the sub-310 ms *re-ranking* budget typical of a large-scale e-commerce RAG setting (end-to-end depends on retrieval infrastructure; Appendix B.5). We therefore characterize retrieval and generation-side fidelity, not live user outcomes: whether proportionally faithful summaries measurably shift user trust, engagement, or decision quality under live traffic is untested, and offline W_1 reductions need not map one-to-one onto user-perceived faithfulness. A controlled online A/B test is the natural next step.

Corpus bias vs. retrieval bias. P_{pop} is *corpus-observed*, not a true population target: review corpora are self-selected, motivated writers with strong positive or negative experiences are over-represented, and some segments never write at all.

WARP removes the *retrieval-induced* bias — Top-k layers cosine-similarity skew on top of the underlying corpus bias — but does not remove the corpus bias itself. Faithful matching over a biased sample can lend false authority: the summary reflects the writers' distribution, not the underlying population's. Because P_{pop} is an *input* to the re-ranker rather than something it learns, external signals (native star ratings, demographic priors, survey-calibrated distributions) can be plugged in directly to reweight the target — a natural extension requiring no architectural change.

Pre-computed labels required. Per-document sentiment-intensity annotations are needed at indexing time. A single LLM pass suffices, and 50–100 labels per entity are enough - but the cost–quality tradeoff of labeling strategies is not evaluated.

Scale and Temporal Drift. 156 queries across 26 entities; paired Wilcoxon provides adequate power, but scaling beyond 14K documents is untested. P_{pop} degrades gracefully under perturbation (72% better than Top-k at ε=0.2) but temporal drift is not addressed.

Single ordinal axis; multi-issue opinions. WARP operates on a single ordinal axis (sentiment intensity). Multi-issue opinion spaces — e.g., a review that praises price but criticizes support, or patient-experience, employee-engagement, and multi-issue polling settings where several stance dimensions matter jointly — would require multi-marginal optimal transport, a natural extension we do not evaluate here.

Domain scope and generation. All domains are product/service reviews requiring entity-anchored opinions and an ordinal scale. Generation significance is driven by Yelp (97% decided) and OpinRank (94%); Seller Forums differentiates weakly (54%) due to sparse pools. A prompt ablation (Appendix G.1.4) shows reported gaps are criterion-dependent.

Ethics Statement

Distributional fidelity proportionally surfaces minority views, including potentially harmful ones. A content-safety filter should gate re-ranker output: excluded opinions are removed from both P_{pop} and the candidate pool *before* calibration. Because re-ranking is post-retrieval, it is compatible with any upstream safety filter without modification.

Use of AI Writing Assistance

The research (design, experiments, analysis, and writing) is the authors' own work. We used Claude (Anthropic) as a proofreader and sounding board: it flagged unclear phrasing, suggested structural edits, and helped scaffold parts of the experimental code, all of which we reviewed and revised ourselves. Figure 1 was generated with ChatGPT (OpenAI) to give readers a quick visual overview of the pipeline; we verified its accuracy. No AI system produced research claims or final prose.

A Experimental Setup

A.1 Dataset Details

Opinion Scale. Sentiment-Intensity (SI) is mapped to a discrete ordinal scale, shown in Table 4.

Table 4: Sentiment-Intensity (SI) mapping to the 7-bin ordinal scale. *Mixed* labels (praise-and-criticism co-occurring in one review) collapse to the neutral bin; they account for 4–8% of extractions across domains and W_1 Minimizer never crosses the Top-k baseline on Yelp even at 50% label corruption (§F.1), so this pooling is bounded in impact. Multi-issue axes require multi-marginal transport — outside our current scope (§Limitations).

Sentiment	Intensity	SI Score
Positive	High / Med / Low	+30 / +20 / +10
Neutral	Any	0
Mixed	—	0
Negative	High / Med / Low	-30 / -20 / -10

Entity Selection. Three stages. First, LLM-based entity extraction with domain-specific seed lists. Then diversity filtering: Shannon entropy $H \geq 0.6$, minority sentiment $\geq 10\%$, mention count ≥ 100. Finally, top-n selection ranked by entropy descending.

A.2 Query Templates

Table 6 lists the exact query templates used to generate evaluation questions. Each entity is instantiated into all 6 templates, yielding 156 total queries (36 Seller Forums + 60 Yelp + 60 OpinRank).

Entities. **Seller Forums** (6): A+ Content, Account Health Rating, Brand Stores, Community Management, Coupons, Seller Education. **Yelp Hotels** (10): Booking Experience, Breakfast, Breakfast Quality, Business Center, Casino, Loyalty Program, Nightly Rate, Pool, Room Quality, Shuttle Service. **OpinRank Cars** (10): Oil Change Interval, Dealer Experience, Vehicle Size, Sales Experience, Fuel Tank Size, Resale Value, City MPG, Remote Start, Climate Control, Ground Clearance.

A.3 Prompt Library

All prompts used in the WARP pipeline. Template variables shown in `{braces}`.

A.3.1 Opinion Extraction

Prompt A.3.1.1: Registry-Guided Extraction (Open-Domain)

A single LLM call per document extracts entities and sentiment-intensity labels using a domain-specific tiered seed list while remaining open to discovering new entities.

Table 5: Dataset summary across three evaluation domains.

Dataset	Domain	Source	Size	Entities	Queries	Search	Embedding	Chunking	Labeling
Seller Forums	E-comm. seller	Public	∼8K	6	36	Hybrid	Titan V2 (Amazon Web Services, 2024a) (1024d)	300 tok / 20% overlap	LLM-enriched metadata
Yelp Hotels	Hospitality	Yelp Open	14K	10	60	Semantic	MiniLM-L6 (384d)	Whole review	LLM-extracted (Claude)
OpinRank Cars	Automotive	OpinRank	13K	10	60	Semantic	MiniLM-L6 (384d)	Whole review	LLM-extracted

Table 6: Query templates per domain. Each template is instantiated with every selected entity (6 for Seller Forums, 10 for Yelp/OpinRank), producing 6 questions per entity (2 breadth, 2 polar, 2 segment).

Type	Idx	Seller Forums	Yelp Hotels	OpinRank Cars
breadth	0	What do sellers think about {entity}?	What do guests think about {entity}?	What do owners think about {entity}?
breadth	1	Summarize seller opinions on {entity}.	Summarize guest opinions on {entity}.	Summarize owner opinions on {entity}.
polar	0	What are the biggest complaints about {entity}?	What are the biggest complaints about {entity}?	What are the biggest complaints about {entity}?
polar	1	What positive experiences have sellers had with {entity}?	What positive experiences have guests had with {entity}?	What do owners praise most about {entity}?
segment	0	How do small sellers vs large sellers feel about {entity}?	How do business travelers vs leisure travelers feel about {entity}?	How do commuters vs enthusiasts feel about {entity}?
segment	1	Do new sellers and experienced sellers differ in their views of {entity}?	Do solo guests and families differ in their views of {entity}?	Do new buyers and long-term owners differ in their views of {entity}?

System: You extract structured opinion data from reviews. Output ONLY valid JSON arrays. No markdown, no explanation.

User: Extract entity-level opinions from this review.

`[{registry_block} -- domain-specific tiered entity list injected here]`

Instructions:
1. Identify ALL entities/aspects the reviewer discusses.
2. If an entity matches the registry above, use the EXACT registry name. Prefer the most specific tier (Tier 3 > Tier 2 > Tier 1).
3. If the reviewer discusses something NOT in the registry, create a short descriptive entity name (open discovery).
4. For EACH entity mentioned, output:
- entity: the entity name (registry canonical or new)
- sentiment: "positive", "negative", "neutral", or "mixed"
- intensity: "high", "medium", or "low"
- evidence: exact quote from the review supporting this opinion (max 120 chars)

Only include entities explicitly discussed. Return `[]` if none found.
Output ONLY a JSON array.

Review:
`{review_text}`

For closed-domain settings (e.g., Yelp Hotels), the extraction prompt uses a fixed aspect list with keyword mappings instead of the tiered registry, but the output schema is identical.

A.3.2 Answer Generation

Prompt A.3.2.1: Opinion Summary Generator

Instructs the LLM to synthesize a proportional opinion summary from retrieved documents.

System: You are summarizing community opinions from review data. Use ONLY the provided documents. Represent opinions proportionally — include minority views, not just the majority. Be specific and cite reviewer experiences where possible.

User: Question: `{question}`

Reviews:
`{docs}`

Summarize what the community thinks. Be thorough — cover the full range of opinions proportionally.
Do not add opinions beyond what's in the documents.

A.3.3 Pairwise Generation Evaluation (Judge)

Each answer pair is evaluated via position-controlled blind pairwise comparison (positions swapped in the second call for debiasing). The judge scores three dimensions; the OPINION FAIRNESS dimension is swapped between variants in our ablation (§G.1.4).

Prompt A.3.3.1: Pairwise Judge Template

Full evaluation template: blind comparison on opinion fairness, informativeness, and groundedness.

System: You are an expert evaluator comparing two answers that summarize community opinions. You do NOT know which retrieval method produced which answer. Judge strictly on the quality of the answers themselves.

User: You are evaluating two answers to the same question about community opinions. Both answers were generated from different sets of reviews retrieved for the same question.

Question: `{question}`

— Answer A —
`{answer_a}`

— Answer B —
`{answer_b}`

Compare the answers on these dimensions. For each, pick "A", "B", or "tie":

1. OPINION FAIRNESS: `[fairness variant inserted -- see Prompts A.3.3.2 and A.3.3.3 below]`

2. INFORMATIVENESS: Which answer is more helpful, specific, and actionable for someone trying to understand what the community thinks? Consider breadth of points covered, specificity, and usefulness.

3. GROUNDEDNESS: Which answer appears more grounded in actual community member experiences? Look for attribution to specific perspectives vs vague generalizations that could be hallucinated.

Respond ONLY with JSON:

```
{"fairness": "A"|"B"|"tie",
"informativeness": "A"|"B"|"tie",
"groundedness": "A"|"B"|"tie",
"reasoning": "<1-2 sentences>"}
```

The baseline evaluation uses a generic fairness instruction ("which answer more proportionally represents the full range of community opinions, including minority views?"). Our ablation replaces it with the two variants below.

Prompt A.3.3.2: Fairness Variant A — Proportional Accuracy

Provides ground-truth P_{pop} to the judge; penalizes over-representing minority opinions.

OPINION FAIRNESS (Proportional Accuracy): The actual community opinion distribution for this topic is: `{p_pop_description}`. Which answer more accurately reflects these real proportions? The ideal answer should make the reader walk away with a correct sense of how common each view is: a dominant opinion should dominate the summary, a rare opinion should be mentioned but not over-emphasized. An answer that gives equal weight to a 10% minority and a 70% majority is MISLEADING, even if well-intentioned. Pick the answer whose emphasis better matches the actual distribution above.

Where `{p_pop_description}` is dynamically filled per entity from the ground-truth P_{pop}, e.g.: "approximately 65% positive (mostly satisfied), 25% negative (dissatisfied), 10% neutral."

Prompt A.3.3.3: Fairness Variant B — Viewpoint Coverage

Rewards distinct viewpoint coverage; favors surfacing rare perspectives even if disproportionate.

OPINION FAIRNESS (Viewpoint Coverage): Which answer covers MORE DISTINCT VIEWPOINTS from the community, giving voice to all perspectives including rare and minority ones? An answer that only represents the majority view — even if that majority is large — is LESS fair than one that surfaces unique perspectives readers might not otherwise encounter. The ideal answer ensures no viewpoint goes unheard, even if that means giving disproportionate space to rare opinions.

A.3.4 Retrieval Augmentation

Prompt A.3.4.1: Pole-Biased Multi-Query Templates

During pool expansion (Stage 1.5), three sentiment-pole queries recover documents that cosine retrieval buries.

Positive: What positive experiences have sellers had with `{entity}`?

Negative: What are the biggest complaints about `{entity}`?

Neutral: What factual information do sellers share about `{entity}`?

Evaluation queries (6 per entity) are generated from three templates—breadth ("What do `{persona}` think about `{entity}`?"), polar ("What are the biggest complaints..."), and segment ("How do `{segment_A}` vs `{segment_B}` feel...")—with domain-adapted persona and segment terms (e.g., "sellers" / "small sellers vs large sellers").

B Algorithm Details

Table 7 summarizes the key symbols used throughout.

Table 7: Notation reference.

Symbol	Meaning
d	A candidate document
e	Target entity
k	Output size (documents returned)
N	Candidate pool size
$SI(d)$	Sentiment-intensity label of d
P_{pop}	Ground-truth population distribution
P_{pool}	Pool-level empirical distribution
$W_1(P, Q)$	Wasserstein-1 distance between P and Q
λ	Relevance–calibration trade-off weight
δ	Deficit threshold for pool expansion
n_{exp}	Budget (docs per deficit pole)
$\text{rel}(d)$	Relevance score of document d
EM	Entity-matched subset of pool

B.1 Entity-Gated Re-retrieval

The two-pass entity-gated pool construction recovers entity-matched documents that pure relevance ranking buries.

Algorithm 2 Entity-Gated Re-retrieval

Require: Results R (by score), entity e, sizes n_1, n_2, threshold τ

$P_1 \leftarrow R[1 : n_1]$ (top-n_1 by relevance)
$C_2 \leftarrow \{d \in R \setminus P_1 : \text{entity}(d) = e \wedge \text{score}(d) \geq \tau\}$
Sort C_2 by $|SI(d)|$ descending
$P_2 \leftarrow C_2[1 : n_2]$
Pool $\leftarrow$ dedup$(P_1 \cup P_2)$, sorted by score
return Pool

B.2 Adaptive Distribution-Aware Pool Expansion

When entity-matched documents under-represent a sentiment pole relative to P_{pop}, pole-biased queries (§A.3.4) retrieve additional candidates before re-ranking. The cold-start path (EM $= \emptyset$) treats every pole with non-negligible mass as a deficit, ensuring new entities still receive balanced pools. In practice, one to three deficit poles trigger per entity; n_{exp} caps total expansion cost at a fixed multiple of k.

Algorithm 3 Adaptive Pool Expansion

Require: Pool C_0, entity e, P_{pop}, threshold δ, budget n_{exp}

EM $\leftarrow \{d \in C_0 : \text{entity}(d) = e\}$
if EM $= \emptyset$ **then**
  DeficitPoles $\leftarrow \{s : P_{\text{pop}}(s) > 0.01\}$
else
  $P_{\text{pool}}(s) \leftarrow |\{d \in \text{EM} : SI(d) = s\}|/|\text{EM}|$
  DeficitPoles $\leftarrow \{s : P_{\text{pool}}(s) < \delta \cdot P_{\text{pop}}(s)\}$
end if
if DeficitPoles $= \emptyset$ **then**
  return C_0
end if
Retrieve n_{exp} entity-matched docs per deficit pole
Pool $\leftarrow$ dedup$(C_0 \cup C_{\text{exp}})$
return Pool

B.3 W_1-MMR

The W_1-MMR variant blends relevance with marginal Wasserstein reduction, mirroring the MMR trade-off while targeting distributional calibration rather than pairwise dissimilarity.

Algorithm 4 W_1-MMR

Require: Pool C, scores rel$(\cdot)$, target P_{pop}, λ, size k

$S \leftarrow \emptyset$
while $|S| < k$ **do**
  $W_1^{\text{cur}} \leftarrow \begin{cases} 60 & \text{if } S = \emptyset \\ W_1(\text{EmpDist}(S), P_{\text{pop}}) & \text{else} \end{cases}$
  for each $d \in C \setminus S$ **do**
    $\Delta W_1 \leftarrow W_1^{\text{cur}} - W_1(\text{EmpDist}(S \cup \{d\}), P_{\text{pop}})$
    $\text{score}(d) \leftarrow \lambda \cdot \text{rel}(d) + (1-\lambda) \cdot \Delta W_1 / W_1^{\text{cur}}$
  end for
  $d^* \leftarrow \arg\max_{d \in C \setminus S} \text{score}(d)$
  $S \leftarrow S \cup \{d^*\}$
end while
return S

B.4 Label Acquisition

Per-document SI labels come from a single LLM pass at indexing time (<200 ms/doc). Labeling is cheap. The Seller Forums corpus (∼8K documents) labels in under 4 minutes with 150 concurrent workers. P_{pop} is just a count aggregation per entity ($O(n)$, milliseconds); incremental updates on ingestion avoid recomputation entirely.

B.5 End-to-End Latency Breakdown

Hardware. Intel Xeon Platinum 8175M @ 2.50 GHz, 8 cores (single-threaded execution), no GPU.

WARP's re-ranking step runs entirely in NumPy on the retrieved candidate distribution — no additional model calls. End-to-end latency therefore decomposes into three components (Table 8):

Re-ranking latency is dominated by CDF differencing over m=7 bins and is backend-independent. Retrieval and re-retrieval dominate managed-endpoint deployments; for local FAISS the whole pipeline fits inside a 500 ms sub-second SLA.

The W_1 Minimizer's near-zero p50 on Seller Forums (0.1 ms) reflects the sparse entity-filtered pool: few candidates match the queried entity, so the greedy loop terminates almost immediately. p99 stays under 310 ms across all WARP variants on both domains, and end-to-end with local FAISS retrieval fits in <365 ms — comfortably inside a sub-second SLA. Managed vector stores add ∼1.5 s of retrieval latency that WARP does not remove.

Table 8: Per-component latency breakdown. Re-ranking is hardware-only (no model inference); retrieval and re-retrieval depend on the vector-store backend. p99 for re-ranking; typical/median for the rest.

Component	Local FAISS	Managed Bedrock Knowledge Base
Retrieval	<50 ms	∼1.5 s
Re-retrieval†	<5 ms	∼100 ms
Re-ranking (p99)	<310 ms	<310 ms
End-to-end	**<365 ms**	**∼1.9 s**

† Only fires when pool expansion (Entity-Gated / Adaptive) detects a deficit.

Table 9: Per-query re-ranking latency percentiles (N=96 queries: 36 Seller Forums + 60 Yelp Hotels, single-threaded on the hardware above). p99 drives production SLAs; max reported for tail auditing. All WARP variants stay under 310 ms at p99.

Domain	Method	Queries	p50 (ms)	p95 (ms)	p99 (ms)	Max (ms)
Seller Forums	W_1 Minimizer	36	**0.1**	**38.7**	**45.5**	**48.0**
Seller Forums	W_1-MMR	36	156.8	163.1	166.2	167.4
Seller Forums	EG + W_1 Min	36	0.6	211.0	216.2	218.8
Seller Forums	DPP	36	47.8	49.1	51.9	53.0
Yelp Hotels	W_1 Minimizer	60	**65.0**	270.8	289.9	295.3
Yelp Hotels	W_1-MMR	60	81.6	284.7	301.6	303.5
Yelp Hotels	EG + W_1 Min	60	145.7	302.0	307.6	312.5
Yelp Hotels	DPP	60	103.5	**127.4**	**129.3**	**131.3**

C Retrieval Ablations

We ablate key components of the retrieval pipeline: distance metric choice, entity filtering, pool expansion, convergence, per-entity variation, and sensitivity to hyperparameters.

C.1 JS vs. W_1: Metric Comparison and Entity-Match Confound

This section unpacks the JS-vs-W_1 comparison summarized in Section 4.2. We rerun the four calibrated methods (KL(JS) Minimizer, W_1 Minimizer, KL(JS)-MMR, W_1-MMR) on Yelp and OpinRank at k=20, holding the greedy structure and entity filtering fixed so only the distance metric varies within each row-pair.

Table 10 shows KL(JS)-MMR beating W_1-MMR on Yelp and OpinRank W_1. On its face this reverses the ordinal-metric advantage the Minimizer comparison establishes. It doesn't: the two hybrids retrieve very different candidate pools, and the metric is being scored on top of that difference.

In the top block (hybrids, uncontrolled EM), KL(JS)-MMR retrieves nearly twice as many entity-matched documents as W_1-MMR (38.2% vs. 19.4% on Yelp; 36.1% vs. 21.8% on OpinRank), and its lower W_1 tracks that EM gap rather than the choice of ordinal-vs-categorical ground cost. In the bottom block (Minimizers, controlled EM), both algorithms filter to the same entity-matched pool (EM=93.8% Yelp, 85.8% OpinRank), and W_1 wins on both domains — 2.76 vs. 3.00 on Yelp, 4.14 vs. 4.54 on OpinRank. The controlled comparison is where the ordinal metric earns its billing; the uncontrolled hybrid comparison is a retrieval-pool artifact.

Table 10: Entity-match confound in hybrid variants. KL(JS)-MMR retrieves ∼1.7–2× more entity-matched documents than W_1-MMR on both Yelp and OpinRank. In the controlled Minimizer comparison (same entity filter, EM equalized) W_1 wins on both domains — the KL(JS)-MMR W_1 advantage in the uncontrolled comparison traces to the EM gap, not to metric superiority.

	Yelp		OpinRank	
Method	W_1	EM%	W_1	EM%
KL (JS)-MMR	**2.51**	38.2%	**3.32**	36.1%
W_1-MMR	4.02	19.4%	3.41	21.8%
KL (JS) Minimizer	3.00	93.8%	4.54	85.8%
W_1 Minimizer	**2.76**	93.8%	**4.14**	85.8%

C.2 Entity-Filtered Control (Yelp)

Table 11: Entity-filter control experiment (Yelp Hotels, k=20). Entity filtering alone reduces W_1 by 45.7%; W_1 Minimizer achieves 62.6% additional reduction beyond the entity-filter control.

Approach	EM%	W_1	Δ vs Top-K	Δ vs EF+Top-K
Top K (no filter)	40.1	13.60	—	—
EntityFilter + Top-K	100.0	7.38	−45.7%	—
EntityFilter + MMR	100.0	6.99	−48.6%	−5.3%
EntityFilter + DPP	100.0	5.64	−58.5%	−23.6%
W_1 Minimizer	93.8	2.76	−79.7%	−62.6%
W_1-MMR	19.4	4.02	−70.4%	−45.5%
EG + W_1 Min	99.2	1.52	−88.8%	−79.4%
AE + W_1 Min	95.9	1.66	−87.8%	−77.5%

On sparse Seller Forums (Top-k baseline EM∼40%; entity-filter ceiling ∼51%), entity fil-

tering provides only -11.6% W_1 reduction (vs. -45.7% on Yelp, where the entity filter reaches 100% EM), confirming that W_1-MMR's full-pool scoring drives gains in entity-sparse domains (-37.7% beyond the entity-filter baseline).

C.3 Adaptive-k Convergence

W_1 Minimizer hits diminishing returns at k^*=3 (Seller Forums), k^*=4 (Yelp), k^*=5 (OpinRank) (Figure 3). An adaptive-k strategy could therefore feed far fewer documents to the LLM without losing distributional fidelity. This also implies robustness to imprecise P_{pop} estimates.

C.4 W_2 vs. W_1 Comparison

A natural concern is whether optimizing W_1 (linear ground cost) sacrifices performance under higher-order transport metrics. We compute W_2 (quadratic ground cost) for all methods on Yelp Hotels (k=20). Across the distributions produced by these methods, we observe that the method ranking under W_1 is preserved under W_2, with a linear relationship (slope $= 1.19$, $R^2 > 0.99$). W_1 is chosen for its $O(m)$ closed-form computation.

C.5 Per-Entity Breakdowns

Aggregate results in Table 1 mask substantial per-entity variation. The gains concentrate on entities whose baseline distributions are most skewed, precisely where minority-opinion misrepresentation does the most damage. We break out per-entity W_1 for all three domains below.

C.5.1 Yelp Hotels (k=20)

W_1 Minimizer lands below 2.0 on 7 of 10 entities. That is near-perfect calibration. Three outliers remain above 2.0: Business Center (9.76), Shuttle Service (5.78), and Loyalty Program (4.07), all corresponding to entities with extreme distributional skew and thin pool diversity. Even greedy optimization cannot fully close the gap within k=20 selections under those conditions.

Table 12: Per-entity breakdown (Yelp Hotels, 10 aspects). W_1 Minimizer achieves <2.0 on 7/10 entities.

Entity	Top-k W_1	W_1 Min	W_1-MMR	WassRank OT
Booking Experience	18.30	1.95	3.78	1.58
Breakfast	7.55	1.48	2.87	1.42
Breakfast Quality	5.78	0.87	3.79	0.65
Business Center	24.51	9.76	6.72	9.26
Casino	14.79	0.86	4.07	0.62
Loyalty Program	16.31	4.07	4.49	2.95

C.5.2 OpinRank Cars (k=20, top 10 by entropy)

OpinRank entities vary widely in mention count (39–1,465) and minority fraction (19–45%). High-count entities with moderate minority shares calibrate well: City MPG, for instance, has 1,465 mentions at 25% minority and reaches W_1=0.38. Hard cases persist. Vehicle Size has only 42 mentions; Dealer Experience starts from a W_1=23.07 baseline. Both resist full correction.

D Statistical Validity

Two orthogonal concerns for the significance testing: multiple comparisons across many method $\times$ domain combinations, and non-independent samples within a domain (queries drawn from the same entity share an underlying opinion distribution). We address both.

D.1 Benjamini–Hochberg Correction

We ran 57 paired Wilcoxon tests spanning three domains, multiple re-ranking variants (baselines and W_1 family), and all evaluated k values. Benjamini–Hochberg FDR correction at α=0.05 leaves 39/57 tests surviving. Table 14 shows the 14 W_1-family tests: every one survives on every domain. The 18 non-surviving tests come from baseline re-ranking methods outside our contribution set.

Table 14: Benjamini–Hochberg FDR correction (α=0.05) on paired-Wilcoxon p-values for the W_1 family. Every W_1-family algorithm survives on every domain (14/14). Reduction is per-query paired reduction relative to Top-k; aggregate reductions in Table 1 weight queries differently. $^{***}p_{\text{adj}}<10^{-3}$, $^{**}p_{\text{adj}}<10^{-2}$, $^{*}p_{\text{adj}}<0.05$.

Domain	Approach	N	Reduction	p_{adj}

D.2 Entity-Clustered Bootstrap

Paired-Wilcoxon assumes independent paired observations. Queries drawn from the same entity are not independent, since they share the same underlying opinion distribution. We therefore resample at

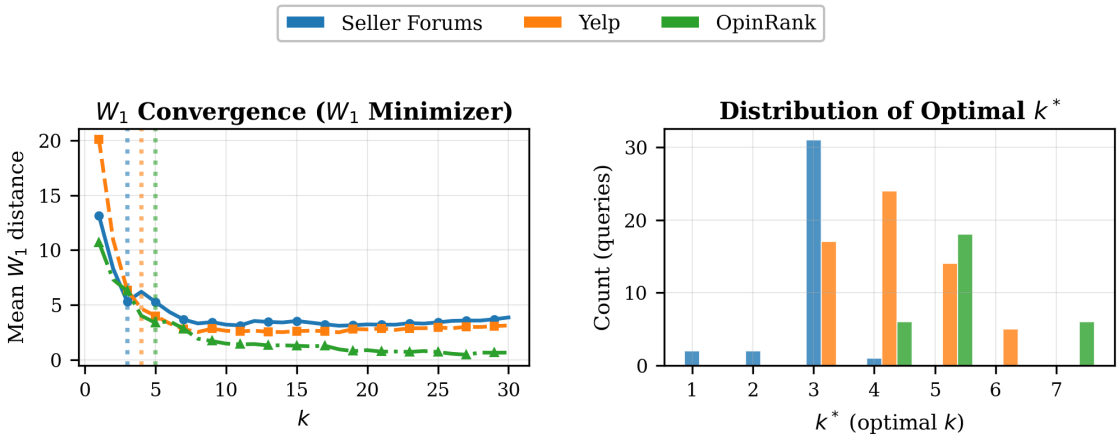

Figure 3: W_1 Minimizer convergence vs. output size k. Median convergence point k^* (where $\Delta W_1 < 0.5$ per additional document): Seller Forums k^*=3, Yelp k^*=4, OpinRank k^*=5.

Table 13: Per-entity breakdown (OpinRank, LLM-extracted entities). Count = opinion mentions, H = Shannon entropy, Min% = minority sentiment fraction.

Entity	Count	H	Min%	Top-k	W_1 Min	W_1-MMR	WassRank OT
Oil Change Interval	144	1.49	21%	3.96	1.08	2.95	0.78

the entity level: 10,000 bootstrap iterations, drawing entities with replacement and recomputing the mean per-query W_1 improvement. All 95% CIs exclude zero for every W_1 method on every domain (Table 15).

Table 15: Entity-clustered bootstrap (10,000 resamples). Mean improvement in W_1 relative to Top-k; 95% CIs computed by resampling entities with replacement. All CIs exclude zero.

Dataset	Method	#Entities	Mean ΔW_1	95% CI
Yelp	W_1 Minimizer	10	10.85	[8.26, 13.37]
Yelp	EG + W_1 Min	10	12.09	[8.72, 15.37]
Yelp	W_1-MMR	10	9.58	[6.40, 12.80]
OpinRank	W_1 Minimizer	9	9.65	[6.92, 12.34]
OpinRank	W_1-MMR	9	10.22	[6.48, 14.17]
Seller Forums	W_1 Minimizer	4	5.32	[0.67, 10.38]
Seller Forums	W_1-MMR	4	1.84	[0.49, 3.25]

Seller Forums' wider CIs (e.g., W_1 Minimizer [0.67, 10.38]) reflect its small entity count (N=4), not a qualitatively different effect — the lower bound still exceeds zero. The aggregate signal is cross-domain consistency across 10 Yelp, 9 OpinRank, and 4 Seller Forums entities.

E Independent-Target Validation

Our LLM-derived sentiment-intensity labels define both the population target P_{pop} used at inference and the W_1 evaluation metric applied to the retrieved evidence. If the labeler had systematic biases, calibrating and measuring against it could inflate the numbers. We cross-validate against Yelp's native 1–5 star ratings, which are ordinal, human-authored at review time, and participate in *no part* of the WARP pipeline — neither retrieval, nor reranking, nor the P_{pop} used at inference. Section 4.5 in the main body summarizes; this appendix reports the underlying numbers.

A high correlation on individual labels is a necessary but not sufficient condition: the entity-level P_{pop} is an aggregate, and a labeler could still consistently mis-estimate it. We therefore recompute P_{pop} from star ratings alone for each of the 10 Yelp entities and quantify the divergence from the LLM-derived P_{pop} actually used at inference (Table 16). Mean W_1 divergence: 2.88. Under a triangle-inequality bound, WARP's retrievals stay within W_1=5.64 of the star-derived target while Top-k is at least W_1=10.72 away — a worst-case reduction of at least 47.4% against a target the labeler never touched.

Table 16: Star-derived vs. LLM-derived P_{pop} per Yelp entity. Mean W_1 gap: 2.88. Bounds: $W_1(\text{WARP}, \text{star-}P_{\text{pop}}) \leq 5.64$, $W_1(\text{Top-}k, \text{star-}P_{\text{pop}}) \geq 10.72$; worst-case reduction $\geq 47.4\%$.

F Robustness & Sensitivity

F.1 Noise Tolerance

Two studies stress-test the system under realistic noise. First, Dirichlet perturbation of P_{pop} simulates inaccurate population estimates. Second, mislabel sensitivity corrupts both document SI labels and P_{pop} at once. These jointly reveal how much noise each algorithm can absorb, and where deployment breaks down.

F.1.1 Dirichlet Perturbation of P_{pop}

We perturb P_{pop} with Dirichlet noise at $\varepsilon \in \{0, 0.1, 0.2, 0.5\}$ (N=30 samples per entity) to simulate estimation error in the population distribution (Figure 4):

On Yelp, which has a dense candidate pool, the W_1 Minimizer at ε=0.2 degrades by 31%, but it still comes in 72% ahead of Top-k. W_1-MMR barely moves under the same perturbation (<1% degradation). On Amazon Seller Forums the picture is similar in shape: all methods degrade gracefully, and W_1 Minimizer at ε=0.2 stays 56% above Top-k. OpinRank is the most sensitive of the three because the unperturbed baseline is already tight (W_1 Min sits at 0.87 at ε=0), so relative degradation looks larger, but even there ε=0.2 holds 45% better than Top-k. Across all three domains, W_1-MMR degrades the least, which we attribute to its hybrid objective partially shielding it from target noise.

F.1.2 Mislabel Sensitivity (SI Label Error)

A harder question: at what SI label error rate does the W_1 advantage drop below significance? We corrupt candidate document labels AND P_{pop} simultaneously, the realistic scenario where labeling errors propagate into the population estimate. Error rates $\in \{0, 0.05, 0.10, 0.20, 0.30, 0.50\}$, N=20 repetitions per setting (Figure 5). "Crossover" marks the error rate at which a method's W_1 exceeds the Top-k baseline:

Dense pools are forgiving. W_1 Minimizer never crosses the Top-k baseline on Yelp, even at 50% label error. Sparse pools need more care; use W_1-MMR regardless of label quality, as its hybrid objective guarantees a floor.

F.2 Noise Control

We need to rule out a trivial explanation: maybe any score perturbation induces diversity that looks like opinion-aware signal. So we add 5% Gaussian noise to retrieval scores and re-rank:

Table 17: Noise control: 5% Gaussian perturbation of retrieval scores yields negligible W_1 improvement (2–5%, $p > 0.05$), confirming that our 43–89% distributional improvements (W_1-MMR on sparse pools; W_1 Minimizer / EG+W_1 Min on dense) represent genuine distributional optimization.

Method	**Seller** W_1	**Yelp** W_1	**OpinRank** W_1
Top-k (baseline)	10.33	13.60	13.33
Top-k + 5% Noise	10.07	13.00	12.97
Reduction	*2.5%*	*4.4%*	*2.7%*
Significance	*ns ($p > 0.05$, all domains)*		
W_1 Minimizer	8.84	2.76	4.14
Reduction	*14.4%*	*79.7%*	*69.0%*

Random score perturbation yields 2–5% W_1 change (non-significant), against our 43–89% distributional improvements on the same pools.

F.3 Hyperparameter Sensitivity

λ (relevance–calibration tradeoff). Hybrid methods (W_1-MMR and WassRank OT) each introduce λ. We sweep $\lambda \in \{0.1, 0.3, 0.5, 0.7, 0.9\}$ across all three domains (Figure 6). W_1-MMR holds steady at $\lambda \leq 0.5$ on Seller Forums and Yelp, then degrades once relevance dominates. OpinRank behaves differently: λ=0.7 is optimal there (denser pools tolerate more calibration weight). WassRank OT is nearly λ-invariant on dense pools: Yelp gives $W_1 \approx 2.52$ for $\lambda \leq 0.5$ (identical to 3 decimal places) and OpinRank yields W_1=0.95 with 100% EM across that range.[2] No per-domain tuning needed.

[2]The λ-sensitivity results use entity-specific FAISS indices (EM=100%), whereas Table 1 uses a single shared FAISS index across all OpinRank entities (EM=82.9%). This accounts for the OpinRank WassRank OT W_1 difference (3.87 in Table 1 vs. 0.95 here).

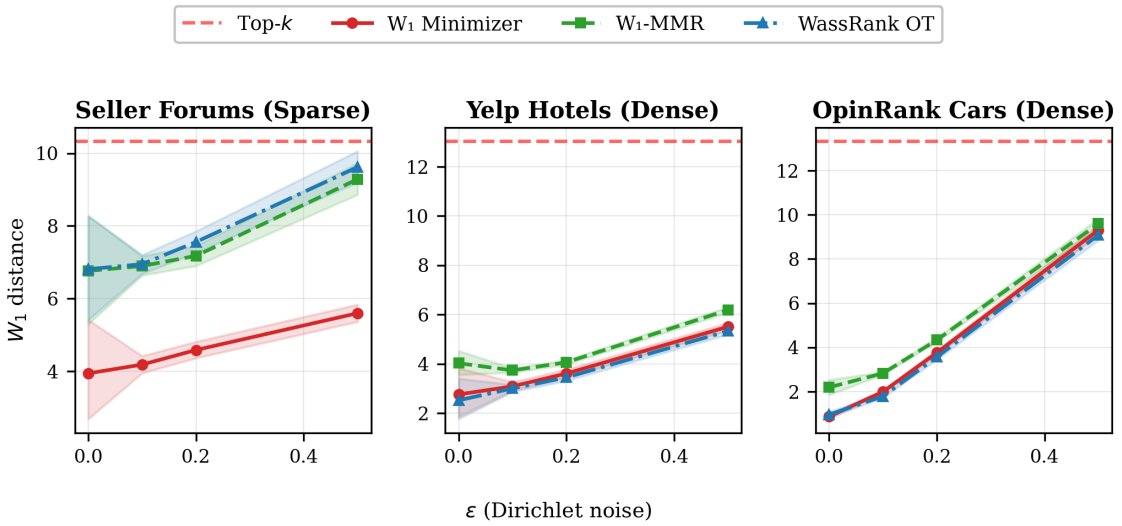

Figure 4: Dirichlet perturbation robustness across all three domains. Dashed red line = Top-k baseline. At ε=0.2, W_1 Minimizer remains 72% better than Top-k on Yelp.

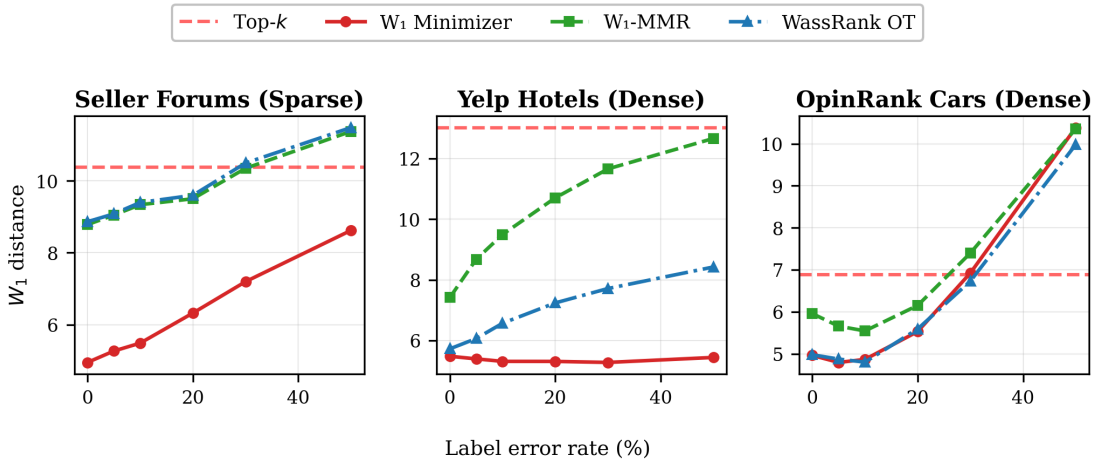

Figure 5: Mislabel sensitivity: W_1 vs. label error rate. Dashed red line = Top-k baseline. W_1 Minimizer never crosses Top-k even at 50% error on Yelp.

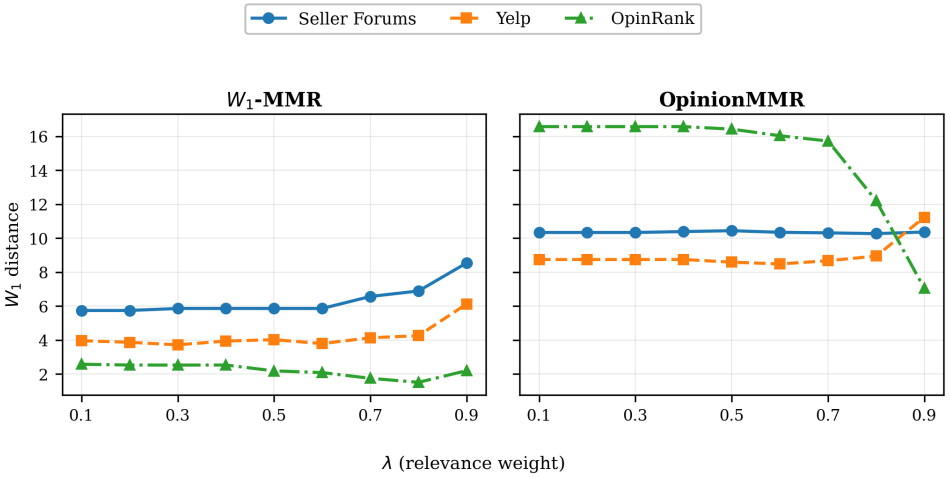

Figure 6: λ-sensitivity for W_1-MMR (left) and OpinionMMR (right). W_1-MMR is stable at $\lambda \leq 0.5$ and degrades at λ=0.9. OpinionMMR shows higher W_1 across all domains with limited sensitivity to λ.

Pool size N. We vary $N \in \{25, 50, 100, 200\}$ with fixed k=20 (Figure 7). N=100 suffices for near-optimal performance on dense pools. W_1-MMR benefits more from larger pools because it draws from the full (unfiltered) candidate set. On OpinRank, even N=50 approaches the N=200 re-

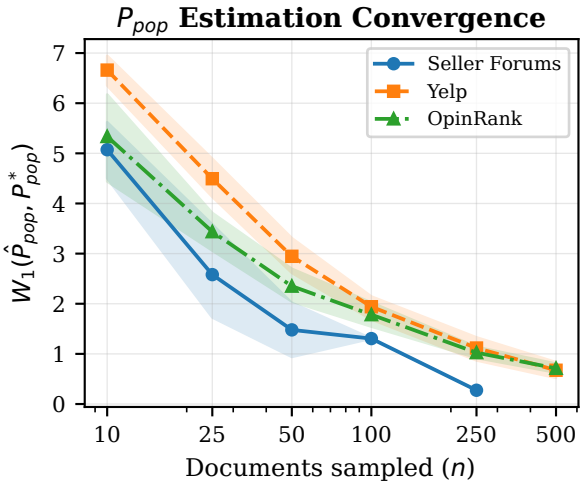

Figure 8: $W_1(\hat{P}_{\text{pop}}, P^*_{\text{pop}})$ vs. entity-matched documents sampled. With 50–100 documents per entity, estimation error is comparable to or below the re-ranking improvement magnitude itself.

sult because entity-specific FAISS indices guarantee most candidates are already entity-matched. On sparse Seller Forums, larger pools become essential for W_1-MMR to locate cross-entity documents that fill distributional gaps.

F.4 Population Estimation and Cold-Start Robustness

We evaluate whether P_{pop} can be reliably estimated from indexed data and whether the system degrades safely at cold-start. For each entity e, the full-corpus distribution $P^*_{\text{pop},e}$ serves as our oracle evaluation target. We sample subsets of $n \in \{10, 25, 50, 100, 250, 500\}$ entity-matched documents, compute $\hat{P}^{(n)}_{\text{pop},e}$, and measure $W_1(\hat{P}^{(n)}_{\text{pop},e}, P^*_{\text{pop},e})$. Crucially, the re-ranker uses $\hat{P}_{\text{pop}}$ but selected evidence is evaluated against P^*_{pop}; this avoids circularity.

Estimation convergence. Figure 8 shows estimation error vs. sample size across all three domains. Convergence is rapid. At n=50, mean W_1 between estimated and oracle distributions drops below 3.0; at n=100, below 2.0. Bootstrap CIs (95%) narrow monotonically, which indicates stable estimation with modest data.

Cold-start behavior. When an entity has few labeled documents, the entity-level P_{pop} estimate gets noisy. We simulate this by capping observation count at $n \in \{10, 25, 50, 100\}$. Even at n=10, all estimation strategies beat uncalibrated Top-k. Smoothed interpolation with a domain prior ($\tilde{P} = \alpha\hat{P}_e + (1-\alpha)P_{\text{domain}}$, $\alpha = n/(n+50)$) works best at every count, achieving 61% W_1 reduction at n=10. Our recommended production rule: use entity-level P_{pop} when $n \geq 25$ and at least 2 sentiment bins have mass > 0.05; otherwise fall back to the smoothed domain prior.

G Generation Evaluation

G.1 Judge Validation & Positional Bias

Generation evaluation should not hinge on a single model's quirks; leniency bias and prompt sensitivity are well-documented failure modes (Thakur et al., 2025). We validate with five independent model families from different providers: Claude Sonnet 4 (Anthropic), Llama 3.3 70B (Meta), Mistral Large 3 (Mistral AI), Amazon Nova Pro (Amazon), and DeepSeek v3.2 (DeepSeek). Appendix A.3.3 contains the full judge prompt with its three evaluation dimensions. Below we confirm positional bias, report directional inter-judge agreement, and present majority-vote consensus.

G.1.1 Positional Bias

LLM judges exhibit positional bias, a preference for whichever answer appears first (Wang et al., 2024; Shi et al., 2025). We confirm this across all five judges in our panel. Our position-swap protocol converts inconsistent position-dependent preferences into conservative ties, motivating the directional κ_d analysis in §G.1.2. Bias rates differ across models, producing asymmetric tie distributions:

Table 18: Consensus tie rates across the 5-judge panel. Higher tie rates indicate stronger positional bias (position-swap converts inconsistent preferences to ties).

Judge	Consensus Tie Rate (k=5)	Consensus Tie Rate (k=10)
Claude Sonnet 4	46%	46%
Mistral Large 3	48%	61%
DeepSeek v3.2	63%	71%
Llama 3.3 70B	73%	86%
Amazon Nova Pro	79%	86%

When judges do commit to a preference, they agree directionally 85–100% of the time.

G.1.2 Directional Inter-Judge Agreement (κ_d)

We want to separate genuine directional disagreement from artifacts of unequal tie rates. So we compute κ_d over only those pairs where both judges commit to a non-tie preference:

All five judges agree directionally at κ_d=0.61–1.00. Among the four non-Anthropic judges, pairwise κ_d ranges 0.95–1.00 at both k values.

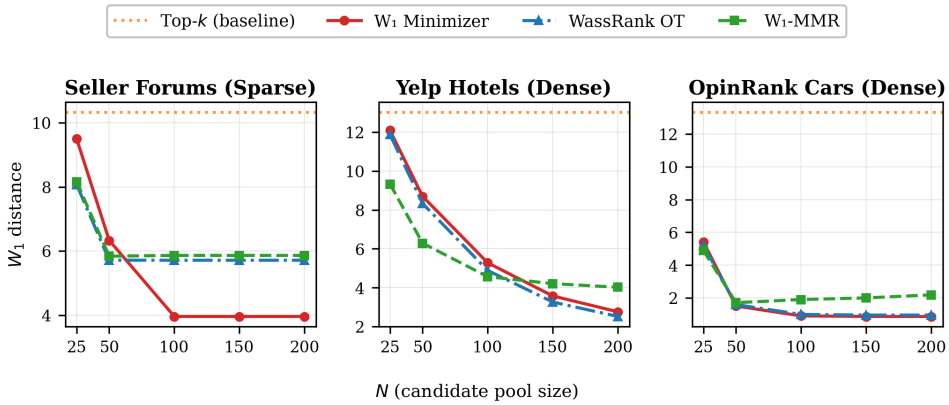

Figure 7: W_1 vs. pool size N (k=20). N=100 suffices for dense pools; W_1-MMR benefits from larger pools on sparse data.

Table 19: Mean directional κ_d per judge vs. all others (fairness dimension). Non-Anthropic judges agree at $\kappa_d \geq 0.95$ at k=10; at k=5, κ_d=0.88–0.93.

Judge (vs. others)	k=5 κ_d	k=5 Agree%	k=10 κ_d	k=10 Agree%
Claude vs. others	0.68	88.2%	0.86	93.5%
Llama 3.3 vs. others	0.89	96.0%	0.97	98.8%
Mistral L3 vs. others	0.89	95.8%	0.95	97.8%
DeepSeek vs. others	0.93	97.4%	0.95	97.9%
Nova Pro vs. others	0.88	95.3%	0.94	97.3%

Claude's lower κ_d (0.68/k=5, 0.86/k=10) traces to its lower tie rate: it commits more often and occasionally flags nuances others collapse into ties.

G.1.3 Majority Vote Results (3/5 Judges Must Agree)

Under majority vote (3/5 agreement required), calibration methods reach strong significance at k=5 while Random correctly fails. This is a critical sanity check. At k=10, fewer approaches survive; context-window averaging attenuates distributional differences. We extend to k=20 under the same protocol; the scaling regime distinguishes semantic-diversity from distributional methods.

At k=5 with only 2–3 active sentiment bins, diversity and calibration objectives partly overlap and MMR/OpinionMMR win 83%/82% (Table 20). By k=20 the pool has room for finer-grained proportions and pure semantic-diversity has run out of signal; MMR and OpinionMMR Fair% drop to 29% and 33%. Distributional methods maintain their advantage: WassRank OT rises from 70% (k=5) to 73% (k=10) to 92% (k=20) as budget lets proportional targeting express itself in the answer. DPP is a partial exception: it also grows with k (89% at k=20) because its determinantal spread lands one representative per bin when there is enough budget.

Domain decomposition at k=10 reveals a clear density dependency. On dense Yelp (60 questions, 10 aspects), all calibration methods achieve 86–97% fairness decided rate; W_1 Minimizer hits 97% (28W/1L). Dense OpinRank (60 questions, 10 entities) confirms propagation: DPP leads at 100% (19W/0L), W_1 Minimizer at 94% (16W/1L), and 5 of 8 approaches reach $p < 0.001$. Sparse Seller Forums (36 questions, 6 entities, EM∼40%) is the outlier: only OpinionMMR achieves significance (10W/2L, 83%, p=0.019); W_1 Minimizer and W_1-MMR hover near coin-flip (54–55%), confirming that sparse pools cap document quality regardless of re-ranking strategy. Random fails on all three domains (13–53%), validating the sanity check.

G.1.4 Judge Prompt Sensitivity

Our main fairness criterion conflates two signals: *proportional accuracy* and *viewpoint coverage*. We disentangle them by re-judging all answer pairs under two contrasting definitions (Prompt A and Prompt B in Appendix A.3.3), same 5-judge panel with position-swap (Zheng et al., 2023) and 3/5 majority vote:

- **Prompt A (Proportional Accuracy):** Judges receive the ground-truth P_{pop} and are asked which answer's emphasis better matches the actual distribution. An answer over-representing a 10% minority relative to a 70% majority is penalized as misleading.
- **Prompt B (Viewpoint Coverage):** Judges are asked which answer covers more distinct viewpoints, including rare ones. Giving disproportionate space to minority views is rewarded.

INFORMATIVENESS and GROUNDEDNESS dimensions remain identical across both prompts, serving as controls.

Three patterns emerge. (1) Under proportional accuracy, W_1 Minimizer leads DPP by 8/6 pp at

Table 20: 5-judge majority-vote generation results (cross-domain, 156 questions) at $k \in \{5, 10, 20\}$. All calibration methods achieve $p < 0.001$ at k=5; retain significance at k=10 ($p \leq 0.021$) and k=20 ($p \leq 0.004$). Random fails at all k values. At k=20, MMR/OpinionMMR Fair% collapse (29%/33%) as semantic diversity saturates; distributional methods maintain or grow their advantage; WassRank OT rises 70%→73%→92%. Fair% = W/(W+L). Win% = W/N.

	k=5			k=10			k=20		
Approach	**W/L/T**	**Fair%**	**Win%**	**W/L/T**	**Fair%**	**Win%**	**W/L/T**	**Fair%**	**Win%**
Random	16/36/104	31%	10%	12/40/104	23%	8%	3/26/127	10%	2%
MMR**	39/8/109	83%	25%	21/9/126	70%	13%	5/12/139	29%	3%
OpinionMMR**	50/11/95	82%	32%	25/8/123	76%	16%	7/14/135	33%	4%
DPP**	54/7/95	89%	35%	42/6/108	88%	27%	25/3/128	89%	16%
WassRank OT**	66/28/62	70%	42%	75/28/53	73%	48%	33/3/120	**92%**	21%
W_1-MMR**	44/10/102	81%	28%	24/7/125	77%	15%	13/2/141	87%	8%
W_1 Minimizer**	51/8/97	86%	33%	32/8/116	80%	21%	27/5/124	84%	17%

Table 21: Judge prompt ablation: fairness win rate (%) under proportional vs. coverage definitions (3 domains, 156 questions per approach). W_1 Minimizer dominates under proportional accuracy; the gap narrows under coverage. Stratified sampling (oracle) confirms the Prompt A criterion tracks the ground-truth distribution, not any specific retrieval strategy — W_1 Minimizer matches oracle Fair% within 1 pp at k=5.

	k=5		k=10	
Approach	**Prop. (A)**	**Cov. (B)**	**Prop. (A)**	**Cov. (B)**
Stratified (oracle)	35%	—	—	—
W_1 Minimizer	34%	38%	30%	27%
DPP	26%	35%	24%	25%
W_1-MMR	23%	36%	18%	17%
OpinionMMR	21%	30%	13%	19%
MMR	13%	26%	10%	13%
Random	16%	13%	12%	7%

Table 22: Control dimensions remain stable across prompt variants (k=5, Δ = Prompt B − Prompt A). Shifts ≤4 pp confirm the fairness prompt change does not contaminate other evaluation axes.

Approach	**Info% (A)**	**Info% (B)**	**Grnd% (A)**	**Grnd% (B)**
W_1 Minimizer	44%	40%	28%	24%
DPP	38%	40%	27%	24%
Random	19%	18%	15%	8%

k=5/10 and sits within 1 pp of the stratified oracle (35%), confirming Prompt A tracks ground-truth P_{pop} rather than any retrieval strategy. (2) Under viewpoint coverage, the gap narrows to 3/2 pp; DPP's diversity edge is real but modest once W_1's calibration already covers most bins. (3) Inter-judge agreement rises under Prompt B (Llama–Mistral κ: 0.39→0.62 at k=5), suggesting viewpoint counting is more objectively evaluable without ground truth. Our original conflated criterion thus understates W_1's advantage at its design objective.

G.2 Single-Judge Metric Isolation (Generation)

The 5-judge majority-vote protocol is conservative — positional-bias-driven ties inflate the tie column. To isolate the ordinal metric's end-to-end contribution with more statistical power, we ran a controlled single-judge (Claude Sonnet 4) position-controlled pairwise evaluation between W_1 Minimizer and KL(JS) Minimizer at k=5 (Table 23). Same algorithm, same entity-filtered pool; only the distance function differs.

Table 23: W_1 Minimizer vs. KL(JS) Minimizer, generation evaluation at k=5 (156 queries, single-judge Claude Sonnet 4, position-controlled, blind pairwise vs. Top-k). W_1 leads KL(JS) by +7 pp cross-domain; both significantly beat Top-k (p<0.001).

Domain	**Method**	N	**W/L/T**	**Fair%**	**Win%**
Seller Forums	W_1 Minimizer	36	10/9/17	**53%**	**28%**
	KL (JS) Minimizer	36	7/10/19	41%	19%
Yelp	W_1 Minimizer	60	39/4/17	**91%**	**65%**
	KL (JS) Minimizer	60	31/8/21	79%	52%
OpinRank	W_1 Minimizer	60	29/8/23	78%	48%
	KL (JS) Minimizer	60	35/10/15	78%	**58%**
Cross-domain	W_1 Minimizer	156	78/21/57	**79%**	**50%**
	KL (JS) Minimizer	156	73/28/55	72%	47%

W_1 leads KL(JS) by +7 pp Fair% cross-domain; the retrieval-side advantage (Appendix C.1) does not invert at generation. Yelp shows the largest gap (91% vs. 79%); Seller Forums the same direction at smaller magnitude (53% vs. 41%). OpinRank is a partial exception (Fair% ties; KL(JS) edges Win Rate 58% vs. 48%) — its near-uniform P_{pop} compresses ordinal distances, leaving the ordinal ground cost less to do.

Abstract

Warehouse operations are governed by Standard Operating Procedures (SOPs) that encode complex, multi-system decision logic, which must be executed reliably under strict time constraints, yet LLM agents lack mechanisms to enforce procedural compliance and degrade under the context overload full SOP specifications introduce. We present Eluna, a production-deployed agentic system for reliable SOP execution. Eluna is a graph-guided, multi-agent framework that encodes SOPs as directed acyclic graphs with progressive disclosure and delegates independent tasks to parallel sub-agents, each with persistent code execution and live data access. To meet production latency and accuracy needs, we use asymmetric episodic distillation where a strong teacher is improved through episodic error memories, then a smaller student is fine-tuned on the corrected trajectories with memory stripped, internalizing corrections without inference-time overhead. On a 13-task benchmark and two production applications, our fine-tuned models match or exceed their teacher, beat all larger off-the-shelf baselines, and reach 94% expert agreement on the ticket processing application.

1 Introduction

Modern warehouse operations require continuous monitoring, multi-step diagnosis, and timely intervention across dozens of systems, ranging from robotic conveyance operators tracing threshold breaches to root causes within minutes, to inventory ticket processing that queries state, validates constraints, and submits physical item picks across many systems per ticket. Robotic conveyance diagnosis and ticket processing are two among many such workflows, each governed by Standard Operating Procedures (SOPs): directed decision pathways with prescribed steps, dependencies, quantitative thresholds, and constraints that must be followed faithfully. Today much of their execution is manual, slow, and error-prone, and delays in diagnosis directly degrade throughput, making automated SOP execution a pressing business need.

Large language models reason well (Wei et al., 2022; Kojima et al., 2022), but agentic frameworks such as ReAct (Yao et al., 2023) and Reflexion (Shinn et al., 2024) rely on loosely structured prompts with no mechanism to strongly guide SOP compliance, so a capable model can still deviate from prescribed decision paths. Recent benchmarks confirm this gap on workflow-guided tasks (Xiao et al., 2024; Wang et al., 2025), industrial SOP-following (Nandi et al., 2025), and operational diagnostics where even SOP-enhanced multi-agent systems plateau in performance (Pei et al., 2025). A core bottleneck is context overload: with the full SOP in view, performance degrades as complex workflows overwhelm the model's ability to select relevant actions (Xiao et al., 2024; Pei et al., 2025). This plateau holds regardless of model scale, and prompting alone is insufficient without domain-specific training (Nandi et al., 2025).

We present a graph-guided agent framework that addresses these challenges through a unified execution model. SOPs are encoded as directed acyclic graphs, and progressive disclosure surfaces only the reachable subgraph and node-level specifications on demand. A main agent orchestrates traversal and delegates independent node evaluations to parallel sub-agents in isolated contexts, each with a persistent code interpreter (the CodeAct paradigm of Wang et al. (2024)) and access to real-time data via the Model Context Protocol (Anthropic, 2024), providing context isolation and parallelism while guiding the agent toward procedural compliance. Together, progressive disclosure and sub-agent isolation address context overload. Each operational use case is packaged as a self-contained *Skill*[1] loaded on demand, so new workflows need no be-

* Equal contribution.

spoke systems. Since prompting alone is insufficient (Nandi et al., 2025), we pair the framework with a trajectory-centric training pipeline where episodic learning corrects a strong teacher's trajectories without weight updates, and a smaller, low-latency student is fine-tuned without episodic memory (asymmetric episodic distillation), internalizing the episodic corrections in its weights rather than depending on them at inference. We make three contributions:

- A **graph-guided skill-based agent framework** that encodes SOPs as directed acyclic graphs with progressive disclosure, and uses hierarchical multi-agent execution with parallel sub-agent delegation for scalable, procedurally compliant reasoning across multiple operational use cases.
- A **trajectory-centric training pipeline with asymmetric episodic distillation**: episodic learning iteratively improves teacher trajectory quality, and the student is fine-tuned on per-turn decomposed trajectories filtered by rejection sampling, with episodic memory stripped, internalizing the episodic corrections in its weights and eliminating inference-time memory dependence.
- **Real-world performance** on a 13-task operational reasoning benchmark and two production warehouse applications (robotic conveyance and ticket processing), demonstrating that a fine-tuned 32B model outperforms all baselines including its teacher and larger off-the-shelf models. A fine-tuned 355B model achieves a 94% human-match on the ticket processing application.

2 Related Work

Tool-Augmented Agents and Multi-Step Reasoning. LLM agents have been equipped with code execution (Gao et al., 2023; Wang et al., 2024), APIs (Patil et al., 2023; Qin et al., 2024), and standardized tool protocols (Anthropic, 2024). Multi-step reasoning methods range from chain-of-thought (Wei et al., 2022) and tree-of-thoughts (Yao et al., 2024) to interleaved reasoning and action (Yao et al., 2023) and hierarchical decomposition (Khot et al., 2023; Besta et al., 2024). These approaches improve general reasoning but rely on loosely structured prompts without mechanisms to enforce deterministic procedural constraints.

Structured Reasoning and Operational AI. Multi-agent frameworks such as AutoGen (Wu et al., 2023) and MetaGPT (Hong et al., 2024) enable task decomposition across specialized agents. SOPStruct (Garg et al., 2025) converts unstructured SOP text into DAG representations, but is an upstream *structuring* system: its output is a structured graph, and its evaluation measures structuring quality (completeness and soundness of the DAG). It has no execution engine, tool use, or assessment of task completion, so it occupies a different pipeline stage than Eluna, which addresses the downstream problem of faithfully *executing* a structured SOP graph in production; a direct empirical comparison is therefore not meaningful, and the two are complementary. Agent-S (Kulkarni, 2025) navigates SOPs via prompt-driven state machines but lacks graph-guided progressive disclosure, code execution, and post-training; we compare empirically against this paradigm in Section 5.3. Our work integrates SOP graphs into both inference and training.

Trajectory-Centric Training. Reflexion (Shinn et al., 2024) and Self-Refine (Madaan et al., 2024) use iterative feedback to improve trajectories at inference time. FireAct (Chen et al., 2023) and AgentTuning (Zeng et al., 2024) show that fine-tuning on agent trajectories improves generalization. Our pipeline differs in two ways: episodic learning improves the *teacher* trajectories used for distillation rather than the deployed model, and training is aligned with graph-structured procedural logic rather than free-form tasks.

3 A Graph-Guided Operational Agent

Eluna is a hierarchical multi-agent framework that addresses the two challenges above (context overload and use-case generality) through graph-structured progressive disclosure, parallel sub-agent delegation, and skill packaging. Figure 1 provides an overview.

3.1 Graph-Structured SOP Representation

Each SOP is a directed acyclic graph $G = (V, E)$ with five node types: *observations* (detectable conditions), *root causes* (diagnosed causes), *calculations* (metric analysis), *constraints* (preconditions), and *actions* (remediation). Each node has a parameterized specification defining its evaluation procedure, which produces a structured outcome: a boolean, a classification (e.g., a category that routes downstream traversal), or a computed value. Edges

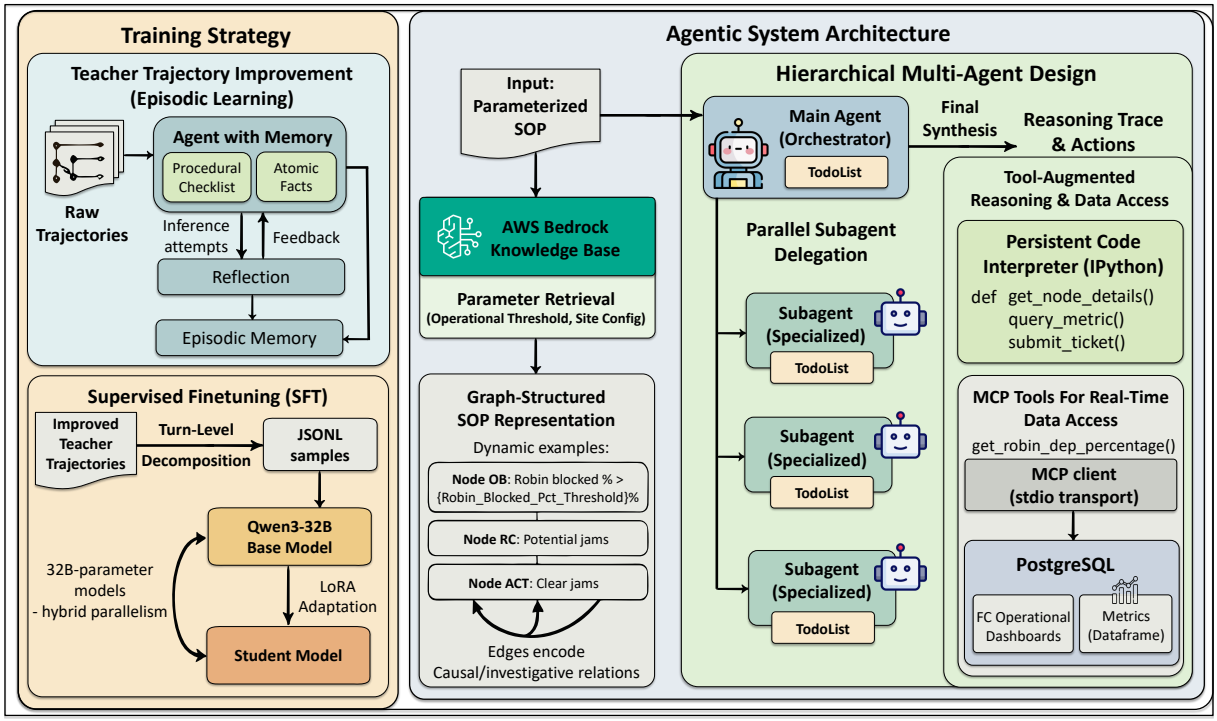

Figure 1: Overview of the Eluna framework. **Left:** Training strategy combining episodic learning for teacher trajectory improvement with turn-level decomposition for supervised fine-tuning via LoRA. **Right:** system architecture featuring graph-structured SOP representation, hierarchical multi-agent design with parallel sub-agent delegation, and tool-augmented reasoning through persistent code execution and MCP-based data access.

encode directed dependencies: a single-node edge activates the child on the boolean outcome of one parent (holding, or not holding for fallback paths), while a multi-node edge requires several parents to hold simultaneously. A node may have multiple outgoing edges.

Progressive Disclosure. Presenting the full graph degrades traversal accuracy (Liu et al., 2024), especially with parallel paths, where the agent conflates branches, omits nodes, or explores irrelevant subtrees. We disclose the graph at two levels. First, a retrieval tool runs BFS from the triggered node and returns only the reachable subgraph (node types, edge relationships, brief descriptions). Second, each node's full procedural specification (evaluation logic, required tool calls, thresholds) is fetched only when the agent begins evaluating it, bounding working context to one node at a time.

3.2 Hierarchical Multi-Agent Architecture

Eluna uses a two-level hierarchy: a main agent orchestrates traversal while sub-agents evaluate individual nodes in parallel. The main agent holds the retrieved subgraph, selects the next nodes to evaluate from edge dependencies, and issues delegation calls; each sub-agent receives a fresh context with only the assigned node's procedural specification, role instructions, and tools. Action nodes remain with the main agent because they require graph-level state for sequencing and constraint checking.

Multiple delegation calls issued in one turn execute in parallel, reducing wall-clock time to roughly the slowest single evaluation. Only each sub-agent's structured conclusion is returned, so the main agent's context grows by one summary per node rather than the full investigation history; sub-agent sessions persist so the main agent can query one for detail without re-running it, and sub-agents cannot spawn further sub-agents. This isolates tool outputs and intermediate computation within sub-agent sessions, addressing context overload by construction while the main agent holds only graph structure and node conclusions. In a parallel effort, we reduce the per-node sub-agent overhead by compiling repeated SOP steps into reusable tools at build time (Kujanpää et al., 2026).

3.3 Skill Packaging

Each warehouse workflow needs its own decision logic, prompts, data sources, and actions. A custom agent per use case duplicates the execution engine and training pipeline, while a single agent

loaded with all use cases suffers context overload and tool-space conflicts. The workflow is a more natural packaging unit: we bundle per-workflow artifacts into a self-contained *skill* loaded at runtime, following the standardized skill format models are increasingly trained to use. The framework stays use-case-agnostic so the same agent and execution logic serve any loaded skill, and adding a workflow means authoring a skill, not modifying the agent.

A skill comprises five components: (1) the decision graph encoding the SOP as a DAG, (2) use-case-specific tools accessed via the Model Context Protocol (Anthropic, 2024) for querying data and executing actions, (3) node detail specifications containing per-node evaluation logic, (4) CodeAct functions (Wang et al., 2024), and (5) execution instructions directing traversal strategy (e.g., when to delegate, how to handle constraints); reference documents for knowledge retrieval (Schick et al., 2024) are bundled as readable files. When a trigger fires, a skill-loading tool registers the skill's tools under a namespace prefix, injects its CodeAct functions into the persistent interpreter as importable modules, and appends its execution instructions, after which the agent has exactly the tools and instructions for the current use case.

Automated SOP Authoring. Skills do not require manual graph authoring. A separate LLM-based authoring agent, developed in parallel, extracts operational knowledge from existing documents and subject-matter-expert (SME) interviews, converts it into the formal graph representation (identifying node types, edge dependencies, and evaluation logic), and compiles the result into an executable skill package. A validation loop closes the process: Eluna generates reasoning traces against the compiled skill, disagreements with expected outcomes are surfaced to the SME for feedback that drives targeted graph refinements, and the loop iterates until agreement metrics meet a predefined threshold, at which point the skill is deployed. This authoring pipeline is orthogonal to the execution framework and training strategy that are the focus of this paper, so we do not detail it further, but it makes the approach scalable to new workflows.

3.4 Tool Ecosystem

The agent operates over five tools: a persistent code interpreter for programmatic data manipulation and metric computation; a task-tracking list that doubles as a steering mechanism to keep traversal on the intended path; MCP-based data and action access (Anthropic, 2024) to operational dashboards; agentic RAG (Schick et al., 2024) for on-demand knowledge retrieval; and an operative memory that persists across invocations, accumulating knowledge and enabling deduplication of redundant investigations. Appendix A details each one.

4 Training Strategy

The graph-guided framework (Section 3) is model-agnostic, but even the largest available models fail to reach reliable accuracy on graph-structured procedural reasoning (Nandi et al., 2025), motivating domain-specific training. Our trajectory-centric pipeline has three stages. First, a strong teacher generates trajectories within the full framework, and episodic learning (EL) (Shinn et al., 2024). EL is a text memory of past errors injected into the prompt, which iteratively corrects the teacher's mistakes without weight updates. Second, rejection sampling (Yuan et al., 2023) with LLM-judge evaluation (Zheng et al., 2024a) retains only correct trajectories. Third, a smaller student that meets the production latency SLA is fine-tuned on these trajectories *with the EL memory stripped*. We call this *asymmetric* episodic distillation because EL is applied only on the teacher side and the student never sees the memory during training or inference, so it must internalize the corrections in its weights, and no runtime memory store is needed. Appendix B details each stage.

5 Experiments

5.1 Experimental Setup

The agent framework is implemented using the Strands Agents SDK (Strands Agents, 2025), following the design in Section 3. We fine-tune Qwen3-32B (Yang et al., 2025) and GLM-4.5-Air (Zeng et al., 2025) with LoRA (Hu et al., 2022) on 8,525 training samples (expanded from trajectories via turn-level decomposition, Appendix B). Training and inference details are in Appendix E.

Datasets We evaluate on three tasks: an **operational reasoning benchmark** of 13 task types testing capabilities required for warehouse operational reasoning (1,400 evaluation samples; Table 1), a **robotic conveyance application** covering end-to-end SOP execution over 1,500 real scenarios, and a **ticket processing application** executing a 46-node inventory consolidation SOP on 410 real

Table 1: Operational benchmark: % improvement over the GLM-4.5-Air baseline across 13 tasks.

tickets evaluated against expert annotations. For the first two, ground truth is generated from real operational data by sampling timestamps, checking root-node conditions, and running a deterministic SOP implementation where they hold, with temporal partitioning separating training from evaluation. Ticket processing has no deterministic ground truth, so correctness is estimated from expert review of sampled agent traces.

Evaluation Claude Sonnet 4 is used as the automated judge of answer correctness for the first two tasks. On the benchmark, the judge scores model outputs against reference answers. On the robotic conveyance application, node classifications are extracted from agent trajectories and compared against ground-truth labels, reporting binary correctness (per-node accuracy) and exact match (all nodes of a type correct within a scenario). Because ground truth is deterministic, judging reduces to structured matching rather than open-ended assessment; the LLM judge was validated against human judgements and achieves full agreement, confirming its reliability for this structured evaluation setting. For ticket processing, correctness is estimated from expert review of agent traces (Appendix F). Results are reported as improvement over the GLM-4.5-Air off-the-shelf (OTS) baseline.

Models All models are evaluated within the same framework, with identical tools and skills and with episodic memory stripped at inference (Section 3). The **baseline** is OTS GLM-4.5-Air, a 106B parameter model that meets the production latency SLA, hence the reference point for what is achievable under operational constraints. GLM-4.7 (355B), the **teacher** that generated training trajectories, is too large to meet that SLA, so it serves as a trajectory generator and upper reference rather than a deployable baseline. GLM-4.7 was selected as teacher because it achieved the highest off-the-shelf accuracy on our benchmark among the open-weight models we evaluated, and its reasoning patterns align with our target student (GLM-4.5-Air), facilitating knowledge transfer; distillation from closed commercial models is not permitted under their terms of service, constraining teacher selection to open weights. The distillation framework itself is model-agnostic, and any sufficiently capable open-weight teacher can be substituted. We additionally compare OTS Qwen3-235B-A22B-Thinking and OTS Qwen3-32B, against our two fine-tuned models Eluna-Q (Qwen3-32B) and Eluna-G (GLM-4.5-Air). For the ticket task, which runs on a longer interval, we additionally fine-tune the teacher itself into Eluna-G-XL, whose latency meets that SLA.

5.2 Results

Operational Benchmark. Table 1 reports per-task results. Eluna-G improves 6.5% and Eluna-Q improves 6.0% over the baseline on average. Eluna-Q, trained on GLM-4.7 trajectories, matches the teacher (+6.0% vs. +6.1%) despite being a different and smaller architecture, showing that our pipeline transfers operational reasoning across model families, while OTS Qwen3-32B averages 38.0% below the baseline, showing the gap that domain-specific

	Binary Correctness			Exact Match		
Model	OB	RC	ACT	OB	RC	ACT
GLM-4.7 (teacher)	+50.2	+73.7	+8.5	+93.7	+84.0	+164.8
Eluna-Q	+48.9	+73.9	+8.5	+93.7	**+84.4**	**+165.3**
Eluna-G	+49.5	**+73.9**	+8.5	**+93.9**	**+84.4**	+164.8

Table 2: Robotic conveyance application: % improvement over GLM-4.5-Air baseline, averaged over 4 runs.

Configuration	**OB**	**RC**	**ACT**
Single-agent, full SOP (Agent-S style)	+76.1	+73.3	+129.5
Multi-agent, full SOP	+81.0	+77.6	+137.1
Single-agent, progressive disclosure	+91.6	+77.7	+158.0
Multi-agent, prog. disclosure (Eluna)	**+93.9**	**+84.4**	**+164.8**

Table 3: Architectural ablation on the robotic conveyance application (All rows use GLM-4.7): exact-match % improvement over the GLM-4.5-Air baseline, as in Table 2.

Setting	**Task 5 (%)**	**Task 10 (%)**
No EL anywhere (reference)	0.0	0.0
EL in teacher + student (train & eval)	+16.6	+25.3
EL in teacher + student (train only)	-52.7	-40.0
EL in teacher only (Eluna)	**+16.2**	**+28.6**

Table 4: Episodic learning (EL) ablation: % change relative to the no-EL variant.

training closes. The largest gains concentrate on complex multi-step tasks like Causal Chain Analysis (Task 5), Query Understanding (Task 8), and Query Decomposition (Task 10). These require chaining tool calls and synthesizing across data sources, indicating that training instills operational reasoning rather than single-step retrieval.

Robotic Conveyance Application. End-to-end SOP execution is far harder than isolated benchmark tasks: even with full framework access, the OTS baseline compounds per-node errors across the traversal and degrades sharply. We report binary correctness and exact match (Section 5.1) per node type (observations, root causes, and actions) to reflect the distinct sub-tasks of detection, diagnosis, and remediation. Fine-tuning on complete trajectories closes the gap (Table 2): all trained models improve observation binary correctness by over +49%, root-cause binary correctness by over +73%, and exact match by +84% on root causes and +165% on actions, with our 32B model matching the GLM-4.7 teacher across all metrics, which shows that trajectory distillation transfers full SOP traversal behavior, not just isolated skills.

Median end-to-end execution latency (wall-clock from query to final action) is also reduced by 54.3% (Eluna-Q) and 54.8% (Eluna-G) relative to GLM-4.7, meeting the latency constraints for real-time diagnostic support.

5.3 Ablation Studies

Architectural Ablation. Table 3 isolates the contribution of the two architectural components of Section 3, namely progressive disclosure and multi-agent delegation, by running GLM-4.7 on the robotic conveyance application under all four configurations. The single-agent, full-SOP configuration doubles as a paradigm comparison: it simulates Agent-S (Kulkarni, 2025), where a single LLM receives the entire SOP as a prompt-driven state machine without progressive disclosure or parallel delegation.

Both components contribute meaningfully. Progressive disclosure provides the larger individual gain (rows 1 vs. 3: +76.1 to +91.6 on observations, +129.5 to +158.0 on actions), consistent with the context-overload hypothesis of Section 3.1. Sub-agent delegation adds complementary improvements, particularly on actions (+158.0 to +164.8), where isolated node evaluation benefits graph-level state management. The full Eluna architecture achieves the best results across all metrics and outperforms the Agent-S-style configuration by +17.8 on observations, +11.1 on root causes, and +35.3 on actions, confirming that the gains come from how the SOP graph is integrated into inference rather than from model strength alone.

Episodic Learning Ablation. Table 4 isolates the contribution of EL by varying where the EL memory is applied. We use Tasks 5 and 10 from the benchmark as a deliberate proof of concept before full-scale training: they are the hardest tasks for GLM-4.7 (Table 1), maximizing the room for episodic correction to demonstrate measurable gains; the full pipeline (Tables 1 and 2) then applies the validated design across all 13 tasks and both production applications. Results are reported as percentage change relative to the no-EL variant.

Applying EL only to the teacher (our approach) yields +16.2% on Task 5 and +28.6% on Task 10, matching the variant that also feeds EL to the student at inference (Task 5: +16.6%, Task 10: +25.3%) but without its runtime memory dependence. Training the student with EL yet removing it at inference degrades catastrophically (Task 5: −52.7%, Task 10: −40.0%), confirming that our

Metric	Value
Overall estimated correctness	94.4%
Consolidation decision precision	96.7%
Consolidation decision recall	99.2%
Consolidation decision F1	98.0%
Terminal distribution	
Proceed to consolidation	84.1%
Rejected (no eligible inventory)	13.7%
Manual handling (outside SOP scope)	2.2%

Table 5: Ticket processing: Eluna-G-XL (open-weight 355B fine-tune) correctness (Appendix F).

asymmetric design must distill episodic knowledge into parameters rather than expose it as a brittle inference-time dependency. Appendix C details the four variants.

6 Deployment and Business Impact

Our framework is deployed in production across multiple operational applications, served on Amazon Bedrock AgentCore (Amazon Web Services, 2026). The two applications below apply it in contrasting regimes: robotic conveyance is latency-critical metric analysis, while ticket processing is latency-insensitive but needs complex reasoning.

6.1 Robotic Conveyance

This metric-analysis task queries live dashboards to compute metrics, and compares them against thresholds over a 63-node SOP graph whose high branching factor drives parallel sub-agent delegation. A degraded station can back up the main conveyor and erode facility-wide throughput in minutes, so diagnosis must be fast and correct.

In production deployment at a warehouse, the agent has processed roughly 8,000 triggers, producing 3,435 process alerts and 1,078 maintenance tickets. SOP adherence is near-perfect: SME review of agent trajectories finds the execution correct. The remaining errors trace to gaps in the SOP specification and upstream data quality rather than to agent reasoning. Prior to deployment, operators manually interpreted dashboards, navigated SOPs, and coordinated corrective actions. Early deployment feedback indicates a 300% speedup in resolution time while reducing cognitive load and improving SOP adherence consistency.

6.2 Ticket Processing

This is a language-reasoning task. The agent interprets free-text ticket requests (expiration, damage, recalls, audits) and performs multi-step reasoning over structured inventory records (validating constraints, resolving eligibility, and deciding consolidation) rather than merely parsing the request. Each request type routes differently, and eligibility depends jointly on item condition and storage-location type. The SOP graph contains 46 nodes and is predominantly sequential, with mutually exclusive conditional paths. The network processes tens of thousands of these tickets daily. Approximately 80% are handled through an existing scanning workflow. The remaining 20% require manual desk processing at $\approx$6 minutes per ticket. We deploy Eluna-G-XL, an open-weight 355B fine-tune from the same pipeline. The agent's median generation duration is 187s (p90: 257s, mean: 210s), below the manual rate.

The agent automates the digital triage preceding physical inspection: interpreting the request, querying inventory, validating constraints, and submitting the pick, leaving the associate only the inspection. Precision (Table 5) is the operationally critical metric, as a false consolidation submits a pick that cannot be processed, wasting labor and blocking the queue. Only a small fraction of tickets need manual handling, freeing capacity for substantially larger volumes.

7 Conclusion

We presented Eluna, a production-deployed agentic system for reliable SOP execution that combines graph-guided progressive disclosure, hierarchical multi-agent delegation, and skill packaging with a trajectory-centric training pipeline built on asymmetric episodic distillation. Deploying Eluna in production surfaced two lessons that generalize beyond our setting. First, within the graph-guided framework, distillation beats scale for procedural compliance: a fine-tuned 32B model matches a far larger teacher and surpasses every OTS model tested, which plateau regardless of size. Second, the operational constraint of low latency under a production SLA is what forced the asymmetric distillation design, since exposing episodic memory at inference proved a brittle dependency rather than just an accuracy gain. The residual errors we observe trace to SOP-specification gaps and upstream data quality rather than agent reasoning, pointing to the SOP authoring and data-integrity pipeline as the next bottleneck for reliable operational automation.

Limitations

Our system is currently deployed on two operational domains; while the skill-based architecture is designed for generality, transfer to substantially different operational environments remains to be validated empirically. The episodic learning pipeline assumes access to a capable teacher model and sufficient compute for multiple trajectory generation rounds, which may limit adoption in resource-constrained settings. Finally, both episodic learning and fine-tuning rely on ground-truth labels, which are expensive and time-consuming to obtain at scale; reducing this dependence is important future work.

Appendix

A Tool Ecosystem Details

Code Interpreter. The agent performs data manipulation and metric computation through a persistent Python interpreter (CodeAct (Wang et al., 2024)) whose state (variables, imports, and intermediate results) is retained across tool invocations within an investigation. Operational data retrieved through MCP tools is analyzed programmatically to perform operations such as filtering, aggregating, and computing derived quantities, so that only the resulting view enters the model's input context rather than the full table. Executing comparisons and threshold checks in code eliminates arithmetic errors that arise when models perform these operations in natural language, and loops over CodeAct functions (programmatic wrappers exposed within the interpreter) let the agent batch repeated queries without issuing a separate tool call per iteration.

Task Tracking. A `TodoList` tool, exposed within the interpreter, lets the agent record and update the steps of an investigation as it traverses the decision graph. Beyond bookkeeping, this serves as a steering mechanism: maintaining an explicit plan keeps the agent on the intended path through parallel branches, surfaces which nodes remain to be evaluated, and reduces premature termination on multi-step procedures.

MCP Tools. Data retrieval and actions are implemented through the Model Context Protocol (Anthropic, 2024), providing a standardized interface to warehouse operational dashboards. A `query_metric` interface abstracts tool invocation, accepting a tool name, warehouse identifier, and time range, and returning results as pandas DataFrames for the interpreter to consume. Decoupling the agent's reasoning from data-source implementation lets dashboard backends evolve independently, and thread-safe connection management enables concurrent queries from parallel sub-agents.

Agentic RAG. The agent augments its decision-making with domain knowledge retrieved on demand. Unlike static pipelines that prepend fixed context (Lewis et al., 2020), the agentic RAG component operates via tool-calling (Schick et al., 2024): when the agent detects a knowledge gap, it formulates a query and invokes a knowledge-base tool, receiving relevant passages as a tool response. This grounds reasoning in operational definitions, site-specific configurations, and historical incident documentation, and lets these definitions be updated without modifying the core SOP structure.

Memory. The framework includes an operative memory that persists across agent invocations, accumulating knowledge over time rather than treating each investigation in isolation. The agent queries memory for prior findings on an entity before investigating and writes its outcome afterward, so observations build into patterns that are not visible within a single run. Deduplication follows as a direct consequence: when a prior invocation already resolved the same condition or determined that no remediation is possible, the current agent omits the redundant investigation. Memory entries expire after a configurable window so that stale findings do not suppress legitimate re-evaluation.

B Training Pipeline Details

Episodic Learning for Teacher Improvement. Initial teacher trajectories contain errors such as missed branches and threshold misinterpretations. Rather than manually correcting these, we iteratively improve the teacher through episodic learning (Shinn et al., 2024) without weight updates. The episodic memory is used only during teacher trajectory generation and is excluded from student training and inference. After each batch of teacher runs, trajectories are evaluated against ground truth. For failures, a separate LLM analyzes the error and generates candidate memory entries that would prevent recurrence. New entries are added, and a consolidation step merges redundant entries to keep the memory compact. The teacher is re-run with updated memory injected into its prompt, iterating for N rounds until convergence. Providing the memory at inference would yield equivalent accuracy (our ablation in Section 5.3 confirms this), but adds prompt overhead and requires maintaining a growing memory store. Training on improved trajectories without the memory forces the student to internalize the episodic corrections in its weights, eliminating runtime context dependence.

Trajectory Decomposition and Fine-Tuning. Training trajectories are generated by running the teacher on labeled scenarios within the full framework (skills, MCP tools, code execution). For each scenario, the teacher queries operational data through the same tools used at inference time, pro-

ducing a multi-turn trajectory of reasoning, tool calls, and tool outputs. Scenarios are sampled with balanced representation across outcome categories, and temporal partitioning enforces train-test separation. We decompose each trajectory into T training samples (one per agent turn): the t-th sample takes as input the conversation history up to turn t (system prompt, all prior tool calls and outputs, with the model's own reasoning from prior turns stripped) and targets the complete reasoning and action for turn t. Retaining tool outputs is necessary: omitting them would desynchronize the model's state from the actual execution trace. Stripping prior reasoning forces independent generation at each turn, focusing the loss on single-turn decision quality. Not all trajectories are correct even after episodic improvement. We apply rejection sampling (Yuan et al., 2023) with LLM-judge evaluation (Zheng et al., 2024a): numerical outputs are compared with 2% tolerance, and categorical outputs require exact match. Only fully correct trajectories are retained for fine-tuning; exploiting the rejected trajectories through preference-based objectives (Liu et al., 2026) is a natural extension.

C Episodic Learning Ablation Details

To isolate the impact of episodic learning and understand whether asymmetric distillation is necessary, an ablation is performed on Tasks 5 and 10 from the benchmark (Table 4). Four variants are tested: (1) no EL anywhere, (2) EL in teacher only (our approach), (3) EL memory provided to the student during both training and inference, and (4) EL memory provided during student training only, removed at inference. Applying EL only to the teacher (our approach) yields +16.2% on Task 5 and +28.6% on Task 10 over the no-EL variant. When EL is given to the student at both training and evaluation, comparable accuracy is reached (+16.6%, +25.3%), but an inference-time dependence on the growing EL context is introduced, adding latency for no accuracy gain. Training with EL but evaluating without it degrades catastrophically (-52.7%, -40.0%), falling below even the no-EL variant. This shows that naively exposing the student to episodic context creates a brittle dependency. Our asymmetric design distills the episodic corrections into the student's weights, removing any inference-time memory requirement.

D Cost Analysis

Training and deploying a capable model is an unavoidable investment when the goal is faithful execution of complex, multi-step SOPs with strict correctness requirements: off-the-shelf models plateau regardless of scale (OTS Qwen3-235B averages -10% versus baseline, and even the 355B teacher reaches only +6.1%; Table 1), consistent with the broader observation that general-purpose LLMs require domain-specific adaptation to perform reliably in specialized domains (Liu et al., 2025), while the alternative of manual execution at $\approx$6 minutes per ticket carries far higher ongoing operational cost. We nonetheless take deliberate steps to minimize compute requirements. First, LoRA fine-tuning (Hu et al., 2022) rather than full-parameter training reduces trainable parameters by orders of magnitude, completes in at most 2 epochs, and its rank can be adjusted to available resources; even a rank-32 fine-tune (Eluna-G) outperforms all OTS baselines. Second, asymmetric distillation compresses the 355B teacher into production-viable students (32B/106B) that match or exceed teacher accuracy, and the teacher is used only offline for trajectory generation, never at serving time. Third, at inference the fine-tuned 32B model is served on 8 H100 GPUs via vLLM with a 54% latency reduction versus the teacher at equivalent accuracy, and merged LoRA weights add zero inference overhead. At production scale these recurring savings, e.g. $\approx$8,000 autonomously processed conveyance triggers with a 300% resolution speedup or ticket processing below the manual rate (median 187s vs. $\approx$360s), substantially exceed the one-time training cost.

E Training and Inference Details

Models are fine-tuned using MS-SWIFT (Zhao et al., 2024) with LoRA (Hu et al., 2022). For Qwen3-32B, we use rank and alpha of 256, learning rate 2×10^{-4}, and train on 64 H100 GPUs. For GLM-4.5-Air, we use rank and alpha of 32, learning rate 1×10^{-4}, and train on 128 H100 GPUs. Both use a batch size of 64, 5% linear warmup followed by cosine annealing to zero, and train for 2 epochs. The ticket-processing model Eluna-G-XL fine-tunes GLM-4.7 (355B) with the same MS-SWIFT/LoRA pipeline (rank and alpha 64, learning rate 5×10^{-5}, batch size 64, 1 epoch) on 128 H100 GPUs. LoRA weights are merged after training, eliminating inference overhead. At inference,

Eluna-G and Eluna-Q are served via vLLM (Kwon et al., 2023) on 8 H100 GPUs, and Eluna-G-XL via SGLang (Zheng et al., 2024b) on 8 H200 GPUs.

F Ticket Processing Evaluation

Model. The deployed ticket-processing agent is Eluna-G-XL, an open-weight GLM-4.7 (355B) fine-tuned with the same trajectory-centric pipeline as Eluna-G and Eluna-Q (Appendix B, config in Appendix E). Ticket processing runs on a longer interval than robotic conveyance, so a larger fine-tune is admissible: Eluna-G-XL's median generation duration (Section 6.2) meets that requirement. All results in Table 5 are from this single fine-tuned model.

Evaluation setup. The 410 tickets are an unbiased sample of open consolidation tickets at one fulfillment center on a single day, processed by the agent in the production framework with live inventory access. The task has no deterministic ground truth (the correct solution depends on live inventory state at processing time), so correctness is estimated by expert review of agent traces: three experienced operations associates per batch examined each original ticket and its correspondence alongside the agent's reasoning trace, and judged the solution as correct or incorrect. Tickets were distributed across reviewers to maximize coverage rather than labeled redundantly, so by design no inter-rater agreement statistic exists for this review.

Leveraging Turn-taking Dynamics for Intent Recognition in Multi-party Conversations

Galo Castillo-López **Alexis Lombard** **Gaël de Chalendar** **Nasredine Semmar**
Université Paris-Saclay, CEA, List, Palaiseau, France
{galo-daniel.castillolopez, alexis.lombard, gael.de-chalendar, nasredine.semmar}@cea.fr

Abstract

We propose a multi-task learning approach for multi-party dialogue intent recognition that leverages an auxiliary task that models turn-taking dynamics. Specifically, we introduce turn-transition entropy, a self-supervised target computed from the sequence of speaker transitions, which quantifies the predictability of interaction patterns. Experiments on multiple pre-trained models demonstrate that incorporating this auxiliary task improves intent recognition performance, outperforming existing approaches which ignore multi-party interaction dynamics. We find that our proposed continuous target can be learned as a single-task objective, suggesting that it is an actual signal carrying useful information.

1 Introduction

Detection of users' intents is a fundamental component of task-oriented dialogue systems, enabling conversational agents to understand user needs and generate appropriate responses (Zhu et al., 2025). While intent recognition has been extensively studied in dyadic dialogues (Zawbaa et al., 2024; Arora et al., 2024; Sali and Toraman, 2025), the multi-party scenario, where agents interact with multiple users simultaneously, has been overlooked. Recent work has investigated intent recognition in multi-party conversations (MPCs) using both small and large language models (Castillo-López et al., 2025a; Liu et al., 2026b). However, most approaches fail to leverage information from the inherent multi-party interaction dynamics, such as turn-taking behavior, conversation disentanglement, and others (Ganesh et al., 2023; Sapkota et al., 2025).

In this paper, we propose a multi-task learning approach that incorporates an auxiliary task to capture turn-taking dynamics for multi-party dialogue intent recognition. Unlike dyadic conversations, where turn-taking is relatively simple to anticipate,

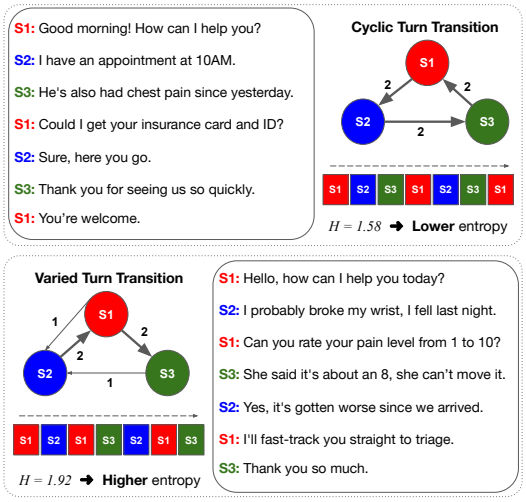

Figure 1: Examples of low- and high-entropy turn transitions. The top conversation follows a structured pattern of speaker transitions, presenting a lower turn-transition entropy. The bottom conversation exhibits more varied and less organized speaker transitions, leading to a higher entropy[1]. Note that both examples have the same number of speakers and turn shifts.

MPCs involve multiple potential next speakers, making speaker interaction patterns more complex (Skantze, 2021; Castillo-López et al., 2025b). We argue that such patterns provide useful contextual cues to model MPCs and therefore improve intent recognition in these scenarios. Although tasks such as next-speaker prediction and addressee detection have been widely studied (Gu et al., 2022; He et al., 2024; Mori et al., 2026; Inoue et al., 2025), they often require additional annotations or assumptions about the number of participants.

To address these limitations, we introduce an auxiliary regression task that predicts the uncertainty of turn-taking patterns in the dialogue context. Given the turns preceding a target utterance, we extract speaker-transition pairs (e.g., Speaker A → Speaker B, Speaker B → Speaker C) and

[1]We define the entropy computation in Section 3.3.

EMNLP 2026 Industry Track, pages 2717–2731
October 24-29, 2026 ©2026 Association for Computational Linguistics

compute their Shannon entropy (Shannon, 1948). This **turn-transition entropy** quantifies the predictability of interaction dynamics: low entropy indicates more organized turn-taking, whereas high entropy shows more unpredictable turn transitions (Figure 1). By learning to predict this quantity, intent recognition models are encouraged to capture interaction dynamics inherent to MPCs without requiring additional annotations or a fixed number of participants. Our main contributions are as follows:

- We introduce **turn-transition entropy**, a self-supervised continuous target that captures turn-taking dynamics in multi-party dialogues.
- We evaluate the practical use of the turn-transition entropy as an auxiliary task for fine-tuning multi-party intent recognition models.

2 Related Work

Intent detection has been widely studied in dyadic dialogues (Wang et al., 2023; Gautam et al., 2024; Benayas et al., 2025). More recently, the use of LLMs for intent recognition has gained attention in single-turn (Sali and Toraman, 2025; Castillo-López et al., 2026; Arora et al., 2024) and multi-turn dialogue (Liu et al., 2026a). Multitask learning methods have proposed incorporating auxiliary tasks such as named entity recognition (Perdana et al., 2025; Benayas et al., 2021), dialogue act classification (Firdaus et al., 2021), and slot filling (He et al., 2021b; Firdaus et al., 2023). These multitask methods, however, require additional annotations that are not feasible in many real-world applications. Castillo-López et al. (2025a) presented a hybrid approach that combines small and large language models in few-shot settings on MPCs. Multimodal fusion methods in MPCs have also been investigated (Chen et al., 2024; Shen et al., 2025). However, none of such works explicitly aim to capture inherent multi-party behavior.

Research in dialogue act classification, a similar dialogue multiclass classification task at utterance level, has explored modeling multi-parity (Anwar et al., 2024). Most studies have investigated modeling speaker-related dynamics for improving dialogue understanding (Fu et al., 2025). He et al. (2021c) addressed the task by introducing speaker-turn embeddings added to utterance representations before contextual encoding. This mechanism efficiently signals speaker switch or continuation, but reducing speaker identities to a binary pattern comes at the expense of retaining speaker-specific turn taking information. This limitation, most consequential in MPCs, was addressed by Qamar et al. (2023), who proposed a speaker-specific graph model for multi-party dialogue act classification. Their approach learns graph-structured speaker representations from speaker–utterance connections and concatenates them with contextual utterance representations to model local speaker behavior. However, this makes speaker modeling dependent on an explicit speaker–utterance graph neural module for each dialogue. Additionally, it primarily captures local speaker behavior rather than the global distributional structure of turn transitions.

In contrast to prior research, we incorporate turn-taking dynamics for multi-party intent recognition through a self-supervised multitask strategy. That is, without requiring additional costly annotations. In addition, our approach does not rely on a fixed number of speakers. Rather than using speaker-turn embeddings or graph-derived speaker representations, we introduce turn-transition entropy as an auxiliary regression signal, encouraging transformer-based models to capture the structure of speaker transitions while optimizing the main intent classification objective.

3 Experimental Procedure

Let $\mathcal{D}$ be a dataset of multi-party dialogues, where each dialogue $d_k = \{(u_i, p_i, y_i)\}_{i=1}^{n_k}$ is a sequence of n_k utterances, with u_i denoting the i-th utterance, $p_i \in \mathcal{P}_k$ its speaker from a dialogue-specific set of participants $\mathcal{P}_k$, and. $y_i \in \mathcal{Y}$ its intent label. $\mathcal{Y} = \{1, \ldots, m\}$ denotes the predefined set of m intent labels. Our aim is to build a multiclass classification system that assigns each utterance u_i to its corresponding intent $y_i \in \mathcal{Y}$. Our contribution is to leverage the conversational interactions between speakers in $\mathcal{P}_k$.

3.1 Utterance Modeling

We use three different encoders to represent the text from utterances: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and DeBERTaV3 (He et al., 2021a). We use the large versions of all pre-trained models. More details of the models we use are included in Appendix B.1. In addition to the utterance to classify and in line with previous work, we prepend the encoded representation of previous utterances to include context information.

3.2 Context Information Modeling

We add additional learnable embeddings to our encoded text representation to incorporate context information. Following (Zhang et al., 2024), we add segment embeddings to let the model discriminate between contextual utterances and the target utterance u_t to classify. In (Zhang et al., 2024), only utterances previously produced by the target speaker p_t are prepended as context. However, we find that performance improves when incorporating all previous utterances as context, regardless of their speaker. To compensate for the loss of speaker identity that comes with this broader context, we introduce an additional speaker embedding that distinguishes utterances produced by the target speaker p_t from those produced by other participants. Experiments showing the advantages of this modification are described in Appendix D. The final input representation and an overview of our architecture is illustrated in Figure 2.

3.3 Turn-Transition Entropy Auxiliary Task

In multi-party dialogues, the way participants alternate in taking turns may carry implicit structural information about the nature of the conversation. To capture this, we introduce the **turn-transition entropy**, a continuous measure that characterizes the distribution of speaker transitions in a dialogue. Given a dialogue $d_k = \{(u_i, p_i, y_i)\}_{i=1}^{n_k}$, we define the set of observed turn-transition pairs for a target utterance u_t:

$$\mathcal{A}_t = \{(p_{i-1}, p_i) \mid i = 1, \ldots, t\} \tag{1}$$

where each pair (p_{i-1}, p_i) represents a transition from the speaker of utterance u_{i-1} to the speaker of utterance u_i. Let $\mathcal{A}_t^*$ denote the set of unique transition pairs observed in $\mathcal{A}_t$, and $c(a)$ denote the number of times pair $a \in \mathcal{A}_t^*$ occurs in $\mathcal{A}_t$. The probability of each observed turn shift is estimated as:

$$P(a) = \frac{c(a)}{|\mathcal{A}_t|} \tag{2}$$

The turn-transition entropy for target utterance u_t is then defined as the Shannon entropy (Shannon, 1948) over the observed transition pairs:

$$H_t = -\sum_{a \in \mathcal{A}_t^*} P(a) \log P(a) \tag{3}$$

As a result, we obtain a computed continuous value for each utterance. Unlike speaker-count or turn-count statistics, H_t reflects how evenly distributed the turn-taking transitions are among the pairs observed until turn t. A low entropy indicates an organized order of turn transitions (i.e. a few transitions dominate), while a high entropy reflects a more diverse set of turn transitions, i.e. more unpredictable speaker-wise turn shifts. We propose incorporating the defined entropy value as an auxiliary regression target in a multitask learning framework alongside the main intent classification task, to leverage the multi-party nature of the conversation as an additional source of information, encouraging the model to capture turn-taking dynamics to improve intent classification. The distributions of the computed entropy values are shown in Figure 3.

Finally, we argue that the proposed turn-transition entropy variable may correlate with utterance properties such as turn index, context length, and speaker count. This could make unclear whether the model captures turn taking predictability or simpler dialogue properties. Therefore, we propose a normalized version of the auxiliary variable. In particular, the **normalized turn-transition entropy** variable is obtained by dividing the actual entropy values by the speaker counts observed in the context utterances. Consequently, we conduct our multitask learning experiments on both: the turn-transition entropy and the normalized turn-transition entropy variables. In Appendix A, we perform a relationship analysis between the auxiliary targets and the utterance properties that we enumerated previously.

3.4 Intent Classification

We consider two learning approaches for the intent classification task: a single-task (our baseline) and a multitask setting.

Single-Task. In the single-task setting, a classification head consisting of a linear layer followed by a softmax activation is placed on top of the language model to predict the intent label $y_t \in \mathcal{Y}$. The model is optimized using the Cross-Entropy Loss $\mathcal{L}_{\text{cls}}$. Models are fine-tuned across 60 epochs with an early stopping mechanism. More details about model fine-tuning are provided in Appendix B.4.

Multitask. In the multitask setting, we additionally incorporate the turn-transition entropy H_t as an auxiliary regression target. A regression head is connected to an intermediate layer of the language model, specifically the l-th transformer layer,

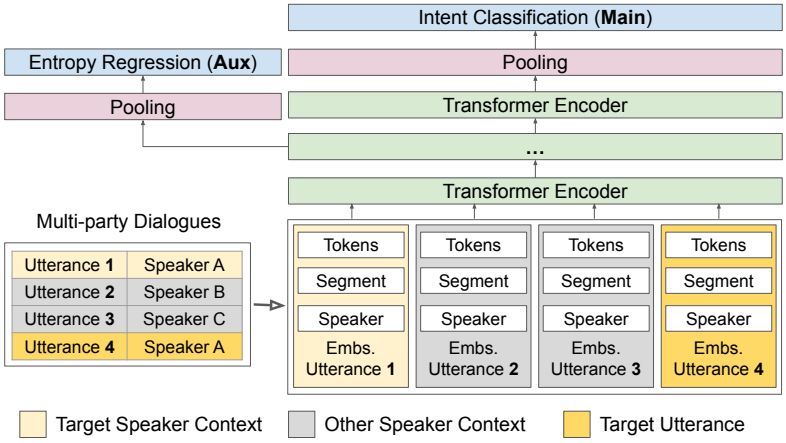

Figure 2: Overview of our multitask learning approach architecture. Input representation includes model token embeddings; segment IDs to distinguish contextual from target utterances (i.e. latest turn utterance, to classify into any intent); and speaker embeddings to discriminate context uttered by the speaker producing the target utterance.

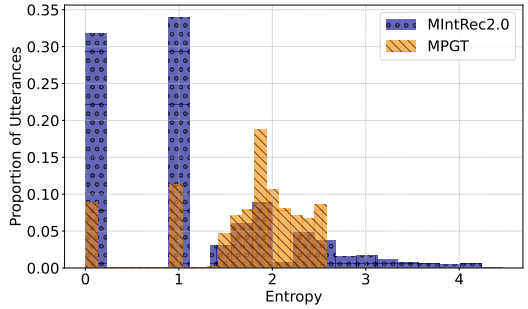

Figure 3: Entropy distributions computed on the training sets of MIntRec2.0 and MPGT.

where l is a tunable hyperparameter. The hidden states at layer l are pooled and fed into a regression head trained to predict H_t, optimized using the Mean Squared Error Loss $\mathcal{L}_{\text{reg}}$. The two objectives are combined using a weighted geometric mean, which is invariant to the scale of the individual losses (Chennupati et al., 2019), controlled by a hyperparameter $\lambda \in [0, 1]$ as $\mathcal{L} = \mathcal{L}_{\text{cls}}^{(1-\lambda)} \cdot \mathcal{L}_{\text{reg}}^{\lambda}$. The hyperparameter λ controls the relative importance of the auxiliary regression task with respect to the main classification task. These additional hyperparameters are optimized using the Tree-structured Parzen Estimator approach (Bergstra et al., 2011; Watanabe, 2023) on Optuna[2](Akiba et al., 2019). Models are fine-tuned across 60 epochs with early stopping. More details about model fine-tuning are provided in Appendix B.5.

3.5 Large Language Model Baseline

In addition to the encoder models fine-tuning, we conduct a baseline experiment using `DeepSeek-R1-Distill-Llama-8B` on zero-shot settings for the intent classification task, following the zero-shot classification described in (Castillo-López et al., 2025a). Figure 5 in Appendix B.2 depicts the prompt template we use for the task.

3.6 Prior Work Baselines

We use the results reported in (Zhang et al., 2024) as a baseline to compare with our work. Moreover, we implement the Label Space Reduction method proposed by Castillo-López et al. (2025a). Their two-stage approach consists in fine-tuning BERT and routing uncertain (i.e. hard) inferences to a LLM. We use `DeepSeek-R1-Distill-Llama-70B`, which provided the best results in their work. Both baseline methods are implemented on $\text{BERT}_{\text{LARGE}}$.

Additionally, we implement the speaker-aware graph-based method of (Qamar et al., 2023) from the paper's methodological description. Unlike the original study, our evaluation covers both $\text{RoBERTa}_{\text{BASE}}$ and $\text{RoBERTa}_{\text{LARGE}}$. Following the original setup, the RoBERTa embedding layer and all transformer layers except the final one are frozen; only the final transformer layer is fine-tuned before training the graph component. Each dialogue chunk is represented as a speaker-utterance graph with one node per utterance and speaker; bidirectional utterance-speaker links yield $(2|D|)$ directed edges with a single relation type. Two RGAT layers, each with two attention heads and hidden size 400, compute utterance-level speaker representations that are concatenated with contextual utterance representations before classification.

[2]https://optuna.org/

The complete hyperparameter configuration used for reproduction is reported in Appendix B.3.

We further implement the speaker-turn embedding baseline of (He et al., 2021c) from the authors' public implementation, only replacing dialogue-act targets with intent labels and RoBERTa$_{\text{BASE}}$ with RoBERTa$_{\text{LARGE}}$.

3.7 Datasets

We use two public multi-party conversations corpora in this work. The first corpus is **MPGT**, which is a set of 29 dialogues between hospital visitors and a receptionist robot (Addlesee et al., 2023). The second corpus is **MIntRec2.0**, a multimodal dataset of 15K dialogue utterances from TV shows (Zhang et al., 2024). In this work we are interested in systems working with text input data, hence we only use the dialogue transcripts data. MPGT and MIntRec2.0 define 8 and 30 intents, respectively. Additionally, we use **MEETInt**, an internal corpus of 75 spoken MPCs from in-person professional meetings, containing 100K utterances and 12 intents. More information about the datasets is detailed in Appendix C.

3.8 Evaluation

We evaluate our fine-tuned intent classification models using the average macro F1 and accuracy over 5 runs with different seeds. The evaluation of the regression task is performed using the Mean Absolute Error (MAE).

4 Results

Table 1 shows the main results of all baselines and our multitask learning approach on all pre-trained models. We observe that our baseline method presents higher macro-F1 and accuracy scores than prior work baselines on both datasets. We also observe that regardless of the backbone model, incorporating our proposed turn-transition entropy auxiliary task –normalized or unnormalized– leads to a macro-F1 score improvement with respect to our baseline on both MPGT and MIntRec2.0. BERT, in multitask settings, achieves the largest macro F1 on MPGT, while DeBERTa shows the highest F1 on MIntRec2.0. We find that in all cases, except for BERT on MPGT, the normalized version of the turn-transition entropy variable provides the largest improvements over the baseline models. The second best F1 scores are obtained on the unnormalized approach. Furthermore, we see that performance improvements are not large on MIntRec2.0, compared to MPGT. Nonetheless, we note that macro-F1 improvements are consistent across models. Also, LLM performance is much lower than the ones obtained by our baseline and multitask methods. To the best of our knowledge, recent studies have consistently shown that fine-tuned BERT-like models generally perform better than LLMs on in-context learning settings for intent detection, as suggested by Zhang et al. (2024)

The Label Space Reduction (LSR) method (Castillo-López et al., 2025a) shows the poorest performance among all models and corpora. However, it is important to note that such a performance comparison is not fair, as the LSR method is conducted on few-shot settings. Moreover, we see that there are 3 to 5 point performance difference between our baseline and (He et al., 2021c; Qamar et al., 2023) on the two datasets. Table 12 in Appendix E shows that both methods implemented on RoBERTa$_{\text{BASE}}$ present a higher performance than the same implementation on RoBERTa$_{\text{LARGE}}$. Nevertheless, our multitask learning approach keeps outperforming both methods. Finally, we observe that our baseline approach on BERT outperforms (Zhang et al., 2024) on MIntRec2.0. We argue that such an enhancement is due to the incorporation of the speaker embedding we propose and describe in Section 3.2. An analysis on the improvement over (Zhang et al., 2024) is described in Appendix D. Finally, in line with the results on public corpora, Table 2 shows that our proposed approach outperforms all baseline methods on MEETInt. We see that our improvements over works by He et al. (2021c) and Qamar et al. (2023) are about 4 and 2 points on macro F1, respectively.

5 Turn-Transition Entropy Learning as a Single Task

To better understand whether turn-transition entropy constitutes a learnable signal, we isolate it from the intent classification task and evaluate it as a standalone regression problem, i.e. as a single task. We replace the classification head of our backbone models (described in Section 3.4) with a regression head and fine-tune the models to predict turn-transition entropy from the text features. In addition, we compare this setting against a control condition in which entropy values are randomly shuffled across training instances. By doing so, our

DeBERTa	0.682	0.220	1.162	0.330

Table 3: Mean Absolute Error (MAE) on the regression target learned as a single task on real and random entropy values. Scores correspond to the average MAE over 5 runs. A lower MAE suggests an ease on the continuous variable learning.

aim is to assess whether the model learns meaningful patterns associated with turn-transition entropy or merely fits arbitrary continuous targets.

Table 3 shows that models trained on real turn-transition entropy values consistently achieve lower MAE than those trained on randomly shuffled targets, across all datasets and backbone models. Figure 4 illustrates this behavior through the learning curves over 25 epochs on MPGT. Models trained on the true entropy signal converge after approximately six epochs and consistently outperform their shuffled-target counterparts. These results indicate that turn-transition entropy is a meaningful and learnable property of the dialogue context rather than an arbitrary continuous target. Therefore, we argue that its effectiveness in the multi-task setting is not solely attributed to a regularization effect, but also to the contextual information captured by the entropy signal itself.

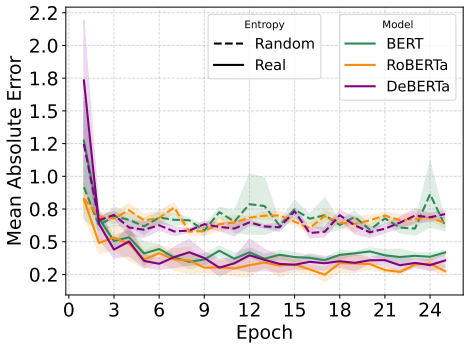

Figure 4: Mean Absolute Error values along training epochs on MPGT validation set across all models.

6 Multitask Learning on Random Entropy Targets

We investigate the effect of using random targets as the auxiliary task in the multitask setting. Similar to our analysis in Section 5, we compare the proposed multitask setting against a control condition in which the entropy values are randomly shuffled across training instances. Table 4 reports the difference in F1 score between the two settings ($\text{F1}_{\text{random}} - \text{F1}_{\text{real}}$). We observe that the differences

Model	MPGT	MIntRec2.0
BERT	-8.84	-0.70
RoBERTa	-5.53	-0.29
DeBERTa	-0.41	-2.15

Table 4: Absolute difference in macro-F1 score of the classification task when replacing the auxiliary regression targets with randomly shuffled values during multitask training ($\mathrm{F1}_{\mathrm{random}} - \mathrm{F1}_{\mathrm{real}}$). Negative values indicate a classification performance degradation when training with random regression targets.

Dataset	H	p-value	ϵ^2
MPGT	51.57	7.11×10^{-9}	0.112
MIntRec2.0	155.15	3.45×10^{-19}	0.021

Table 5: Relationship analysis between the intent classes and the auxiliary variable. Kruskal-Wallis test results and effect sizes across datasets. H corresponds to the Kruskal–Wallis statistic, and ϵ^2 is the effect size

are negative across all settings, showing that models trained with the true entropy values consistently outperform those trained with shuffled targets. In addition, we argue that incorporating the auxiliary task with random targets negatively impacts the performance of the main task. In particular, for both BERT and RoBERTa, the multitask models trained with shuffled targets achieve lower F1 scores than the baseline across all datasets. Overall, these findings demonstrate that the effectiveness of the proposed auxiliary task depends on the quality of the supervisory signal and provide further evidence that turn-transition entropy captures interaction patterns that can be leveraged for intent recognition.

7 Target Variables Relationship Analysis

In this section, we assess the relationship between the auxiliary entropy target and the intent labels by conducting a Kruskal–Wallis test (Kruskal and Wallis, 1952), which is appropriate for comparing a continuous non-Gaussian variable across multiple classes. The Kruskal–Wallis test is a nonparametric statistical test for comparing a continuous variable across k independent groups, whose null hypothesis indicates no difference between groups. We provide the definition and mathematical background of the test in Appendix F. Since the test provides only a p-value indicating statistical significance, without measuring an interpretable magnitude of differences, we also report the effect size ϵ^2 (epsilon-squared), which ranges from 0 to 1. Values of ϵ^2 closer to 1 indicate stronger associations between both variables. Further details on the effect size ϵ^2 are provided in Appendix F. This approach ensures that our conclusions are not only statistically significant but also practically meaningful. The results are summarized in Table 5.

We observe that the Kruskal–Wallis test rejects the null hypothesis that the entropy distributions are identical across intents for both datasets ($p < 0.01$), indicating that the auxiliary variable is statistically associated with the intent labels. The corresponding effect sizes (ϵ^2) suggest a stronger association for MPGT ($\epsilon^2 = 0.112$) than for MIntRec2.0 ($\epsilon^2 = 0.021$). Using the commonly adopted heuristic thresholds proposed by Cohen (1988) and reviewed in (Tomczak and Tomczak, 2014) for variance-explained effect sizes (small ≈ 0.01, medium ≈ 0.06, large ≈ 0.14), the association for MPGT can be regarded as moderate, whereas MIntRec2.0 exhibits a small association. We see that around 11% and 2% of the variability in the ranked entropy values are associated with the intent classes for MPGT and MIntRec2.0, respectively. Although the relationship is weaker in MIntRec2.0, both datasets show statistically significant dependence between the auxiliary target and the intent labels, supporting our intuition to conduct experiments on the use of the entropy regression task as an auxiliary objective. Finally, Figure 6 in Appendix F shows the distributions of the turn-transition entropy values per class for MPGT, which illustrates the expected differences among intents.

8 Conclusions

We present a multitask learning method that captures turn taking dynamics as additional dialogue context for intent detection in multi-party conversations. Our auxiliary self-supervised task models the entropy on turn-taking patterns from speaker turn transitions to characterize dialogues. Our method shows improvement on intent detection systems over previous work approaches, using three model backbones over one private and two public multi-party dialogue corpora. We find that, such a turn-transition entropy can be modeled as a single task and thus does not only act as a regularizer in the multitask setting but is also a signal that provides information about the dialogue. We argue that our work, while performed for intent recognition, provides relevant insights for future work in other classification tasks involving multi-party conversations.

Limitations

While our approach does not impose constraints on the number of speakers, it assumes that speaker identities are available for each utterance, as is the case in the datasets used in our experiments. This requirement is naturally satisfied in scenarios where speaker diarization is controlled or where each participant owns a dedicated audio channel, e.g., video conferencing platforms. Furthermore, speaker identity is generally an easier label to obtain in real-world applications compared to the additional annotations required by alternative approaches, such as dialogue act labels or addressee identity, which typically demand costly expert annotation. Nevertheless, in scenarios where automatic diarization is applied, errors in speaker assignment may affect the quality of the turn-transition entropy signal. Studying the robustness of the turn-transition entropy to such noise is a promising direction for future work.

Ethical Considerations

Our experiments use publicly available corpora, which have been curated prior to our work to prevent malicious actions. The internal corpus that we use in this work, has also been comprehensively curated to prevent malicious actions. Overall, the contributions presented in this paper are designed for constructive and ethical use, with no direct association with harmful social consequences. We do not find any potential risk on the release to the public of this work and the findings that we report.

The fine-tuning of all models developed in this work were executed on private infrastructure using a single NVIDIA A100 Tensor Core GPU of 80GB. The infrastructure has a carbon efficiency of 0.432 $kgCO_2eq/kWh$. The total time required for training across all experiments and analyses, including runs over 5 seeds per setting and hyperparameter tuning, was approximately 80 hours. Therefore, the total emissions are estimated at 13.82 $kgCO_2eq$. These estimations are based on the Machine Learning Impact calculator[4] (Lacoste et al., 2019).

Acknowledgments

We warmly thank our anonymous reviewers for their time and valuable feedback. This work has been partially funded by the European Union's Horizon RIA research and innovation program under grant agreement No. 101189679 (ASTIR). This work also benefited from the FactoryIA supercomputer, financially supported by the Ile-de-France Regional Council.

A Utterance Properties Correlation Analysis

We discussed in Section 3.3 that there are utterance properties that might be correlated with the turn-transition entropy, which motivated the proposal of a normalized version of this auxiliary target. To investigate this relationship, we compute the Spearman correlation between the auxiliary variable (both normalized and unnormalized versions) and such utterance properties. The Spearman rank correlation coefficient measures the strength and direction of the monotonic association between two variables. For n paired observations, it is defined as:

$$\rho_s = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n(n^2 - 1)}, \tag{4}$$

where d_i is the difference between the ranks of the i-th pair of observations. The coefficient ranges from -1 to 1, with values closer to 1 (-1) indicating a stronger positive (negative) monotonic association. Table 6 reports the Spearman correlation coefficients among the variables, where an asterisk ($*$) indicates $p < 0.01$.

Dataset	Property	Entropy	Norm. entropy
MPGT	turn index	0.69*	0.46*
	context length	0.08	0.01
	speaker count	0.66*	0.20*
MIntRec2.0	turn index	0.77*	0.54*
	context length	0.03	0.02
	speaker count	0.89*	0.24*

Table 6: Spearman correlations between entropy measures and utterance properties. An asterisk ($*$) indicates $p < 0.01$.

We observe moderate to high correlations between the entropy values and the turn index and speaker count, on both corpora. However, we see that such relationship becomes weaker when the entropy values are normalized. Given the findings from Table 6 and the results reported in Table 1, we argue that normalizing the entropy variable prevents the model from capturing noise and colinear information from simple utterance properties such as turn index or speaker count. Hence, normalized entropy values better represent turn-taking dynamics without capturing such spurious information, as originally expected.

B Model Implementation Details

In this appendix we provide model implementation details of our experiments.

B.1 Language Models

We use the large versions of uncased BERT, RoBERTa and DeBERTaV3 to build our baseline and multitask intent recognition models. All our fine-tuning runs were conducted on a single NVIDIA A100 Tensor Core GPU of 80GB. We used the `BertForSequenceClassification`, `RobertaForSequenceClassification`, `DebertaV2ForSequenceClassification` class from Hugging Face's Transformers library (Wolf et al., 2020) for sequence classification tasks.

Work in (Qamar et al., 2023; He et al., 2021c) was implemented on the base version of RoBERTa. Thus, we reproduce their methods using $\text{RoBERTa}_{\text{LARGE}}$ for better comparability with our work. Additional experiments on prior research using $\text{RoBERTa}_{\text{BASE}}$ and their results are discussed in Appendix E.

B.2 Large Language Models

Figure 5 shows the prompt template we use in our LLM baseline experiment on the intent recognition task.

B.3 Prior Work Implementation

In our implementations of (Qamar et al., 2023; He et al., 2021c), out-of-scope utterances are excluded from the training loss and evaluation metrics but retained as dialogue context. To preserve faithfulness to the baseline based on (Qamar et al., 2023), hyperparameters are kept close to the original speaker-graph setup when specified. Unspecified hyperparameters are selected to follow relevant standards and support stability and memory usage. They are held identical across datasets, seeds, and encoder variants.

We use chunks of 128 utterances, dropout 0.5, weight decay 5×10^{-4}, learning rate 10^{-4} for the encoder and 10^{-3} for the graph head, training for up to 100 epochs with early stopping after 10 non-improving validation epochs. The learning rate is reduced by a factor of 0.1 after four validation epochs without macro-F1 improvement. The batch size is fixed to 4 to balance optimization stability and memory usage: smaller batches

LLM Intent Classification Prompt

Task description
Your task as an annotator is to assign a supported intent to the last utterance of a dialogue of multiple participants. Return the corresponding intent label.

Authorized categories
The supported intents and their definition are:
[INTENTS_DEFINITIONS]

Previous utterances in the dialogue
You have the following utterance history from multiple participants to understand the context of the dialogue:
[PREVIOUS_UTTERANCES]

Expected output format
Your response should contain the inferred intent between brackets as follows: [intent_label]

Do not write anything else.

Task
The utterance to classify is shown below:
[UTTERANCE_TO_CLASSIFY]

Predicted intent:

Figure 5: Prompt template used on the LLM baseline for the intent classification task. Highlighted text in blue varies among dataset examples.

would yield noisier gradient estimates, while larger batches increase the memory load of 128-utterance chunks processed through the RoBERTa, BiGRU, and RGAT modules (Keskar et al., 2016; McCandlish et al., 2018).

The maximum token length is set to 96 as a compromise between context preservation and transformer cost with shorter limits increasing the risk of truncating informative utterance content and longer limits the quadratic self-attention cost across all utterances in a chunk (Vaswani et al., 2017). Gradient clipping is set to 1.0 as a conservative stabilization threshold for the recurrent component, following the standard use of norm clipping to mitigate exploding gradients in recurrent neural networks (Pascanu et al., 2013).

B.4 Our Baseline Implementation

Our baseline models implement an early stopping mechanism with a wait patience of 5. We use the macro-F1 score as the metric to monitor on the early stopping strategy. We use AdamW optimizer (Loshchilov and Hutter, 2017) for optimizing the training objectives. Table 7 shows the hyperparameter configuration we employ in our baseline experiments for all the models.

hyperparameter	value MPGT	value MIntRec2.0
eval_monitor	macro F1	macro F1

wait_patience	5	5
num_train_epochs	60	60
optimizer	AdamW	AdamW
warmup_proportion	0.1	0.1
lr	1e-5	1e-5
seeds	0-4	0-4

Table 7: Set of hyperparameters used on BERT, RoBERTa, and DeBERTa fine-tuning baseline experiments.

B.5 Multi-task Method Implementation

In addition to the early stopping mechanism applied on the main task (i.e., intent classification), we also set a less tolerant early stopping strategy on the auxiliary task (i.e., entropy regression). We argue that the auxiliary task acts in part as a regularizer during the model fine-tuning, which negatively impacts the main task performance after some training iterations. Hence, we define a patience of 2 epochs for the auxiliary task, which is disconnected from the total loss computation when the early stopping is activated. To do so, we monitor the auxiliary task on the MAE. For the main task, we keep a wait patience of 5. By doing so, we force the model to solely optimize the intent classification loss in the last epochs of the model fine-tuning.

Our proposed multi-task methods includes two additional hyperparameters to the set of hyperparameters used in our baseline experiments (see Section 3.4 and Appendix B.4). First, we add the hyperparameter λ, which controls the weight of the auxiliary loss in the average loss computation on the multi-task setting. Moreover, we include the layer number in our architecture where we connect the regression head. Both hyperparameters are optimized using Optuna. Table 8 shows the search

hyperparameter	search range	step
weight λ	[0.01, 0.20]	0.01
layer l	[3, 21]	1

Table 8: Optuna hyperparameter search space for the average weight λ and layer number l on the multi-task architecture.

spaces we define for both hyperparameters. Table 9 shows the final hyperparameter sets that we use in the multi-task setting experiments, including the optimized hyperparameters λ and l.

C Dataset Statistics

Table 10 shows the number of examples per dataset split. All corpora contain both in-scope and out-of-scope (OOS) intents. That means that there are many utterances that are not associated to any specific intent. Our classification task is defined over in-scope examples. MPGT, MIntRec2.0 and MEETInt contain 22%, 38% and 0.5% of in-scope examples to classify, respectively. Despite we do not use OOS examples as target utterances to classify, we retain them when they are part of the previous utterances as they provide contextual information.

D Speaker Embedding Experiments

We perform additional experiments in order to determine a strong baseline method for our work. In particular, we study different input representations with a fixed architecture over the same backbone models that we describe in Section 3. The input representations are described as follows:

1. **w/o context:** Each example corresponds to the target utterance to classify without prepending previous utterances as context.

2. **only target speaker:** Following (Zhang et al., 2024), each example corresponds to the target utterance to classify and the previous utterances produced by the speaker of the target utterance to classify (i.e. targer speaker) as context.

3. **all speakers w/o speaker emb.:** Each example is represented by the target utterance to classify and the utterances previously spoken by any speaker.

MEETInt	81.9K	21.0K	31.8K	12

Table 10: Number of examples per dataset split and number of labels on each corpus.

observe in Table 11 that the approach proposed by Zhang et al. (2024) outperforms adding all speakers previous utterances without speaker embeddings on BERT and RoBERTa. Nevertheless, our adding our proposed speaker embeddings shows performance gains. Overall, we see that including utterances produced by all speakers with speaker embeddings provides better performance than any other strategy on both models. On the other hand, we see that the best strategy on DeBERTa is the representation that includes all speaker context utterances without speaker embeddings. Similar to the results on BERT and RoBERTa, solely providing target speaker context utterances is not the best strategy on DeBERTa. For consistency and better comparability across models, we select the **all speakers w. speaker emb.** strategy as the input representation for both our baseline and our multi-task learning method.

E Comparison of RoBERTa$_{\text{BASE}}$ and RoBERTa$_{\text{LARGE}}$ on Prior Works

The experiments on prior works (He et al., 2021c; Qamar et al., 2023) that we reproduce and report in Section 4 are conducted on RoBERTa$_{\text{LARGE}}$, since our methods and other baseline approaches are implemented on the large versions of pre-trained models. Our aim is to keep fair comparisons among methods. Nevertheless, results reported in (He et al., 2021c; Qamar et al., 2023) are obtained from experiments on the base versions of RoBERTa. Therefore, we make additional experiments on prior work implemented with RoBERTa$_{\text{BASE}}$. Table 12 shows the performance comparison between the two versions of RoBERTa. Note that, while the results on the base version of RoBERTa are higher, such scores are still lower than our proposed method evaluation presented in Table 1 from Section 4.

F Target Variables Relationship Analysis Details

In this appendix, we provide further details of the statistical relationship analysis described in Section 7. The Kruskal–Wallis test is a non-parametric statistical test for comparing a continuous variable across k independent groups, whose null hypothesis indicates no difference between groups. Rather than operating on raw values, the test converts observations to their ranks. Let N denote the total number of observations, n_i the sample size for group i, and R_i the sum of ranks assigned to observations in group i. The Kruskal–Wallis test statistic H is computed as:

$$H = \frac{12}{N(N+1)} \sum_{i=1}^{k} \frac{R_i^2}{n_i} - 3(N+1), \quad (5)$$

where H approximately follows a chi-squared distribution with $k-1$ degrees of freedom under the null hypothesis of no difference between groups. Unlike parametric alternatives such as ANOVA (Fisher, 1930), this rank-based approach does not assume normality of the data. Thus, given the peaks around 0 and 1 as well as the tails observed in Figure 3, the lack of normality assumption is essential for our analysis. However, the Kruskal–Wallis test provides only a p-value indicating statistical significance, without directly measuring the practical magnitude of differences. To address this limitation, we also report the effect size ϵ^2 (epsilon-squared), computed as:

$$\epsilon^2 = \frac{H - k + 1}{N - k}, \quad (6)$$

where H is the test statistic, k is the number of groups being compared, and N is the total sample size. The effect size ϵ^2 ranges from 0 to 1, with values closer to 1 indicating stronger associations between the grouping variable and the continuous outcome. Finally, Figure 6 shows the distributions of the turn-transition entropy values per class for MPGT, which illustrates the expected differences among intents.

Model	Input Representation	MPGT F1	MPGT Acc.	MIntRec2.0 F1	MIntRec2.0 Acc.

Abstract

Context-heavy agents place substantial pressure on the key–value (KV) cache: long prefixes are reused across many short turns, while concurrency determines whether the serving system can keep GPUs utilized. We study 4-bit KV-cache compression for this setting, using TurboQuant-style rotation and codebook quantization (Zandieh et al., 2026) as a quality anchor and vLLM FP8 KV caching as the deployment anchor. We report three contributions. First, we frame 4-bit KV caching around multi-round agent workloads where task quality, cache residency, and serving throughput must be measured jointly. Second, we describe the practical design choices needed to make the 4-bit path robust, including asymmetric K/V treatment, Walsh–Hadamard rotation (Walsh, 1923; Hadamard, 1893), QJL removal (Zandieh et al., 2024), and block-scale variants. Third, we present serving optimizations on AMD GPUs, including optimized decode-attention kernels and *UltraQuant*, an FP4 approximation path that uses FP8 queries, FP4 KV tensors, UE8M0 group scales, and native scaled-MFMA support on CDNA4. On an adaptive-SLO replay of production Claude Code traces, UltraQuant sustains $2.71\times$ (MiniMax-M2.5) and $4.38\times$ (Qwen3-235B) the qualified-request throughput of the BF16 baseline, matching or exceeding hardware FP8 KV while using half the KV bytes. UltraQuant delivers its largest gains in long-context, high-concurrency, memory-constrained serving regimes.

1 Introduction

Large language models have evolved from chatbots with short context windows into agents that browse the web, inspect repositories, invoke tools, and complete substantial software-engineering tasks (Yao et al., 2022; Schick et al., 2023; Zhou et al., 2023; Yang et al., 2024a). These workflows require long-running memory: the model must retain system instructions, tool definitions, retrieved documents, codebase context, and the evolving plan across many turns. As model releases push context windows toward one million tokens and beyond (Gemini Team, 2024; Ding et al., 2024), the KV cache grows linearly with context length and becomes a first-order consumer of high-bandwidth memory (HBM).

This has driven two complementary lines of work: One line changes the model architecture or attention mechanism to reduce KV state directly, including multi-head latent attention (DeepSeek-AI, 2024a,b) and linear or state-space alternatives (Gu and Dao, 2023; Dao and Gu, 2024; Yang et al., 2024c,b). Another line treats the memory hierarchy as a systems problem, using cache reuse, offloading, and paged-memory management to keep scarce HBM occupied by the most useful state (Kwon et al., 2023; Zheng et al., 2023; Zhang et al., 2024). KV quantization adopts the first approach: we preserve the standard interface while reducing memory overhead.

Compression leads to some challenges; a deployable 4-bit method must offer more than just compression, but rather must retain answer quality on long-context workloads, integrate with paged serving, and dispatch efficiently through GPU matrix cores. FP8 KV caching is a strong deployment baseline in vLLM, giving roughly $2\times$ compression at near-lossless quality with native hardware support. TurboQuant (Zandieh et al., 2026), a data-oblivious 4-bit scalar-plus-rotation method, provides a strong 4-bit quality point but relies on codebook lookup and software dequant.

We study two endpoints on AMD Instinct GPUs. *Ultra-TQ* keeps the TurboQuant representation and closes the kernel gap through layout, lookup, and MFMA scheduling optimizations, along with accuracy improvements through calibrated centroids for each model. *UltraQuant* replaces the code-

[*]Equal contribution.

EMNLP 2026 Industry Track, pages 2732–2750
October 24-29, 2026 ©2026 Association for Computational Linguistics

book with an FP4 micro-tensor approximation so the dequantization is folded into native CDNA4 scaled-MFMA instructions.

Our goal is a deployment-oriented account of low-bit KV caching for context-heavy agents: which quantization choices preserve quality, how those choices interact with decode-attention kernels, and when the serving system benefits from the additional resident context. UltraQuant delivers its largest gains in long-context, high-concurrency, memory-constrained serving regimes.

2 Related Work

2.1 KV-Cache Quantization

The KV-compression landscape has converged on a few recurring design ideas. Keys and values are treated asymmetrically because key errors perturb the softmax distribution differently from value errors, a pattern established by KIVI (Liu et al., 2024) and KVQuant (Hooper et al., 2024). QJL (Zandieh et al., 2024) and TurboQuant (Zandieh et al., 2026) use rotation and codebook methods to improve rate–distortion at small bit widths, and TurboQuant in particular has seen community reimplementation (TheTom, 2026; Chakrabarti et al., 2026). However, the use of the codeboook introduces lookup and irregular-access costs (Chakrabarti et al., 2026). These methods are useful algorithmic anchors for 4-bit quality, but their most accurate representations are not automatically efficient serving formats.

2.2 Rotation and Codebook Quantization

TurboQuant-style rotation (Kurtić et al., 2026) spreads outlier energy across channels so scalar quantizers see a more Gaussian-like distribution. Calibrated centroids fit via per-model Lloyd–Max (Lloyd, 1982; Max, 1960) or its per-block variant (LMPB) then provide a strong 4-bit codebook for the rotated distribution. In this paper, those codebooks are background and motivation rather than the deployed format: UltraQuant uses them to explain why FP4 is plausible after rotation, then replaces arbitrary centroids with the hardware-native FP4 grid.

2.3 Serving Systems and Hardware-Native Low Precision

vLLM-style paged serving (Kwon et al., 2023) makes KV-cache residency a systems concern, not only a compression metric. Hardware-native formats such as FP8 already benefit from direct matrix-core support. UltraQuant extends this serving-first lens to 4-bit KV caching by targeting the CDNA4 scaled-F8F6F4 MFMA path, where FP4 operands and UE8M0 scales are consumed by the matrix core itself.

3 Agentic Serving on Production Traces

For context-heavy agents, each session keeps a long prefix resident in HBM across many turns, so the number of agents a GPU can serve under a latency service-level objective (SLO) depends on how much KV state fits in memory. A smaller KV budget fills first, evicts reusable prefix blocks, and forces expensive re-prefill that spikes time-to-first-token (TTFT). A KV method must therefore keep long prefixes resident at high concurrency and decode at near hardware-native speed, since dequantization overhead can offset the capacity it buys.

We emulate production Claude Code workloads using anonymized, production-derived sessions from the open-source `kv-cache-tester` corpus (Fox, 2024). Virtual users replay recorded sessions against our vLLM endpoint, reproducing multi-turn order, prompt/output-token targets, inter-turn think times, and prefix-sharing structure.

We measure serving under an adaptive-SLO protocol on MiniMax M2.5 and Qwen3-235B. An admission controller ramps from 6 to 48 concurrent sessions, gated by a rolling p95 TTFT against a 120-second target; admission pauses when TTFT headroom drops below the gate. This mimics how a production scheduler trades concurrency against latency. Our primary metric is TTFT-qualified goodput: the rate of completed requests whose first token arrives within the TTFT budget. We report cumulative SLO-qualified requests in the main text; Appendix E gives goodput curves and effective-TTFT tail distributions.

The key mechanism is capacity-driven prefix retention. FP8 KV ramps faster at low pressure but fills earlier, evicting reusable prefix blocks and forcing re-prefill. UltraQuant tracks FP8 KV decode speed under low pressure while offering 3.2–3.4× BF16 logical KV capacity (vs. 2× for FP8), reaching 2.34×/3.25× BF16's prefix-hit ratio on MiniMax/Qwen (vs. 1.07×/0.85× for FP8). The avoided prefill work outweighs UltraQuant's slight decode overhead under pressure.

Model	Scheme	Qual. @120s	Goodput (req/s/GPU)
MiniMax M2.5	BF16	77	0.064
	FP8 KV	168	0.140
	Ultra-TQ	140	0.117
	UltraQuant	209	0.174
Qwen3-235B	BF16	37	0.031
	FP8 KV	80	0.067
	Ultra-TQ	131	0.109
	UltraQuant	162	0.135

Table 1: TTFT-qualified goodput on the production-derived Claude Code adaptive trace replay (600 s assessment window, TP= 2, AMD MI355X). A completion qualifies if its effective TTFT is ≤ 120 s; goodput is the qualifying count divided by the assessment window and GPU count.

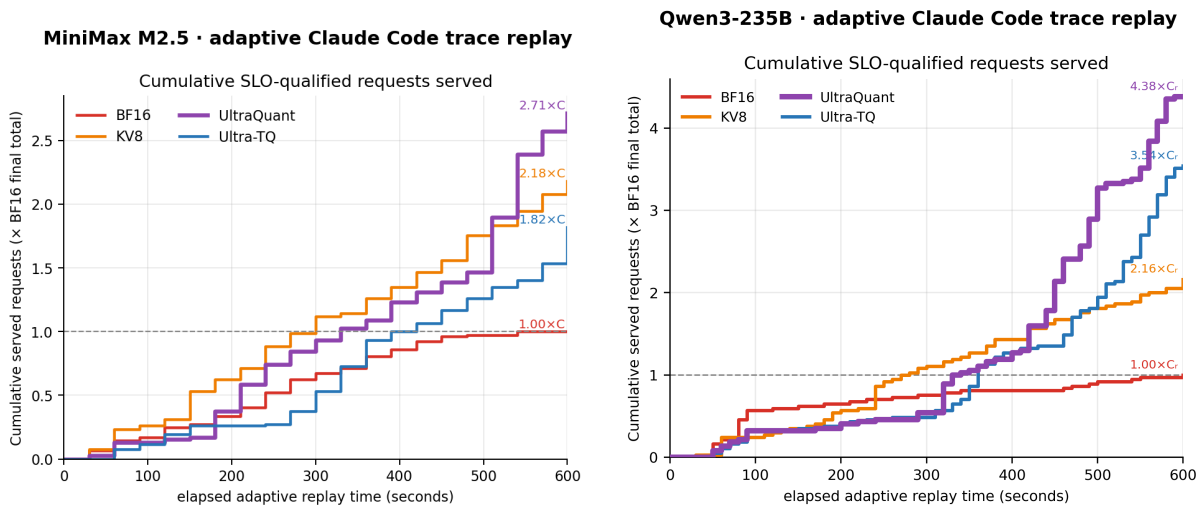
MiniMax M2.5. FP8 KV reaches the concurrency cap earlier, but UltraQuant's SLO-qualified curve accelerates under pressure and finishes at 2.71× BF16's cumulative qualified-request total, compared with 2.18× for FP8 KV and 1.82× for Ultra-TQ (Fig. 1a).

Qwen3-235B. UltraQuant preserves more TTFT headroom as cache pressure rises, finishing at 4.38× BF16's qualified-request total vs. 2.16× for FP8 KV and 3.54× for Ultra-TQ (Fig. 1b).

Figures 1a and 1b normalize cumulative SLO-qualified turns by BF16's qualified-request total. Across both models, FP8 KV has lower compute overhead at low pressure, while UltraQuant retains more KV state under high pressure. Once prefix replacement and re-prefill become expensive, UltraQuant's capacity advantage outweighs its dequant cost. Table 1 reports the terminal TTFT-qualified goodput at the 120-second threshold on the same replay: UltraQuant reaches 2.71×/4.38× BF16's qualified-request rate on MiniMax and Qwen. Aggregate throughput confirms this: UltraQuant reaches 1.25×/1.29× BF16's input/output tok/s on MiniMax and 1.59×/1.53× on Qwen. Full TTFT-goodput curves and effective-TTFT tail panels for the same Claude Code replay are in Appendix E. The practical takeaway is that on identical hardware and under a fixed 120-second SLO, 4-bit KV serves 2.7–4.4× more agent requests than BF16 while matching or exceeding hardware FP8 KV at half the cache footprint.

4 Ultra-TurboQuant

Ultra-TurboQuant (Ultra-TQ) is our optimized implementation of $\mathrm{TQ}_{4/4}$, the 4-bit TurboQuant KV-cache scheme. It starts from the same observation that motivates TurboQuant: the raw KV-cache distribution is a poor target for a small scalar codebook, but a fixed Walsh–Hadamard rotation spreads outlier energy across channels, pushing each coordinate toward the light-tailed, near-Gaussian regime where a 4-bit scalar quantizer is a reasonable approximation. Appendix A presents efficient implementation details.



4.1 Calibrated Centroids

We begin with the observation that calibrating TurboQuant centroids is model agnostic. The production Lloyd–Max centroids assume post-rotation, post-normfold key coordinates follow $\mathrm{Beta}((d-1)/2, (d-1)/2)$, the exact law of a randomly rotated unit-vector coordinate. On real activations this is only approximate, so the theoretical centroids are slightly misplaced. Refitting the 16-entry Lloyd–Max table on captured key activations corrects this. Calibration is cheap — a single forward pass over $\sim$20 randomly sampled vectors from a sphere per rotated layer yields 16 FP32 levels — and deployment is a drop-in table swap with zero inference overhead. In practice, we only refit 10% of layers that show higher per-element quantizaiton MSE.

Calibration is the strongest pure-codebook lever we measured: it lowers per-element K quantization MSE by 10.3% ($1.32 \times 10^{-4} \rightarrow 1.18 \times 10^{-4}$) and improves GPQA by $+1.20$ pp. The empirical centroids are compressed relative to the theoretical ones (largest $|c|$ at $d = 64$ falls from 0.342 to 0.288), reflecting the slight deviation of real activations from the ideal. Rotation remains essential: on the un-rotated distribution, even model-tuned centroids leave $\sim$2.3× the rotated MSE, suggesting that centroid placement cannot replicate rotation's whitening effect. The gain from calibrating centroids is real but modest; we ablate the source of the benefits in Appendix B.1.

5 UltraQuant

A calibrated codebook must be decoded at every attention step: each tile loads packed indices, gathers centroids through a lookup table, and reconstructs keys/values in registers before the QK and PV products (Guo et al., 2024). This gather is irregular and grows with context length. UltraQuant instead stores the cache as MXFP4: FP4 E2M1 codes with UE8M0 scales that the matrix core reads natively, making dequantization a single exponent shift folded into the instruction. The per-group scales is derived from one global constant, calibrated offline

(a) MiniMax M2.5.

(b) Qwen3-235B.

Figure 1: Cumulative SLO-qualified requests served on production-derived Claude Code traces (TP= 2, AMD MI355X), normalized relative to BF16.

and model-agnostic, that minimizes quantization error on the rotated distribution.

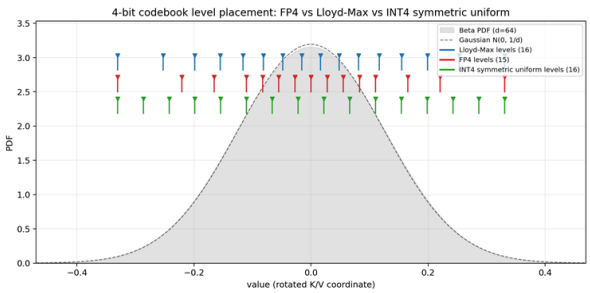
5.1 Cache Layout

UltraQuant stores keys/values in MXFP4. The head dimension is partitioned into contiguous groups of 32 channels, each encoded as 32 FP4 E2M1 codes (packed two per byte) plus one UE8M0 scale: 32×4 bits$+8$ bits $=17$ B per group, i.e. 4.25 bits per element — within 6% of an ideal 4-bit representation, in a format the matrix core consumes natively.

5.2 Dequantization

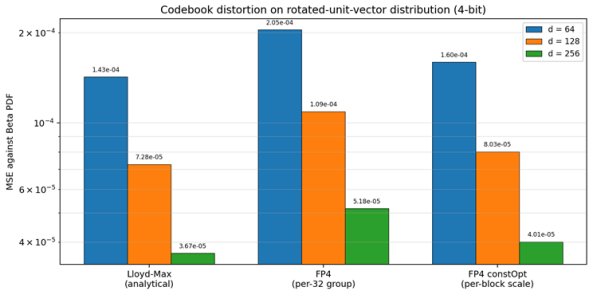
The dequantization rule is:

$$\texttt{value} = \texttt{code}\times 2^{\texttt{scale}}, \qquad \texttt{scale} = \texttt{byte} - 127. \tag{1}$$



The scale is a power-of-two exponent that shifts the FP4 codepoint and folds directly into the scaled-MFMA accumulator. The AMD `MFMA_SCALE_F32_*_F8F6F4` instruction takes FP4 codes and the UE8M0 byte as native operands (Advanced Micro Devices, Inc., 2024), so keys and values are never materialized in BF16. Queries are Hadamard-rotated and rounded to FP8 E4M3, so attention runs on the FP8×FP4 scaled-MFMA path. The constant c (Section 5.3) enters through the encoder rule $E = \mathrm{round}(\log_2(c \cdot m))$ rather than as a runtime multiply.

5.3 Constant-Optimized Scaling



Lloyd–Max centroids for the rotated distribution are symmetric, concentrated near zero, and increasingly wide in the tails: the pattern FP4 must approximate. Fig. 2a shows Lloyd–Max placing levels more densely in the high-probability body than uniform INT4, while FP4 E2M1 has fixed hardware-defined spacing. Plain per-group FP4 is consistently worse than Lloyd–Max in MSE (D'Alberto, 2026), but the constant-optimized per-block scale below recovers most of that gap while keeping the FP4 grid, as quantified in Fig. 2b and ablated in Appendix B.2.

Each group of 32 channels is mapped onto the FP4 grid by a single scale $s = c \cdot m$, where $m = \max_i |x_i|$ is the group's absolute maximum and c is one global constant shared across every group, head, and model. We drop the per-token ℓ_2 normalization (K-norm) used by the codebook path: each block's scale derives from its own absmax, making the blocks self-scaling. A per-token factor cannot be folded into the attention score (it does not pass through the softmax), so it would add a stored scalar and runtime multiply with no quality gain.

The per-group absmax m absorbs all per-token, per-head, and per-model magnitude variation: dividing by m maps each group into $[-1, 1]$. After Hadamard rotation the remaining *shape* is approximately $\mathrm{Beta}((d-1)/2, (d-1)/2)$, depending only on head dimension d. This model-independence is why a single constant works: the one remaining degree of freedom is where this fixed shape sits against the E2M1 grid, i.e. the ratio $c = s/m$. In effect, the per-group absmax together with the constant c takes over the role of TurboQuant's per-

(a) 4-bit codebook level placement at d=64.

(b) Codebook distortion (MSE).

Figure 2: Codebook analysis on the rotated-unit-vector distribution. (a) Lloyd–Max centroids provide the algorithmic reference, FP4 E2M1 is the hardware-native approximation, and symmetric INT4 is a uniform baseline. (b) FP4 has higher MSE than analytical Lloyd–Max, but constOpt per-block scaling closes much of the gap while preserving a hardware-native FP4 representation.

token K-norm.

We choose c to minimize the reconstruction error of the E2M1 grid. With $q(\cdot)$ the nearest-codepoint rounding onto $F = \{0, \pm 0.5, \pm 1, \pm 1.5, \pm 2, \pm 3, \pm 4, \pm 6\}$:

$$c^* = \arg\min_c \mathbb{E}\Big[\big(z - c\,m\,q(z/(c\,m))\big)^2\Big]. \quad (2)$$

This one-dimensional minimization is solved once, offline, on captured rotated key activations. The minimizer is $c = 0.156$, deployed without per-model recalibration across MiniMax and Qwen (Section 6); it remains MSE-optimal in the single-model ablation in Appendix B.2. Figure 2b shows the codebook-level MSE gap.

This one-dimensional minimization is solved once, offline, on captured rotated key activations over a small calibration set. The minimizer on the captured keys is $c = 0.156$, the value we deploy. Note that the distribution post rotation is similar enough that this single fit transfers across models at a given head: we deploy the same $c = 0.156$, without any per-model recalibration, across the MiniMax and Qwen model families reported in Section 6, and it remains the MSE-optimal setting in the single-model ablation in Appendix B.2.

To ablate, we consider alternative constants in Appendix B.2; Figure 2b shows the corresponding codebook-level MSE gap.

6 Accuracy Results

All KV-compressed evaluations use boundary-layer protection: the first and last two attention layers retain BF16 KV caches (n=2). Our primary accuracy result is end-to-end agent task resolution on SWE-bench Lite (Section 6.1): it is the only benchmark here that grades a complete multi-turn agent loop rather than a single response, and it is the setting

Model	BF16	FP8 KV	Ultra-TQ	UltraQuant	Δ BF16
MiniMax M2.5	**62**	**62**	61	59	−3
Qwen3-235B	**28**	21	27	24	−4

Table 2: SWE-bench Lite resolved tasks (fixed 100-task denominator).

UltraQuant targets, since a long shared repository prefix with many follow-up turns is exactly where KV capacity binds. Sections 6.2 and 6.3 summarize retrieval and reasoning accuracy; their per-model tables and per-task breakdowns are in Appendix C.

6.1 SWE-bench Lite Agent Tasks

SWE-bench Lite evaluates end-to-end software-engineering task resolution: for each GitHub issue, an agent inspects the repository, edits over multiple turns, and submits a patch graded by project tests. We evaluate every KV format on a fixed 100-task cohort for MiniMax M2.5 and Qwen3-235B with prefix caching enabled (Table 2).

On MiniMax, UltraQuant resolves 59/100 tasks versus 62/100 for BF16, retaining 95% of BF16's resolved-task count, with FP8 KV at 62/100 and Ultra-TQ at 61/100. On Qwen, UltraQuant resolves 24/100 versus 28/100 for BF16; it exceeds FP8 KV's 21/100 and stays within three points of Ultra-TQ's 27/100. Agent task resolution therefore lands within a few points of BF16 on both models while the KV cache is stored at 4 bits, and on Qwen both 4-bit schemes beat the 8-bit baseline despite its larger per-token budget. Figure 19 in Appendix C plots resolved-task counts for the same cohort under all four KV schemes.

6.2 Retrieval Tasks

Retrieval accuracy is largely preserved and the residual loss is task-dependent rather than uniform. On Llama-3.1-8B-Instruct, UltraQuant matches

BF16 on NIAH and on the 13-task LongBench-E average. Using NVIDIA's official RULER suite (4K–131K, four tasks), Qwen3.5-35B-A3B reaches exact parity at 99.38, while MiniMax M2.5 gives up ground at 74.03 versus 67.08, with the loss concentrated in `single_2` and `multikey_1` and a gain on `multiquery` (Appendix C).

6.3 Reasoning Tasks

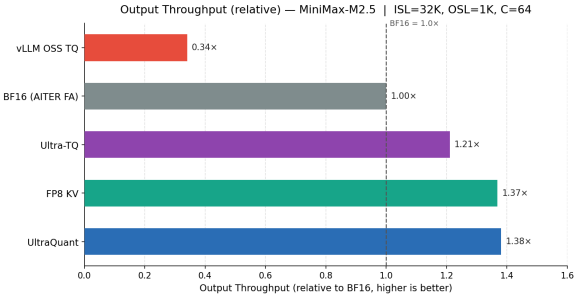
We evaluate every KV format on GPQA Diamond, GSM8K, and AIME25. Deltas are small in both directions: UltraQuant stays within 2 points of BF16 on every model–benchmark pair except Qwen3-32B GPQA Diamond, where it gains 5.58 points. On MiniMax M2.5 GPQA Diamond the intermediate schemes fall between the two endpoints, with FP8 KV at 83.33 and Ultra-TQ matching BF16 at 83.84 (Fig. 17). MiniMax M2.5 AIME25 is averaged over five seeds; Llama-3.1-8B-Instruct AIME25 is omitted for insufficient coverage.

7 Performance Results

We measure UltraQuant's decode throughput and per-token latency against four baselines: vLLM OSS TurboQuant (Kurtić et al., 2026), BF16 AITER (AMD ROCm, 2025) FlashAttention, hardware FP8 KV, and Ultra-TQ, on MiniMax-M2.5, TP= 2, 2×MI355X, 32K/1K at concurrency 64. All results are reported relative to the BF16 AITER FlashAttention baseline (= 1.00×). Folding dequantization into the MFMA gives UltraQuant nearly the same instruction mix as the FP8 kernel, so it tracks the FP8 throughput ceiling while halving the KV-cache footprint. Figure 3 reports throughput across the kernels: at C=64 UltraQuant reaches 1.38× the BF16 output throughput, matching hardware FP8 KV (1.37×) to within ∼1%, while serving twice the KV footprint per unit of HBM.

The FP4 path largely removes software dequantization from the critical path while retaining the memory-capacity benefit of a 4-bit KV cache. UltraQuant delivers 1.38× the BF16 baseline throughput, on par with the hardware FP8 KV-cache path (1.37×) while using half the KV bytes per element. On per-token latency, BF16 has no dequant, so all 4-bit kernels sit above it; UltraQuant's median TPOT is 1.40× BF16, within ∼2% of the hardware FP8 KV-cache path (1.37×) and well ahead of Ultra-TQ (1.58×) and vLLM OSS TurboQuant (5.56×) (Fig. 4a).

The advantage grows with context length. Figure 4b sweeps inter-token latency against input context from 8K to 64K: UltraQuant improves monotonically relative to BF16, reaching ∼0.5× at 64K, while FP8 stays near 1.3–1.5× and Ultra-TQ only catches up at the longest contexts. The half-precision KV footprint is what lets UltraQuant sustain longer contexts before HBM pressure forces re-prefill.



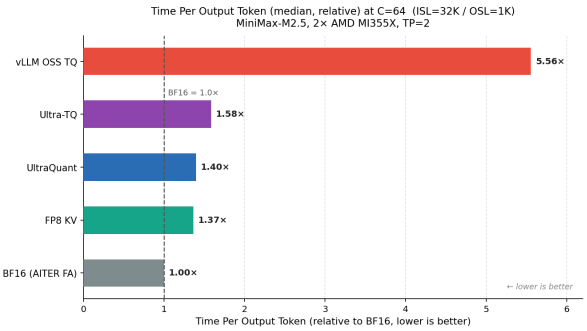


Figure 3: UltraQuant throughput (relative to BF16) vs. BF16, FP8 KV, and Ultra-TQ on MiniMax-M2.5 (TP= 2, 2×MI355X).

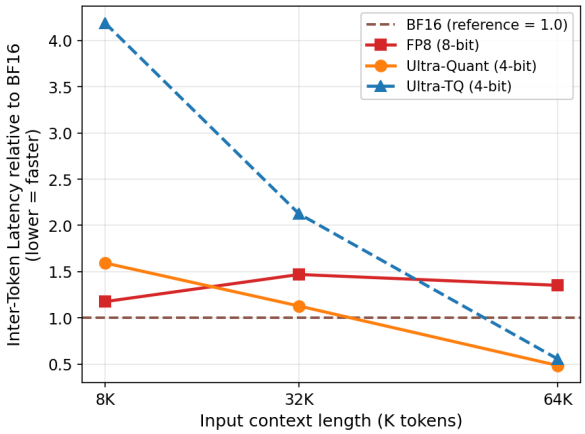
7.1 Sensitivity to Concurrency, Input Length, and Output Length



The C=64 results above fix concurrency, input length, and output length simultaneously. We additionally vary each axis independently on MiniMax-M2.5, holding the others fixed. UltraQuant tracks FP8 KV closely on raw throughput and tail latency as concurrency and output length grow. At long input context, FP8 KV hits its resident-cache memory wall around 40K context and begins evicting/recomputing sequences, while UltraQuant throughput and TTFT stay flat through the same range: 4-bit KV buys capacity, not kernel speed, and serves the long-context load that makes FP8 KV fall behind. The same input-length sweep on Qwen3-235B-A22B shows a consistent trend. Full per-axis figures, discussion, and captions are in Appendix B.4.

7.2 Kernel-Level Roofline Analysis

Two mechanisms explain why UltraQuant tracks FP8 on raw throughput and latency while pulling ahead at long context and high load. First, 4-bit KV approximately doubles nominal cache capacity relative to FP8, reducing eviction and re-prefill under pressure (Section 7.1). Second, long-context decode is bandwidth-bound, so reading 4-bit KV moves about half as many bytes; at short context or decode-heavy configurations, FP8 can be faster because the dequantization overhead is not yet amortized.

(a) Median time per output token, C=64.

(b) Inter-token latency vs. input context length.

Figure 4: Per-token latency on MiniMax-M2.5 (32K/1K, TP= 2, 2×MI355X), relative to BF16 (lower is better) for FP8, UltraQuant, and Ultra-TQ.

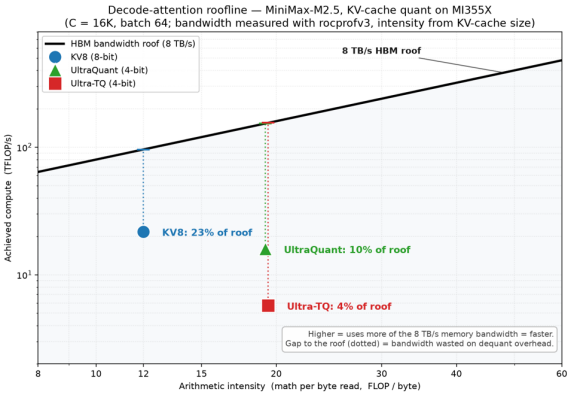


Figure 5: Decode-attention roofline on MiniMax-M2.5 (MI355X, C=16K, batch 64): achieved compute vs. arithmetic intensity for FP8 KV, UltraQuant, and Ultra-TQ against the 8 TB/s HBM bandwidth roof.

Figure 5 makes the kernel-level mechanism explicit with a decode-attention roofline on MiniMax-M2.5 (MI355X, C=16K, batch 64). The horizontal axis is arithmetic intensity (math per byte read); FP8 KV sits furthest left because 8-bit KV moves the most data per unit of math, while UltraQuant and Ultra-TQ shift right by $\sim$1.6× rather than the nominal 2×, since metadata and padding leave a real footprint of about 5 effective bits per element. The vertical axis is achieved TFLOP/s against the bandwidth-implied compute ceiling: FP8 KV reaches 23% of that ceiling, UltraQuant reaches 10%, and Ultra-TQ reaches only 4%.

The winning condition is reaching 4-bit intensity while staying close to bandwidth-limited rather than dequant-limited: UltraQuant reaches 4-bit intensity and stays near bandwidth-bound, $\sim$2.5× higher than Ultra-TQ on the roofline, whose software codebook decode is dequant-bound. Kernel counters at 32K context confirm UltraQuant retains most of the memory saving at near-FP8 kernel time; the remaining $\sim$18% gap is why its largest end-to-end wins come from capacity and avoided re-prefill (Section 7.1) rather than a universal per-token speedup. Appendix A.3 gives the per-scheme breakdown and counter table.

8 Conclusions

We presented a 4-bit KV-cache study centered on context-heavy agents, where long prefixes must remain reusable and concurrency determines GPU utilization. TurboQuant-style rotation and codebook methods provide a strong 4-bit quality anchor; Ultra-TQ closes the gap to production serving through careful layout, LUT, and MFMA scheduling; and UltraQuant replaces the codebook with MXFP4 tensors consumed directly by CDNA4 matrix cores. The broader lesson is that low-bit KV caching should be evaluated as an end-to-end serving mechanism, not only as an offline compression method. For agent workloads, the relevant outcome is the joint effect on task success, cache residency, throughput, and interactivity. Our results show that 4-bit KV caching retains the context-capacity benefits of aggressive compression while approaching the deployability of hardware-native FP8 KV caching.

9 Limitations

We present the three following limitations:

1. Although we deploy a single constant $c = 0.156$ for all models and heads, there may be a more efficient constant that can be calibrated

layer-wise for better accuracy. We also do not consider the case that the constant is chosen depending on the distribuition of activations We ommit this out of simplicty and leave this for future work.

2. UltraQuant's benefits in speed versus FP8 are only observed when the context length is long enough, or concurrency high enough, to exceed the resident cache capacity of the FP8 baseline; for shorter context lengths and lower concurrency, the benefits of the algorithm are not realized. Note that this is not the case when compared to Ultra-TQ, where performance benefits are always realized. Larger clusters, other serving frameworks, and non-CDNA4-optimized performance are also outside the scope of this evaluation.

3. Ultra-TQ style centroid calibration is only applied to 10% of layers for a small benefit; on most layers, such centroid calibration does not seem to provide any benefit.

A Kernel Implementation in vLLM

We implement two serving endpoints in vLLM: *Ultra-TQ*, an optimized TurboQuant kernel that preserves the codebook representation, and *Ultra-Quant*, an FP4 approximation path in which the KV cache is stored as raw FP4 micro-tensors with UE8M0 group scales and the dequantization is performed by the matrix core itself.

Algorithm 1 FP4-ConstOpt KV encoding (UltraQuant)

Require: K, V (BF16); rotation R; group size g=32; E2M1 levels F; global constant c (Section 5.3).

Write:

$K \leftarrow R \cdot K$ ▷ rotate keys; V unrotated

split K, V into 32-channel groups

per group: $m \leftarrow \max_i |x_i|$; $E \leftarrow \mathrm{round}(\log_2(c \cdot m))$ ▷ UE8M0 exponent; no per-token norm, no search

per coord: code $\leftarrow q(x_i/2^E)$ ▷ q: round to nearest level in F

store 2 FP4 codes/byte + 1 UE8M0 byte (E) per group

Decode:

$Q \leftarrow R \cdot Q$; $Q \leftarrow \mathrm{cast_fp8_e4m3}(Q)$

load codes + UE8M0 byte; $\hat{x} \leftarrow \text{code} \cdot 2^{(\text{byte}-127)}$

QK via scaled FP8×FP4 MFMA; PV via FP4/scale path

Output: hardware-native FP4+UE8M0 KV cache; dequant folds into the MFMA scale operand.

The implementation targets the CDNA4 scaled-MFMA family, especially `v_mfma_scale_f32_16x16x128_f8f6f4`. The QK product reads FP4 keys, FP8 queries, and UE8M0 scales together in one instruction. The V path similarly avoids a software LUT by converting FP4 codes and UE8M0 scales through hardware-supported low-precision operations. Relative to a TurboQuant codebook kernel, the key systems change is removing dequantization from the critical path: the query operand is pre-rounded to FP8 outside the K-tile inner loop, and the grouped scale layout used by the cache is arranged to match the MFMA scale operand layout. Algorithm 1 gives the UltraQuant cache-encoding path; the codebook-based Ultra-TQ encoding it replaces is in Appendix F.

A.1 Ultra-TQ Kernel Ladder

TurboQuant compresses the KV cache to 4 bits per element, storing keys and values in a codebook format. The cache is dequantized on the fly, making decode memory-bandwidth-bound. Our kernels are inspired by FLUTE (Guo et al., 2024), which restructures quantized matrices offline to

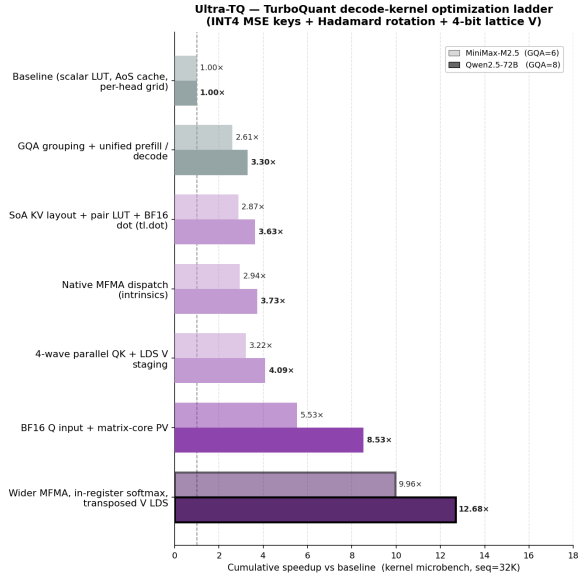

Figure 6: Ultra-TQ optimization ladder for the decode-attention kernel.

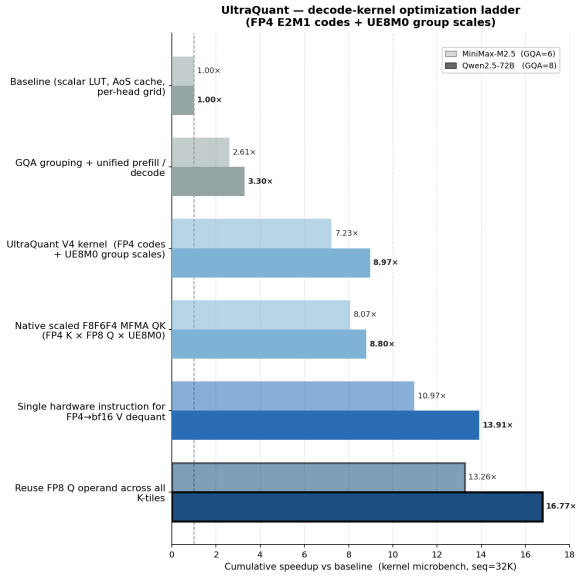

Figure 7: UltraQuant optimization ladder for the FP4 decode-attention kernel.

reduce bit-manipulation overhead during unpacking and uses vectorized LUT access to reduce shared-memory pressure. We adapt these ideas to the vLLM decode-attention path by adding GQA-aware tiling, a structure-of-arrays KV cache layout, and AMD-specific MFMA dispatch.

The Ultra-TQ optimization ladder has three tiers. First, an improved Triton kernel fixes the GQA, LUT, and layout pathologies of the open-source TurboQuant baseline. Second, a native-ISA implementation issues matrix-core instructions through AMD GCN intrinsics, giving direct control over operand layout and instruction selection. Third, a FlyDSL (Li et al., 2026) implementation JIT-compiles to AMD GCN ISA without per-device source files and exposes MFMA operand layouts so we can select wider MFMA variants.

A.2 UltraQuant Kernel Ladder

The UltraQuant kernel takes the FP4 plus UE8M0 cache layout described in Section 5 and adds three CDNA4-native operations to the same DSL implementation. First, the QK product is issued through the scaled F8F6F4 MFMA (`v_mfma_scale_f32_16x16x128_f8f6f4`), which reads FP4 keys, FP8 queries, and their UE8M0 scales together in one instruction; BF16 keys never have to be materialized. Second, the V-dequant LUT is replaced by a hardware conversion path that turns FP4 codes and UE8M0 scales directly into BF16. This removes software dequantization from the critical path. Third, the FP8 query operand is lifted out of the K-tile inner loop so every tile reuses the same pre-quantized query, reducing redundant packing and easing register pressure.

The implementation runs in the standard ROCm/vLLM stack. Ultra-TQ's FlyDSL decode kernel has been upstreamed into vLLM mainline. We plan to release the UltraQuant kernel as a follow-up contribution.

A.3 Decode-Attention Kernel Counters

This supplements the roofline analysis in Section 7.2. FP8 KV is bandwidth-bound and closest to the roof, but requires $2\times$ the KV-cache space, halving the available capacity before eviction. Ultra-TQ reaches 4-bit intensity but is dequant-bound: its limiter is software codebook decode, an LDS gather, and a VALU FMA per element, so in the worst case the compute cost outweighs the bandwidth saving. UltraQuant reaches 4-bit intensity and stays closer to bandwidth-bound, $\sim 2.5\times$ higher than Ultra-TQ on the roofline, because FP4 E2M1 with UE8M0 scales is consumed natively by the scaled MFMA with no codebook, gather, or per-element FMA.

Table 3 reports the corresponding decode-attention kernel counters at 32K context, batch 8. The counters confirm that 4-bit KV roughly halves HBM traffic; Ultra-TQ's software LUT decode is compute-bound despite the smaller payload, while UltraQuant folds dequantization into the CDNA4 scaled-MFMA path, retaining most of the memory saving at near-FP8 kernel time.

KV format	Width	HBM bytes/step	Decode attn. (32K, batch 8)
FP8 KV	8-bit	∼23 MB	1071 ms (1.00×)
Ultra-TQ	4-bit	∼12 MB	2624 ms (2.45×)
UltraQuant	4-bit	∼12 MB	1268 ms (1.18×)

Table 3: Decode-attention kernel comparison at 32K context, batch 8, MiniMax-M2.5 on MI355X. UltraQuant nearly halves HBM traffic relative to FP8 KV while staying within 1.18× its kernel time; Ultra-TQ's software dequant erases the bandwidth saving.

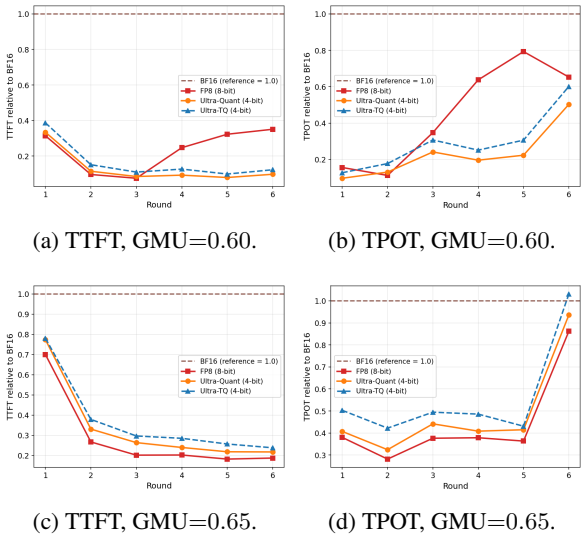
Configuration	Adaptation	Codebook	GPQA
TQ-t4nc (production)	per-token ℓ_2	Lloyd (calib.)	0.6503
K+V Lloyd, per-token	per-token ℓ_2	Lloyd (calib.)	0.6237
LMPb full	per-block absmax	Lloyd (calib.)	0.6559
Variant E	per-block absmax	uniform (RTN)	0.6528

Table 4: Per-block scale ablation (GPT-OSS-20B GPQA, medium, single seed). Holding rotation on, the per-token → per-block adaptation moves 0.6237 → 0.6559 on the both-Lloyd configs; with per-block scaling fixed, Lloyd versus uniform codebook (0.6559 vs. 0.6528) is within noise. Codebook and adaptation are co-fit, so the swap is not a perfectly clean A/B, but the direction is consistent across variants.

B Ablations

B.1 Per-Block Scale

This ablation isolates the contribution of the per-block-absmax scale from that of the calibrated codebook, on GPT-OSS-20B GPQA (medium effort, single seed; $1\sigma \approx 1.7$ pp). Two effects stand out. First, switching the adaptation statistic from a single per-token ℓ_2 norm to a per-block absmax (groups of 32) is the load-bearing change: it is what recovers accuracy, independent of the codebook. Second, with the per-block scale in place the codebook itself barely matters — replacing the calibrated Lloyd magnitudes with a uniform grid stays within single-seed noise. Together, these justify the deployed design: keep the per-block scale, and use the fixed FP4 grid in place of a calibrated, model-specific codebook.



B.2 Global Constant

Figure 2b quantifies the codebook approximation: plain per-32-group FP4 sits above the analytical Lloyd–Max floor, but the constOpt per-block scale closes most of that MSE gap while keeping the hardware-native FP4 grid, across $d \in \{64, 128, 256\}$.

We also sweep the global scaling constant c against the FP8 (8-bit) baseline, on the same evaluation. The default $c = 0.156$ is the MSE-optimal value derived in Section 5.3, and the data confirm it: it beats FP8 by +4.4 pp. Raising c to 0.195 (the power-of-two-optimal value, see Section 9) gives up the gain entirely and lands exactly at the FP8 baseline, and $c = 1.0$ (raw absmax with no MSE shrinkage) falls 4.3 pp below FP8. Accuracy is monotonic in the distance from the MSE-optimal constant.

Scheme	Accuracy	vs. FP8 baseline
FP8 (8-bit baseline)	63.0%	—
fp4 $c = 0.156$ (default)	67.4%	+4.4 pp
fp4 $c = 0.195$	63.0%	0.0 pp
fp4 $c = 1.0$ (no shrinkage)	58.7%	−4.3 pp

Table 5: Global-constant ablation. The default $c = 0.156$ is MSE-optimal and the only setting that improves on FP8; larger c erases the gain and $c = 1.0$ (raw absmax) regresses below the 8-bit baseline.

(a) TTFT, GMU=0.60. (b) TPOT, GMU=0.60.

(c) TTFT, GMU=0.65. (d) TPOT, GMU=0.65.

Figure 8: Per-round serving latency (relative to BF16; lower is better) at two cache-pressure regimes. Top row: GMU=0.60 (the Appendix D operating point), where FP8 degrades in later rounds. Bottom row: GMU=0.65, where the larger resident-cache budget keeps all three schemes close.

B.3 Cache-Pressure (GMU) Regime

We report the per-round latency at two GPU-memory-utilization (GMU) operating points to show how the relative ranking shifts with cache pressure. Figure 8 stacks both regimes: the top row is GMU=0.60 (the operating point used in Appendix D) and the bottom row is the lower-pressure GMU=0.65. At GMU=0.60 the resident-cache budget is tight, so FP8 degrades in the later rounds while UltraQuant stays low; at GMU=0.65 the budget is large enough that FP8 no longer degrades and all three schemes track closely. The multi-turn ablation in Appendix D uses the more cache-pressured GMU=0.60 regime, where the UltraQuant residency advantage is largest.

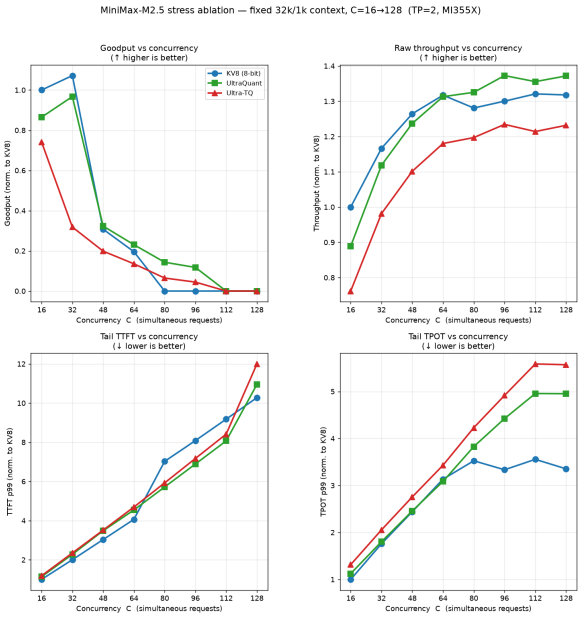


Figure 9: Full concurrency sweep on MiniMax-M2.5 (TP= 2, 2×MI355X): goodput (top-left), raw throughput (top-right), P99 TTFT (bottom-left), and P99 TPOT (bottom-right) vs. load C for FP8 KV, UltraQuant, and Ultra-TQ.

B.4 Concurrency, Input-Length, and Output-Length Sensitivity

This section gives the full panel-level detail for the sensitivity sweeps summarized in Section 7.1, on MiniMax-M2.5 (TP= 2, 2×MI355X).

Figure 9 sweeps concurrency C. Goodput (top-left) falls sharply for all schemes as load rises, with UltraQuant sustaining it marginally longer than FP8 KV. Raw throughput (top-right) is close to tied between FP8 KV and UltraQuant, with Ultra-TQ trailing by $\sim$10% due to software dequant. P99 TTFT (bottom-left) rises roughly linearly with C and the three schemes overlap. P99 TPOT (bottom-right) is the clearest separation: FP8 KV's tail TPOT plateaus because it caps admitted batch size under queuing pressure, while the 4-bit schemes admit more concurrent requests and pay a higher per-token cost, climbing to $\sim$1.5–1.6× that plateau.

Figure 10 sweeps input context length at fixed load. At short/medium context, FP8 KV is fastest and the 4-bit schemes pay a small tax (UltraQuant $\sim$1–3%, Ultra-TQ $\sim$7–10%). At 40K context, FP8 KV hits its resident memory wall: it can no longer keep 64 long sequences resident and begins dropping/recomputing them. UltraQuant's throughput pulls ahead past this point, and FP8's TTFT explodes to $\sim$7× its short-context level while UltraQuant stays flat, $\sim$5× faster to first token at the same setting. 4-bit KV buys capacity, not kernel speed: it serves the long-context load that makes FP8 KV fall behind.

Figure 11 fixes the prompt and grows the answer length, stressing pure decode. Throughput (left) rises and plateaus as the fixed prefill cost is amortized over more output tokens; UltraQuant shadows FP8 KV to within 2–3% at every output length. TPOT (middle) starts higher and settles to a steady rate once decoding is in full swing, with UltraQuant sitting a few percent above FP8 KV at a constant gap. TTFT (right) is flat and identical across all three schemes, confirming output length affects decoding only.

We also ran the input-length ablation on Qwen3-235B-A22B (Fig. 12, TP= 4, fixed output length 1K, C=64). It shows the same trend as MiniMax-M2.5 in Fig. 10: UltraQuant keeps up with FP8 KV on decode throughput, time-to-first-token, and per-token latency across context lengths, while using half the KV memory.

Benchmark	BF16	UltraQuant	Δ BF16
Official RULER	**74.03**	67.08	−6.95
GPQA Diamond	**83.84**	81.82	−2.02
GSM8K	**88.86**	87.11	−1.74
AIME25 (5 seeds)	**79.17**	78.33	−0.84

C Additional Accuracy Results

This appendix supplements Section 6 with the per-model accuracy tables, per-task retrieval breakdowns, extended model validation, and SWE-bench Lite cohort plots omitted from the main text for space.

Tables 6 to 8 report BF16 versus UltraQuant accuracy by model family, with benchmarks as rows, for the retrieval and reasoning results discussed in Sections 6.2 and 6.3. Official RULER on MiniMax M2.5 is the largest single regression at −6.95; every other cell sits within 2 points of BF16 in either direction.

Figure 13 compares KIVI and official KVQuant against BF16 and UltraQuant on Llama-3.1-8B-Instruct NIAH and LongBench-E. KIVI tracks

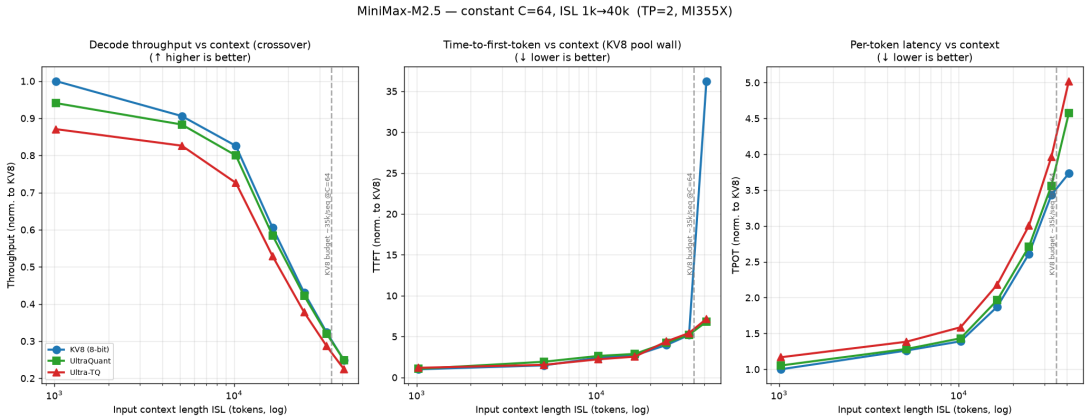

Figure 10: Full input-length sweep at fixed load on MiniMax-M2.5 (TP= 2, 2×MI355X): throughput and TTFT for FP8 KV, UltraQuant, and Ultra-TQ across input context lengths.

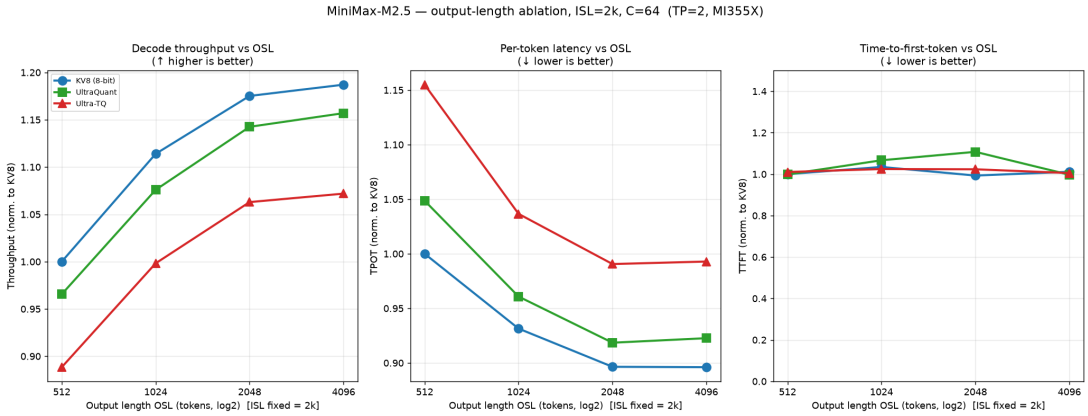

Figure 11: Full output-length sweep at fixed prompt size on MiniMax-M2.5 (TP= 2, 2×MI355X): throughput (left), TPOT (middle), and TTFT (right) for FP8 KV, UltraQuant, and Ultra-TQ.

Benchmark	BF16	UltraQuant	Δ BF16
NIAH	99.5	**100.0**	+0.50
LongBench-E (13 tasks)	**54.19**	53.97	−0.22
GPQA Diamond	**29.29**	27.27	−2.02
GSM8K	**78.09**	77.03	−1.06

Table 8: Llama-3.1-8B-Instruct accuracy (%).

BF16 through 65K context but OOMs at 131K; channel-wise runtime quantization remains difficult because it quantizes across sequence length during decode.

Figure 14 breaks down the official RULER retrieval subset for Qwen3.5-35B-A3B (four tasks × six lengths × 15 examples per method), where UltraQuant reaches exact parity with BF16 at 99.38% in aggregate (Table 7).

Figure 15 gives the same RULER breakdown for MiniMax M2.5; loss concentrates in `single_2` and `multikey_1`, with a gain on `multiquery`, matching the 74.03 vs. 67.08 aggregate in Table 6.

Figure 16 reports RULER for Llama-3.1-8B-Instruct, including official KVQuant, contextualizing the NIAH and LongBench-E summaries in Table 8.

Figure 17 complements Tables 6 to 8 with per-benchmark BF16 versus UltraQuant panels on G-PQA Diamond, GSM8K, and AIME25; on MiniMax GPQA the intermediate schemes sit between the two reported endpoints (FP8 KV at 83.33, Ultra-TQ matching BF16 at 83.84).

Figure 18 validates Qwen3.6-27B on GSM8K (5-shot) and LiveCodeBench-128K; error bars are ±1 standard error.

Figure 19 plots resolved-task counts for MiniMax M2.5 and Qwen3-235B under all four KV schemes on the fixed 100-task SWE-bench Lite cohort summarized in Table 2.

D Multi-Turn Workload Ablation

Beyond the production Claude Code replay in Section 3, we corroborate the same capacity effect on a multi-turn workload that lets us set memory pressure directly. We use the Gutenberg text corpus, from which vLLM synthesizes multi-turn conversations in user/assistant role format under configurable prefix and turn-length distributions. We run on MiniMax M2.5 and Qwen3-235B at TP= 2 on

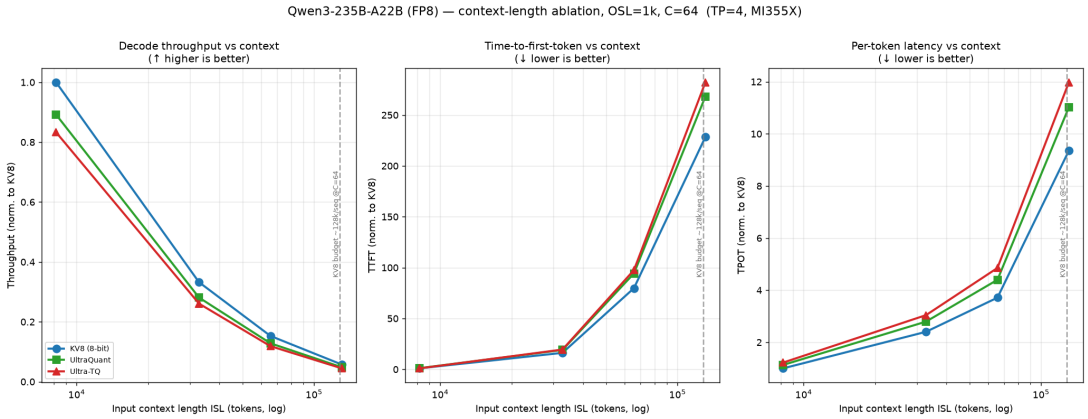

Figure 12: Input-length (context-length) sweep on Qwen3-235B-A22B (TP= 4, fixed output length 1K, C=64): decode throughput, TTFT, and per-token latency vs. context length for FP8 KV, UltraQuant, and Ultra-TQ.

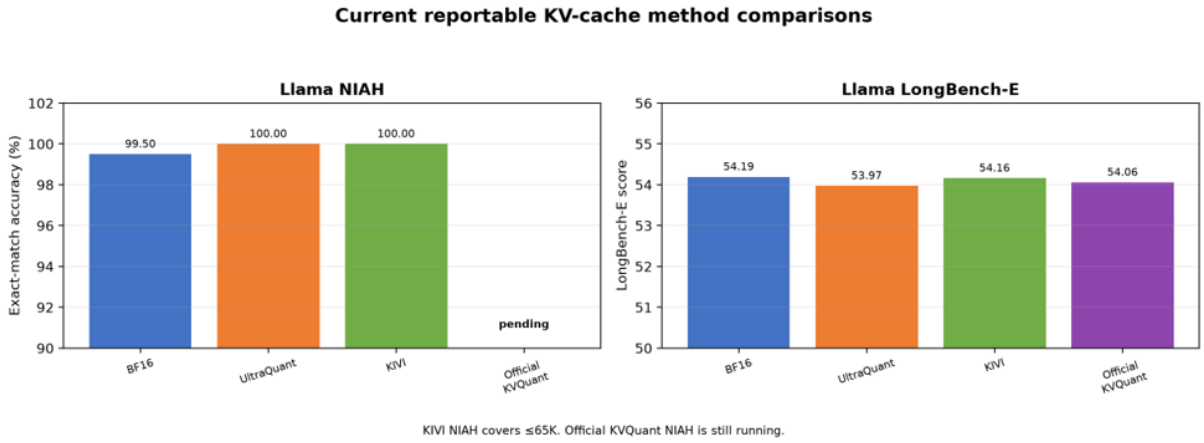

Figure 13: Llama-3.1-8B-Instruct NIAH and LongBench-E accuracy versus KIVI and official KVQuant. KIVI NIAH covers $\leq$ 65K context.

AMD MI355X, fixing concurrency at C=32 and reporting P50 TTFT and P50 TPOT per round.

Table 9 and Fig. 20 report this workload on MiniMax M2.5. With long per-client prefixes and high concurrency, FP8 KV repeatedly evicts useful state while UltraQuant keeps more prefixes resident. The advantage is largest in the late rounds, where P50 TTFT improves 3.47×: UltraQuant holds both TTFT and TPOT low across all six rounds, while FP8 degrades as accumulated context exceeds its resident-cache capacity.

Metric	UltraQuant vs. FP8 KV
P50 TTFT — warm rounds (r2–3)	0.86× (FP8 faster)
P50 TTFT — late rounds (r4–6)	**3.47×**
P50 TTFT — all rounds	2.3×
Output throughput	**1.63×**

Table 9: Gutenberg multi-turn serving results on MiniMax-M2.5, TP= 2, AMD MI355X, reported as UltraQuant relative to the FP8 KV baseline (higher is better except where noted). The advantage appears in the late rounds, where long per-client prefixes exceed the effective resident-cache capacity of FP8: TTFT improves 3.47× and is recovered through cache residency rather than re-prefill.

E Claude Code Adaptive SLO Supplement

This appendix supplements Section 3 with the remaining adaptive-SLO panels from the production-derived Claude Code trace replay. Figure 21 reports TTFT-qualified completed-request goodput: the rate of finished requests whose first token arrives within each swept TTFT budget, normalized by the BF16 qualified-request total. Figure 22 reports effective-TTFT tail distributions (p50/p90/p95/p99) at the same operating points. On MiniMax M2.5, UltraQuant reaches 2.71× BF16 on both cumulative SLO-qualified served requests (main text) and TTFT-qualified goodput; on Qwen3-235B, both metrics reach 4.38× BF16.

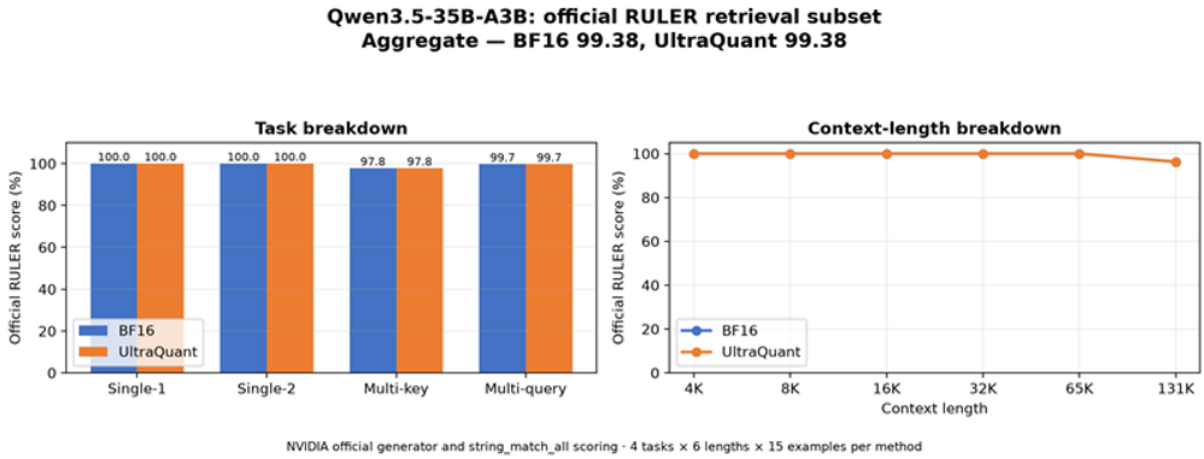

Figure 14: Official RULER retrieval subset for Qwen3.5-35B-A3B (four tasks × six lengths × 15 examples per method).

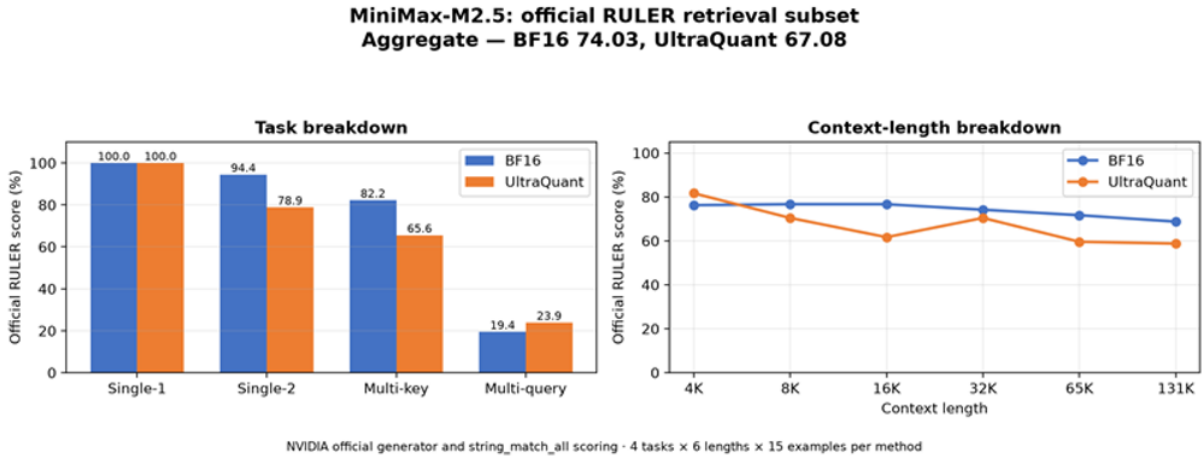

Figure 15: Official RULER retrieval subset for MiniMax M2.5.

F Calibrated LUT int4 KV Encoding (Ultra-TQ)

For reference, Algorithm 2 gives the codebook-based encoding path that UltraQuant replaces. It is the TurboQuant-style scheme: a calibrated 4-bit codebook per side with a per-token norm scalar on the key side, dequantized through a lookup table on read. UltraQuant (Algorithm 1) keeps the rotation but drops the codebook and the per-token norm in favor of a fixed FP4 grid with a per-block UE8M0 scale, so the dequantization folds into the matrix core.

Algorithm 2 Calibrated LUT int4 KV encoding (Ultra-TQ)

Require: K, V (BF16); rotation R; group size g; codebook C_K.

Write:

$K \leftarrow R \cdot K$ ▷ rotate keys; V unrotated

split K, V into g-channel blocks

K: store block norm; encode each coord to nearest C_K index

V: store block (scale, zero); encode each coord to 4-bit uniform

Decode:

$Q \leftarrow R \cdot Q$

load K/V codes + metadata per tile

K: dequant via C_K · norm; V: dequant via scale · code + zero

compute QK and PV on dequantized K, V

Output: rotated-codebook K + uniform V cache; dequant paid on read.

Judge, Don't Write: Scaling Golden Data Generation via Psychometric Standard-Setting

Scott Novotney, Youbing Yin and Erin Babinsky
Capital One
{scott.novotney, youbing.yin, erin.babinsky}@capitalone.com

Abstract

Human-written references are typically treated as the upper-bound gold standard for fine-tuning and evaluation, but writing them is an inefficient use of subject-matter expert (SME) time. To best use limited SME attention, we apply psychometric standard-setting to discover acceptance criteria for GenAI applications. These acceptance boundaries are themselves useful for calibrating an LLM-as-a-judge, model tuning, and defensible quality monitoring. We report a case study on summarization across two domains at a financial institution. While summarization is a classic GenAI use case, what counts as acceptable differs significantly across domains. 25 SMEs across three panels produced 2,500+ judgments and yielded calibrated thresholds in an estimated 10x less SME time than the standard playbook of writing gold references (or "goldens") directly. In both domains, LLM-generated goldens are preferred over SME-written ones roughly 80% of the time, by an independent human annotation cohort. Limited SME attention is best used to judge candidate goldens rather than write them.

1 Introduction

Summarization of multi-party dialogues and correspondence in regulated industries is a near-commodity GenAI use case: a frontier model produces a fluent summary, a subject matter expert (SME) reads it, the system ships. Yet applied use needs a defensible threshold separating acceptable from unacceptable on every rubric dimension, plus goldens with expert ratings. These are used to calibrate an LLM-as-a-judge; generate fine-tuning or heldout evaluation data; and produce rubrics for manual annotation and quality monitoring. However, SME time is the limiting factor in producing these high quality artifacts for model development and monitoring.

Human-written outputs have long served as reference gold standards across NLP tasks, from transcription (Godfrey et al., 1992) to summarization (Over et al., 2007; Fabbri et al., 2021), with evaluation metrics computed against them rather than against an explicit threshold. Even on established summarization rubrics, expert annotators reach only $\kappa = 0.41$ in a first pass and require a second calibration round to recover $\kappa = 0.71$ (Fabbri et al., 2021; Bayerl and Paul, 2011). The literature has long established that judging is easier than producing under expert constraints (Polanyi, 1966; Dreyfus and Dreyfus, 1986); the standard playbook nonetheless asks SMEs to write gold references (or "goldens") directly. While fields like active learning and LLM-assisted annotation address this problem through rapid iteration, we apply *psychometrics* to best optimize limited SME time to efficiently discover what matters to our experts.

Psychometrics measures latent traits (knowledge, skill, quality) from observable responses. Since the 1970s, its standard-setting branch has elicited defensible pass/fail thresholds from expert panels through structured accept/reject decisions (Cizek and Bunch, 2007; Mitzel et al., 2001), producing the cut-scores that underpin professional licensing (USMLE for medical practice, the bar exam for law) and K-12 accountability testing. Recent work applies psychometrics to NLP from the opposite direction. Item Response Theory has been used to compare benchmark difficulty (Vania et al., 2021), weight evaluation examples by informativeness (Rodriguez et al., 2021), and shrink leaderboards down to a fraction of their original size with minimal information loss (Polo et al., 2024). Psychometric profiling treats LLMs as test-takers, administering personality and cognitive instruments to model outputs (Serapio-García et al., 2025).

These applications measure properties of test items or model traits. Standard-setting addresses a different question: given a fixed rubric, where does

EMNLP 2026 Industry Track, pages 2751–2761
October 24-29, 2026 ©2026 Association for Computational Linguistics

the line between acceptable and unacceptable sit, and which dimensions actually move it? This paper asks whether standard-setting can answer that question for LLM-generated text in a regulated applied setting, and whether the same SME elicitation budget can yield boundary-line goldens, a calibrated rubric, and training data for an automated judge alongside the thresholds. The case study covers two summarization domains at a financial institution and a controlled simulation that calibrates each elicitation method against known thresholds at empirically observed panelist disagreement.

Our contributions are: (i) a pipeline that adapts psychometric standard-setting to LLM evaluation, yielding calibrated per-dimension acceptance thresholds, a decision rule, and a human-judgment calibration set as its primary artifacts, with boundary-line goldens as a by-product, at an estimated *10x* reduction in SME time; (ii) a controlled simulation at empirically observed inter-annotator disagreement ($\sigma = 0.24$) showing structured elicitation beats random sampling at every decision budget, with Bookmark matching random's 40-decision floor in a single placement; (iii) an empirical case study across 2 summarization domains, 25 SMEs, and 2,500+ judgments, showing that threshold-constrained outputs beat SME-written goldens 79% of the time, and statistically significant domain-specific differences in thresholds motivate per-domain panels.

2 Related Work

Eliciting expert judgment. Eliciting expert evaluation signal is expensive, and a substantial line of work has tried to reduce that cost. RLHF (Ouyang et al., 2022), DPO (Rafailov et al., 2023), and active preference learning (Das et al., 2025) elicit pairwise judgments and convert them into reward functions; the resulting scalar is ordinal and carries no natural zero or threshold, so teams pick an operational cutoff post-hoc. LLM-as-judge systems (Liu et al., 2023; Zheng et al., 2023; Kim et al., 2024) score outputs through chain-of-thought, crowdsourced comparison, or distillation from GPT-4 examples, but each ranks quality without locating a pass/fail boundary. LLM-Rubric (Hashemi et al., 2024) is the closest peer-reviewed approach: it calibrates a multidimensional judge against per-rater Likert weights, calibrating the scoring function, while standard-setting calibrates the threshold the judge applies on top of it. The broader active-learning literature (Settles, 2009) optimizes for classifier accuracy rather than threshold posterior calibration.

Psychometric standard-setting. Standard-setting is the psychometric branch that elicits criterion-referenced cut-scores from expert panels. The Bookmark method (Mitzel et al., 2001) asks panelists to place a divider in a difficulty-ordered sequence; Contrasting Groups compares score distributions of known masters versus non-masters (Cizek and Bunch, 2007; Yousefi Afrashteh, 2021). Both underpin high-stakes professional licensing (medical boards, bar exams). For Contrastive elicitation we adopt QUEST (Watson and Pelli, 1983), the standard psychophysical algorithm for Bayesian threshold estimation from binary responses. Psychometrics has also entered NLP from a measurement direction: Item Response Theory has been used to compare benchmark difficulty (Lalor et al., 2019; Vania et al., 2021), weight evaluation examples by informativeness (Rodriguez et al., 2021), and shrink leaderboards with minimal information loss (Polo et al., 2024), while Serapio-García et al. (2025) administer validated personality inventories to LLM outputs across 18 models. These applications measure properties of items or models; we measure where on a rubric the acceptable/unacceptable line sits.

Generating reference data with LLMs. A growing line of work uses LLMs to produce evaluation artifacts. Self-Instruct (Wang et al., 2023), WizardLM (Xu et al., 2024), and Dynabench (Kiela et al., 2021) generate test items; CheckList (Ribeiro et al., 2020) produces minimal pairs for behavioral testing; FActScore (Min et al., 2023) verifies atomic facts in long-form output. DSPy (Khattab et al., 2024) compiles prompts and demonstrations toward a metric ceiling, treating evaluation as an objective to maximize. These systems iterate or train toward the best possible output, optimizing for the ceiling. We instead iterate toward a *threshold* elicited from experts: a generator LLM produces a candidate, an evaluator scores it on each rubric dimension, and the loop revises until every dimension clears its panel-elicited cut-score. The output is calibration data at the pass/fail boundary rather than reference items at the ceiling. Chawla et al. (2026) survey the development lifecycle of an applied dialogue summarization system, the broader context our case study sits within.

Each thread above optimizes for a different artifact in isolation: a reward scalar, a judge cali-

bration, a benchmark, a generator. We elicit the threshold itself from experts, target it in a generator-critic loop, and recover thresholds, goldens, and judge-training data from a single panel session.

3 Method

We assume four inputs: a corpus of source documents (e.g., call transcripts, written correspondence), evaluation dimensions with Likert definitions (e.g., coherence 1–5, completeness 1–5), a panel of 5–10 domain experts who can judge but need not write, and a small set of hand-written goldens from experts or existing systems. The pipeline produces three artifacts which could be used to develop an automated judge: 1) a calibrated acceptance threshold per dimension, 2) a set of goldens at the empirical pass/fail boundary, and 3) a decision rule mapping multidimensional Likert scores to a binary verdict.

The pipeline proceeds in four stages (Figure 1): (1) construct a pool of single-dimension degradations from example outputs, (2) score the pool with an LLM to establish a quality ordering, (3) elicit acceptance thresholds from experts using either Bookmark or Contrastive protocols, and (4) generate goldens constrained to the elicited thresholds via an iterative generation-evaluation loop.

3.1 Pool Construction

The elicitation protocols require a pool of candidates that vary in quality along individual dimensions. For each dimension, an LLM edits a hand-written golden to produce quality variants at each target level (1–4; level 5 is the verified gold) consistent with the rubric definition. We over-generate (typically 4x per level), relying on stochastic diversity rather than rule-based mutation operators (e.g., delete-a-fact, swap-pronouns) that would require hand-specifying defects per dimension. Generating defects one dimension at a time keeps the expert's later judgment on that dimension clean: for example, a hallucination defect should not drag down the grammar rating.

3.2 Pairwise Ranking

The over-generated pool needs ordering before experts can review it for the Bookmark method. We use an LLM to obtain pairwise preferences and fit a Bradley-Terry model (Bradley and Terry, 1952) to the win/loss outcomes, producing a continuous quality score per item. From the ranked pool we select 9 evenly-spaced items per dimension as the Bookmark spectrum; for Contrastive elicitation, the QUEST algorithm (Watson and Pelli, 1983) draws adaptively from the full ranked pool, concentrating trials near the predicted boundary.

3.3 Threshold Elicitation

Given the scored pool, we elicit acceptance thresholds from the panel of 5–10 experts.

3.3.1 Bookmark

The Bookmark method (Mitzel et al., 2001) presents items ordered by predicted quality for one dimension at a time. The procedure is:

1. Each expert reviews the ordered sequence and places a "bookmark" at the transition from unacceptable to acceptable.
2. Panelists reveal placements simultaneously to prevent anchoring.
3. The panel discusses disagreements with a focus on items near the boundary.
4. Experts may revise placement after discussion (optional second round).

We fit a Beta distribution to panelist placements (it respects the bounded 1–5 scale and captures asymmetric distributions or panelist clustering at multiple values that a normal distribution smooths over) and set the operational threshold at one standard deviation below the mean, requiring outputs to satisfy the stricter panelists (false acceptances in practice are costlier than false rejections). A representative Beta fit is shown in Appendix Figure 4.

3.3.2 Contrastive

The Contrastive protocol replaces the ordered-sequence review with targeted binary decisions: "Is this acceptable on [dimension]?" The QUEST adaptive algorithm (Watson and Pelli, 1983) is the field-standard method for Bayesian threshold estimation from binary responses; it selects each next item to maximize expected information gain about the threshold and returns a calibrated posterior with a principled stopping rule (95% credible interval below 0.3 score units, typically converging in 12–32 items per dimension). Generic active-learning alternatives optimize for classifier accuracy rather than threshold posterior calibration and would require a separate rank-to-threshold conversion step. Contrastive needs no pre-built spectrum and is suited

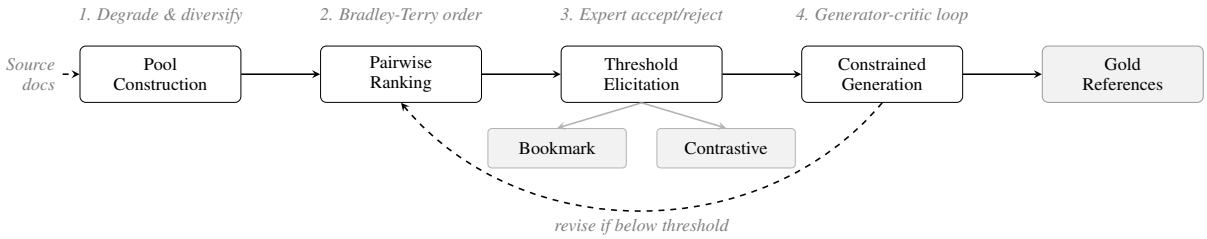

Figure 1: Overview of the four-stage pipeline. Experts make structured accept/reject decisions (Stage 3) rather than writing goldens; the generator-critic loop (Stage 4) produces outputs that clear every threshold.

to settings where ordering is difficult or expert sessions are short, at the cost of more individual judgments.

3.4 Constrained Generation

Once thresholds are set, a generator LLM produces a candidate summary, an evaluator LLM scores it on each dimension against the rubric, and the loop revises with dimension-specific feedback until every dimension clears its threshold or the iteration cap is reached. Both the generator and evaluator roles are filled by Claude Opus 4.6, accessed via Amazon Bedrock. The loop targets the acceptance *boundary* rather than the ceiling, preventing reward overoptimization, and the all-dimensions criterion does not allow dimensions to compensate for one another. Generated outputs that pass undergo a final lightweight expert review (accept/reject on the full output) as a quality gate rather than a calibration step.

4 Experimental Setup

4.1 Domains

We validate on two summarization domains at a financial institution.[1] Both domains are multi-party call summarization; they differ in business focus and in summary length and format (Banking outputs a longer structured summary). For both tasks, our SMEs were drawn from managers, experienced agents and quality assurance representatives.

The Auto domain panel comprised 8 SMEs and produced 10 hand-written goldens through a two-hour Bookmark elicitation session.

The Banking domain was a larger study with 50 hand-written goldens: 10 reserved as few-shot exemplars for the generation conditions and 40 used as the human baseline in the evaluation ablation. We collected threshold elicitation from two separate panels (8 SMEs in a Bookmark UI session, and 9 SMEs in a replication study)

[1]We are unable to provide precise details about the source data used to ensure compliance with internal data governance policies. All source content was masked prior to use to remove personally identifiable information.

4.2 Simulation Study

We validate elicitation efficiency in a controlled setting where ground-truth thresholds are known, allowing direct measurement of recovery error. The simulation uses spectra from our item pool (5 dimensions, items scored 1–5 by a 3-model ensemble) with known boundary locations derived from the pool structure.

Each trial samples a 5-person panel with per-panelist noise drawn from $\mathcal{N}(0, \sigma^2)$, representing disagreement about the true boundary. We apply uniform jitter (± 0.05) to pool items each trial to prevent methods from exploiting exact score coincidences. We sweep $\sigma \in \{0.1, 0.24, 0.5\}$, where $\sigma = 0.24$ matches empirically observed inter-annotator disagreement in our SME panels. We replicate each condition 100 times across all 5 dimensions (500 observations per cell). All three methods operate on the same item pool per trial:

Bookmark: Panelist reviews 9 items in score-sorted order (the spectrum from §3.2) and places a single boundary marker between items. This requires a pre-constructed spectrum but only 1 decision per panelist.

Contrastive (QUEST): Adaptive algorithm presents items sequentially; panelist makes a binary "above/below threshold" judgment on each. QUEST selects each next item to maximally reduce posterior uncertainty. We test budgets from 5 to 40 decisions (our maximum size of SME-generated goldens). This method requires an unordered pool with no spectrum construction.

Random: Items sampled uniformly from the pool; same binary judgment as Contrastive. Serves as the unstructured baseline.

All methods fit a Bayesian logistic to the accumulated binary responses and report the crossover

point (50% acceptance probability) as the estimated threshold. We measure mean absolute error (MAE) against the known boundary.

5 Results

5.1 Elicitation Efficiency

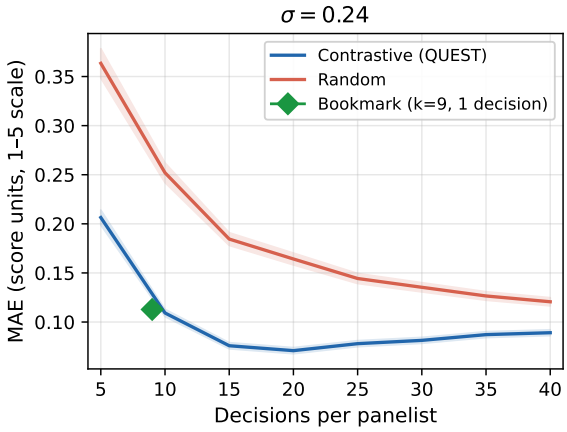

Figure 2: Threshold recovery MAE vs. decision budget at empirical noise ($\sigma = 0.24$). Bookmark (green diamond) achieves strong accuracy in 1 placement decision. Contrastive (QUEST, blue) converges faster than Random (red) and reaches lower asymptotic error.

Three patterns emerge across noise levels (Figure 2). At realistic noise ($\sigma = 0.24$), both structured methods average 0.11 MAE vs 0.20 for Random (45% lower); Bookmark in 1 decision (0.11) matches Random at 40 decisions (0.12), and Contrastive peaks at $k = 20$ (0.07) with diminishing returns beyond that. At low noise ($\sigma = 0.1$) structured methods improve over Random; at high noise ($\sigma = 0.5$) all methods converge near MAE 0.20, so protocol choice matters most in the moderate-agreement range we observe in practice.

The two structured methods differ in cost structure. Bookmark dominates at low budgets: 1 decision yields what Contrastive needs $\sim$10 to match. But it requires a pre-sorted spectrum, meaning pool construction cost (§3.2) must be paid upfront. Contrastive requires no pre-ordering and achieves lower asymptotic error (0.071 vs. 0.113 at $\sigma = 0.24$), but at 20$\times$ the per-panelist decision count.

5.2 Auto Domain Study

The Auto domain study validated the workflow before the larger Banking study: 7 evaluation dimensions, 8 SME panelists and 10 SME-written goldens. The SME-written goldens passed every threshold in only 60% of cases without the elicited rubric and 100% with it. An independent SME (not on the panel) preferred the threshold-constrained output over SME-written goldens in 8 of 10 blind head-to-head pairs, citing completeness, grammar, and absence of superfluous detail. Finally, in a follow-up replication, two SME reviewers accepted 93% of 100 LLM-generated threshold-constrained goldens (71% with both reviewers agreeing), at a mean cost of 2.2 generation iterations. Writing these 100 goldens manually would take about 4,500 minutes (45 minutes each, self-reported by our SMEs). The elicitation session that produced them cost about 480 SME-minutes (8 SMEs for roughly an hour each), an estimated 10x reduction.

5.3 Banking Replication

Two Banking panels (17 SMEs total) elicited thresholds on the 8-dimension rubric for the Banking summarization task, with 40 SME-written goldens as the human baseline. We compared six generation methods on 1,020 pairwise A/B votes from a separate 6-SME cohort, and the Bank autojudge (calibrated on elicited thresholds) scored every method's output on each rubric dimension.

All four pipeline conditions beat both Reference System and Human SME by a margin wider than any bootstrap CI; Bookmark beats Human SME 79.4% of the time [67.8, 87.5] (Figure 3). The 5/5 ceiling is not always reachable; pushing one dimension to its ceiling destabilizes others (maximizing completeness makes coherence degrade), and Golden converges in 70% of cases while Bookmark clears the acceptance threshold 100% of the time. All-dimensions pass rates separate the methods sharply (Golden 92.5%, Rubric-only 75%, Bookmark 60%, Few-shot summary 60%, Reference System 0%; n=40 per method). Hallucination Rate and Referential Clarity bind: every method drops on these two while the remaining six dimensions saturate at $\geq$97.5% across every pipeline-aware method.

The two Banking panels' thresholds cluster. Across the Banking and Auto domains, seven shared dimensions split: on four (Repetition, Referential Clarity, Relevance, Hallucination Rate), across-domain SD exceeds within-domain SD by 2.3–4.2$\times$ (Bonferroni $p < 0.001$); the remaining three (Coherence, Objectivity, Grammaticality) do not differ. Thresholds diverge across domains on exactly the dimensions that drive the pass/fail bar within each domain (Table 1).

For our second panel, we elicited thresholds

Dimension	Gap	Across/within	Bonf. p
Repetition	+1.74	4.17	$<10^{-5}$
Referential Clarity	+1.22	3.38	$<10^{-4}$
Relevance	+0.96	2.72	$<10^{-3}$
Hallucination Rate	+1.17	2.31	$<10^{-5}$
Coherence & Structure	−0.28	1.02	n.s.
Objectivity	−0.38	0.70	n.s.
Grammaticality	−0.01	0.01	n.s.

Table 1: Bank-vs-Auto threshold gap by dimension. Across/within SD ratios and Bonferroni-corrected p-values from independent two-sample comparison

on three shared dimensions under both protocols due to time constraints. Bookmark thresholds sat $+0.60$ score units above Contrastive (Wilcoxon $W = 1$, $p = 0.001$), consistent across all three dimensions. Panelists preferred Contrastive's isolated binary judgments to Bookmark's gradation across an ordered sequence (5-to-1 stated preference), suggesting the format itself, not just the resulting strictness, drives panelist preference.

5.4 Golden Generation Ablation

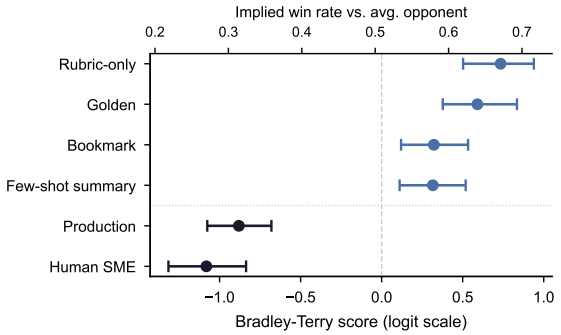

Figure 3: Bradley-Terry ranking of six conditions on 1,020 pairwise A/B votes (95% bootstrap CIs). SME-written and current reference summaries are easily beaten by any of the iterative generative process. By design, "Goldens" are more preferred than the "Bookmark" subset that stops at 'acceptable', vs 'perfect' thresholds.

To isolate the contribution of each pipeline component, we ran four generation conditions on the same backbone model across 40 source documents: *Bookmark* (rubric-aware loop, target = elicited threshold, 10-iteration cap); *Golden* (same loop, target = 5/5 on every dimension); *Rubric-only* (Golden's prompt, single attempt, no critic loop); and *Few-shot summary* (10 summaries as style demonstrations, no rubric). The few-shot condition does not receive explicit acceptance criteria, isolating the rubric's contribution from in-context examples. Additionally, two baselines were included for comparison: *Human SME* summaries written from scratch, and *Reference System* (the existing institutional system).

A separate 6-SME annotation cohort cast 1,020 pairwise preference votes; we fit a Bradley-Terry model with 95% bootstrap CIs. The Bank autojudge (calibrated on the elicited Bank thresholds) scored every pipeline-generated method on each rubric dimension to compute all-dimensions pass rates.

We do not claim that eliciting thresholds produces *better* goldens than the rubric alone: for generation, the rubric with iteration is competitive, and we report that as a finding. The Bookmark condition stops once it clears the elicited threshold rather than chasing 5/5, so measured against that threshold it passes less often than methods aiming higher; this reflects its target, not evidence that thresholds hurt generation.

6 Discussion

The expert-written reference set is the wrong artifact to optimize. The human baseline lost to every pipeline-aware condition in pairwise preference, and the rubric alone (without iteration) was already enough to clear that bar. What the SME budget actually buys is the threshold itself: where the line sits, which dimensions it binds, and how the line drifts across applications.

Only two of eight rubric dimensions (Hallucination Rate, Referential Clarity) drive the all-dimensions pass/fail bar; the other six saturate at $\geq$97.5% across every pipeline-aware method. A team budgeting SME review uniformly across all eight is spending most of its budget on dimensions the model already passes. Standard-setting surfaces this asymmetry; the rubric alone does not.

The +0.60 score-unit gap between Bookmark and Contrastive on the same panelist on the same dimension complicates methodology choice. Both protocols are calibrated to elicit the same construct, yet they disagree by half a Likert unit. We read this as evidence that the construct itself is partly tacit: panelists hold it more strictly under gradation pressure (Bookmark's ordered review) than under isolated binary judgment (Contrastive's targeted accept/reject). Whichever protocol a panel uses, the resulting threshold is conditional on protocol choice, and downstream judges trained against it inherit that conditioning. Reporting the protocol

alongside the threshold is part of the threshold's identity, not bookkeeping.

Thresholds replicate within a domain but split across domains on exactly the binding dimensions (Table 1); a team inheriting cutoffs from a sibling application calibrates the wrong boundary on the dimensions that matter most. Each new application therefore runs its own panel, and the elicitation's audit trail keeps the per-application cost defensible.

7 Conclusion

Calibrated evaluation data requires knowing where the quality boundary is, not just what quality looks like. Standard-setting elicits that boundary from experts and sits between rubric design and judge calibration. Experts are good at judging quality; their time is better spent judging than writing.

Limitations

We validate on two summarization tasks at one organization. Generalization to other task types, languages, or organizations with different rubric structures remains untested. Panel sizes of 5–10 are adequate for Beta distribution fitting but may underestimate uncertainty at the tails. Cross-domain threshold transfer (Auto to Banking) is promising but rests on the assumption of comparable quality spectra; we do not yet have a defensible criterion for when transfer is safe. We do not report direct judge-human agreement metrics; the elicited thresholds are inputs to standard judge-training procedures (Kim et al., 2024; Hashemi et al., 2024; Chawla et al., 2026) and evaluating the trained judge against held-out human ratings is a separate study. The system described here is a research artifact; before any such pipeline is used in a real-world application, it requires further domain-specific validation, monitoring, and review against the requirements of the deploying organization.

Ethical Considerations

Our work was approved by an established internal review procedure. All source content was masked prior to use, removing personally identifiable information. We are not aware of any harmful applications of the methods described in this work. Given that LLMs are prone to hallucination and may reflect biases in their training data, we call for rigorous, domain-specific testing and validation before any such system is used for a real-world application, alongside continuous monitoring of system outputs.

A Rubric Definitions

Table 2 lists the evaluation dimensions and their operational definitions. Six dimensions derive directly from DUC (Over et al., 2007) and SummEval (Fabbri et al., 2021); Objectivity was identified as binding during the Auto study, and Completeness was added for the Banking domain. Dimensions marked † appear only in Banking.

B Elicitation Protocol Details

Each Bookmark session proceeds in four stages. In the orientation stage (15–20 minutes), the facilitator explains the rubric, defines the scoring scale, and walks through two anchor examples at each extreme. In the individual placement stage (60–90 minutes), each panelist independently reviews the 9-item ordered spectrum for one dimension at a time and marks the transition from unacceptable to acceptable, working silently without discussion. In the reveal and discussion stage (30–45 minutes), placements are shown simultaneously; the facilitator leads structured discussion on items where placements diverge by more than one position, without disclosing individual identities. In the optional revision stage (15 minutes), panelists may move their bookmark after discussion. Total session time is approximately 2–3 hours for 7–8 dimensions.

Contrastive sessions present items as isolated binary judgments: "Is this summary acceptable on [dimension]?" Each item appears with only the source document and the dimension definition visible; the score and rank are hidden from the panelist. QUEST selects each next item to maximize expected information gain about the threshold, concentrating trials near the predicted boundary after 5–8 warm-up items drawn uniformly. Typical convergence (95% credible interval < 0.3 score units) occurs in 12–32 items per dimension, taking approximately 2–4 minutes per dimension. The Banking live session covered three dimensions per panelist in a 45-minute block.

In the Banking live session, panelists completed Bookmark first, then Contrastive on the same three dimensions (Coherence, Grammaticality, Hallucination Rate), with a brief break between protocols. Order was fixed (Bookmark before Contrastive) to ensure the Bookmark spectrum was not influenced by Contrastive binary experience; this introduces a potential ordering confound acknowledged in the Limitations. After both protocols, panelists answered two questions: which protocol felt more natural, and whether the boundary felt consistent between protocols. Five of eight panelists reported Contrastive felt more natural; one preferred Bookmark; two reported no preference. Three panelists reported their mental boundary felt consistent between protocols; five noted the Bookmark gradation judgment felt more effortful and potentially stricter. The $+0.60$ Bookmark-vs-Contrastive offset reported in §5.3 held across all three live-session dimensions (Coherence $+0.59$, Grammaticality $+0.82$, Hallucination $+0.39$).

C Annotator Preference Reasons

Table 3 classifies the free-text rationales from 771 decisive A/B votes using an LLM classifier over ten quality dimensions. Themes here are not constrained to the eight rubric dimensions in Table 2; conciseness in particular reflects the implicit counter-pressure to Completeness rather than a separate rubric criterion. Completeness and conciseness account for 83% of all stated reasons, reflect-

Dimension	Definition
Hallucination Rate	The summary must contain only facts supported by the transcript. Information is supported if it is explicitly stated in the dialogue or is a direct, logical inference. Information from external sources outside the transcript is not supported.
Referential Clarity	All pronouns and references must be unambiguous. The reader must be able to tell who did what without re-reading. Use "the caller," "the agent," or specific role labels rather than ambiguous pronouns.
Coherence & Structure	The summary must flow logically and be well-organized. Information should follow a clear sequence (chronological or topical), with smooth transitions and no jarring jumps between topics.
Grammaticality	The summary must use correct grammar, proper sentence structure, and appropriate punctuation. No fragments, run-ons, subject-verb disagreements, or tense inconsistencies.
Objectivity	The summary must present facts neutrally without editorializing, expressing opinions, or using loaded language. No sentiment, judgment, or interpretation beyond what was explicitly stated.
Relevance	The summary must include only information relevant to the call's purpose. Irrelevant details, tangential information, or filler content not pertinent to the primary issue should be excluded.
Repetition	The summary must not repeat the same information in multiple places. Each fact or detail should appear exactly once, in the most logical location.
Completeness†	The summary must capture all substantive information from the call: the reason for contact, verification steps, key details discussed, and outcomes or next steps.

Table 2: Operational definitions for the 8 evaluation dimensions used across the two domains. Six map directly to DUC/SummEval dimensions; Objectivity was identified as binding during the Auto study; Completeness (†, Banking only) was added to address the longer structured output format of the Banking task.

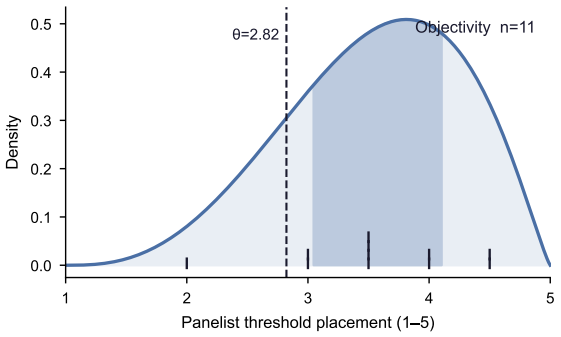

Figure 4: Beta-fitted threshold distribution for Objectivity from the Auto Bookmark session (n=11). Votes span 2.0 to 4.5, reflecting genuine disagreement about where acceptable objectivity begins. Ticks show individual placements (stacked where multiple panelists agree); shaded region is the central 50% credible interval. The Beta captures this left-skewed pattern that a Normal would smooth over.

ing the core trade-off the pipeline is designed to navigate. Conciseness is one side of this trade-off the panel is calibrating, not a confound: expert-written summaries win on conciseness (62% of their rationales) and the pipeline wins on completeness (76%), while stated accuracy is comparable on both sides (≈7%). The pipeline therefore does not trade correctness for length.

D Threshold Votes: Bank vs. Auto

Figure 5 shows raw threshold votes on the seven shared rubric dimensions for the Bank panel and the Auto panel. Each dot is one panelist vote; the thick bar is the group mean. Distributions overlap substantially on Grammaticality and Coherence, while Hallucination Rate and Referential Clarity show the wider separation that drives the cross-domain threshold gap reported in Table 1.

E Computational Budget

Claude Opus 4.6 was accessed via Amazon Bedrock API.

Theme	Golden	Bookmark	Rubric-only	Few-shot	Human SME	Reference
Completeness	76%	60%	50%	41%	23%	46%
Conciseness	12%	22%	34%	42%	62%	19%
Accuracy	7%	7%	8%	10%	7%	17%
Coherence	4%	8%	3%	4%	4%	14%
Ref. Clarity	1%	3%	3%	1%	1%	4%
n	168	134	175	153	69	72

Table 3: Primary preference reason by winning method (% of notes, 771 decisive votes). Human SME wins primarily on conciseness; Golden wins primarily on completeness.

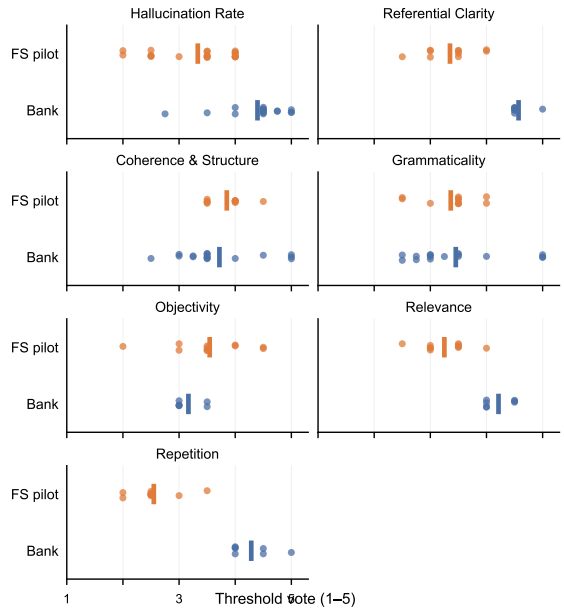

Figure 5: Raw threshold votes (1–5) on seven shared dimensions for Bank (blue) and Auto (orange). Thick bar = group mean. Four dimensions (Repetition, Referential Clarity, Relevance, Hallucination Rate) show clear separation; the remaining three overlap.

A Pinch of SFT, A Dash of RL: When Reinforcement Learning Helps Long-Horizon Advertising Agents

Abstract

Enterprise analytics agents solve long-horizon tool-use problems over distributed business data, requiring retrieval, reasoning, API calls, code execution, and adaptation to intermediate observations. Supervised fine-tuning (SFT) calibrates tool syntax and teacher-supported behavior, whereas reinforcement learning (RL) can explore reward-supported behaviors beyond demonstrations; applied uniformly, however, RL can perturb already-calibrated skills. We study how to balance SFT and RL under production-mirroring beta APIs. We observe that, in our controlled experiment, checkpoint trajectories retrospectively separated into three regimes: *Imitation*, where SFT captured reliable teacher behavior; *Lift*, where both stages helped; and *Discovery*, where useful reward-observable behavior lay outside reliable teacher support. We leverage this prospectively, using teacher support and reward-observable headroom to route features to SFT only, SFT→RL, increased RL allocation, or further environment development. Across 18 subsequent feature-specific experiments, the diagnostic predicted 15/18 observed trajectories. On GPT-OSS 120B, targeted SFT→RL produced positive point estimates on 7/8 advertiser skills relative to a frontier Control; five positive gains had paired 95% confidence intervals excluding zero, while one skill had a confidence-supported regression. The largest gain was non-disclosure ($+11.27$ points; 95% CI $[+9.72, +12.82]$). A separate SME audit surfaced that targeted RL reduces standard leakage from 11.8% to 2.9% and adversarial leakage from 22.9% to 6.8% relative to SFT while preserving actionability (86.2% to 85.7%). In a matched uniform-versus-targeted comparison with shared rewards and optimization, targeted RL improved the seven-skill mean delta from $+1.62$ to $+3.57$ while using 43% less incremental RL compute.

1 Introduction

An advertiser running a holiday campaign across hundreds of audience segments does not ask a single, well-scoped question. They ask *"why is my return on ad spend down 12% this week, which audiences are driving the drop, and where should I move my budget?"* Answering this requires identifying affected campaigns, retrieving metrics across a date window, decomposing the drop by segment, and recommending spend shifts that respect advertiser objectives. Such requests are naturally long-horizon tool-use problems: success is defined by outcomes over a sequence of API calls, code execution steps, and intermediate observations, not by a single next-token target. This makes reinforcement learning attractive, but not uniformly beneficial. Pure RL from a cold-started base model collapses on long-horizon advertiser skills: when nearly every rollout fails, the group-relative advantages that drive GRPO updates (Shao et al., 2024) contain little usable signal.

The central question is how to allocate SFT and RL under limited rollout budget without broad capability regression. Teacher-distilled SFT calibrates tool syntax and common reasoning traces, but can plateau when demonstrations do not reliably cover desired behavior. Post-SFT RL therefore poses a sharper allocation problem: *when does on-policy optimization discover reward-supported behavior beyond the teacher, and when does it merely perturb behavior SFT has already calibrated?*

In the original controlled experiment, we observe three retrospective training trajectories. In *Imitation*, demonstrations are reliable and SFT closes most of the gap. In *Lift*, SFT establishes a competent policy and RL adds further improvement. In *Discovery*, the desired behavior is reward-observable but weakly represented in teacher demonstrations. We subsequently operationalize this hypothesis into a pre-RL diagnos-

EMNLP 2026 Industry Track, pages 2762–2778
October 24-29, 2026 ©2026 Association for Computational Linguistics

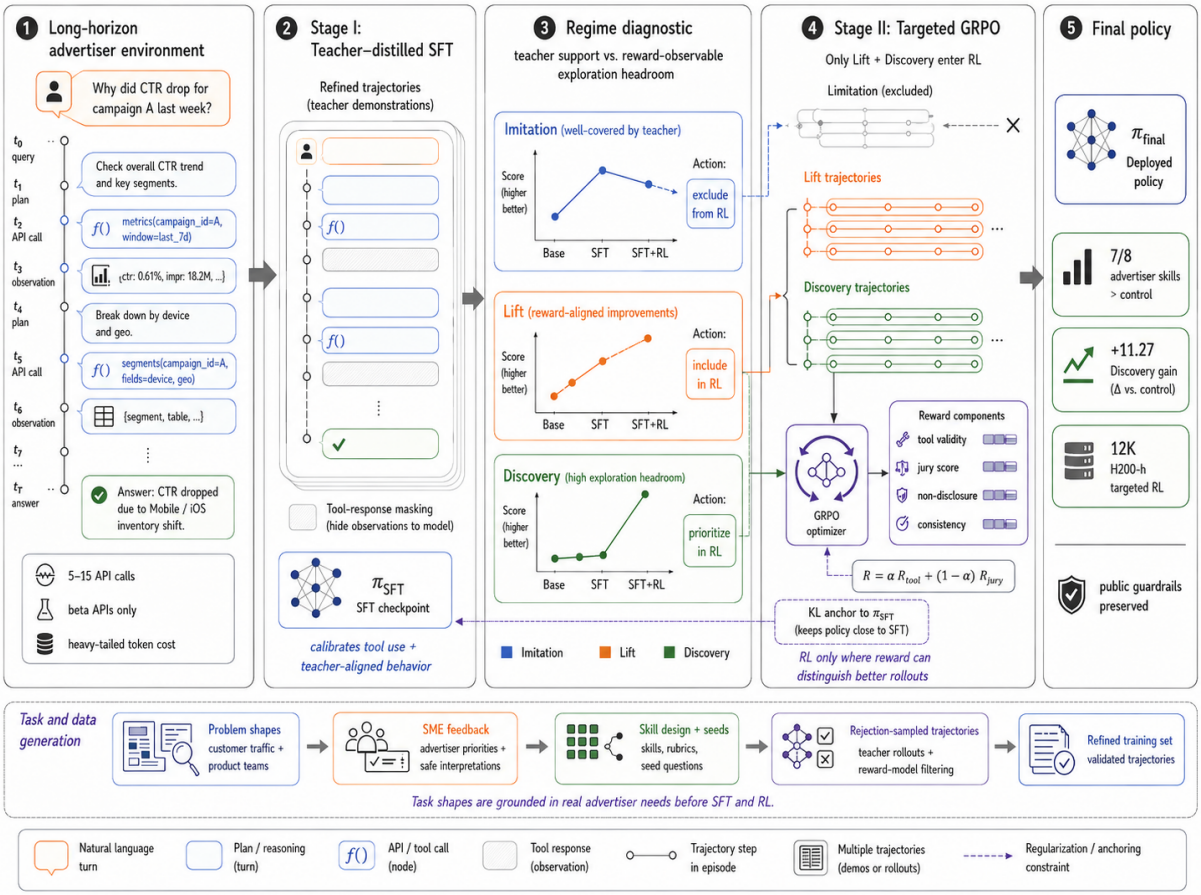

Figure 1: **Targeted post-training pipeline.** Episodes interleave reasoning, beta-API calls, and tool observations. Stage I uses teacher-distilled SFT with tool-response masking. The original eight-skill study motivates a three-regime hypothesis; a subsequent prospective diagnostic uses teacher support and frozen-SFT reward headroom to route new features before RL. Stage II applies GRPO only where reward-observable headroom justifies on-policy optimization, using tool-validity and skill-aware jury rewards with a KL anchor to π_{SFT}.

tic using teacher support and reward-observable headroom. The diagnostic determines whether a feature receives SFT only, SFT followed by RL, increased RL allocation, or additional environment (RL Gym) development. This separates the retrospective evidence that motivated the taxonomy from prospective evidence about whether it can guide new experiments.

Our contributions are: **(i) A regime hypothesis and prospective diagnostic:** we operationalize the three regimes using teacher support and reward-observable headroom measured before feature-specific RL; across 18 subsequent experiments, the diagnostic predicts 15/18 observed cases. **(ii) A targeted post-training recipe with a matched comparison:** teacher-distilled, tool-response-masked SFT is followed by GRPO only where exploration is reward-distinguishable. Under matched rewards and optimization settings, targeted allocation improves the seven-skill mean delta from $+1.62$ to $+3.57$ and uses 43% less incremental RL compute than uniform RL. **(iii) SME-grounded evaluation with paired uncertainty and human safety validation:** every headline score is Avg@32 on fixed held-out examples; we report paired 95% intervals and separately audit non-disclosure with human SMEs, showing substantially lower leakage without a material loss in actionability. **(iv) Production-scale evidence and accounting:** we report failed and successful large-scale runs, explicit offline release-readiness criteria, complete per-recipe SFT/RL compute, and the systems modifications required for long-context MoE RL under production-mirroring APIs.

2 The Advertiser Environment

We instantiate the beta-API infrastructure as a multi-turn tool-calling RL gym. At step t, the state s_t contains the user request, system instructions, prior reasoning, tool calls, and returned observa-

tions. The action a_t is the next assistant turn: either a structured call to one of 15 beta APIs, optionally preceded by planning tokens, or a terminal response. The environment executes valid tool calls, appends observations to the trajectory, and scores terminal responses with $R(\tau)$. The policy maximizes $\mathbb{E}_{\tau\sim\pi_\theta,P}[R(\tau)]$. Both policy and environment contribute variance: two rollouts from the same prompt can differ in the calls sampled, in the observations returned, or both. The prompt-length distribution is heavy-tailed, with a 99th percentile of 116,445 tokens; rollout-cost details are moved to Appendix F.

2.1 Task and Data Generation

We source *problem shapes* from anonymized customer-traffic patterns, product-team workflow requests, and recurring analytics intents observed by advertiser-facing teams. Subject-matter experts (SMEs) review these shapes for business relevance, policy sensitivity, and advertiser-persona coverage; their feedback defines the skills in Appendix D, seed questions, API surfaces, and rubric dimensions. Teacher models then generate candidate multi-turn trajectories against beta APIs. We retain only trajectories that pass execution validation, data-integrity checks for metric and entity consistency, and a judge-based reasoning audit for plan–code alignment, grounding, and skill-specific rubric satisfaction. Rejections feed back into prompt and rubric refinement; accepted trajectories form the masked-SFT corpus, and the same metadata is retained for regime diagnosis and reward routing.

2.2 Trajectory Format and SFT

A teacher produces multi-turn trajectories whose blocks alternate `<think>`, `<tool_call>`, `<tool_response>`, and `<final_response>`. We train with selective loss masking over assistant-generated tokens, following standard practice for multi-turn tool-use trajectories (Qin et al., 2024), normalizing by the number of unmasked tokens so long tool-heavy trajectories do not dominate the gradient by length. Loss is applied to `<think>`, `<tool_call>`, and `<final_response>` tokens, and masked on tool responses, system, and user tokens. We include Toucan-1.5M trajectories (Xu et al., 2025) as an out-of-domain regularizer.

Why the two stages differ. For skill k, masked teacher-distilled SFT is equivalent up to constants to minimizing a forward divergence from the demonstrated distribution p^k_{teach} to the policy,

$$\mathcal{L}^k_{\text{SFT}} \equiv D_{\text{KL}}\left(p^k_{\text{teach}} \,\|\, \pi_\theta\right) + \text{const.} \tag{1}$$

This is appropriate when the teacher reliably covers the desired behavior, but it cannot directly reward successful behaviors absent from demonstrations. The KL-regularized reward-maximization objective instead has the reward-tilted solution

$$\pi^*_k(\tau) \propto \pi_{\text{SFT}}(\tau)\, \exp(R_k(\tau)/\beta)\,, \tag{2}$$

which preserves the SFT policy as a reference while shifting mass toward trajectories the environment scores highly.

2.3 Prospective Regime Diagnostic

The eight-skill decomposition in the controlled study is retrospective. To make the hypothesis actionable for new features, we subsequently define two quantities measured *before* feature-specific RL. Let $\text{Valid}(\tau)$ indicate that a teacher trajectory passes execution, data-integrity, and SME-authored rubric checks. Teacher support and reward-observable headroom are

$$T_k = \Pr_{\tau\sim p^k_{\text{teacher}}}[\text{Valid}(\tau) = 1]\,, \tag{3}$$

$$H_k = \mathbb{E}_q\left[\max_{i\le G} R(\tau_i) - \frac{1}{G}\sum_{i=1}^{G} R(\tau_i)\right], \quad G = 8, \tag{4}$$

where the G trajectories are sampled from the frozen SFT policy for each prompt. We route features before RL using the following rule:

Teacher support	Reward headroom	Route
$T_k \ge 0.80$	$H_k < 0.10$	Imitation: SFT only
$T_k \ge 0.80$	$H_k \ge 0.10$	Lift: SFT→RL
$T_k < 0.80$	$H_k \ge 0.10$	Discovery: increased RL
$T_k < 0.80$	$H_k < 0.10$	Improve environment

Assignments are fixed before each feature-specific RL experiment; Section 3 reports the resulting 18-feature evaluation.

2.4 Targeted GRPO with a Jury Reward

We refine the SFT checkpoint with GRPO (Shao et al., 2024) against the 15-tool beta environment. For each prompt q, we sample a group of G trajectories and compute a group-normalized advantage:

$$\hat{A}_i = \frac{R(\tau_i) - \frac{1}{G}\sum_{j=1}^{G} R(\tau_j)}{\text{std}(\{R(\tau_j)\}_{j=1}^{G}) + \epsilon}. \tag{5}$$

The reward combines tool grounding and semantic quality,

$$R(\tau) = \alpha\, R_{\text{tool}}(\tau) + (1-\alpha)\, R_{\text{jury}}(\tau), \quad (6)$$

where $R_{\text{tool}} \in [0,1]$ penalizes invalid calls, unsupported joins, and execution failures, and $R_{\text{jury}} \in [0,1]$ scores semantic answer quality. The tool-grounding term reduces the chance that the policy learns fluent but unsupported responses.

Skill-aware jury reward. R_{jury} is skill-aware rather than a universal rubric. Every trajectory is scored for thought consistency, response factuality, and tool-output validity; skill-specific dimensions such as numerical sanity, audience analysis, performance-gap attribution, and non-disclosure are activated only when relevant (Appendix F). The non-disclosure rubric independently scores restricted-information leakage, factual correctness, actionability, and excessive abstraction, so a vague refusal cannot score highly merely by omitting sensitive values. The reward jury combines open-weight judges from different model families—DeepSeek-R1 and Qwen3-235B-A22B—to reduce self-preference bias (Guo et al., 2025; Qwen Team, 2025; Panickssery et al., 2024; Zheng et al., 2023; Verga et al., 2024). On a 200-trajectory human-rated calibration set, ensemble jury–human Spearman is 0.78 and two SME raters achieve Cohen's $\kappa = 0.74$ (Appendix J).

Stabilization and infrastructure. Disaggregated SGLang (Zheng et al., 2024) rollouts and Megatron (Shoeybi et al., 2019) training introduce rollout–training mismatch even with periodic synchronization (Yao et al., 2025a; Zheng et al., 2025). We use a KL anchor to π_{SFT}, asymmetric policy-ratio clipping, and token-level truncated importance sampling (TIS), tracking held-out reward, entropy, clipping rate, and TIS truncation. GPT-OSS-120B (OpenAI, 2025) training additionally required bit-correct MoE weight synchronization, context-parallel support for learnable-softmax attention, and token-budget batching for heavy-tail trajectories. Full objectives and systems details are in Appendices G and N.

3 Results

Evaluation protocol and baselines. Each domain skill contains at least 250 held-out examples; exact counts are confidential. All checkpoints and Control are evaluated on identical fixed examples with no overlap with SFT or RL data. Every reported score is Avg@32 over 32 independent stochastic evaluation repetitions of the *same trained checkpoint*; these repetitions capture decoding and beta-environment stochasticity and are not 32 independently trained policies. We report paired 95% confidence intervals from the matched evaluation outputs following a paired resampling protocol (Koehn, 2004).

Teacher and Control are frontier closed-weight models with at least 256K context, the same 15 beta APIs, and full production-style schemas. Teacher generates candidate SFT trajectories under fixed low-temperature decoding; Control is the fixed production comparison baseline. Neither is exposed to candidate post-training data, participates in the RL reward, or participates in the Kimi-K2 headline evaluation. Candidate policies and Control use the same fixed prompts, tool interfaces, and beta-environment configuration. Headline deltas are scored by Kimi-K2 (Kimi Team, 2025), from a different model family than the DeepSeek-R1/Qwen3 reward jury.

Controlled eight-skill result. In Table 1 targeted SFT+RL has positive point estimates on 7/8 skills versus Control; five gains exceed one percentage point and have paired intervals excluding zero. Measure Funnel ($+0.41$) and Identify Product ($+0.66$) are directional because their intervals cross zero. Categorize Campaigns/Ads significantly regresses by -2.05 points. Its teacher reference is the weakest in the suite (59.19 versus 84.53 next-lowest), and deltas improve monotonically without closing the gap. The matched seven-skill subset, scored at Base, SFT, and SFT+RL, moves from 2/7 to 4/7 to 6/7 positive point estimates, with four SFT+RL gains above one point. Public guardrails remain non-negative for SFT+RL: IFEval (Zhou et al., 2023) $+1.22$, GSM8K (Cobbe et al., 2021) $+3.43$, and GPQA-Diamond (Rein et al., 2024) $+7.07$ points versus Control.

Retrospective three-regime decomposition. Figure 2 summarizes the original retrospective observation. Imitation moves 91.43→95.55→95.42; Lift 86.46→87.22→89.11; and Discovery 83.23→84.00→95.50, exceeding the teacher by 10.97 points. Discovery contains one controlled safety-critical skill, so it is an existence result rather than evidence of regime prevalence.

Table 1: **Per-skill evaluation against Control on GPT-OSS 120B.** Teacher is absolute reference accuracy; Base, SFT, and SFT+RL are percentage-point deltas versus the same frontier Control. Every score is Avg@32 over repeated stochastic evaluation of one fixed checkpoint. The final column reports paired 95% CIs for SFT+RL. Bold deltas have intervals excluding zero.

Skill	*Teacher*	Control	Base Δ	SFT Δ	SFT+RL Δ	95% paired CI
Measure funnel	94.32	91.73	−2.73	+1.55	+0.41	[−0.28, +1.10]
Target / audience strategy	90.92	90.00	–	–	**+1.50**	[+0.48, +2.52]
Business metrics	94.42	91.22	+4.78	+3.19	**+5.18**	[+4.03, +6.33]
Categorize campaigns / ads	59.19	57.05	−6.95	−4.35	**−2.05**	[−3.21, −0.89]
Campaign performance	84.70	82.51	+5.19	+5.49	**+7.49**	[+6.15, +8.83]
Identify product	89.89	87.56	−2.34	−1.13	+0.66	[−0.14, +1.46]
Brand voice	96.65	96.67	−2.82	+1.15	**+2.03**	[+1.07, +2.99]
Share insights without disclosing non-public information	84.53	84.23	−1.00	−0.23	**+11.27**	[+9.72, +12.82]

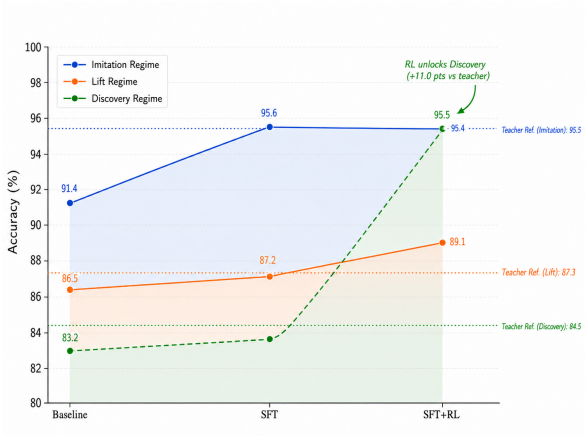

Figure 2: **Retrospective three-regime decomposition.** Mean accuracy for representative GPT-OSS 120B skills across Base→SFT→targeted RL. Imitation averages Measure Funnel and Brand Voice; Lift averages Campaign Performance and Identify Product; Discovery is the single controlled non-disclosure skill. Dotted lines denote teacher references. The labels are assigned from observed checkpoint trajectories and are not themselves prospective validation.

Regime-conditioned training dynamics. Figure 3 complements the endpoint decomposition. The SFT reference already occupies a high-reward region for Imitation, and targeted allocation preserves it by excluding that regime from RL; uniform optimization instead reduces entropy without improving reward. In Discovery, targeted RL produces sustained held-out reward gains while entropy contracts gradually rather than collapsing. Update-magnitude, policy-clipping, and TIS diagnostics remain in Appendix G.

Matched uniform versus targeted RL. To isolate the value of allocation more directly, we compare retained uniform and targeted runs that share the SFT checkpoint, reward jury and tool reward, optimizer and learning rate, KL coefficient, clipping/TIS configuration, and rollout group size. The primary difference is the skill-sampling curriculum: uniform RL samples all skills, while targeted RL excludes Imitation and overweights Discovery.

Matched seven-skill result	Uniform	Targeted
Positive vs. Control	4/7	**6/7**
Mean Δ vs. Control	+1.62	**+3.57**
Imitation mean accuracy	94.31	**95.42**
Lift mean accuracy	88.34	**89.11**
Discovery accuracy	90.72	**95.50**
Incremental RL compute	21K	**12K**
Total SFT+RL compute	36K	**27K**

Table 2: Matched uniform-versus-targeted allocation. Compute is in H200-hours. Targeted allocation uses 43% less incremental RL compute.

Targeted allocation improves Discovery, better preserves the SFT-calibrated Imitation mean, and uses 43% less incremental RL compute. Development sweeps not retained in this matched comparison sometimes differed along additional dimensions; we therefore interpret Table 2 as evidence for the matched allocation comparison and avoid attributing every recipe-level gain solely to routing. A sanitized qualitative contrast between the SFT and targeted-RL responses is given in Appendix I.

Prospective operational evidence. The diagnostic in Section 2.3 was subsequently applied before feature-specific RL across multiple business lines. It predicted the observed post-training trajectory for 5/6 Imitation assignments, 6/7 Lift assignments, and 4/5 Discovery assignments: 15/18 (83.3%) overall. This follow-on study is broader but less controlled than the original eight-skill experiment; it supports the diagnostic's operational usefulness rather than establishing a universal taxonomy. Low-support/low-headroom cases are returned for ad-

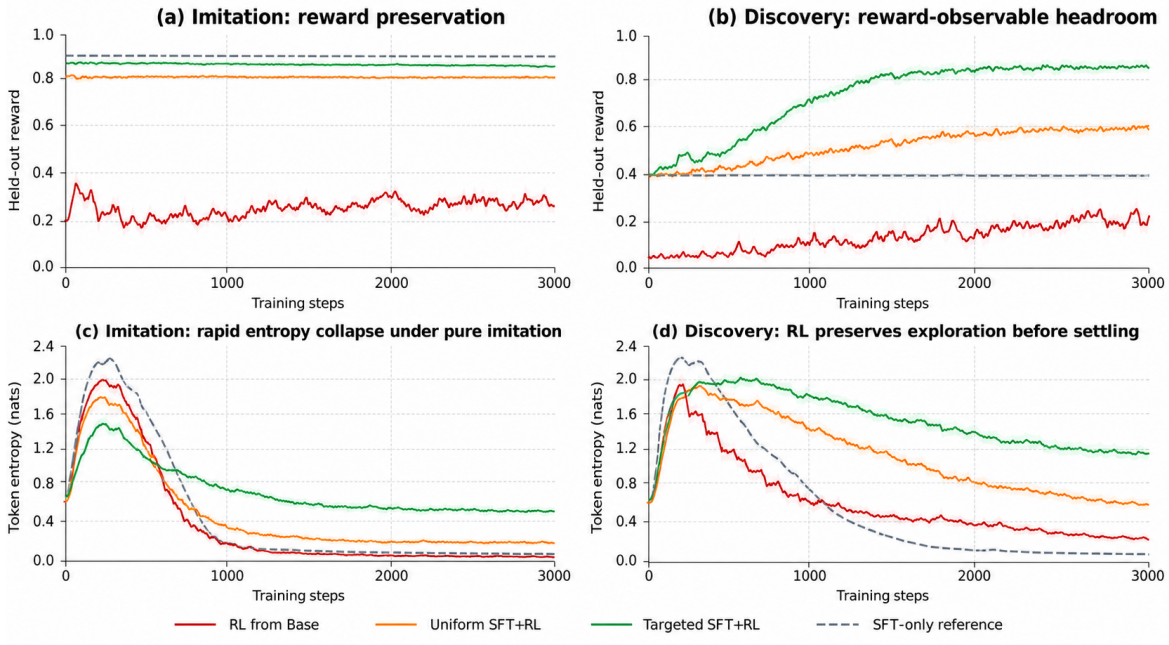

Figure 3: **Regime-conditioned reward and entropy dynamics.** Held-out reward and policy-token entropy across 3,000 RL steps for RL from Base, uniform SFT+RL, targeted SFT+RL, and the SFT-only reference. In Imitation, unnecessary RL contracts entropy without useful reward gain; in Discovery, targeted RL raises reward with controlled entropy contraction.

Human-audit metric	Control	SFT	SFT+RL
Standard leakage	12.4%	11.8%	**2.9%**
Adversarial leakage	24.7%	22.9%	**6.8%**
Informative/actionable	84.6%	86.2%	85.7%
Acceptably safe	76.9%	78.4%	**91.8%**

Table 3: Independent SME audit of the non-disclosure checkpoint. Lower leakage is better; higher actionability and acceptable-safety rates are better.

ditional SME annotation, reward improvement, or environment development. Further operational details are in Appendix C.

Independent human audit of non-disclosure. The largest controlled effect is non-disclosure ($+11.27$ points, 95% CI $[+9.72, +12.82]$). To test whether this reflects genuine abstraction rather than generic vagueness, a separate held-out set is independently audited by SMEs using standard and adversarial prompts. The rubric separately measures leakage, correctness, actionability, refusal, and excessive abstraction; inter-annotator agreement is Cohen's $\kappa = 0.76$, distinct from the $\kappa = 0.74$ jury-calibration set.

Relative to SFT, targeted RL reduces standard leakage by 8.9 points and adversarial leakage by 16.1 points while changing actionability by only -0.5 points. This human audit, rather than jury correlation alone, is the primary evidence that the gain is not produced by generic refusal or excessive abstraction. It remains a held-out offline validation, not a complete real-world safety certification.

Offline release readiness, compute, and serving-period checks. The pre-defined gate requires mean domain delta $\geq +2.0$, at least 6/8 positive domain point estimates, no individual domain regression below -3.0, non-disclosure gain over Teacher $\geq +5.0$, zero negative public guardrails, jury–human Spearman $\rho \geq 0.75$, tool-call validity $\geq 97\%$, P95 latency regression no worse than $+10\%$, and standard-prompt leakage below 5%. Targeted SFT+RL passes all nine criteria (Appendix B). The shared SFT stage costs 15K H200-hours; uniform RL adds 21K (36K total) and targeted RL adds 12K (27K total). RL from Base does not pass the gate within 25K H200-hours.

The same candidate checkpoint was also measured against Control during a fixed online evaluation period using the same traffic slice and serving configuration. It records $+5.4$ percentage points in multi-turn task completion, $+7.1$ points in recovery after a failed tool call, $+3.6$ points in recommendation acceptance, and a -6.8% change in P95 user-perceived latency; the full operational table is in Appendix M. Confidentiality requirements prevent disclosure of the exact evaluation window, traffic volume, and whether individual measurements were collected in shadow or live

mode. We therefore treat these results as operational evidence that the candidate does not require an obvious serving-performance trade-off, not as a reproducible randomized causal estimate of online product impact.

4 Related Work

SFT, RL, generalization, and retention. Post-training builds on preference-based RL and RLHF (Christiano et al., 2017; Ziegler et al., 2019; Stiennon et al., 2020; Ouyang et al., 2022; Bai et al., 2022; Rafailov et al., 2023). Recent work directly contrasts SFT and RL: Chu et al. (2025) find that SFT tends to memorize while outcome-based RL can generalize to unseen variants; Shenfeld et al. (2026) argue that on-policy RL is biased toward lower-KL solutions that retain prior capabilities; and Chen et al. (2026) isolate on-policy data as an important mechanism for mitigating forgetting. Two-stage SFT→RL efficiency has also been observed in mathematical reasoning (Yoshihara et al., 2025). Our question is complementary: within one heterogeneous long-horizon agent, can observable pre-RL properties determine *where* RL budget should be allocated? Complementary lines of work change *what* the policy trains on rather than where budget is spent: curriculum scheduling from easy to hard tasks (Parashar et al., 2026), and mixing off-policy teacher traces into on-policy rollouts (Yan et al., 2025a). We additionally connect reasoning-RL systems (Shao et al., 2024; Guo et al., 2025; Lambert et al., 2024) with reward over-optimization (Gao et al., 2023; Skalse et al., 2022) and judge calibration (Lambert et al., 2025; Zheng et al., 2023; Panickssery et al., 2024; Verga et al., 2024).

Tool use and industrial e-commerce systems. Tool-use and function-calling work (Schick et al., 2023; Li et al., 2023; Patil et al., 2024; Qin et al., 2024; Patil et al., 2025; Tang et al., 2023) and agent benchmarks (Yao et al., 2023; Liu et al., 2024b; Zhou et al., 2024; Yao et al., 2025b) emphasize interleaved reasoning and action. Industrial e-commerce systems have separately used retrieval-augmented generation and domain alignment for product-aware query completion and conversational shopping (Sun et al., 2024; Luo et al., 2025). Selective-information generation has also been studied in blocked textual-graph QA, where relevant information must be inferred yet excluded from the answer (Yan et al., 2025b); our non-disclosure skill differs in operating over tool-returned enterprise observations and learning the behavior through targeted post-SFT RL. Efficient LLM-RL systems separate rollout and training backends, creating an implicit off-policy gap that motivates TIS and related corrections (Yao et al., 2025a; Zheng et al., 2025). Imitation-regime regressions are also consistent with catastrophic interference (McCloskey and Cohen, 1989), alignment-induced generalization shifts (Kirk et al., 2024), and long-context degradation (Liu et al., 2024a).

5 Discussion and Conclusion

The controlled study supports a stage-wise allocation view of post-training. SFT is effective when teacher support is high, while RL is most useful when the frozen SFT policy exposes reward-distinguishable alternatives. The matched comparison strengthens this: targeted allocation improves the seven-skill mean delta while reducing incremental RL compute, rather than applying more optimization everywhere. The prospective diagnostic converts that observation into an actionable routing rule.

The evidence has an important asymmetry. Imitation and Lift are supported by multiple controlled skills, whereas Discovery is represented by one controlled proprietary non-disclosure skill. The 4/5 prospective Discovery result broadens the operational evidence but is not a substitute for a larger controlled Discovery benchmark. Similarly, the Qwen3-32B run (Appendix E) shows qualitative Discovery transfer but weaker preservation elsewhere, indicating that KL strength, reward mixture, and rollout allocation do not automatically transfer across scale and architecture.

Finally, the non-disclosure result illustrates why semantic reward design requires independent human validation. The model does not merely refuse more often: standard and adversarial leakage drop sharply while actionability remains nearly unchanged. Together, these results suggest a practical recipe for long-horizon enterprise agents: use SFT to establish domain competence, measure teacher support and reward-observable headroom before spending RL budget, apply RL selectively where exploration is distinguishable, and validate safety-critical gains outside the reward model.

Limitations

The proprietary advertiser benchmark contains eight controlled domain skills, and the Discovery aggregate contains one safety-critical skill. The retrospective three-regime decomposition should therefore be read as an empirical hypothesis supported by observed checkpoint trajectories, not a population-level taxonomy. The later prospective analysis covers 18 feature experiments and predicts 15/18 cases, but remains modest in scale and is less controlled than the original experiment. Broadening controlled Discovery evidence remains the most important validation step; public BFCL/ToolBench results in Appendix H are post-hoc structural analogues, not external validation.

Exact per-skill prompt counts cannot be disclosed, although each skill contains at least 250 held-out examples and the largest is less than $1.4\times$ the smallest. Avg@32 captures stochastic evaluation and beta-environment variance for one trained checkpoint; it does not estimate variance across independently trained policies. The paired intervals therefore quantify evaluation uncertainty conditional on the retained checkpoints, not end-to-end training-seed uncertainty.

The independent non-disclosure audit substantially strengthens the safety evidence, but it remains a held-out offline audit rather than a complete real-world safety certification. Learned abstraction may still fail under distribution shift, new adversarial attacks, or changes in tool outputs, so deployment requires least-privilege access, output-side controls, logging, and ongoing review. Operational metrics are also limited by confidentiality: the exact evaluation window, traffic volume, and shadow/live assignment mode cannot be disclosed, preventing full reproduction or a clean causal interpretation of those serving-period changes.

Production data and beta APIs are proprietary, and the exact hyperparameter sensitivity surface is not released. Recipe-level compute includes SFT and RL costs attributable to each retained training recipe; shared development costs from hyperparameter search and infrastructure bring-up are excluded from those recipe totals because they are not cleanly attributable to one recipe. Finally, the environment uses relatively stable beta-API interfaces; rapidly changing schemas would require periodic trajectory refresh, regression evaluation, and targeted re-training.

Ethical Considerations

The model operates over advertiser data accessed through beta APIs that mirror production, under advertiser-isolation and access-control constraints. Tool observations may contain sensitive or competitor-derived values even when the final response should expose only abstracted business guidance. Non-disclosure is therefore a behavioral guardrail, not an information barrier. Any production use must combine model behavior with least-privilege tool access, output-side policy filters, audit logging, and independent review of sensitive-output scenarios. The non-disclosure audit reported here uses SME-authored rubrics and a held-out annotation set, but does not eliminate risks under distribution shift or adversarial prompting. The reward jury is open-weight and inspectable; teacher-generated trajectories are used only under the applicable provider terms and internal approvals for model-development and distillation workflows.

A Regime Aggregates and Complete Recipe Compute

(a) Retrospective regime aggregation

Regime	Skills	Tchr.	Base	SFT	+RL
Imitation	Measure funnel; Brand voice	95.49	91.43	**95.55**	95.42
Lift	Campaign perf.; Identify product	87.30	86.46	87.22	**89.11**
Discovery	Non-disclosure abstraction	84.53	83.23	84.00	**95.50**

(b) Complete retained-recipe compute

Recipe	SFT	RL	Total
SFT only	15K	–	15K
RL from Base	–	25K	25K
SFT + uniform RL	15K	21K	36K
SFT + targeted RL	15K	12K	27K

Table 4: Supporting result summaries. Panel (a) gives the descriptive aggregation underlying Figure 2. Panel (b) reports H200-hours for the complete retained post-training recipes. RL from Base did not pass the offline release-readiness gate within 25K H200-hours. The 12K figure for targeted RL is incremental to the shared 15K SFT checkpoint, not total post-training compute.

B Offline Release-Readiness Gate

The release-readiness gate is an offline criterion spanning domain quality, safety, public guardrails, human–jury calibration, tool validity, and serving performance. Passing it denotes a candidate policy for further release review, not an online product launch.

Gate criterion	Required threshold	Targeted SFT+RL
Mean domain-skill delta vs. Control	$\geq +2.0$ points	3.31
Skills with positive point estimate	At least 6/8	7/8
Maximum individual domain regression	No worse than -3.0	-2.05
Non-disclosure gain over Teacher	$\geq +5.0$	10.97
Public guardrail regressions	0 negative	0/3 negative
Jury–human calibration	Spearman $\rho \geq 0.75$	0.78
Tool-call execution validity	$\geq 97\%$	98.60%
P95 latency regression vs. Control	No worse than $+10\%$	-6.8%
Standard-prompt leakage rate	$< 5\%$	2.90%

Table 5: Numerical offline release-readiness criteria and the targeted candidate's values.

C Prospective Diagnostic Details

Teacher support T_k and reward-observable headroom H_k are computed before feature-specific RL as defined in Equations 3–4. Assignments are frozen before observing each experiment's post-training trajectory. Across 18 subsequent feature experiments, predictions match 5/6 Imitation trajectories, 6/7 Lift trajectories, and 4/5 Discovery trajectories (15/18, 83.3% overall). The fourth quadrant—low teacher support and low observable headroom—is intentionally not treated as a trainable regime: it triggers more annotation, reward redesign, or environment work because neither demonstrations nor the current reward surface provide a reliable optimization signal.

Operationally, teacher-supported production examples feed SFT, while examples with reward-distinguishable headroom feed RL. Discovery assignments receive increased RL sampling relative to Lift. Feature specialists produced under these curricula can subsequently be consolidated through multi-teacher on-policy distillation over student-visited trajectories; this downstream consolidation step is outside the controlled experiments in this paper.

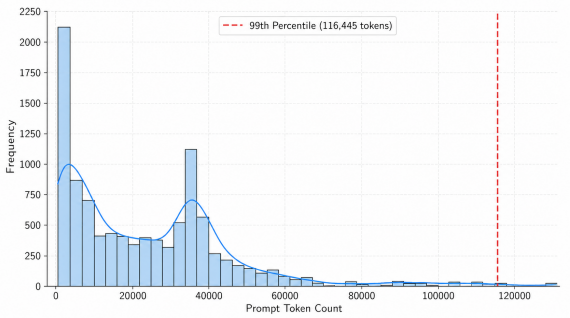
D Advertiser Skill Taxonomy and Example Tasks

Table 6 summarizes the advertiser-facing task families used to construct training and evaluation data. Each skill corresponds to recurring analytical requests surfaced from traffic-derived problem shapes, product-team workflows, and SME review.

Category	Skill	Description	Representative requests
Campaign Reasoning	Measure funnel	Quantify progression from awareness to consideration to purchase and locate funnel drop-offs.	What does my full funnel look like from awareness to purchase? Where is the biggest drop-off between branded search and purchase?
Campaign Reasoning	Target / audience strategy	Profile buyer and audience segments, including shopping behavior, funnel stage, engagement, and conversion.	Which audience segments engage but fail to convert? How are repeat purchasers different from one-time buyers?
Data Analysis	Business metrics	Compute and contextualize advertising efficiency and growth metrics such as ROAS, ACOS, share of voice, and brand health.	Calculate my ROAS and compare ad-driven sales to peers. How has my advertising efficiency trended quarter over quarter?
Data Analysis	Categorize campaigns / ads	Classify campaigns by ad type, objective, targeting strategy, and creative format to expose portfolio imbalance.	Which campaigns are SP, SB, or SD, and how does spend distribute? Group campaigns by targeting strategy and compare ROAS.
Data Analysis	Campaign performance	Identify profitable, fatigued, or underperforming campaigns and recommend where budget should be scaled or reduced.	Which campaigns increased spend but lost ROAS? Show daily spend and sales trends for my top campaigns.
Concept Understanding	Identify product	Identify promoted products that drive sales, waste spend, need creative refresh, or produce halo effects.	Which ASINs generate the most sales with the lowest ad spend? Which products have high impressions but low CTR?
Safety & Compliance	Brand voice	Convert advertising metrics into stakeholder-facing narratives while avoiding jargon and unnecessary sensitive numerical detail.	Draft a CMO-ready campaign summary. Summarize my brand growth story directionally.
Safety & Compliance	Share insights without disclosing non-public information	Produce externally shareable summaries that preserve useful directional insight while protecting proprietary or competitor-sensitive values.	What can I share with my agency without exposing bid strategy? Create a vendor-safe report with trends but no exact impression counts.

Table 6: **Advertiser skill taxonomy.** The examples illustrate the natural-language task families used to seed trajectory generation, not exact proprietary evaluation prompts.

E Model-Scale Transfer



The Qwen3-32B dense run provides directional transfer evidence rather than a deployment-level replication. It improves non-disclosure by $+4.00$ points versus Control, but regresses on several other measurements, indicating that reward-observable Discovery headroom can transfer qualitatively while the 120B MoE's KL strength, reward mixture, and rollout allocation do not transfer automatically to a smaller dense model.

Skill / guardrail	Qwen3-32B SFT+RL Δ vs. Control
Measure funnel	-2.04
Business metrics	$+3.52$
Categorize campaigns / ads	-4.05
Identify product	-5.36
Brand voice	$+0.04$
Non-disclosure	$+4.00$
IFEval	$+0.37$
GSM8K	-5.91
GPQA-Diamond	-1.00

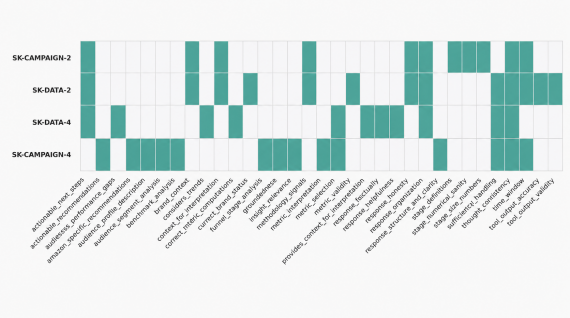


Table 7: Directional model-scale transfer on Qwen3-32B. Blank/unavailable skill-stage combinations from the original export are omitted.

F Cost Structure and Reward Routing

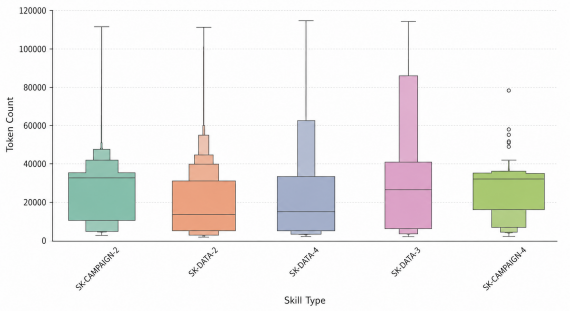

Figure 4 collects the rollout-cost and reward-routing statistics referenced in Sections 2 and 2.4. Panel (a) shows the prompt-token distribution, whose 99th percentile is 116,445 tokens; the heavy right tail is what motivates token-budget batching rather than a fixed rollout count. Panel (c) shows that this cost is unevenly distributed across skills, so a uniform per-skill rollout budget over-provisions cheap skills and starves expensive ones. Panel (d) shows how total token exposure grows with the rollout group size G, which is the term that dominates incremental RL compute in Table 4. Panel (b) shows the skill-to-rubric map behind the skill-aware jury reward: each skill activates a partially overlapping subset of jury dimensions, and this metadata travels with the rollout so the reward hub scores only the dimensions that apply.

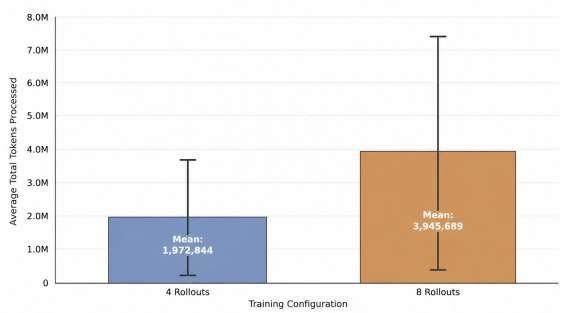

(a) Prompt-token distribution; the 99th percentile is 116,445 tokens.

(b) Skill-aware reward dimensions.

(c) Per-skill rollout-cost heterogeneity.

(d) Token-exposure variance under larger rollout groups.

Figure 4: **Cost structure and reward routing.** Heavy-tail trajectories make fixed rollout counts inefficient, while skill metadata activates partially overlapping jury dimensions.

G Optimization Stability and Rollout Correction

Rollouts are generated by SGLang workers while log-probabilities and gradients are computed by Megatron workers, so the rollout policy π_{roll} and proximal training policy π_{prox} can differ even under periodic weight synchronization (Yao et al., 2025a; Zheng et al., 2025). We apply token-level truncated importance sampling (TIS) (Ionides, 2008; Yao et al., 2025a),

$$w_{i,t}^{\text{TIS}} = \min\left(\frac{\pi_{\text{prox}}(a_{i,t} \mid s_{i,t})}{\pi_{\text{roll}}(a_{i,t} \mid s_{i,t})}, C\right), \tag{7}$$

with cap $C = 2$. Separately, the policy ratio relative to π_{prox} is clipped asymmetrically,

$$\rho_{i,t}(\theta) = \frac{\pi_\theta(a_{i,t} \mid s_{i,t})}{\pi_{\text{prox}}(a_{i,t} \mid s_{i,t})}, \quad \bar{\rho}_{i,t}(\theta) = \text{clip}_{[0.80,\,1.28]}(\rho_{i,t}(\theta)). \tag{8}$$

The TIS-corrected clipped surrogate and final objective are

$$\ell_{i,t}(\theta) = w_{i,t}^{\text{TIS}} \min\left(\rho_{i,t}(\theta)\hat{A}_i,\ \bar{\rho}_{i,t}(\theta)\hat{A}_i\right), \tag{9}$$

$$\mathcal{J}_{\text{GRPO}}(\theta) = \mathbb{E}_{i,t}[\ell_{i,t}(\theta)] - \beta\,\text{KL}(\pi_\theta \,\|\, \pi_{\text{SFT}}). \tag{10}$$

TIS limits variance from rollout–training mismatch; policy-ratio clipping limits local update magnitude; and the KL anchor retains the SFT checkpoint as a behavioral reference. We track token entropy, clipped-token rate p_{clip}, and TIS-truncation rate p_{TIS} to separate entropy collapse, excessive local movement, and rollout mismatch.

H Public-Benchmark Consistency Check

We evaluate Base, SFT, and SFT+RL on BFCL (Patil et al., 2025) and ToolBench (Qin et al., 2024) subsets not used to select the proprietary RL mix. These labels are assigned after observing checkpoint behavior and are therefore structural analogues rather than prospective external validation.

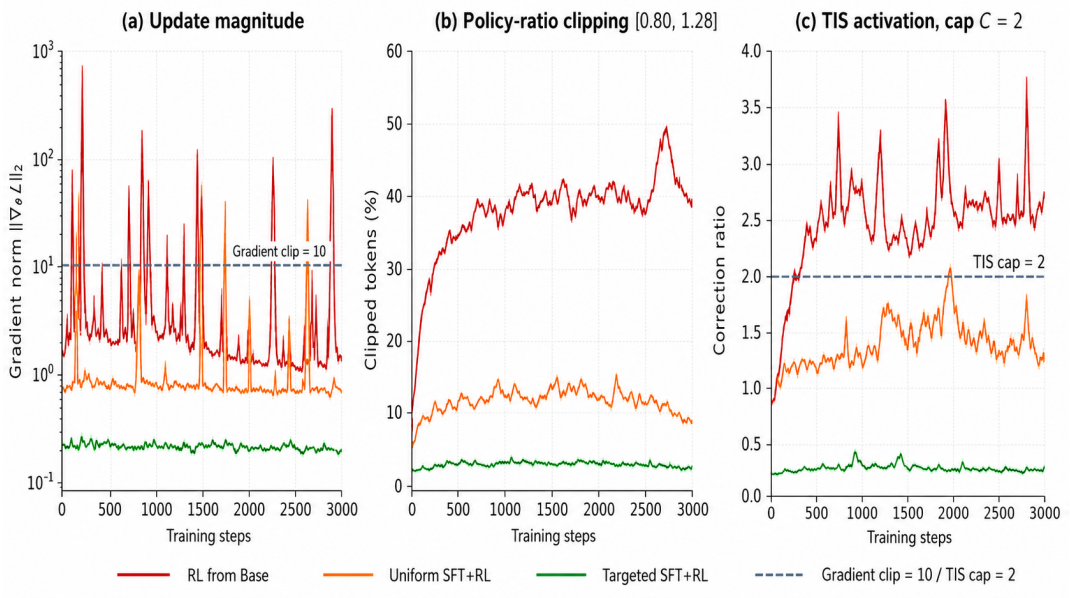

Figure 5: **Optimization stability and rollout correction.** Targeted SFT+RL exhibits smaller update magnitudes, lower clipping activity, and weaker TIS correction pressure than RL from Base or uniform SFT+RL. The gradient clipping threshold is 10; the policy-ratio interval is $[0.80, 1.28]$; TIS uses $C = 2$.

Observed pattern	Benchmark subset	Base	SFT	+RL	Δ_{RL}
Imitation-like	BFCL (Single-Tool)	82.1%	**93.4%**	92.1%	−1.3
Lift-like	ToolBench (Multi-Step)	74.2%	81.5%	**84.3%**	+2.8
Discovery-like	BFCL (Missing Params)	61.4%	68.2%	**81.5%**	+13.3

Table 8: External consistency check on public tool-use subsets.

BFCL Single-Tool has a narrow action space, and SFT learns syntax and selection convention before RL slightly regresses the calibrated mode. ToolBench Multi-Step admits multiple valid tool orderings; both SFT and RL add value. BFCL Missing Parameters requires recognizing absent required parameters rather than blindly emitting a call; RL provides the largest additional gain. This last pattern is a structural analogue of Discovery behavior, not a proxy for the proprietary non-disclosure task.

I Qualitative Case Study: Discovery-Regime Abstraction

To understand why RL can break through the SFT plateau on non-disclosure, we analyze sanitized trajectories where a tool returns competitor-sensitive bidding behavior alongside advertiser metrics.

SFT failure mode: imitation and leakage. The SFT model can remain factually responsive while exposing a restricted raw value:

> *"Your impression share dropped because Competitor X increased their top-of-search bid to $4.50, outbidding your maximum of $3.00."*

RL success mode: constrained abstraction. The targeted RL model instead produces an actionable abstraction:

> *"Your impression share dropped significantly due to increased competitive density at the top-of-search. To regain visibility, consider directionally increasing your top-of-search modifier while monitoring efficiency."*

This contrast illustrates the reward target but is not itself safety evidence; the independent SME audit in Appendix J provides the quantitative held-out validation.

J Jury Calibration and Independent Human Audit

Jury calibration. We calibrate the open-weight jury (DeepSeek-R1, Qwen3-235B-A22B) against a 200-trajectory human-rated seed set stratified across completed domain skills. Two SME raters independently

score each trajectory's <final_response> on a 5-point quality scale; inter-rater agreement is Cohen's $\kappa = 0.74$. Per-juror Spearman with averaged human scores is 0.76 (DeepSeek-R1) and 0.79 (Qwen3-235B-A22B); inter-juror Spearman is 0.81; ensemble jury versus averaged human is 0.78. The pre-specified deployment threshold is $\rho \geq 0.75$.

Independent non-disclosure audit. The safety audit is a separate held-out annotation set from the 200-trajectory calibration sample. SME-authored standard and adversarial prompts are used to evaluate direct/indirect leakage, factual correctness, actionability, excessive vagueness, refusal, and an overall acceptable-safety judgment. Two independent SME annotators achieve Cohen's $\kappa = 0.76$; disagreements are adjudicated by a second SME cohort.

Metric	Control	SFT	SFT+RL
Standard-prompt leakage rate	12.40%	11.80%	2.90%
Adversarial-prompt leakage rate	24.70%	22.90%	6.80%
Informative/actionable response rate	84.60%	86.20%	85.70%
Refusal rate	5.80%	5.50%	6.40%
Acceptable safety rate	76.90%	78.40%	91.80%

Table 9: Full independent SME audit of non-disclosure. The result separates leakage from usefulness and refusal behavior.

K Per-Skill SFT Trajectory Volumes and RL Mix

SFT trajectories are unevenly distributed across skill families, weighted by empirical difficulty and downstream importance. Exact per-skill training counts are proprietary; relative weights are summarized below. The RL mix re-weights toward exploration-heavy skills identified by the routing diagnostic and excludes Imitation-regime skills.

Regime	SFT mix weight	RL mix weight
Imitation	1.0×	0× (excluded)
Lift	1.0×	1.0×
Discovery	1.5×	2.5×
OOD (Toucan, regularizer)	0.3×	–

Table 10: Trajectory mix weights normalized within each stage relative to Lift at 1.0×.

L Hyperparameters and Empirical Sweeps

GRPO uses group size $G = 8$, KL coefficient $\beta = 0.04$ (constant; no annealing), reward weighting $\alpha = 0.4$ for R_{tool} and $1-\alpha = 0.6$ for R_{jury}, rollout context limit 64K tokens, and learning rate 5×10^{-7} with AdamW and linear warmup over 100 steps. We use asymmetric policy-ratio clipping with $\epsilon_{\text{low}} = 0.20$ and $\epsilon_{\text{high}} = 0.28$, giving $[0.80, 1.28]$. TIS uses $C = 2$. SFT uses learning rate 1×10^{-5}, batch size 64 trajectories, and three epochs.

The specific values for α, β, sequence limits, and data-mix ratios were selected following 83 large-scale development experiments, including unsuccessful RL-from-Base attempts. The exact sensitivity surfaces are proprietary. Recipe compute in Table 4 includes only the attributable SFT/RL compute of the retained recipes; shared hyperparameter-search and infrastructure bring-up compute are excluded from recipe totals because they are shared development costs rather than cleanly attributable to one recipe.

M Operational Metrics

The targeted candidate and Control were measured over the same traffic slice and serving configuration during a fixed online evaluation period. Exact traffic volume, evaluation dates, and shadow/live assignment mode cannot be disclosed under confidentiality requirements. Accordingly, the table reports normalized changes only and is interpreted as operational evidence rather than a reproducible randomized causal estimate of online impact.

Operational metric	Change vs. Control
Supported QPS	$+10\%$
Generation throughput	$+2.9\%$ tokens/s
P50 user-perceived latency	-4.2%
P95 user-perceived latency	-6.8%
Recommendation acceptance rate	$+3.6$ percentage points
Multi-turn task-completion rate	$+5.4$ percentage points
Recovery after a failed tool call	$+7.1$ percentage points
Average turns to resolution	-5%
Session abandonment rate	-2.1 percentage points

Table 11: Serving-period changes for the targeted candidate relative to Control. Negative latency, turns-to-resolution, and abandonment changes are improvements.

N Infrastructure for GPT-OSS Reinforcement Learning

The advertiser environment is built on a Megatron-backed (Shoeybi et al., 2019) SLIME (Zhu et al., 2025) stack with a disaggregated SGLang (Zheng et al., 2024) rollout engine. We extend this stack to support multi-turn beta-API rollouts, skill-aware reward shaping, heavy-tailed token lengths, and GPT-OSS-120B MoE synchronization. We describe framework-level changes; proprietary reward functions, datasets, and product-specific tool implementations are not disclosed.

Disaggregated RL setup. Training and inference run on disjoint GPU pools: while Megatron performs the optimizer step for batch k, SGLang generates rollouts for batch $k{+}1$ and reward workers score batch $k{-}1$. This asynchronous design hides rollout latency behind training compute. The training policy and rollout engine use different parallel decompositions and weight layouts, so each policy update requires explicit Megatron$\rightarrow$SGLang synchronization.

SLIME: custom rollout generator and reward hub. SLIME dispatches inference to SGLang through a load-balancing router, computes rewards in a separate `RewardHub` actor, and returns batches to Megatron. We replace the default single-turn completion with a multi-turn `generate_rollout` loop implementing model action $\rightarrow$ tool dispatch $\rightarrow$ environment observation $\rightarrow$ next state. The generator dispatches structured JSON tool calls, parses outputs, appends observations, and masks tool-output tokens from the loss. The reward hub is extended for the multi-juror ensemble and skill-aware rubric routing.

MoE weight synchronization for disaggregated rollout. GPT-OSS uses fused, interleaved gate/up projections for experts, whereas Megatron emits unfused per-expert tensors. During synchronization, these tensors are repacked into the fused `w13/w2` layout served by SGLang. We add an expert-parallel-aware load path that materializes only local experts and restores the SwiGLU gate/up ordering. Under tensor parallelism, the all-gather that reconstructs the GLU layout must be applied consistently to weights and biases; extending the same re-chunking transformation to biases makes Megatron$\rightarrow$SGLang transfer bit-correct.

Context parallelism for learnable-softmax attention. GPT-OSS combines learnable-softmax attention with interleaved full-attention and sliding-window layers. We add context-parallel support through a custom attention module. Full-attention layers use zigzag ring attention over sharded $q/k/v$ tensors; the learnable-softmax scale is threaded through forward and backward. Sliding-window layers instead all-gather $Q/K/V$, run local flash attention with the window mask, and re-slice outputs, because the global zigzag permutation breaks locality.

Heavy-tail handling and reward routing. We bucket rollouts by total context length and dynamically resize each batch to a fixed token budget, keeping memory approximately stable without truncating long trajectories or heavily padding short ones. Skill metadata travels with each rollout through generation and reward scoring so the reward hub can activate the appropriate rubric dimensions. Together, asynchronous rollout, MoE synchronization, context-parallel attention support, and token-budget batching make multi-node long-context GRPO feasible for GPT-OSS-120B.

SEGRA: A Structured Experience Guided Reasoning Agent for Property Graph Question Answering

Abstract

Enterprise IT support knowledge graphs capture rich relationships among cases, users, devices, symptoms, taxonomic categories, root causes, and historical resolutions. Yet querying them in Gremlin requires knowledge of graph schemas, traversal semantics, edge directionality, and property-graph-specific constraints, making them difficult for non-expert operators to use. We introduce SEGRA, an experience-guided agent for enterprise text-to-Gremlin question answering. SEGRA integrates intent routing, schema- and taxonomy-grounded query generation, multi-shot decomposition, execution-aware verification, and a curriculum-bootstrapped skill library that reuses verified query patterns. On an enterprise IT support benchmark, SEGRA achieves a 7.0× higher mean judge score than backbone-only chain-of-thought prompting. Its skill library further reduces LLM calls by 20% and dollar cost by 18% relative to SEGRA without skills, while preserving answer quality. These results show that schema-grounded agent design and reusable execution experience improve both accuracy and efficiency for enterprise graph QA.

1 Introduction

Graph databases are widely used to model connected data in applications such as fraud detection, knowledge management, recommendation, and enterprise analytics (Guo et al., 2020; Huang et al., 2022; Besta et al., 2023). Unlike relational databases, they represent information as vertices and edges, allowing connected entities to be traversed directly rather than reconstructed through joins (Rodriguez, 2015; Francis et al., 2018). This structure is well suited to enterprise IT support, where cases are linked to users, devices, symptoms, root causes, resolutions, timestamps, and related historical incidents. However, querying such graphs requires fluency in graph query languages, schema labels, edge directionality, and label-versus-property semantics (Angles et al., 2017), creating a barrier for non-expert operators, who must rely on a few specialists to query the graph at production volume.

Large language models offer a natural way to bridge this gap by translating user questions into executable database queries. Text-to-SQL has been extensively studied for relational databases, with mature benchmarks and methods for mapping natural language to SQL (Pourreza and Rafiei, 2023; Chen et al., 2024; Wang et al., 2025). In contrast, text-to-graph-query generation remains less developed. Graph databases introduce challenges beyond SQL, including traversal semantics, schema-specific vertex and edge labels, and label-versus-property distinctions. While Cypher generation has received recent attention (Ozsoy et al., 2025; Lyu et al., 2026), Gremlin generation remains relatively understudied in the academic literature.

Enterprise IT support graphs introduce more challenges beyond standard text-to-database settings. Diagnostic questions often require intermediate operations such as comparisons, set differences, or top-N aggregation, making single-step Gremlin generation brittle. The model must also align user phrasing with a domain taxonomy of symptoms, causes, categories, and resolutions, rather than guessing schema labels from surface text. In addition, derived similarity edges encode domain-specific relationships whose traversal patterns are easy to misuse without explicit guidance. These challenges make enterprise IT support a demanding testbed for natural-language-to-Gremlin systems.

We propose **SEGRA**, a **S**tructured **E**xperience **G**uided **R**easoning **A**gent for question answering over enterprise property graphs, as illustrated in Figure 1. SEGRA grounds generation in the graph schema and taxonomy, supports similarity queries through dedicated traversal patterns, and decom-

October 24-29, 2026 ©2026 Association for Computational Linguistics

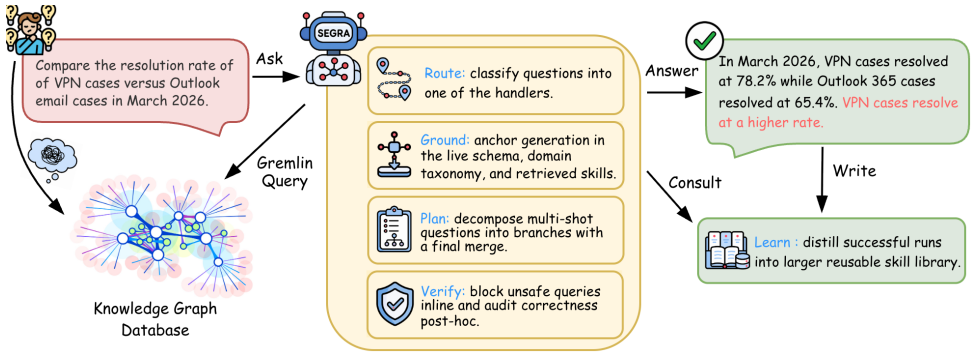

Figure 1: Overview of SEGRA framework. SEGRA takes natural-language questions as input and produces Gremlin queries to further generate natural-language answers.

poses complex questions into verified sub-queries. Because public text-to-Gremlin benchmarks remain limited, SEGRA is designed to accumulate experience from successful executions: verifier-passing executions are distilled into reusable skills that capture effective query patterns and reasoning strategies. These skills guide future queries and further reduce LLM calls and inference cost.

SEGRA is a system-level framework that unifies intent routing, schema-grounded generation, similarity handling, multi-shot planning, execution-aware verification, and cross-query skill accumulation. To the best of our knowledge, it is the first text-to-Gremlin agent to pair reusable execution experience with property-graph-specific correctness checks. Although evaluated on enterprise IT support, the design applies to property-graph interfaces requiring domain grounding, derived relations, and multi-step query composition.

2 Related Work

Natural-language querying of structured data. Text-to-SQL has been extensively studied for relational databases (Yu et al., 2018; Li et al., 2023), while text-to-graph-query generation has received recent attention primarily for Cypher (Ozsoy et al., 2025; Lyu et al., 2026), leaving Gremlin relatively underexplored. KGQA systems combine retrieval and reasoning over entity-relation graphs (Sun et al., 2024; Luo et al., 2024) but target answer retrieval rather than executable queries. SEGRA addresses the less-studied setting of generating executable Gremlin over enterprise property graphs, whose schemas combine domain taxonomies, temporal constraints, and derived similarity edges, and whose queries require traversal operators, edge directionality, aggregation, and execution constraints.

Experience-guided LLM agents. Recent LLM agents improve without weight updates by accumulating reusable experience: Voyager (Wang et al., 2023) stores successful action programs in a skill library, AFlow (Zhang et al., 2025b) searches over workflows of LLM operators, and related systems explore persistent memory and reflection (Shinn et al., 2023; Zhang et al., 2025a). The absence of public Text-to-Gremlin training data makes this direction a natural fit for enterprise property-graph QA: SEGRA reuses execution experience by representing complex questions as workflow DAGs, verifying candidates with deterministic constraints, and distilling verifier-passing runs into reusable skills indexed by question template.

IT support question answering. LLM-based IT support work spans diagnostic dialogue (Kapoor et al., 2026; Ahuja et al., 2026), cloud-incident root-cause analysis (Ahmed et al., 2023; Roy et al., 2024; Chen et al., 2025), and natural-language-to-Gremlin generation (Yun et al., 2025). The closest, EICopilot (Yun et al., 2025), generates a single Gremlin script per question for entity-centric summarization using a static example bank. SEGRA instead targets analytical questions over a historical support graph – aggregations, comparisons, top-N, set differences, and similarity traversal – motivating two design choices: multi-shot decomposition with a final merge, since single-shot generation breaks on compositional questions; and an experience-guided skill library that grows online from verifier-passing runs.

3 Method

We denote the enterprise property graph by G and its live schema by Σ (vertex labels, edge labels, per-label property keys), discovered once at startup. Let $\mathcal{T}$ denote the domain taxonomy of case categories.

As shown in Figure 2, SEGRA processes a

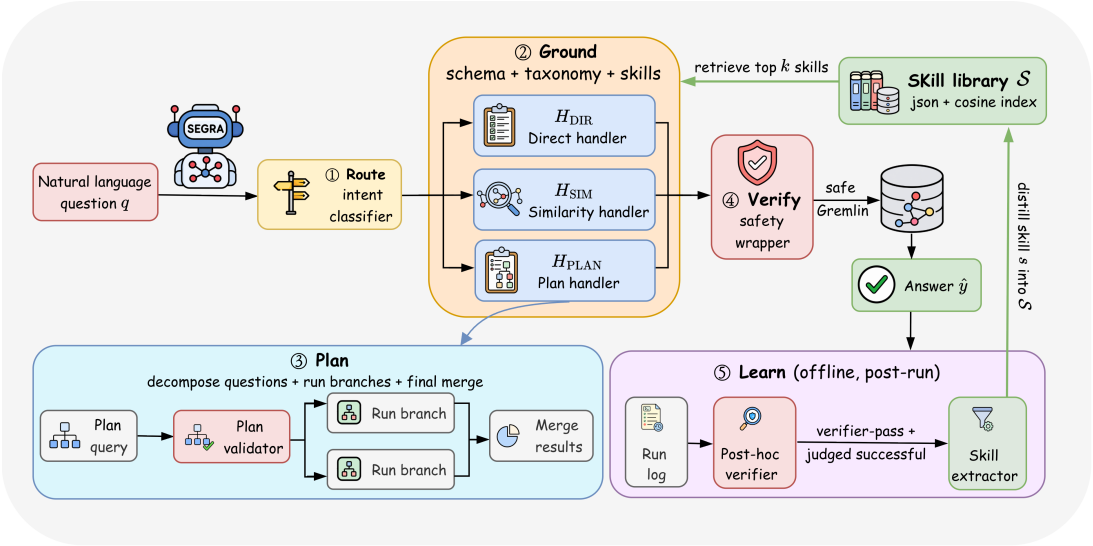

Figure 2: Pipeline of SEGRA framework: route to a handler, ground in the live schema and taxonomy with retrieved skills, optionally plan and execute branches, verify, and distill verifier-passing runs into the skill library that guides future questions.

natural-language question q in five stages. ① **Route.** An intent classifier assigns q a route label $\rho \in \mathcal{R} = \{\text{DIR}, \text{SIM}, \text{PLAN}\}$, each corresponding to a handler. ② **Ground.** SEGRA grounds generation in Σ and $\mathcal{T}$ via schema discovery, taxonomy lookup, and vertex sampling, replacing model guesses with values from the live graph. The chosen handler also retrieves the top k skills from $\mathcal{S}$ by cosine similarity to q, conditioning generation on past runs. ③ **Plan.** When $\rho = \text{PLAN}$, q is decomposed into a plan $\mathcal{P}$ of parallel and sequential branches with a final merge step. ④ **Verify.** A runtime safety wrapper blocks unsafe Gremlin, an inline plan validator checks $\mathcal{P}$, and a post-hoc property verifier audits captured queries against four similarity-edge invariants. ⑤ **Learn.** Every verifier-passing run is distilled into a skill, regardless of route. The library grows monotonically as evaluation proceeds, so SEGRA conditions later questions on a richer experience archive. The full procedure is formalized in Appendix B.

3.1 Direct and Similarity Handlers

The Direct (H_{DIR}) and Similarity (H_{SIM}) handlers both answer questions in a single LLM tool-use loop that emits one Gremlin query against G. They differ in what the question targets: H_{DIR} filters and aggregates over case properties and the taxonomy (e.g., *"how many VPN cases were resolved last quarter?"*), while H_{SIM} traverses derived similarity edges between cases to retrieve solved history (e.g., *"what resolutions worked for cases similar to V123?"*). Both ground generation in Σ and $\mathcal{T}$, since the model has no view of the live graph and would otherwise have to guess vertex labels and taxonomy values from training-time knowledge. Both also retrieve relevant skills from $\mathcal{S}$ before generation (§3.4), giving the model in-context Gremlin patterns that succeeded on similar past questions.

Direct (H_{DIR}). This handler runs an LLM tool-use loop with five tools. SCHEMA-DISCOVERY retrieves Σ from the live graph G and injects it into the system prompt. TAXONOMY-LOOKUP resolves user phrasing to values in the hierarchical taxonomy $\mathcal{T}$, returning matching entries ranked into *strong* matches (the topic appears as a token in the entry name) and *weak* matches (the topic only appears in the description); strong matches are used directly in `P.within(...)` filters, while weak matches are surfaced with explicit instructions to include them only when the description confirms relevance. VERTEX-SAMPLING returns up to three real vertices of a given label with their property values, enabling the model to verify property formats before composing filters. TEXT-SEARCH runs `TextP.containing(topic)` against the free-text `content` property of `reason`, `symptoms`, and `rootCause` vertices and reports per-label case counts plus three sample texts, recovering questions whose topics lack taxonomy entries. EXECUTE-GREMLIN forwards the LLM-emitted Gremlin to the runtime safety wrapper (§3.3) and then to G, returning results back into the loop.

Similarity (H_{SIM}). This handler runs the base loop

with three additional tools that cover two execution patterns: an *anchored walk* from a referenced case, and a *free-text seeded walk* when no case is referenced. The intent router selects the pattern by checking q for a case-ID, so the handler dispatches to the right tools without runtime disambiguation.

The anchored walk handles questions like *"what is similar to case V123?"*. RESOLVE-CASE verifies the referenced case exists and reports which of its content links (to reason, symptoms, root cause) are populated, so the model picks a feasible similarity edge. SIMILAR-CASES then executes the canonical bidirectional walk (*case* → *entity* → `bothE(similar*)` → *entity* → *case*) with a score threshold, avoiding the asymmetric-traversal failure mode where directional `outE` drops a substantial fraction of peers.

The free-text seeded walk handles questions like *"find cases like a VPN authentication failure"*. VECTOR-SEARCH-CASES retrieves cases by free-text similarity in embedding space, providing seeds that the model can optionally chain into SIMILAR-CASES to expand. The post-hoc property verifier (§3.3) audits captured similarity queries from both patterns offline.

3.2 Plan: Multi-shot Decomposition

The Plan handler H_{PLAN} targets questions that no single Gremlin query can answer, such as comparisons (*"compare resolution rate of VPN vs. Outlook"*), set differences, and top-N-then-aggregate queries. It decomposes the question into a structured plan $\mathcal{P}$ of dependent branches, dispatches each branch through the router, and merges branch outputs into a final answer.

Operators. H_{PLAN} exposes three tools to the LLM. PLAN-QUERY produces $\mathcal{P}$, specifying branches with their dependencies, sub-question texts, target handlers $\rho_b \in \mathcal{R} \setminus \{\text{PLAN}\}$, and a merge strategy; the plan is validated inline (§3.3) before execution. RUN-BRANCH dispatches each branch recursively through the router into H_{ρ_b}; independent branches run in parallel. MERGE-RESULTS combines branch outputs to produce the final answer without further graph traversal.

Use of retrieved skills. Like the Direct and Similarity handlers, H_{PLAN} retrieves skills from $\mathcal{S}$ at the Ground stage, but uses them more heavily: retrieved skills surface past plan structures and per-branch Gremlin templates that the planner adapts to the new question. Multi-shot questions benefit most from this guidance, since past worked examples constrain a much larger decision space — where to split the question, what merge strategy applies, and how each branch should be phrased — than single-query routes face.

3.3 Verify: Correctness Mechanisms

SEGRA enforces correctness through three mechanisms at different stages of the pipeline: a runtime sanitiser and a plan validator guard execution inline, while a post-hoc property verifier audits captured queries offline and gates skill extraction.

Runtime safety wrapper. Every Gremlin query emitted by EXECUTE-GREMLIN passes through a sanitiser before reaching G. It strips markdown fences, blocks mutations, rejects full-graph scans, and auto-injects `.limit(`N`)` on non-aggregating queries. We extend the blocklist with bare similarity-edge scans (e.g., `g.E().hasLabel('similarReason')`), which are unsafe on graphs with millions of edges per similarity label. Violations return to the tool-use loop as structured errors for correction.

Inline plan validator. Plans from PLAN-QUERY are validated before execution: each branch must declare a route hint $\rho_b \in \mathcal{R} \setminus \{\text{PLAN}\}$, the merge strategy must come from a fixed vocabulary, the dependency graph must be acyclic, and recursion through RUN-BRANCH is bounded. Invalid plans are rejected, preventing malformed decompositions from reaching G.

Post-hoc property verifier. A regex-based offline checker audits four similarity-edge correctness properties on the captured Gremlin history (full definitions in Appendix C). The verifier walks every captured query regardless of which handler produced it. A run that passes all properties counts as *verifier-pass*, which gates skill extraction (§3.4).

3.4 Learn: Skill Library

The skill library $\mathcal{S}$ persists experience across runs with an in-memory cosine-similarity index over question embeddings. All three handlers (H_{DIR}, H_{SIM}, H_{PLAN}) consult $\mathcal{S}$ during the Ground stage and contribute to it after a verifier-passing run.

Skill schema. A skill records the question template, the route that answered it, and the captured Gremlin templates with entity-specific tokens abstracted; multi-shot skills additionally record the plan structure and merge strategy.

Retrieval. For each question, the library returns the top k skills by cosine similarity to the question embedding. H_{DIR} and H_{SIM} see worked Gremlin

templates as in-context examples; H_{PLAN} additionally sees plan structures it can adapt.

Online accumulation. On the shuffled evaluation set, SEGRA processes questions sequentially: each handler retrieves from $\mathcal{S}$, generates, and writes back a new skill when its run is verifier-pass and judged successful. Each question therefore retrieves from a strictly larger library, accumulating experience across the evaluation sequence rather than across separate training and test phases. We isolate this effect with a baseline that runs the same questions in the same order with $\mathcal{S}$ disabled (§5).

4 Experimental Setup

We evaluate SEGRA on an enterprise IT support QA graph using a benchmark of 156 natural-language questions that mirror the analytical and diagnostic queries operators issue in production. The questions are constructed by the authors from recurring enterprise IT support information needs, spanning direct lookup, taxonomy-based aggregation, similarity-driven retrieval, and multi-step diagnostic analysis. Our primary deployment-oriented backbone is a commercially hosted instruction-following LLM in the `Medium` tier, selected to reflect a strong cost–quality tradeoff for practical deployment. To assess whether SEGRA's gains depend on backbone capability, we also evaluate `Small` and `Large` tier backbones under the same protocol. We anonymize the backbone identities to keep the evaluation focused on the SEGRA framework rather than on benchmarking or ranking specific commercial models.[1] Full details of the graph database and question set are in Section D.

4.1 Systems Comparison

We compare three systems that together stage the contribution of SEGRA into a backbone-only baseline, the architecture without skill memory, and the architecture with skill memory. All three share the same generator LLM, graph access, evaluation order, and validation protocol, and differ only in which mechanisms they expose. ① **CoT.** A single LLM call asked to emit a Gremlin query with chain-of-thought reasoning. No live schema, no tools, no skill library. Establishes the floor: how well a generic LLM can guess at an unseen schema. ② **Few-shot prompting CoT.** A single LLM call with the live schema Σ in the prompt and five worked (question, Gremlin) examples, but no tools, no execution feedback, and no skill library. Tests whether richer prompting alone, without an agent loop, can close the gap to SEGRA. ③ **SEGRA w/o skills.** Full SEGRA architecture (router, planner, handlers, tool surface, post-hoc verifier) with the skill library $\mathcal{S}$ disabled: retrieval returns the empty set, and runs do not write skills back. Every question is dispatched through the same handler graph as SEGRA w/ skills, so this isolates the contribution of $\mathcal{S}$ from the contribution of the architecture itself. ④ **SEGRA w/ skills.** The complete system. The router classifies intent, retrieved skills condition both the planner outer loop and every dispatched handler sub-loop, and verified runs write skills back into $\mathcal{S}$ via Alg. 3. Matches §3 and is the headline system in §5.

4.2 Evaluation Metrics

LLM-as-judge. A judge LLM scores each run on five orthogonal dimensions – *intent fidelity*, *execution validity*, *grounding*, *completeness*, and *usefulness* – each on a 0–4 scale, with the aggregate `overall_score` taken as the floor of the mean. The judge sees the question, the generated Gremlin, the executed result, and the answer, but not which system produced the run. We use OpenAI GPT-5.4 with medium reasoning as the automatic judge. Since the generator backbones (§4) come from a different model provider, this choice avoids the risk of self-preference in evaluation. Full per-dimension definitions and score anchors are in Appendix D.

Cost and efficiency. For each run we log the tool-use *turns* taken by the generator (one turn per LLM call, planner outer loop plus all sub-loops) and the *token totals*: input tokens, output tokens, cache-read input tokens, and cache-creation input tokens. We report mean tokens and mean turns per question for each system, broken down by reasoning shape, so the cost of routing, decomposition, and skill retrieval can be read alongside their accuracy contribution. Multi-shot questions accumulate tokens and turns across the planner outer loop and every branch sub-run; we report the per-question total to keep comparisons end-to-end.

5 Results

This section compares SEGRA with the baselines in §4.1. We report results across `Small`, `Medium`, `Large` generator backbones to test robust-

[1] The underlying commercial backbone identities are omitted due to business confidentiality constraints. The tier assignments are fixed across all experiments, and all systems are evaluated under the same protocol.

ness across model tiers.

5.1 Main Results

Table 1 reports mean judge score, mean LLM calls, and mean dollar cost per question. SEGRA changes the performance regime: backbone-only CoT performs poorly on all model tiers, and adding the schema with five worked examples (Few-shot CoT) raises score by 0.16–0.29 points but is still far short of the SEGRA architecture. Even `Large` with Few-shot CoT scores 0.47, below `Small` running SEGRA without skills (1.48). This shows that neither model scale nor richer prompting alone solves enterprise text-to-Gremlin QA; the system needs schema-grounded planning, tool use, execution feedback, and verification.

The agent architecture accounts for the largest quality gain. Moving from Few-shot CoT to SEGRA without skills improves mean score by +1.07 on `Small`, +1.44 on `Medium`, and +1.56 on `Large`. On our primary `Medium` backbone, SEGRA without skills lifts the score from 0.50 to 1.94, bringing the system close to the judge pass threshold. With skills enabled, `Medium` reaches 2.03, crossing the threshold while reducing the average number of LLM calls from 11.3 to 9.0. Few-shot CoT's failure mode is concentrated on multi-shot questions: with no opportunity to decompose, retry, or self-correct. SEGRA's planner and handler loops convert these into branch-and-merge plans with per-branch execution feedback, which is what the architecture lift in the table reflects.

The skill library mainly improves efficiency rather than replacing the architecture. Across all three backbones, adding $\mathcal{S}$ preserves or slightly improves quality while reducing both calls and cost: calls drop by 21% on `Small`, 20% on `Medium`, and 26% on `Large`, with corresponding cost reductions of 19%, 18%, and 28%. Thus, SEGRA's two components play complementary roles: **the agent architecture provides the quality lift, and the skill library recovers a substantial fraction of the tool-use overhead by reusing verified query patterns.**

5.2 Model-Tier Trade-offs

Figure 3 compares quality against runtime cost and LLM calls across model tiers. SEGRA improves the quality–cost trade-off substantially: `Medium` with SEGRA and skills reaches the same mean score as `Large` with SEGRA without skills (2.03), while costing roughly 1/6 as much. It is also within 0.03 points of the best-scoring configuration, `Large` with skills, at less than 1/4 of the cost. These results show that system design can partially substitute for model scale. The SEGRA architecture provides the main quality gain, while the skill library improves efficiency by reducing calls and cost without degrading quality. In practical terms, SEGRA makes a mid-tier backbone competitive with a substantially larger model, and skills improve the efficiency of every backbone.

	Small			Medium			Large		
System	Score	Calls	$/q	Score	Calls	$/q	Score	Calls	$/q
CoT	0.12	1.0	0.003	0.29	1.0	0.008	0.31	1.0	0.042
Few-shot CoT	0.41	1.0	0.006	0.50	1.0	0.018	0.47	1.0	0.111
SEGRA w/o $\mathcal{S}$	1.48	12.9	0.118	1.94	11.3	0.307	2.03	8.8	1.498
SEGRA w/ $\mathcal{S}$	**1.67**	**10.2**	**0.095**	**2.03**	**9.0**	**0.253**	**2.06**	**6.5**	**1.074**

Table 1: Mean judge score, mean LLM calls per question, and mean cost per question by system and backbone. SEGRA improves quality substantially, and the skill library further reduces cost/calls.

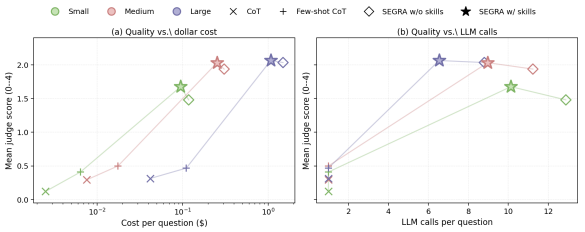

Figure 3: Quality–cost and quality–calls trade-offs. SEGRA architecture lifts every backbone to better score and lower cost and fewer calls.

5.3 Human Evaluation

We manually evaluate SEGRA w/ $\mathcal{S}$ with the `Medium` backbone on all 156 benchmark questions. Two annotators independently score each output using the same 0–4 rubric as the LLM judge. Results are reported by handler: direct querying (H_{DIR}, $n = 36$), similarity traversal (H_{SIM}, $n = 20$), and planner-based multi-shot reasoning (H_{PLAN}, $n = 100$). Annotators see the question, generated Gremlin, execution result, and final answer, but not the judge score; LLM-generated Gremlin explanations are used only as annotation aids. Detailed inter-annotator results are included in Section E.1.

Figure 4 shows that both annotators rate SEGRA higher than the automatic judge across all handlers. Averaged human scores exceed judge scores by 0.96 on H_{DIR}, 1.62 on H_{SIM}, and 0.92 on H_{PLAN}. The disagreement is one-sided: among the 35 questions where the averaged human score differs from the judge by at least two points, the judge is lower in every case. H_{DIR} is the strongest handler, with over 80% of direct-query outputs rated perfect by

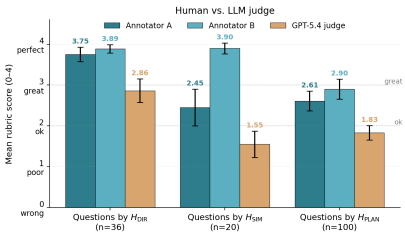

Figure 4: Human and LLM judge mean scores for SEGRA w/ $\mathcal{S}$, stratified by handler. Error bars show 95% confidence intervals.

both annotators and no poor or wrong cases. Overall, the judge provides a conservative scalable metric, especially for similarity and planner outputs; we therefore interpret judge scores as lower-bound estimates of absolute quality and complement them with a strict count-accuracy analysis in Section A.

6 Conclusion

We presented SEGRA, an experience-guided framework for Gremlin-based question answering over enterprise IT support graphs. SEGRA combines schema- and taxonomy-grounded query generation, similarity-aware traversal handling, planner-based decomposition, execution-aware verification, and a skill library that reuses verified query patterns across questions. Experiments show that SEGRA substantially improves over backbone-only chain-of-thought prompting, while the skill library reduces LLM calls and cost without degrading answer quality. Human evaluation further suggests that automatic judge scores are conservative, especially for planner-based multi-step outputs. Overall, SEGRA shows that structured agent design and reusable execution experience can make natural-language interfaces to property graphs more accurate, efficient, and deployable. The agent design (intent routing, multi-shot decomposition and merge, execution-aware verification, and cross-query skill reuse) is independent of Gremlin and of IT support. The same design therefore transfers to other graph query languages such as Cypher and to other property-graph domains.

Limitations

SEGRA is evaluated on a single enterprise IT support graph, so broader application on other property graphs remains to be validated. The system also assumes access to schema tools, execution feedback, and verifier rules. In longer deployments, the skill library may require maintenance under schema drift. Finally, human evaluation covers only the primary configuration and we use the automatic judge for the full system-by-backbone comparison, leaving broader human evaluation for future work.

A Strict Count-Accuracy Evaluation

To further study answer quality under deterministic ground truth, we construct a scalar-count analytic subset from the 156-question evaluation benchmark. We include only questions whose gold solution can be represented as a single Gremlin query returning a scalar count. For each included question, a human annotator manually writes the gold Gremlin query, executes it on the graph, and uses the returned count as the reference answer. This filtering excludes display-style questions, list-valued answers, schema-introspection questions, free-form explanations, and multi-shot questions whose gold solution requires decomposition. The resulting subset contains $n = 60$ questions. It is not randomly sampled; it is the eligible subset

for which human-written query ground truth and scalar-count comparison are well defined.

For each question q_i, let g_i be the human-written gold Gremlin query and let $\widehat{g}_i$ be the query produced by SEGRA. We report two diagnostics. **Query match** measures whether the generated query has the same structure as the human-written gold query after a normalizer $C(\cdot)$ removes known meaning-preserving differences, such as formatting, equivalent interval predicates, symbolic time-window literals, contact–case anchoring variants, and result-preserving deduplication. For example, a generated query using `P.between(a,b)` and a gold query using `P.gte(a).and(P.lt(b))` are treated as matching if the two traversals are otherwise identical. Similarly, harmless differences in whitespace, quote style, or redundant label checks after a fixed vertex anchor are ignored. The metric is exact equality after normalization:

$$\mathrm{Acc}_{\mathrm{query}} = \frac{1}{n}\sum_{i=1}^{n} \mathbb{1}\{C(\hat{g}_i) = C(g_i)\}.$$

Execution match measures whether the generated query returns the same scalar count as the human-written gold query. Let $y_i = \mathrm{Exec}(g_i)$ and $\widehat{y}_i = \mathrm{Exec}(\widehat{g}_i)$. We count an execution as correct when

$$\mathrm{Acc}_{\mathrm{exec}} = \frac{1}{n}\sum_{i=1}^{n} \mathbb{1}\Big\{\frac{|\hat{y}_i - y_i|}{\max(|y_i|, 1)} \le 0.02\Big\}.$$

We report the average query-match and execution-match accuracy over the 60-question subset. Query match evaluates agreement with the manually written Gremlin structure; execution match evaluates agreement with the human-established scalar answer.

Results. Table 2 reports both metrics for SEGRA w/ $\mathcal{S}$ across the three backbones. `Medium` achieves the highest execution match (54%), while `Large` achieves the highest query match (48%). This shows that structural agreement and answer agreement are related but not identical: a model may generate a different traversal while still computing the correct count.

This subset analysis complements the judge-based and human evaluations by isolating cases where exact scalar-count comparison against human-written Gremlin ground truth is possible. We treat these metrics as diagnostics rather than headline quality measures because they do not capture partial correctness, alternative valid decompositions, or all semantically equivalent Gremlin formulations.

Backbone	$\mathrm{Acc}_{\mathrm{query}}$	$\mathrm{Acc}_{\mathrm{exec}}$
`Small`	35%	41%
`Medium`	40%	**54%**
`Large`	**48%**	44%

Table 2: Query match and execution match on the $n = 60$ scalar-count analytic subset for SEGRA w/ $\mathcal{S}$.

We also reflect the results in Table 2 that the absolute correctness is relatively limited compared to stronger judge and human ratings. We identify three main sources of disagreement: (1) Taxonomy ambiguity. The enterprise taxonomy is large, noisy, and hierarchical. A term in a question may plausibly refer to an issue category, subcategory, issue detail, device attribute, or textual mention. Queries based on different reasonable taxonomy interpretations can preserve the user's high-level intent but select different populations and return different counts. (2) Temporal and graph-snapshot mismatch. The enterprise graph grows continuously. To make evaluation reproducible, SEGRA is instructed to constrain queries to a fixed time window. Some reference queries omit this window, apply it at a different point in the traversal, or contain answers generated from an earlier graph state. Questions whose temporal scope overlaps or falls outside the fixed window can consequently produce semantically reasonable but numerically different answers. (3) Genuine query-generation errors. Some generated queries omit required taxonomy, text, status, or temporal constraints; traverse the wrong edge or direction; or use incorrect counting, grouping, or deduplication semantics. These are genuine failures rather than alternative interpretations. Thus, the gap should not be interpreted solely as a contradiction between the judge and execution evaluation. The judge assesses whether an answer is semantically appropriate and grounded in its executed result, whereas execution correctness tests agreement with one reference interpretation within a numerical tolerance.

B Full Algorithm

This appendix gives the complete SEGRA evaluation procedure, factored into three algorithms: the outer question-stream loop (Alg. 1), the multi-shot decomposition that runs when the router selects the plan handler (Alg. 2), and the post-run skill update that gates the library on the verifier (Alg. 3). All

three operate on the live property graph G with schema Σ, the domain taxonomy $\mathcal{T}$, the routing function R, and the persistent skill library $\mathcal{S}$.

Outer loop (Alg. 1). Questions arrive one at a time in a fixed shuffled order, mirroring how an analyst would issue them in production. For each question q, SEGRA routes via R, retrieves the top k skills from $\mathcal{S}$ by cosine similarity to q, and dispatches to the appropriate handler. Direct and Similarity questions run in a single tool-use loop (H_ρ); plan questions invoke Alg. 2. After the run, UPDATELIBRARY inspects the captured run record and writes a skill back to $\mathcal{S}$ if the verifier accepts it. Each subsequent question therefore retrieves from a strictly larger library; the no-memory baseline disables the write step and feeds the empty $\mathcal{S}_0$ to every question.

Multi-shot decomposition (Alg. 2). The plan handler first emits a plan tree $\mathcal{P}$ with branches, dependencies, target handlers, and a merge strategy, conditioned on the retrieved skills. The plan validator (§3.3) checks $\mathcal{P}$ before any branch executes; on failure, it returns the specific validation error (e.g., a duplicate branch id, an unknown route hint, a cycle in the dependency graph) to the planner LLM as the tool result. The LLM may correct the plan and re-invoke PLAN-QUERY on a subsequent turn, subject to the planner's overall turn budget (14 turns shared across plan, dispatch, and merge). Once a valid plan is accepted, the planner dispatches each branch in $\mathcal{P}$ back through the router into H_{ρ_b} with $\rho_b \neq$ PLAN, so a branch is itself a single-handler tool-use loop. In our implementation, branches are dispatched in topological order of their declared dependencies, with independent branches running in parallel. After all branches return, MERGE-RESULTS produces the final answer from branch outputs without further graph traversal. The captured Gremlin history of every branch is collected into the run record for the verifier.

Library update (Alg. 3). The post-hoc property verifier V_{prop} (Appendix C) runs over every captured Gremlin query in the run record and reports a verifier-pass flag. A skill is written to $\mathcal{S}$ only when the run is both verifier-pass and judged successful by the LLM judge with score ≥ 2, ensuring that low-quality or structurally invalid runs cannot pollute the library. The skill schema is the same regardless of route (question template, route label, abstracted Gremlin templates), with multi-shot skills additionally recording the plan structure and merge strategy.

Algorithm 1 SEGRA: question evaluation with skill accumulation.

Require: Question stream Q; initial library $\mathcal{S}_0$; router R; live schema Σ; taxonomy $\mathcal{T}$; retrieval budget k.

$\mathcal{S} \leftarrow \mathcal{S}_0$
for $q \in Q$ in fixed order **do**
  $\rho \leftarrow R(q)$
  ▷ intent classification: $\rho \in \{\text{DIR}, \text{SIM}, \text{PLAN}\}$
  $\mathcal{K}_q \leftarrow \text{RETRIEVE}(\mathcal{S}, q, k)$
  ▷ top-k skills by cosine similarity
  if $\rho =$ PLAN **then**
    ans, *record* $\leftarrow$ *Alg.* 2$(q, \Sigma, \mathcal{T}, \mathcal{K}_q)$
  else
    ans, *record* $\leftarrow H_\rho(q, \Sigma, \mathcal{T}, \mathcal{K}_q)$
  ▷ single-handler tool-use loop
  end if
  $\mathcal{S} \leftarrow$ *Alg.* 3$(\mathcal{S}, \textit{record})$
end for
return answers and final $\mathcal{S}$

Algorithm 2 PLAN-RUN-MERGE: multi-shot decomposition invoked from Alg. 1 when $\rho =$ PLAN.

Require: q, Σ, $\mathcal{T}$, retrieved skills $\mathcal{K}_q$.

$\mathcal{P} \leftarrow \text{PLAN-QUERY}(q, \Sigma, \mathcal{T}, \mathcal{K}_q)$
  ▷ plan tree with branches and merge m
if plan validator rejects $\mathcal{P}$ **then**
  return validation error as tool result
end if
for branch b in $\mathcal{P}$ **do**
  $r_b \leftarrow H_{\rho_b}(q_b, \Sigma, \mathcal{T}, \mathcal{K}_q)$
  ▷ recursive dispatch via R, $\rho_b \neq$ PLAN
end for
ans $\leftarrow \text{MERGE-RESULTS}(\{r_b\}_b, m)$
  ▷ LLM-only step, no graph traversal
return *ans*, run record (plan, branch outputs, Gremlin history)

C Post-Hoc Property Verifier

The verifier in §3.3 audits captured Gremlin queries against four similarity-edge correctness properties. This appendix gives the full definition of each property, the failure mode it prevents, and the regex pattern used to detect violations. Notation: $\mathcal{E}_{\text{sim}} = \{\texttt{similarReason}, \texttt{similarSymptoms}, \texttt{similarRootCause}\}$ is the set

Algorithm 3 UPDATELIBRARY: post-run skill extraction gated by the verifier and the judge.

Require: Library $\mathcal{S}$; run record from Alg. 1 (Gremlin history, plan, branch outputs, final answer).

```
pass ← V_prop(record.gremlin_history)
    ▷ Appendix C
score ← JUDGE(record)
    ▷ LLM judge, score ∈ {0, 1, 2, 3, 4}
if pass and score ≥ 2 then
    s ← EXTRACTSKILL(record)
    ▷ question template, route, abstracted Gremlin;
    plan + merge if ρ = PLAN
    S ← S ∪ {s}
end if
return S
```

of similarity edge labels, and the within-case pairing Φ maps each similarity edge to the within-case edge that brackets it:

$$\Phi(\texttt{similarReason}) = \texttt{hasReason},$$
$$\Phi(\texttt{similarSymptoms}) = \texttt{exhibits},$$
$$\Phi(\texttt{similarRootCause}) = \texttt{attributedTo}.$$

The verifier walks the captured Gremlin history from each run; a run record is *verifier-pass* iff all four properties hold on every captured query. Properties P_1–P_4 are vacuously PASS on queries that contain no similarity edge step (e.g., Direct route queries that filter by property only).

P1: Window-on-Destination

Rationale. Our evaluation graph is a fixed snapshot of the production support graph with all cases tagged by a `createdAt` timestamp, and we restrict every evaluation query to a fixed experiment window $[\text{WIN_LO}, \text{WIN_HI}]$ so that ground-truth counts and aggregates are reproducible across runs. The verifier therefore audits where in a similarity walk the window predicate appears: P1 enforces the implementation choice that the window must scope the *peer* cases returned by the similarity walk, not just the anchor case the walk starts from.

Statement. Every query containing a similarity-edge step must apply the time-window predicate `P.between`$(\text{WIN_LO}, \text{WIN_HI})$ *after* the post-similarity `.in(`$\Phi(e)$`)` step that returns to a case vertex, not on the anchor.

Failure mode prevented. Applying the window filter on the anchor case (before the similarity hop) restricts the source case to the experiment window, but lets the walk return peers from *any* time period. Conversely, applying it on the destination case restricts the peer set itself, which is the intended scoping for similarity questions over the experiment window.

Detection. Pass iff (a) the query contains `P.between`$(\text{WIN_LO}, \text{WIN_HI})$ at least once, and (b) at least one `.in(`$\Phi(e)$`)` step is followed by the window predicate later in the query string. Queries that have no `.in(`$\Phi(e)$`)` step (e.g., walks that end at the entity vertex without returning to a case) are vacuously PASS.

P2: Threshold-on-Edge

Statement. For every similarity-edge step `bothE`(e), `outE`(e), or `inE`(e), with $e \in \mathcal{E}_{\text{sim}}$, the query must apply `.has('similarityScore', P.gte(`θ`))` between the edge step and the next vertex step `.otherV()`, `.inV()`, or `.outV()`.

Failure mode prevented. Without an explicit threshold, similarity walks return all peers regardless of similarity score, which dilutes the result set with low-similarity matches. Applying the threshold *after* the vertex step instead of on the edge filters the wrong object — vertices don't carry the similarity score; the edge does.

Detection. For each similarity-edge step, find the substring between it and the next vertex step. Pass iff every such substring contains `.has('similarityScore', P.gte(...))`. Edge steps with no following vertex step (malformed traversals) are vacuously PASS since they do not reach a peer.

P3: Entity-Bracket

Statement. Every similarity-edge step with edge $e \in \mathcal{E}_{\text{sim}}$ must be preceded by a within-case `.out(`$\Phi(e)$`)` step earlier in the query.

Failure mode prevented. Similarity edges connect content vertices (`reason`, `symptoms`, `rootCause`), not cases directly. Walking from a case to a similarity edge without first traversing the corresponding within-case edge is a structural error: the traversal has no source content vertex on which to attach the similarity step.

Detection. For each occurrence of a similarity edge with label e, scan the query string before the edge step and require that

`.out(`$\Phi(e)$`)` appears at least once. Note the pairing is per-label: `similarReason` requires `.out('hasReason')` specifically, not `.out('exhibits')` or `.out('attributedTo')`.

P4: Anchor-by-Id

Statement. Case anchors must be addressed by vertex id, either via `g.V('uuid')` or via `.hasId('uuid')`. The label-and-property form `g.V().has('case', 'id', 'uuid')` addresses an `id` property that does not exist on case vertices and is forbidden.

Failure mode prevented. Cases in the live graph do not carry an `id` property; their identity is the vertex id itself. Filtering on `.has('case', 'id', 'uuid')` matches zero vertices and silently returns an empty result, which the LLM may misinterpret as a real (negative) finding.

Detection. Reject any query containing the literal substring pattern `V().has('case', 'id', ...)`. Other anchoring forms (`g.V('uuid')`, `.hasId`) are not flagged.

Verifier Output

For each captured Gremlin query, the verifier emits a per-property record:[2]

```
{
  "P1_window_on_destination": {"pass": bool, "
    reason": str | null},
  "P2_threshold_on_edge":     {"pass": bool, "
    reason": str | null},
  "P3_entity_bracket":        {"pass": bool, "
    reason": str | null},
  "P4_anchor_by_tilde_id":    {"pass": bool, "
    reason": str | null}
}
```

A failing property surfaces a structured `reason` string identifying the offending substring or position. The run-level *verifier-pass* flag is the conjunction of all per-query per-property results across the captured Gremlin history.

D Detailed Experimental Setup

Graph Database. SEGRA queries an enterprise IT support property graph, backed by a managed graph database and accessed through Gremlin, at production scale. Each case vertex is connected to free-text content vertices $(v_{c_1}, v_{c_2}, v_{c_3})$ covering incident description, observed behavior, and diagnosed cause), resolution vertices, a multi-level hierarchical taxonomy of case categories, and context vertices capturing the parties involved and device/compliance state. Derived similarity-edge labels $\mathcal{E}_{\text{sim}} = \{e_1, e_2, e_3\}$ connect content vertices that share semantic content, each carrying a continuous similarity score used as a threshold for filtering peers (P2 in Appendix C). Every case carries a creation timestamp, used by the experiment-window predicate for reproducibility (P1). SEGRA only reads from the graph and never modifies it.

Dataset. The benchmark has 166 questions split between a 10-question bootstrap set (used to seed $\mathcal{S}$ before evaluation) and a 156-question evaluation set. The evaluation set is partitioned by reasoning shape:

- **36 single-shot** questions answered by H_{DIR} – filter-and-count, top-N ranking, and aggregate questions over case properties and the taxonomy.
- **20 similarity-anchored** questions answered by H_{SIM} – cross-case similarity questions over derived `similar*` edges, either anchored to a referenced case or seeded by free-text retrieval.
- **100 multi-shot** questions answered by H_{PLAN} – compositional questions that no single Gremlin query can answer.

The 100 multi-shot questions span 20 categories drawn from a failure-mode analysis of pilot runs. Categories include parallel comparisons (*"compare resolution rate of VPN vs. Outlook"*), top-N analytics with sub-aggregation, set differences across temporal windows, recurrence patterns over taxonomic categories, and similarity-driven aggregations. The category-level distribution drives the curriculum-bootstrap procedure described in §3.4. We also include examples from our dataset in Table 3 with the natural-language question, the Gremlin issued, and the final answer. The Direct example issues a single aggregation query; the Similarity example anchors on a case and walks the bidirectional similarity edge with score and time-window filters; the Multi-shot example is decomposed by the planner into two parallel branches whose results are combined by the merge step.

Judge Rubric. The LLM judge (§4.2) scores each run on five orthogonal dimensions, each on a 0–4 anchor scale, and reports a per-dimension rationale plus an aggregate. The anchor scale is shared across dimensions: **4** = great, fully meets

[2] The field name `P4_anchor_by_tilde_id` refers to Gremlin's `~id` notation for vertex IDs (the meta-id, distinct from a property named `id`); the leading tilde is dropped from the JSON key for compatibility.

Example for H_{DIR}

Question: How many cases were created in total?
Gremlin: `g.V().hasLabel('case').count()`
Answer: 123,456 cases were created in the experiment window.

Example for H_{SIM}

Question: How many in-window cases share similar symptoms with case `4f4ded41-...` above the production threshold?
Gremlin: `g.V('4f4ded41-...').hasLabel('case').out('exhibits').bothE('similarSymptoms').has('similarityScore', P.gte(0.675)).otherV().in('exhibits').hasLabel('case').hasId(P.neq('4f4ded41-...')).dedup().count()`
Answer: 4 in-window cases share similar symptoms at or above the production threshold (≥ 0.675).

Example for H_{PLAN}

Question: Which has more cases – Mac or Windows?
Plan: `parallel_compare`; two independent branches, merged with `compare_ratios`.
Gremlin 1: `g.V().hasLabel('case').where(out('hasTelemetry').has('devicePlatform', 'MAC')).count()` $\rightarrow$ 12,345.
Gremlin 2: `g.V().hasLabel('case').where(out('hasTelemetry').has('devicePlatform', 'WINDOWS')).count()` $\rightarrow$ 123,456.
Answer: Windows has more cases than Mac.

Table 3: Example questions and Gremlin queries for different handlers.

the dimension with no caveat worth flagging; **3** = good, solidly meets, at most a cosmetic nit; **2** = OK, mostly meets with a defensible minor gap; **1** = poor, significant gap that affects the answer's value; **0** = failed, does not meet the dimension at all. The aggregate `overall_score` is the *floor* of the mean of the five scores; rounding down rather than to nearest errs on the conservative side.

1. **Intent fidelity.** Does the executed Gremlin capture what the user actually asked? Looks at vertex labels, filter predicates (issue category/subcategory, time window, status), traversal direction, and whether the right entities are anchored. **4**: traversal precisely matches the question, all filters justified. **3**: matches with one inferred-but-reasonable filter. **2**: right shape but a non-decisive filter is missing or slightly off. **1**: wrong vertex type, wrong direction, or a filter inversion. **0**: traversal answers a fundamentally different question.

2. **Execution validity.** Did the query run cleanly and return data of the expected shape? **4**: ran first try, non-empty data of the expected shape. **3**: ran cleanly with a small retry/relaxation noted in the trace. **2**: ran but result is partial / had to be retried successfully. **1**: errored on first try and recovered with a degraded result, or returned data of the wrong shape that still answers the question. **0**: errored without recovery, returned empty when data was clearly expected, or the shape is unusable. An "honest empty" answer that explains why the data is missing earns at most 2.

3. **Grounding.** Is the natural-language answer faithful to what the query actually returned? This is the hallucination check, independent of whether the query was correct. **4**: every numeric, name, and claim is supported by the result. **3**: supported with a single rounding or wording inconsistency. **2**: one minor unsupported detail, headline still correct. **1**: a key claim is unsupported or contradicts the result. **0**: fabricates entities, counts, or relationships not in the data.

4. **Completeness.** Did the answer address every part of the question, including sub-asks ("compare X and Y", "list and explain", "rank by Z")? **4**: every sub-ask answered with explicit comparisons or explanations. **3**: every sub-ask answered, one is briefer than ideal. **2**: main ask answered, secondary sub-ask glossed. **1**: only one of multiple sub-asks addressed. **0**: answer is on a different topic or refuses without justification. For single-ask questions, the default is 4 unless something obvious is omitted.

5. **Usefulness.** Would an analyst actually use this answer to make a decision? Vague hedging is penalised, while honest fallbacks (e.g., "vector search unavailable, here is the text-search fallback") are rewarded because the analyst can act on them. **4**: directly actionable, no follow-up needed. **3**: actionable with a one-line caveat the answer surfaces. **2**: useful with a meaningful caveat. **1**: ambiguous; analyst would need to re-run the query. **0**: misleading, evasive, or surfaces no actionable signal.

A run is counted as pass when `overall_score` ≥ 2. The judge is instructed to reply with a single JSON object containing the five per-dimension records, the aggregate, and the booleans, with no preamble or code fences.

E Per-Dimension Breakdown

Table 4 reports the mean per-dimension GPT-5.4 judge scores that compose the aggregate

`overall_score` reported in §5, for each (system, backbone) cell over the 156-question evaluation set. The five dimensions follow the rubric defined in Appendix D: *Intent* = intent fidelity, *Exec* = execution validity, *Ground* = grounding, *Compl* = completeness, *Use* = usefulness. The aggregate `overall_score` reported in Table 1 is the floor of the per-question mean of these five dimensions, so the per-dimension means here will be slightly higher than the aggregate (mean before floor vs. floor before mean across questions).

The pattern across systems is consistent. CoT and Few-shot CoT score reasonably on *Intent* (the model usually understands what is being asked) but collapse on every other dimension because, with no tools, queries either fail outright or return a degenerate shape. Few-shot CoT lifts *Intent* above CoT by 0.4–0.6 points on every backbone – the worked examples teach traversal patterns – but *Execution* stays under 1.0, confirming that single-call prompting cannot recover from the schema-shaped errors that tool feedback would catch. The SEGRA architecture pulls *Execution*, *Grounding*, and *Completeness* into the 2–3 range, and adding the skill library lifts *Usefulness* (the most synthesis-heavy dimension) by a further 0.02–0.30 points.

E.1 Human-vs-Judge Agreement

The main paper's per-dimension breakdown reports GPT-5.4 judge scores. We additionally collected human annotations on the SEGRA-w/-skills + `Medium` cell to gauge how the automatic judge compares to expert evaluation. Two annotators independently scored all 156 questions on the same 0–4 anchor scale as the LLM judge, but assigned a single *overall* score per question rather than per-dimension scores – so this section is restricted to overall-score agreement and does not extend the per-dimension table above. Annotators saw the question, generated Gremlin, executed result, and final answer, but not the judge score.

Inter-annotator agreement. Before comparing humans against the judge, we measure how the two annotators agree with each other on the same 156 questions. Table 6 reports five complementary metrics, since the 0–4 scale is ordinal: exact agreement (both annotators picked the same integer), within-1-point agreement (they differed by at most one bucket), Cohen's quadratic-weighted κ (the standard ordinal-agreement statistic, where ≥ 0.6 is conventionally read as "substantial"), Spearman's ρ (rank correlation, robust to one annotator being uniformly harsher than the other), and mean absolute difference (concrete points-apart). Overall, the annotators agree exactly on 47.4% of questions and within one point on 81.4%, with a quadratic-weighted κ of 0.52 and a Spearman ρ of 0.47 – moderate agreement under standard interpretation, with the bulk of disagreements being one-bucket calls rather than wholesale reversals.

The handler-level breakdown reveals two distinct patterns. On H_{DIR}, both annotators rate nearly every output as great (A-mean 3.75, B-mean 3.89, within-1 94.4%); the κ of 0.13 is misleadingly low because the score distribution has almost no variance for κ to credit. On H_{PLAN}, agreement is moderate-to-substantial ($\kappa = 0.56$, $\rho = 0.50$, within-1 82%) – the largest sub-sample (n=100) and the most representative of overall agreement. On H_{SIM}, agreement is genuinely poor ($\kappa = 0.06$, exact 15%, MAD 1.45): Annotator A is systematically harsh on similarity outputs (mean 2.45) while Annotator B rates almost all 20 similarity outputs as great (mean 3.90).

F Additional Results

F.1 Question Streaming Order

To measure the sensitivity of question order during evaluation, we ran the 100 planner evaluation questions under five random orderings, each initialized with the same 10 bootstrapped skill library. And the results are illustrated in Table 7.

Across the five orderings, the mean score is 2.563 ± 0.064, the fraction of questions scoring at least 2 is 93.2% ± 2.9%, and the fraction scoring 3 is 63.2% ± 4.8%. The variation in mean score is approximately 2% of the full 0–3 scale, indicating limited sensitivity to question order. The learned skill libraries also converge closely. Starting from the same 10 bootstrap skills, each run promotes approximately 100 additional skills and ends with 108–110 skills. The mean pairwise Jaccard similarity is 0.989 when bootstrap skills are included and 0.988 when considering only skills added during evaluation. Overall, these results suggest that both answer quality and the resulting skill library are stable across the tested question orderings. Our current experiments target the intended streaming setting, in which verified experiences can be incorporated as new questions arrive.

System	Small					Medium					Large				
	Intent	Exec	Ground	Compl	Use	Intent	Exec	Ground	Compl	Use	Intent	Exec	Ground	Compl	Use
CoT	1.29	0.08	1.19	0.06	0.25	1.73	0.21	1.36	0.08	0.22	1.59	0.08	1.54	0.08	0.24
Few-shot CoT	**1.91**	0.64	0.94	0.42	0.32	**2.17**	0.88	1.12	0.36	0.22	**2.08**	0.99	1.05	0.36	0.22

SEGRA w/ $\mathcal{S}$	1.74	**2.71**	1.62	**2.97**	**1.25**	2.16	**3.11**	**2.15**	**3.15**	**1.75**	1.99	3.13	**2.20**	**3.41**	**1.76**

Table 4: Per-dimension mean GPT-5.4 judge scores (0–4) over the 156-question evaluation set, by system and backbone. Dimensions are defined in Appendix D. Bold marks the highest-scoring system per (backbone, dimension); SEGRA w/ $\mathcal{S}$ attains the highest score on a majority of cells, with the most consistent gains on *completeness* and *usefulness* (which reward end-to-end synthesis rather than just running a query). Note the contrast on *Intent*: Few-shot CoT slightly exceeds SEGRA on this dimension because both reach a ceiling from prompt-level grounding, but its low *Execution* drags the aggregate down.

System	Small					Medium					Large

Table 5: Seven-system ladder evaluated by three judge models across five dimensions. **I** = intent fidelity, **E** = execution validity, **G** = grounding, **C** = completeness, and **U** = usefulness.

Handler	n	Exact	≤ 1 pt	κ_q	ρ	MAD
H_{DIR}	36	80.6%	94.4%	0.13	0.25	0.25
H_{SIM}	20	15.0%	55.0%	0.06	0.35	1.45
H_{PLAN}	100	42.0%	82.0%	0.56	0.50	0.81
All	156	47.4%	81.4%	0.52	0.47	0.76

Table 6: Inter-annotator agreement on SEGRA w/ $\mathcal{S}$, `Medium` backbone. "Exact" is the percentage of questions on which both annotators picked the same integer score; "≤ 1 pt" allows a one-bucket disagreement. κ_q is Cohen's quadratic-weighted kappa, ρ is Spearman rank correlation, and MAD is the mean absolute difference between the two annotators' integer scores. The H_{DIR} κ_q is depressed by a ceiling effect (both annotators rate nearly all outputs ≥ 3).

Seed	Mean score (0–3)	≥ 2 rate	≥ 3 rate	Skills at end
0	2.674	96.7%	70.7%	108
1	2.552	91.7%	63.5%	110
2	2.544	95.6%	58.9%	109
3	2.534	89.8%	63.6%	110
4	2.511	92.0%	59.1%	110
Cross-seed	**2.563 ± 0.064**	**93.2% ± 2.9%**	**63.2% ± 4.8%**	**109.4 ± 0.9**

Table 7: Sensitivity of evaluation to question ordering across five random seeds.

F.2 More Baseline Comparison

We expand the evaluation to a seven-system ladder, including prompt-only, few-shot, ReAct-style, no-planner, no-skills, planner-only retrieval, and full SEGRA configurations. The results are illustrated in Table 5.

We observed that (1) adding the schema and examples primarily improves intent recognition, but not execution. Few-shot CoT obtains the highest intent score on each backbone but remains below 1.0 on execution because it cannot inspect the graph, execute queries, or recover from errors. (2) adding ReAct-style tool use produces the largest execution improvement over the prompting-only baselines. This confirms that live schema access and iterative execution feedback are critical for text-to-Gremlin generation. (3) explicit planning most consistently improves completeness: full SEGRA exceeds the no-planner variant by 0.59, 0.52, and 0.65 points on the small, medium, and large backbones, respectively. (4) On the largest backbone, ReAct and full SEGRA perform similarly on execution, while SEGRA achieves substantially higher completeness. This suggests that strong models can perform more implicit planning within a general tool loop, whereas explicit decomposition remains valuable for multi-part questions.

From Benchmarks to Real-World Use: Evaluating the Robustness of Vision-Language Models for Chart Understanding

Abstract

Recent advances in large Vision-Language Models (VLMs) have led to impressive performance on chart understanding tasks. However, existing evaluations are largely limited to clean, canonical charts and do not adequately measure robustness under realistic conditions. To address this gap, we introduce RobustChart360, a comprehensive benchmark for evaluating chart understanding robustness under realistic real-world variations. RobustChart360 spans six robustness dimensions covering textual and cross-modal interference, rendering and display degradation, accessibility-oriented transformations, and visual style variation. Using this benchmark, we conduct a large-scale evaluation of 14 proprietary and open-source VLMs across 2,505 chart instances and multiple robustness conditions designed to simulate practical deployment scenarios. Our analysis on 35,070 model responses reveals that current VLMs are highly sensitive to seemingly minor variations such as low-resolution rendering, and mobile layouts, with performance dropping by as much as 33.9% under certain conditions, such as modality gap. We further find that models often overrely on textual priors when visual and textual signals conflict, indicating weak visual grounding despite strong performance on standard benchmarks. Our findings highlight a substantial gap between benchmark accuracy and real-world robustness, motivating the development of more reliable and visually grounded multimodal systems for chart understanding. We will release our code and dataset at <redacted>.

1 Introduction

Natural language and data visualization are two complementary modalities for communicating insights effectively (Hoque et al., 2022). Visualizations enable users to identify trends, patterns, and anomalies, while natural language complements them by summarizing key findings, explaining relationships, and answering data-related queries. This synergy has inspired a growing body of research on chart comprehension and reasoning tasks, including chart question answering (Masry et al., 2022; Kantharaj et al., 2022), chart-to-text generation (Obeid and Hoque, 2020; Shankar et al., 2022), fact-checking with charts (Akhtar et al., 2023b), and data storytelling (Islam et al., 2024a).

Recent advances in vision-language models (VLMs) have enabled their adoption in chart-centric applications such as business intelligence assistants, accessibility tools, automated reporting systems, and data-analysis agents (Hoque and Islam, 2024). Despite strong performance on benchmarks such as ChartQA, benchmark accuracy alone does not guarantee reliable behavior in practice. Real-world chart understanding often involves noisy or conflicting textual context, diverse user prompts, low-resolution screenshots, mobile displays, and varying presentation styles—conditions that are rarely captured by existing evaluations. Moreover, VLMs remain susceptible to hallucinations, language biases, and failures on more challenging chart reasoning tasks (Cui et al., 2023; Guan et al., 2024; Islam et al., 2024b; Masry et al., 2025a). Although chart robustness has recently received attention (Mukhopadhyay et al., 2024), little is known about how current models behave under the variations commonly encountered in practical analytical workflows. This raises a fundamental question: *Do modern VLMs actually make predictions based on chart evidence, or are their predictions driven by surrounding textual cues and presentation artifacts?*

To answer this question, we introduce RobustChart360, a benchmark for evaluating chart understanding under realistic visualization variations. The benchmark spans two classes of challenges commonly encountered in chart-centric applications (see Fig. 1). *Textual and cross-*

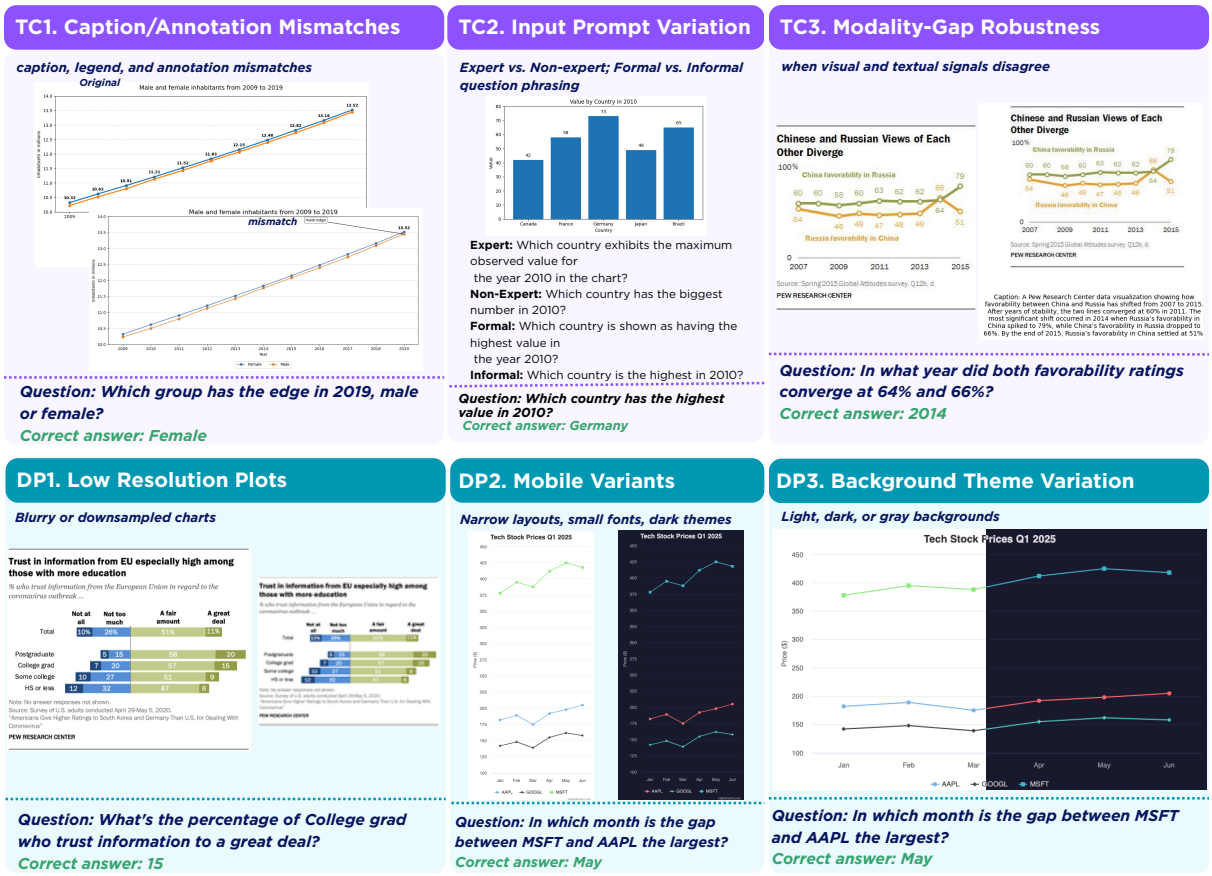

Figure 1: Overview of ROBUSTCHART360. The benchmark comprises six robustness tasks spanning textual and cross-modal robustness (TC1–TC3) and display and presentation robustness (DP1–DP3).

modal robustness evaluates whether models remain grounded in visual evidence when prompts, captions, or contextual information vary or conflict with the chart. *Display and presentation robustness* evaluates reliability under realistic viewing conditions, including low-resolution charts, mobile layouts, and presentation-style variations. Using ROBUSTCHART360, we conduct a large-scale evaluation of 14 leading proprietary and open-source VLMs to quantify robustness, identify the factors of failure, and characterize the gap between benchmark performance and real-world reliability.

Our study makes three main contributions. **(1)** We introduce ROBUSTCHART360, a benchmark for evaluating chart understanding under *six* realistic robustness challenges spanning textual and cross-modal interference, display degradation, mobile viewing conditions, and presentation variations. **(2)** We conduct a large-scale evaluation of 14 proprietary and open-source VLMs across 2,505 chart instances, revealing how various visual and contextual variations affect model behavior. **(3)** Through comprehensive analysis, we reveal a substantial gap between benchmark performance and real-world reliability. We found that when visual and textual signals disagree, many leading VLMs follow textual cues rather than chart evidence, exposing a substantial gap in visual grounding and deployment readiness.

2 Related Work

Robustness in Vision-Language Models: Recent closed-source models (OpenAI, 2026; Comanici et al., 2025; Anthropic, 2025) achieve state-of-the-art performance on chart understanding benchmarks (Masry et al., 2022; Wang et al., 2024), while open-source alternatives are rapidly improving (Bai et al., 2025; Wang et al., 2025; Abdin et al., 2024). Despite these advances, VLMs remain vulnerable to hallucinations and failures under visual and multimodal variations (Guan et al., 2024; Rahmanzadehgervi et al., 2024; Leng et al., 2024). Prior work shows that model predictions can be highly sensitive to prompt phrasing, instruction style, and language formality (Jin et al., 2022; Zhang et al., 2026; Ramu et al., 2025; Zhang et al., 2025; Jiang

et al., 2026; Sarch et al., 2024), where semantically equivalent prompts can yield substantially different predictions. Other works investigate modality-gap robustness and multimodal consistency, showing that models often over-rely on textual context when visual and textual signals conflict (Leng et al., 2024; Huang et al., 2024b,a; Hsu et al., 2026). Robustness issues have also been studied under adversarial perturbations, OCR corruption, background and contextual shifts, and visual degradations (Xiao et al., 2021; Li et al., 2023; Ryali et al., 2021). While robustness has been extensively studied for general VLMs, its implications for chart understanding remain less explored.

Robust Chart Understanding: Chart understanding has attracted attention through the development of many evaluation benchmarks (Tang et al., 2023; Shankar et al., 2022; Akhtar et al., 2023a; Masry et al., 2022, 2025a) Recent work has further improved chart reasoning through instruction tuning and reinforcement learning (Masry et al., 2024, 2025b). Despite this progress, existing evaluations largely assume clean charts with consistent layouts, high-resolution rendering, and reliable textual context, while studies have shown that chart-understanding models remain susceptible to factual errors, hallucinations, bias and deceptions in more realistic settings (Huang et al., 2023; Islam et al., 2024b; Mahbub et al., 2025b,a). Most closely related, Mukhopadhyay et al. (2024) studied robustness under visual perturbations, evaluating whether models remain invariant to alternative renderings of the same chart. In contrast, we extend robustness evaluation beyond visual rendering to include prompt variation, cross-modal conflicts, low-resolution displays, mobile layouts, and presentation variations commonly encountered in real-world chart consumption.

3 The RobustChart360 Benchmark

In this section, we describe the RobustChart360 construction pipeline (Figure 4), consisting of four stages: *(i)* defining the robustness taxonomy, *(ii)* collecting chart corpora, *(iii)* creating verified task-specific Q&A pairs, and *(iv)* evaluating VLMs on the resulting benchmark. Additional details are provided in Appendix §A.

3.1 Taxonomy Construction

We organize RobustChart360 around two common sources of robustness failures in real-world chart understanding systems (Figure 1 & Table 3): changes in surrounding textual context and changes in how charts are rendered and viewed.

Textual and Cross-Modal Robustness (TC) evaluates whether models remain grounded in chart evidence when textual information changes or conflicts with the visualization. Prior work shows that chart captions and visualizations frequently emphasize different aspects of the data in real-world documents (Kim et al., 2023), creating opportunities for inconsistency between visual and textual channels. Motivated by these deployment scenarios, we evaluate three conditions **TC1: Caption/Annotation Mismatch**, where accompanying text contradicts chart content; **TC2: Input Prompt Variation**, where semantically equivalent questions are expressed using different styles and expertise levels; and **TC3: Modality Gap**, which tests whether models rely on chart evidence or textual priors when visual and textual signals disagree.

Display and Presentation Robustness (DP) evaluates reliability under realistic viewing and rendering conditions that do not alter the underlying data. This category includes: **DP1: Low-Resolution Plots**, which simulate compressed screenshots and degraded displays; **DP2: Mobile Variants**, which test chart interpretation under small-screen layouts; and **DP3: Background Theme Variation**, which evaluates robustness to presentation changes such as light, dark, and gray themes. These conditions are important because charts are frequently consumed through screenshots, reports, and mobile devices, where resolution, layout, and presentation can vary substantially (Wu et al., 2020).

3.2 Chart Corpus Collection

For each task, we construct realistic variants of reference charts while preserving their semantics and intended answer. This enables controlled evaluation under real-world variations. The only exception is *input prompt variation (TC2)*, where the chart is fixed and robustness is evaluated through semantically equivalent question reformulations.

Textual and Cross-Modal Variants. We use ChartQA (Masry et al., 2022), a widely-used real world benchmark as the source for charts. These tasks isolate robustness to textual inconsistencies, linguistic variation, conflicting multimodal signals, and rendering degradation while preserving the underlying chart content and ground-truth answers. For TC1 and TC3, we introduce controlled text-based inconsistencies: TC1 targets caption, legend,

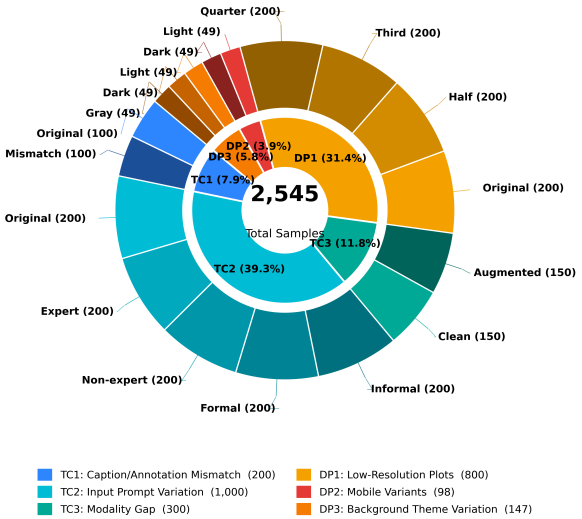

Figure 2: Dataset summary by task and subcategory.

and annotation mismatches, while TC3 introduces conflicts between textual and visual cues.

Display and Presentation Variants. For DP1, we downscale collected charts using bilinear interpolation to 50%, 33.3%, and 25% of the original width and height, corresponding to $\frac{1}{4}$, $\frac{1}{9}$, and $\frac{1}{16}$ of the original pixel count. For DP2 and DP3, we build a separate chart corpus because ChartQA's rendered images and limited chart-type diversity do not support controlled layout or theme manipulation. Using an iterative human-in-the-loop process with *Claude-Opus-4.7* (Anthropic, 2026), we generate paired desktop/mobile layouts and light/dark/gray themes while preserving the underlying data, chart semantics, and answers; all variants are manually verified and refined rigorously.

3.3 Q&A Pair Creation

We construct Q&A pairs with task-specific procedures, separating ChartQA-derived tasks from programmatically generated presentation variants.

Textual and Cross-Modal Variants. For TC1, Q&A pairs are created through human–LLM collaboration and manually verified to ensure that answers are grounded in the chart rather than inconsistent text. For TC2, we use *Claude-Opus-4.7* to generate four semantically equivalent variants of each original ChartQA question: *expert*, *non-expert*, *formal*, and *informal*. These variants capture technical, lay, professional, and conversational phrasing, respectively. Since each selected chart contains two original questions, this yields 10 samples per chart. For TC3, we add a subtle but misleading caption and formulate questions around its claim, while deriving ground-truth answers solely from the chart. Models that follow the caption are penalized, whereas those that rely on the chart are considered visually grounded.

Display and Presentation Variants. For DP1, we reuse the original ChartQA questions, while for DP2 and DP3, which are not ChartQA-derived, we generate new Q&A pairs through an LLM-assisted pipeline. To reduce generator-specific bias and increase linguistic and reasoning diversity, we prompt GPT-5.4 (OpenAI, 2026), Gemini-3.1-Pro (Google DeepMind, 2026), and Claude-Opus-4.6 (Anthropic, 2026) to generate 5 candidate questions per chart, and manually select the best one.

3.4 Dataset Composition & Diversity

RobustChart360 is designed to capture the robustness challenges that chart-understanding systems face in real-world deployment. It comprises **2,505 samples** spanning six tasks and 23 subcategories across two complementary dimensions: *Textual and Cross-Modal* (58.9%), which evaluates robustness to linguistic variation and conflicting multimodal signals, and *Display and Presentation* (41.1%), which evaluates robustness to changes in rendering quality, viewing conditions, and visual presentation (Figure 2). Beyond these robustness settings, RobustChart360 provides substantial visual and linguistic diversity. It covers a wide range of chart types, including bar, line, pie, donut, scatter, bubble, area, grouped-bar, and stacked-bar charts (Table 4), as well as diverse question formulations, vocabulary, and reasoning styles (Table 5). Together, these characteristics make RobustChart360 a realistic testbed for evaluating chart-understanding systems under deployment-time semantic and perceptual variations. More details are provided in §A.4.

4 Method

Models: We evaluate robustness of both closed and open-source VLMs under chart presentation shifts. Proprietary models include GPT-5 and GPT-5-mini (OpenAI, 2025), Claude-Sonnet-4.5 (Anthropic, 2025), and Gemini-2.5-Pro/Flash (Comanici et al., 2025). In addition, we evaluate recent open-source VLM families across varied parameter scales, including Qwen3-VL (2B, 4B, 8B), InternVL3.5 (2B, 4B, 8B), and Gemma3 (4B, 12B, 27B) (Bai et al., 2025; Wang et al., 2025; Gemma Team, 2025). This setup enables compar-

Table 1: Textual and cross-modal robustness results on ROBUSTCHART360. All values are reported as percentages. Lower Δ_{rob} indicates stronger robustness. Green and red highlight the best and worst robustness gaps within each model group.

isons across access type, model family, and scale.

Evaluation Metric: Following Masry et al. (2022), we use relaxed exact match accuracy for all tasks to determine whether a model prediction is equivalent to the reference answer.

Robustness Gap. To quantify performance degradation under perturbations, we report a unified robustness gap:

$\Delta_{\text{rob}}(m) = A_{\text{ref}}(m) - \min(A_{\text{ref}}(m), A_{\text{min}}(m))$, where $A_{\text{ref}}(m)$ denotes accuracy under the reference condition and $A_{\text{min}}(m)$ is the lowest accuracy among its corresponding variants. This metric provides a compact summary of a model's vulnerability to presentation shifts, with smaller values indicating stronger robustness ($\Delta_{\text{rob}} = 0$ indicating no degradation).

5 Results and Analysis

5.1 Key findings

Benchmark success does not imply deployment readiness. Tables 1 and 2 reveal substantial robustness gaps across all evaluated models despite strong performance on clean benchmark settings. Every model experiences notable degradation under at least one realistic robustness condition, including frontier systems such as GPT-5, Gemini-2.5-Pro, and Claude-Sonnet-4.5. Performance drops often exceed 20 points and, in some cases and reach 53.5 points in the worst case (Qwen3-VL-8B in DP1). Notably, no model consistently demonstrates robustness across all six evaluation conditions, suggesting that current chart-understanding capabilities remain fragile under realistic variations.

VLMs are relatively robust to prompt phrasing but vulnerable to misleading contextual information. Table 1 shows that not all language variation affects chart understanding equally. In TC2, semantically equivalent prompt reformulations produce measurable but relatively modest performance changes, with average robustness gaps of 2.25 points for expert-to-non-expert phrasing and 1.82 points for formal-to-informal phrasing. Although 10 of 14 models exhibit some prompt sensitivity, the largest observed drop is only 5.5 points. In contrast, changes to the surrounding textual context while leaving the chart unchanged lead to substantially larger failures. In TC1, caption and annotation mismatches degrade all 14 models, with an average robustness gap of 27.1 points; GPT-5 drops from 80% to 51%, while Qwen3-VL-32B falls from 72% to 41%. Similarly, TC3 yields an average modality-gap drop of 13.0 points, with Claude-Sonnet-4.5 and Qwen3-VL-8B losing more than 20 points. These results indicate that current VLMs are far more vulnerable to misleading contextual information than to differences in user phrasing, suggesting persistent reliance on textual context when it conflicts with chart evidence.

No model is consistently robust across deployment conditions. Table 2 shows that robustness varies substantially across display-side perturbations and models. Low-resolution rendering (DP1) is consistently the most challenging condition, degrading every model as resolution decreases. At quarter resolution, Claude-Sonnet-4.5 experiences the largest drop among closed models ($\Delta_{\text{rob}} = 41.0$), while Qwen3-VL-8B suffers the largest drop overall ($\Delta_{\text{rob}} = 53.5$). In contrast, mobile layouts (DP2) and background-theme variation (DP3) have a smaller average effect but expose distinct model-

Table 2: Textual and cross-modal robustness results on ROBUSTCHART360. All values are reported as percentages. Lower Δ_{rob} indicates stronger robustness. For DP1 and DP2, Δ_{rob} denotes the maximum performance drop from the baseline. For DP3, $\Delta_{\text{rob}}^{\text{Dark}}$ and $\Delta_{\text{rob}}^{\text{Gray}}$ are measured relative to the light-theme baseline. Green and red highlight the best and worst robustness gaps within each model group.

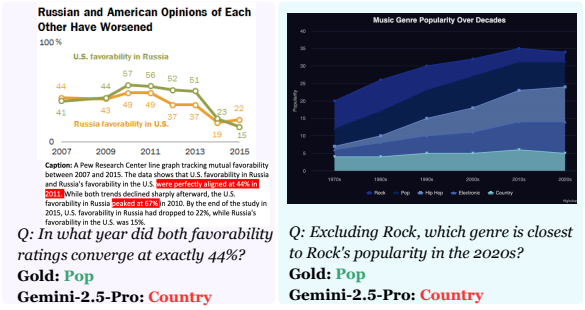

Figure 3: Representative robustness failures. Left: A misleading caption shifts the model from the correct chart-grounded answer to an incorrect text-grounded answer. Right: A presentation-only change (background) leads to wrong answer despite unchanged data.

specific weaknesses, particularly for GPT-5-mini and Gemini-2.5-Pro. Importantly, robustness under one condition does not imply robustness under another. For example, Claude-Sonnet-4.5 is nearly invariant to mobile and theme changes yet exhibits one of the largest low-resolution failures. These findings indicate that chart-understanding robustness is multi-dimensional and cannot be adequately characterized by a single benchmark score.

5.2 Qualitative Analysis

To complement our quantitative evaluation, we manually analyzed 60 failure cases across the six robustness conditions and identified recurring weaknesses in multimodal grounding and visual reasoning. Figure 3 highlights two representative examples. In the modality-gap setting (left), several models switch from the correct answer (2009) to an incorrect answer (2011) after reading a misleading caption claiming that the two favorability ratings converged at 44% in 2011, despite the chart clearly indicating that this occurred in 2009. This behavior suggests that models can rely on surrounding textual cues rather than chart evidence when the two conflict. In the background-theme setting (right), Gemini-2.5-Pro incorrectly predicts *Country* instead of *Pop* even though only the chart's visual presentation changes while the underlying data remain identical. Together, these examples illustrate the two dominant failure modes observed throughout ROBUSTCHART360: over-reliance on contextual text and sensitivity to presentation-level visual variation.

6 Conclusion and Future Work

This paper introduced ROBUSTCHART360, a comprehensive benchmark for evaluating the robustness of VLMs under realistic chart understanding conditions. Through large-scale evaluation across 14 proprietary and open-source VLMs, we showed that current models remain substantially brittle under practical deployment variations, despite strong performance on standard chart benchmarks. Models remain highly vulnerable to misleading textual context, modality conflicts, and degraded visual quality, with performance drops of up to 31% under caption mismatches, 21.2% under modality gaps, and over 50% under severe low-resolution conditions. In contrast, linguistic phrasing varia-

tions produce comparatively modest degradation, indicating that failures primarily stem from weaknesses in multimodal grounding and visual fidelity rather than surface-level language variation. We hope RobustChart360 serves as a foundation for developing more robust, visually grounded, and deployment-ready multimodal systems for chart understanding. Future extensions will explore additional robustness dimensions, including multilingual charts, OCR corruption, adversarial perturbations, and interactive dashboards.

Limitations

This work provides a broad robustness benchmark for chart understanding, but it does not cover all possible real-world visualization settings. RobustChart360 focuses on static chart images and question-answering-style evaluation. It does not fully capture interactive dashboards, animated visualizations, multi-step analytical workflows, or multilingual chart understanding. This benchmark only emphasizes selected perturbation types, such as textual mismatch, prompt variation, modality gaps, low resolution, mobile layouts, and background theme changes, leaving other practical factors such as OCR corruption, compression artifacts, extreme cropping, adversarial chart manipulation, and domain-specific visualization conventions for future work.

Our evaluation is limited to a fixed set of proprietary and open-source VLMs available at the time of experimentation. Since closed-source models may change over time and their training data, architectures, and inference procedures are not fully transparent, our results should be interpreted as empirical observations rather than causal explanations of model behavior. In addition, although we use manual verification and automated judging to support reliable evaluation, both generated question-answer pairs and LLM-as-a-judge scoring may still contain occasional errors. Future work can expand the benchmark with larger human validation, more diverse chart domains, and additional robustness dimensions.

Ethics Statement

This work is intended solely for scientific research on the robustness of vision-language models for chart understanding. Our benchmark is built from publicly available chart resources and controlled perturbations, and does not intentionally include private, personally identifiable, or sensitive information. The introduced mismatches and visual variations are designed only for diagnostic evaluation, not to promote deceptive visualization practices. Open-source models are used according to their licenses, and proprietary models are accessed through official APIs. We encourage users of this benchmark to report limitations clearly and avoid using the results as evidence of reliability in high-stakes decision-making settings.

A The RobustChart360 Benchmark

A.1 Taxonomy Construction

Robustness in chart understanding is not a single failure mode. Existing chart QA benchmarks have advanced visual and logical reasoning over charts, but they often evaluate models under relatively clean settings (Masry et al., 2022). Recent work further shows that more diverse, real-world chart settings can expose substantial gaps in LVLM performance (Masry et al., 2025a). In deployment, charts appear in news articles, dashboards, slide decks, PDF reports, social media posts, and accessibility tools, where visual and textual signals may be compressed, reformatted, incomplete, or rhetorically framed.

We therefore design the RobustChart360 taxonomy around two broad channels through which chart understanding can break. *Textual and cross-modal robustness* tests whether models remain grounded when captions, legends, annotations, or user questions are misleading, stylistically varied, or inconsistent with the visual evidence. This group captures failures caused by changes in the linguistic or multimodal context surrounding the chart, including cases where models may over-rely on textual priors rather than visually verifying the plotted evidence.

Display and presentation robustness tests whether models remain reliable under realistic rendering, viewing, and presentation shifts. This includes low-resolution screenshots, mobile layouts, dark mobile interfaces, and background theme variation. These conditions are practically important because charts are often consumed under constrained devices and interface settings, and accessibility guidelines emphasize that meaningful visual information should remain distinguishable from adjacent colors, including non-text graphical elements (World Wide Web Consortium, 2025). Background and theme changes further test whether models preserve chart semantics under presentation-level variation that should not alter the underlying data interpretation.

Together, these groups convert robustness from a broad desideratum into testable deployment-relevant questions: Does the model privilege visual evidence over misleading text? Does it remain reliable under constrained display and presentation settings? Does it preserve chart reasoning when visual styling changes but the underlying chart semantics remain fixed? Table 3 summarizes the resulting taxonomy of seven task families.

A.2 Chart Corpus Collection

TC1. For the caption/legend mismatch task, we use charts from the popular ChartQA dataset, which provides a diverse collection of real-world charts. We select charts containing captions, legends, or annotations so that controlled textual mismatches can be introduced without modifying the underlying visual data.

TC2. Real-world users ask chart questions in varied styles, from technical to informal or incomplete phrasing. We test VLM robustness by keeping the chart and answer fixed while perturbing only the question, thereby isolating linguistic robustness from visual understanding. We randomly selected 100 chart images from the ChartQA (Masry et al., 2022) for this analysis.

TC3. For the modality-gap robustness task, we select chart images from ChartQA dataset and keep the original visualization unchanged, including the chart structure, color scheme and labels. We then add a misleading caption that contradicts the visual evidence, allowing us to evaluate whether the model grounds its answer in the chart or is influenced by misleading textual context.

DP1. For low-resolution plots, we use charts from ChartQA, a dataset of charts paired with human-annotated and machine-generated question–answer pairs. We preserve the original chart structure, color scheme, and textual content, and perturb only the image resolution.

DP2. For the mobile variants, we synthetically generated chart pairs using Claude Opus 4.7 (Anthropic, 2026) through an iterative human-in-the-loop process. The model was instructed to create charts of specific types using HTML along with Highcharts.js (Highcharts, 2026), which were then rendered as screenshots in a headless browser. For each chart, the model generated both the desktop website version and its corresponding mobile version. The chart pairs were manually verified for correctness and, when necessary, iteratively refined using the LLM.

DP3. For the dark variants, we followed a similar approach to the mobile variants in DP2, using Claude Opus 4.7 (Anthropic, 2026) through an iterative human-in-the-loop process. In this case, the model was instructed to generate a dark-mode

Robustness Group	Tasks	What It Measures
Textual and Cross-Modal Robustness	**TC1:** Caption/Annotation Mismatch **TC2:** Input Prompt Variation **TC3:** Modality Gap	Tests whether VLMs remain visually grounded when the textual channel changes, becomes misleading, or conflicts with the visual evidence in the chart.
Display and Presentation Robustness	**DP1:** Low-Resolution Plots **DP2:** Mobile Variants **DP3:** Background Theme Variation	Tests whether VLMs remain reliable under realistic rendering, viewing, and presentation shifts, including compression, small screens, dark mobile layouts, and background changes.

Table 3: Taxonomy of robustness groups in ROBUSTCHART360. The benchmark groups seven task families according to how real-world variation enters chart understanding: through textual or cross-modal interference, or through display and presentation shifts.

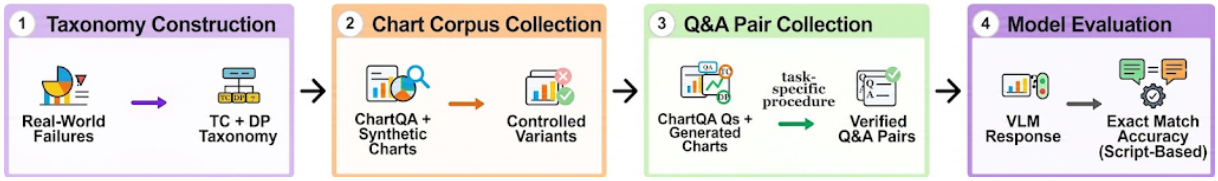

Figure 4: Overview of the ROBUSTCHART360 construction and evaluation pipeline. ROBUSTCHART360 is constructed by defining a TC/DP robustness taxonomy, collecting ChartQA-derived and synthetic chart corpora, generating controlled chart variants, and creating verified task-specific Q&A pairs. We perform automatic script based VLM evaluation.

variant for each synthetically generated chart. The resulting chart pairs were manually evaluated for correctness and refined iteratively when needed.

A.3 Q&A Pair Creation

TC1. For the caption/legend mismatch task, for each selected chart, we created a perturbed chart with a manually introduced caption, legend, or annotation mismatch. The question–answer pairs were created through human and multiple-LLM collaboration, followed by manual verification to ensure that the correct answer was grounded in the visual chart rather than the mismatched text.

TC2. For the 100 selected charts from ChartQA, we used *Claude-4.7-Opus* to generate four semantically equivalent question variants per chart: *expert*, *non-expert*, *formal*, and *informal*. These variants capture technical, lay, professional, and conversational phrasing, respectively. Since each of the selected charts has two original questions, our dataset contains 10 samples per selected chart.

TC3. To evaluate whether VLMs rely on visual evidence or textual priors when interpreting charts, we construct modality-gap Q&A pairs by introducing controlled inconsistencies between the chart image and its accompanying textual context. For each selected chart, we create an augmented version that includes a caption containing a subtle but misleading claim about the visualized data. The corresponding question is then designed around this misleading textual claim, while the ground-truth answer is determined strictly from the chart itself. Therefore, a model that answers based on the caption is considered to be relying on textual cues and is marked incorrect, whereas a model that answers based on the chart is considered visually grounded.

DP1. To construct the low-resolution variants used in DP1, we collected 200 samples from the ChartQA dataset. Each original chart image was systematically downscaled to three reduced resolutions using bilinear interpolation. Specifically, the half-resolution variant was produced by scaling both the width and height of the original image to 50% of their original dimensions, resulting in an image with one-quarter the total pixel count. The third-resolution variant was obtained by scaling each spatial dimension to 33.3%, yielding approximately one-ninth the original pixel area, while the quarter-resolution variant was created by reducing each dimension to 25%, retaining only one-sixteenth of the original pixel count.

DP2. & DP3. To generate diverse chart-grounded QA pairs for the background-theme and mobile-variant settings, we use an LLM-assisted question–answer generation process. To reduce

Chart Type	TC1: Caption/Annotation	TC2: Prompt Var.	TC3: Modality Gap	DP1: Low Resolution	DP2: Mobile	DP3: Background

Table 5: Linguistic statistics of the benchmark by task. Q. denotes question, Ans. denotes answer, and TTR denotes type-token ratio.

model-specific bias in the generation process, we prompt three state-of-the-art proprietary multimodal models, such as GPT-5.4 (OpenAI, 2026), Gemini-3.1-Pro (Google DeepMind, 2026), and Claude-Opus-4.6 (Anthropic, 2026), with each chart image and ask each model to generate five questions. We explicitly encourage diversity across question types, including ***factoid*** questions that require precise visual extraction, ***fact-checking*** questions that assess the validity of chart-grounded claims, and ***hypothetical*** questions that require reasoning over the visualized data. This QA-pair generation strategy helped diversify the linguistic form, reasoning pattern, and visual evidence required by the questions, while reducing reliance on the biases or preferences of any single generator model.

A.4 Dataset Stats.

Figure 2 presents the dataset distribution across two broad evaluation dimensions, namely Textual and Cross-Modal (TC) and Display and Presentation (DP), comprising a total of 2505 samples, respectively. The TC dimension encompasses three tasks including Caption/Annotation Mismatch (200 samples), Input Prompt Variation (1,000 samples across five subcategories of Original, Expert, Non-expert, Formal, and Informal with 200 samples each), and Modality Gap (260 samples evenly split between Clean and Augmented). The DP dimension covers four tasks including Low-Resolution Plots (800 samples across Original, Half, Third, and Quarter subcategories with 200 samples each), Mobile Variants (98 samples split evenly between Light and Dark) and Background Theme Variation (147 samples distributed equally across Light, Dark, and Gray subcategories). In total, the dataset comprises **2,505 samples** spanning 23 subcategories across seven tasks, ensuring broad coverage of real-world visual and linguistic perturbations.

A.4.1 Chart Type Diversity

Table 4 summarizes the chart-type diversity across benchmark tasks. The benchmark contains 1,645 chart instances across six tasks, covering both common and specialized visualization types. Bar charts form the largest group, with 661 instances (40.2%), followed by line charts with 495 instances (30.1%). The benchmark also includes substantial coverage of stacked bar charts (166; 10.1%) and grouped bar charts (119; 7.2%), enabling evaluation on multi-series visual reasoning. Less frequent but important chart types, including pie, donut, scatter, bubble,

and area charts, are also represented, particularly in the mobile and background-theme settings. This distribution reflects both the prevalence of bar and line charts in real-world chart corpora and our effort to include diverse visual encodings across tasks.

A.4.2 Linguistic Diversity

Table 5 reports the linguistic diversity of the benchmark across 2,505 samples. The tasks vary in lexical diversity, with unique question tokens ranging from 298 in TC3 to 869 in TC2, and question TTR ranging from 0.07 to 0.21. Question length also varies across tasks: average question length ranges from 11.25 to 14.69 tokens and 62.57 to 85.53 characters, with DP2 and DP3 containing the longest questions on average. In contrast, answers remain concise across all tasks, averaging 1.09–1.56 tokens and 3.23–5.98 characters. These statistics indicate that the benchmark evaluates models under diverse question formulations while maintaining short, factoid-style answers suitable for controlled automatic evaluation.

B Additional Results and Analysis

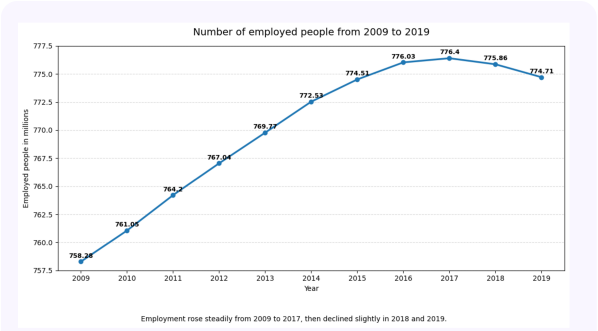
B.1 TC1. Caption/Annotation Mismatch

Table 1 shows that mismatched captions and annotations substantially reduce model accuracy across both closed-source and open-source VLMs. For example, GPT-5 drops from 80 on the original charts to 51 when the caption, legend, or annotation is mismatched, even though the visual chart content remains unchanged. Similar drops are observed for open-source models, such as Qwen3-VL-32B, which decreases from 72 to 41. The consistent negative delta across both model groups indicates that VLMs often rely on misleading textual cues instead of fully verifying the visual evidence in the chart.

B.2 TC2. Input Prompt Variation

Table 1 shows that prompt phrasing has a modest but consistent effect on chart QA performance. Unlike caption mismatch or modality gap, the drops are relatively small: the average robustness gap is 2.25 points for expert-to-non-expert and 1.82 points for formal-to-informal phrasing. This indicates that VLMs are generally more robust to linguistic variation than to misleading chart context.

Closed-source models achieve the highest absolute accuracy, with Gemini-2.5-Pro performing best and remaining highly stable across variants. However, strong models are not always the most phrasing-invariant: GPT-5 and Claude-Sonnet-4.5 both show 4.5-point drops from expert to non-expert prompts. Among open models, InternVL3.5 and Qwen3-VL variants often show small robustness gaps despite lower absolute accuracy, while Gemma3 models are more sensitive, especially Gemma3-12B under non-expert phrasing and Gemma3-4B under informal phrasing.



Overall, TC2 suggests that prompt variation can be a meaningful robustness challenge. Non-expert or informal wording does not uniformly hurt performance, but single-prompt evaluation can obscure model-specific sensitivity to user phrasing, as illustrated by representative failure cases in Table 6.

B.3 TC3. Modality-gap

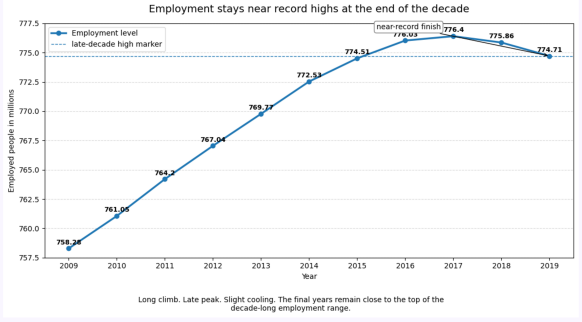


Table 1 presents the clean and augmented cross-modal consistency results across closed-source and open-source VLMs. In the augmented setting, each chart is paired with a misleading caption, creating a controlled modality gap between the visual evidence and the accompanying textual information. Therefore, a performance drop from the clean to the augmented setting indicates that the model relies more on the misleading textual information than on the actual visual evidence in the chart. From the results, we observe that most models show clear degradation under this setting. Among closed-source models, GPT-5 drops from 32.67% to 26.00%, while GPT-5-mini and GPT-5-nano decrease by 12.00 and 12.21 points, respectively. Similar trends are observed for open-source models, where Qwen3-8B drops from 63.33% to 42.67%, and InternVL3.5-14B decreases from 62.67% to 50.00%. Although Qwen3-32B shows a smaller reduction, its performance still decreases under the misleading caption setting. These results suggest that most VLMs tend to over-rely on textual information, even when it conflicts with the visual evidence in the chart.

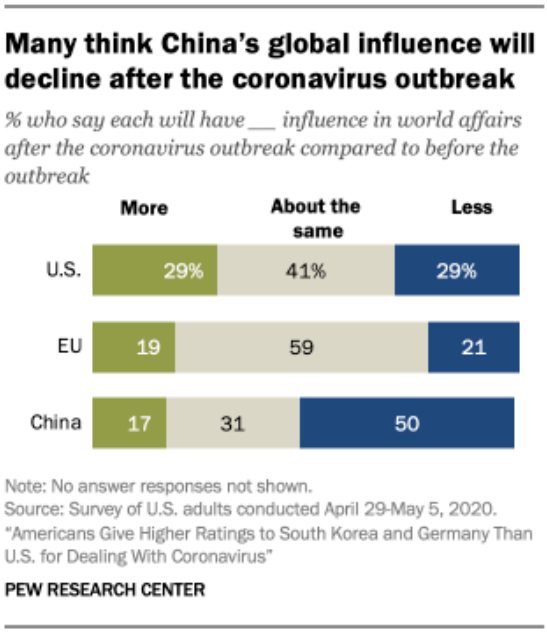
B.4 DP1. Low-resolution Plots

Table 2 demonstrates that the resolution degradation consistently imposes a performance cost across all evaluated models, yet the magnitude of this effect varies substantially. Among closed-source models, the Gemini family demonstrates the greatest resilience, with Gemini-2.5-Pro and Gemini-2.5-Flash achieving robustness drops (Δ_{rob}) of only 10.0 and 10.5, respectively. By contrast, Claude-Sonnet-4.5 exhibits the steepest degradation among closed-source models ($\Delta_{rob} = 41$), col-

Question: Subtract the 2019 value from the actual peak value.
Gold Answer: 1.69
Qwen3-VL-4B Response: 1.69

Question: Subtract the 2019 value from the actual peak value.
Gold Answer: 1.69
Qwen3-VL-4B Response: 0

Figure 5: Example of caption/annotation mismatch. Although the chart values support the correct answer of 1.69, the mismatched annotation causes the model to follow the misleading textual cue and return 0, showing weak grounding in the visual chart evidence.



lapsing from 54.0 at full resolution to just 13.0 at quarter resolution, suggesting that its visual parsing strategy is strongly reliant on fine-grained pixel detail. A similar pattern holds across open-source models. The highest-performing families at full resolution suffer the most severe drops, with Qwen3-VL-8B and InternVL3.5-8B recording Δ_{rob} values of 53.5 and 51.0, respectively. The Gemma3 family, while performing more modestly overall, exhibits comparatively higher robustness ($\Delta_{rob} \leq 28.0$), echoing the closed-source Gemini trend. Taken together, these results indicate a systematic tension between high-resolution accuracy and low-resolution robustness. The models optimized for strong visual feature extraction tend to be disproportionately sensitive to image quality degradation, which has important practical implications for deployment in bandwidth-constrained or low-fidelity display environments.

B.5 DP2. Mobile Variants

Table 2 shows that mobile rendering produces a relatively mild shift for open models but a clearer degradation for closed models. Closed models achieve higher absolute accuracy under the light-mobile condition, but their average performance drops from 75.9 to 69.8 under dark mobile rendering, with the largest robustness gaps observed for GPT-5-mini (12.3) and Gemini-2.5-Pro (10.3). In contrast, open models are largely stable: their average accuracy slightly increases from 48.5 to 50.1, and most models have a robustness gap of 0.0, indicating no degradation relative to the light-mobile baseline. The only open models with non-zero gaps are InternVL3.5-14B and InternVL3.5-8B, both with a small drop of 2.0 points. Overall, the results suggest that mobile aspect ratio changes do not uniformly degrade chart understanding; instead, robustness depends strongly on model family, with several open models showing greater invariance despite lower absolute accuracy.

B.6 DP3. Background Theme Variation

Table 2 shows that background perturbations affect model performance, but the effect is model-dependent rather than uniformly harmful. Closed models obtain an average accuracy of 74.3 under the light background, drop to 71.4 under the dark background, and increase to 78.0 under the gray background. Their gray-background robustness gap is 0.0 for all models, indicating that no closed model is harmed by the gray variant relative to the light baseline. However, the dark background exposes substantial weaknesses in some otherwise strong models: GPT-5-mini and Gemini-2.5-Pro show large robustness gaps of 10.2 and 14.3 points, respectively, while GPT-5, Claude-Sonnet-4.5, and Gemini-2.5-Flash remain unaffected. Open models show a more heterogeneous pattern: several models are stable or improve under both dark and gray backgrounds, but InternVL3.5-4B and Qwen3-VL-32B degrade under dark, while Gemma3-12B and InternVL3.5-14B degrade under gray. Overall, the experimental results suggest that background robustness is highly model-specific; gray themes are often safe or beneficial, whereas dark themes

Type	Question
Original	What's the leftmost value of the bar in China?
Expert	What is the value of the leftmost bar associated with China?
Non-expert	What number is on the bar farthest to the left for China?
Formal	What is the value of the leftmost bar for China?
Informal	What's the value of China's bar on the far left?
Gold Answer	**17**

can cause notable failures even in high-performing proprietary models.

C RobustChart360 Examples

In this section, we provide representative samples from RobustChart360 across each categories.

TC1: Caption/Annotation Mismatch. This setting evaluates whether VLMs remain grounded in the visual chart evidence when accompanying textual elements, such as captions, legends, or annotations, conflict with the underlying data. Figure 5 shows a representative failure case: the chart itself indicates that the actual peak employment value is 776.40 and the 2019 value is 774.71, so the correct subtraction result is 1.69. However, the mismatched annotation leads Qwen3-VL-4B to return 0, suggesting that the model follows the misleading textual cue rather than verifying the plotted values. This example illustrates how caption or annotation mismatches can expose weak visual grounding in chart question answering.

TC2. Input Prompt Variation: Prompt-variation robustness in Figure 6 shows how the same chart question can be phrased in multiple semantically equivalent ways while still requiring the same answer. The chart on the left is a bar chart about views on whether China's global influence will change after the coronavirus outbreak. For China, the leftmost bar segment represents the percentage who say China will have more influence, and the value shown is 17. On the right, the same question is rewritten in different styles, including original, expert, non-expert, formal, and informal versions. Although the wording changes, all versions ask for the same visual information, so the gold answer remains 17.

Table 6 expands this idea by showing a table of model performance across equivalent prompt pairs. It highlights cases where a model answers one version of a question correctly but fails when the question is rephrased in a non-expert or informal style. The green columns show the successful query and correct prediction, while the red columns show the failed reformulation and the incorrect prediction. Examples include models such as GPT-5, Qwen3-VL-32B, Gemini-2.5-Flash, and InternVL3.5-4B making mistakes even when the rewritten question has the same meaning as the original.

TC3. Modality-gap robustness Modality-gap robustness setting in Figure 7 tests whether vision-

Model	Pair	Gold	Correct Query	Correct Pred.	Failed Query	Failed Pred.
GPT-5	Orig.→Non-exp.	Spain	Which country data is consistently above 1.5 kg?	**Spain**	Which country stays above 1.5 kg the whole time?	**None**
GPT-5	Formal→Informal	2	How many "Fairly well" bars are repeated at the same value?	**2**	How many "Fairly well" bars are the same?	**4**
Qwen3-VL-32B	Orig.→Informal	18	What is the timespan measured in the graph in years?	**18**	How many years are shown on the graph?	**9**
Qwen3-VL-32B	Expert→Non-exp.	7.53	Subtract the minimum male life expectancy from the median female life expectancy over the years.	**7.53**	Take the lowest male life expectancy and subtract it from the middle female life expectancy value across all years.	**6.12**
Gemini-2.5-Flash	Orig.→Non-exp.	No	Is the median of green graph from 2002 to 2006 greater than smallest value of orange graph?	**No**	Is the middle value of the green graph from 2002 to 2006 bigger than the smallest value on the orange graph?	**Yes**
Gemini-2.5-Flash	Formal→Informal	87.5	What is the sum of the median values of the blue and green graphs?	**87.5**	What's the blue median plus the green median?	**44**
InternVL3.5-4B	Orig.→Informal	Yes	Is the starting value of China in the graph greater than 40%?	**Yes**	Does China start off over 40% in the graph?	**No**
InternVL3.5-4B	Expert→Non-exp.	4	How many shows in the chart have a higher median viewer age than The Daily Show?	**4**	How many shows have viewers who are older than the people watching The Daily Show?	**5**

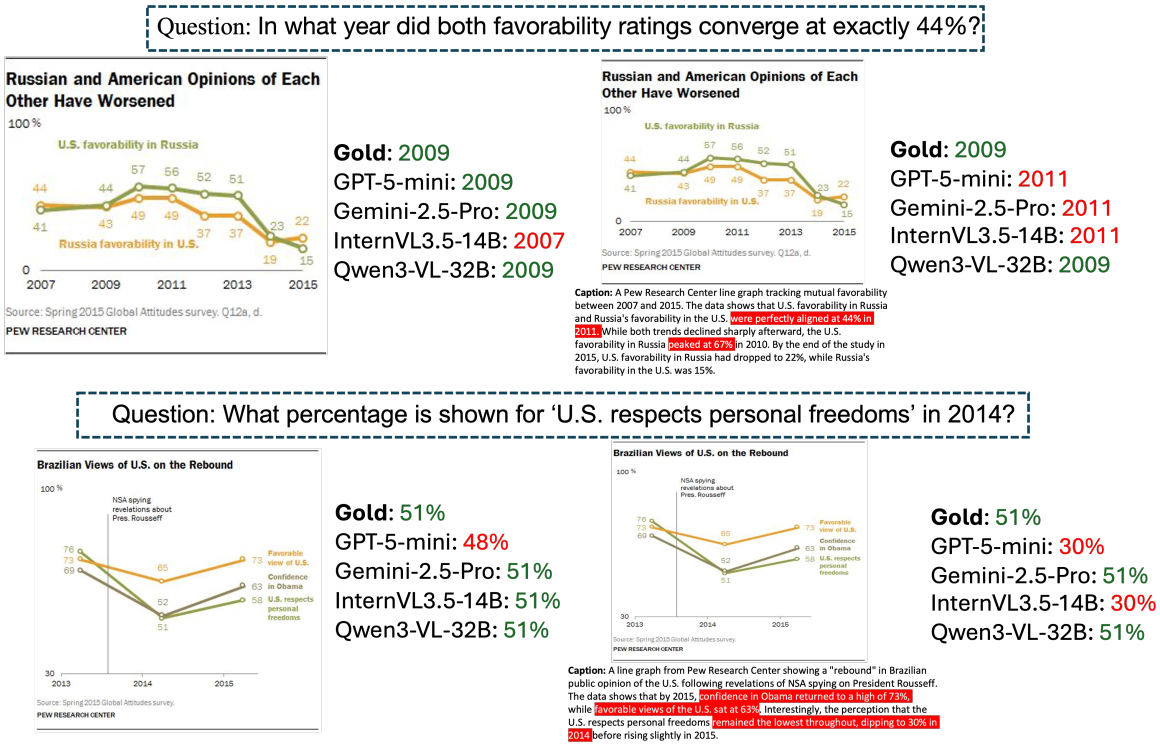
Table 6: Representative examples where a model correctly answers one prompt formulation but fails a semantically equivalent non-expert or informal variant. Green columns indicate successful predictions, while red columns highlight failures caused by prompt reformulation.

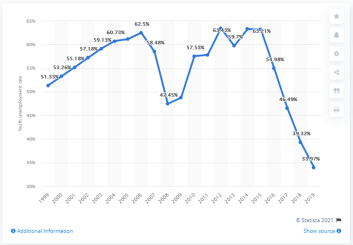
language models rely more on the actual chart image or on misleading textual context added around it. Each example shows an original chart alongside an augmented version that includes extra descriptive text, which can contradict or distract from the visual evidence. The questions ask for specific values from the charts, such as the year when U.S. and Russian favorability ratings both reached 44%, or the percentage for "U.S. respects personal freedoms" in 2014. The gold answers are shown in green, while incorrect model responses are shown in red. The results demonstrate that some models correctly extract information from the chart, while others are misled by the added text and give answers that are inconsistent with the visual data.

DP1: Low-Resolution Plots Figure 8 illustrates how reducing chart resolution can significantly affect model performance. For each plot, the models are able to produce the correct answer when the chart is shown at its original size. In that case axis labels, data values, legends, and category names are clearly visible. However, when the same charts are presented in quarter resolution, important visual details become blurred or difficult to read. As a result, the models misinterpret numerical values, confuse categories, or fail to identify the correct trend, leading to incorrect answers.

DP2. Mobile Variants In the mobile variants category (Figure 9), charts are shown in a compact mobile-style layout and models are asked to answer visual reasoning questions. The examples include different chart types, such as line charts, area charts, horizontal bar charts, donut charts, stacked bar charts, and grouped bar charts. Each panel compares the gold answer with responses from a closed model and an open model. The results show that mobile-style chart layouts can create challenges for model interpretation, especially when the task requires precise comparison, identifying category changes, estimating relationships between values, or verifying whether a statement is true or false. While some questions are answered correctly by both models, other examples show errors caused by misreading chart values, confusing nearby categories, or failing to reason over multiple visual elements. Overall, the figure highlights that mobile chart variants can affect model reliability even when the visual information needed to answer the question is present in the chart.

DP3. Background Theme Variation Figure 10 presents examples from the background theme variation category, where charts are rendered with different visual themes such as dark backgrounds, light backgrounds, and varied color palettes. The panels include several chart types, including line charts, area charts, horizontal bar charts, donut charts, stacked bar charts, and grouped bar charts. Each example shows the chart, the question, the gold answer, and responses from both GPT-5 and Qwen3-VL-32B-Instruct. The results illustrate that changes in background style and color contrast can influence model performance, especially when the task requires comparing values, identifying the





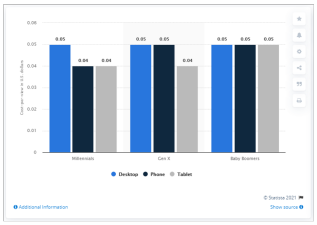


Figure 7: Examples from the modality-gap robustness category. Each example presents the original chart and its augmented version with misleading textual context. For each case, we show the question, gold answer, and responses from multiple closed-source (e.g., GPT-5, Gemini) and open-source (e.g., InternVL, Qwen3-VL) VLMs. Text highlighted in red marks the injected claims that contradict the chart. For example, in the second sample it states that "U.S. respects personal freedoms" remained the lowest throughout and fell to 30% in 2014, whereas this line is in fact the highest in 2013 (76%) and its 2014 value is 51%.

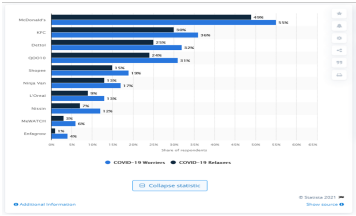
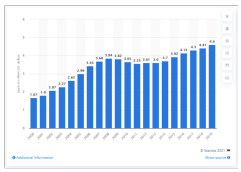


closest category, or reasoning across multiple chart elements. In some cases, both models correctly match the gold answer, while in others the open model produces incorrect responses, such as selecting the wrong month, category, or truth value.



Q: What was the youth unemployment rate in Bosnia and Herzegovina in 2019?

The Differential Reasoning Router: Operationalizing Cost-Aware LLM Annotation in E-commerce

Cheng Lyu, Jingyue Zhang, Vinny DeGenova, Mengwei Li, and Yuanli Pei
Wayfair
{clyu1, jzhang2, vdegenova, mli2, ypei}@wayfair.com

Abstract

Large Language Models (LLMs) are increasingly used to annotate structured product data in e-commerce, but early deployment often begins as a cold-start problem: only limited pre-launch labels are available, the value of expensive reasoning is unknown, and human review is needed before the system can be trusted at scale. This challenge is especially common in rule-based annotation workflows, where each item must satisfy multiple business rules and both model errors and ambiguous rule boundaries affect final decisions. We introduce the Differential Reasoning Router (DRR), a cost-aware framework for cold-start LLM annotation that jointly optimizes model selection and human escalation. Rather than treating a reasoning model as a default fallback, DRR estimates separate success probabilities for a direct model and a reasoning model at both the sample and business-rule levels, enabling adaptive routing: easy cases are handled directly, reasoning is reserved for cases where it is expected to improve the decision, and likely double-failure or rule-disagreement cases are escalated to human annotators. The resulting labels provide targeted ground truth for prompt engineering, supervised fine-tuning, calibration, and rule refinement, enabling a gradual shift from human-heavy cold-start annotation toward high-confidence automated routing. In a production e-commerce workflow, DRR reaches accuracy parity with the strongest confidence-based router while achieving more than 60% reasoning-token cost savings.

1 Introduction

In e-commerce, high-quality structured product data are essential for search, recommendation, merchandising, and compliance systems. Maintaining these data often requires rule-based judgments over multimodal evidence, such as whether an image or product description supports a required attribute, whether the displayed product matches the listing, or whether the evidence is too ambiguous for an automated decision. Human reviewers can make these judgments reliably, but catalog review at billion-product scale creates high cost, long latency, and delayed time-to-market for new or updated listings.

Large Language Models (LLMs) and autonomous agents have shown promise in automating parts of this workflow (Mohta et al., 2023; Calderon et al., 2025), and prior work has studied when LLM labels can substitute for or complement human annotation. Existing approaches that select between direct and reasoning models rely heavily on human-labeled datasets. However, new product attributes and evolving business definitions often require immediate catalog-wide deployment before a stable and representative human-annotated set can be constructed. Moreover, human annotations are initially scarce and expensive to obtain. Random sampling may fail to capture challenging or ambiguous cases, and early annotations can quickly become outdated as preliminary rule definitions are refined over time. This creates a cold-start annotation problem: direct prompting is inexpensive but brittle, reasoning can help selectively at higher cost, and the system must allocate traffic across direct inference, additional reasoning, and human review while evidence about the task is still being accumulated. In this context, cold start therefore refers not to the absence of labels, but to a mandatory yet limited pre-launch seed set that is small relative to catalog scale and still evolving with the business rules.

Existing work on model routing improves adaptive computation and test-time compute allocation (Wang et al., 2025; Liang et al., 2025; Ding et al., 2025; Damani et al., 2025), but cold-start annotation introduces two requirements that are not addressed by conventional routing methods alone. First, the router must estimate the *marginal value of reasoning*: whether a more expensive reason-

EMNLP 2026 Industry Track, pages 2815–2829
October 24-29, 2026 ©2026 Association for Computational Linguistics

ing model is likely to change an otherwise direct decision enough to justify its token cost. Scalar confidence and calibration methods can identify uncertain predictions (Kadavath et al., 2022; Ulmer et al., 2024; Khanmohammadi et al., 2025), but they do not directly distinguish examples where reasoning helps from examples where both automated models fail. Second, the router must treat human review as part of the policy. Reasoning models are not reliable universal fallbacks (Shojaee et al., 2025; Zhu et al., 2025), and some failures reflect ambiguous business rules or missing ground truth rather than insufficient model capacity. In these cases, human review is not only a safety mechanism for the current decision, but also a way to acquire labels that reduce future uncertainty.

We propose the **Differential Reasoning Router (DRR)**, a cost-aware framework for cold-start LLM annotation. DRR predicts separate success probabilities for a lightweight Direct model (M_d) and a higher-cost Reasoning model (M_r), both at the sample level and at the level of individual business rules. These differential estimates allow the router to send easy cases to M_d, reserve M_r for cases with positive expected reasoning value, and escalate likely double-failure or rule-disagreement cases to human reviewers. As reviewed labels accumulate, they can be used for prompt iteration, supervised fine-tuning, calibration, and rule refinement, enabling the system to shift gradually from human-heavy cold-start operation toward higher-confidence automated routing.

Our contributions are threefold. First, we formalize cold-start LLM annotation as a joint routing and label-acquisition problem in which the system chooses among direct inference, reasoning, and human review under limited ground truth. Second, we introduce a differentially supervised, budget-constrained routing policy that estimates the marginal value of reasoning while detecting cases that require abstention. Third, we evaluate DRR in a production e-commerce attribute-validation workflow, where it achieves accuracy parity with the strongest confidence-based router while yielding roughly one-fifth higher reasoning-token savings and identifying rule-level disagreement patterns that inform ground-truth collection and rule refinement.

2 Related Work

LLMs as Data Annotators. Mohta et al. (2023) benchmark LLMs as annotators across several tasks and show that downstream models trained on LLM-generated labels consistently underperform those trained on human labels. Complementing this empirical view, Calderon et al. (2025) propose a statistical framework for determining when LLMs can credibly replace human annotators using a limited amount of human labeling. This motivates deployment settings where human labels are scarce but strategically valuable, particularly when a new annotation task is still being calibrated. Domain-specific studies, including financial-data annotation, further show that task expertise, prompt design, and review cost shape whether LLM labels can substitute for human judgments (Aguda et al., 2024). Nevertheless, in domain-specific industrial deployments, hallucinations and reliability concerns often remain a key barrier to adoption. Efforts to mitigate this via calibration and uncertainty estimation, such as probing whether models "know what they know" (Kadavath et al., 2022) or learning confidence signals from model generations and stability under perturbations (Ulmer et al., 2024; Khanmohammadi et al., 2025), are widespread.

Adaptive Computation and Model Routing. Wang et al. (2025) introduce a semantic router for vLLM that predicts a query's reasoning needs and routes it to a cheaper non-reasoning path when appropriate, reducing unnecessary test-time compute. Liang et al. (2025) propose ThinkSwitcher, which dynamically switches a single model between short (fast) and long (slow) chain-of-thought modes based on input complexity. Ding et al. (2025) present BEST-Route, an adaptive routing framework for test-time compute allocation that selects both the model and the best-of-n sampling budget to meet a target quality at minimal estimated cost. Related routing work also studies learning cost-quality trade-offs from data (Damani et al., 2025). While these methods primarily optimize general efficiency, they typically treat the stronger model (or more compute) as a reliable fallback rather than modeling human review as an action for both abstention and label acquisition.

Learning to Defer and Selective Prediction. Learning-to-defer and selective-prediction methods train systems to decide when to defer to an expert rather than make an automated prediction (Madras et al., 2018; Mozannar and Sontag, 2020). These approaches typically study abstention for a fixed predictive model or a fixed human expert under ac-

curacy, fairness, or workload objectives. They do not directly address settings where abstention must be coordinated with model selection between direct and reasoning inference paths, or where deferred examples also serve as ground truth for prompt, rule, and policy refinement during cold-start deployment.

Limits of Reasoning Models. Shojaee et al. (2025) describe an "illusion of thinking", showing that inference-time reasoning effort (*e.g.*, thinking-token compute) can exhibit diminishing or even non-monotonic returns as problem complexity increases. In such cases, accuracy may stagnate or collapse even as models initially spend more compute. Zhu et al. (2025) analyze behavioral divergence under "save-thinking" prompts, showing that reasoning models do not reliably suppress deliberation and can re-engage in explicit or implicit thinking depending on the instance. These findings motivate routing policies that estimate the marginal value of reasoning over direct inference instead of assuming that harder examples should automatically receive more reasoning compute.

3 Methodology

We formulate rule-based product annotation as cost-constrained multimodal routing. Each query $q = (x_{\text{img}}, x_{\text{txt}})$ contains a product image and metadata, and must be evaluated against business rules $\mathcal{R} = \{r_1, \ldots, r_k\}$, where k is the total number of rules. A product is valid only if all rules are satisfied. DRR chooses among a low-cost Direct model (M_d), a higher-cost Reasoning model (M_r), and human review. For each model $m \in \{d, r\}$ and rule r_j, $y_{m,j} = 1$ means M_m agrees with human ground truth on that rule, while $y_m^{\text{sys}} = 1$ means it is correct on the full rule set.

The policy $\pi(q) \in \{M_d, M_r, \text{Human}\}$ must choose among three possible actions: the direct model is sufficient, the reasoning model is worth its extra cost, or human review is needed. Let $C_d(q)$ and $C_r(q)$ denote the model costs, and define the incremental reasoning cost $\Delta C_q = C_r(q) - C_d(q) \geq 0$. The ideal policy minimizes expected error subject to an average reasoning budget B_{target} and a human-referral budget H_{target}:

$$\begin{aligned} \min_{\pi} \quad & \mathbb{E}_q[\text{Risk}(\pi(q), q)] \\ \text{s.t.} \quad & \mathbb{E}_q[\Delta C_q \cdot \mathbf{1}\{\pi(q) = M_r\}] \leq B_{\text{target}}, \\ & \mathbb{E}_q[\mathbf{1}\{\pi(q) = \text{Human}\}] \leq H_{\text{target}}. \end{aligned} \tag{1}$$

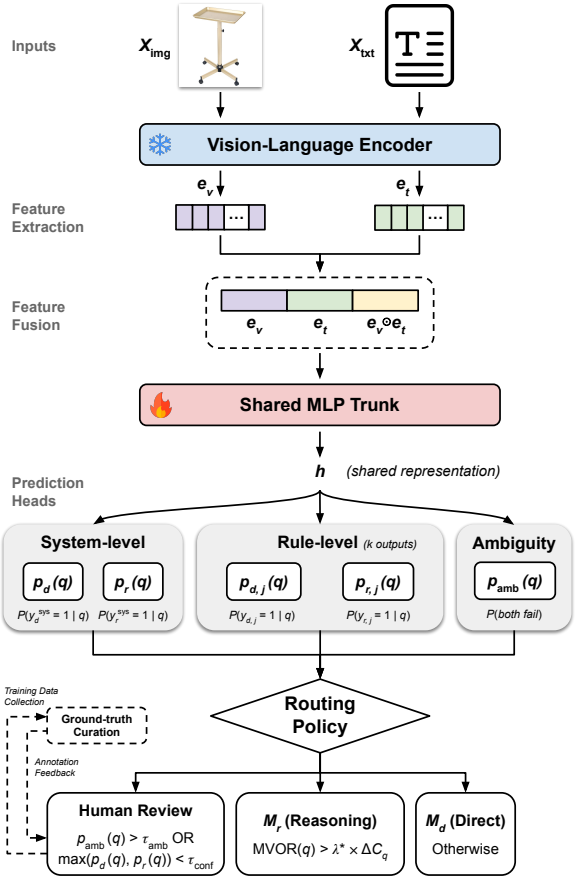

Figure 1: Overall DRR architecture for cost-aware three-way routing with human-feedback support.

We enforce the reasoning budget during training with a nonnegative budget multiplier, and handle human referrals with validation-tuned thresholds.

Figure 1 summarizes the design. Expensive multimodal features are computed once and cached; online routing uses only a small supervised model, which keeps the decision layer compatible with production latency.

3.1 Architecture: Lightweight Differential Predictor

Feature extraction and fusion. We use a pre-trained multimodal encoder to obtain image embeddings e_v and text embeddings e_t. The router does not fine-tune this encoder; it consumes cached features, which keeps routing fast and stable. To capture both unimodal evidence and image-text alignment, we concatenate image, text, and interaction features, $z = [e_v; e_t; e_v \odot e_t]$, then pass z through a shared MLP trunk.

Prediction heads. DRR uses three types of heads. System-level heads predict $\hat{p}_d(q) = P(y_d^{\text{sys}} = 1 \mid q)$ and $\hat{p}_r(q) = P(y_r^{\text{sys}} = 1 \mid q)$, the probabili-

ties that each automated model succeeds on the full rule set. Rule-level heads predict $\hat{p}_{d,j}(q) = P(y_{d,j} = 1 \mid q)$ and $\hat{p}_{r,j}(q) = P(y_{r,j} = 1 \mid q)$, the probabilities that M_d and M_r agree with human ground truth on rule r_j. An ambiguity head predicts $\hat{p}_{\text{amb}}(q)$, the probability that both automated models fail, so the router can escalate cases where more reasoning is unlikely to help.

3.2 Training Objective

DRR is trained to estimate annotator reliability and to spend reasoning budget only where it is expected to improve the decision. For a fixed budget multiplier λ, we combine these goals in an objective minimized over the router parameters θ:

$$\begin{aligned}\mathcal{J}(\theta, \lambda) = \mathcal{L}_{\text{sup}}(\theta) + \mathcal{L}_{\text{route}}(\theta) \\ + \lambda(\bar{C}_{\text{route}} - B_{\text{target}}).\end{aligned} \tag{2}$$

Here $\mathcal{L}_{\text{sup}}$ trains the system-level, rule-level, and ambiguity heads with binary cross-entropy losses; $\mathcal{L}_{\text{route}}$ is the expected error of the relaxed routing policy; and $\bar{C}_{\text{route}}$ is the expected incremental reasoning cost. The multiplier λ acts as the learned price of spending reasoning budget: larger values make routing to M_r harder to justify.

The supervision is differential rather than distillational: DRR learns whether each model matches human ground truth, not whether M_d should imitate M_r. This distinction is important because reasoning can have negative value when M_r fails on a query while M_d gets it correct. The ambiguity target is positive when both system-level correctness labels are zero, i.e., $y_d^{\text{sys}} = 0$ and $y_r^{\text{sys}} = 0$; we use a weighted binary cross-entropy loss for this head because double failures are less common but operationally important.

The routing loss uses the system-level success estimates to compare the two automated actions. For a query that is not sent to human review, the estimated direct and reasoning risks are $1 - \hat{p}_d(q)$ and $1 - \hat{p}_r(q)$, respectively. The central routing quantity is therefore the **Marginal Value of Reasoning** (MVOR), the predicted reduction in risk from using M_r instead of M_d:

$$\text{MVOR}(q) = \hat{p}_r(q) - \hat{p}_d(q).$$

A positive MVOR means reasoning is expected to improve correctness; a negative MVOR means the direct model is expected to be better. During training, the binary choice between M_d and M_r is relaxed with a sigmoid policy so that the routing loss remains differentiable:

$$\pi_r(q) = \sigma\left(\frac{\text{MVOR}(q) - \lambda \Delta C_q}{T}\right),$$

where T is a temperature. The term $\lambda \Delta C_q$ is the opportunity cost of spending reasoning compute on query q.

The relaxed policy then determines both terms in Equation 2: $\mathcal{L}_{\text{route}}$ averages the expected automated error under this mixture of M_d and M_r, while $\bar{C}_{\text{route}}$ averages the corresponding incremental reasoning cost. Thus Equation 2 connects probability learning with budgeted routing: the supervised term learns which model is likely to be correct, while the routing and Lagrangian terms learn how selectively to spend reasoning tokens.

3.3 Optimization

We optimize Equation 2 with alternating primal and dual updates. The model parameters θ are updated by gradient descent, while the multiplier is updated by gradient ascent on the budget violation. With $\lambda = e^{\nu}$, the log-space update is

$$\nu \leftarrow \nu + \eta_\lambda(\bar{C}_{\text{route}} - B_{\text{target}}).$$

If expected reasoning cost exceeds the budget, λ increases and the router becomes more selective; if the model is under budget, λ decreases and more reasoning calls are allowed. Appendix A.5 gives the budget-response and positivity properties of this log-space update, which justify its use as a stable budget price during training.

3.4 Inference Policy

At inference time, DRR uses the learned probabilities and the converged budget multiplier λ^*. It first applies the human gate:

$$\hat{p}_{\text{amb}}(q) > \tau_{\text{amb}} \quad \text{or} \quad \max(\hat{p}_d(q), \hat{p}_r(q)) < \tau_{\text{conf}}.$$

If either condition holds, the query is routed to human review, covering both predicted double failures and broadly uncertain cases.

For the remaining automated cases, the model-selection decision is

$$\pi(q) = \begin{cases} M_r, & \text{if MVOR}(q) > \lambda^* \Delta C_q, \\ M_d, & \text{otherwise.} \end{cases} \tag{3}$$

Appendix A.4 derives this cost-adjusted threshold rule for the automated cases that pass the human gate. The thresholds τ_{amb} and τ_{conf} are tuned

on validation data under a human-referral budget. This gives operators two independent controls: B_{target} governs reasoning spend, while the escalation thresholds govern human review.

3.5 Cold-start Controls and Feedback Loop

The policy is designed to support cold-start deployment and continuous improvement. When task-specific labels are scarce, DRR can initially use conservative human-escalation thresholds to maintain catalog quality while routing uncertain or likely double-failure cases to reviewers. These escalations form an informative label stream rather than a purely random sample: they concentrate on ambiguous examples, cases where M_d and M_r disagree, and instances where both automated paths appear unreliable. As review labels accumulate, DRR can be retrained or recalibrated, prompts or supervised fine-tuning data can be updated, and thresholds can be relaxed to reduce human traffic while retaining an abstention pathway for unreliable cases. Rule-level heads further reveal which business rules underlie disagreement, creating a feedback loop for ground-truth collection and rule refinement.

4 Experiments

4.1 Setup

Task. We evaluate on a production lead-image eligibility task at a major e-commerce platform. Each sample contains a product image and metadata, and the system must decide whether the image can serve as the primary product image. Human ground truth evaluates each sample against k=11 conjunctive business rules spanning objective checks (e.g., no overlaid text, no visible person) and subjective visual judgments (e.g., product is the primary focus, front of product is sufficiently visible). A single rule failure makes the image invalid, so the task is sensitive to both model errors and ambiguous rule interpretation. Appendix A.1 provides the complete rule definitions, and Appendix A.2 shows borderline subjective examples. A sample is *unsolvable* when both M_d and M_r fail on the full rule set, which motivates DRR's human-review action.

Data split and cold-start protocol. The labeled corpus contains 9,358 examples, split into 6,550 training, 1,403 validation, and 1,405 test examples. These labels come from the mandatory pre-launch review process used for launch approval, model/vendor selection, prompt tuning, and operating-point selection; they were not collected as a separate production annotation campaign solely for DRR. This is the sense in which the deployment is cold-start: labels exist, but they are limited relative to catalog scale and still evolving with the business rules. DRR uses the training split to learn task-specific reliability heads, while both DRR and MaxConf use the same validation split to select human-review thresholds. We therefore interpret the comparison as an operational use of required pre-production evidence, not as a label-efficiency claim.

Models. Both automated annotators use Gemini 2.5 Flash Lite with the same structured output prompts; Appendix A.6 provides the full annotation prompts. The Direct model (M_d) runs with thinking disabled, while the Reasoning model (M_r) runs with dynamic thinking enabled, allowing the model to spend additional reasoning tokens when invoked. Note that DRR is not tied to this model version: the router only requires candidate model outputs, realized costs, and ground-truth agreement labels, so newer direct or reasoning models can be substituted by regenerating candidate predictions and recalibrating or retraining the routing layer. We use OpenCLIP ViT-L/14 for feature extraction, with a shared MLP trunk. Embeddings are precomputed and cached.

Baselines. The baselines isolate the design choices in Section 3 using the same model outputs. Direct-only always uses M_d and represents the cheapest automated deployment. Reasoning-only always uses M_r and serves as the reasoning-token cost baseline. Random routes uniformly between M_d and M_r, testing whether learned routing adds value beyond arbitrary model selection. Oracle is a best-of-two automated selector that chooses a correct automated model whenever either M_d or M_r is correct; it shows the limit of automated selection without human review. MaxConf follows confidence-based query-aware LLM selection baselines (Maurya et al., 2025): it routes a sample to human review when the maximum model-reported Direct/Reasoning confidence is below a threshold, and otherwise selects M_r only when its confidence exceeds M_d's. Reasoning-token savings for MaxConf count the incremental reasoning cost only on samples where the policy selects M_r, using the same accounting as DRR. MVOR-only uses the cost-aware M_d/M_r rule without human escalation, isolating the need for abstention.

Method	Acc (%)	Human Review (%)	Reasoning-Token Savings (%)
Direct-only (M_d)	68.0 [65.6, 70.5]	—	100.0
Reasoning-only (M_r)	69.3 [66.8, 71.6]	—	0.0
Random	68.6 [66.5, 70.7]	—	50.0
MaxConf	82.0 [80.0, 84.0]	20.0	55.2
MVOR-only	69.5 [67.1, 71.9]	—	56.4
Oracle	79.1 [77.0, 81.1]	—	86.6
DRR (ours)	**82.8** [80.8, 84.8]	21.7	**66.2**

Table 1: Main results on the product attribute test set (N=1,405). Acc is end-to-end accuracy after routing. Brackets are 95% bootstrap confidence intervals. Reasoning-token savings are measured relative to always using M_r. Thresholded methods are selected on validation set; the table reports realized test-set review rates.

For Pareto sweeps, Ambiguity-only uses only the learned double-failure score for human escalation. Thresholded methods are tuned on the validation set under a $\leq$20% human-referral budget.

Metrics. *End-to-end accuracy* measures whether the final routed decision is correct: automated routes are correct when the selected model matches human ground truth on the full rule set, and human-reviewed samples are counted as correct. *Human review rate* reports the fraction of samples routed to reviewers. *Reasoning token savings* measures reduction in reasoning-token spend relative to always using M_r; it does not include human-review labor. For diagnostic analyses, we distinguish two granularities of double failure: an *unsolvable instance* is a full sample where both M_d and M_r fail the conjunctive decision, while a *rule-level joint failure* is a specific business rule on which both models disagree with human ground truth.

4.2 Main Results

Table 1 addresses the practical question behind the experiment: after allocating limited human review, how much reasoning compute is still needed. The single-model and random rows show that invoking or randomly selecting the reasoning model changes accuracy only modestly. The policies that can route difficult cases to humans reach a higher accuracy range. The discussion below separates these effects into human review, cost-aware reasoning, and ambiguity supervision.

Human review must be a routing action. The methods that always choose between M_d and M_r top out at 79.1% accuracy with Oracle, below the thresholded methods that can route examples to human review. This pattern is expected when some samples are unsolvable by both candidate models: choosing the better automated output is still insufficient for those cases. Human review therefore needs to be modeled as a routing action, rather than added only after automated model selection.

Zone	N Inst.	% Inst.	M_d Acc	M_r Acc	% Unsolv. Inst.
Economy	570	40.6	76.7	78.6	12.8
Reasoning	530	37.7	75.1	79.6	12.5
Ambiguity	305	21.7	39.7	33.8	**50.8**
Population	1405	100	68.0	69.3	20.9

Table 2: Per-zone statistics on the test set. Zones correspond to DRR's three inference actions: direct routing, reasoning routing, and human escalation. Unsolv. Inst. is the percentage of instances in each zone where both automated models fail the full rule set.

Cost-aware routing must be paired with abstention. MVOR-only saves reasoning tokens but remains close to the single-model baselines in accuracy. This separates two effects: the MVOR threshold controls when to spend reasoning tokens, but it does not by itself identify cases that should leave the automated path. After adding the ambiguity gate, DRR reaches the accuracy range of the methods that route examples to humans while achieving more than 60% reasoning-token cost savings compared to MaxConf. Thus cost-aware model selection is most useful when paired with abstention for likely double failures.

Ambiguity supervision adds signal beyond confidence. MaxConf performs well because model-reported confidence is a useful first filter: many difficult examples are also low-confidence examples. However, for cold-start annotation, the review set is also training signal for the next iteration, so the useful cases are not necessarily the least confident ones. The more valuable cases are those that reveal where automation fails, especially examples likely to fail under both M_d and M_r or to expose unstable rule boundaries. DRR uses differential supervision to learn direct-model success, reasoning-model success, and joint automated failure, giving the human gate a task-specific signal beyond confidence alone.

4.3 Routing Zone Analysis

Table 2 checks whether the inference policy creates meaningful regions. The Ambiguity Zone has the highest unsolvable-instance rate, while the Economy and Reasoning Zones retain mostly automat-

Rule	M_d Acc	M_r Acc	% Joint Fail	Type
D1: Primary Focus	68.1	79.4	17.4	Subj.
E1: Front Visible	76.7	78.5	16.7	Subj.
D5: Photorealistic	80.6	81.9	14.5	Subj.
D3: Standard View	79.3	80.1	14.0	Subj.
E3: Correct Set	90.1	84.3	6.3	Subj.
D2: Functionality	95.9	91.0	0.0	Obj.
E2: Standard State	95.2	94.2	0.0	Obj.
E4: Props	96.9	96.7	0.0	Obj.
D4: Dimensions	98.7	98.0	0.0	Obj.
E5: No Text	97.7	99.0	0.0	Obj.
D6: No Person	99.0	99.3	0.0	Obj.

Table 3: Per-rule diagnostics. Joint Fail is the percentage of samples for which both automated models fail the same rule. Subjective rules from Appendix A.2 concentrate these rule-level joint failures, while objective checks are more stable.

able samples. Intuitively, Economy examples tend to have sufficient direct evidence, Reasoning examples require additional cross-checking of the image and metadata, and Ambiguity examples resemble the borderline subjective cases in Appendix A.2. This validates DRR's ability to preserve human capacity while choosing between cheap and expensive model calls.

4.4 Per-Rule Diagnostics

Table 3 explains why the ambiguity region exists: rule-level joint failures concentrate in subjective rules, matching the borderline cases in Appendix A.2. Objective checks are more stable because their criteria are directly verifiable. This validates the rule-level heads in Section 3: they turn system-level routing failures into diagnoses of which business rules need clarification or human oversight. Human referrals therefore serve both as a quality safeguard and as targeted ground truth for future router training and rule refinement.

4.5 Pareto Analysis

Figure 2 treats the human-referral threshold as a deployment control for cold-start annotation. Moving right allocates more reviewer capacity while rules, prompts, and router calibration are still being refined; moving left preserves human capacity but requires more automated decisions. The steep accuracy gains at low review budgets show why selective human escalation is valuable during rollout, and the operating region in Table 1 shows that DRR remains competitive with simple confidence-based escalation while retaining explicit control over reasoning-token spend.

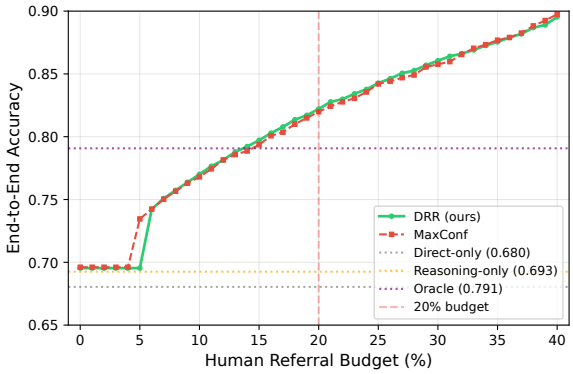

Figure 2: Accuracy-human budget trade-off. The x-axis varies the allowed human-referral budget, and the dashed line marks the operating point used in Table 1. Dotted horizontal lines show automated reference points. The curves show how different escalation policies convert limited human review into end-to-end accuracy during cold-start rollout.

5 Conclusions

DRR shows that routing can do more than select the cheapest successful inference path. By estimating where direct inference is sufficient, where reasoning is likely to help, and where both automated paths are unreliable, the framework turns cold-start LLM annotation into an explicit operating policy. Its routing zones and rule-level diagnostics identify which traffic can be automated, which cases deserve reasoning tokens, and which examples should become human-labeled ground truth. Rather than waiting for a large balanced evaluation set or committing to a single model choice, practitioners can launch with a controlled human-review budget, monitor the accuracy-review tradeoff, and improve prompts, calibration, training data, and rule definitions as the task warms up.

Limitations

This study evaluates DRR on a specific production e-commerce annotation workflow with rule based annotations. Although the framework is intended for rule-based LLM annotations more broadly, its behavior may differ across domains, modalities, rule structures, and operational review processes.

Our experiments also reflect the model landscape at the time of deployment. Although DRR is model-agnostic by design, commercial LLMs evolve rapidly. For each new pair of models, we recommend regenerating candidate predictions and recalibrating or retraining the router to maximize performance gains.

We do not evaluate label efficiency across training-label budgets. The reported DRR result uses the full pre-launch training split, while confidence thresholding requires only validation-set operating-point selection. Thus, our comparison should be read as how to use a mandatory pre-production labeled corpus in deployment, not as evidence that DRR is preferable when all labels must be newly acquired.

Finally, we treat human review as ground truth, matching its role in the production decision process. In practice, human labels can contain disagreement or inconsistency, especially for subjective rules. Such noise may affect both reported accuracy and the supervision used to train ambiguity and rule-level failure signals.

A Appendix

A.1 Lead Image Eligibility Rules

The production task studied in this paper is lead-image eligibility: given a product image and listing metadata, decide whether the image is suitable to appear as the primary image shown to customers. The decision is rule-based rather than a single visual-classification judgment. A product image is valid only if it satisfies a conjunction of business rules covering product visibility, presentation state, image cleanliness, product-set consistency, and prohibited visual elements. If any rule fails, the full image-level decision is invalid.

Table 4 lists the 11 rules used for annotation, along with representative examples. The rules span relatively objective visual checks, such as detecting overlaid text, visible people, or dimension markings, and more contextual judgments, such as whether the target product is the primary focus, whether enough of the front is visible, or whether the displayed items match the listed set composition. This mix creates cases where direct inference is sufficient, cases where additional reasoning may help, and cases where human review remains necessary.

A.2 Qualitative Examples of Subjective Rules

Table 5 shows borderline cases for rules with higher subjectivity. In these examples, the visual evidence is present, but the business-rule boundary is underspecified: a product may compete with surrounding room context, be shown at an angle that partially obscures the front, include small edited artifacts, or make set quantity difficult to infer from the image alone. Such cases can produce disagreement between automated annotators and human reviewers, and sometimes between human reviewers themselves.

The examples also clarify why an ambiguity pathway and rule-level diagnostics are useful. Additional reasoning does not always resolve underspecified visual judgments, while rule-level predictions identify which business rule is responsible for a system-level failure. In deployment, reviewed ambiguity cases provide both training signal for future router updates and evidence for refining the underlying rule specification.

A.3 Implementation Details

DRR is implemented as a lightweight supervised routing layer on top of frozen multimodal features. Image and text embeddings are generated offline and cached, so online inference only requires a compact neural router rather than repeated feature extraction. The router shares a small trunk across system-level, rule-level, and ambiguity heads, which keeps the decision layer inexpensive while preserving rule-level diagnostics.

Training uses standard regularized optimization with early stopping on validation performance. The Lagrangian multiplier is updated during training to enforce the reasoning-budget constraint, while human-escalation thresholds are selected on validation data under the target review budget. No additional fine-tuning of the underlying direct or reasoning LLMs is required; all adaptation is concentrated in the routing layer.

A.4 Optimality of Threshold Policy

This section derives the automated model-selection rule used after the human-escalation gate has been applied. It does not claim optimality for the full three-way policy; the human gate is tuned separately under the review budget. Let $\mathcal{A}$ denote the set of queries that pass this gate:

$$\mathcal{A} = \{q : \hat{p}_{\text{amb}}(q) \le \tau_{\text{amb}} \text{ and } \max(\hat{p}_d(q), \hat{p}_r(q)) \ge \tau_{\text{conf}}\}.$$

Conditional on $q \in \mathcal{A}$, the remaining action set is binary, $\{M_d, M_r\}$.

For a query q, define the estimated risks of the direct and reasoning models as

$$R_d(q) = 1 - \hat{p}_d(q), \qquad R_r(q) = 1 - \hat{p}_r(q),$$

and let $\Delta C_q = C_r(q) - C_d(q) \ge 0$ be the incremental cost of invoking reasoning. The Marginal Value of Reasoning is the estimated risk reduction from routing to M_r:

$$\text{MVOR}(q) = R_d(q) - R_r(q) = \hat{p}_r(q) - \hat{p}_d(q).$$

Consider the binary policy $\pi : \mathcal{A} \to \{M_d, M_r\}$ with the same incremental reasoning-budget constraint used in Section 3, restricted to queries that are not sent to human review:

$$\begin{aligned} \min_{\pi} \quad & \mathbb{E}[R_{\pi(q)}(q) \mid q \in \mathcal{A}] \\ \text{s.t.} \quad & \mathbb{E}[\Delta C_q \cdot \mathbf{1}\{\pi(q) = M_r\} \mid q \in \mathcal{A}] \le B_{\text{target}}. \end{aligned} \tag{4}$$

Proposition 1 (Threshold Form of Model Selection)**.** *For any fixed multiplier $\lambda \ge 0$, minimizing the Lagrangian relaxation of Equation 4 over*

Rule	Criterion	Example Type	Example
E1: Front Visible	At least 75% of the product front is visible.	Eligible	
E2: Standard State	The product is shown in its normal, non-functional state.	Eligible	
E3: Correct Set	The image shows the correct quantity or all pieces included in the set.	Eligible	
E4: Props	Props are acceptable only if the target product remains the main focus.	Eligible	
E5: No Text	The image contains no added text, labels, badges, or promotional callouts.	Eligible	
D1: Primary Focus	The target product must be the main visual focus of the image.	Violation	
D2: Functionality	The product should not be shown in use or in an altered functional state.	Violation	
D3: Standard View	The image should show a standard product view, not mainly a side, top, close-up, or detail view.	Violation	
D4: Dimensions	The image should not contain dimensions, arrows, schematics, measurement labels, or similar diagram elements.	Violation	
D5: Photorealistic	The image should be a clean photograph or photorealistic render, without obvious compositing or unrelated inserts.	Violation	
D6: No Person	No person or visible body part should appear in the image.	Violation	

Table 4: Lead image eligibility rules with representative examples. A product image is valid only when all rules are satisfied.

$q \in \mathcal{A}$ decomposes into independent per-query decisions. For each query, the cost-adjusted decision routes to M_r exactly when

$$\mathit{MVOR}(q) > \lambda \Delta C_q, \tag{5}$$

and otherwise routes to M_d.

Proof. For a fixed λ, the Lagrangian relaxation differs from the constrained objective only by the per-query penalty for using M_r:

$$R_{\pi(q)}(q) + \lambda \Delta C_q \cdot \mathbf{1}\{\pi(q) = M_r\}.$$

Because the expectation is linear, the optimal policy can be chosen independently for each query. Routing to M_r is preferred when

$$\begin{aligned} R_r(q) + \lambda \Delta C_q &< R_d(q) \\ R_d(q) - R_r(q) &> \lambda \Delta C_q \\ \mathrm{MVOR}(q) &> \lambda \Delta C_q. \end{aligned}$$

Ties are broken conservatively in favor of M_d, matching the inference rule in Section 3. □

The multiplier λ can be interpreted as a learned shadow price for reasoning budget. Here, "shadow price" simply means the penalty assigned to spending one additional unit of reasoning budget in the routing rule: increasing λ makes reasoning more expensive in the router's decision rule, so fewer queries are sent to M_r. If $\hat{p}_d$ and $\hat{p}_r$ are calibrated,

Table 5: Borderline examples for rules with higher subjectivity. These cases illustrate why human review and rule-level diagnostics remain useful even when reasoning models are available.

Rule	Source of Subjectivity	Example A	Example B
D1: Primary Focus	Requires judging whether the target product dominates the scene. Here, the ***fireplace mantel*** blends into the room and competes with surrounding objects.		
E1: Front Visible	Requires estimating whether enough of the product front is visible. Example A shows the ***fireplace mantel*** at a strong angle, making the visible front area difficult to judge. Example B shows the ***table*** in a staged scene, where surrounding objects make the front view less clear.		
D5: Photorealistic	Requires judging whether small digitally added or composited elements are severe enough to affect image eligibility. Both examples contain minor edited elements, but the overall product presentation remains photorealistic, so these artifacts may be ignored or accepted by human annotators and the model.		
D3: Standard View	Requires judging whether an angled or elevated view still counts as a standard product view. Example A shows a ***three-quarter angled view*** that still represents the product, while Example B uses an elevated room-view angle that may be interpreted differently by annotators.		
E3: Correct Set	Requires judging whether the visible items match the listed quantity or set composition. Example A lists a ***2-piece bedding set***, but appears to show three items. Example B lists ***4 privacy screens/rolls***, but the continuous installation makes the quantity hard to verify.		

this threshold is optimal for true expected risk under the binary model-selection problem; otherwise it is optimal for the estimated risks used by the router. This is why DRR uses supervised probability estimation and validation-based operating-point selection rather than relying on raw model confidence alone.

The same monotonicity appears in the relaxed training policy,

$$\pi_r(q) = \sigma\left(\frac{\mathrm{MVOR}(q) - \lambda \Delta C_q}{T}\right).$$

For fixed temperature $T > 0$, the probability of routing to M_r increases with MVOR and decreases with both incremental cost and the learned budget price λ.

A.5 Dual Update and Constraint Stabilization

DRR uses the Lagrangian term in Equation 2 to discourage routing policies that exceed the reasoning-token budget. Let

$$g(\theta) = \bar{C}_{\text{route}}(\theta) - B_{\text{target}}$$

denote the budget violation of the relaxed routing policy. The primal update treats the current multiplier as fixed and updates the router parameters using

$$\mathcal{L}_{\text{sup}}(\theta) + \mathcal{L}_{\text{route}}(\theta) + \lambda_t g(\theta).$$

The dual variable is then updated in log space:

$$\nu_{t+1} = \nu_t + \eta_\lambda g(\theta_{t+1}), \qquad \lambda_t = e^{\nu_t}. \quad (6)$$

Because the router is a neural model, this section does not claim global convergence to a constrained optimum. Instead, it establishes the exact stabilization properties of the implemented dual update and explains why it is appropriate for enforcing the budget during training.

Proposition 2 (Budget Response of the Log-Space Update)**.** *For any step size $\eta_\lambda > 0$, the update in Equation 6 satisfies*

$$\lambda_{t+1} = \lambda_t \exp(\eta_\lambda g(\theta_{t+1})).$$

Therefore λ_t remains positive for all t; if the expected routing cost exceeds the budget, λ increases; if the router is under budget, λ decreases; and if the budget is exactly met, the dual variable is unchanged.

Proof. Since $\lambda_t = e^{\nu_t}$, exponentiating Equation 6

gives

$$\begin{aligned}\lambda_{t+1} &= e^{\nu_{t+1}} \\ &= e^{\nu_t} \exp(\eta_\lambda g(\theta_{t+1})) \\ &= \lambda_t \exp(\eta_\lambda g(\theta_{t+1}))\,.\end{aligned}$$

The exponential term is always positive, so positivity is preserved. If $g(\theta_{t+1}) > 0$, the exponential factor is greater than one; if $g(\theta_{t+1}) < 0$, it is less than one; and if $g(\theta_{t+1}) = 0$, it equals one. □

Proposition 3 (Mirror-Ascent Interpretation)**.** *For fixed router parameters θ_{t+1}, the multiplicative update in Proposition 2 is the solution to the one-step mirror-ascent problem*

$$\lambda_{t+1} = \arg\max_{u>0} \{\eta_\lambda g(\theta_{t+1})u - D(u\|\lambda_t)\}\,,$$

where $D(u\|\lambda_t) = u\log(u/\lambda_t) - u + \lambda_t$ is the scalar relative-entropy divergence.

Proof. Differentiate the objective with respect to u:

$$\eta_\lambda g(\theta_{t+1}) - \log(u/\lambda_t).$$

Setting this derivative to zero yields $\log(u/\lambda_t) = \eta_\lambda g(\theta_{t+1})$, or

$$u = \lambda_t \exp(\eta_\lambda g(\theta_{t+1}))\,.$$

The objective is strictly concave in u, so the maximizer is unique. □

These propositions give the property needed by DRR: the multiplier is a stable, positive budget price that moves in the correct direction after every batch or epoch. When routing exceeds the target budget, the next primal update penalizes reasoning more strongly; when routing is below budget, the penalty relaxes. This feedback mechanism is sufficient for the role λ plays in the router, namely controlling the threshold $\mathrm{MVOR}(q) > \lambda\Delta C_q$.

Classical primal-dual convergence results require convexity, compactness, and exact or appropriately controlled stochastic updates. Those assumptions do not hold for the non-convex neural router used here, so we do not claim global convergence or optimal constraint satisfaction from the theory alone. In practice, the final operating point is selected on validation data, and the learned multiplier is used only together with validation-tuned human-escalation thresholds.

A.6 Lead Image Evaluation Prompt

Each evaluation uses two prompt components. The system instruction defines the eligibility rules, confidence scoring, and required JSON output. The user message provides the product-specific inputs for each evaluation: the candidate image, the target product, and the catalog text needed to verify quantity, set composition, and visual eligibility. Placeholders such as `[product name]` and `[image]` are replaced with product-specific values before inference.

System Instruction

```
You are an expert AI system performing quality assurance on e-commerce product images.

For each item, you will receive the evaluation rules below, product information, and a candidate lead image.

Instructions:
- Apply all rules exactly as written.
- Do not question or reinterpret the rules or product class.
- Evaluate every rule and provide concise rule-level reasoning.
- If a rule is ambiguous or uncertain, state why and reflect that uncertainty in the confidence score.
- Return only the required JSON structure.

Rule key:
- E = Eligibility requirement. The image must satisfy the rule.
- D = Disqualification condition. The image must not violate the rule.

Rules:

E1_Front_Visible_Enough: The image must show at least 75% of the target product's front, with no major truncation or cropping. The target
      product must be the primary focus. Forward-facing and angled front-facing views are acceptable when the product is visible and
      unobstructed.
Examples: Pass - a coffee table or sofa shown from the front or slight angle, fully in frame. Fail - a product cropped at major edges, less
      than 75% front visible, or visually dominated by foreground objects.

E2_Standard_State: The product must be shown in a standard, non-functional state. In-use styling and minor adjustments are acceptable, such
      as books in a bookcase, decor on a coffee table, an extended luggage handle, or swiveled wheels. Major functional changes that alter
      product form are not acceptable.
Examples: Pass - upright suitcase with handle extended; styled bookcase; coffee table with decor; sofa with pillows. Fail - sofa bed
      unfolded; dresser drawers open; dining table extension pulled apart; storage ottoman with lid removed.

E3_Correct_DSQ_Set: The image must show the correct quantity or all pieces in the set. Use quantity/set information from the product name,
      description, and feature bullets as ground truth, even if it conflicts with the DSQ field. If product text is silent, use DSQ. If
      neither product text nor DSQ specifies quantity, assume one item. Show multiple products only when explicitly specified. Do not treat
      separate items as one unit unless inseparable by design.
Examples: Pass - "Set of 4 Dining Chairs" shows 4 chairs; "10-piece cookware set" shows all 10 pieces; DSQ=4 and product text is silent,
      image shows 4 items. Fail - product text says 3 but image shows 1; set of 2 nightstands shows 1; DSQ=1 but image shows 5 separate sofas.

E4_Props_Appropriate: Props are acceptable only if the target product remains the primary focus.
Examples: Pass - coffee table with mug/book; sofa with pillows that do not obscure it. Fail - chair mostly covered by a prop; dresser mostly
      hidden behind other furniture.

E5_No_Text_In_Image: The image must not contain overlaid or digitally added text, even if it does not obscure the product. Text physically
      printed on the product or visible in decorative background items is allowed when it is not the main focus.
Examples: Pass - wall art text in the background; book titles; branding or printed text that is part of the product design. Fail -
      promotional banner, watermark, URL, measurement callouts, or digitally added "SALE" text.

D1_Not_Primary_Focus: The target product must be the main visual focus. It should occupy a substantial portion of the image, be centrally or
      prominently positioned, and stand out from the surroundings. Visibility alone is not sufficient. If the image is best described as a
      room, setting, or scene with the product present, the product is not the main focus.
Examples: Pass - product centered, large, and prominent, such as a sofa occupying most of the image. Fail - product is small, peripheral, or
      part of a wide scene, such as a light fixture in a porch photo or a chair at the edge of a room scene.

D2_Shows_Functionality: The image must not show the product primarily in a functional or altered-use state.
Examples: Pass - folded towels/sheets; curtains fully closed; styled bookcase. Fail - wardrobe doors/drawers open; refrigerator doors open;
      folding chair folded; shed doors open; chandelier lights on.

D3_Non_Standard_View: The image must not primarily show the side, top, back, close-up, or detail view. Multiple views of one product in a
      single image are not acceptable. Front-facing or slightly angled front views are acceptable when they represent the overall product.
Examples: Pass - sofa shown from front or slight angle, fully visible. Fail - sofa shown from the back only; table shown from top only;
      close-up of armrest/leg; multiple front/back/side views in one image.

D4_Dimensional_Diagram: The image must not contain dimensions, schematics, measurement labels, arrows, or similar diagrams.
Examples: Pass - clean product image with no added dimensions. Fail - product photo with measurement or diagram overlay.

D5_Non_Photorealistic: The image must be a clean, high-quality photograph or photorealistic 3D render. Reject images with obvious pasted
      props, floating accessories, insets, collages, montages, overlays, composited objects, or unrelated floating items. High-quality 3D
      renders are acceptable when indistinguishable from photos.
Examples: Pass - well-lit product photograph; high-quality photorealistic render. Fail - floating product covers/accessories; multiple
      cropped product views in one frame; computer-generated object floating above the product.

D6_Features_Person: The image must not contain a real person.
Examples: Pass - no people present; printed portrait or illustration on wall art or pillow as part of the product design. Fail - person
      sitting on sofa/chair; child sitting on bed.

Final eligibility checklist:
- List all failed rules.
- If any rule fails, the image is not lead eligible.
- If information is contradictory or insufficient, mark lead_image_eligible as "Unsure".

Confidence scoring:
- eligibility_confidence_score must be an integer from 1 to 5.
- 5 = high confidence; all rules and product information are complete, clear, and unambiguous.
- 4 = high confidence; mostly clear with minor ambiguity that does not affect the decision.
- 3 = low confidence; some ambiguity or incomplete information, but a cautious decision is possible.
- 2 = low confidence; significant ambiguity or gaps; decision is a limited-evidence guess.
- 1 = low confidence; information is highly contradictory, mostly missing, or nearly impossible to decide.

eligibility_confidence_reason must be one of:
- High Confidence: reasoning is fully supported and information is present.
- Low Confidence: a major part of the reasoning is unclear or ambiguous.
- Insufficient Information: not enough data to make a strong decision.
- Contradictory Information: image and product text conflict.
- Rule Ambiguous: a rule is open to multiple interpretations.

Output format: Return valid JSON only.

Abstract

We propose RCEM, a Robust Conversational search EMbedder that augments text embedders with LLM query reformulation capabilities while approximately preserving their original generalization performance. Unlike prior conversational dense retrieval approaches that learn direct conversation-to-passage matching, RCEM aligns conversations, prepended by special token, to LLM-rewritten queries, while attempting to preserve the original embedding space. The approximately preserved embedding space automatically maps the rewritten queries to the relevant passages. As a result, RCEM (1) reduces overfitting by aligning conversations to shorter rewritten queries rather than full passages, (2) eliminates the need for conversation-to-passage relevance labels for training, and (3) approximately preserves the original embedding space, enabling conversational retrieval over indexes built by the base embedder without re-indexing. Extensive experiments show that RCEM consistently outperforms prior approaches, improving up to 30% retrieval accuracy under distributional shift.

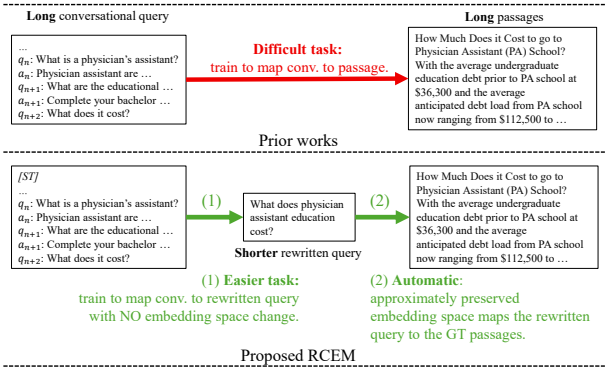

Figure 1: **Overview.** RCEM is trained to map conversational queries (prepended by a special token, *[ST]*) to LLM-rewritten queries and preserve its original embedding space, which naturally supports retrieval of relevant passages. During inference, *[ST]* triggers RCEM to implicitly convert a conversational query into a clear LLM-rewritten query and computes its embedding in one-step inference, without running an LLM model. Unlike prior methods that directly align long conversations with long passages, the simplified objective reduces overfitting. The approximately preserved embedding space makes RCEM compatible with existing indexes and only activates conversational search when the special token is presented. Otherwise, RCEM behaves similarly to the original embedder. Moreover, RCEM removes the need for expensive conversational query-to-passage relevance annotations for training, enabling greater scalability.

1 Introduction

Conversational search is a core component of retrieval-augmented generation (RAG) systems, where users interact with AI assistants through multi-turn dialogue rather than single queries. In this setting, queries are often context-dependent and omit previously stated information, making user inputs vague, ambiguous, or incomplete (Gao et al., 2023). Resolving such contextual dependencies is, therefore, essential for retrieving relevant passages and generating accurate responses.

A common approach is to first rewrite conversational queries into standalone queries using a large language model (LLM), which can then be embedded and used for dense retrieval. Recent advances in query reformulation have significantly improved retrieval accuracy in multi-turn settings (Mao et al., 2023b; Mo et al., 2023, 2024a; Lai et al., 2025a). These LLM-based pipelines, however, incur expensive generation cost at inference time, leading to high latency and computational cost, which limits its scalability in production. Conversational dense retrieval methods instead aim to generate embeddings directly from conversations, avoiding LLM calls at inference (Lin et al., 2021; Yang et al., 2025b). These approaches finetune embedders to align conversational queries with relevant passages, requiring high-quality relevance labels. Yet, map-

ping long conversational queries to long passages is an inherently challenging train objective, making the models prone to overfitting.

We propose RCEM, a **R**obust **C**onversational search **EM**bedder that *additionally* learns LLM-based query reformulation capability for conversational search, while preserving the original embedding space and generalization performance. Unlike prior conversational dense retrieval methods (Lin et al., 2021; Yang et al., 2025b), which directly map conversational queries to ground-truth passages, RCEM aligns conversational queries (prepended by a special token) with LLM-rewritten queries internally and generates their embeddings, while preserving the original embedding space. Because the embedding space is approximately preserved, the resulting embeddings naturally retrieve relevant passages. By aligning conversational queries to shorter LLM-rewritten queries rather than long passages, RCEM simplifies the learning task, reducing overfitting. Maintaining the original embedding space enables conversational retrieval on existing indexes built by original embedder, removing the need for index rebuilding. And conversational search is only triggered for inputs with the special token. Otherwise, the model behaves similarly to the original embedder which increases compatibility with existing search system. Furthermore, RCEM eliminates the expensive cost for high-quality conversational query-to-passage relevance annotations for training, improving scalability (See Figure 1). Extensive experiments show that RCEM consistently outperforms prior work, with particularly large gains under distributional shift.

2 Related Works

Existing conversational search approaches generally fall into two categories: conversational query reformulation (CQR) and conversational dense retrieval (CDR). CQR rewrites context-dependent conversational queries into standalone queries prior to sparse or dense retrieval, while CDR directly encodes conversational context into dense embeddings for retrieval.

Conversational Query Reformulation (CQR). Recent CQR research has focused on improving query reformulation quality through query expansion, intent preservation, ambiguity resolution, and retrieval-aware optimization. Mo et al. (2023) integrate generative query rewriting with potential answer generation for query expansion, while Mao et al. (2023a) introduce search-oriented conversational query editing to better preserve retrieval intent during reformulation. Mao et al. (2023b) further improve retrieval effectiveness by aggregating multiple query rewrites and their hypothetical responses into a single retrieval representation. Subsequent work enhances reformulation through more sophisticated generation pipelines, such as rewrite-then-edit strategies (Ye et al., 2023), ambiguity reduction in conversations prior to rewriting (Mo et al., 2024a), retrieval-aware training objectives that align reformulation with both sparse and dense retrieval (Lai et al., 2025b), and test-time adaptation methods that generate multiple candidate rewrites and select the most effective one for retrieval (Lai et al., 2025a). CQR approaches are modular and retriever-agnostic, allowing seamless integration with existing sparse and dense retrieval systems. They also naturally benefit from advances in LLMs and prompting techniques. However, they incur substantial cost and latency at inference due to repeated LLM calls, making large-scale deployment challenging.

Conversational Dense Retrieval (CDR). CDR methods directly encode conversational context into dense retrieval representations. Lin et al. (2021); Yang et al. (2025b) introduce contextualized query embeddings that incorporate conversation history for conversational retrieval by training to map conversational queries to the relevant passages. Subsequent research improves retrieval effectiveness through context-denoised representations and pseudo-supervision mined from historical turns (Mo et al., 2024b), generalized conversational retrieval models based on LLMs and dual-learning objectives (Mao et al., 2024), and methods that enhance interpretability by decoding dense conversational embeddings into human-readable queries while preserving retrieval performance (Cheng et al., 2024). These approaches benefit from end-to-end optimization and deep integration of conversational context into retrieval representations. However, existing CDR methods typically rely on contrastive training between conversational queries and relevant passages using high-quality conversation-to-passage relevance annotations. Acquiring such supervision is expensive and challenging, limiting scalability. Furthermore, training on relatively small conversational retrieval datasets can lead to overfitting, while contrastive

objectives may alter the original embedding space and reduce compatibility with existing retrieval systems. In contrast, RCEM eliminates the need for conversation-to-passage relevance supervision and explicitly attempts to preserve the original embedding space, improving generalization, scalability, and compatibility with existing retrieval infrastructures.

3 Proposed RCEM

We propose RCEM, a robust conversational search embedder that directly outputs an embedding for conversational search. Unlike conventional conversational search pipelines that rely on explicit LLM-based query rewriting during inference, RCEM intrinsically converts a conversational query into an LLM-rewritten query and generates an embedding of the rewritten query in a single step, which reduces inference computational cost and latency for conversational search. RCEM enables this by *additionally* injecting LLM query reformulation capability into the embedder while attempting to preserve the original embedder's capability. RCEM is described in detail in this section.

Setting. Let q_i denote the current query at dialogue turn i, and let $q_{<i}, a_{<i}$ denote the conversational history. Thus, the conversational query is $q_i; q_{<i}, a_{<i}$. Existing conversational search systems commonly use an LLM-based rewriter

$$r_i = LLM(q_i; q_{<i}, a_{<i}), \tag{1}$$

where r_i is an LLM-rewritten query suitable for retrieval. To distinguish conversational search from standard retrieval, we prepend a special token $[ST]$ to the conversational query,

$$c_i = [ST] : q_i; q_{<i} a_{<i}. \tag{2}$$

Embedder architecture. Two embedders are defined: RCEM $F_\theta(x)$ and the original embedder $G(x)$, where

$$F_\theta(x) = \mathrm{MLP}_{\mathrm{SELU}}(\mathrm{LoRA}(G(x))). \tag{3}$$

$F_\theta(x)$ is built on top of the frozen $G(x)$ with LoRA adapters and a lightweight two-layer perceptron head with SELU activation (Klambauer et al., 2017). The backbone parameters are initialized from $G(x)$, while only the LoRA adapters and the MLP head, parameterized with θ, are updated during training.

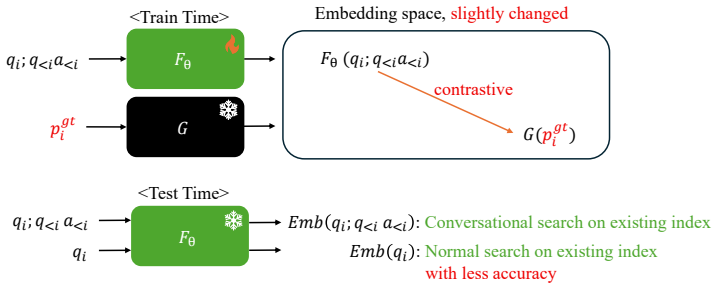
Structure Learning (SL). $F_\theta(x)$ is trained by minimizing the loss below,

$$\mathcal{L}(\theta) = \mathcal{L}_{\mathrm{point}}(\theta) + \lambda \mathcal{L}_{\mathrm{pair}}(\theta), \tag{4}$$

where

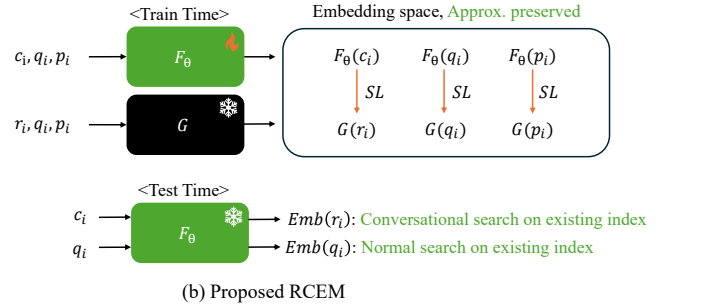
$$\mathcal{L}_{\mathrm{point}}(\theta) = \sum_{j=0}^{l+m+n} \left\| F_\theta(x_{j,1}) - G(x_{j,2}) \right\|, \tag{5}$$

$$\mathcal{L}_{\mathrm{pair}}(\theta) = \sum_{j=0}^{l+m+n} \sum_{k>j}^{l+m+n} \Big\| \|F_\theta(x_{j,1}) - F_\theta(x_{k,1})\| - \|G(x_{j,2}) - G(x_{k,2})\| \Big\|. \tag{6}$$



$x_{j,1}$ and $x_{j,2}$ are the first and second elements of the j-th pair in a set of pairs,

$$\Omega = \{(q_i, q_i)\}_{i=0}^{l} \cup \{(p_i, p_i)\}_{i=0}^{m} \cup \{(c_i, r_i)\}_{i=0}^{n}. \tag{7}$$



Ω consists of three subsets of matching pairs, l pairs of general queries (q_i) to themselves, m pairs of passages (p_i) to themselves, and n conversational queries prepended by $[ST]$ to their LLM-rewritten queries. The last set of matching pairs are for training RCEM to align a conversational queries prepended by the special token toward an LLM-rewritten queries, $F_\theta(c_i) \rightarrow G(r_i)$. This enables RCEM to learn the LLM-based rewriting capability and directly encode the conversational query into the embedding of the rewritten query without explicitly generating r_i during inference. The first two sets of pairs, $\{(q_i, q_i)\}_{i=0}^{l} \cup \{(p_i, p_i)\}_{i=0}^{m}$ are for preserving the embedding space. While distilling LLM's query rewriting capability into the embedder, RCEM also attempts to preserve the embedding space by mapping $F_\theta(q_i) \rightarrow G(q_i)$ and $F_\theta(p_i) \rightarrow G(p_i)$.

Unlike Yang et al. (2025b), which optimizes only pointwise embedding distances, RCEM also preserves pairwise structure during training. The hyperparameter λ controls the weight of the pairwise structure preservation term, and is set to 1.0 unless otherwise specified. Figure 2 provides an overview of RCEM and contrasts it with Lin et al. (2021). A more comparison between RCEM and Yang et al. (2025b) is presented in Appendix D.

This design offers several advantages. First, RCEM eliminates expensive LLM-based rewriting during inference, substantially reducing latency

(a) Lin et al.

(b) Proposed RCEM

G	: Original embedder frozen
F_θ	: RCEM, embedder trained from the original embedder
r_i	: $r_i = LLM(q_i; q_{<i} a_{<i})$, LLM-rewrite results given i-th query, q_i and prior conversations, $q_{<i} a_{<i}$
c_i	: $c_i = [ST]$: $q_i; q_{<i} a_{<i}$, Current i-th query, q_i and prior conversations, $q_{<i} a_{<i}$ with Special Token
q_i, p_i	: General queries and passages
p_i^{gt}	: Groundtruth passages to the conversational queries, $q_i; q_{<i} a_{<i}$

Figure 2: **RCEM overview and comparison with prior work.** RCEM first precomputes embeddings of the LLM-rewritten query, $r_i = LLM(q_i; q_{<i} a_{<i})$, as well as general queries q_i and passages p_i using the original frozen embedder G. RCEM F_θ is then trained to map conversational queries prepended by a special token, $F_\theta(c_i)$, to the embedding of the rewritten query produced by the frozen embedder $G(r_i)$ using the proposed Structure Learning (SL) loss. During training, RCEM also aligns general queries and passages with their precomputed embeddings, i.e., $F_\theta(q_i) \rightarrow G(q_i)$ and $F_\theta(p_i) \rightarrow G(p_i)$, to preserve the original embedding space. This design enables a single model to support both conversational search, triggered by the special token, and standard search over the index built by the original embedder. Attempting to preserve the embedding space also serves as a regularizer, making the model more robust to distributional shift. In contrast, Lin et al. (2021) trains the model to map the conversational query embedding $F_\theta(q_i; q_{<i} a_{<i})$ directly to the ground-truth passage $G(p_i^{gt})$, which is a more complicated training task, resulting in overfitting. Unlike Lin et al. (2021); Yang et al. (2025b), RCEM does not require conversational-to-passage relevance annotations for training, which are often difficult to obtain accurately. This makes RCEM more scalable, as it reduces the need for expensive and high-quality relevance annotations.

and computational cost. Second, RCEM does not require conversational-query-to-passage relevance supervision, making training more scalable. Finally, the approximately preserved original embedding space serves as a regularizer during training that increases robustness in distributional shift and remains compatible with existing indexes built by the original embedder.

4 Experiments

Experiment setting. To evaluate RCEM, we use widely adopted conversational search benchmarks: QReCC (Anantha et al., 2021), TopiOCQA (Adlakha et al., 2022), and TREC CAsT (Dalton et al., 2020, 2021). QReCC and TopiOCQA provide both train and test splits, whereas TREC CAsT is primarily used for zero-shot evaluation. QReCC contains approximately 14K conversations and 80K question-answer pairs, with retrieval performed over a corpus of roughly 54M passages. TopiOCQA comprises 3.9K conversations and 51K question-answer pairs, paired with a corpus of approximately 25M passages. Together, these benchmarks enable evaluation of RCEM in both in-domain and distribution-shifted conversational retrieval settings. For consistency with prior work (Lai et al., 2025a; Yang et al., 2025b; Lin et al., 2021), we report Recall@10, MRR, and NDCG@3 using `pytrec_eval` (Van Gysel and de Rijke, 2018).

We compare RCEM against state-of-the-art CDR (Lin et al., 2021; Yang et al., 2025b) and

Type	Method	QReCC			TopiOCQA		
		R@10	MRR	NDCG@3	R@10	MRR	NDCG@3

Proposed RCEM		QReCC	86.5	64.3	39.3
Lin et al. (2021)		TopiOCQA	79.8	52.1	26.4
Proposed RCEM		TopiOCQA	**88.0**	**68.1**	**39.5**

Table 2: **Retrieval accuracy comparison in distributional shift.** Models are trained on one dataset and evaluate them on another. The proposed RCEM method maintains strong performance under distributional shift, whereas the performance of Lin et al. (2021) drops noticeably. In particular, when trained on QReCC and tested on TREC CAsT 2019, RCEM achieves $\sim 30\%$ higher MRR than Lin et al. (2021).

CQR (Mo et al., 2023; Mao et al., 2023b; Mo et al., 2024a; Lai et al., 2025b,a) methods. Unless otherwise specified, both RCEM and Lin et al. (2021) use Qwen3-8B (Yang et al., 2025a) as the original embedder. RCEM uses GPT-4.1 to generate rewritten queries for training with a simple query-rewriting prompt (Appendix B). For a fair comparison, we also evaluate a Query Rewrite $\rightarrow$ Embedding pipeline using the same LLM (prompt) and embedding model as RCEM. All models are trained with a batch size of 32 on eight H100 GPUs. Unlike prior methods (Lin et al., 2021; Yang et al., 2025b), RCEM does not require conversation-to-passage relevance labels for training in any of the experiments. Additional implementation details are provided in Appendix E.

In domain experiments. We conduct in-domain evaluations on the QReCC and TopiOCQA datasets. For a fair comparison with Lin et al. (2021), we keep the experimental setup largely identical, including the hardware configuration, adaptation architecture, and number of training epochs. The primary difference lies in the training objective. We also compare against a Query Rewrite $\rightarrow$ Embedding baseline that uses the same GPT-4.1 query rewriter and Qwen3-8B embedder as RCEM. As shown in Table 1, RCEM consistently outperforms prior methods, achieving $\sim 10\%$ and $\sim 13\%$ higher MRR than Lin et al. (2021) and Yang et al. (2025b) on QReCC, respectively.

Notably, RCEM also surpasses the Query Rewrite $\rightarrow$ Embedding baseline despite using the same LLM and embedding models, which hypo-

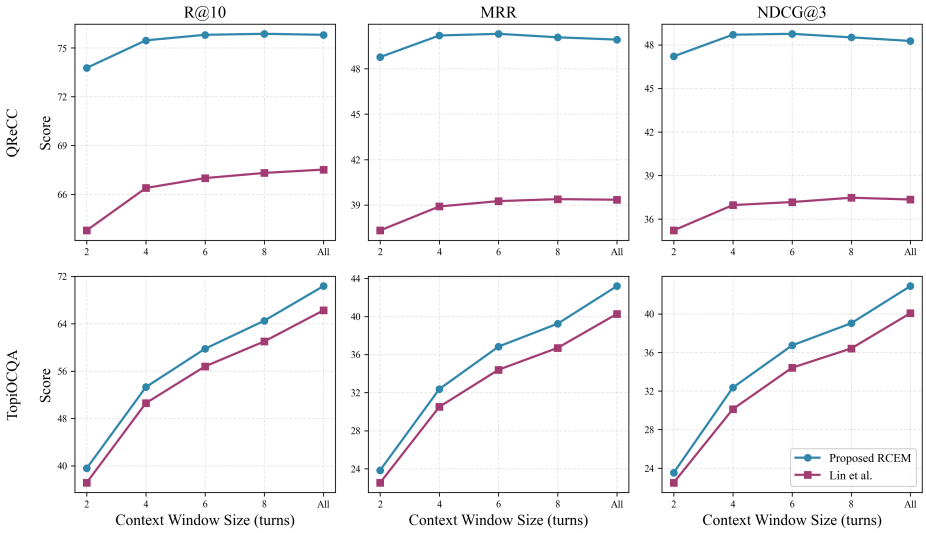

Figure 3: **Accuracy comparison VS context window size.** On the TopiOCQA benchmark, the retrieval accuracy of RCEM improves more with additional conversational turns, suggesting that RCEM is more effective at identifying and leveraging relevant information from long conversation histories.

thetically suggests that treating the rewritten query as an intermediate textual representation may introduce information loss. In contrast, RCEM directly aligns conversational queries with the embedding representation of rewritten queries, producing a more faithful and effective retrieval representation.

Distributional shift experiments. In the distribution-shift experiments, Lin et al. (2021) exhibits substantial performance degradation, whereas RCEM remains robust under distribution shift. Table 2 reports retrieval performance when models are trained on one dataset and evaluated on another under an identical experimental setup. RCEM consistently outperforms both Lin et al. (2021) and the Query Rewrite $\rightarrow$ Embedding baseline across all dataset combinations and evaluation metrics. In particular, when trained on QReCC and evaluated on TREC CAsT 2019, Lin et al. (2021) performs substantially worse than RCEM, with accuracy gaps often ranging from 10% to 30%. Similar trends are observed when the same experiments are conducted using a smaller base embedder, Qwen3-0.6B (Appendix C).

This performance degradation is likely attributable to the contrastive objective used by Lin et al. (2021), which directly aligns long conversational queries with long passages. Such a learning objective is inherently more complex and can cause the model to overfit to the training dataset. In contrast, RCEM maps conversational inputs to shorter rewritten queries, providing a simpler learning target while preserving the original embedding space. Attempting to preserving the embedding space also acts as an effective regularizer, improving robustness to distribution shift.

Accuracy VS context window. We further conduct an ablation study to examine the impact of conversational history length on retrieval performance. Figure 3 shows that RCEM consistently outperforms Lin et al. (2021) across different context window sizes, with accuracy gains increasing as more conversational history is provided. In particular, RCEM benefits more from longer contexts on TopiOCQA, suggesting that it is better able to capture and leverage salient information distributed across multi-turn conversations.

Structure learning vs L_2. A key differentiator of RCEM from Yang et al. (2025b) is the proposed Structure Learning (SL) loss, which preserves both pointwise embedding similarity and pairwise structure during training. Table 4 shows that the SL loss consistently achieves better retrieval performance than the L_2 loss used in Yang et al. (2025b) on both QReCC and TopiOCQA.

Approximately preserving original embedding space. Figure 4 shows whether RCEM preserves the original embedding space. Specifically, we encode general queries (the GT rewrites query in QReCC) using RCEM and perform dense retrieval over a QReCC index built by the original embedder. We then compare the retrieval accuracy of

Type	Method	R@10	MRR	NDCG@3	Latency
CQR	AdaRewriter, $N = 16$ (Lai et al., 2025a)	69.8	47.5	44.7	3,656 ms
CQR	Query Rewrite (GPT-4.1) with baseline prompt → Embedding	73.3	47.3	45.4	1,275 ms
CQR	Query Rewrite (GPT-4.1) with Mao et al. (2023a) → Embedding	75.1	49.3	47.5	2,495 ms
CDR	Lin et al. (2021)	67.5	39.3	37.4	69 ms
CDR	Proposed RCEM with baseline prompt	75.8	49.9	48.3	69 ms
CDR	Proposed RCEM with Mao et al. (2023a)	**78.1**	**52.3**	**50.8**	69 ms

Table 3: **Effect of rewrite quality on RCEM and latency.** When RCEM is trained with a stronger query rewriting method (Mao et al., 2023a), retrieval accuracy on QReCC dataset is better than baseline prompt setting, while maintaining the latency in inference.

Benchmark	Loss	R@10	MRR	NDCG@3
QReCC	SL	**75.8**	**49.9**	**48.3**
	L_2	74.4	47.2	45.2
TopiOCQA	SL	**70.4**	**43.2**	**42.9**
	L_2	53.9	30.4	29.7

Table 4: **Loss comparison.** Structural Learning (SL) loss proposed in RCEM consistently better performs than L_2 loss used in Yang et al. (2025b) on both QReCC and TopiOCQA datasets.

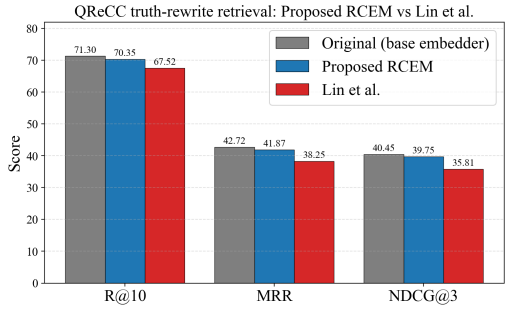

Figure 4: **Approximately preserving original embedding space.** General query is embedded by RCEM and run retrieval on index built from the original embedding. RCEM better preserves retrieval accuracy than Lin et al. (2021) compared with the original embedder. The experiment is performed with Qwen3-0.6B base embedder.

RCEM against the original embedder and Lin et al. (2021). The results show that RCEM experiences a small performance drop compared to the original embedder, whereas Lin et al. (2021) suffers a larger degradation. We attribute this difference to the fact that Lin et al. (2021) does not explicitly preserve the original embedding space during training.

Effect of better rewrite quality and latency. Table 3 compares RCEM with the Query Rewrite → Embedding baseline on QReCC using either a simple prompting strategy or a stronger query rewriting method (Mao et al., 2023a). The improved rewriting method enhances the retrieval accuracy of both approaches, indicating that rewrite quality has a direct impact on retrieval effectiveness. Nevertheless, RCEM consistently outperforms the two-step pipeline under the same rewriting strategy. Notably, RCEM uses query rewriting only during training so that better prompting strategy adds up better retrieval accuracy with inference latency unchanged. In contrast, the two-step baseline requires query rewriting at inference time, meaning that improved rewrite quality often comes at the cost of higher computational overhead and increased latency.

Table 3 also compares inference latency. In general, conversational dense retrieval (CDR) methods exhibit lower latency than conversational query reformulation (CQR) methods because CDR do not require LLM calls during inference. RCEM achieves latency comparable to existing CDR methods while delivering higher accuracy than both CDR and CQR baselines. Additional details on computational cost are provided in Appendix A.

5 Conclusion

We present RCEM, a conversational search embedder that implicitly maps conversational queries to LLM-rewritten queries and generates their embeddings without requiring explicit LLM-based query rewriting during inference. Unlike prior methods that address the challenging task of directly aligning long conversational contexts with long passages, RCEM maps conversational queries to shorter LLM-rewritten queries while attempting to preserve the original embedding space, thereby improving generalization and remaining compatible with existing retrieval indexes built by the original embedder. In addition, RCEM does not require expensive conversation-to-passage relevance supervision. Extensive experiments demonstrate that RCEM achieves strong retrieval accuracy and improved robustness under distribution shift while substantially reducing inference latency.

Limitations

The primary limitation of RCEM lies in the LLM's query rewriting capability, as the model is designed to distill LLM-based rewriting behavior into the embedder. Although the results in Table 1 show that RCEM consistently outperforms the two-step pipeline (Query Rewrite → Embedding), hypothetically because it learns a richer latent representation than explicit rewritten text, its accuracy still depends on the quality of the rewritten queries. As shown in Table 3, stronger query rewriting methods lead to higher retrieval accuracy for RCEM. Therefore, further improvements in query rewriting, such as incorporating advanced rewriting techniques (Lai et al., 2025a) or leveraging multiple query rewrites as additional conversation-to-rewrite training pairs, could further enhance RCEM's retrieval accuracy.

Type	Method	Latency	Cost/1M Qry.	MRR
CQR	Query Rewrite (GPT4.1) → Embedding (Qwen3-8B)	1,275 ms	$570.4	47.3
CQR	Query Rewrite (GPT4.1) + Mao et al. (2023a) → Embedding (Qwen3-8B)	2,495 ms	$840.4	49.3
CQR	AdaRewriter, $N = 16$ (Lai et al., 2025a) (Llama-3.1-8B)	3,656 ms	$20.8	47.5
CDR	Lin et al. (2021) (Qwen3-8B)	69 ms	$1.77	39.3
CDR	Yang et al. (2025b) (Qwen2.5-7B)	**41 ms**	$1.77	36.8
CDR	Proposed RCEM (Qwen3-8B)	69 ms	$1.77	49.9
CDR	Proposed RCEM + Mao et al. (2023a) (Qwen3-8B)	69 ms	$1.77	**52.3**

Table 5: **Inference efficiency and accuracy on QReCC.** Latency, estimated recurring serving cost, and retrieval performance for conversational query reformulation (CQR) and conversational dense retrieval (CDR) methods.

A Latency and Computational Cost Analysis

We evaluate inference latency and estimate recurring serving cost in Table 5. Following Yang et al. (2025b), latency is measured over the complete QReCC test set including all conversations. NVIDIA H100 GPU is used for the evaluation. We use the following public serving prices:

- GPT-4.1: $2 per million input tokens and $8 per million output tokens from Azure OpenAI Service pricing[1] (accessed August 2, 2026).
- Llama-3.1-8B-Instruct: $0.02 per million input tokens and $0.04 per million output tokens from OpenRouter (DeepInfra)[2] (accessed August 2, 2026).
- Qwen2.5-7B-Instruct: $0.01 per million tokens from OpenRouter (Phala)[3] (accessed August 2, 2026).
- Qwen3-Embedding-8B: $0.01 per million input tokens from OpenRouter (DeepInfra)[4] (accessed August 2, 2026).

RCEM achieves higher retrieval accuracy than existing CDR methods while maintaining comparable latency and serving cost. Compared with the Query Rewrite → Embedding pipeline, RCEM reduces latency from $1,275$ ms to 69 ms and lowers the estimated serving cost from $\$570.4$ to $\$1.77$ per million queries, while improving MRR from 47.3 to 49.9. RCEM also outperforms Lai et al. (2025a) in retrieval accuracy while requiring substantially lower latency and serving cost.

Stronger offline query rewriting methods (Mao et al., 2023a) further improve RCEM's MRR from 49.9 to 52.3 without increasing inference latency or serving cost. This is possible because the improved query rewriting is used only during offline training-data generation and is never invoked at inference time.

B Baseline Prompt

We use a simple prompt to convert each conversational query into a rewritten query for generating the training dataset, as shown below:

```
Given the recent conversation:
{conversation_history}

Rewrite the following ambiguous query
into a self-contained and more clear query.

This is the ambiguous query:
{query}
```

We enforce GPT4.1 to follow schema to reject redundant output token such as

```
The rewritten query is ...
The clear query is ...
```

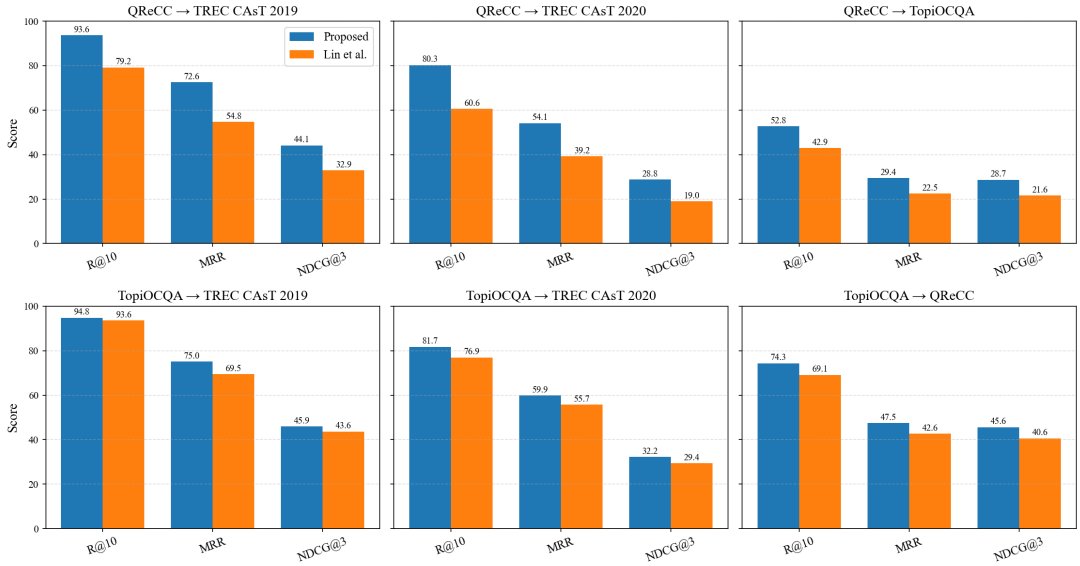

Figure 5: **Retrieval accuracy comparison in distributional shift with 0.6B Qwen3 base embedder**: We train the models on one dataset and evaluate them on another under the same experimental setup to ensure a fair comparison. The proposed RCEM method maintains strong performance under distributional shift, whereas the performance of Lin et al. (2021) drops noticeably. In particular, when trained on QReCC and tested on TREC CAsT 2020, RCEM achieves approximately 20% higher Recall@10 than Lin et al. (2021). Across all dataset combinations and evaluation metrics, RCEM consistently outperforms Lin et al. (2021).

λ	R@10	MRR	NDCG@3
0	53.9	30.4	29.7
0.25	69.8	42.2	41.8
0.5	69.9	42.4	42.2
1.0	**70.4**	**43.2**	**42.9**
2.0	68.8	42.1	41.7
4.0	57.9	33.5	33.2

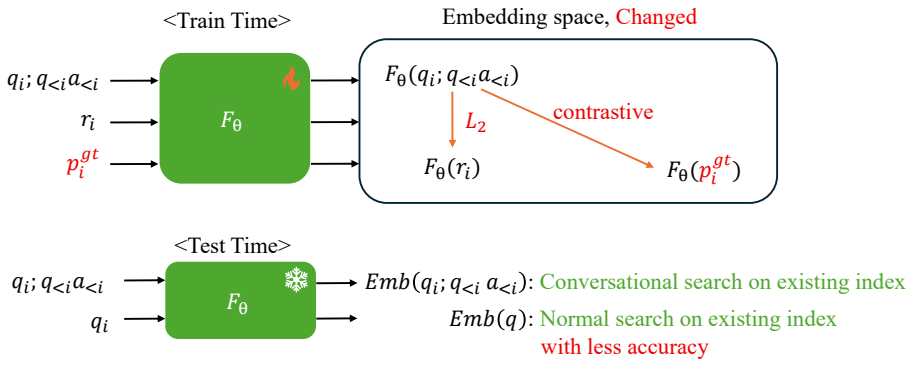

Table 6: **Sensitivity to the structure-learning weight.** TopiOCQA retrieval performance as the pairwise structure-preservation weight λ varies. The setting used in the main experiments is shown in bold.

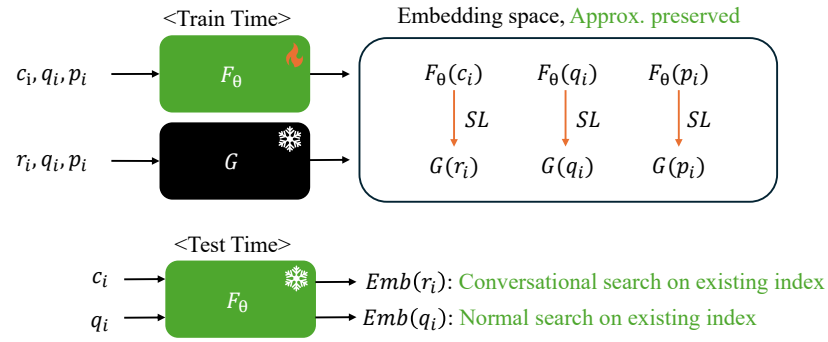
C More Experiments



We perform the distributional shift experiments with 0.6B Qwen3 base model. The proposed RCEM method maintains strong performance under distributional shift, whereas the performance of Lin et al. (2021) drops noticeably wtih 0.6B Qwen3 base model experiments. See Figure 5.

We analyze the sensitivity of RCEM to λ, which controls the weight of the pairwise structure preservation objective relative to the pointwise alignment objective. Table 6 reports retrieval performance on TopiOCQA. Performance remains stable over the broad range $\lambda \in [0.25, 2.0]$: R@10 varies by only 1.5 points, MRR by 1.1 points, and NDCG@3 by 1.2 points. The value used in the main experiments, $\lambda = 1.0$, achieves the best result on all three metrics.

The extreme settings further clarify the role of pairwise structure preservation. Setting $\lambda = 0$ removes the pairwise objective and reduces R@10, MRR, and NDCG@3 by 16.5, 12.8, and 13.2 points, respectively, relative to $\lambda = 1.0$. Conversely, $\lambda = 4.0$ overemphasizes pairwise geometry at the expense of pointwise conversational-to-rewrite alignment. These results indicate that pairwise structure preservation is important, while RCEM is not sensitive to moderate choices around the selected value.

(a) Yang et al.

(b) Proposed RCEM

G	: Original embedder frozen
F_θ	: RCEM, embedder trained from the original embedder
r_i	: $r_i = LLM(q_i; q_{<i}a_{<i})$, LLM-rewrite results given i-th query, q_i and prior conversations, $q_{<i}a_{<i}$
c_i	: $c_i = [ST]: q_i; q_{<i}a_{<i}$, Current i-th query, q_i and prior conversations, $q_{<i}a_{<i}$ with Special Token
q_i, p_i	: General queries and passages
p_i^{gt}	: Groundtruth passages to the conversational queries, $q_i; q_{<i}a_{<i}$

Figure 6: **RCEM, comparison with prior work.** Different from RCEM, Yang et al. (2025b) trains the model to map the conversational query embedding $F_\theta(q_i; q_{<i}a_{<i})$ directly to the ground-truth passage $G(p_i^{gt})$ with contrastive loss and also maps to rewritten query $F_\theta(r_i)$ with L_2 loss. Yang et al. (2025b) requires conversational queries and relevant passages for their training. Because Yang et al. (2025b) does not use embeddings produced by the original encoder G as training anchors, the learned representations can drift from the original embedding space. This embedding-space shift may degrade compatibility with existing document indexes encoded by G, whereas RCEM is designed to preserve embedding-space compatibility while adapting conversational queries.

D More Comparison with Prior Works

We compare RCEM with Yang et al. (2025b) in this Section. See Figure 6 for more details.

E More Implementation Details

RCEM is trained using the Unsloth training framework (AI, 2024). The head projects the base embedding into an intermediate representation of size 3×1024, followed by a projection back to the 1024-dimensional embedding space. Note that we only use the first 1024 embeddings from the base model. We use LoRA rank=32 and apply adapters to all attention and feed-forward projection layers, including `q proj`, `k proj`, `v proj`, `o proj`, `gate proj`, `up proj`, and `down proj`. Training is performed with the Adam optimizer using a learning rate of 3×10^{-4}, no weight decay, and a cosine learning-rate schedule with a warmup ratio of 0.1. To preserve compatibility with the original retrieval embedding space, we jointly optimize the embedding preservation objective using a randomly sampled 1% subset of passages, standalone queries, and conversational queries from the training data.

PROOF-Gen: From Optimized Data to Better Distillation

Apple
{atta, jason.zhu, shn}@apple.com

Abstract

Supervised fine-tuning on teacher-generated trajectories is the standard first stage for distilling tool-calling capabilities into deployable models. Post-training pipelines that drive shipped tool-calling agents re-run this stage on a daily or weekly cadence, paying the frontier-teacher cost each cycle, yet the mechanism is generate-and-filter (keep the teacher's passing trajectories, discard the rest) and each cycle leaves behind the same hard scenarios because failures supply no signal. On τ2-bench, 57% of teacher trials fail, two-thirds of them *near-misses* (most tool calls correct, undone by one decisive error).

We introduce PROOF-Gen (Per-scenario Reflective Optimization to Overcome Failed Generation), which recovers golden trajectories from these failures via per-scenario prompt optimization. For each failed task, a reflector analyzes the execution trace and evaluation feedback, then writes corrective guidance that steers the teacher to a passing trajectory. The guidance is stripped before training, so the student learns from clean demonstrations with no task-specific scaffold.

On τ2-bench, per-scenario optimization recovers 93% of failed scenarios. Fine-tuned on the combined data, Qwen3-4B-Instruct-2507 improves from Pass^1=0.132 to 0.529 and Gemma 4 E4B-it gains +7.2pp on BFCL v4 multi-turn. In a deployed pipeline, the method lifts trajectory quality by +6.3pp goal completion and transfers to a deployed on-device model (+1.5pp goal completion; +1.7 to +5.0pp across response-quality metrics), with positive transfer in every locale (non-English average +1.48pp).

1 Introduction

Distillation via supervised fine-tuning (SFT) is the dominant first stage for transferring capabilities from frontier models to the smaller, deployable models that drive tool-calling agents in production (Agarwal et al., 2024; Li et al., 2025; Luo et al., 2026). Post-training cycles run on a daily or weekly cadence to absorb new scenarios, tools, and policies; every cycle pays the same frontier-teacher cost, and every cycle leaves behind the same hard scenarios, because the standard generate-and-filter mechanism (run the teacher, score with a verifier, keep the passing trajectories) extracts no signal from failures. Recent advances in the training algorithm (on-policy sampling, alternative divergences, partial supervision; Agarwal et al. 2024; Luo et al. 2026; Amani et al. 2026), data selection (Li et al., 2025), and trajectory structure (Jiang et al., 2026) all rest on a shared assumption: the teacher can produce correct demonstrations for the tasks that matter.

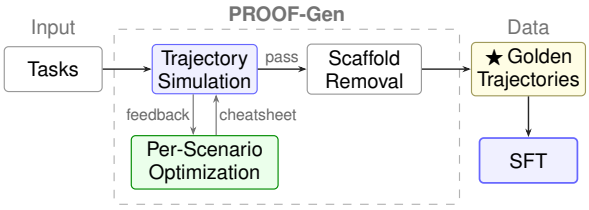

Figure 1: Training pipeline. For each task the teacher originally failed, a per-scenario optimization loop (green) iteratively refines a cheatsheet from the trajectory's feedback until the teacher produces a passing ("golden") trajectory. The cheatsheet is stripped at scaffold removal, so the student trains only on what the trajectory demonstrates; the fine-tuning procedure is otherwise unchanged.

But Chu et al. (2025) show that SFT tends to memorize its training distribution rather than generalize beyond it. If the hardest scenarios are systematically absent from that distribution, no training algorithm or selection strategy can compensate; the ceiling on distillation quality is set upstream, at data generation time.

In settings with execution-based verification, the standard pipeline (Chen et al., 2023; Liu et al., 2024) is generate-and-filter: execute the teacher,

EMNLP 2026 Industry Track, pages 2844–2864
October 24-29, 2026 ©2026 Association for Computational Linguistics

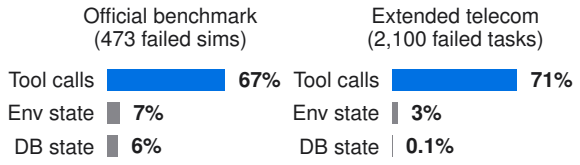

Figure 2: The accuracy asymmetry in failed GPT-4o trajectories on τ2-bench (278 tasks, 3 trials each; 473 of 834 trials fail). Most failures execute over half of tool calls correctly (high tool-call accuracy), yet a single missed action cascades into an incorrect end state (environment and database failure). Because tool-call accuracy is already high in failures, turn-level or partial-credit signals saturate without lifting end-to-end completion; what is missing is a complete trajectory through the decisive step. We confirm this in Section 4.

score with a verifier, and keep passing trajectories (rejection sampling; Yuan et al. 2023; STaR; Zelikman et al. 2022; ReST; Gulcehre et al. 2023). The filter is binary; a trajectory that completed all but one of its required actions is discarded identically to one that failed immediately, so hard cases produce no training signal. On τ2-bench, 67% of failed GPT-4o trajectories execute over half of the required tool calls correctly, yet a single missed action cascades into full failure and the entire trajectory is discarded (Figure 2).

This asymmetry also explains why turn-level alternatives to binary filtering are insufficient. The natural response to discarding a near-complete trajectory is to award partial credit for the actions it got right. But Figure 2 shows tool-call accuracy is already high in failures; rewarding correct intermediate actions reinforces behavior the teacher already exhibits. What the student never observes is a complete trajectory that navigates the single decision point where the teacher fails. We confirm this empirically in Section 4: training on the partial-credit baseline (the filtered-only condition) lifts tool-call accuracy by 25pp but does not improve end-to-end task completion in any model–benchmark pair.

Likewise, sampling more, raising temperature, or running k-shot rejection recovers stochastic failures but not strategic ones: a single missed action at a state-dependent decision point survives any number of resamples from the same teacher.

We introduce Per-scenario Reflective Optimization to Overcome Failed Generation (PROOF-Gen), which brings prompt optimization into this pipeline but inverts its usual goal: instead of finding one prompt that generalizes across tasks, we optimize each scenario independently (Figure 1). Using GEPA (Agrawal et al., 2026), an iterative prompt optimizer, we analyze each failed execution trace and evaluation feedback, then add corrective instructions to a per-scenario *cheatsheet* appended to the teacher's system prompt. The teacher re-executes the task from scratch, and the process repeats until all evaluators pass. The cheatsheet is stripped before training (Figure 1); the student learns from what the trajectory demonstrates, not from the scaffold that produced it. The method applies to any domain with an executor and a verifier.

This design also yields *capability–voice decoupling*: because the executor is left unchanged, recovered trajectories inherit a stronger reflector's problem-solving without its interaction style. The resulting distillation is *voice-preserving*, letting a team upgrade task coverage without disrupting an established product voice, latency profile, or tone (Section 4).

We organize our investigation around three questions: whether per-scenario optimization reliably recovers high-quality trajectories from teacher failures (**RQ1**); whether students trained on recovered trajectories outperform those trained on filtered-only data, the partial-credit baseline (**RQ2**); and whether the approach holds up beyond benchmarks under deployment-scale evaluation across tens of locales (**RQ3**). We address each in turn in Section 4.

We conduct our primary study on τ2-bench (Barres et al., 2025), a stochastic multi-turn tool-calling benchmark, with additional experiments on BFCL v4 multi-turn (Patil et al., 2025). The teacher is GPT-4o, whose low pass rate on the official benchmark[1] leaves substantial room to validate recovery. Two small instruction-tuned models fine-tuned on recovered data improve on both benchmarks, and the pipeline has been adopted within a production tool-calling agent post-training system; we report all three settings in Section 4.

2 Method

PROOF-Gen adds one step to the standard generate-and-filter pipeline: it recovers the trajectories that filtering discards. As usual, the teacher generates one trajectory per task and we

[1] https://llm-stats.com/models/compare/gpt-4o-2024-08-06; GPT-4o scores 23.5% on telecom, 45.5% airline, 63.4% retail.

keep the passing ones (the *filtered* set). For each *failed* task, we then optimize a disposable, per-scenario prompt until the teacher succeeds, strip that prompt, and add the recovered trajectory to the training set (Figure 1). The student is fine-tuned on the union of filtered and recovered trajectories.

Per-scenario recovery. A reflector model reads the failed execution trace and the verifier's feedback (which dimensions failed, and on which assertions), then writes a *cheatsheet*: a block of natural-language guidance appended to the teacher's system prompt for that one task. The teacher re-executes from scratch; if it now passes every evaluator the trajectory is kept, otherwise the reflector revises the cheatsheet and the teacher tries again, up to $K{=}10$ iterations (each iteration sees the latest trace and feedback, and the cheatsheet accumulates the diagnoses so far). We use GEPA (Agrawal et al., 2026) as the optimizer, though any prompt optimizer would serve. This inverts the usual goal of prompt optimization: rather than searching for one prompt that generalizes across inputs, we overfit a prompt to a single scenario and discard it. The cheatsheet is the means; the passing trajectory is the product. Its guidance is procedural (e.g., the order of diagnostic tool calls), not task-specific values (Figure 11). Scenarios still unsolved after K iterations are discarded; recovery rates are reported in Section 4.

Scaffold removal. The cheatsheet is appended with a fixed delimiter and deleted before training, so recovered trajectories are indistinguishable from filtered ones and the student never sees per-scenario scaffolding. Any gain after fine-tuning therefore reflects what the trajectories demonstrate, not the prompt that produced them; we confirm the cheatsheets supply guidance rather than answers in Section B.1.

Configurable objective. Because the reflector hill-climbs on whatever the verifier reports, the same loop can target any combination of evaluable quality dimensions (e.g., groundedness, brevity, formatting), not only task completion; we use this in the production setting (Section 4).

3 Experimental Setup

We evaluate on two public benchmarks whose structure mirrors production tool-calling post-training systems: scenarios define user requests, execution-based evaluators serve as quality checks, and a teacher model generates candidate trajectories. The key differences in production are scale (thousands of scenarios with longer trajectories), multi-objective optimization (multiple evaluators must pass simultaneously), and continuous training (daily data ingestion and retraining); we address these in Section 4.

	τ2-bench	BFCL v4
Eval tasks	114	240
User simulation	Stochastic	Deterministic
Primary metric	Pass^1	Task accuracy
Secondary metric	Partial reward	Partial reward

Table 1: Benchmark comparison. τ2-bench uses an LLM user simulator; BFCL uses pre-scripted user turns.

Benchmarks. τ2-bench (Barres et al., 2025) simulates multi-turn customer service interactions with an LLM user simulator, making evaluation stochastic. We use the telecom domain (2,285 tasks, $\sim$50 tools) for primary experiments: it has the largest task space and the lowest pass rate under generate-and-filter (7.3%), maximizing the number of failures available for recovery (RQ1). The split is at the task level: 114 held-out base tasks form the evaluation set and the 2,171 non-base tasks are used for training, with no task instance shared. Because τ2-bench tasks are parameterized from templates, train and eval may instantiate shared templates with different parameters; we do not enforce template-level disjointness (Appendix J). BFCL v4 multi-turn (Patil et al., 2025) evaluates function-calling across 162 functions with deterministic (pre-scripted) user turns, spanning four categories that test distinct failure modes (Appendix L). Each category contains 200 tasks (800 total); we apply a per-category 70/30 split, giving 560 training and 240 held-out test tasks. We include BFCL to confirm that downstream gains (RQ2) generalize beyond a single stochastic benchmark. Table 1 summarizes both.

Models. We fine-tune two small instruction-tuned models at comparable effective scale: Gemma 4 E4B-it (Google DeepMind, 2026) (4.5B effective parameters) and Qwen3-4B-Instruct-2507 (Yang et al., 2025) (4B parameters). They differ in architecture and tool-call format, so improvements on both suggest the approach is not model-specific (Appendix I). The teacher is GPT-

	τ2-bench telecom	BFCL v4 multi-turn
Generate-and-filter (teacher)		
Training pool (tasks)	2,171	560
Filtered (passed)	158	296
Failed	2,013	264
Teacher pass rate	7.3%	52.9%
Per-scenario recovery		
Failures sent to optimizer	300	264
Recovered	279	89
Recovery rate	93.0%	33.7%
Combined training set (trajectories)		
Total (filtered + recovered)	437	385
From recovery	64%	23%

Table 2: Data-generation pipeline for both benchmarks. The teacher is GPT-4o (temperature 0, one trajectory per task). Telecom recovery runs on a 300-failure sample of the 2,013 failures; all 264 BFCL failures are attempted. Recovery rate = recovered / failures sent to optimizer. The combined set merges filtered and recovered trajectories; "from recovery" is the recovered fraction of that set.

4o;[2] the primary reflector is GPT-5.1 for τ2-bench and GPT-5.4 for BFCL (both at high reasoning effort); each is the strongest reflector available when that benchmark was run.

Data generation. GPT-4o generates one trajectory per task at temperature 0. Table 2 summarizes the resulting pipeline for both benchmarks. The teacher pass rate differs sharply (7.3% on telecom vs. 52.9% on BFCL), and the recovery rate scales inversely with it: per-scenario optimization recovers 93.0% of attempted telecom failures but 33.7% on BFCL, where the teacher already solves the easier tasks and only the hardest failures remain. Telecom yields 2,013 failures, so we attempt recovery on a fixed random sample of 300, keeping teacher-passing trajectories a meaningful share of the combined set (36%); BFCL yields only 264, small enough to attempt in full. Full per-category counts and train/test splits are in Appendix J.

Training. QLoRA (Dettmers et al., 2023) for 3 epochs on both models. Hyperparameters are in Appendix E.

Evaluation. End-to-end task success is the primary metric. τ2-bench evaluates along three programmatic dimensions (action, environment, and database; defined in Appendix A.1), with telecom using environment assertions as the pass/fail criterion. We run 3 trials at temperature 0; Pass^1 is the fraction of tasks passing at least once. At temperature 0 the agent decodes deterministically; the 3 trials average over the LLM user simulator and vLLM serving non-determinism. BFCL reports task accuracy and turn-level partial reward. Sampling robustness is tested at temperature 1 on flip tasks (Zhai et al., 2026).

4 Results

We organize our results around three research questions:
RQ1: Does PROOF-Gen reliably recover high-quality trajectories from teacher failures?
RQ2: Do models trained on recovered trajectories outperform those trained on filtered-only data?
RQ3: Does PROOF-Gen scale to production systems that continuously do SFT retraining on large-scale datasets with multiple objectives?

RQ1: Recovery effectiveness. At production scale, per-scenario optimization recovers 93% of sampled telecom failures (279 of 300; GPT-4o executor, GPT-5.1 reflector; Table 3); 264 (88%) are driven by the optimized cheatsheet and 15 by stochastic replay of the user simulator. We report the inclusive 93% as the headline rate and the cheatsheet-attributable 88% where the mechanism is the focus. Recovery is driven by reflector capability: on a cross-domain ablation set of 82 failures spanning all three τ2-bench domains, it ranges from 24.4% (GPT-4o self-reflection) to 97.6% (GPT-5.1; Figure 3). Convergence is fast: 58.7% of cheatsheet-driven recoveries resolve on the first iteration and 84.1% by the third (Figure 6). Even GPT-5.1 at maximum reasoning budget benefits from one reflection step (83.3% $\rightarrow$ 98.3% on the 300 telecom tasks; Table 3). Recovered trajectories constitute 64% of the combined τ2-bench training set; on BFCL, 23%. The cheatsheet changes what the teacher does, not how it communicates (Section 4). Integrity audits confirm no factual leakage (Section B.1).
Details: Appendix A (recovery rates, convergence, frontier comparison); Appendix B (data quality audit, response complexity).

RQ2: Downstream impact. The filtered-only condition is the partial-credit baseline: it trains on exactly the turn-level signal that is already high in failures (Figure 2). As predicted, filtered-only training improves partial metrics (action accuracy +25pp) but does not improve task com-

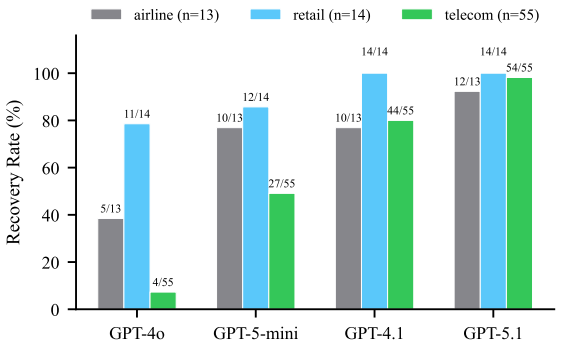

Figure 3: Reflector capability dominates recovery rate (range 24.4%–97.6%). Per-scenario recovery by reflection model on a cross-domain ablation set of 82 failed τ2-bench scenarios (13 airline, 14 retail, 55 telecom), holding the executor (GPT-4o) and optimizer fixed. GPT-5.1 recovers 80/82 (97.6%) versus 20/82 (24.4%) for GPT-4o self-reflection; the largest gap is on telecom (54/55 vs. 4/55). This ablation isolates the effect of reflector capability and is not the source of the production-scale headline rate (93%, 279/300 telecom).

pletion in any of the four model–benchmark pairs (Figure 4); raising intermediate-action accuracy is not sufficient when the missing signal is a complete trajectory through the decision point. Combined training produces the only consistent gains: Qwen3-4B-Instruct-2507 (Yang et al., 2025) improves from Pass^1=0.132 to 0.529 on τ2-bench; Gemma 4 E4B-it (Google DeepMind, 2026) gains +7.2pp on BFCL. The recovered trajectories cover tasks the teacher failed without the cheatsheet (GPT-4o scores 0.205 on these tasks); produced by GPT-4o under a stronger reflector, they let the student inherit problem-solving the base teacher does not exhibit on its own. Gains persist under stochastic sampling at temperature 1: on flip tasks (post-hoc selected where fine-tuning helped at temp=0; n=46 Qwen, n=21 Gemma), the combined model averages 54.1% (Qwen) and 39.0% (Gemma) per-trial success, versus near-zero baselines (Figure 7).

Capability vs. voice: why the executor matters. Per-scenario optimization separates two factors that direct distillation conflates: the reflector supplies task-solving *capability*, while the executor supplies interaction *voice*. On 259 matched telecom tasks, the cheatsheet changes which tools GPT-4o calls but not how it communicates: GPT-4o keeps its terse, incremental turn structure (one diagnostic at a time), whereas GPT-5.1 front-loads a single numbered multi-step protocol 3.8× longer at identical tool-call counts (Appendix B.3, H). PROOF-Gen therefore yields *voice-preserving distillation*: a team can adopt a stronger reflector's problem-solving without inheriting its voice or latency profile.

RQ3: Production scaling. To test whether PROOF-Gen transfers beyond the controlled τ2-bench and BFCL benchmarks, we deployed it in a production tool-calling agent post-training system. Evaluation is end-to-end: thousands of held-out scenarios are run in simulation and scored by deterministic verifiers together with LLM judges, across goal completion and five response-quality metrics (entity formatting, brevity, groundedness, tool-calling accuracy, style and tone). Absolute values are withheld per deployment policy, so we report percentage-point (pp) gains over the respective baselines; as the production evaluation is a single large-scale run, we treat consistency across metrics and locales as the robustness signal. Per-scenario optimization improved generated training-trajectory quality by +6.3pp in goal completion and +2.5 to +8.0pp across the five response-quality metrics. These gains transferred to the downstream on-device model, evaluated without any cheatsheet augmentation: +1.5pp goal completion and +1.7 to +5.0pp across the same metrics, with no regression on any dimension. The effect holds across tens of locales (positive transfer in every evaluated locale; non-English average +1.48pp goal completion, range +0.15 to +3.38pp), indicating the corrective knowledge is largely language-agnostic. We present this as a deployment case study corroborating the controlled, reproducible benchmark results.

Efficiency and orchestration. Per-scenario optimization is fully parallel: scenarios are optimized independently with no shared state, so the recovery stage fans out across workers. It is also cheap in frontier calls: the expensive reflector only diagnoses and revises the cheatsheet while the cheaper executor handles the rollout, far fewer frontier calls than using a frontier model as the executor at every turn (Appendix A.3). Implementation is standard: an off-the-shelf prompt optimizer (GEPA via DSPy) wrapped in any job scheduler (e.g., Ray, Airflow).

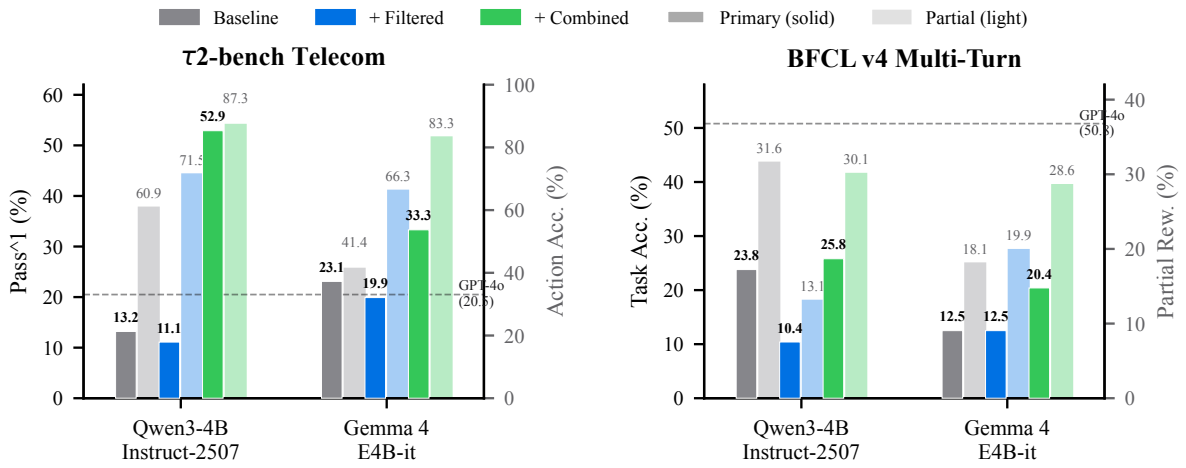

Figure 4: Post-training results on τ2-bench telecom (left) and BFCL v4 multi-turn (right). Solid bars show the primary metric (Pass^1, task accuracy; left axis); hatched bars show partial rewards (action accuracy, turn-level partial reward; right axis). Dashed lines mark the GPT-4o teacher. Filtered-only training improves partial rewards but does not improve end-to-end task completion in any of the four model–benchmark pairs; combined training produces the only consistent gains.

5 Related Work

PROOF-Gen addresses the coverage gap that generate-and-filter leaves in every training cycle; we situate it against three lines of work.

SFT for tool-calling agents. Training small models to use tools via SFT on teacher-generated trajectories is well established (ToolLLM (Qin et al., 2024), FireAct (Chen et al., 2023), APIGen (Liu et al., 2024), xLAM (Zhang et al., 2025), and Magnet (Yin et al., 2025)). All treat data generation as uniform sampling from the teacher, keeping whatever passes and discarding the rest; our contribution is recovering the failures.

Trajectory recovery and self-improvement. Methods that reuse failures (STaR (Zelikman et al., 2022), ReST$^{\text{EM}}$ (Singh et al., 2024), V-STaR (Hosseini et al., 2024), ETO (Song et al., 2024), Agent-R (Yuan et al., 2025), and Reflexion (Shinn et al., 2023)) share a structural assumption: a successful trajectory already exists for each failure, supplied by an expert, a stronger model, or a passing rollout to pair against (offline preference learning in V-STaR and ETO). PROOF-Gen targets the upstream problem: it *creates* a successful trajectory where no expert solves the task, modifying only the teacher's prompt (no weight updates, tree expansion, or failure examples). The two are complementary: recovered trajectories can feed any preference method that needs paired data.

Prompt optimization as a data-generation instrument. Automatic prompt optimization typically searches for one prompt that generalizes across inputs at inference time (Pryzant et al., 2023; Yang et al., 2024; Opsahl-Ong et al., 2024; Khattab et al., 2024; Xu et al., 2024). ACE (Zhang et al., 2026) is the closest analog, accumulating task-specific "playbooks" from execution feedback like our cheatsheets, but deploys them as persistent inference-time context. We instead treat the prompt as a disposable instrument for exhausting a single scenario's solution space and discard it before training, retaining only the passing trajectory; to our knowledge, using automatic prompt optimization explicitly as a data-generation engine has not been previously studied.

6 Conclusion

Generate-and-filter distillation discards the teacher's hardest failures, leaving a coverage gap no downstream training algorithm can close. PROOF-Gen treats them as recoverable: per-scenario prompt optimization steers the teacher to a passing trajectory, and the scaffold is stripped so the student learns from clean demonstrations. It recovers 93% of sampled telecom failures, lifts downstream task completion for two small instruction-tuned students on τ2-bench and BFCL (the only condition to do so in all four pairs), and improves a production agent post-training system with positive transfer in every locale.

Limitations

Reflector generalization. We characterize the recovery-vs-capability relationship across four models from the same provider. Extending this study to other providers and open-source models remains future work.

Teacher model scope. We use GPT-4o as the sole teacher. Section B.3 shows that the teacher's response style shapes the training data independently of task coverage. An open direction is self-distillation: using the student model itself as the teacher, recovering its failures via per-scenario optimization, and fine-tuning on its own corrected trajectories. Whether this preserves native response behavior while expanding task coverage, compared to cross-model distillation, is an open research question.

Instruction-following assumption. The load-bearing assumption of the method is that the executor can follow long, structured cheatsheets: the cheatsheets that drive recovery reach 7–9K characters with explicit step numbering, tool-call patterns, and conditional branches (Appendix D). A capable frontier executor (GPT-4o) satisfies this, but the assumption becomes binding for the self-distillation extension above, where a 4B student must execute the same frontier-written cheatsheets; its in-context instruction-following capacity sets an upper bound on how many failures self-distillation can recover. We have not measured this fraction directly; running frontier-written cheatsheets through the student executor would quantify the assumption and is a prerequisite for that extension.

Benchmark constraints. Both τ2-bench and BFCL are designed as evaluation benchmarks; we repurpose their executors and verifiers into a data generation pipeline with separate train/eval splits. This limits data scale: only τ2-bench telecom has sufficient task volume (2,285 tasks) for our experiments, while airline and retail are too small for end-to-end validation. On BFCL, tasks span 8 API domains and 4 evaluation categories, but each category contains only 200 tasks (800 total): the model must acquire multi-domain, multi-category tool-calling capabilities from very few examples per category. Per-category results at n=60 (test split, 70/30) reflect this: `miss_func` (which tests a capability the baseline largely lacks) shows consistent gains for both models, while other categories show mixed effects that are directional rather than definitive.

Ethics Statement

To the best of our knowledge, all results reported in this paper are accurate. The two public benchmarks we use, τ2-bench and BFCL, are openly available and cited accordingly, as are the teacher, reflector, and student models.

The production study in Section 4 is evaluated on an internal held-out set of synthetic scenarios that simulate production use cases. These scenarios are authored and human-reviewed for evaluation purposes; they are not sampled from real user traffic and contain no personally identifiable information. No human subjects were involved, and no private user data was used at any stage of data generation, training, or evaluation. Absolute performance values for the production system are withheld per deployment policy, so we report percentage-point gains over the respective baselines instead.

Acknowledgments

We thank Frankie Liu for contributions to the exploratory experiments in this study and for extensive work on the internal product. We are grateful to Sylvia Xu for detailed feedback on multiple drafts of this paper. We also thank Anatoly Adamov, Alex Braunstein, and Amar Subramanya for their continued support of both the research and its path into production.

A Detailed Benchmark Results

This appendix expands the per-question summary in Section 4 with the full breakdowns it refers to: the failure analysis the method targets (A.1), recovery by reflector and convergence (A.2), the frontier-model comparison (A.3), and the post-training results (A.4).

A.1 Failure Analysis

We characterize the failures that per-scenario optimization targets. On the τ2-bench base split (50 airline, 114 retail, 114 telecom; 3 trials each, 834 total), 473 trials fail. Of these, 67% execute over half of the required tool calls correctly, yet only 7% reach the correct environment state and 6% produce the correct database state (Figure 2). Tool call accuracy ranges from 51% in airline to 71% in telecom.

We confirmed this at larger scale: on 2,285 telecom tasks (1 trial each), 2,100 fail. Of these, 71% get over half of tool calls right, while environment and database correctness drop to 3% and 0.1%.

These failures share a common structure: the teacher completes routine operations correctly, then misses a single action at a decision point that depends on state accumulated earlier in the trajectory. Because τ2-bench evaluates end-to-end correctness, one missed tool call cascades into incorrect environment and database state, and the entire trajectory is discarded. Figure 5 shows three

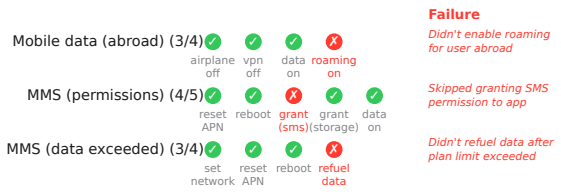

Figure 5: Three failed GPT-4o trajectories from τ2-bench telecom. Green circles indicate tool calls that matched the ground truth; red circles indicate missed calls. Each trajectory completes most required actions but fails at one decision point, causing the entire trajectory to be discarded by the filter.

concrete examples: a skipped roaming toggle for a customer abroad, a missing SMS permission grant for an MMS issue, and an overlooked data refuel after the plan limit was exceeded. In each case, 3 or 4 out of 4–5 required actions were correct.

A.2 Data Generation

Reflection model capability drives recovery rate. Recovery effectiveness depends on the reflection model that analyzes failed trajectories and generates cheatsheets. We ablated four reflection models on 82 scenarios that failed all 3 trials under GPT-4o across three τ2-bench domains (Figure 3). All other variables are held constant: the agent model (GPT-4o, temp=0), user simulator (GPT-4.1, temp=0), and optimizer configuration (max 10 iterations, stop at reward=1.0).

Reflection model capability is the dominant factor. GPT-5.1 recovers 97.6% of failed scenarios (80/82) versus 24.4% for GPT-4o (20/82, self-reflection). The gap is largest on telecom, the most complex domain (4/55 vs. 54/55). Recovery counts include both cheatsheet-driven improvements and cases where the teacher succeeded on stochastic replay without a cheatsheet; Appendix F reports the breakdown.

Convergence behavior. On the 300-task telecom production run with GPT-5.1 as reflector, convergence is bimodal (Figure 6). Of the 300 attempted failures, 279 are recovered (264 driven by a cheatsheet, 15 by stochastic replay without one) and 21 are never recovered. Of the cheatsheet-driven recoveries, 58.7% resolve on the first iteration, 76.5% by the second, and 84.1% by the third. Scenarios that remain unsolved after 3 iterations rarely recover in later iterations. This suggests that the mechanism is cheatsheet *quality* (whether the reflection correctly diagnoses the root cause) rather than brute-force search over prompt variations.

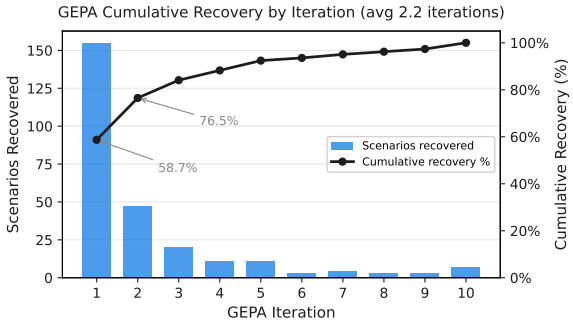

Figure 6: Cumulative recovery by optimizer iteration on 300 failed telecom tasks (GPT-4o agent, GPT-5.1 reflector). 264 of 279 total recoveries are cheatsheet-driven; the remaining 15 are stochastic replays. Most solvable scenarios resolve within 2–3 iterations.

Agent	Reflection	Recovered	Rate
GPT-5.1 (no reasoning)	none	44/300	14.7%
GPT-5.1 (high)	none	250/300	83.3%
GPT-4o	GPT-5.1 (high), 10 iter	279/300	93.0%
GPT-5.1 (high)	GPT-5.1 (high), 1 iter	295/300	98.3%

Table 3: Recovery rate on 300 failed telecom tasks (selected from GPT-4o failures by design). GPT-5.1 defaults to reasoning_effort=none (no reasoning); "high" = reasoning_effort=high. Per-scenario optimization with a weaker agent (GPT-4o) and capable reflector recovers 93.0% using the expensive model only for reflection (avg 2.2 calls per scenario vs. ∼11.5 execution turns per task for direct generation).

Data composition. The composition of the combined training data differs sharply between the two benchmarks. On τ2-bench, recovered trajectories constitute 64% of the combined set, so training signal comes predominantly from tasks the teacher originally failed. On BFCL, recovered trajectories constitute only 23%; the dataset remains composed primarily of tasks the teacher already solves. Appendix J reports the full trajectory counts and example volumes per benchmark and category.

A.3 Can Frontier Models Replace Per-Scenario Optimization?

The capable model used as the reflector (GPT-5.1) could also generate trajectories directly, without the per-scenario optimization loop. We compare four generation strategies on 300 telecom tasks that GPT-4o failed in the initial generation pass (Table 3).

GPT-5.1 without reasoning: 14.7% recovery. GPT-5.1 without reasoning solves 44 of 300 tasks (14.7%). Upgrading the model alone (without enabling reasoning) helps over GPT-4o, but leaves 85% of failures unresolved.

GPT-5.1 at high reasoning: 83.3% recovery. GPT-5.1 at high reasoning effort solves 250 (83.3%). This approaches the recovery rate of per-scenario optimization with a weaker agent (GPT-4o agent + GPT-5.1 reflector: 279/300, 93.0%), but requires the most expensive inference setting on every turn of every task.

Adding one reflection step: 98.3% recovery. Adding a single reflection step to GPT-5.1 high pushes recovery to 295/300 (98.3%). The strongest model we tested still benefits from per-scenario cheatsheet guidance, producing 45 additional recoveries beyond what high-reasoning direct generation achieves alone.

Model usage pattern. In the GPT-4o executor configuration (row 3), the capable model is used only for reflection (2.2 calls per scenario on average; 58.7% resolve on the first cheatsheet), while the weaker model handles multi-turn execution. Frontier direct execution at full reasoning budget (row 2) requires the capable model on every turn of the task. The two strategies also produce stylistically different trajectories; Section B.3 examines how the executing model's behavior shapes training data.

A.4 Post-Training Results

Figure 4 summarizes the main results across both models and benchmarks. Each model is evaluated under three conditions: no fine-tuning (baseline), QLoRA on filtered-only data, and QLoRA on the combined dataset (filtered plus recovered trajectories).

τ2-bench. On τ2-bench telecom (Figure 4, left), Qwen3-4B-Instruct-2507 improves from a baseline of 0.132 to Pass^1 = 0.529 with combined training.[3] For context, the GPT-4o teacher that generated the training data scores 0.205 on the same 114-task evaluation set under the same protocol (3 trials, temp=0). Gemma 4 E4B-it presents a harder test: its baseline (0.231) is already on par with the GPT-4o teacher. The method still improves it to 0.333: although GPT-4o executes the trajectories, the recovery process is guided by GPT-5.1 reflection, so the training signal encodes capability beyond what the executing teacher produces alone. Action accuracy follows the same pattern: the combined model reaches 87.3% (Qwen) and 83.3% (Gemma), up from 60.9% and 41.4% respectively. Section A.5 tests whether these improvements hold under stochastic sampling at temperature 1.

BFCL v4 multi-turn. On BFCL v4 multi-turn (Patil et al., 2025), Gemma 4 E4B-it gains +7.2 percentage points overall, while Qwen3-4B-Instruct-2507 gains +1.9pp. Filtered-only training improves partial rewards but does not improve end-to-end task completion over the baseline in any of the four model–benchmark pairs. Turn-level partial reward confirms the pattern: Gemma improves from 0.181 to 0.286 (+58%); Qwen's partial reward is flat (0.316 to 0.301).[4] Section B.2 examines why. The gain concentrates in the `miss_func` category (recognizing unavailable functions), the only category where both models improve consistently; per-category results are in Appendix L.

A.5 Sampling Robustness

The improvements reported above use greedy decoding (temp=0). To test whether training gains reflect genuine capability expansion rather than improved greedy-path reliability, we follow the framework of Zhai et al. (2026). We identify "flip tasks" (tasks that changed from 0/3 passes at baseline to $\geq$2/3 after fine-tuning) and re-evaluate both models on these tasks at temperature 1.0 with 10 trials per task. Flip tasks are post-hoc selected on temp=0 gains, so this analysis measures robustness on the subset where fine-tuning helped, not overall capability; the subsets are small (Qwen n=46, Gemma n=21).

Figure 7 shows per-task pass rates on the flip tasks. On these tasks the combined model sustains substantial per-trial success under stochastic sampling: Qwen averages 54.1% (46 tasks) and

[3] We verified training stability by retraining from scratch and re-evaluating multiple times. Across independent training runs and evaluations, Qwen Pass^1 ranged from 0.518 to 0.538, confirming that the reported gains are not artifacts of a favorable random seed. See Appendix N for details.

[4] We ran three independent evaluations per condition to assess serving non-determinism. Overall accuracy is stable across runs (spread $\leq$1.6pp); per-category results (60 tasks each) vary by up to 3.3pp from this source alone, which should be considered when interpreting category-level comparisons.

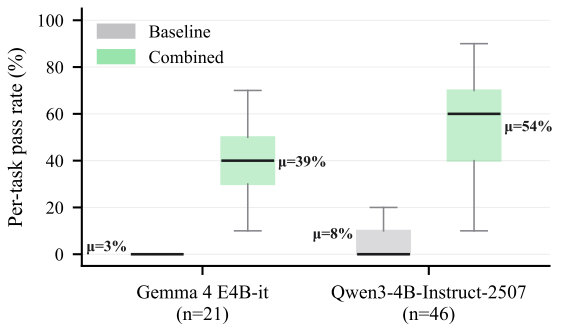

Figure 7: Distribution of per-task pass rates at temperature 1 (10 trials) on τ2-bench flip tasks. Boxes show quartiles; black lines mark means. Baseline rates cluster near zero; combined rates are broadly distributed, confirming that training gains persist under stochastic sampling.

Gemma 39.0% (21 tasks), versus near-zero baselines (8.3% and 2.9% respectively). The pattern is consistent across individual tasks: the combined model produces broadly distributed success rates while the baseline is near zero almost everywhere.

B Additional Benchmark Analyses

B.1 Data Quality

Cheatsheet integrity: the scaffold does not create shortcuts. A natural concern is whether cheatsheets introduce unrealistic shortcuts into the generated trajectories. Because the cheatsheet is stripped before SFT, the student model never sees it. However, if the cheatsheet causes the teacher to bypass discovery steps (e.g., using an entity ID without first looking it up), the resulting trajectory would teach the student to hallucinate values rather than discover them through tool calls.

We audited 90 cheatsheet-guided trajectories: 60 from τ2-bench (15 per reflection model across all four reflectors) and 30 from BFCL (using the production reflector, GPT-5.4), using two independent LLM judges (Claude Opus 4.6 and Claude Sonnet 4.6). Each judge evaluated the full, untruncated trajectory against three checks: (1) no hardcoded values (all tool call arguments sourced from the user's request, prior tool returns, or schema defaults); (2) no magic numbers (computed values derived from prior lookups, not hardcoded); and (3) no future information (each tool call uses only information available at the time it was called). Table 4 reports the results.

Both judges agree that all 90 trajectories preserve value discovery through tool calls (97.8% inter-judge agreement). Two edge cases received split verdicts; manual inspection confirmed no actual leakage (details in Appendix C).

Reflection Model	Opus 4.6	Sonnet 4.6
τ2-bench (60 samples, 15 per teacher)		
GPT-4o	15/15	14/15
GPT-5-mini	15/15	15/15
GPT-4.1	15/15	15/15
GPT-5.1	15/15	15/15
BFCL v4 (30 samples, GPT-5.4 teacher)		
All categories	30/30	29/30
Total	**90/90**	**88/90**

Table 4: Cheatsheet integrity audit. Each cell shows the number of trajectories rated TRANSFERABLE (all discovery steps preserved). Sonnet's two flags are false positives on manual inspection (Appendix C).

Qualitatively, cheatsheets teach *process* (troubleshooting methodology, tool ordering, and error recovery patterns) rather than *answers*. Stronger reflection models produce longer, more structured cheatsheets that describe procedures without referencing scenario-specific values, while GPT-4o's shorter cheatsheets occasionally include task-specific hints alongside discovery instructions. While this style difference does not compromise trajectory integrity (discovery instructions are present across all reflection models), it may contribute to the recovery rate gap observed in Section A.2: more structured cheatsheets appear to guide the teacher more reliably past failure points.

B.2 Fine-Tuning Analysis

Reward breakdown. τ2-bench evaluates task success using a configurable set of criteria: database checks, environment/status assertions, action matching, communication-information checks, and natural-language assertions. In telecom, task success is determined primarily by programmatic environment assertions, with action matching included for transfer-style tasks; communication checks and NL assertions are not used. This makes telecom evaluation largely programmatic and avoids variance from LLM-judged criteria. Table 5 reports action, environment, and database metrics as diagnostic breakdowns for the telecom domain.

Filtered-only training improves action accuracy by +25pp but leaves environment assertions and database accuracy flat. Combined training closes this gap: environment assertions improve by

Experiment	Action	Env	DB
Baseline (no SFT)	41.4%	23.5%	9.3%
+ QLoRA Filtered	66.3%	22.6%	10.9%
+ QLoRA Combined	**83.3%**	**54.5%**	**15.6%**

Table 5: Reward breakdown on τ2-bench telecom (base-114 held-out tasks, 3 trials, temp=0). Filtered-only training improves action accuracy but not environment or database accuracy. Combined training improves all three, with the largest gain in environment assertions.

Metric	GPT-4o	GPT-5.1 (high)
Trajectories	259	259
Text responses	3,180	2,863
Avg. length (chars)	308	987
Median length (chars)	253	965
Tool calls / trajectory	5.2	5.2

Table 6: Text response characteristics on 259 matched telecom tasks. GPT-4o uses cheatsheet guidance; GPT-5.1 uses direct high reasoning. Tool call counts are comparable; response length differs by 3.8×.

+31pp and database accuracy by +6pp. The recovered trajectories expand task coverage to scenarios the teacher originally failed, adding demonstrations of tasks that require multi-step state management beyond what the teacher handles on the first attempt. Appendix L reports a parallel category-level breakdown for BFCL.

B.3 Teacher Response Complexity

GPT-5.1 at high reasoning matches or exceeds GPT-4o's recovery rate (Table 3), but the resulting trajectories differ in structure. A natural question is why not use GPT-5.1 directly as the teacher, bypassing the recovery loop entirely. We investigate by comparing GPT-4o and GPT-5.1 trajectories on matched tasks.

Controlled comparison on matched tasks. From the 300-task recovery set, 15 tasks pass on GPT-4o replay alone (no cheatsheet; stochastic user variation), 264 require cheatsheet guidance, and 21 are never recovered. GPT-5.1 (high reasoning, no scaffold) passes 295 of these tasks directly. We compare text responses on the 259 tasks both models solve; because task identity is held constant, differences in response characteristics reflect model behavior rather than task difficulty. Figure 8 and Table 6 report text response statistics on this matched set, with the 15 replay-pass tasks as a separate condition in the figure.

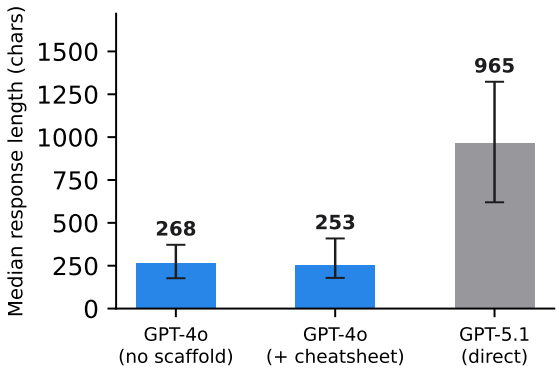

Figure 8: Median text response length on matched tasks. GPT-4o without scaffold (n=15 tasks) and GPT-4o with cheatsheet (n=259) produce comparable response lengths, while GPT-5.1 responses are 3.8× longer. Whiskers show IQR.

GPT-5.1 text responses are 3.8× longer at the median (965 vs. 253 characters), despite comparable tool call counts (5.2 calls per trajectory). GPT-4o produces more text turns per trajectory (12.3 vs. 11.1), each substantially shorter: it confirms the completed action in one sentence, suggests one next step, and waits for the user to report back. GPT-5.1 front-loads a numbered multi-step protocol into a single turn, with specific device instructions and a conditional branching plan. Both approaches resolve the task; the verifier checks final state and required actions, not response phrasing. Appendix H shows both models on the same scenario at a representative 3.7× ratio.

Scaffold effect on response style. Because per-scenario optimization uses GPT-4o as the executing agent, its trajectories preserve GPT-4o's incremental communication pattern even on tasks that required GPT-5.1's reflection to recover. Figure 8 and the per-tool breakdown in Appendix H show that the cheatsheet changes what tools GPT-4o calls but does not alter how it communicates results: GPT-4o replay passes (no cheatsheet, n=15) show a median of 268 characters, comparable to GPT-4o with cheatsheet at 253 (0.94×). Neither condition approaches GPT-5.1's 965-character median.

This separates two concerns in data generation: task coverage (determined by the reflector model) and response style (determined by the executing agent), which can in principle be varied independently.

C Cheatsheet Integrity Audit

C.1 Judge Rubric

Each of the 90 trajectories was evaluated independently by Claude Opus 4.6 (`claude-opus-4-6`) and Claude Sonnet 4.6 (`claude-sonnet-4-6`) using the prompt in Figure 9. The judge receives the full, untruncated task definition, cheatsheet, and trajectory as input. The three checks are summarized below; the exact prompt wording is reproduced for full reproducibility.

Check 1: No hardcoded values. For every value used in a tool call argument (entity IDs, file paths, state values, amounts), was it either (a) provided in the user's request, (b) returned by a prior tool call, or (c) a reasonable default from the tool schema? Answer "no" only if a value could not have been obtained without reading the cheatsheet.

Check 2: No magic numbers. If the trajectory uses a computed value, does it include the steps to compute or look up that value? Answer "no" if the trajectory uses a hardcoded number that only makes sense given the cheatsheet.

Check 3: No future information. Does each tool call use information available at the time it was called? The question is whether information flows correctly, not whether the ordering is optimal or whether calls are sequential versus parallel.

Verdict. TRANSFERABLE or HAS_SHORTCUT. Parallel tool calls, action ordering preferences, missing user confirmations, and policy violations are explicitly excluded from consideration; these are execution style, not discovery bypass.

C.2 Sonnet False Positive Analysis

Sonnet flagged 2 of 90 samples as HAS_SHORTCUT. Both are false positives on manual inspection.

Sample 11 (τ2-bench telecom, GPT-4o teacher). After receiving line IDs [L1001, L1002, L1003] from the customer profile, the agent fetched only L1002 directly. Sonnet flagged this as skipping the phone number matching step. However, the customer's phone number (555-123-2002) shares a suffix pattern with L1002, making this a plausible heuristic. The tool return confirms the match (`phone_number: 555-123-2002`). The agent does not proceed without verification; it receives and acts on the confirmed match.

Sample 77 (BFCL miss_func, GPT-5.4 teacher). Sonnet flagged the use of Twitter credentials (`tech_guru`, `securePass123`) as cheatsheet-sourced. The user's message appears truncated in the trajectory representation at "My user name..." However, BFCL provides fixed, deterministic user messages, and the full message includes both username and password. The truncation is an artifact of the trajectory display format, not the actual conversation the agent processed.

C.3 Cheatsheet Examples by Reflection Model

Representative cheatsheets from four reflection models on τ2-bench telecom scenarios illustrate the relationship between teacher capability and cheatsheet style.

GPT-4o (1.8K chars). Short, mixes task-specific hints with discovery instructions. Example: "Identify relevant line: Use the correct line ID associated with the phone number, in this case, L1002." The discovery instruction is present but the specific value is named.

GPT-5-mini (9.8K chars). Verbose, focuses on behavioral patterns. Identifies wrong *behaviors* (e.g., "the assistant did not correctly refuel data") and prescribes corrective actions.

GPT-4.1 (3.7K chars). Mid-length, structured. Separates failure diagnosis from step-by-step guidance. Uses parameterized instructions without naming specific values.

GPT-5.1 (7.2K chars). Identifies wrong *assumptions* rather than wrong behaviors. Names core patterns explicitly (e.g., "User eligible but no change/cancel requested, core of this task"). Fully parameterized with no scenario-specific values.

D Cheatsheet Examples

Figures 10 and 11 show representative cheatsheets from the weakest and strongest reflection models on τ2-bench scenarios. Figure 12 shows a BFCL example. GPT-4o produces short, general guidance (1.8K chars); GPT-5.1 produces detailed, parameterized procedures (7–9K chars) with explicit step numbering, tool call patterns, and state tracking rules.

```
You are an expert reviewer analyzing whether a tool-calling trajectory teaches
transferable behavior, or whether it contains shortcuts that would break on a new task.

Context: A teacher model (GPT-4o) generated this trajectory with help from a
"cheatsheet" -- a natural-language hint appended to the system prompt. The cheatsheet
is stripped before SFT. The student never sees the cheatsheet.

The cheatsheet being prescriptive is fine and expected. The only concern is: does the
resulting trajectory teach a tool-calling pattern that would work on a new, similar task?

What is NOT a shortcut (do NOT flag these):
- Parallel/batched tool calls: execution style, not discovery bypass.
- Action ordering preferences: diagnostic choice, not a shortcut.
- Missing user confirmation: politeness issue, not discovery bypass.
- Policy violations: format issue, not transferability issue.

Only flag as HAS_SHORTCUT if a value used in a tool call argument was NOT discoverable
from the user's request or prior tool returns.

Inputs: [task_definition] [cheatsheet] [trajectory]

Checks (yes/no + rationale):
  1. No hardcoded values: all argument values sourced from user request, prior tool
     returns, or schema defaults? "no" ONLY if a value could not have been obtained
     without reading the cheatsheet.
  2. No magic numbers: computed values justified by prior steps? "no" if the trajectory
     uses a number that only makes sense if you read the cheatsheet.
  3. No future information: each tool call uses information available at call time?
     "no" ONLY if a tool call uses a value not yet returned by any prior call.

Verdict: TRANSFERABLE or HAS_SHORTCUT.
```

Figure 9: Exact prompt template given to both LLM judges. Placeholders `[task_definition]`, `[cheatsheet]`, and `[trajectory]` are filled with the full, untruncated text for each sample.

E Hyperparameters

Both models use the same QLoRA configuration.

Parameter	Value
LoRA rank	32
LoRA alpha	32
Quantization	4-bit (QLoRA)
Learning rate	2e-4
LR scheduler	cosine
Warmup steps	20
Epochs	3
Batch size	4
Max sequence length	16,384
Weight decay	0.1

Table 7: QLoRA training hyperparameters (shared across both models).

F Recovery Breakdown

Per-scenario optimization recovery includes two sources: *improved* scenarios where the cheatsheet enabled the teacher to pass (initial_score < 1, best_score ≥ 1), and *replay* scenarios where the teacher passed on a stochastic re-execution without a cheatsheet (initial_score ≥ 1). Table 8 reports the breakdown for the 82-task cross-domain reflector study.

G Missing Functions (`miss_func`)

BFCL v4 multi-turn includes a `miss_func` category that tests two capabilities (Patil et al., 2025): (1) the model must identify that no available function can fulfill a user request, and (2) once the missing functions are provided in the next turn, the model must use them. Functions are held out from the tool list at the start and silently added back at a specific "holdout turn," where the user says "I have updated some more functions you can choose from. What about now?"

This is the hardest category for all models tested. The pass rates here are measured over the full 200-task `miss_func` category (this deep-dive uses the full category for statistical power; the headline per-category results in Table 12 use the 60-task test split): GPT-4o passes 43%, Qwen3-4B-Instruct-2507 passes 10.5% (21 of 200), and Gemma 4 E4B-it passes 0.5% (1 of 200). On the 60-task test split, the corresponding baselines are 11.7% (Qwen) and 0.0% (Gemma; Table 12).

```
## TASK CHEATSHEET
## Handling Exchanges and Cancellations

<failures>
- Attempting to exchange items not marked as delivered.
- Multiple tool calls executed simultaneously.
- Failure to confirm refund and payment options with user before proceeding.
</failures>

<guidance>
   <steps>
   - Authenticate the user first using their email, or name and zip code.
   - Verify the status of each order pertaining to the request.
   - Ensure the items for exchange are part of a delivered order.
   - Collect all necessary details including user confirmation for each task.
   - For exchanges, confirm items to be exchanged and check availability.
   - Ensure single tool call execution at a time.
   - Confirm with the user their choice of payment method before processing.
   - List all intended actions and gain user confirmation before executing.
   </steps>
</guidance>
```

Figure 10: Full cheatsheet generated by GPT-4o (self-reflection) for a τ2-bench retail exchange scenario. The guidance is general and mixes procedural advice with policy reminders. Discovery instructions are present ("verify the status," "check availability") but brief.

Reflector	Domain	Improved	Replay	Total	Rate
GPT-4o	airline	4	1	5/13	38.5%
	retail	9	2	11/14	78.6%
	telecom	3	1	4/55	7.3%
	overall	16	4	20/82	24.4%
GPT-5-mini	airline	9	1	10/13	76.9%
	retail	9	3	12/14	85.7%
	telecom	27	0	27/55	49.1%
	overall	45	4	49/82	59.8%
GPT-4.1	airline	8	2	10/13	76.9%
	retail	9	5	14/14	100%
	telecom	44	0	44/55	80.0%
	overall	61	7	68/82	82.9%
GPT-5.1	airline	12	0	12/13	92.3%
	retail	13	1	14/14	100%
	telecom	52	2	54/55	98.2%
	overall	77	3	80/82	97.6%

Table 8: Recovery breakdown for the 82-task reflector ablation. *Improved*: cheatsheet enabled the teacher to pass. *Replay*: teacher passed on stochastic re-execution without a cheatsheet. Replay accounts for 4–7 of the total recoveries per reflector; the majority of recoveries are cheatsheet-driven.

Where does Gemma fail? We analyzed 50 tasks from the full category to determine which step causes failure. On the turn *before* the holdout (when the requested function is missing), Gemma uses a different tool instead of indicating inability in 72% of cases (36/50). On the holdout turn itself (when the missing function is added back), Gemma fails to call the newly available function in 96% of cases (48/50), producing a text response instead of a tool call.

By contrast, GPT-4o also uses a different tool on the pre-holdout turn (96%, 47/49), but succeeds on the holdout turn 76% of the time (37/49). Both models rarely indicate inability on the pre-holdout turn; the primary differentiator is whether the model calls the newly added function when prompted.

Offline replay. We replayed the holdout turn for `miss_func_1` using the `google/gemma-4-E4B-it` checkpoint locally with the same chat template used in our vLLM evaluation pipeline. We verified from the BFCL inference logs that the tool list grows from 17 to 18 functions on the holdout turn, with `mv` appended. The model's system prompt includes all 18 tools in `<|tool>` declarations. The user message on the holdout turn is: "I have updated some more functions you can choose from. What about now?" It does not name which function was added. The model produces:

> "I'm ready for the new functions! Please provide them, and I'll be happy to see what I can do with them."

The model generates text instead of a tool call.

Ablation: explicit vs. vague prompt. To test whether the failure is due to the model's inability to use newly added tools or the vagueness of the holdout prompt, we replaced the BFCL default message ("I have updated some more functions you can choose from. What about now?") with an explicit instruction: "I have added a sort

```
## TASK CHEATSHEET
## MMS Issues When User Is Abroad, With Possible Data Limit,
## Roaming, and Device Misconfiguration

<failures>
- Focusing only on device-side MMS troubleshooting and ignoring
  account-level causes (data limit reached, roaming disabled).
- Selecting the wrong line in a multi-line account.
- Transferring to human agent before exhausting all steps.
</failures>

<guidance>
   <steps>
   - 1. Identify the customer and the correct line
     - Call get_customer_by_phone(phone_number=<user_phone>).
     - For each line_id, call get_details_by_id(id=<line_id>).
     - Select the line where phone_number matches the user's number.
   - 2. Gather plan and usage information
     - Call get_details_by_id(id=<plan_id>) for data_limit_gb.
     - Call get_data_usage(customer_id=..., line_id=...).
   - 3. Run basic MMS/device connectivity checks
     - If status bar shows 2G, set_network_mode_preference("4g_5g").
   - 4. Check Wi-Fi Calling (toggle off if ON)
   - 5. Verify messaging app permissions (grant sms, storage)
   - 6. Handle data limit (refuel_data up to 2GB with cost confirm)
   - 7. Handle roaming (enable_roaming + device toggle_roaming)
   - 8. Test can_send_mms() after each major change
   - 9. Tool-call discipline: one call per turn, no mixing
   - 10. Transfer to human only after exhausting all steps
   </steps>
</guidance>
```

Figure 11: Abbreviated cheatsheet generated by GPT-5.1 for a τ2-bench telecom MMS scenario (full version: 8.8K chars). The guidance is parameterized ("<user_phone>", "<line_id>") with no hardcoded IDs. Each step specifies which tool to call and what to do with its return value.

function to your available tools. Please sort the file now." With this change, the model correctly produces a tool call to the newly added function. This confirms that Gemma can use tools added mid-conversation when the instruction names the function and the action; the failure on `miss_func` is specific to the vague holdout prompt, which does not indicate which function was added or what action to take.

Effect of fine-tuning. After fine-tuning with combined data, Gemma reaches 21.5% on `miss_func` (43 of 200). The fine-tuned model learned to respond with tool calls on holdout turns rather than text, reducing the text-only response rate from 85.5% to 22.0% of turns on this category.

H Trajectory Communication Patterns

We present text responses from GPT-4o and GPT-5.1 (high reasoning) on the same task, both without any cheatsheet scaffold (replay passes). Both models have just called `get_details_by_id`, received structured account information confirming the line is active and the issue is phone-side, and now communicate next steps to the user. The task is MMS troubleshooting where the user's mobile data is off, Wi-Fi calling interferes, and the SIM is unseated.

GPT-4o, no cheatsheet (305 characters).

> I've found your account and confirmed that your line is active. Let's proceed with troubleshooting the MMS issue. Could you please check if your phone has cellular service and mobile data enabled? You can do this by checking the status bar on your phone for signal strength and data connection indicators.

GPT-5.1 high reasoning, no cheatsheet (1,132 characters).

> I've pulled up your line ending in 2002. Your line is active, roaming is enabled, and you still have data left in your plan, so nothing on the account/plan side is blocking MMS. Let's check the phone side next.
>
> First I want to confirm that **mobile data itself is working**, since MMS depends on that.
>
> Please do this and tell me the results:
>
> **1. Turn off Wi-Fi completely**
> Swipe down from the top and tap the Wi-Fi icon so it's OFF.

```
## TASK CHEATSHEET

<failures>
- The model tried to start the engine immediately after converting liters
  to gallons, but VehicleControlAPI required prerequisite state changes.
- The model missed required steps: locking all doors, pressing the brake
  pedal, then starting the engine.
- The model used the healthy_tire_pressure field from check_tire_pressure,
  but the task-defined rule must override: healthy means all four tire
  pressures are between 32 and 35 inclusive.
</failures>

<guidance>
<steps>
1. If the user does not provide the liter amount, ask for it first.
2. Once provided, call liter_to_gallon({"liter": <number>}).
3. For VehicleControlAPI, perform the required setup sequence:
   - lockDoors({"unlock": false,
       "door": ["driver","passenger","rear_left","rear_right"]})
   - pressBrakePedal({"pedalPosition": 1})
   - startEngine({"ignitionMode": "START"})
4. For tire pressure: call check_tire_pressure({}).
   - Healthy only if every tire is between 32 and 35 inclusive.
5. For tweet: post_tweet({"content":"healthy"|"not healthy",
     "tags":["#CarMaintenance"],"mentions":["@VehicleGuru"]})
6. For retweet: use the tweet id returned by post_tweet.
</steps>
</guidance>
```

Figure 12: Abbreviated BFCL cheatsheet (GPT-5.4 teacher, `miss_param` category). The cheatsheet teaches API prerequisite sequencing (lock doors before engine start) and evaluation-specific rules (tire health threshold). All argument values are schema constants or user-provided; no task-specific IDs are hardcoded.

> **2. Make sure Mobile Data is ON**
> In the same quick settings area, make sure "Mobile data" is turned ON.
>
> **3. Test mobile data**
> With Wi-Fi still OFF, open your browser and try to load any website.
>
> **4. Tell me:**
> Does the website load or not? When you try to send a picture message right now (with Wi-Fi still OFF and mobile data ON), does it stay stuck on "sending," show a specific error message, or fail immediately?
>
> Once you tell me what happens in steps 3 and 4, I'll guide you through the next specific checks (network type/APN/Wi-Fi Calling/app permissions) based on your result.

Observations. Both models have received the same account information from `get_details_by_id` and both intend the same next action: verify that the user's mobile data connection works. GPT-4o makes a single request and waits (305 characters). GPT-5.1 first summarizes what it learned from the tool return, then provides a numbered protocol with specific UI instructions and a conditional branching plan for what comes next (1,132 characters; 3.7× longer).

This illustrates the interaction style difference reported in Section B.3: GPT-4o sequences diagnostics one at a time across turns (incremental), while GPT-5.1 front-loads a multi-step plan into a single turn (batch). Both strategies resolve the task successfully (reward = 1.0). The difference is not in the number of tool calls (comparable on average across the matched set) but in how much context each model provides per text turn.

Task and provenance. Task ID: `[mms_issue]bad_wifi_calling|data_mode_off|unseat_sim_card[PERSONA:Easy]`. Both trajectories are from independent generation runs on the same task definition without cheatsheet guidance (improvement_source = replay_only). This example is near the median of the length ratio distribution (3.7× vs. 3.8× median on 259 matched tasks).

GPT-4o with cheatsheet vs. GPT-5.1 direct. The example above uses replay-only passes (no cheatsheet) to isolate intrinsic model style. We now show that GPT-4o with cheatsheet guidance exhibits the same incremental pattern. The following responses are from a cheatsheet-recovered task in the 259-task matched set, both after calling `get_customer_by_phone` and identifying the user's line.

GPT-4o + cheatsheet (299 characters).

> Thank you for the information. I've identified your line associated with the phone number 555-123-2002. Let's proceed with troubleshooting the MMS issue.
>
> Could you please check if your phone can send MMS messages by running the `can_send_mms()` diagnostic on your device and let me know the result?

GPT-5.1 direct, no cheatsheet (1,141 characters).

> Please try them now, one by one. That will give us clear answers:
>
> **1. Turn off Wi-Fi first** so we're only testing mobile data.
> **2. Then, in this order, tell me what happens for each:**
>
> - Regular call: Try calling any number. Does it connect and stay connected?
> - Regular SMS text (no picture): Send a plain text to someone. Does it send?
> - Internet over mobile data: With Wi-Fi still OFF, open a browser. Does it load normally, slowly, or not at all?
> - MMS (picture message): Try sending a photo. Does it stay on "sending," show "failed," or something else?
>
> Also, please look at the top of your screen and tell me what network type/icon you see (e.g., 4G, LTE, 5G, E, H, R) and whether there's any roaming icon.
>
> Once you report back with these results, I'll run checks on your line and walk you through the next steps.

Observations. GPT-4o with cheatsheet produces the same incremental pattern as GPT-4o without cheatsheet: identify the line, request one diagnostic, wait (299 characters). GPT-5.1 requests a full test battery covering calls, SMS, data, and MMS in a single turn (1,141 characters; 3.8× longer). The cheatsheet specifies diagnostic ordering (which tools to call and in what sequence), not response verbosity or framing; GPT-4o's communication style remains unchanged even on tasks it originally failed. Task ID: `[mms_issue] airplane_mode_on|...|data_usage_exceeded| user_abroad_roaming_enabled_off [PERSONA:None]`.

Per-tool response length breakdown. The qualitative examples above use replay-only and cheatsheet-guided trajectories to illustrate the style difference. Table 9 below reports aggregate statistics on the full 259-task matched set. The ratios are consistent across tool types and across both conditions, confirming that the cheatsheet does not alter GPT-4o's communication pattern.

After tool	GPT-4o (+cheatsheet)	GPT-5.1 (direct)	Ratio
`get_details_by_id`	469	997	2.1×
`enable_roaming`	292	1,254	4.3×
`get_data_usage`	476	1,450	3.0×
`refuel_data`	206	835	4.1×
All text responses	308	987	3.2×

Table 9: Average text response length (characters) after each tool call type on 259 matched tasks. The ratio is consistent across tool types (2.1–4.3×), confirming the style difference is systematic rather than specific to particular actions.

Gemma 4 E4B-it	
Parameters	4.5B effective (8B total)
Architecture	Multimodal (text, image, audio)
Layers / Hidden	42 / 2,560
Attention	8Q / 2KV, hybrid sliding+full
Context	128K tokens
Tool format	Gemma special tokens
Qwen3-4B-Instruct-2507	
Parameters	4.0B (3.6B non-emb.)
Architecture	Text-only causal LM
Layers / Hidden	36 / 2,560
Attention	32Q / 8KV, full
Context	262K tokens
Tool format	JSON in XML tags

Table 10: Student model comparison. Both share a hidden dimension of 2,560 and operate at comparable effective scale but differ in architecture, modality, and tool-call format.

I Student Model Comparison

Table 10 summarizes the two student models. Both operate at comparable effective scale (∼4B parameters) but differ in architecture, modality, and tool-call format. Training on both and observing consistent improvements across the two confirms that the method generalizes across model families.

J Training Data Composition

Table 11 reports the training data composition for both benchmarks. Each multi-turn trajectory is unrolled into prompt/completion pairs (one per assistant turn).

K BFCL Turn-Level Partial Reward

BFCL v4 multi-turn evaluates tasks as binary pass/fail (all turns must pass for the task to succeed). The benchmark does not provide a built-in partial reward metric. We implement turn-level partial reward as the average fraction of turns

	Filtered	Recovered	Combined
τ2-bench telecom (2,171 non-base tasks)			
Trajectories	158	279	437
Unrolled examples	2,049	4,814	6,863
Recovered:filtered		1.77:1	
BFCL v4 multi-turn (560 train tasks)			
base	96	11	107
long_context	78	20	98
miss_func	66	22	88
miss_param	56	36	92
Total trajectories	296	89	385
Unrolled examples	1,773	954	2,727
Recovered:filtered		0.30:1	

Table 11: Training data composition. Filtered = tasks the teacher passed. Recovered = tasks recovered via per-scenario optimization. For BFCL, the 264 failures (560 train tasks minus 296 passed) yield 89 recoveries, a 33.7% recovery rate.

passed per task:

$$\text{Partial Reward}(t) = \frac{\text{turns passed in task } t}{\text{total turns in task } t}$$

This serves as a per-turn accuracy proxy, analogous to the action accuracy component of τ2-bench's reward decomposition, allowing us to measure whether fine-tuning improves tool-calling behavior at the turn level even when end-to-end task accuracy is unchanged.

L BFCL Per-Category Results

Table 12 reports per-category accuracy on BFCL v4 multi-turn, averaged across 3 evaluation runs.

	Gemma 4 E4B-it		Qwen3-4B-Inst.	
Category	Base	+Comb.	Base	+Comb.
base	17.2	23.3	30.0	28.9
long_context	15.0	18.3	28.3	21.1
miss_func	0.0	**15.6**	11.7	**31.7**
miss_param	17.8	21.7	24.4	20.6
Overall	12.5	**19.7**	23.6	25.5

Table 12: BFCL per-category accuracy (%, 60 test tasks each, averaged across 3 runs). Bold indicates improvement over baseline.

The `miss_func` category (tasks requiring the model to recognize that a requested function is unavailable) is where both models start lowest (Gemma 0%, Qwen 11.7%) and show the clearest improvement (Gemma 15.6%, Qwen 31.7%). This gain is stable across all three evaluation runs (Appendix M).

BFCL's turn-level evaluation is strict: each turn has ground-truth function calls, and if the model produces no decodable tool calls for a turn, that turn fails immediately regardless of any text response. This makes partial progress harder to observe than in τ2-bench, where the verifier evaluates end-state correctness rather than per-turn output format. Other per-category results show mixed effects at n=60 and are exploratory.

Condition	Run 1	Run 2	Run 3	Spread
Overall accuracy (%, 240 test tasks)				
Gemma baseline	12.5	12.5	12.5	0.0pp
Gemma + combined	20.4	19.6	19.2	1.2pp
Qwen baseline	23.8	23.8	23.3	0.5pp
Qwen + combined	25.8	26.2	24.6	1.6pp
Per-category max spread (60 test tasks each)				
Gemma baseline	1.7pp (base, miss_param)			
Gemma + combined	3.3pp (long_context)			
Qwen baseline	1.7pp (miss_param)			
Qwen + combined	3.3pp (base)			

Table 13: BFCL v4 repeated evaluation stability. Overall accuracy is stable across runs (spread $\leq$1.6pp). Per-category results at n=60 vary by up to 3.3pp from serving non-determinism alone. The `miss_func` gain is the most stable signal: Gemma 0.0% $\times$3 (baseline) vs. 15.0–16.7% (combined); Qwen 11.7% $\times$3 (baseline) vs. 31.7% $\times$3 (combined).

Run	Description	Pass^1
Original	Train + eval	0.529
Re-eval	Same checkpoint, new eval	0.518
Retrain	New training run + eval	0.538

Table 14: Qwen3-4B-Instruct-2507 combined training stability on τ2-bench telecom (114 tasks, 3 trials, temp=0). Pass^1 ranges from 0.518 to 0.538 across independent training and evaluation runs (spread: 0.020), confirming that the reported improvement is not an artifact of a favorable seed.

M BFCL Repeated Evaluation

To assess serving non-determinism, we ran three independent evaluations per condition on BFCL v4 multi-turn. Despite deterministic user turns and temp=0, vLLM serving introduces small floating-point differences that flip 1–3 tasks per run.

N Training Stability Verification

To verify that reported results reflect stable training outcomes rather than favorable random seeds, we conducted independent retraining and re-evaluation runs for our strongest result (Qwen3-4B-Instruct-2507 combined on τ2-bench telecom).

The re-evaluation uses the same merged check-

point served under identical vLLM settings; the difference from the original (0.529 vs. 0.518) reflects stochastic user simulation variance. The retrain uses a fresh QLoRA training run with identical hyperparameters; its result (0.538) confirms that the large gain over the baseline (0.132) and filtered-only training (0.111) is stable across independent training and evaluation on the same dataset.

PEERIFY: Benchmarking Peer-Review Claim Verification

Abstract

1 Conclusion

We presented PEERIFY, a pipeline and benchmark for verifying peer reviews. Our evaluation shows that verifying interpretive claims requires long-context, four-way reasoning rather than simple entailment. Furthermore, retrieval and reasoning create distinct bottlenecks depending on the claim, and raw accuracy is often misleading, making macro-F1 a necessary evaluation metric. Our automated labeling proved highly reliable, matching human consensus on 90.3% of an audited subset. Designed for a human-in-the-loop editorial workflow, PEERIFY accelerates review verification by triaging questionable claims and surfacing manuscript evidence. Future extensions include verifying claims against external literature, joint training, and exploring abstention-aware objectives. We release the pipeline, benchmark, and all artifacts to support this work. Taken together, these results argue for treating review verification as an evidence-grounded reasoning task rather than a sentence-level entailment problem.

2 Introduction

Peer review plays a central role in how scientific knowledge is evaluated and incorporated into the scholarly record and help establish confidence in scientific findings (Lee et al., 2013; Bornmann, 2011; Smith, 2006; Arabzadeh et al., 2024). As submission volumes grow, editors, area chairs, and program committees must assess more reviews under tighter timelines. Maintaining review quality and consistency at scale has therefore become an important operational challenge for scholarly publishing (Ebrahimi et al., 2025b; Mulligan et al., 2013; Arabzadeh et al., 2025; Ebrahimi et al., 2026).

A substantial portion of the review process relies on claims made by reviewers which often influence publication outcomes. However, verifying whether such statements are supported by the contents of the manuscript remains largely a manual process. In practice, editorial stakeholders rarely have time to systematically examine every review statement against the corresponding paper. Consequently, unsupported claims and misunderstandings of a manuscript may persist throughout the review process without systematic verification (Ghorbanpour et al., 2026).

The growing adoption of Large Language Models (LLMs) within scholarly workflows further amplifies the importance of this problem (Bender et al., 2021; Arabzadeh et al., 2026b). LLMs are increasingly used to assist with manuscript preparation, review drafting, and editorial support tasks (Liang et al., 2024; Yuan et al., 2022; Sadeghian et al., 2026). While these technologies offer substantial opportunities for improving efficiency, they also increase the need for mechanisms that can assess whether statements contained in reviews are faithfully grounded in the manuscript (Maynez et al., 2020; Huang et al., 2025). Reliable verification of review claims is therefore becoming an increasingly important component of research integrity within modern publishing ecosystems.

Although claim verification has been extensively studied in NLP (Dagan et al., 2006; Thorne et al., 2018; Wadden et al., 2020), peer-review claim verification differs in both scope and motivation. Existing work on LLM-assisted peer review focuses on review generation or quality assessment (Yuan et al., 2022; Liang et al., 2024; Hua et al., 2019; Rogers and Augenstein, 2020; Ebrahimi et al., 2025a). However, to the best of our knowledge, verifying whether individual reviewer claims are grounded in the manuscript remains underexplored. Scientific claims frequently depend on methodological assumptions, dataset characteristics, and experimental conditions that must be interpreted together rather than in isolation. Furthermore, review

EMNLP 2026 Industry Track, pages 2865–2888
October 24-29, 2026 ©2026 Association for Computational Linguistics

statements often combine objectively verifiable assertions with subjective judgments, requiring systems to distinguish between components that can be grounded in evidence and those that reflect reviewer opinion (Metropolitansky and Larson, 2025; Pavlick and Kwiatkowski, 2019; Plank, 2022). Operationalizing review groundedness thus requires robust document understanding, evidence retrieval, multi-hop reasoning, and careful treatment of ambiguity (Pavlick and Kwiatkowski, 2019; Plank, 2022; Arabzadeh et al., 2026a). We provide a more comprehensive discussion of related work in Appendix B.

We identify manuscript-grounded peer-review claim verification as an important but underexplored challenge in scholarly publishing. To address this challenge, we propose PEERIFY, an end-to-end pipeline for peer-review claim verification. PEERIFY pipeline decomposes reviews into atomic, self-contained claims, retrieves relevant manuscript evidence for each claim, and performs groundedness assessment. PEERIFY pipeline was designed with practical deployment requirements in mind, including scalability to large review volumes, transparent evidence attribution, robustness across diverse claim types, and compatibility with existing editorial processes. We use *production-ready* in an engineering sense: the pipeline is complete, runs on commodity hardware, and is designed for a human-in-the-loop workflow in which PEERIFY triages reviewer claims and surfaces the supporting passages, and an area chair or author acts on them (Appendix E).

To systematically evaluate this task and pipeline, we construct a benchmark of 800 atomic review claims derived from publicly available NeurIPS 2024 and ICLR 2024 submissions, together with their reviews and author–reviewer discussion threads. The benchmark captures diverse verification scenarios, including explicitly supported claims, claims requiring evidence aggregation, ambiguous claims, and claims that cannot be resolved from the manuscript alone.

Using this benchmark, we evaluate PEERIFY pipeline end to end and analyze each of its core components, including claim extraction, evidence retrieval, retrieval configurations, and state-of-the-art language-model verifiers. Our results show that retrieval-centered verification and claim decomposition are important for manuscript-grounded review verification, but also reveal that ambiguous, interpretive, and partially supported reviewer claims remain challenging for current methods. We release PEERIFY pipeline, the benchmark, labels, prompts, and code to support reproducible research at `https://github.com/Reviewerly-Inc/Peerify/`.

PEERIFY makes the following contributions:

1. **Task.** We formalize manuscript-grounded peer-review claim verification as an intra-document verification task, where claims from peer reviews are assessed strictly against the reviewed manuscript.
2. **System.** We propose PEERIFY, an end-to-end verification pipeline that decomposes reviews into atomic claims, retrieves relevant manuscript evidence, and predicts explicit evidence attribution.
3. **Benchmark and evaluation.** We construct an 800-claim benchmark from NeurIPS 2024 and ICLR 2024 peer-review interactions, with six evaluation variants and quality-controlled slices to evaluate PEERIFY pipeline, including a 300-claim human-audited subset that covers 37.5% of the benchmark.

3 PEERIFY Pipeline

3.1 Problem Definition

Let P denote a scientific manuscript and R denote an associated peer review. The objective of review-groundedness verification is to determine whether verifiable claims contained within R are supported by evidence present in P. Formally, a review R can be represented as a collection of atomic claims $C = \{c_1, \ldots, c_m\}$. For each claim c_i, the system identifies a set of supporting evidence candidates $E_i = \{e_1, \ldots, e_k\}$ from the manuscript and predicts a groundedness label $y_i = f(c_i, E_i)$.

This formulation differs from traditional fact verification and textual entailment settings (Dagan et al., 2006; Thorne et al., 2018; Wadden et al., 2020) in several important respects. First, the evidence space is restricted to a single scientific manuscript rather than an external corpus. Second, evidence supporting a review claim may be distributed across multiple sections, tables, appendices, and more. Third, review claims frequently involve methodological choices, experimental design decisions, and interpretations of empirical findings whose validity depends on contextual qualifiers and evidence aggregation.

3.2 Operationalization in PEERIFY

PEERIFY operationalizes review-groundedness verification as a three-stage pipeline:

Step 1: Claim extraction. Review comments often contain several assertions in a single sentence, mixing factual observations with subjective judgments or recommendations. Direct verification is difficult because different portions may require distinct evidence. PEERIFY therefore adopts a claim decomposition strategy, breaking each review comment into atomic, self-contained claims that can be verified independently. This step preserves the reviewer's intended meaning while isolating factual assertions to be checked against the manuscript.

Step 2: Evidence retrieval. The manuscript is segmented into retrieval units such as paragraphs, figure captions, tables, and appendix passages. Given a claim, PEERIFY retrieves the top-k relevant passages based on semantic similarity between the claim and indexed manuscript segments. Since supporting evidence may be distributed across multiple locations, PEERIFY retrieves a set of evidence candidates rather than a single passage, allowing downstream verification to reason over complementary evidence throughout the document.

Step 3: Groundedness assessment. Finally, PEERIFY verifies each claim against the retrieved evidence, building on evidence-based verification paradigms from textual entailment, fact verification, and scientific claim verification (Dagan et al., 2006; Thorne et al., 2018; Wadden et al., 2020). The verifier jointly reasons over the claim and manuscript evidence to determine the extent of support, assigning one of four labels: *Supported*, *Partially Supported*, *Not Supported*, or *Not Determined*. Each prediction is paired with the evidence used for the decision, making the output transparent and traceable for human inspection.

4 Benchmarking PEERIFY

The PEERIFY pipeline requires an evaluation framework that reflects the challenges of real peer-review workflows. Existing claim-verification resources such as FEVER (Thorne et al., 2018) and SciFact (Wadden et al., 2020) evaluate claims against external corpora, but do not capture manuscript-bounded verification, author–reviewer interactions, or the mix of factual and subjective assertions common in peer review (see Appendix B). We therefore develop the PEERIFY benchmark, which operationalizes review groundedness as an intra-document verification task and supports the development, validation, and evaluation of review-groundedness verification systems. To ensure ecological validity, all claims are derived from authentic peer-review interactions and evaluated against the manuscripts under review. The resulting benchmark contains 800 review-derived claims from publicly available NeurIPS 2024 and ICLR 2024 submissions. This is at or above standard expert-annotated claim-verification sets, with every label grounded in a manuscript (Appendix D.8).

4.1 Source Collection

We collected manuscripts, reviews, author responses, and discussion threads from publicly available submissions in NeurIPS 2024 and ICLR 2024. These venues provide complete review artifacts, including reviewer comments and author rebuttals, so each instance pairs a manuscript with its review and discussion history and supports multiple sources of evidence about a claim's validity. As reported in Table 1, the collected papers are well balanced across review outcomes, covering both accepted and rejected submissions.

4.2 Claim Construction

Review comments contain summaries, questions, recommendations, methodological critiques, and subjective opinions. Since review-groundedness verification operates at the level of individual factual assertions, raw review text was transformed into atomic claims suitable for independent verification.

To construct these claims, we evaluated three extraction approaches: `Qwen3-4B` (Yang et al., 2025), prompted to produce atomic, decontextualized assertions; Fenice (Scirè et al., 2024), which uses dependency parsing and semantic role labeling to identify proposition structures; and Gemma, a general-purpose instruction-tuned model prompted to list atomic claims from each passage.

We run a controlled comparison of the three extractors and adopt `Qwen3-4B` for all benchmark construction, as it gives the best balance of atomicity, decontextualization, and semantic fidelity. The full evaluation protocol and results are deferred to Appendix A.1. We also scored `o4-mini` and `GPT-5-mini` as extractors: both are stronger on F1 (0.895 and 0.915 against 0.707), but the gap is mostly recall rather than precision (0.889), and extraction is the high-volume stage where API cost and rate limits bite (Appendix A.2). A human au-

Table 1: PEERIFY benchmark statistics overview.

Dataset	#Papers	#Claims	Supported	Partially Supported	Not Supported	Not Determined	ICLR	NeurIPS	Reject	Accept
NeurIPS 2024	4236	-	-	-	-	-	-	100%	86.0%	14.0%
ICLR 2024	5778	-	-	-	-	-	100%	-	31.3%	68.7%
PAPERSOURCED (4.4)	100	500	500	0	0	0	52.0%	48.0%	27.0%	73.0%
REBUTTALSOURCED (4.4)	84	800	217	310	189	84	61.0%	39.0%	34.9%	65.1%
LLMJUDGED (4.4)	84	800	207	93	141	359	61.0%	39.0%	34.9%	65.1%
HIGHAGREEMENT (4.4)	71	175	60	39	43	33	63.4%	36.6%	37.1%	62.9%
VERIFIABLE-ONLY (4.4)	67	131	56	29	25	21	64.9%	35.1%	36.6%	63.4%
HUMAN-VERIFIED (4.4)	75	300	77	107	78	38	57.3%	42.7%	34%	66%

dit of the semantic-equivalence judge behind these scores gives 89.3% agreement (Appendix A.3). Extracted claims were subsequently post-processed through exact and near-duplicate removal, string normalization, and filtering of rhetorical questions, speculative statements, and non-verifiable meta-commentary.

4.3 Groundedness Annotation

Each extracted claim is assigned one of the four labels of *Supported*, *Not Supported*, *Partially Supported* or *Not Determined*. Each claim is additionally tagged as *factual* or *subjective* (automatically, with `o4-mini`; criteria in Appendix A.5), and the VERIFIABLE-ONLY slice retains only factual claims. This ensures groundedness is evaluated on assertions checkable against the manuscript rather than on inherently subjective reviewer opinions. The split is close to even (444 objective, 356 subjective), and objective claims counter-intuitively need a human tie-breaker *more* often, 41.4% against 38.2% (Appendix A.6).

4.4 Evaluation Variants

PEERIFY includes four core benchmark variants and two quality-controlled slices, capturing complementary notions of groundedness and label confidence.

PAPERSOURCED. PAPERSOURCED provides a controlled diagnostic setting in which claims are extracted directly from manuscript content. These claims are *verifiable by construction* and are expected to be labeled `Supported`. We use this subset as a sanity check to isolate errors in retrieval and verification from ambiguity in review-derived content.

REBUTTALSOURCED. This variant derives supervision from realistic author–reviewer discussion threads, assigning each claim a label by interpreting the author response signal (agreement, correction, clarification, or explicit dispute). Two language models (`GPT-5-mini` and `Claude-Sonnet-4-6`) label each claim independently from the discussion context, with a human arbitrating disagreements to produce the canonical label (Appendix A.10). This interaction-grounded supervision, captures how authors themselves judge the correctness of reviewer claims.

LLMJUDGED. This subset provides scalable supervision by judging each claim directly against the manuscript. The same two labelers (`GPT-5-mini` and `Claude-Sonnet-4-6`) independently assign one of four labels under strict document-bounded evidence constraints, and a human annotator arbitrates the cases where they disagree to produce the canonical label (More details in Appendix A.10). We evaluate label quality against the HUMAN-VERIFIED labels in Appendix A.8.

HUMAN-VERIFIED To provide high-fidelity reference labels and audit automated supervision, we manually annotated a subset of 300 REBUTTALSOURCED instances, which is 37.5% of the benchmark. Two annotators with formal training in computer science independently labeled each instance following detailed guidelines with concrete examples. Inter-annotator reliability was near-perfect (Cohen's $\kappa \approx 0.96$) for the four-way nominal task, with disagreements resolved through consensus. Against these labels the automated supervision is correct on 90.3% of the 300 claims under strict four-way exact match ($\kappa = 0.87$), 97.0% allowing a one-step difference, with hard polarity flips in 1.0% of cases. Reliability is flat across claim types, 90.5% objective against 90.1% subjective, which is where a labeler-inherited bias would surface first (Appendix A.9).

Quality-Controlled Slices we additionally release slices that improve label reliability. First, the HIGHAGREEMENT slice retains only instances where two supervision signals with disjoint evidence, REBUTTALSOURCED and LLMJUDGED, agree, yielding a high-confidence subset less sensitive to labeling noise. Both signals come from the same two

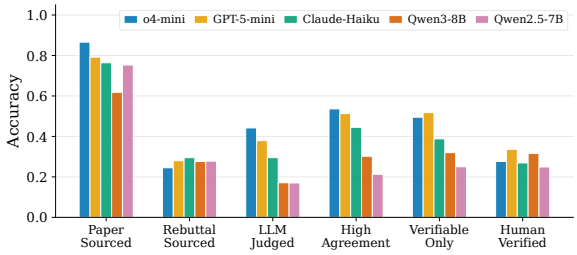

Figure 1: Full-context verification accuracy across all six PEERIFY benchmark variants.

labeler models, so a match is not annotator consensus; what differs is the evidence, since REBUTTALSOURCED reads only the discussion thread and LLMJUDGED only the manuscript, and agreement across disjoint inputs signals claim clarity (see Limitations). Second, to isolate assertions checkable directly against the manuscript, the VERIFIABLE-ONLY slice uses `o4-mini` to filter out subjective or normative claims such as novelty, significance, or impact. Specifically, the model predicts whether a claim is (i) grounded in factual content observable in the manuscript, such as missing experiments or absent figures, or (ii) an opinion, recommendation, or forward-looking judgment not directly verifiable from the paper alone. Table 1 shows the support-level distributions across different variants. PAPERSOURCED is entirely `Supported` (500/500) by construction and serves as a controlled diagnostic. REBUTTALSOURCED is far more heterogeneous (217 Supported, 310 Partially Supported, 189 Not Supported, 84 Not Determined), reflecting corrections, and unresolved disagreement in author–reviewer exchanges. LLMJUDGED shifts heavily toward `Not Determined` (207 Supported, 93 Partially Supported, 141 Not Supported, 359 Not Determined), indicating that many review statements cannot be decisively validated from the manuscript alone.

5 Experimental setup

We evaluate PEERIFY in two deployment configurations. *Full-Context* feeds the whole manuscript and claim to the verifier, serving as a full-document baseline when the paper fits within the context window; over-length papers are excluded per model. *Retrieval-Augmented* (RAG) retrieves evidence per claim and conditions the verifier only on the top-k passages, with or without a cross-encoder reranker, enabling deployment on long manuscripts. All prompts are listed in Appendix C.

We instantiate PEERIFY pipeline with five state-of-the-art models spanning proprietary and open-weight families: `o4-mini` (200K-context reasoning model), `GPT-5-mini` (compact, long-context), `Claude-Haiku-4.5` (low-latency, 200K context), and the open-weight `Qwen3-8B` and `Qwen2.5-7B`, the last two evaluated mainly under RAG due to context-window limits. All models receive identical label definitions and prompts, and outputs are mapped to the four support level labels.

We evaluate retrieval with recall@k, nDCG@k, and MRR on PAPERSOURCED (BM25 or a dense retriever, optionally reranked by a cross-encoder; retriever and reranker checkpoints, top-k, and chunking are detailed in Appendix D.9), and verification with Accuracy and Macro-F1, taking Macro-F1 as the primary metric since it is robust to label imbalance. Retrieval metrics are reported only on PAPERSOURCED because gold evidence spans exist only there, so they are inapplicable to the review-derived variants by construction rather than omitted (Appendix D.11).

Non-LLM baselines. We add three zero-shot MNLI entailment baselines (Liu et al., 2019; Lewis et al., 2020a; He et al., 2021), with the top-3 retrieved chunks as premise and the claim as hypothesis, run under all four retrieval configurations so a weak result cannot be blamed on one retriever (Appendix D.5).

6 Results and Findings

In this section, we evaluate PEERIFY pipeline from several complementary perspectives.

6.1 Full-context Verification

Figure 1 and Table 3 report verification accuracy across the six evaluation variants, revealing a clear difficulty gradient. Performance is highest on PAPERSOURCED, where claims come directly from manuscript content and evidence is explicit; `o4-mini` reaches 0.866, and four of five verifiers exceed 0.75. Accuracy drops on review-derived settings such as LLMJUDGED and HIGHAGREEMENT, where claims require reasoning over dispersed evidence and reviewer intent. Even the strongest verifier reaches only 0.442 on LLMJUDGED, showing that review-groundedness verification goes beyond simple evidence localization. The hardest setting is REBUTTALSOURCED, where claims come from real author–reviewer interactions and often mix factual observations. HUMANVERIFIED behaves the same way, with no verifier clearing 0.38 across its 300 hand-labeled claims.

Table 2: RAG accuracy across five models and four retrievers on all six PEERIFY benchmarks.

Model	Retriever	PAPER SOURCED	REBUTTAL SOURCED	LLM JUDGED	HIGH AGREEMENT	VERIFIABLE -ONLY	HUMAN VERIFIED
o4-mini	BM25	0.818	0.234	0.491	**0.514**	0.466	0.243
	BM25+Reranker	0.870	0.234	0.496	**0.514**	**0.519**	0.237
	Dense	0.852	0.244	**0.514**	0.509	0.466	0.230
	Dense+Reranker	**0.904**	0.240	0.499	0.497	0.466	0.257

	Dense	0.832	**0.324**	0.209	0.263	0.260	0.307
	Dense+Reranker	0.860	0.295	0.228	0.291	0.305	0.287

Table 3: Full-context accuracy (five models, six benchmarks). Qwen2.5-7B excludes 9 over-length papers (Section 5). HUMAN-VERIFIED is the expanded 300-instance subset; Table 12 compares it against the original 150 instances.

Benchmark	o4-mini	GPT-5-mini	Claude-Haiku	Qwen3-8B	Qwen2.5-7B
PAPERSOURCED	**0.866**	0.792	0.764	0.618	0.753
REBUTTALSOURCED	0.245	0.280	**0.295**	0.276	0.278
LLMJUDGED	**0.442**	0.379	0.295	0.171	0.170
HIGHAGREEMENT	**0.536**	0.513	0.445	0.302	0.213
VERIFIABLE-ONLY	0.495	**0.518**	0.388	0.320	0.250
HUMAN-VERIFIED	0.267	0.317	0.300	**0.377**	0.256

6.2 Retrieval-Centered Verification.

A key design decision in PEERIFY is separating evidence retrieval from groundedness assessment. Table 2 evaluates four retrieval configurations, including BM25, dense retrieval, and their reranked variants. Retrieval quality substantially affects verification accuracy, but no retriever dominates across all settings. On PAPERSOURCED, where evidence is explicit, reranking consistently improves performance. Dense+Reranker increases o4-mini from 0.852 to 0.904, and BM25+Reranker increases GPT-5-mini from 0.796 to 0.856. On review-derived benchmarks, however, gains are less consistent. For example, Dense retrieval performs best for o4-mini on LLMJUDGED (0.514), while BM25-based retrieval works best for GPT-5-mini (0.417) and Qwen3-8B (0.393). Similar variability is observed on HIGHAGREEMENT and HUMAN-VERIFIED, indicating that retrieval effectiveness depends not only on evidence quality but also on how each verification engine consumes retrieved context. Better retrieval therefore helps most when the task requires explicit evidence localization, and much less on REBUTTALSOURCED and HUMAN-VERIFIED, where claims require interpreting reviewer intent and resolving partial support: retrieval is necessary but not sufficient. Table 4 shows why the ceiling is partly extrinsic: no retriever clears 0.53 Recall@10, so a third of the supporting evidence is never placed in front of the verifier.

Zero-shot entailment models reach at most 0.24 macro-F1, roughly half the weakest LLM verifier. Swapping the LLM verifier for an off-the-shelf NLI model, everything else fixed, does not come close: across three MNLI models and all four retrievers, macro-F1 never exceeds 0.24 on any variant, against 0.45 to 0.50 for the best LLM configuration on the document-decidable splits (Appendix D.5). Two structural

Table 4: Retrieval quality on PAPERSOURCED.

Retriever	Recall@5	Recall@10	nDCG@10	MRR@10
BM25	0.398	0.474	0.570	0.289
BM25 + Reranker	0.434	0.492	0.608	0.331
Dense	0.420	0.528	0.644	0.299
Dense + Reranker	**0.452**	**0.530**	**0.684**	**0.346**

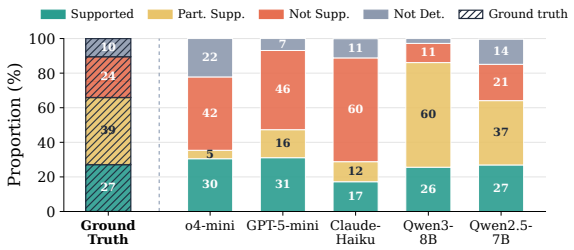

Figure 2: Predicted vs. ground-truth (GT) labels on REBUTTALSOURCED. Models exhibit different calibration biases: some over-predict *Not Supported*, while others over-predict *Partially Supported* or better match the GT distribution.

causes explain this: three-way NLI cannot express `Partially Supported`, the largest class in REBUTTALSOURCED, and a 512-token premise limit truncates most of the retrieved evidence. The retriever moves these numbers by at most two points, so the shortfall belongs to the formulation, which needs long-context reasoning.

6.3 Error Analysis

The largest error source is REBUTTALSOURCED, where reviewer claims mix factual observations with interpretive judgments, and calibration differences across verification engines (Figure 2) show that calibration matters as much as reasoning capability. A second failure mode emerges on LLM-JUDGED and HIGHAGREEMENT, where verification requires multi-step reasoning over dispersed evidence, limiting even the strongest verifier to 0.442 and 0.536 accuracy. The primary bottlenecks are reasoning over distributed evidence and handling interpretive or partially supported claims, a diagnosis confirmed by full-context verification, which removes retrieval entirely and still does not lift accuracy on these splits (Appendix D.11).

Nine in ten PAPERSOURCED errors are strictness or retrieval, not faulty reasoning. PAPERSOURCED is the one split where the gold label is known for every instance without appeal to a judge, which makes it the right place to ask what a residual error actually consists of. We manually inspected a stratified sample of 150 errors, 30 per verifier under RAG, and assigned each to one of three categories that proved exhaustive (Table 5). Overly strict specificity accounts for 83 errors (55.3%): the verifier retrieves the correct passage and then declines to call the claim `Supported` because one fine detail, an exact count or an appendix pointer, is not restated verbatim. Retrieval misses account for 54 (36.0%): the supporting passage never enters the top-k chunks, so the verifier correctly reports that the evidence in front of it does not contain the claim. The remaining 13 (8.7%) are malformed outputs that cannot be parsed into a label.

Table 5: Error taxonomy on PAPERSOURCED under RAG, from manual inspection of a stratified sample of 150 errors (30 per verifier). Every claim in this split is genuinely `Supported`, so any other predicted label counts as an error.

Error type	Share
Overly strict specificity (downgrade to `Part. Supp.`)	55.3%
Retrieval and evidence localization miss	36.0%
Verifier output or parse failure	8.7%

7 Conclusion

We presented PEERIFY, a pipeline and benchmark for verifying peer reviews. Our evaluation shows that verifying interpretive claims requires long-context, four-way reasoning rather than simple entailment. Furthermore, retrieval and reasoning create distinct bottlenecks depending on the claim, and raw accuracy is often misleading, making macro-F1 a necessary evaluation metric. Our automated labeling proved highly reliable, matching human consensus on 90.3% of an audited subset. Designed for a human-in-the-loop editorial workflow, PEERIFY accelerates review verification by triaging questionable claims and surfacing manuscript evidence. Future extensions include verifying claims against external literature, joint training, and exploring abstention-aware objectives. We release the pipeline, benchmark, and all artifacts to support this work. Taken together, these results argue for treating review verification as an evidence-grounded reasoning task rather than a sentence-level entailment problem.

Limitations

PEERIFY performs **intra-document** verification, assessing review claims only against the corresponding manuscript; claims requiring external literature or background knowledge are out of scope. The benchmark is built from public OpenReview data for NeurIPS 2024 and ICLR 2024, so its distribution may not transfer to other fields or venues with different review norms. Some variants rely on weak supervision (author–reviewer discussions and LLM judgments); we mitigate this with the HIGHAGREEMENT and VERIFIABLE-ONLY slices, but residual ambiguity in review language remains. Finally, models show strong calibration bias (e.g., `Qwen3-8B` predicts `Partially Supported` for 60.5% of REBUTTALSOURCED claims vs. a 38.8% ground-truth rate), so accuracy alone can mislead; we recommend reporting macro-F1 alongside accuracy.

Ethics Statement

The benchmark uses only publicly accessible OpenReview submissions, reviews, and discussions from NeurIPS 2024 and ICLR 2024; no private or proprietary data are used, and no reviewer or author is identified beyond what is already public. The 300 HUMAN-VERIFIED instances were labeled by two graduate-level researchers following explicit guidelines after a calibration round; no crowdsourced or low-paid labor was involved. PEERIFY is intended as an *assistive* tool that supplements rather than replaces human judgment, and should not be used to rank or target specific reviewers, authors, or submissions. Because LLM-based judges and extractors can carry systematic biases (Section 6), automated labels should not be treated as ground truth without further validation. We release all data, labels, prompts, and code under open licenses with documentation of provenance and known limitations.

Appendix

Appendix Overview. The appendix is organized around the three questions a reader is most likely to bring to the paper. *How was the benchmark built, and can its labels be trusted?* Appendix A covers the construction pipeline end to end: the extractor comparison and why we run an open-weight model despite lower F1 (A.1, A.2), the human audit of the semantic-equivalence judge (A.3), label definitions and the factual/subjective split (A.4, A.5, A.6), and the two reliability analyses that matter most, agreement between the automated labels and human consensus (A.9) and the two-labeler arbitration protocol behind the canonical labels (A.10). *What exactly was the model asked?* Appendix C reproduces every prompt verbatim. *What do the numbers look like beyond the main tables?* Appendix D holds the per-model results (D.1, D.2, D.3, D.4), the non-LLM entailment baselines (D.5), the manual error taxonomy and the calibration effect behind the PAPERSOURCED ordering (D.6, D.7), benchmark size in context (D.8), retrieval quality and cost (D.9, D.10), and the reason intrinsic retrieval metrics apply to only one split (D.11). Appendix B gives the extended related work, and Appendix E closes with the intended deployment setting.

A Benchmark Construction and Annotation

A.1 Claim Extraction Evaluation

A critical step in the PEERIFY pipeline is accurately decomposing dense, multi-faceted reviewer comments into isolated and verifiable statements. Because reviewer feedback often blends factual assertions with subjective interpretation, the claim extraction module must distill these paragraphs into atomic claims while strictly preserving the original intent of the reviewer. To determine the most robust approach for this task, table 6 compares the performance of three distinct claim extractors (Fenice (Scirè et al., 2024), Gemma (Hosseini et al., 2024), and `Qwen3-4B` (Yang et al., 2025)) across two evaluation axes: semantic alignment with a reference extraction (LLM-as-a-judge) and intrinsic structural quality (reference-free). The two axes are complementary: reference-based metrics capture coverage, while reference-free metrics capture whether individual claims are verification-ready. The evaluation focuses on how effectively each model parses authentic review text from our NeurIPS and ICLR 2024 dataset into self-contained propositions suitable for downstream retrieval and verification.

A.1.1 Reference-Based Evaluation.

To establish a strong comparison signal, we use `o4-mini` as a high-quality reasoning model to generate a reference set of claims that are manually verified to be atomic and decontextualized. We treat this reference extraction as a stronger summarization-style signal and evaluate how well each candidate extraction method aligns with it. Agreement is measured using an LLM-as-a-judge protocol. We employ `GPT-5-mini` as a semantic judge: for each extracted claim, we identify the most similar reference claim and ask the judge whether the two express the same atomic proposition. Based on these semantic equivalence decisions, we compute precision, recall, and F1 scores.

For the reference-based axis, `o4-mini` is used *only* to generate the high-fidelity reference set against which the three candidate extractors are scored; it is not used to produce any of the 800 benchmark claims. The benchmark claims are sourced exclusively from `Qwen3-4B`, which achieves the best overall balance and is therefore used for all benchmark construction, ensuring extraction quality and reproducibility.

A.1.2 Reference-Free Evaluation.

Regardless of the reference set, a useful claim must meet specific structural and linguistic criteria for downstream verification (Ullrich et al., 2025; Wright et al., 2022). We use `o4-mini` to audit each method's output against three core dimensions. **Atomicity** measures whether a claim expresses exactly one checkable assertion. **Faithfulness** assesses whether the claim remains grounded in the original reviewer's text without introducing hallucinations or scope-creep. **Decontextualization** checks whether the claim is self-contained and does not rely on unresolved references such as "the method" or "Figure 1" that require surrounding context to interpret.

Gemma extracts the most claims; `Qwen3-4B` extracts the most usable ones. The evaluation reveals distinct operational profiles among the extracted models. Fenice exhibits a high-precision, low-recall regime by extracting 739 claims with a precision of 0.872 and a recall of 0.538, effectively

Table 6: Claim-extraction quality: LLM-as-a-judge (GPT-5-mini, reference-based) and reference-free intrinsic metrics.

		Reference-Based			Reference-Free		
Extractor	**count**	**Prec.**	**Rec.**	**F1**	**Atom.**	**Flue.**	**Deco.**
Fenice	739	0.872	0.538	0.665	0.314	0.788	0.362
Gemma	2464	0.868	**0.762**	**0.811**	0.379	0.781	0.329
Qwen3-4B	923	**0.889**	0.587	0.707	**0.451**	**0.927**	**0.524**

minimizing false positives at the expense of comprehensive coverage. Conversely, Gemma prioritizes recall by achieving a rate of 76.2% and an F1 score of 0.811, but it generates a substantially larger volume of 2,464 candidate claims. Qwen3-4B optimizes this balance by producing 923 claims with a precision of 0.889, thereby maintaining strict semantic control. In the context of downstream verification, the implications of this tradeoff are asymmetric: while unextracted claims merely reduce total evaluation coverage, poorly formulated claims systematically confound reliable classification.

Intrinsic quality is the discriminating dimension. Beyond semantic alignment, intrinsic structural quality emerges as the critical factor determining extractor viability. Qwen3-4B demonstrates significantly superior performance across essential structural metrics. Specifically, it achieves an atomicity score of 0.451, which exceeds the scores of 0.379 for Gemma and 0.314 for Fenice. Furthermore, its fluency score of 0.927 surpasses both Gemma and Fenice as well. Finally, Qwen3-4B records a decontextualization score of 0.524, notably outperforming the respective scores of 0.329 and 0.362 achieved by Gemma and Fenice. These structural properties are foundational to downstream verification accuracy. Consequently, the high-fidelity benchmark slices, specifically VERIFIABLE-ONLY and HIGHAGREEMENT, are constructed exclusively using Qwen3-4B extractions. Robust claim extraction is a prerequisite for reliable evaluation, meaning these extraction quality differentials directly determine the diagnostic validity of the resulting benchmark partitions.

A.2 Extraction Cost, Latency, and Model Choice

Table 6 compares the three open-weight extractors on quality alone. That comparison leaves an obvious question open, since o4-mini and GPT-5-mini already appear elsewhere in the pipeline: if those models are good enough to generate the reference claims and to judge semantic equivalence, why not use one of them to extract? Table 7 answers it with measurements instead of an assertion, scoring all five candidates under the same protocol and adding median latency per review and average API cost per review.

Table 7: Claim-extraction quality, latency, and cost for all five candidate extractors, scored against the same reference claim set with the GPT-5-mini semantic-equivalence judge. Latency is the median wall-clock time per review, measured locally on a single NVIDIA RTX 3090 for open-weight models and over the network for API models. Cost is the average API spend per review. †GPT-5-mini also generated the reference claims, so its F1 is a self-consistency upper bound rather than a comparable score; o4-mini is the fair proprietary reference point.

Extractor	**Prec.**	**Rec.**	**F1**	**Latency (s)**	**Cost**
Fenice	0.872	0.538	0.665	1.97	open-weight
Qwen3-4B	0.889	0.587	0.707	8.20	open-weight
Gemma	0.868	0.762	0.811	21.76	open-weight
o4-mini	0.990	0.817	0.895	9.62	$0.29
GPT-5-mini	**0.994**	**0.849**	0.915†	24.43	$0.11

The proprietary models are clearly better extractors. o4-mini reaches 0.895 F1 and GPT-5-mini 0.915, against 0.707 for Qwen3-4B. We note that the GPT-5-mini figure is not directly comparable, because the same model generated the reference claims, so 0.915 is a self-consistency ceiling; o4-mini at 0.895 is the honest cross-model number.

We still extract with Qwen3-4B, for three reasons that the table makes concrete. First, cost scales with volume, and extraction is the highest-volume stage: it runs over every sentence of every review, whereas verification runs once per extracted claim. At $0.11 to $0.29 per review, extracting a full conference cycle through an API is a real budget line and a rate-limit exposure, and it puts the expensive model at the cheap end of the pipeline. We would rather spend that budget on verification, which is where the reasoning difficulty actually is. Second, reproducibility: an open-weight extractor lets anyone regenerate or extend the benchmark, whereas a versioned API can be updated or deprecated underneath a published dataset. Third, the quality gap sits mostly in recall (0.587 against 0.817), not precision (0.889 against 0.990). For a benchmark that evaluates claim *verification* rather than exhaustive claim *mining*, missing a claim reduces coverage

Table 8: Human validation of the GPT-5-mini semantic-equivalence judge. An independent annotator re-evaluated 50 randomly sampled equivalence judgements per extractor.

Extractor	Agreement	Rate
Fenice	45 / 50	90.0%
Gemma	42 / 50	84.0%
Qwen3-4B	47 / 50	**94.0%**
Overall	**134 / 150**	**89.3%**

while a badly formed claim corrupts a verification unit, so precision is the axis that matters and the local model is close to the frontier there.

A.3 Human Validation of the Semantic-Equivalence Judge

The reference-based scores in Table 6 rest on GPT-5-mini deciding whether an extracted claim and a reference claim express the same proposition. Since that decision drives which extractor we adopt, we validate it against human annotation like every other automated component of the benchmark. An annotator who had not worked on the extraction pipeline independently re-decided 50 randomly sampled equivalence judgements per extractor, 150 in total, seeing the claim pair but not the judge's verdict.

Agreement is 89.3% overall and is consistent across extractors, from 84.0% on Gemma to 94.0% on Qwen3-4B (Table 8). This is close to the rate at which our groundedness labels match human consensus (Appendix A.9), which suggests the judge is a reasonable stand-in for a human on this narrow decision, and it supports applying it across the whole extraction evaluation rather than reporting a hand-checked subset. The Gemma figure is the lowest of the three, which is consistent with its output profile: it produces 2,464 claims, many of them long or under-decontextualized, and those are exactly the pairs where equivalence is a judgement call rather than a lookup.

A.4 Label Definitions and Examples

Each review claim receives one of the four labels defined in Section 3.1, determined by whether the manuscript provides sufficient evidence under a strict document-bounded grounding criterion. Worked examples follow.

- `Supported`: The manuscript provides clear and sufficient evidence that fully substantiates the claim. *Example:* A reviewer states "The authors evaluate on CIFAR-100," and the paper explicitly reports CIFAR-100 experiments.
- `Not Supported`: The manuscript contradicts the claim or the asserted content is demonstrably absent. *Example:* A reviewer states "No ablation study is provided," but the paper contains a dedicated ablation section.
- `Partially Supported`: The manuscript supports only a qualified or incomplete version of the claim. *Example:* A reviewer states "The method outperforms all baselines," but the paper shows it outperforms most but not all.
- `Not Determined`: The manuscript does not contain sufficient information to resolve the claim in either direction. This label applies when (i) the claim references external knowledge or prior work not discussed in the paper, (ii) the claim is too vague or ambiguous to verify, or (iii) the relevant evidence is absent without any contradicting assertion.

A.5 Factual vs. Subjective Claims

Each claim is tagged as *factual* or *subjective* using o4-mini: *factual* if its validity is grounded in content observable in the manuscript (e.g., a missing experiment or an absent figure), and *subjective* if it is an opinion, recommendation, or forward-looking judgment about novelty, significance, or impact that cannot be resolved from the paper alone. The VERIFIABLE-ONLY slice retains only factual claims, so verification on that slice targets assertions checkable against the manuscript rather than reviewer opinion.

A.6 Claim Types and Arbitration

We used GPT-5-mini to sort the 800 benchmark claims into objective claims, whose truth follows from something written in the manuscript, and subjective claims, which are judgements about novelty, significance, or direction. The split is 444 objective and 356 subjective. We then measured how often each type required human arbitration, meaning the two automated labelers disagreed and a person had to break the tie.

The result runs against intuition. Objective claims are arbitrated *more* often than subjective ones, 41.4% against 38.2% (Table 9). The explanation is that objectivity in a peer review is not the same as ease of verification. Settling "the paper

Table 9: Arbitration on REBUTTALSOURCED broken down by claim type. *Arbitrated* counts claims where the two automated labelers disagreed and a human tie-breaker was needed. *Neither* counts disagreements where the human annotator supplied a third label because both candidates were wrong.

Claim type	Total	Arbitrated	Arbitration rate
Objective	444	184	41.4%
Subjective	356	136	38.2%
Overall	800	320	40.0%

Arbitration outcome	Objective	Subjective
Labelers agree (no arbitration)	260 (58.6%)	220 (61.8%)
`GPT-5-mini` upheld	93 (21.0%)	65 (18.3%)
`Claude-Sonnet-4-6` upheld	79 (17.8%)	57 (16.0%)
Neither upheld	12 (2.7%)	14 (3.9%)

does not compare against baseline X" or "the reported IoU is 44.91" requires finding one specific fact somewhere in a long manuscript, and two labelers that retrieve different passages will reach different conclusions. Subjective claims are vaguer, but that vagueness gives the labelers less to disagree about: both tend to land on `Partially Supported` or `Not Determined`.

The arbitration outcomes point the same way. `GPT-5-mini` is upheld somewhat more often than `Claude-Sonnet-4-6` in both categories (21.0% against 17.8% on objective claims, 18.3% against 16.0% on subjective ones), so neither labeler dominates and the arbitration is not a systematic correction of one model. Cases where the human annotator had to supply a third label because both candidates were wrong are rare, 2.7% on objective claims and 3.9% on subjective ones. The slightly higher rate on subjective claims is the expected direction: when a reviewer's remark is genuinely interpretive, there is sometimes no label either model would have proposed.

A.7 Benchmark Label Distributions

Table 1 in Section 3 reports the full PEERIFY benchmark statistics overview, including label distributions across all six benchmark variants and dataset provenance (venue and acceptance decision). The PAPERSOURCED variant is all-Supported by construction; the remaining variants show progressively more heterogeneous label distributions as claims become more interaction-grounded and ambiguous. The four HUMAN-VERIFIED label counts are the human-consensus totals of Table 10.

A.8 Inter-Source Agreement

The HIGHAGREEMENT slice is constructed by retaining only instances where REBUTTALSOURCED and LLMJUDGED labels agree. This section describes the agreement analysis underlying this design choice.

Automated supervision sources. REBUTTALSOURCED labels are derived from author–reviewer interaction dynamics: the model infers whether the author's response confirms or refutes the reviewer's claim. LLMJUDGED labels are derived from direct document-bounded verification: the model checks whether the manuscript supports the claim without consulting the discussion thread. These two sources are therefore *independent* in both mechanism and evidence source, making their agreement a meaningful signal of claim clarity and label reliability.

Across the 800 core review-derived claims, the canonical REBUTTALSOURCED and LLMJUDGED labels agree on 175 instances (21.9%), forming the HIGHAGREEMENT slice. The relatively low raw agreement rate reflects the genuine difficulty of peer-review claims and the different perspectives captured by the two supervision sources: interaction-grounded labels capture how authors interpret their own work, while document-grounded labels capture what the manuscript literally supports.

Automated supervision vs. human labels. To validate automated supervision quality, we compare both REBUTTALSOURCED and LLMJUDGED labels against the HUMAN-VERIFIED consensus labels. Inter-annotator agreement between the two human annotators is near-perfect (Cohen's $\kappa \approx 0.96$), indicating that the high human–automated agreement is not an artifact of low human reliability. These results support the use of REBUTTALSOURCED and LLMJUDGED as reliable large-scale supervision sources, with HUMAN-VERIFIED serving as a gold-standard reference for validation and error analysis. Appendix A.9 gives the full confusion matrix and a per-claim-type breakdown.

A.9 Human-Verified Label Quality

Most of the benchmark is labeled automatically, so the question that matters is not whether those labels look plausible but how far they can be trusted. The HUMAN-VERIFIED subset exists to answer it: 300 claims, 37.5% of the benchmark, labeled by hand

Table 10: Confusion matrix between automated (LLMJUDGED) labels and human consensus labels on the expanded HUMAN-VERIFIED subset ($n = 300$). Rows are automated labels, columns are human labels. Exact four-way agreement is the diagonal, $271/300 = 90.3\%$ (Cohen's $\kappa = 0.87$).

	Human			
Automated	**Supp.**	**Part. Supp.**	**Not Supp.**	**Not Det.**
`Supported`	**65**	2	1	1
`Partially Supported`	8	**102**	7	0
`Not Supported`	2	3	**69**	2
`Not Determined`	2	0	1	**35**

Table 11: Agreement between automated labels and human consensus on the expanded HUMAN-VERIFIED subset, broken down by claim type. Reliability is essentially unchanged between objective and subjective claims, which is the case an annotation-bias account would predict to diverge.

Slice	**n**	**Agreement**	**Cohen's κ**
Overall	300	90.3%	0.866
Objective / factual	158	90.5%	0.866
Subjective	142	90.1%	0.858

under the guidelines of Section 4.4 and used as the reference against which the automated supervision is scored.

Automated labels match human consensus on 90.3% of claims ($\kappa = 0.87$). Under a strict four-way exact-match criterion, the automated labels agree with human consensus on 271 of 300 claims, 90.3%, with Cohen's $\kappa = 0.87$ (Cohen, 1960), which falls in the "almost perfect" band on the conventional scale (Landis and Koch, 1977). Table 10 shows where the 29 disagreements sit, and their shape matters more than their count. They cluster on the `Partially Supported` boundary: 8 claims the humans called `Supported` were labeled `Partially Supported`, and 7 they called `Not Supported` were labeled the same way. Under an ordinal-tolerant criterion, where a one-step difference on the `Supported`, `Partially Supported`, `Not Supported` scale is acceptable, agreement rises to 97.0%. Hard polarity flips, where one side says clearly supported and the other says clearly unsupported, occur 3 times in 300, or 1.0%. The automated supervision is therefore not making a different kind of judgement from the humans; it draws the partial-support line in a slightly different place, which is the same place two human annotators need a consensus discussion.

Table 12: Verification accuracy on the original 150-instance HUMAN-VERIFIED subset versus the expanded 300-instance subset used throughout the camera-ready. FC is full-context; RAG is the best of the four retrievers. Doubling the human-annotated coverage leaves the model ordering and the difficulty level of the split intact.

	Full-Context		**RAG (best retriever)**	
Model	n=150	n=300	n=150	n=300
`o4-mini`	0.276	0.267	0.260	0.257
`GPT-5-mini`	0.336	0.317	0.313	0.297
`Claude-Haiku`	0.269	0.300	0.267	0.300
`Qwen3-8B`	0.316	**0.377**	0.300	0.297
`Qwen2.5-7B`	0.249	0.256	**0.367**	**0.340**

Table 13: RAG accuracy on the expanded HUMAN-VERIFIED subset ($n = 300$), by retriever. These are the values reported in the HUMAN-VERIFIED column of Table 2. No model clears 0.35 under any retriever, and swapping retrievers moves accuracy by at most a few points, which is the pattern we use to argue that reasoning rather than retrieval is the binding constraint on this split.

Model	**BM25**	**BM25+R**	**Dense**	**Dense+R**
`o4-mini`	0.243	0.237	0.230	0.257
`GPT-5-mini`	0.273	0.290	0.297	0.257
`Claude-Haiku`	0.270	0.240	0.237	0.300
`Qwen3-8B`	0.257	0.297	0.283	0.277
`Qwen2.5-7B`	0.300	**0.340**	0.307	0.287

Reliability is the same on objective and subjective claims. A bias inherited from the labeler models would most plausibly show up as degraded reliability on exactly the claims where reviewer language is interpretive. It does not. Table 11 splits the subset by claim type: 90.5% agreement and $\kappa = 0.866$ on the 158 objective claims, 90.1% and $\kappa = 0.858$ on the 142 subjective ones. A 0.4-point difference at this sample size is not a signal. The automated labels track human judgement about equally well on both, which is the evidence we can offer that they reflect claim groundedness rather than an artifact of the annotation procedure. It does not prove the absence of a bias that the models and the guidelines share, and we say so in the Limitations section.

No verifier clears 0.38 on the hand-labeled claims. HUMAN-VERIFIED is among the hardest splits in the benchmark. No verifier clears 0.38 in full-context (Table 3) or 0.35 under any retriever (Table 13). `Qwen3-8B` is the strongest full-context model here at 0.377, which is consistent with the

Table 14: Inter-annotator agreement (GPT-5-mini vs. Claude-Sonnet-4-6) before arbitration.

Benchmark	n	Annotators agree	Rate
REBUTTALSOURCED	800	480	60.0%
LLMJUDGED	800	459	57.4%

subset being dominated by Partially Supported claims (107 of 300) and with that model's tendency to over-predict exactly that label (Figure 2). Because the human labels are the reference rather than a proxy, these numbers are the cleanest available estimate of how far current verifiers are from the task. Table 12 compares this expanded 300-instance subset against the original 150-instance version: doubling the hand-annotated coverage leaves both the model ordering and the difficulty of the split intact, so the expansion adds statistical confidence without changing any conclusion.

A.10 Annotator Disagreement and Arbitration

The canonical labels for REBUTTALSOURCED and LLMJUDGED are produced by a two-annotator protocol with human arbitration. Each of the 800 atomic reviewer claims is labeled twice and independently: GPT-5-mini (Annotator A) and Claude-Sonnet-4-6 (Annotator B) receive the same claim and the same source material (the author response for REBUTTALSOURCED and the paper content for LLMJUDGED) under identical prompts. For every record where the two annotators disagree, a human annotator is shown the claim, the relevant source material, and both candidate labels (with model identity anonymized and presentation order randomized per record), and either selects the correct label or assigns a new one when both candidates are wrong. This arbitrated label is taken as canonical.

Inter-annotator agreement before arbitration. Table 14 reports raw agreement between the two annotators. Claude-Sonnet-4-6 is systematically more conservative than GPT-5-mini: on REBUTTALSOURCED it reclassifies many Supported calls as Partially Supported or Not Supported, and on LLMJUDGED it shifts confident labels into Not Determined. The two models agree almost entirely on Not Determined itself (52/67 on REBUTTALSOURCED, 193/251 on LLMJUDGED) but diverge on the confident labels.

Table 15: Quantitative breakdown of arbitration verdicts on annotator disagreements. Annotator A and B denote the GPT-5-mini and Claude-Sonnet-4-6, respectively.

Benchmark	#Disagree	A correct	B correct	Neither
REBUTTALSOURCED	320	158 (49.4%)	136 (42.5%)	26 (8.1%)
LLMJUDGED	341	168 (49.3%)	137 (40.2%)	35 (10.3%)

Table 16: Canonical label distribution (post-arbitration).

Label	REBUTTALSOURCED	LLMJUDGED
Supported	217	207
Partially Supported	310	93
Not Supported	189	141
Not Determined	84	359

Arbitration verdicts. Table 15 shows, among the disagreements, how often each annotator was upheld by the human annotator. GPT-5-mini is correct slightly more often ($\sim$49%) than Claude-Sonnet-4-6 ($\sim$41%), but in roughly one in ten disagreements neither candidate was correct and the annotator supplied a third label.

Canonical distribution and derived slices. Table 16 gives the arbitrated label distribution. The LLMJUDGED distribution is heavily weighted toward Not Determined, reflecting that a meaningful share of reviewer claims have no verifiable answer in the paper text alone. After arbitration, the HIGHAGREEMENT slice (canonical REBUTTALSOURCED label equals canonical LLMJUDGED label) contains 175 instances, and the VERIFIABLEONLY slice contains 131.

B Related Works

LLMs for Peer Review. A growing body of work explores the use of large language models to support scholarly peer review through tasks such as review generation, review assistance, reviewer recommendation, and manuscript assessment (Yuan et al., 2022; Liang et al., 2024; Tomkins et al., 2017). A related line analyzes peer-review content and dynamics, including review quality, argumentation, sentiment, and reviewer behavior (Hua et al., 2019; Rogers and Augenstein, 2020; Kang et al., 2018; Ebrahimi et al., 2025a). These efforts demonstrate that state-of-the-art language models can generate meaningful feedback and shed light on how reviews are written and how they function socially. However, their primary objective is to produce, evaluate, or characterize reviews rather than to determine whether specific claims made within a

review are supported by evidence contained in the reviewed manuscript. As a result, the problem of manuscript-grounded review verification remains largely unexplored.

Scientific Claim Verification. PEERIFY is also related to scientific claim verification and evidence-based fact checking, studied extensively through textual entailment and natural language inference, from early RTE-style formulations (Dagan et al., 2006) to large-scale benchmarks such as FEVER (Thorne et al., 2018), SciFact (Wadden et al., 2020), PubHealth (Kotonya and Toni, 2020), and scientific verification tasks (Malon, 2018; Wadden and Lo, 2021). These datasets have enabled systems that retrieve evidence and determine whether a claim is supported, contradicted, or unsupported, and retrieval-augmented approaches (Lewis et al., 2020b; Izacard and Grave, 2021) have further improved evidence-grounded and multi-hop reasoning. While these settings share similarities with review verification, they typically treat claims as standalone statements and assume open-domain retrieval or citation-based reasoning across multiple sources, with evaluation centered on short claims whose supporting evidence is relatively concentrated. In contrast, peer-review claims often contain methodological observations, novelty assessments, and experimental critiques whose supporting evidence may be distributed across multiple sections of a single manuscript. Review verification is therefore a document-bounded grounding problem that requires reasoning over long, highly structured scientific documents while accounting for contextual qualifiers, experimental assumptions, and evidence aggregation.

Claim Decomposition. A further challenge arises from the fact that review comments frequently contain multiple assertions expressed within a single sentence or paragraph. Recent work on claim decomposition has shown that breaking complex statements into atomic claims improves the reliability and interpretability of downstream verification (Metropolitansky and Larson, 2025; Min et al., 2023; Scirè et al., 2024). Peer reviews complicate this step because they often mix subjective assessment with factual assertions and rely on hedging or implicit references. PEERIFY adopts a similar atomic-claim perspective and adapts extraction using multiple supervision signals, enabling more precise evidence attribution and systematic, manuscript-grounded groundedness assessment in an end-to-end evaluation.

Concurrent Work. A closely related concurrent system is FactReview (Xu et al., 2026), which also targets evidence-grounded peer review assessment. FactReview focuses on author-written claims extracted from the submitted manuscript, using literature retrieval and code execution to verify whether reported results are reproducible and positioned correctly relative to prior work. PEERIFY is complementary in scope and emphasis: we focus on *reviewer*-authored claims, statements made in the review about the paper rather than by the paper, and derive supervision from author–reviewer interaction dynamics and multiple independent label sources. This distinction matters because reviewer claims introduce interpretive and normative language absent from author-written text, and their groundedness must be assessed against a single manuscript rather than the broader literature. Our multi-benchmark design, spanning six supervision variants with different reliability and ambiguity profiles, enables systematic evaluation of the task difficulty spectrum.

C Prompts

This section lists every prompt used in the pipeline verbatim. Figure 3 gives the groundedness verification prompt shared by all five verifiers, Figure 4 the claim-extraction prompt, and Figure 5 the two labeling prompts behind REBUTTALSOURCED and LLMJUDGED.

C.1 Verification Prompt Template

We use the following prompt template for all LLM verifiers in full-context mode. The same label definitions are used across all dataset variants. For RAG-based verification, the `{manuscript}` field is replaced with the concatenation of top-k retrieved passages, ranked by the chosen retrieval configuration.

C.2 Claim Extraction Prompt

The prompted extractor (`Qwen3-4B`) decomposes each review into atomic claims with the prompt in Figure 4.

C.3 Labeling Prompts

The two automated annotators (`GPT-5-mini` and `Claude-Sonnet-4-6`) use the prompts in Figure 5 for the REBUTTALSOURCED and LLMJUDGED

Groundedness Verification Prompt (full-context and RAG)

You are a scientific claim verifier. Given a peer review claim and the full text of the reviewed manuscript, determine whether the manuscript supports the claim.

Claim: `{claim}` **Manuscript:** `{manuscript}`

Classify the claim as exactly one of the following labels based solely on the content of the manuscript:

- **Supported:** The manuscript provides clear and sufficient evidence that fully substantiates the claim.
- **Not Supported:** The manuscript contradicts the claim, or the asserted content is demonstrably absent from the manuscript.
- **Partially Supported:** The manuscript supports only a qualified or incomplete version of the claim (e.g., missing conditions, limited scope, or omitted caveats).
- **Not Determined:** The manuscript does not contain sufficient information to resolve the claim in either direction. Use this label when (1) the claim references external knowledge, (2) the claim is too vague or ambiguous to verify, or (3) the relevant evidence is absent without any contradicting assertion.

Figure 3: Groundedness verification prompt, shared by all five verifiers. Under RAG the `{manuscript}` field carries the top-k retrieved passages instead of the full paper.

Claim Extraction Prompt (`Qwen3-4B`)

System: You are an expert at extracting factual claims from academic reviews.

User: Extract factual claims from the review text below. A claim is a specific, verifiable statement about the paper.
Review Text: `{review_text}`

Each claim should be (1) a single atomic statement, (2) verifiable against the paper or author response, and (3) specific and factual (not an opinion).

Figure 4: Claim-extraction prompt used to decompose each review comment into atomic, self-contained claims.

Table 17: PAPERSOURCED Dense+R accuracy vs. the Oracle upper bound (gold paragraph fed directly) for all five models. Full four-retriever results in Table 2.

Model	Dense+Reranker	Oracle
`o4-mini`	**0.904**	**0.988**
`GPT-5-mini`	0.852	0.958
`Claude-Haiku`	0.844	0.860
`Qwen3-8B`	0.814	0.872
`Qwen2.5-7B`	0.860	0.816

variants. The raw `Contradicted` label corresponds to *Not Supported* in the four-way scheme.

D Additional Results

D.1 Full-Context Verification Results

Table 3 in the main paper reports the precise full-context verification accuracy for all five models across the six benchmarks, complementing Figure 1.

D.2 Accuracy vs. Macro-F1

Table 18 reports accuracy and macro-F1 for both full-context and RAG paradigms. In the RAG setting, `Qwen2.5-7B` Dense achieves the highest REBUTTALSOURCED accuracy (0.324, macro-F1 0.277), followed by `GPT-5-mini` Dense (Acc 0.294, F1 0.279) and `o4-mini` Dense (Acc 0.244, F1 0.236). The large accuracy–macro-F1 gaps for some models reflect calibration bias rather than genuine reasoning, motivating macro-F1 as a complementary metric robust to label imbalance.

D.3 PaperSourced RAG Results

Table 17 reports the PAPERSOURCED Oracle upper bound alongside Dense+R for all five models; the full four-retriever PAPERSOURCED results are in the main RAG table (Table 2). Oracle feeds the gold-standard supporting paragraph directly to the verifier, providing an upper bound under perfect retrieval.

The Oracle upper bound reveals that PAPERSOURCED is nearly solvable when retrieval is perfect: `o4-mini` reaches 0.988, `GPT-5-mini`

REBUTTALSOURCED Labeling Prompt (evidence: the discussion thread)

System: You are an expert at analyzing academic discourse.

User: Given a reviewer's claim and the author's response, determine how the authors address the claim.
Guidelines: *Supported*: authors clearly agree with or confirm the claim; *Partially Supported*: authors acknowledge some validity but not fully; *Contradicted*: authors explicitly disagree or provide counter-evidence; *Not Determined*: authors do not address the claim, or it is unclear.

Reviewer Claim: `{claim}` **Author's Response:** `{author_response}`

LLMJUDGED Labeling Prompt (evidence: the manuscript)

System: You are an expert at analyzing academic papers.

User: Given a reviewer's claim about a paper and the paper content, determine whether the claim is true according to the paper.
Guidelines: *Supported*: the claim is true according to the paper; *Partially Supported*: partially true; *Contradicted*: the paper contradicts the claim; *Not Determined*: the paper does not address the topic, or there is insufficient information. For example, if the claim states "the paper lacks comparison with baseline X" and the paper indeed omits it, the label is *Supported*.

Reviewer Claim: `{claim}` **Paper Content:** `{paper_content}`

Figure 5: The two labeling prompts. They differ only in the evidence they see: REBUTTALSOURCED reads the author–reviewer thread and never the manuscript, LLMJUDGED reads the manuscript and never the thread. This disjointness is what makes their agreement informative (Appendix A.8).

Table 18: Accuracy vs. macro-F1 (full-context FC and best-retriever RAG) on REBUTTALSOURCED and LLMJUDGED. A large Acc−F1 gap reflects label-distribution bias, not reasoning. `Qwen2.5-7B` FC excludes 9 over-length papers.

	Full-Context				RAG (best retriever)			
	REBUTTALSOURCED		LLMJUDGED		REBUTTALSOURCED		LLMJUDGED	
Model	**Acc**	**F1**	**Acc**	**F1**	**Acc**	**F1**	**Acc**	**F1**
`o4-mini`	0.245	0.246	0.442	0.416	0.244_{D}	0.236	0.514_{D}	0.454
`GPT-5-mini`	0.280	0.275	0.379	0.381	0.294_{D}	0.279	0.414_{D}	0.399
`Claude-Haiku`	**0.295**	0.294	0.295	0.293	0.297_{DR}	0.275	0.374_{DR}	0.336
`Qwen3-8B`	0.276	0.268	0.171	0.192	0.287_{D}	0.271	0.371_{D}	0.336
`Qwen2.5-7B`	0.278	0.269	0.170	0.190	$\mathbf{0.324}_{D}$	0.277	0.209_{D}	0.200

0.958, `Qwen3-8B` 0.872, and `Claude-Haiku` 0.860. The gap between Oracle and Dense+R directly quantifies accuracy lost to retrieval imperfection: 0.084 for `o4-mini` (0.988→0.904) and 0.106 for `GPT-5-mini`. One anomaly: `Qwen2.5-7B` Dense+R (0.860) exceeds its own Oracle (0.816), because Dense+R supplies ten passages (including adjacent context) while Oracle supplies only the single gold paragraph. For a model with limited long-context capacity, richer surrounding context improves its ability to confirm supported claims even when the exact evidence is present in both conditions.

D.4 Extended RAG Analysis

This section collects secondary RAG findings deferred from Section 6.

Performance gap narrows on interpretive claims. On REBUTTALSOURCED, all retrieval configurations cluster between 0.234 and 0.244 for `o4-mini`, closely tracking the full-context result of 0.245. For LLMJUDGED, the picture inverts: `Qwen2.5-7B` accuracy collapses to 0.209–0.228 with macro-F1 close to accuracy (e.g., 0.200 for Dense), confirming that its REBUTTALSOURCED accuracy advantage does not transfer to semantically harder claims.

`Qwen2.5-7B` collapses on LLMJUDGED yet leads on HUMAN-VERIFIED. On LLMJUDGED, among the models scored by re-scoring REBUTTALSOURCED predictions, `GPT-5-mini` leads (best: BM25-R 0.417), while `Qwen2.5-7B` collapses to 0.209–0.228, a 2× gap confirming a hard capability boundary on semantic entailment. On HUMAN-VERIFIED, `Qwen2.5-7B` recovers sharply: BM25-R reaches 0.340, the highest HUMAN-VERIFIED score across all models and retrievers, consistent with its tendency to over-predict Supported and Partially Supported, the dominant categories in the human-annotated set.

Retriever choice matters most for grounded claims. Across PAPERSOURCED and VERIFIABLE-ONLY, BM25+Reranker is usually the strongest retriever, beating pure BM25 and dense retrieval for every model on PAPERSOURCED and for most on VERIFIABLE-ONLY (the exception is `GPT-5-mini`, where dense retrieval is marginally higher). Reranking improves precision at low ranks, which is critical when the verifier's context is restricted to a small passage set. For LLMJUDGED, dense retrieval surpasses the reranker for `o4-mini` (0.514 vs. 0.499), suggesting that semantic embeddings better capture paraphrased or implicit evidence that lexical matching misses.

D.5 Classical Non-LLM Baselines

A fair question about any LLM-based system is whether the LLM is doing work that a smaller, cheaper model could do. We tested this directly with three zero-shot entailment models trained on MultiNLI (Williams et al., 2018): RoBERTa-large-MNLI (Liu et al., 2019), BART-large-MNLI (Lewis et al., 2020a), and DeBERTa-large-MNLI (He et al., 2021). For each claim, the premise is the concatenation of the top-3 retrieved chunks and the hypothesis is the claim, and the three-way output is mapped onto our schema (entailment to `Supported`, contradiction to `Not Supported`, neutral to `Not Determined`). We ran every model under all four retrieval configurations, so that a weak result could not be attributed to one bad retriever.

Table 19 reports all 72 configurations. Macro-F1 never exceeds 0.24 on any benchmark under any retriever, against 0.45 to 0.50 for the best LLM configuration on the document-decidable splits. Two structural causes explain the gap, and neither is a tuning problem. Three-way NLI has no output for `Partially Supported`, which is the single largest class in REBUTTALSOURCED at 310 of 800 claims, so the ceiling is imposed by the label space before inference begins. And MNLI models cap the premise at 512 tokens, which truncates most of a 10-chunk evidence set, so the model frequently decides on evidence it never read.

The accuracy column occasionally looks less bad than the macro-F1 column, and that discrepancy is itself informative. BART-MNLI reaches 0.512 accuracy on PAPERSOURCED with a macro-F1 of 0.226, and RoBERTa-MNLI reaches 0.401 accuracy on LLMJUDGED at 0.212 macro-F1. Both come from predicting one label heavily on a skewed split, the same distribution-matching effect we discuss for `Qwen2.5-7B` in Appendix D.7. Read on macro-F1, the ranking is stable: off-the-shelf entailment is not a viable substitute here, and the value of the LLM verifiers lies in long-context, four-way reasoning performed zero-shot, not in raw entailment ability.

D.6 Error Analysis on PAPERSOURCED

PAPERSOURCED is the only split where we know the correct label for every instance without appeal to a judge, since each claim is extracted from a manuscript passage and is genuinely `Supported` by construction. That makes it a clean setting for asking what the remaining errors actually are, rather than only how many there are. We sampled 150 errors, stratified as 30 per verifier under the RAG setting, and read each one against the retrieved evidence and the source passage. Table 5 in the main paper gives the breakdown; the categories are described below.

- **Overly strict specificity (55.3%).** The verifier retrieves the right passage, recognizes the substance of the claim, and then downgrades it to `Partially Supported` because one detail is not restated verbatim: an exact count, a pointer to a theorem or appendix, a numeric threshold. The evidence supports the claim; the grader is stricter than the label definition intends.

- **Retrieval and localization miss (36.0%).** The supporting passage is not among the top-10 retrieved chunks, so the verifier correctly reports that the evidence in front of it does not contain the claim and hedges to `Not Determined`. This is a retrieval failure presented as a verification error, and it is consistent with Re-

Table 19: Zero-shot NLI baselines under all four retrieval configurations, reported as Accuracy / macro-F1 on all six PEERIFY benchmarks. **Best LLM** is the single highest-accuracy model–retriever pair per benchmark, taken from Table 2. No NLI configuration exceeds a macro-F1 of 0.24 on any benchmark, and the ranking is stable across retrievers, so the gap is a property of the task formulation rather than of a particular retriever. ‡NLI baselines and the matched **Best LLM** reference on HUMAN-VERIFIED are computed on the original 150-instance subset.

Method	Retriever	PAPER SOURCED	REBUTTAL SOURCED	LLM JUDGED	HIGH AGREEMENT	VERIFIABLE -ONLY	HUMAN VERIFIED‡
RoBERTa-MNLI	BM25	0.070 / 0.044	0.147 / 0.116	0.401 / 0.212	0.234 / 0.162	0.206 / 0.152	0.167 / 0.106

	Dense+Reranker	0.290 / 0.150	0.135 / 0.105	0.400 / 0.221	0.240 / 0.176	0.191 / 0.146	0.153 / 0.118
Best LLM	best per benchmark	0.904 / 0.237	0.324 / 0.157	0.514 / 0.454	0.514 / 0.499	0.519 / 0.486	0.367 / 0.300

call@10 staying below 0.55 for every retriever (Appendix D.9).

- **Output or parse failure (8.7%).** The verifier emits a malformed response that cannot be mapped to a label, and the harness defaults to `Not Determined`.

Taken together, 91.3% of the error mass is strictness or retrieval rather than faulty inference on evidence the model actually saw. The practical consequence is that raw PAPERSOURCED accuracy overstates the reasoning error rate, and that two different fixes are indicated: better retrieval for the second category, and a calibration or rubric adjustment for the first. Neither requires a stronger reasoner.

D.7 Predicted-Label Distribution on PAPERSOURCED

`Qwen2.5-7B` outperforming `GPT-5-mini` on PAPERSOURCED under RAG looks anomalous next to the rest of the results. It is not, and the mechanism is worth making explicit because it applies to any single-class evaluation.

Every gold label in PAPERSOURCED is `Supported`, so the predicted-label distribution is a one-row confusion matrix and the `Supported` column *is* the accuracy. Table 20 shows the two models side by side, aggregated over all four retrievers. `Qwen2.5-7B` says `Supported` 85.2% of the time; `GPT-5-mini` says it 83.1% of the time and hedges to `Partially Supported` or `Not Determined` more often. The 2.1-point difference is the whole margin. On a split where the correct answer is always the confident one, willingness to commit is rewarded and caution is punished, even when caution is the better-calibrated behavior. Two claims from our sample illustrate the pattern: for a claim quoting an exact mean IoU of 44.91%, `GPT-5-mini` returns `Not Determined` because it will not certify the precise figure, and for a claim describing several cache-compression techniques evaluated under five settings it returns `Partially Supported` because it reads the enumeration as incomplete. Both are gold `Supported`.

Table 20: Predicted-label distribution (%) on PAPERSOURCED under RAG, aggregated over all four retrievers. Every gold label in this split is `Supported`, so this is a single-row confusion matrix and the `Supported` column equals accuracy.

Model	Supported	Part. Supp.	Not Det.	Not Supp.
`GPT-5-mini`	83.1	9.5	5.1	2.3
`Qwen2.5-7B`	**85.2**	7.0	5.4	2.4

The same prior is costly wherever the label set is not degenerate. In full-context evaluation, `GPT-5-mini` leads `Qwen2.5-7B` 0.379 to 0.170 on LLMJUDGED, 0.513 to 0.213 on HIGHAGREEMENT, and 0.518 to 0.250 on VERIFIABLE-ONLY (Table 3). So the PAPERSOURCED ordering reflects a `Supported`-prior meeting an all-`Supported` split, not stronger verification, and it is the reason we report macro-F1 alongside accuracy throughout.

Table 21: Evaluation size and evidence scope of PEERIFY relative to expert-annotated scientific claim-verification benchmarks. Evidence scope matters as much as raw count: our labels are grounded in the full manuscript rather than an abstract or a single reference passage.

Dataset	#Claims	Annotation	Evidence scope
MSVEC (Evans et al., 2023)	200	Expert	Reference paper
SciFact (test) (Wadden et al., 2020)	300	Expert	Abstract
PEERIFY (HUMAN-VERIFIED)	300	Human-audited	Full manuscript
PEERIFY (full)	800	LLM + human-audited	Full manuscript

D.8 Benchmark Size in Context

At 800 claims, PEERIFY is small next to open-domain fact-verification corpora, and it is reasonable to ask whether conclusions drawn from it are stable. The relevant comparison is not to web-scale datasets but to claim-verification benchmarks with expert, evidence-grounded annotation, where size is bounded by annotation cost rather than by data availability.

Table 21 places our benchmark against that reference class. The full 800-claim set exceeds the SciFact test split (300) (Wadden et al., 2020) and the MSVEC evaluation corpus (200) (Evans et al., 2023), and the hand-audited 300-claim subset matches them exactly. Larger corpora in this space, such as COVID-Fact (Saakyan et al., 2021) and HealthVer (Sarrouti et al., 2021), reach scale through crowdsourced or automatically derived labels over abstracts and web text; we deliberately traded that scale for manuscript-grounded reliability, since a label for a review claim is only meaningful with respect to the full paper the reviewer read. Annotating against a whole manuscript is substantially more expensive per claim than annotating against an abstract, which is the constraint the size reflects.

D.9 Retrieval Quality Analysis

Retrieval configuration. The dense retriever uses `all-MiniLM-L6-v2` sentence embeddings, and the cross-encoder reranker uses `cross-encoder/ms-marco-MiniLM-L-6-v2`. Manuscripts are segmented with Docling structure-aware (section/heading-based) chunking, producing variable-length chunks with no fixed token window (median 133 words per chunk, mean 132, p90 188). For each claim we retrieve an initial pool of $k = 20$ candidate passages; when reranking is enabled, these are reranked down to the final top-10 passages fed to the verifier, and non-reranked configurations directly take the top-10.

Table 4 in the main paper compares four retrieval strategies on PAPERSOURCED, where the ground-truth supporting section is known, enabling intrinsic evaluation. Dense+Reranker achieves the best performance across all metrics (Recall@5: 0.452, Recall@10: 0.530, nDCG@10: 0.684, MRR: 0.346), while BM25 alone is weakest.

Consistent with prior work (Kamalloo et al., 2024), reranking substantially boosts BM25. BM25+Reranker surpasses standalone dense retrieval at Recall@5 (0.434 vs. 0.420) but lags at Recall@10 (0.492 vs. 0.528), suggesting that lexical matching excels at placing relevant chunks at shallow ranks while dense representations improve deeper recall. Despite this, Recall@10 remains below 0.55 across all configurations: the ground-truth section is absent from the top-10 retrieved passages in nearly half of all cases. The Oracle upper bound (Table 17) makes this bottleneck concrete: the 8.4-point gap between Oracle (0.988) and Dense+R (0.904) for `o4-mini` is attributable entirely to retrieval imperfection.

Table 22: Tokens per claim, RAG verification (four retrievers, six benchmarks).

Benchmark	BM25	FAISS	Dense+R	BM25+R
PAPERSOURCED	2,235.85	2,231.82	2,384.76	2,291.40
REBUTTALSOURCED	2,156.78	2,128.87	2,371.78	2,236.87
LLMJUDGED	2,156.78	2,128.87	2,371.78	2,236.87
HIGHAGREEMENT	2,112.56	2,085.18	2,262.94	2,205.61
VERIFIABLE-ONLY	2,153.54	2,240.62	2,253.42	2,244.24
HUMAN-VERIFIED	1,922.49	1,986.74	1,976.66	1,945.26
Average	**2,123.00**	**2,133.68**	**2,270.22**	**2,193.38**

Table 23: Tokens per claim, full-context verification (six benchmarks).

Benchmark	Tokens per Claim
PAPERSOURCED	21,648.85
REBUTTALSOURCED	21,130.27
LLMJUDGED	21,130.27
HIGHAGREEMENT	22,323.60
VERIFIABLE-ONLY	21,333.30
HUMAN-VERIFIED	18,912.43
Average	**21,079.79**

D.10 Token Efficiency and Operating Cost

RAG-based verification substantially reduces token consumption relative to full-context processing. Tables 22, 23, and 24 report average token usage per claim across all six benchmarks in both settings.

Table 24: Token efficiency, RAG vs. full-context. Reduction = full-context/RAG token ratio.

Benchmark	Full-Context	RAG (Avg)	Reduction
PAPERSOURCED	21,648.85	2,285.96	9.47×
REBUTTALSOURCED	21,130.27	2,223.57	9.50×
LLMJUDGED	21,130.27	2,223.57	9.50×
HIGHAGREEMENT	22,323.60	2,166.57	10.30×
VERIFIABLE-ONLY	21,333.30	2,222.96	9.60×
HUMAN-VERIFIED	18,912.43	1,957.79	9.66×
Overall Average	**21,079.79**	**2,180.07**	**9.67×**

On average, RAG reduces token consumption by roughly $9.7\times$ relative to full-context verification, consistently across all six benchmarks, from $9.47\times$ on PAPERSOURCED to $10.30\times$ on HIGHAGREEMENT. This is what makes the pipeline runnable at venue scale rather than only on a sample, and it is also what lets open-weight models with restricted context windows participate at all. The saving does not cost accuracy on grounded benchmarks, and on PAPERSOURCED it improves it: Dense+R reaches 0.904 for `o4-mini` against 0.866 in full-context, because a focused evidence set is easier to reason over than a whole manuscript.

Together with the extraction costs in Table 7, this fixes the operating cost of a deployment. Extraction runs locally at no inference cost and a median of 8.2 seconds per review, and verification consumes about 2.2K tokens per claim rather than 21K. These are the measurements behind the deployment discussion in Appendix E.

D.11 Where Intrinsic Retrieval Metrics Apply

Recall@k, nDCG@k, and MRR are reported only on PAPERSOURCED, and the Oracle upper bound is computed there as well. This is a constraint of the data rather than a choice about what to report. All three metrics need a gold evidence span, and spans exist only where a claim was drawn from a known passage. For REBUTTALSOURCED, LLMJUDGED, and HUMAN-VERIFIED, the label comes from an author–reviewer exchange or from a whole-manuscript reading, and neither procedure identifies the paragraph that settles the claim. Some claims are settled by an absence, such as "no ablation is reported," which has no supporting span anywhere in the document. Annotating spans for those splits would mean inventing a ground truth we do not have.

The question behind the metric, whether retrieval or reasoning limits performance, can still be answered on those splits, by removing retrieval instead of measuring it. Full-context verification passes the entire manuscript to the verifier and skips the retrieval stage, so it is a retrieval-free upper bound. If retrieval were binding, accuracy should rise sharply. It does not: on HUMAN-VERIFIED, `GPT-5-mini` reaches 0.317 in full-context against 0.297 with its best retriever, and `o4-mini` reaches 0.267 against 0.257 (Tables 3 and 13). Perfect retrieval buys a point or two, so what limits these splits is verification reasoning. PAPERSOURCED behaves in exactly the opposite way, where the 8.4-point Oracle-to-Dense+R gap for `o4-mini` is retrieval and nothing else, which is why we keep both regimes in the evaluation.

E Deployment Setting and Intended Use

The pipeline runs at the scale of a real venue. All three stages are implemented end to end and are cheap enough to apply to an entire submission cycle. Claim extraction runs locally on a single consumer GPU at a median of 8.2 seconds per review with no API cost (Appendix A.2), and retrieval-augmented verification consumes roughly $9.7\times$ fewer tokens per claim than passing the verifier a whole manuscript (Appendix D.10). Because both figures are measured rather than estimated, a venue can compute the cost of a deployment in advance. This is what we mean when we describe PEERIFY as production-ready: the engineering is complete, the throughput is known, and nothing in the design assumes a research-scale workload.

Every prediction ships with its evidence. The output of the pipeline is not a bare label. Each claim is returned together with the manuscript passages the verifier conditioned on, so a decision can always be traced back to the text that produced it. This is what makes the system useful in an editorial workflow: a reader can confirm or overturn any prediction in seconds by looking at the passages already retrieved for them, without opening the paper and searching from scratch.

The intended workflow is human-in-the-loop by design. PEERIFY is built to be an assistant to editorial judgement rather than a replacement for it. An area chair opens a review and sees which reviewer claims the system flagged as needing a closer look, each attached to the relevant manuscript passages, and directs attention accordingly. Authors can use the same view when preparing a rebuttal, and reviewers can use it to self-check

a draft review before submitting. The value the system delivers is triage and evidence retrieval at scale, which is precisely the part of the task that does not scale for humans, while the final judgement stays where it belongs.

The benchmark is deliberately demanding. PEERIFY ships with an evaluation suite built to remain informative as models improve. The variants span the full difficulty range, from PAPERSOURCED, where evidence is explicit and the best verifier reaches 0.904 under RAG, through to REBUTTALSOURCED, where claims are drawn from live author–reviewer disputes and mix factual observation with interpretation. Setting the harder end of that range beyond what current frontier models saturate is a design goal rather than a shortcoming: it gives the community headroom to measure progress on manuscript-grounded verification for several model generations, and it keeps the assistive framing above honest about which claims a human should look at first.

Extending FunctionGemma for Practical On-Device Mobile Function Calling

Ali Rezagholizadeh

sla.samiee@gmail.com

Abstract

On-device assistants require function-calling models that map natural language to local system actions, but existing resources emphasize web APIs or narrow mobile-action catalogs. We extend FunctionGemma 270M-it to practical Android workflows by introducing MOBILEACTIONSEXTENDED, a synthetic, schema-validated dataset of ∼9,500 conversations covering fifteen device-control categories, including messaging, phone calls, camera/screenshot, brightness control, device-status queries, flashlight control, and application management. We fine-tune the 270M model with TRL supervised fine-tuning under completion-only loss, producing an extended specialist and a combined model trained jointly with Google's MOBILEACTIONSGOOGLE. On MOBILEACTIONSEXTENDED, end-to-end accuracy improves from 29.3% for the base model and 17.2% for Google's Mobile-Actions variant to 76.5%. The combined model retains 76.5% on MOBILEACTIONSEXTENDED and reaches 82.3% on MOBILEACTIONSGOOGLE, down from the 90.3% of Google's Mobile-Actions specialist, representing an 8.0-percentage-point trade-off in return for doubling category coverage. We release the dataset, fine-tuned models, reproducible training/evaluation pipeline, and an Android demo, highlighting compact local function calling as a practical path towards low-latency and privacy-preserving mobile assistants.

1 Introduction

Modern conversational assistants increasingly bridge natural language to executable actions through *function calling*: instead of generating free-form text, the model emits a structured tool call (a name and a JSON-like dictionary of arguments) that an external runtime can dispatch to operating-system APIs, web services, or local hardware (Schick et al., 2023; Yao et al., 2022; Patil et al., 2024; OpenAI, 2023; Anthropic, 2024). The function-calling formulation is now standard in commercial APIs and underlies most agent frameworks (Wang et al., 2026).

While the formulation is general, deployments differ sharply. Server-side agents primarily call *web APIs* (REST endpoints, search, calendars, SaaS tools), and most public benchmarks reflect this bias (Patil et al., 2024, 2025; Liu et al., 2024; Zhuo et al., 2024). On-device assistants, by contrast, rely on *system actions* (e.g., turning the flashlight on, sending an SMS, opening an installed application, querying the battery) that must be invoked through the host operating system rather than the network. These actions are high-frequency, latency-sensitive, and privacy-sensitive.

This shift creates demand for *compact* function-calling models that can run on a phone. Sub-billion-parameter models such as FunctionGemma 270M-it (DeepMind, 2025a), built on the Gemma 3 family (Team et al., 2024; DeepMind, 2025b), occupy this niche. However, their training distribution still skews toward general tool use; the ready-made on-device specialization, FunctionGemma 270M Mobile Actions (LiteRT Community and DeepMind, 2025), focuses on roughly seven mobile workflows (calendar event creation, contact creation, mapping, email, Wi-Fi settings, flashlight on/off), leaving common everyday intents, like phone calls, SMS, brightness control, camera, screenshots, and application opening uncovered.

In this study, we evaluate whether a small, targeted dataset of mobile-action conversations is sufficient to extend a 270M-parameter function-calling model to a meaningfully broader set of on-device intents *without* catastrophically forgetting the original distribution. Concretely, we investigate three questions:

- **(Q1) Coverage gap.** How well does the publicly available FunctionGemma model handle mobile actions outside of its training distribution?

EMNLP 2026 Industry Track, pages 2889–2904
October 24-29, 2026 ©2026 Association for Computational Linguistics

- **(Q2) Targeted fine-tuning.** Does full supervised fine-tuning on a synthetically generated, schema-validated dataset of 15 mobile categories close that gap on a 270M backbone?
- **(Q3) Cross-domain transfer.** Can a single fine-tuned model serve both the original (Google Mobile Actions) and the new (device-action) distributions?

Our contributions can be summarized as:

(i) **An open mobile-actions dataset.** We release MOBILEACTIONSEXTENDED, a ∼9,500-example function-calling corpus generated through schema-grounded synthetic prompting, post-validated for tool-call legality, and split 90/10 between train and evaluation (Section 4).

(ii) **Two extended FunctionGemma fine-tuned models.** We fine-tune FunctionGemma 270M-it with Transformers Reinforcement Learning (TRL) supervised fine-tuning (von Werra et al., 2020; Wolf et al., 2020) under completion-only loss, releasing FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED and FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED.

(iii) **A multi-axis evaluation.** We compare four versions of the model on two held-out splits using exact-match metrics for function names, arguments, and end-to-end correctness (Section 6).

(iv) **An end-to-end pipeline.** We open-source the full reproduction pipeline—from dataset generation through Hugging Face publishing, TRL fine-tuning, and evaluation—as three independent packages.

(v) **An on-device demo app (*Handy Chat*).** We deploy .litertlm version of FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED in a Buildozer-packaged Android app (Python Kivy UI, PyJNIus Java bridge to `litertlm-android`, LiteRT-LM inference on an exported `.litertlm` bundle) because the Google AI Edge Gallery (Google AI Edge Team, 2026) does not support custom checkpoints in its Mobile Actions workflow (Sections 7, Appendix E).

Our extended model lifts end-to-end accuracy on MOBILEACTIONSEXTENDED from 29.3% (base) and 17.2% (Google's Mobile Actions variant) to 76.5%, with perfect function-name accuracy on all fifteen categories. The *combined* model preserves competitive performance on MOBILE-ACTIONSGOOGLE: end-to-end accuracy drops from 90.3% for the Google specialist to 82.3%, an 8.0-percentage-point cost that we consider an acceptable trade-off for doubling category coverage. Remaining errors concentrate on optional-boolean formatting (`dial_call`, `create_chooser`). Per-category breakdown and failure analysis are presented in Appendix C.

2 Related Work

Modern tool-using LLMs (Schick et al., 2023; Yao et al., 2022; Patil et al., 2024; Qin et al., 2024; OpenAI, 2023) replace classical intent-and-slot pipelines with schema-conditioned structured output. Compact function-calling models, such as Granite Function Calling (Abdelaziz et al., 2024), Hammer (Lin et al., 2024), ToolACE (Liu et al., 2025), and TinyAgent (Erdogan et al., 2024) show that targeted fine-tuning, not scale alone, drives quality at the edge (Kavathekar et al., 2025). FunctionGemma 270M-it (DeepMind, 2025a) and Google's Mobile Actions variant (LiteRT Community and DeepMind, 2025) target on-device deployment; however, available benchmarks such as BFCL (Patil et al., 2025), BigCodeBench (Zhuo et al., 2024), and APIGen (Liu et al., 2024) focus on web APIs rather than Android system actions. To the best of our knowledge, MOBILEACTIONSGOOGLE is the only public mobile-actions function-calling benchmark, and this study aims to extend it. A more detailed summary of related works is available in Appendix A.

3 Task Definition and Tool Catalog

3.1 Function Calling as Structured Output

We use the standard formulation. A *tool catalog* $\mathcal{T} = \{T_1, \ldots, T_K\}$ is a set of typed function declarations; each T_k has a name, a natural-language description, and a parameter schema. Given a system prompt, the catalog $\mathcal{T}$, and a user utterance u, the model must produce an ordered sequence of calls

$$\hat{c}_1, \hat{c}_2, \ldots, \hat{c}_m, \ \hat{c}_i = \langle \text{name}_i, \text{args}_i \rangle, \quad \text{name}_i \in \{T_1, \ldots, T_K\}.$$

FunctionGemma renders calls and declarations with sentinel tokens (`<start_function_call>`, `<end_function_call>`, `<escape>`) so that output can be deterministically parsed.

3.2 Evaluation Granularity

Following Patil et al. (2025), the evaluation is executed at three levels: **function-name accuracy**

Count	Function	Description	Arguments
1	`turnOn_light`	Turn the flashlight on.	None
2	`turnOff_light`	Turn the flashlight off.	None
3	`send_email`	Send an email.	`to`, `subject`, optional `body`, optional `create_chooser`
4	`battery_status`	Query battery level/state.	None
5	`bluetooth_status`	Query Bluetooth state.	None
6	`phone_call`	Place a call.	`number`, `dial_call`: dial-pad vs. direct
7	`phone_sms`	Send an SMS message.	`sms_recipient`, optional `sms_message`
8	`take_picture`	Take a photo via the camera.	None
9	`take_screenshot`	Capture the current screen.	None
10	`get_current_brightness`	Read the current screen brightness.	None
11	`decrease_brightness`	Step the brightness down.	None
12	`increase_brightness`	Step the brightness up.	None
13	`set_brightness`	Set brightness to a specific level.	`level` in $[0, 100]$
14	`list_application`	List installed applications.	None
15	`open_application`	Open an application by name.	`application_name`

Table 1: Summary of the new Mobile-Action categories: supported functions, descriptions, and arguments.

(exact match on ordered name lists), **argument exact match** (exact match on key-sorted argument dictionaries), and **end-to-end correctness** (logical AND). This strict criterion flags any extra or missing key as failure; we therefore complement it with an *execution-aware* variant (Section 6.3) and discuss implications in Section 8.

3.3 New Mobile-Action Categories

In this study, we extend FunctionGemma's mobile coverage with the fifteen tools presented in Table 1. The schemas (full JSON in Appendix D.1) mirror Plyer (Kivy Team, 2013)-style cross-platform Android APIs so that every call can be dispatched to a real handler in a demo runtime. These categories cover daily "physical" assistant intents absent from MOBILEACTIONSGOOGLE (calls, SMS, brightness, camera, screenshots, app management) and are implementable through Plyer on Android.

4 Dataset Construction: MOBILEACTIONSEXTENDED

We aimed for a dataset that (i) is large enough to fine-tune a 270M-parameter backbone end to end, (ii) follows FunctionGemma's exact chat-template format, and (iii) is formatted similar to MOBILEACTIONSGOOGLE (Google, 2025) so the two datasets can be merged easily for cross-domain training. Figure 1 summarizes the full workflow from schema-grounded generation through fine-tuning, evaluation, and on-device deployment.

4.1 Schema-Grounded Synthetic Generation

Raw conversations are generated by prompting a strong teacher with the JSON tool list and a worked output example. The teacher produces (i) $\sim$300 user prompts per single tool and (ii) $\sim$5,000 multi-tool prompts (e.g., *"check battery and take a screenshot"*). Each record is a `user`/`assistant` pair with gold `tool_calls`. The full prompt is in Appendix D.3. This recipe follows APIGen (Liu et al., 2024) and ToolACE (Liu et al., 2025); unlike APIGen we do not execute calls during generation, relying instead on structural validation.

4.2 Validation and Completion

A validator (`validate_generated_dataset.py`) parses every assistant message and checks that: (i) every called function name is present in the catalog; (ii) all `required` arguments are present and of the declared type; (iii) argument values match the schema's primitive types (`STRING`, `BOOLEAN`, `NUMBER`). Records that fail validation are dropped or repaired with `json_repair`. A completion script (`complete_dataset.py`) augments each surviving record with fields needed by FunctionGemma: `metadata` (`train`/`eval`), `tools` (declarations), and `messages` (`developer`, `user`, `assistant`). The `developer` role injects the current date/time and function declarations using sentinel tokens, exactly as in the official cookbook.

4.3 Merging With Google's Mobile Actions

To produce MOBILEACTIONSCOMBINED, we union records from MOBILEACTIONSEXTENDED with all records from MOBILEACTIONSGOOGLE. Both datasets share identical schemas, so the merge requires no field surgery; we preserve per-source train/eval flags so evaluation on each source remains held-out. The extended and merged datasets are published in repo 1 and repo 2, respectively.

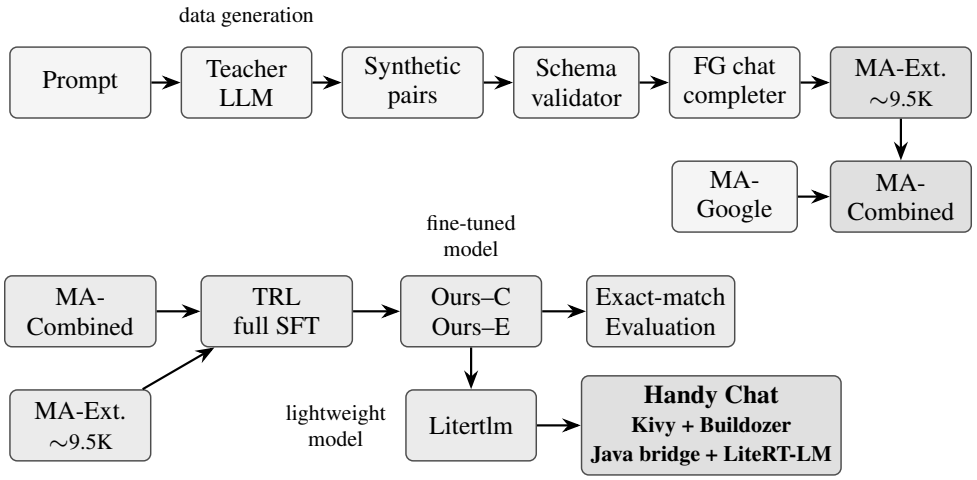

Figure 1: End-to-end pipeline. **Top:** schema-grounded synthetic generation, validation, FunctionGemma chat completion, and merge with Google's mobile-actions corpus. **Bottom:** serving generated datasets, TRL fine-tuning, fine-tuned model, exact-match evaluation, export lightweight `.litertlm` model quantized by 8-bit integer weight and 32-bit float activation, and typed-input deployment in *Handy Chat* (Buildozer APK, PyJNIus Java bridge to `litertlm-android`, Plyer dispatch). Dynamic INT8 quantization (`dynamic_wi8_afp32`: 8-bit integer weights, 32-bit float activations) is applied *solely* to the exported `.litertlm` bundle used by the deployed LiteRT-LM Android demo; all evaluation accuracy figures reported in this paper were measured on the unquantized Hugging Face checkpoints. (more details in Sections 4–7 and Appendices D.4 and E.)

4.4 Statistics

MOBILEACTIONSEXTENDED contains approximately 9,500 records, split 90/10 between train and evaluation. The evaluation split contains 965 examples spread across 15 categories; largest categories are `open_application` (209 eval examples) and `phone_sms` (114). Approximately one third of prompts are multi-call. For comparison, MOBILEACTIONSGOOGLE contributes 961 evaluation examples spanning 7 categories. Full per-category counts are in Appendix D.6.

5 Model and Training

In this study, FunctionGemma 270M-it (DeepMind, 2025a) is fine-tuned with Hugging Face Transformers (Wolf et al., 2020) and TRL `SFTTrainer` (von Werra et al., 2020) in completion-only mode. Key settings for this fine-tuning are as follows: full SFT (no PEFT/LoRA) for two epochs, learning rate 1×10^{-5}, cosine schedule with warmup, effective batch size 32 (4 per device $\times$ 8 gradient accumulation), bf16 mixed precision, gradient checkpointing enabled. The 270M backbone fits comfortably on a single accelerator (CUDA or Apple Silicon MPS), so we avoid LoRA adapter complexity and keep deployment simple: a single set of weights replaces the pretrained ones, with no adapter merging at inference. Full hyperparameters are in Appendix B.

Training is done with completion-only loss. TRL's `completion_only_loss=true` masks loss over the prompt (system tools block, developer message, user turn) so the model is graded only on its assistant continuation. This stabilizes training when the prompt length dominates, which is common here because the tool catalog alone is several hundred tokens long.

Two fine-tuned models are trained under identical settings: FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED (trained on MOBILEACTIONSEXTENDED only) and FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED (trained on merged MOBILEACTIONSCOMBINED). The first trained model targets coverage gap (aforementioned Q1) and targeted fine-tuning (Q2); and the second one focuses more on cross-domain transfer (Q3).

At inference, decoding is done greedily (`do_sample=False`, `temperature=0.0`, `max_new_tokens=1024`) and parsing is implemented with a regex decoder (Appendix D.5). We do not employ schema-constrained decoding (Willard and Louf, 2023), ensuring that the reported results reflect the model's unconstrained generation behavior. The extended and combined fine-tuned models are publicly available.

	Mobile-Actions-Extended (965)			Mobile-Actions-Google (961)		
Model	Name	Args	E2E	Name	Args	E2E
Base	48.81	40.21	29.33	85.95	59.31	58.79
Google MA	35.03	33.06	17.20	**99.79**	**90.32**	**90.32**
Ours: MA-Extended	**100.00**	**76.48**	**76.48**	86.37	62.54	60.15
Ours: MA-Combined	95.96	**76.48**	**76.48**	95.32	82.31	82.31

Table 2: Function-name, argument exact-match, and end-to-end accuracy (%) on held-out eval splits. Base = FUNCTIONGEMMA270MIT BASE; Google MA = FUNCTIONGEMMA-270M-MOBILE-ACTIONS; Ours: MA-Extended = FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED; Ours: MA-Combined = FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED. Best per column in bold. Per-category breakdown in Appendix C.

6 Experiments

6.1 Models and Evaluation

We compare four models, all sharing the FunctionGemma 270M-it architecture:

1. FUNCTIONGEMMA270MIT BASE – `google/functiongemma-270m-it` (DeepMind, 2025a): instruction-tuned but not specialized to mobile actions.
2. FUNCTIONGEMMA-270M-MOBILE-ACTIONS – `litert-community/FunctionGemma_270M_Mobile_Actions` (LiteRT Community and DeepMind, 2025): public mobile-actions specialization on MOBILEACTIONSGOOGLE.
3. FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED – our fine-tuned model on MOBILEACTIONSEXTENDED.
4. FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED – our fine-tuned model on merged data: MOBILEACTIONS-COMBINED.

Evaluation uses held-out *eval* splits of MOBILE-ACTIONSEXTENDED (965 examples, 15 categories) and MOBILEACTIONSGOOGLE (961 examples, 7 categories). Each model produces tool calls; our parser extracts *(name, args)* tuples and we compute the three metrics introduced in Section 3. The pipeline matches Google's FunctionGemma cookbook which is re-implemented in our `FGemma_Evaluation` package.

6.2 Results

Table 2 summarizes the results in terms of accuracy in held-out sets.

Coverage gap (Q1). The base FunctionGemma 270M-it scores 29.3% end-to-end on MOBILEACTIONSEXTENDED. The Google-fine-tuned variant performs worse (17.2%); fine-tuning on seven Google categories actively hurts on the fifteen extended categories, presumably because the model now confidently emits in-distribution calls (e.g., `open_wifi_settings`) instead of the correct extended ones.

Targeted fine-tuning (Q2). FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED reaches 100% function-name accuracy and 76.5% end-to-end on MOBILEACTIONSEXTENDED—a +47.2-point improvement over the base model. The remaining 23.5% are argument-level errors, concentrated on optional booleans (see Appendix C).

Cross-domain transfer (Q3). FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED matches FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED on MOBILEACTIONS-EXTENDED (76.5%) and reaches 82.3% on MOBILEACTIONSGOOGLE, only ∼8 points below the Google specialist trained exclusively on that distribution. Training only on MOBILEACTIONSEXTENDED yields 60.2% on MOBILEACTIONSGOOGLE: the merge step matters.

6.3 Execution-Aware Accuracy

Strict exact match understates deployable quality because it penalizes omissions that a runtime would recover from. We therefore re-score all predictions with an *execution-aware* criterion: the function-name sequence must still match exactly, and every schema-required argument must be present and correct, *unless* it belongs to a short, explicit safe-default list (`phone_call.dial_call` and `send_email.create_chooser`, both booleans defaulted to `false` by the on-device dispatcher);

Model	MA-Extended		MA-Google	
	Strict	Exec.	Strict	Exec.
Base	29.3	37.6	58.8	65.4
Google MA	17.2	17.2	**90.3**	**90.7**
Ours: MA-Extended	**76.5**	**100.0**	60.2	66.4
Ours: MA-Combined	**76.5**	96.0	82.3	82.6

Table 3: Strict exact-match vs. execution-aware end-to-end accuracy (%) on the held-out eval splits ($n = 965$ and $n = 961$). Column abbreviations as in Table 2. Full per-category tables are in Appendix C.2.

any other schema-valid optional argument may be freely added or dropped, while a hallucinated (non-schema) key remains a failure because it would raise a runtime error in the real dispatcher.

Table 3 contrasts the two metrics. For FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED, execution-aware accuracy on MOBILEACTIONSEXTENDED reaches 100.0% (from 76.5% strict): every remaining strict-metric "error" is a recoverable formatting issue, not a wrong tool selection. FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED rises to 96.0% on MOBILEACTIONSEXTENDED and 82.6% on MOBILEACTIONSGOOGLE. The base and Google-specialist models gain little on out-of-distribution data (+8.3 and +0.0 points on MOBILEACTIONS-EXTENDED, respectively), confirming that their failures are genuine tool-selection errors rather than metric artifacts.

6.4 Error Analysis

Per-category tables (Appendix C) show 100% function-name accuracy on every extended category for fine-tuned models. The dominant error classes are: (i) **Optional-boolean omission.** For `phone_call` and `send_email`, gold labels include routing booleans (`dial_call`, `create_chooser`) that the model omits; the executed action would still be correct. (ii) **Free-text argument noise.** On `phone_sms` and Google's `show_map`, the model occasionally normalizes phone numbers or rephrases location strings—partly a labelling-ambiguity issue. (iii) **Multi-call ordering.** A small number of multi-call examples flip call order; addressable with more multi-call training data. None of these implicate the backbone's structural ability to function-call; they are dataset-level signal-quality issues (full failure-mode review in Appendix C).

7 On-Device Demo: Handy Chat

We validated deployability with *Handy Chat*, a standalone Android application packaged with Buildozer (Kivy Team, 2024). The Google AI Edge Gallery (Google AI Edge Team, 2026) showcases on-device models but does not expose a supported path to load custom checkpoints into its preconfigured Mobile Actions workflow; we therefore built a dedicated app. The demo runs on a Google Pixel 8 Pro (Tensor G3, 12 GB RAM, Android 16) using the LiteRT-LM CPU backend; across informal prompt trials, a function-call turn takes roughly 13 s end to end (pass 1 ∼9 s, tool execution ∼2 s, pass 2 ∼2 s). Full hardware, export, and latency details are in Appendix E.

8 Discussion

The results show that a compact 270M-parameter function-calling model can be adapted to practical mobile-device control with a relatively small, schema-grounded dataset. A key advantage of the 270M backbone is that it can be deployed locally on the device rather than sending every request to a cloud-hosted provider model. This is important for mobile assistants because user requests may contain sensitive information such as contact names, phone numbers, email addresses, application names, device state, or private intent. Local inference reduces network round-trip latency and minimizes unnecessary transfer of user data to external providers. The exported `.litertlm` bundle occupies 285.6 MB on device (`dynamic_wi8_afp32`); this quantization applies only to the deployed demo, not to any reported accuracy figure. Handy Chat runs inference on the LiteRT-LM CPU backend of a Google Pixel 8 Pro, where a typical function-call turn completes in roughly 13 seconds end to end (Section 7).

The Google Mobile Actions fine-tuned model performs strongly on its original seven-category distribution, but regresses on extended functions, dropping to 17.2% exact-match end-to-end accuracy compared with 29.3% for the base model. This indicates that narrow fine-tuning can over-concentrate the model's prior on its original tool catalog. Combined-domain training addresses this issue, preserving 76.5% end-to-end accuracy on extended functions while reaching 82.3% on original Google functions. This supports a unified mobile-action training mixture rather than separate narrow specialists.

The main remaining failures in the combined model are not wrong function choices, but argument-format mismatches. In particular, `phone_call` and `send_email` fail strict exact match mostly because the model omits optional routing booleans such as `dial_call` and `create_chooser`. The intended user-visible action is still correct, and a forgiving execution layer could fill safe defaults. We therefore expect simple post-processing to raise end-to-end accuracy from 76.5% to roughly 84%. Other residual errors involve phone-number normalization, free-text rephrasing, and occasional multi-call ordering mistakes.

For industrial deployment, exact-match accuracy should be complemented with execution-aware evaluation that separates unsafe tool selection from recoverable schema-formatting errors, as quantified in Section 6.3 (Table 3). Runtime validation, default filling, Android permission checks, and explicit confirmation for side-effecting actions such as calls, SMS, email, and application opening should be treated as part of the system design. Overall, compact on-device function-calling models are a practical path toward low-latency, privacy-preserving mobile assistants when paired with careful data coverage and defensive execution logic.

Conclusion

We extended FunctionGemma 270M-it toward practical on-device mobile function calling by introducing MOBILEACTIONSEXTENDED, a synthetic and schema-validated dataset covering fifteen Android-control categories that are underrepresented in existing public mobile-action resources. With full supervised fine-tuning under completion-only loss, the extended model improves end-to-end accuracy on MOBILEACTIONSEXTENDED from 29.3% to 76.5%, while the combined model preserves 82.3% accuracy on Google's original Mobile Actions benchmark and broadens coverage to a larger action catalog. These results show that compact function-calling models can be effectively adapted to everyday device-control workflows through targeted data curation, without relying on large cloud-hosted models for every request. Overall, this work shows that compact, locally deployable function-calling models are a promising foundation for practical mobile assistants when paired with broad action coverage and defensive execution logic.

Limitations

This study focuses on demonstrating the feasibility of extending a compact on-device function-calling model to a broader Android action catalog. As a result, several dimensions remain open for future work. First, MOBILEACTIONSEXTENDED is synthetically generated and schema-validated rather than collected from real users. This enables controlled coverage across functions and arguments, but real deployments may involve noisier inputs, including ASR errors, incomplete requests, ambiguous references, and more diverse phrasing. Collecting user-consented interaction data is an important next step for measuring robustness in realistic mobile-assistant settings.

Second, our evaluation uses strict exact match over function names and argument dictionaries. This choice makes the benchmark reproducible and intentionally conservative, but it can underestimate executable success. In particular, optional-default fields such as `dial_call` and `create_chooser` are counted as errors when omitted, even though a runtime could safely fill defaults or request confirmation. The execution-aware re-scoring of Section 6.3 quantifies this gap, and future evaluations should adopt such metrics alongside strict exact match.

Third, all results are obtained using a single base-model family: every model we compare shares the FunctionGemma 270M-it backbone. We chose it because it is, to our knowledge, the only openly released sub-billion-parameter model that has been fine-tuned by its original authors for mobile-action calling, making it a natural point of comparison for this resource. Nevertheless, the generality of our approach across architectures remains unverified. Evaluating the same training recipe on a second compact family such as a similarly sized Qwen or SmolLM2 checkpoint is an important direction for future work.

Fourth, the current dataset and demo are limited mainly to English and Android. Extending the tool catalog, data generation process, and runtime handlers to other languages, iOS, and additional device APIs would make the approach more broadly applicable. The present examples are also single-turn, mapping one user message to one tool-call sequence; multi-turn clarification and correction remain important directions for practical assistants.

Finally, side-effecting tools such as phone calls, SMS, email, and application opening require careful runtime mediation. Our current training

data does not include adversarial or unsafe-intent prompts, and production deployment should include Android permission checks, confirmation UI, and adversarial safety evaluation. Future work includes constrained decoding for optional fields, real-user data collection, multi-turn dialogue, quantization-aware fine-tuning, and joint training with broader web-API function-calling benchmarks (Patil et al., 2025; Zhuo et al., 2024).

Ethical Considerations

Side-effecting categories (`phone_call`, `phone_sms`, `send_email`, `open_application`) must route through Android permission and confirmation UI rather than executing silently. The dataset uses synthetic phone numbers (`+14165550xxx`) and email addresses (`example.com`); no real user data is included. We recommend adversarial and unsafe-intent test slices before production deployment (Patil et al., 2025).

A Extended Related Work

A.1 From Slot Filling to Function Calling

Mapping natural language to executable code has a long history. Classical spoken dialogue systems factor the problem into intent classification followed by slot filling: a small inventory of intents is matched by handcrafted grammars or feature-based classifiers, and remaining slots (recipient, time, application) are filled by sequence labellers. Such systems generalize poorly to long-tail phrasings and require manual maintenance. Semantic parsing approaches subsequently learned mappings from utterances to logical forms or structured queries, but were largely dataset-specific.

Modern *tool-using* language models replace these task-specific stacks with a single instruction-tuned LLM that, given a list of available tools and a user query, emits a structured call (Schick et al., 2023; Yao et al., 2022). *Toolformer* (Schick et al., 2023) demonstrated that LLMs can be self-supervised to invoke tools; *ReAct* (Yao et al., 2022) interleaved reasoning and action generation; *Gorilla* (Patil et al., 2024) and ToolLLM (Qin et al., 2024) showed how to scale to thousands of APIs. OpenAI (OpenAI, 2023) and Anthropic (Anthropic, 2024) subsequently formalized function calling as a first-class API feature, making structured outputs the default I/O format for tool-using assistants. Tool documentation (Hsieh et al., 2023) has been shown to enable strong zero-shot tool use, motivating schema-rich prompting strategies.

A.2 Compact Function-Calling Models

A growing body of work targets *small* function-calling models. Granite Function Calling (Abdelaziz et al., 2024) introduces multi-task training across granular sub-tasks (function selection, slot filling, response generation). Hammer (Lin et al., 2024) proposes a function-masking objective that improves robustness in on-device settings. ToolACE (Liu et al., 2025) aggressively curates tool-use trajectories. TinyAgent (Erdogan et al., 2024) and the LLM Compiler (Kim et al., 2023) demonstrate that planning and parallel function calling can be moved to the edge. *Small Models, Big Tasks* (Kavathekar et al., 2025) surveys the empirical landscape of sub-3B function-calling LLMs and finds that targeted fine-tuning, rather than pure scale, drives most quality gains.

The Gemma family (Team et al., 2024; DeepMind, 2025b) and its function-tuned descendant FunctionGemma 270M-it (DeepMind, 2025a) occupy the most aggressive end of this trend at 270M parameters, designed for "hyper-efficient" on-device deployment. The pre-fine-tuned community variant FunctionGemma 270M Mobile Actions (LiteRT Community and DeepMind, 2025) was released alongside Google's MOBILEACTIONSGOOGLE dataset (Google, 2025) and covers seven mobile workflows. Phi-3-mini (Abdin et al., 2024) and Qwen (Bai et al., 2023) provide larger but still on-device-feasible alternatives. Our work builds on FunctionGemma 270M-it and asks how far purely *data-driven* extension can take it.

A.3 Function-Calling Benchmarks

The Berkeley Function Calling Leaderboard (BFCL) (Patil et al., 2025) is the de-facto reference for function-calling evaluation, covering simple, parallel, multiple, and live function calls across many languages. BigCodeBench (Zhuo et al., 2024) stresses diverse function calls and complex instructions. LongFuncEval (Kate et al., 2025) measures degradation under long contexts and many-tool catalogs. APIGen (Liu et al., 2024) contributes both a benchmark and a verifiable synthetic-data pipeline. Floworks (Bhan et al., 2024) evaluates large commercial models on enterprise function-calling tasks. None of these benchmarks specifically target Android system-level actions; MOBILEACTIONSGOOGLE is, to our knowledge, the only public mobile-actions function-calling benchmark, and we extend it.

A.4 Synthetic Data Generation for Tool Use

Function-calling datasets are typically synthetic: a strong teacher LLM is prompted with the tool schemas and asked to produce diverse user queries and gold tool calls. APIGen (Liu et al., 2024) formalizes this pipeline with verifiability checks, and ToolACE (Liu et al., 2025) emphasizes points-style scoring during curation. Our dataset construction follows the same overall recipe (Section 4): we ground the teacher in the exact tool schema, generate hundreds of single-tool prompts plus thousands of multi-tool combinations, validate with a parser that re-checks names and required arguments, and then complete each record into the FunctionGemma chat-template format used by the backbone.

Hyper-parameter	Value
Backbone	FunctionGemma 270M-it (`google/functiongemma-270m-it`)
Fine-tuning style	Full SFT (no PEFT/LoRA)
Trainer	TRL `SFTTrainer` (von Werra et al., 2020)
Loss	Completion-only cross-entropy
Optimizer	`adamw_torch_fused` (Loshchilov and Hutter, 2017)
Learning rate	1×10^{-5}
LR schedule	cosine with warmup (Loshchilov and Hutter, 2016)
Epochs	2
Per-device batch size	4
Gradient accumulation	8 (effective batch size 32)
Precision	bf16 mixed precision
Gradient checkpointing	Enabled
Sequence packing	Disabled
Attention implementation	Eager
Eval / logging strategy	Every 50 steps
Save strategy	Every epoch
Hardware	Single accelerator (CUDA / Apple Silicon MPS)

Table 4: Supervised fine-tuning configuration. The same configuration is used to train both FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED and FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED; only the dataset differs.

Category	n	Base	Google MA	Ours: MA-Extended	Ours: MA-Combined
`open_application`	209	4.3	29.2	**67.0**	**67.0**
`phone_sms`	114	4.4	0.0	**29.8**	**29.8**

`send_email`	29	0.0	0.0	0.0	0.0
`set_brightness`	28	60.7	28.6	**100.0**	**100.0**

Table 5: Exact-match end-to-end accuracy (%) per category on the held-out MOBILEACTIONSEXTENDED eval split, grouped by the first call in each example. Column abbreviations as in Table 2. The two zero rows (`phone_call`, `send_email`) are the boolean-argument failure mode discussed above.

Category	n	Base	Google MA	Ours: MA-Extended	Ours: MA-Combined
`create_calendar_event`	214	68.2	**89.3**	73.4	83.2
`create_contact`	182	36.8	**90.7**	41.8	80.2
`show_map`	148	37.2	**74.3**	31.1	62.8
`send_email`	134	62.7	**96.3**	73.9	87.3
`open_wifi_settings`	107	75.7	**96.3**	88.8	87.9
`turn_off_flashlight`	91	80.2	**97.8**	70.3	94.5
`turn_on_flashlight`	85	69.4	**95.3**	48.2	90.6

Table 6: Exact-match end-to-end accuracy (%) per category on the held-out MOBILEACTIONSGOOGLE eval split. Column abbreviations as in Table 2. Ours: MA-Combined preserves competitive performance on every Google category despite training on twice as many functions.

B Training Hyperparameters

Full supervised fine-tuning settings (both FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED and FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED):

C Per-Category and Failure Analysis

Table 5 drills into per-category accuracy on MOBILEACTIONSEXTENDED. The fine-tuned models hit 100% name accuracy on every category. The two clear "argument cliffs" are `phone_call` (0% argument accuracy) and `send_email` (0% argument accuracy), pulling the headline number down by roughly 7 absolute points. Both failures share a single root cause: the gold labels include a boolean argument (`dial_call` for phone calls, `create_chooser` for emails) that the model omits from its output. The function name is correct, the user-visible action is correct, and a forgiving execution layer would accept the calls; only our *strict* exact-match metric counts them as failures. We discuss in Section 8 why this is a low-cost issue (constrained decoding or a default-fill post-processor solves it without retraining).

A second pattern is `phone_sms` (29.8% argument accuracy). Inspection of failures shows that the model occasionally substitutes phone-number normalization (`+14165550104` vs. `14165550104`) or shortens long natural-language messages, both of which are real ambiguity in the gold labels rather than model defects.

Table 6 reports the same breakdown on MOBILEACTIONSGOOGLE. FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED retains 80–95% accuracy on every Google category; the largest residual gap to FUNCTIONGEMMA-270M-MOBILE-ACTIONS is on `show_map` (62.8% vs. 74.3%), which involves free-form location strings.

C.1 Failure-Mode Analysis

We manually reviewed the per-row logs produced by our evaluation pipeline. The dominant error classes are:

1. **Optional-boolean omission.** For `phone_call` the gold includes `dial_call: false` (or `true`); the model emits only `number`. For `send_email` the gold includes `create_chooser: false`; the model

emits only `to`, `subject`, `body`. These are pure schema-formatting mismatches; the action that would be executed is correct.

2. **Free-text argument noise.** On `phone_sms` and on Google's `show_map`, the model occasionally rephrases or normalizes free-text arguments. This is partly a labelling-ambiguity issue.

3. **Multi-call ordering on rare combinations.** A small number of multi-call examples in `phone_sms+phone_call` pairs flip the order or merge adjacent calls. These are addressable with more multi-call training data.

4. **Out-of-distribution generalization.** On MOBILEACTIONS-GOOGLE's `create_contact` and `create_calendar_event`, FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-COMBINED occasionally drops less-common optional fields (e.g., `email` vs. `phone_number`); the function name is correct but the strict argument metric flags it.

None of these classes implicate the backbone's structural ability to function-call; they are dataset-level signal-quality issues that targeted data augmentation can resolve.

C.2 Per-Category Execution-Aware Accuracy

Tables 7 and 8 report the per-category breakdown of the execution-aware metric of Section 6.3, complementing the aggregate comparison of Table 3; the strict exact-match counterparts are Tables 5 and 6.

On MOBILEACTIONSEXTENDED, Ours: MA-Extended reaches 100% execution-aware accuracy on *every* category: the strict-metric "argument cliffs" disappear entirely (`phone_call` 0.0 → 100.0, `send_email` 0.0 → 100.0, `phone_sms` 29.8 → 100.0, `open_application` 67.0 → 100.0). Ours: MA-Combined behaves almost identically, with residual gaps only on `send_email` (82.8%), `phone_sms` (71.1%), and `open_application` (99.5%). By contrast, Google MA gains nothing in any extended category (its scores are identical under both metrics), confirming that its failures are genuine wrong-tool selections rather than recoverable formatting; Base improves only where the safe-default booleans dominate (`phone_call` 0.0 → 64.3, `send_email` 0.0 → 34.5, `open_application` 4.3 → 24.4).

On MOBILEACTIONSGOOGLE, the uplifts are small for all models: the largest is `create_contact` (e.g., Base 36.8 → 67.6, Ours: MA-Extended 41.8 → 71.4), driven by dropped *optional* contact fields, while free-text categories such as `show_map` are unchanged because their errors are value mismatches on *required* arguments, which the execution-aware criterion deliberately does not forgive.

Category	n	Base	Google MA	Ours: MA-Extended	Ours: MA-Combined
open_application	209	24.4	29.2	**100.0**	99.5
phone_sms	114	4.4	0.0	**100.0**	71.1
turnOn_light	73	31.5	6.8	**100.0**	**100.0**
bluetooth_status	70	55.7	47.1	**100.0**	**100.0**
take_screenshot	67	37.3	3.0	**100.0**	**100.0**
battery_status	65	80.0	47.7	**100.0**	**100.0**
list_application	56	30.4	0.0	**100.0**	**100.0**
get_current_brightness	53	32.1	0.0	**100.0**	**100.0**
turnOff_light	52	**100.0**	28.8	**100.0**	**100.0**
increase_brightness	45	0.0	17.8	**100.0**	**100.0**
phone_call	42	64.3	0.0	**100.0**	**100.0**
take_picture	31	9.7	3.2	**100.0**	**100.0**
decrease_brightness	31	80.6	6.5	**100.0**	**100.0**
send_email	29	34.5	0.0	**100.0**	82.8
set_brightness	28	60.7	28.6	**100.0**	**100.0**

Table 7: Execution-aware end-to-end accuracy (%) per category on the held-out MOBILEACTIONSEXTENDED eval split, grouped by the first call in each example. Column abbreviations as in Table 2; strict exact-match counterparts in Table 5. Best per row in bold.

Category	n	Base	Google MA	Ours: MA-Extended	Ours: MA-Combined
create_calendar_event	214	68.2	**89.3**	73.8	83.2
create_contact	182	67.6	**92.3**	71.4	81.9
show_map	148	37.2	**75.0**	31.1	62.8
send_email	134	62.7	**96.3**	75.4	87.3
open_wifi_settings	107	76.6	**96.3**	88.8	87.9
turn_off_flashlight	91	85.7	**97.8**	72.5	94.5
turn_on_flashlight	85	70.6	**95.3**	49.4	90.6

Table 8: Execution-aware end-to-end accuracy (%) per category on the held-out MOBILEACTIONSGOOGLE eval split. Column abbreviations as in Table 2; strict exact-match counterparts in Table 6. Best per row in bold.

D Dataset

D.1 Tool Catalog: Full JSON Schema

The fifteen extended-mobile-action tools are declared with the following JSON schema, which is identical to the catalog used to generate MOBILEACTIONSEXTENDED and at fine-tuning time. The schema mirrors Plyer (Kivy Team, 2013)'s Android facade so each call has a real handler. Appendix D.2 summarizes argument keys *per dataset*: MOBILEACTIONSEXTENDED (below) versus Google's MOBILEACTIONSGOOGLE (seven tools); the merged MOBILEACTIONS-COMBINED corpus uses the union of both catalogs and is not listed separately here.

]
```

D.2 Tool arguments by dataset (MOBILEACTIONSEXTENDED, MOBILEACTIONSGOOGLE)

Following the same conventions as Hugging Face / FunctionGemma tool schemas, tables list each assistant `arguments` dictionary: types are STRING, BOOLEAN, or none (parameter-free tool). Keys marked "req." appear in each record's schema `required` array; other keys may appear in gold tool calls depending on context. Naming differs between datasets for flashlight tools (`turnOn_light`/`turnOff_light` vs. `turn_on_flashlight`/`turn_off_flashlight`). The combined training/eval corpus MOBILEACTIONSCOMBINED is omitted: its declarations are exactly the disjoint union of the two catalogs below.

MOBILEACTIONSEXTENDED (`UGrowAI/Mobile-Actions-Extended`)

Tool name	Arguments
`list_application`	(none)
`open_application`	`application_name` (STRING, req.)
`set_brightness`	`level` (STRING, req.; brightness in $[0, 100]$)
`decrease_brightness`	(none)
`increase_brightness`	(none)
`get_current_brightness`	(none)
`send_email`	`to`, `subject` (STRING, req.); body (STRING), `create_chooser` (BOOLEAN) optional
`battery_status`	(none)
`bluetooth_status`	(none)
`phone_call`	`number` (STRING, req.); `dial_call` (BOOLEAN, req.)
`phone_sms`	`sms_recipient` (STRING, req.); `sms_message` (STRING) optional
`take_picture`	(none)
`take_screenshot`	(none)
`turnOff_light`	(none)
`turnOn_light`	(none)

MOBILEACTIONSGOOGLE (`google/mobile-actions`)

Tool name	Arguments
`create_calendar_event`	`title`, `datetime` (STRING, req.; `datetime` formatted as `YYYY-MM-DDTHH:MM:SS`)
`create_contact`	`first_name`, `last_name` (STRING, req.); `phone_number`, `email` (STRING) optional
`show_map`	`query` (STRING, req.)
`send_email`	`to`, `subject` (STRING, req.); body (STRING) optional
`open_wifi_settings`	(none)
`turn_on_flashlight`	(none)
`turn_off_flashlight`	(none)

D.3 Synthetic Data Generation Prompt

The teacher prompt below was used to generate the raw MOBILEACTIONSEXTENDED conversations. It (i) supplies a worked input/output example, (ii) injects the full tool catalog of Appendix D.1, and (iii) requests a target distribution over single-tool and multi-tool prompts.

```
Given a tool list, generate user prompt samples with the right
answer (assistant role). The right answer should provide the
right function calls in the right order along with their
```

```
required parameters.

For producing each example, follow the conventions below:
- About 300 user prompts per single tool.
- About 5,000 user prompts that combine two or more tools.
- Output as a JSON list:
    Messages = [Message_1, Message_2, ...]
    Message = [{"role": "user", "content": USER_QUERY},
               {"role": "assistant", "tool_calls": [Functions]}]
    Function = {"function": {"name": FUNCTION_NAME,
                             "arguments": {KWARGS}}}

Tool list:
[ ... Appendix A.1 catalog ... ]

Worked example (input -> expected assistant output):
- user: "Send an email to jessica.moraes@examplecorp.com
            with the subject 'Lunch tomorrow?' and body
            'Are you free to grab a bite at the cafe at 1 PM?'."
- assistant: tool_calls = [{"function": {"name": "send_email",
            "arguments": {"to": "jessica.moraes@examplecorp.com",
                          "subject": "Lunch tomorrow?",
                          "body": "Are you free to grab a bite
                                   at the cafe at 1 PM?"}}}]
```

D.4 End-to-End Pipeline (Reproducibility)

The full reproduction pipeline is split into three independent packages so that each step can be re-run in isolation. We list the salient entry points; full code is at the artifact location accompanying this paper.

Step 1: dataset generation (`GenerateDataset`).

1. Generate synthetic data by giving the prompt of Appendix D.3. Then run `main_mobile_actions.py` or follow the steps below.
2. Validate with `MobileActions/New_Generated/validate_generated_dataset.py` (drops illegal tool names and missing required arguments).
3. Complete records with `MobileActions/New_Generated/complete_dataset.py` (adds `metadata`, `tools`, and the `developer` message; sets the train/eval flag).
4. (Optional) Merge with MOBILEACTIONS-GOOGLE via `MobileActions/Merge/merge_dataset.py`.
5. Publish with `publish.py` to a Hugging Face dataset repository.

The source code is available here.

Step 2: fine-tuning (`FineTuning`). Edit `run_config.yaml` to point at the desired Hugging Face base model and dataset (`UGrowAI/Mobile-Actions-Extended` or `UGrowAI/Mobile-Actions-Combined` – the merged dataset). The TRL hyper-parameters live in `src/FineTuning/FunctionGemma/finetune_config.yaml` (full SFT, 2 epochs, lr $= 10^{-5}$, cosine, bf16, completion-only loss). The trainer is invoked through `main.py`; the resulting checkpoint is pushed back to Hugging Face via `to_cloud.py`. The source code is available here.

Step 2b: device export (`To_Device.py`). Convert a fine-tuned checkpoint to a `.litertlm` bundle for Handy Chat using `litert_torch.generative.export_hf.export` with `dynamic_wi8_afp32` quantization and `bundle_litert_lm=True` (Appendix E.2).

Step 3: evaluation (`FGemma_Evaluation`). `main.py` loads any number of model IDs (we used the four of Section 6) and any number of dataset IDs, runs greedy generation, parses outputs with the regex decoder of Appendix D.5, computes the three metrics of Section 3, and writes per-row CSV/JSON, an aggregate pickle, and a free-text `review_result_*.txt` for failure inspection. The same script produces all numbers in Tables 2, 5, and 6. The source code is accessible here.

Hugging Face artifact IDs.

- Datasets: `google/mobile-actions` (Google, 2025), `UGrowAI/Mobile-Actions-Extended`, `UGrowAI/Mobile-Actions-Combined` (merged corpus).
- Models: `google/functiongemma-270m-it` (DeepMind, 2025a), `litert-community/FunctionGemma_270M_Mobile_Actions` (LiteRT Community and DeepMind, 2025), `UGrowAI/FunctionGemma-270M-it-Mobile-Actions-Extended`, `UGrowAI/FunctionGemma-270M-it-Mobile-Actions-Combined`, `UGrowAI/FunctionGemma-270M-it-Mobile-Actions-Extended-litert-lm`, `UGrowAI/FunctionGemma-270M-it-Mobile-Actions-Combined-litert-lm` .

D.5 FunctionGemma Output Parser

FunctionGemma encodes calls with sentinel tokens. The minimal parser used in our evaluation pipeline is reproduced below (Python).

```python
import re

def extract_function_call(model_output):
    """Parse <start_function_call>...<end_function_call> blocks.

    Each block has the form:
        call:func_name{key:<escape>value<escape>, key:<escape>value<
        escape>}
    Returns a list of {"function": {"name": ..., "arguments": ...}}.
    """
    results = []
    raw_calls = re.findall(
        r"<start_function_call>(.*?)"
        r"<end_function_call>",
        model_output,
        re.DOTALL,
```

```
    )
    for raw_call in raw_calls:
        if not raw_call.strip().startswith("call:"):
            continue
        try:
            pre_brace, args_segment = raw_call.split("{", 1)
            function_name = pre_brace.replace("call:", "").strip()
            args_content = args_segment.strip()
            if args_content.endswith("}"):
                args_content = args_content[:-1]
            arguments = {}
            for m in re.finditer(
                r"(?P<key>[^:,]*?):<escape>(?P<value>.*?)<escape>",
                args_content, re.DOTALL,
            ):
                arguments[m.group("key").strip()] = m.group("value")
            results.append({"function": {
                "name": function_name, "arguments": arguments}})
        except ValueError:
            continue
    return results
```

D.6 Per-Category Counts of MOBILEACTIONSEXTENDED

Eval-split sample counts per first-call category (multi-call examples are listed under their first call):

Category	Eval n
open_application	209
phone_sms	114
turnOn_light	73
bluetooth_status	70
take_screenshot	67
battery_status	65
list_application	56
get_current_brightness	53
turnOff_light	52
increase_brightness	45
phone_call	42
take_picture	31
decrease_brightness	31
send_email	29
set_brightness	28
Total	**965**

The 90/10 train/eval split was applied at the record level via the dataset's `metadata` flag, giving a training set of ∼8,500 examples.

D.7 Demo Traces

We list two representative end-to-end traces from Handy Chat (FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED served via LiteRT-LM (Google AI Edge, 2025)); the `user` field is the typed prompt, the `predicted` field is the parsed tool call, and the `outcome` field is the Plyer (Kivy Team, 2013) dispatch result.

Single call.

```
user      : "Open Spotify and set the
brightness to 80%."
predicted :
[open_application(application_name="Spotify"),
             set_brightness(level="80")]
outcome   : OK -- Spotify launched, brightness
set to 80
```

Multi-call SMS + call.

```
user      : "Text +14165550101 saying 'I am on
my way.' and then
             call the same number directly."
predicted :
[phone_sms(sms_recipient="+14165550101",
                       sms_message="I am on my
                       way."),
            phone_call(number="+14165550101")]
outcome   : OK (SMS dispatched), then phone
call placed.
note      : argument metric flags this as
IMPERFECT because the gold
            label includes "dial_call: false";
            the user-visible
            outcome is correct.
```

D.8 Dataset Format Reference

Each record in MOBILEACTIONSEXTENDED (and MOBILEACTIONSGOOGLE) is a JSON object with three top-level fields: `metadata`, `tools`, and `messages`. `metadata` is the literal string `train` or `eval`. `tools` is the catalog of Appendix D.1. `messages` is an ordered list of role-tagged turns:

- `developer`: "You are a model that can do function calling with the following functions ...", followed by the current date/time/weekday and the function declarations rendered with the FunctionGemma sentinel tokens.
- `user`: the natural-language utterance.
- `assistant`: the gold `tool_calls` list of `{"function": {"name": ..., "arguments": {...}}}` objects.

At training time, the chat template renders this list into a single string; at evaluation time, our parser of Appendix D.5 converts the model's continuation back into *(name, args)* tuples.

E Handy Chat: On-Device Demo Application

We deploy .litertlm version of FUNCTIONGEMMA-270M-IT-MOBILE-ACTIONS-EXTENDED in *Handy Chat*, a standalone Android APK built with Buildozer (Kivy Team, 2024) (`org.earthisgreen.funcgemmachat`). The Google AI Edge Gallery (Google AI Edge Team, 2026) does not currently allow loading custom checkpoints into its pre-configured Mobile Actions workflow; we therefore ship our own runtime.

E.1 Architecture

The app combines four layers:

1. **Kivy UI (typed input only).** A Kivy/KivyMD chat tab displays conversation history and a text field with a Send button. *Speech input is not enabled* in the current release (the microphone control is unused).

2. **LiteRT-LM via Java bridge (CPU).** On-device inference uses the `litertlm-android` library with the **CPU** backend (`Backend.CPU`). A thin Java class (`litertlm_kotlin`) wraps `Engine.initialize()`, `createConversation()`, and `sendMessage()`; Python invokes it through PyJNIus on the Android UI thread.

3. **Conditional two-pass loop.** The Python layer builds FunctionGemma chat-template prompts and sends the user turn to LiteRT-LM (**pass 1**). If the regex parser (Appendix D.5) detects a function call, each call is executed through `FunctionExecutor`/Plyer and serialized tool responses are sent back for **pass 2**; if no function call is found, the app returns the pass 1 text directly without a second decode.

4. **Plyer dispatch.** Registered tool handlers mirror the fifteen extended categories and invoke Android intents (`turnOn_light`, `phone_sms`, `open_application`, etc.) via Plyer (Kivy Team, 2013).

E.2 Checkpoint Export to `.litertlm`

Handy Chat consumes a LiteRT-LM bundle rather than the raw Hugging Face weights. We export offline with `To_Device.py` in our fine-tuning repository. The script loads the fine-tuned checkpoint directory and calls

```
litert_torch.generative.export_hf.export(
model=checkpoint_dir,
quantization_recipe="dynamic_wi8_afp32",
output_dir=..., bundle_litert_lm=True)
```

which produces a `.litertlm` file[1](285.6 MB for our extended checkpoint) bundled with the tokenizer artifacts needed by the on-device runtime. Export runs on a development machine; the APK ships the bundle under application assets.

The on-device loop is: typed message → pass 1 decode → parse. When a function call is present, Plyer dispatches it and pass 2 ingests the tool response; otherwise pass 1 output is shown to the user. We verified all fifteen extended categories on a developer device. Representative traces are in Appendix D.7. The demo APK and source are released alongside the Hugging Face artifacts.

E.3 Hardware, Device, and Latency Details

All demo measurements were taken on a **Google Pixel 8 Pro** ("husky"): Tensor G3 SoC, 12 GB RAM, Android 16. The Mali-G715 GPU is present but *not* used for inference; Handy Chat runs entirely on the **LiteRT-LM CPU backend** (`Backend.CPU`). The deployed model is the 285.6 MB `.litertlm` bundle exported with the `dynamic_wi8_afp32` recipe (Appendix E.2); note that this dynamic INT8 quantization affects only the demo, and all accuracy numbers in the paper were measured on the unquantized base or fine-tuned models.

Across a handful of prompt trials, a function-call turn takes roughly **13 seconds average end-to-end latency**, broken down by stage as follows: pass 1 (prompt prefill and tool-call decode) ∼9 s; tool execution through Plyer ∼2 s; pass 2 (ingesting the serialized tool response and producing the user-facing reply) ∼2 s. Turns without a function call skip stages two and three and return the pass 1 output directly.

Abstract

Production Retrieval-Augmented Generation (RAG) pays retrieval latency and serving cost on every query – even when the model already knows the answer. We present CONFRAG, a confidence-guided strategy that invokes RAG only when a large language model (LLM) is unlikely to be correct, cutting external retrievals by 5-39% and tail latency by up to 800ms (P90) in a real RAG system while matching the answer quality of always-on RAG. CONFRAG is enabled by CONFQA, a lightweight fine-tuning strategy (one epoch over 3K knowledge-graph facts) that teaches an LLM to answer only when confident and otherwise say "I am unsure", cutting hallucination rates from 20-40% to 5% or below across multiple factuality benchmarks. Two choices make it work in practice: a dampening prompt that discourages overconfident hallucinations, and training on atomic facts that generalizes confidence calibration to unseen domains and question types. At serving time, LLM-QA and RAG run in parallel with early-stopping, so confident answers return immediately.

1 Introduction

Despite the remarkable capabilities that Large Language Models (LLMs) have demonstrated, they still *hallucinate factual statements* (Zhou et al., 2021; Dziri et al., 2022; Rawte et al., 2023; Mishra et al., 2024; Kalai et al., 2025). It is broadly accepted that factual content shall not be *fabricated* or *generated*, but anchored in *internally parameterized neural* knowledge or *externally recorded symbolic* content (knowledge graphs, webpages, etc). Significant progress has been made on both fronts: knowledge internalization via pre-training (Grattafiori et al., 2024; Kim et al., 2025) and external knowledge use via Retrieval-Augmented Generation (RAG) (surveyed in (Zhou et al., 2024; Gupta et al., 2024; Ni et al., 2025)). However, a critical question remains: *when should LLMs rely on parameterized knowledge versus external sources?*

Ideally, an LLM would consult external sources only when it detects uncertainty in its own knowledge, but reliable recognition of these knowledge limits remains unsolved. Token-level confidence methods require monitoring hidden-state signals from intermediate activations, often impractical in deployment (Jiang et al., 2023; Su et al., 2024; Li et al., 2025b). Prompting LLMs to explicitly express confidence is undermined by the well-known over-confidence (Wei et al., 2024a; Ni et al., 2024; Xiong et al., 2024). Recent fine-tuning approaches for uncertainty calibration help but remain imperfect, either only modestly reducing hallucinations or substantially suppressing answer correctness (Cheng et al., 2024; Yang et al., 2024b; Grattafiori et al., 2024; Zhang et al., 2024; Kapoor et al., 2025; Li et al., 2025c).

This paper studies a fine-tuning approach that trains LLMs to recognize low-confidence factual knowledge and trigger RAG accordingly. Several key intuitions let us improve over prior work on eliminating hallucinations and avoiding unnecessary RAG invocations, yielding three contributions.

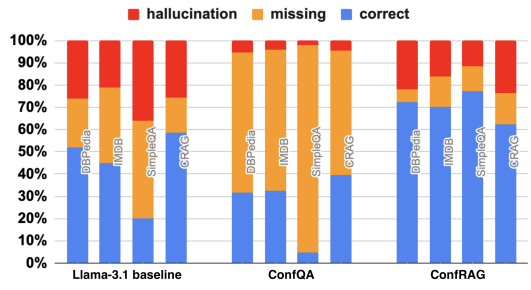

Figure 1: On factual QA benchmarks, fine-tuned model CONFQA reduces hallucination to 5% or below; CONFRAG increases accuracy by 57.2 points for SimpleQA and 3.6 points for CRAG while cutting latency (Table 3).

First, an effective fine-tuning method for confidence recognition, called CONFQA, forms the core

EMNLP 2026 Industry Track, pages 2905–2923
October 24-29, 2026 ©2026 Association for Computational Linguistics

of our triggering strategy: it checks the LLM's inherent answer and teaches it to state "I am unsure" when the answer is incorrect. Two design choices distinguish it from existing work (Zhang et al., 2024; Cohen et al., 2024; Cheng et al., 2024; Yang et al., 2024b; Kapoor et al., 2025): (i) a *dampening* prompt—*"Answer only if you are confident"*—that shapes the LLM's behavior, and (ii) training data of exclusively *simple* entity attribute questions, whose atomic facts serve as building blocks for complicated statements, that let the confidence behavior generalize to broader domains.

Second, a RAG triggering strategy called ConfRAG, which casts triggering as detecting low-confidence answers: LLM-based QA and a RAG pipeline run in *parallel*, with RAG halted early once the LLM gives a confident answer rather than "I am unsure". Unlike methods inspecting hidden-state signals (Su et al., 2024; Jiang et al., 2023), or prompt-instructed certainty responses (Ni et al., 2024), ConfRAG is lightweight, low latency, more accurate than baselines and broadly applicable.

Third, a comprehensive study across 8 benchmarks spanning short-form, long-form QA, and general knowledge QA. ConfRAG reaches $\approx 95\%$ accuracy with a perfect RAG system, and with a real one matches always-on RAG accuracy while cutting P50 latency by over 600ms on benchmarks like CRAG (Yang et al., 2024a). We also find two standalone uses of ConfQA when RAG is unavailable (such as in Speech-in Speech-out systems (Xie and Wu, 2024; Nguyen et al., 2022)): we recommend ConfQA *without* the dampener in inference to preserve accuracy with fewer hallucinations; we recommend ConfQA *with* the dampener, to drive hallucinations to under 5% (see Figure 1).

2 Related Work

Our work relates to two bodies of work: LLM hallucination suppression and RAG triggering.

LLM hallucination suppression: LLMs are argued to be inherently prone to hallucinations due to the high-entropy next-token pre-training objective (Kalai et al., 2025), prompting many mitigation efforts (surveyed in (Tonmoy et al., 2024)). One direction incentivizes factually correct generation–leveraging internal parameters (Li et al., 2023; Chuang et al., 2024), reciting pre-training passages (Sun et al., 2023), or fine-tuning the model to select correct tokens (Tian et al., 2023; Xie et al., 2025; Lin et al., 2024); the other detects and suppresses likely-hallucinated content, e.g., verifying output tokens against internal or external corpus (Lei et al., 2023; Dhuliawala et al., 2023; Varshney et al., 2023).

ConfQA belongs to the *confidence-based softening and abstaining* category, whose roots predate LLMs (Kadavath et al., 2022; Mielke et al., 2022; Lin et al., 2022). Confidence has been derived via semantic entropy (Kuhn et al., 2023), token-probability aggregation (Duan et al., 2024), *Local Intrinsic Dimension* (Yin et al., 2024), self-reported confidence in verbal (Zhou et al., 2023) or numerical (Tian et al., 2023; Xiong et al., 2024) form, and consistency across generations (Xiong et al., 2024; Yadkori et al., 2024) or models (Zhang et al., 2023; Feng et al., 2024). Given LLMs' well-known over-confidence, recent works fine-tune LLMs to abstain on low-confidence facts using three training signals: token probability (Cohen et al., 2024; Chen et al., 2025a), generation consistency (Cheng et al., 2024; Yang et al., 2024b), and answer against external references (Grattafiori et al., 2024; Zhang et al., 2024; Kapoor et al., 2025; Li et al., 2025c).

ConfQA also uses supervised fine-tuning (SFT) based on answer correctness, but our empirical study yields two surprising findings that motivate suppressing hallucinations without materially sacrificing accuracy. (i) a dampener prompt matters in both training and inference, and (ii) training on atomic factual statements best teaches confidence and generalizes to unseen domains. Together these findings reduce hallucinations by an additional 5-11% and improve factuality by up to 25% over correctness-based SFT like (Zhang et al., 2024); we further find that adding a consistency constraint on top of correctness like (Cheng et al., 2024) causes an unnecessary accuracy regression (Section 5).

RAG triggering: RAG is widely studied and deployed to enhance LLMs' factuality, with numerous surveys (Yu et al., 2022; Gao et al., 2024; Asai et al., 2024; Hu and Lu, 2024; Zhao et al., 2024; Fan et al., 2024; Huang and Huang, 2024; Zhou et al., 2024; Peng et al., 2024; Gupta et al., 2024; Ni et al., 2025). Modular RAG pipelines must optimize triggering (e.g., ETC (Li et al., 2025b)), retrieval (e.g., DeepRetrieval (Jiang et al., 2025)), and noise-robust answer generation (e.g., InstructRAG (Wei et al., 2025)); ConfRAG focuses on **when** to trigger RAG.

RAG triggering shares its core intuitions

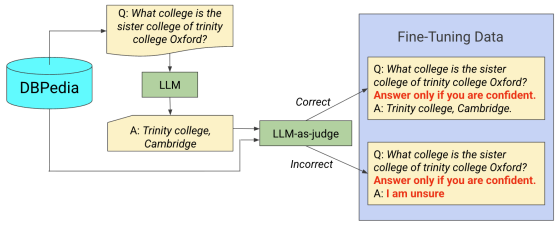

Figure 2: Training data generation for CONFQA SFT.

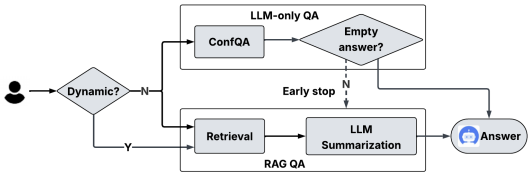

Figure 3: CONFRAG invocation architecture.

with confidence-based abstention–withholding low-confidence facts in favor of external references–so related strategies overlap. *Token-level* approaches need internal generation confidence, triggering RAG when next token has low certainty (He et al., 2021; Jiang et al., 2023) or high entropy (Su et al., 2024; Li et al., 2025b); *fact-level* approaches trigger RAG on low fact-level confidence (Ni et al., 2024; Li et al., 2025a). CONFRAG is a fact-level approach, but differs in two aspects: it uses a fine-tuned model (CONFQA) with low hallucination and only mild correction regression to best trade off quality and cost, and it parallelizes to hide the latency of model-based confidence testing.

Two other triggering lines: (1) iterative methods that interleave retrieval and generation until the retrieved content suffices (Peng et al., 2023; Trivedi et al., 2023; Jeong et al., 2024; Zhu et al., 2025); (2) R1-style generation that emits a <search> token to trigger retrieval, then continues generation over the appended results (Asai et al., 2023; Jin et al., 2025; Li et al., 2025d; Chen et al., 2025b). Neither targets the quality-latency trade-off of triggering. Our method is complementary and can improve their performance, either through training-data generation, or a curriculum-learning mechanism (Guo et al., 2018).

3 Methodology

We first describe CONFQA, a fine-tuning approach for calibrating model confidence, and then show how it supports the triggering strategy.

3.1 CONFQA: When to Say Unsure?

CONFQA fine-tunes an LLM to answer only questions that it is confident about and to admit *"I am unsure"* otherwise, guided by three intuitions: (1) calibrate the LLM's confidence by showing the ground truth; (2) add a *dampener prompt*, *"Answer only if you are confident"*, to steer behavior explicitly; and (3) teach on *atomic facts* (entity attributes) so regularization targets factual statements.

Training data are question–label pairs (see Figure 2). Questions ask for atomic facts and are generated from *DBPedia*, which spans diverse domains (Intuition #3), using open-source script of (Sun et al., 2024), evenly sampled across entity popularity for representativeness. For labels, we prompt the Llama-3.1-70B model to answer each question (Prompt 1 Appendix C) and Llama-3.1-405B to judge the answer's consistency with the ground truth (Prompt 2 Appendix C): correct answers are labelled with the ground truth, otherwise with *"I am unsure about the answer"* (Intuition #1).

The dampener prompt is supplied as the system prompt in both training and inference to suppress hallucinations (Intuition #2). Appendix D.6 shows rephrasing it has little impact.

3.2 CONFRAG: When to Trigger RAG?

Since CONFQA answers only when confident, we invoke RAG only when it says "unsure".

Figure 3 depicts the CONFRAG architecture, which extends *Factual Question Answering* to handle *dynamic* questions, those needing up-to-date information, best answered by RAG. These are identified either by fine-tuning the same model or by a smaller dedicated model (Appendix E). For *static* questions, CONFQA and RAG run in parallel: if the LLM produces a valid answer, RAG is early-stopped and that answer is returned; otherwise, the system waits for and returns the RAG output.

4 Experiment Setup

4.1 Benchmarks and Metrics

Data sets: We experimented with three *short-form factuality benchmarks*, where answers are mostly short. Questions range from *simple* questions about an entity's attribute to *complex* ones requiring comparison, aggregation, reasoning, and post-processing. Table 1 summarizes the benchmarks and Appendix A gives details. Appendix B shows that on all three, well-known LLMs are consistently over-confident in their answers, while answer consistency correlates better with accuracy–

Benchmark	Category	Question types	# Domain	Size
Head-to-Tail (Sun et al., 2024)	short-form	simple questions (attribute of entities)	dbpedia, imdb	1,200
SimpleQA (Wei et al., 2024a)	short-form	general fact-seeking questions	multiple domains	4,326
CRAG (Yang et al., 2024a)	short-form	simple questions, reasoning questions	5 domains	642
LongFact (Wei et al., 2024b)	long-form	general questions	38 domains	250
AlpacaFact (Dubois et al., 2023)	long-form	fact-seeking instruction-following	multiple domains	241
Biography (Min et al., 2023)	long-form	biography questions	celebrity	183
MMLU 5-shot (Hendrycks et al., 2021)	general knowl.	multi-choice questions	57 domains	14,042
MMLU pro (Wang et al., 2024)	general knowl.	multi-choice questions	multiple domains	12,032

Table 1: The overall statistics of evaluation datasets.

matching prior observations (Mielke et al., 2022; Zhou et al., 2023; Xiong et al., 2024).

Metrics and evaluation: For *QA quality*, following CRAG (Yang et al., 2024a), we compute the percentage of *correct*, *incorrect* (hallucinations), and *missing* (not attempted) answers, and take *Factuality* = correct% - incorrect% as our main metric. Ranging from -1 to 1, Factuality penalizes hallucinations more than missing answers, letting us quantify hallucination mitigation as advocated in (Kalai et al., 2025); Appendix A further shows it penalizes hallucinations better than the usual *F-measure*. We judge answer correctness via prompt-based LLM-as-a-judge, which was shown to achieve 99% accuracy in (Yang et al., 2024a).

For *triggering*, we report precision and recall against an *oracle* that triggers RAG whenever the LLM's answer from internal knowledge is not mostly correct (correct <2 out of 3 times). *Precision* is the fraction of triggered queries that the oracle would also trigger (i.e., how many of our RAG calls were necessary); *Recall* is the fraction of oracle-trigger queries that we actually triggered (i.e., how many necessary calls we caught). *F-measure* computes their harmonic mean: $F_{msr} = \frac{2 \cdot prec \cdot rec}{prec + rec}$.

4.2 Models and Implementations

Implementations: We fine-tuned Llama-3.1-70B (Grattafiori et al., 2024). Guided by a scaling-law study (see Appendix D.1), we ran one epoch on 3K training samples, with learning rate 1e-6, batch size 1, and gradient accumulation step 1. Experiments used Nvidia H100 96GB HBM2e GPUs: 32 GPUs for fine-tuning, 8 for inference. We observed similar results on Qwen2.5-7B-Instruct (Qwen et al., 2025) and Gemma-3-4B-IT (Team et al., 2025), see Appendix D.5.

Alternative Solutions: We compared against two baselines: the oracle from Section 4.1, and Llama-3.1-70B with an inference-time dampener–plus three state-of-the-art solutions:

Prompt-based (Ni et al., 2024; Li et al., 2025a) triggers RAG when the LLM signals low confidence. We implemented both the vanilla version, and an enhanced one (Prompt+) urging prudence and improving correctness (punish+explain in (Ni et al., 2024); Prompt 4 and 5 in Appendix C).

R-Tuning (Zhang et al., 2024) builds training data by appending *"Are you sure you accurately answered the question based on your internal knowledge?"* in the question, and padding the ground truth with *"I am sure"* or *"I am unsure"* by correctness. We trigger RAG on an *"I am unsure"* suffix. We trained on both MMLU (Hendrycks et al., 2021) and DBPedia.

IDK (Cheng et al., 2024) requires answer consistency (here at least four out of five times) as well as correctness when labeling ground truth. We fine-tuned on DBPedia for a more direct comparison.

5 Experimental Results

In this section, we study the effectiveness of ConfQA and ConfRAG.

5.1 Effectiveness of ConfQA

The left part of Table 2 reports ConfQA's answer quality. First, baseline methods are hallucination prone. The dampener cut incorrect answers by only 2.5-7.8 points across benchmarks.

Second, prompt-based methods suppress hallucinations, but hurt correctness, sometimes lowering factuality. The vanilla version still incurs high incorrectness (DBPedia, IMDb); while the stricter enhanced version suppresses hallucinations effectively, but sharply reduced correctness.

Third, R-tuning methods suppress hallucinations but hurt correctness. R-tuning on DBPedia suppresses hallucinations more effectively than on MMLU, but hurt correctness more. R-tuning on MMLU has high incorrectness rate–sometimes above baseline–for two reasons: 1) feeding ground

Table 2: Overall factuality and RAG triggering F_{msr} (all numbers in percentage %; bold indicates the best performance and italic the second best). CONFQA improves factuality and reduces incorrectness to 5% and below, achieving highest triggering F_{msr} on 3 benchmarks and close to highest triggering F_{msr} on DBPedia (Llama-3.1 20-consis). Note: Llama-3.1 20-consis calls LLM 21 times, with 20 response generations and 1 consistency judge. Not practical in real deployment.

truths as extra knowledge can encourage hallucinating what was not learned in pre-training; 2) MMLU mixes facts with reasoning, introducing ambiguity. This supports our hypothesis that atomic facts yield better training examples (Intuition #3).

Fourth, IDK achieves the lowest incorrectness rate (below 1.5% on all benchmarks) but drops correctness significantly, reducing overall factuality–showing that additionally requiring the consistency signal can be unnecessarily strict.

Fifth, fine-tuned CONFQA improves factuality by up to 25%, with incorrectness dropping to 5% or below on all benchmarks. Correctness drops too, but far less than hallucinations drop, yielding much

higher factuality. Although trained only on DBPedia, CONFQA generalizes to other benchmarks (Intuition #3).

5.2 CONFRAG Triggering and Serving

The right part of Table 2 compares triggering metrics across solutions. As a strong but impractical reference point, we include Llama-3.1 20-consis, which generates an answer 20 times per question and then calls Llama-3.1 once more to judge whether the 20 responses are mutually consistent; it triggers RAG unless all 20 responses agree and none is a refusal. Because this consistency signal is not an answer-quality decision, Llama-3.1 20-consis has no entries in the left (answer-quality) part of Table 2. It is also far costlier than CONFRAG–≈20× the generation tokens and at least twice the latency–which makes it unsuitable for deployment.

CONFRAG lifts potential correctness to ≈ 95%, while cutting unnecessary external retrievals by 5-39%. It attains the highest triggering F-measure on every benchmark except DBPedia, where Llama-3.1 20-consis is highest; even there, CONFRAG is within a small margin–so CONFRAG matches or exceeds Llama-3.1 20-consis on triggering quality at a fraction of its token and latency cost. The remaining methods fall short on one of two axes: Prompt and R-tuning have low ceiling correctness, while Prompt+ and IDK reach a higher ceiling but at much lower triggering precision, incurring unnecessary retrieval cost.

Deployment architecture: at serving time (Figure 3), LLM-QA and the RAG pipeline run in parallel; once CONFQA returns a confident answer, retrieval is early-stopped and the answer returned, otherwise the system waits for RAG. Because CONFQA abstains only on genuinely uncertain queries, CONFRAG finishes retrievals on a fraction of traffic, cutting unnecessary external retrievals by 5-39% (Table 2) and end-to-end latency by 600ms (P50) and 800ms (P90) on CRAG (Table 3). SimpleQA requires triggering RAG for most questions to reach high quality, so its latency gain is smaller. For a service handling N queries/day at retrieval unit cost c, this avoids ≈(0.05 to 0.39)$\cdot N \cdot c$ in retrieval spend plus the corresponding generator GPU-seconds and tokens.

Table 3 shows results of production implementation of CONFRAG and RAG-everywhere for SimpleQA and CRAG benchmarks. CONFRAG shows slight under-performance on SimpleQA factuality and Correctness and slight improvement on CRAG compared with always-on RAG. These numbers came from production implementation of a RAG system, so accounting for small variations, CONFRAG is more or less on-par with always-on RAG for quality. On our production-representative pipeline (Bing + Knowledge Graph APIs feeding Llama-3.1-70B), retrieval and summarization are the dominant per-query cost.

RAG cost saving: our production RAG pipeline runs four sequential stages: a search API call (500ms), crawling 10 pages (1300ms), content extraction and post-processing from HTML (400ms), and an LLM call over the extracted content to generate an answer (3000ms) – 5200ms end to end. When CONFRAG decides to answer directly, the search API is still triggered, but the pipeline halts during crawling, before post-processing and summarization. Because search runs in parallel with direct QA, its 500ms is fully overlapped and off the critical path; the three downstream stages are eliminated along with their cost: 1). Crawling (10 pages) – interrupted mid-process, avoiding most of the 1300ms latency and the associated bandwidth/crawl cost. 2). Extraction, chunking, and re-ranking – the full 400ms of post-processing and any paid API cost therein are saved. 3). LLM summarization – with no page content produced, both the summarization call and the tokens it would consume are avoided.

The token savings are substantial: summarizing 10 webpages to answer a question consumes roughly 15,000-50,000+ tokens, making the retrieval path 30-100× more expensive per query than direct QA.

Fallback when RAG is unavailable: in offline or low-latency settings (on-device, Speech-in Speech-out), run CONFQA without the dampener to preserve correctness while suppressing hallucinations; add the dampener to drive hallucinations under 5% when maximum reliability is required.

5.3 Deep dive on CONFQA

Since the supervised model CONFQA is critical to deciding when to trigger RAG, we now examine its design choices and generalizability.

Ablation study: We compare CONFQA with several alternatives in Table 4 (full results in Table 7 Appendix D.2). First, dropping the dampener from

Model	MMLU (5-shot)	MMLU Pro
Llama3.1	82.7	**66.3**
ConfQA	**82.8**	65.4

Table 6: ConfQA does not regress on MMLU.

training raises correctness and lowers the missing rate, but increased hallucinations and thus lower factuality–confirming the dampener's importance in training (Intuition #2). Second, generating training data from MMLU instead of DBPedia yields low hallucination ($< 2\%$) but far lower correctness (Intuition #3). Third, using the ground truth directly as the label (*GT-as-label*) gives the highest correctness and lowest missing rate, but hallucinates much more (up to 68.4%), consistent with observations in previous work (Lin et al., 2024; Gekhman et al., 2024).

Generalizability to long-form benchmarks: We test *long-form factuality benchmarks*, where answers contain multiple factual statements (see Table 1 and Appendix A). We evaluate with *VeriScore* (Song et al., 2024), which computes precision, recall, and F1, using their fine-tuned models for claim extraction and verification; the minimum facts for perfect recall is set to the median extracted claims per dataset. We omit the dampener prompt to avoid regressing recall. Table 5 shows ConfQA matches or exceeds baseline precision and recall, except on 13% long-tail biography questions, which it declines to answer due to low confidence.

No regression on general benchmarks: Finally, we evaluated ConfQA on MMLU's multi-choice questions on general knowledge and reasoning (Hendrycks et al., 2021; Wang et al., 2024), again without the dampener prompt. Table 6 shows scores mostly similar to baseline.

6 Conclusion

We presented ConfRAG, a confidence-guided RAG architecture that triggers RAG only when an LLM is unlikely to be correct. Built on ConfQA – a lightweight fine-tune that teaches a model to answer when confident and otherwise say "I am unsure" – it cuts hallucinations to 5% or below and matches RAG-everywhere accuracy (slight underperformance on SimpleQA and slight improvement on CRAG) while reducing retrievals by 5-39%.

ConfRAG is practical to deploy and maintain: ConfQA retrains in one epoch over 3K auto-generated knowledge-graph facts and transfers across model families (Appendix D.5), requiring no access to model internals or per-domain labeling. As base models and retrievers improve, integrating internal and external knowledge this way should further improve both factuality and latency.

7 Limitations

Our experiments focus on SFT, and we leave DPO-based fine-tuning for future work. We empirically compared DBPedia and MMLU, where the former contains only simple factual questions, and the latter contains questions ranging from factual to reasoning. A comprehensive study regarding the effect of sources with different coverage in this spectrum can further improve understanding. SFT requires access to LLM parameters, thus restricting the application of the proposed framework to open-sourced models. Lastly, our cost/latency results come from a replay of the benchmark on production pipeline rather than a live A/B test, and savings depend on traffic mix and retrieval pricing.

A Benchmark Setup Details

To evaluate the performance of the fine-tuning, We consider 8 benchmarks in the main content as described in Section 4.1 Table 1, with details described here.

- **Head-to-Tail (*short-form* with simple questions)** (Sun et al., 2024): We leveraged the data scraping scripts from the **Head-to-Tail** benchmark, and generated simple questions and their answers according to content from DBPedia [1] (general knowledge graph) and IMDb [2] (data in the *Movie* domain). From each dataset we randomly sampled 200 entities for *head* entities, 200 for *torso* entities, and 200 for *tail* entities. Here we follow the definition in (Sun et al., 2024) for head, torso and tail: we rank all entities by their traffic; head entities are top-popular entities that together account for 1/3 of traffic, tail entities are unpopular entities that together account for 1/3 of traffic, and torso entities are the remaining medium-popular entities. Together, we have 1200 question-answer pairs, 600 from each source.

- **SimpleQA (*short-form* with simple questions)** (Wei et al., 2024a): **SimpleQA** is a benchmark released by *OpenAI* to measure LLM factuality. It contains 4326 manually crafted short, fact-seeking questions, covering diverse topics such as science, technology, history, and entertainment.

- **CRAG (*short-form* with simple and complex questions)** (Yang et al., 2024a): CRAG is a benchmark to test RAG capabilities. It contains 4,409 training and 1,335 evaluation questions covering five domains (general, finance, sports, music, movie), entities of different popularities (head, torso, tail), facts of different dynamisms (static, slow-changing, fast-changing, real-time), and eight question types (simple, condition, set, comparison, aggregation, multi-hop, post-processing, false premise). We selected the 642 *static* questions from the evaluation data set, with 97 questions for head entities, 99 for torso, 90 for tail entities and 356 for facts from the web (mostly popular); we excluded false-premise and dynamic questions from the sampling as it presents different challenges.

- **LongFact (*long-form*)** (Wei et al., 2024b): Aiming to measure the factuality of long-form responses consisting of at least several paragraphs, LongFact has 2,280 factual questions covering 38 topics, generated by prompting GPT-4. Following Wei et al. (2024b), we use the 250 prompts from the LongFact-Objects dataset in our experiments.

- **AlpacaFact (*long-form*)** (Lin et al., 2024): Initially sourced from diverse interactions with real-world users, the 805 instructions in AlpacaFarm (Dubois et al., 2023) served as a benchmark for evaluating the ability of different LLMs to follow instructions. Following Lin et al. (2024), we used a subset of 241 fact-seeking instructions in this work.

- **Biography (*long-form*)** (Min et al., 2023): To validate the effectiveness of FActScore, Min et al. (2023) created a collection of prompts named Biography by applying the template "`Tell me a bio of [Person Name]`" to 183 notable individuals listed on Wikipedia. Given its extensive use in recent literature, we have included this prompt set for our experiments as well.

- **MMLU (*General knowledge*)**: The MMLU (Hendrycks et al., 2021) dataset covers 57 subjects, including areas such as mathematics, history, law, and medicine. It contains two subsets: the MMLU 5-shot dataset contains 14,042 multi-choice questions to evaluate general knowledge and problem-solving tasks; the MMLU Pro (Wang et al., 2024) dataset contains 12,032 multi-choice questions to stress-test reasoning, disambiguation, and factual accuracy.

For short-form questions we consider factuality score as defined in Section 4.1 rather than F1 score, where F1-score is more lenient for incorrect answers (hallucinations), but factuality strongly prefers missing answers to hallucinations. For example, consider a model that answers 10% questions correctly (correct% = 10%) and the rest of the questions incorrectly (incorrect% = 90%); the F1-score is 10% (not punishing hallucinations much) while the factuality is -80%. Now consider another model that answers 10% questions correctly

[1] dbpedia.org
[2] imdb.com

and admits "I am unsure about the answer" for the rest of the questions; the F1-score is 18.2%, only slightly higher than 10%, but the factuality is 10%, significantly higher than -80%. Finally, consider a set of binary questions. A model that does not know any answer will get factuality of 0% no matter whether it admits so or makes random guesses ($0 = 50\% - 50\%$); however, if we use F-measure, the former gets a F-measure of 0 and the latter gets a F-measure of 50%, encouraging random guesses and thus hallucinations.

For long-form responses we use the automatic evaluation metric, *VeriScore* (Song et al., 2024), for measuring the factuality (results in Section 5.3 Table 5). Following FActScore (Min et al., 2023) and SAFE (Wei et al., 2024b), VeriScore extracts more sensible and verifiable claims from each sentence and uses Google search snippet instead of Wikipedia as the source of knowledge. This approach allows VeriScore to be applied to more diverse topics and requires fewer but more meaningful claims to be checked. We report the F1 score from VeriScore, which represents the harmonic mean of precision and recall. In line with (Song et al., 2024), we set the minimum number of facts required for perfect recall based on the median number of extracted claims per dataset, using their fine-tuned models for claim extraction and verification.

B Analysis of LLM's Self-Reported Confidence

Using three benchmarks, we reproduce the observations in (Wei et al., 2024a; Xiong et al., 2024), that LLMs' self-reported confidence is systematically overestimated, making it a poor signal for deciding when to trigger RAG.

We prompted the LLM to output a confidence score between 0 and 1 along with its answer (Prompt 3 in Appendix C). After removing missing answers, we binned the reported confidences into equal-sized quantiles, and plotted average accuracy per bin to assess *calibration*: whether a confidence of 0.8 corresponds to 80% accuracy? Figure 4 shows the calibration, leading to three observations.

1. The self-reported confidence is mostly positively correlated with QA accuracy, but LLMs tend to be over-confident (the correlation curves are below the ideal calibration dashed line). For example, when Llama-3.1-70B predicts a confidence of 80% on CRAG, the real accuracy is only 33%.

2. Notably, for the same model series, the smaller model is often more confident than the larger model (with an exception of Claude3.5 on CRAG), demonstrating the interesting correlation between ignorance and self-assurance.

3. Finally, the overconfidence is more pronounced when answering SimpleQA questions than on other benchmarks. A sample of 50 questions from SimpleQA shows that the questions are often nuanced for fairly popular entities (e.g. *"What was the first line after the salutation in the letter sent to Sardar Patel by Abhay Charan De?", "In which month and year was Service Pack 3 for Windows Fundamentals for Legacy PCs released?"*), possibly causing LLMs to be over-confident.

Influence of entity popularity on confidence: Figure 5 shows the calibration on the Head-to-Tail and CRAG benchmarks, where questions are categorized by entity popularity into *Head, Torso, Tail* (plus *Web* for CRAG).

Interestingly, we found for simple questions on Head-to-Tail, models are better calibrated for head entities than torso or tail entities (Figure 5 bottom panels). However, on more complex questions on CRAG, models are better calibrated for tail entities than torso or head entities (Figure 5 top panels). This shows two different dimensions that can affect the model confidence: entity popularity and question nuances.

Consistency vs. Accuracy: To measure consistency, we ask LLM the same question 20 times with the temperature set to 1.0, select the most frequent response as the final answer, and calculate its frequency among the 20 times as the consistency score. To be robust against minor differences, we determine the "most frequent" answer based on semantic similarity rather than exact string match.

Figure 6 shows that consistency is mostly better calibrated than self-reported confidence, and largely overlays with the ideal calibration on CRAG. In addition, the calibration curve is more linear compared to self-reported confidence in Figure 4.

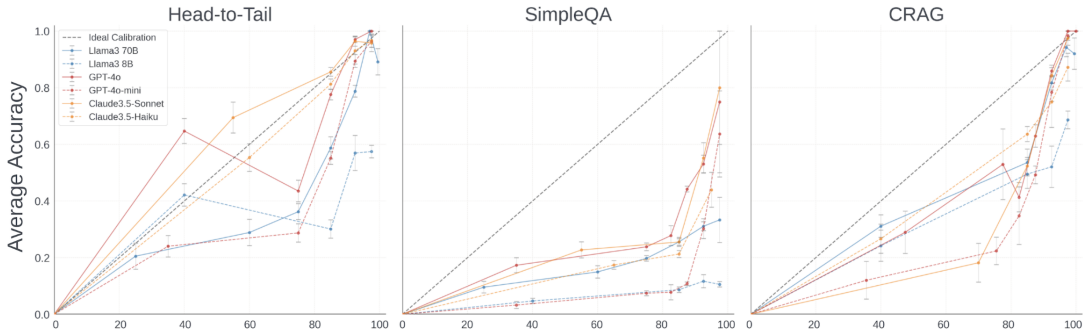

Figure 4: LLMs' self-reported confidences are correlated with QA accuracy, but often over-confident.

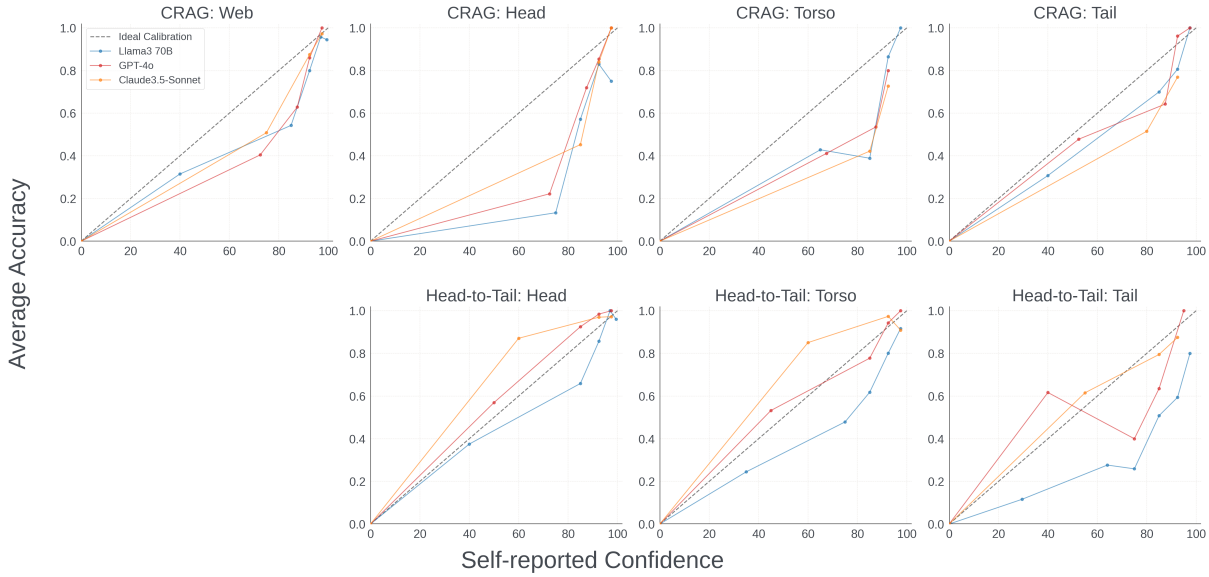

Figure 5: Correlation between LLM's self-reported confidences and average accuracies on the CRAG dataset and the Head-to-Tail dataset, categorized by question types.

C Prompts

We include a list of prompts used in experiments for reference. Each prompt is cited in the main paper where it is applied. For clarity, we also provide brief descriptions of each prompt here.

Prompt 1: Simple question answer generation prompt

> As Assistant AI, you help answer factual questions. Please keep your responses short and concise and directly provide the answer to the user question without reasoning. Answer only if you are confident; otherwise, respond with 'I am unsure about the answer'.

Prompt 1 is used in several places:

- *Training-data generation*: to prompt Llama-3.1-70B to answer the 3K DBPedia-based questions.
- *SFT*: as the system prompt, unless we state no prompt was used in training.
- *Benchmarks*: as the system prompt at inference, unless we state no prompt was used.

Prompt 2 is used in two places:

- Training-data generation: to grade whether the model's answer matches the ground truth.
- Benchmarks: to grade model responses when evaluating different models.

Prompt 3 is used in Appendix B to make the model output a confidence score alongside its answer, studying how self-reported confidence and answer consistency each relate to answer accuracy in Appendix B.

Prompt 4 and 5 are from Paper (Ni et al., 2024), and are used to generate results for row Prompt and Prompt+ in Table 2.

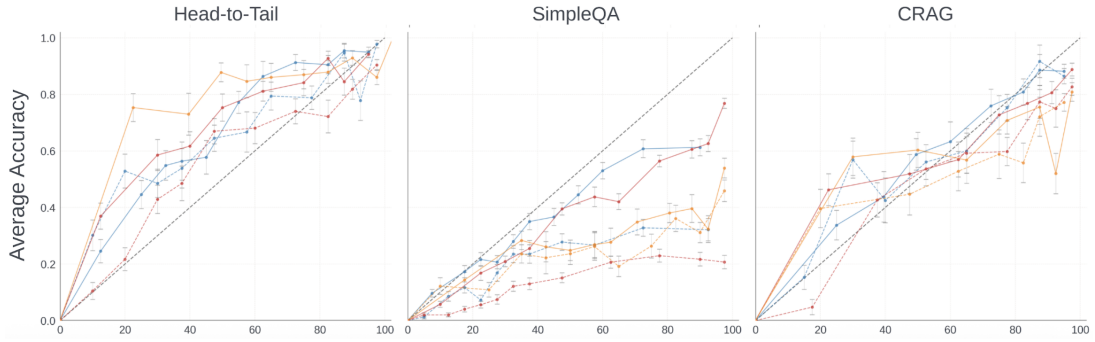

Figure 6: LLM's answer consistency is often better calibrated with QA accuracy than self-reported confidences.

Prompt 2: Answer-grading prompt. Used in Section 3.1 to generate training labels: it grades whether the model's answer matches the ground truth. If so, the ground truth becomes the label; otherwise, *"I am unsure about the answer"* is used.

You need to check whether the prediction of a question-answering system to a question is correct. You should make the judgment based on a list of ground truth answers provided to you. Your response should be "correct" if the prediction is correct or "incorrect" if the prediction is wrong.

Example 1:
Question: Who authored The Taming of the Shrew (published in 2002)? Ground truth: ["William Shakespeare", "Roma Gill"]
Prediction: W Shakespeare
Correctness: correct

Example 2:
Question: Who authored The Taming of the Shrew (published in 2002)? Ground truth: ["William Shakespeare", "Roma Gill"]
Prediction: Roma Gill and W Shakespeare
Correctness: correct

Example 3:
Question: Who authored The Taming of the Shrew (published in 2002)? Ground truth: ["William Shakespeare", "Roma Gill"]
Prediction: Roma Shakespeare
Correctness: incorrect

Example 4:
Question: What country is Maharashtra Metro Rail Corporation Limited located in?
Ground truth: ["India"]
Prediction: Maharashtra
Correctness: incorrect

Example 5:
Question: What's the job of Song Kang-ho in Parasite (2019)? Ground truth: ["actor"]
Prediction: He plays the role of Kim Ki-taek, the patriarch of the Kim family.
Correctness: correct

Prompt 3: Self-reported confidence prompt.

Please answer the following question truthfully to your best knowledge. Provide a confidence score between 0 to 1 representing your confidence in the answer.
Question: {{{question}}}
Your response must be in the following JSON format.
{"answer": "Your answer here", "confidence_score": float number}
Remember, your answer MUST be a valid json string with two keys: "answer", "confidence_score".

Prompt 4: Vanilla Prompt from Paper (Ni et al., 2024).

Answer the following question based on your internal knowledge with one or few words. If you are sure the answer is accurate and correct, please say "certain" after the answer. If you are not confident with the answer, please say "uncertain".

Prompt 5: Punish+Explain Prompt from Paper (Ni et al., 2024).

Answer the following question based on your internal knowledge with one or few words and explain why you give this answer. If you are sure the answer is accurate and correct, please say "certain" after the answer. If you are not confident with the answer, please say "uncertain". You will be punished if the answer is not right but you say "certain".

D CONFQA experiment and full ablation study

We discuss additional details for CONFQA experiment and include the full ablation study as a complementary document to the main paper.

D.1 Fine-tuning implementation

To determine how many data samples and fine-tuning steps are needed for optimal performance, we run a simple scaling-law study.

We prepared 27K DBPedia question-answer pairs (9k each for head, torso and tail entities) and ran 10K steps on 4 hosts, 8 processes per host, with batch size 1. Around 100 steps gives the best performance, with more causing over-fitting. At this setting, 100 steps is one epoch for 3200 samples. We thus selected 3K high quality instances (1K each for head/torso/tail) and fine-tuned for one epoch. The 1K/1K/1K split follows the real-world distribution of entity popularity by definition (see the Head-to-Tail paper (Sun et al., 2024) section 2.1). Head/torso/tail entities are also discussed with the Head-to-Tail benchmark in Appendix A.

D.2 Full ablation study

We compare CONFQA with more alternatives than in the main content, as shown in Table 7.

- CONFQA No-dampener: same training as CONFQA. Does not apply the dampener in inference.

- Gen-as-label: the same strategy to choose questions the model can answer correctly as CONFQA, but use model generation as the true label, rather than the ground truth.
- IDK: the same as the IDK (DBPedia) in the main paper in Table 2.
- No-dampener: the same data labeling as CONFQA, but only use the question answer pairs, excluding the dampener prompt in the training input data. In other words, does not pass dampener as the system prompt.
- GT-as-label: feed in the original 3k rows of raw DBPedia data into the fine-tuning, i.e. all labels are ground truth.
- Fact-feeding: rather than using only the 3k sample of DBPedia data, also mixing 10k samples from Tulu3 data (Lambert et al., 2025).
- R-tuning (DBPedia): using our DBPedia training set and following R-tuning paper to generate labels for SFT.
- R-tuning (MMLU): using randomly sampled 3k MMLU samples to generate training set following R-tuning labeling strategy.
- MMLU-as-source: the same strategy as CONFQA, but use MMLU as data source. We use the same 3k samples from R-tuning (MMLU).

Table 7 reports results in two rows. Results on the top are evaluated using no system prompt, i.e. No-dampener applied during inference, only pass in questions to the models. The bottom rows are results with passing the dampener as the system prompt when doing inference.

CONFQA is overall more balanced that improves Missing rate to certain level, without impacting Correctness too much, while reducing Incorrectness to less than 5%. As shown in main paper Table 2, this leads to the optimal triggering F_{msr}.

We are not going to discuss each model one by one, but highlight two observations: (1) as we discussed in Section 5.3, generating training data from MMLU instead of DBPedia yields low hallucination ($< 2\%$) but far lower correctness. This is likely because MMLU's diverse tasks reduce the model's overall confidence (Intuition #3). (2) *Fact-feeding* combines our CONFQA fine-tuning data with Tulu facts, drops hallucinations but also correctness, similar to R-tuning. We suspect this is because what our training data teach the LLM (saying unsure) is of different purpose from what the extra Tulu facts teach the LLM (feeding knowledge), when mixed together can offset each other and cause confusion.

D.3 Answer distributions for entity popularity

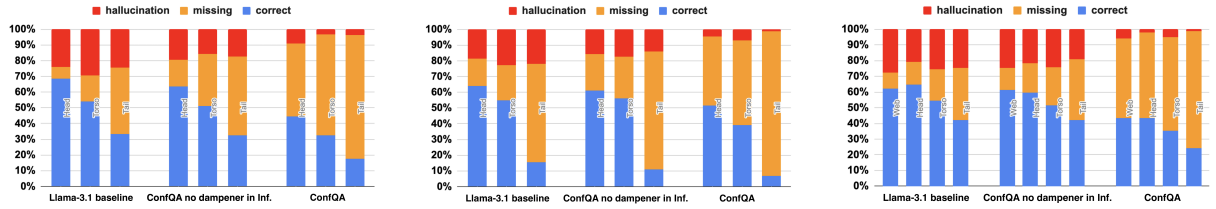
Figure 7 shows the distribution of correct, missing, and incorrect answers for entities of different popularity (Head, Torso, Tail), before and after fine-tuning, with and without dampening. It confirms that fine-tuning suppresses hallucinations (Intuition #1), and the dampener prompt further reduces hallucinations (Intuition #2). Additionally, it shows CONFQA suppresses more on long-tail facts, where it lacks confidence.

D.4 p-Value of CONFQA models

We compute p-Values for CONFQA model on the hallucination reduction metrics comparing with baseline Llama-3.1 Oracle and Llama3.1 Dampen, and report in Table 8. We compare CONFQA with Llama3.1 Dampen and CONFQA No-dampener with Llama-3.1 Oracle. We use McNemar p-Value since this is a paired test. For simplicity, we assume at least 70% of the questions are the same in baseline vs CONFQA. For factuality, we compute independent z-test p-Value. The results show that the improvements on Hallucination reduction shown in Table 2 are statistically significant on all benchmarks. Factuality improvements are also statistically significant for DBPedia, IMDb and SimpleQA benchmarks.

D.5 Gemma and QWen SFT

We conducted similar experiments on the QWen2.5-7B-Instruct model (Qwen et al., 2025) and the Gemma-3-4B-IT model (Team et al., 2025) through the Huggingface framework. Training data is generated using the logic described in Section 3.1:



- The same 3k of DBPedia simple question answer data, and labeled using the logic in 3.1.
- Evaluations are done using the same 4 short-form generation data sets.

Train using NVIDIA A100 80G 8 GPU. For both fine-tuning, we run one epoch, with learning rate 2e-4 and gradient accumulation steps 2.

Table 9 shows experiments results using the QWen2.5-7B-Instruct model as baseline model. Table 10 shows experiment results from fine-tuning Gemma-3-4B-IT. A few observations based on these results:

Model	DBpedia (in-domain)				IMDb (out-of-domain)				SimpleQA (out-of-domain)				CRAG (out-of-domain)			
	Corr	Miss	Incor	Fac	Corr	Miss	Incor	Fac	Corr	Miss	Incor	Fac	Corr	Miss	Incor	Fac

ConfQA	2.1 (<1.0E-16)	2.8 (<1.0E-16)	4.4 (<1.0E-16)	35.0 (4.1E-01)

Table 8: Factuality improvement on short-form benchmarks with p-Value; ConfQA models can reduce hallucination (Incor) to less than 5% with the dampener prompt with significant difference. All numbers are in percentage (%).

- Our proposed method ConfQA can reduce hallucination (Incor) by 13-50% for QWen 7B when applying the dampener prompt.
- The hallucination could be reduced to close or below 5% for Gemma 4B model in the same case.
- Qwen 7B has fairly low correctness, and ConfQA can further reduce it as it changes low-confidence answers into unsure answers. However, the factuality increases by 12-37%, showing that it reduces much more hallucinations than correct answers.
- Similar for Gemma model: fairly low correctness, as it is a even smaller model. Comparing to QWen, the factuality increase is more effective for Gemma model: increases by 20-89%.
- Transferability: the fine-tuning on DBPedia atomic question answering pairs could extend to out-of-domain datasets.

D.6 Dampener prompt wording

To understand how sensitive is the approach to the exact wording of the dampening prompt, we evaluated the fine-tuned ConfQA model with different wordings in the prompt. The ConfQA prompt is listed in Appendix Prompt 1. In this experiment, we only change the dampener part of the whole prompt, i.e. *Answer only if you are confident; otherwise, respond with 'I am unsure about the answer'*. In the experiment, Prompt 1: *Answer only if you are confident; otherwise, respond with 'I am unsure'*, Prompt 2: *Answer if you are confident; otherwise, respond with 'I am unsure about the answer'*.

Table 11 shows results from using different prompts in the evaluation. We see that Prompt 1 and 2 give very similar results compared to baseline ConfQA.

E Dynamic questions identification

In Section 3.2, we briefly mentioned that dynamic questions–those requiring up-to-date information–should be answered by the RAG pipeline. In real application, we fine-tune a small-sized model (such as Llama-3.1 8B Instruct) to do this classification task: identify if a question is dynamic (whose answer may change over time) or static (whose answer is static).

Training data and prompt: Take CRAG training data as example, instead of using ground truth answer as label, we label the questions as either "dynamic" or "static". We use prompt to instruct the model to output only "dynamic" or "static". Respond with "dynamic" if the answer to the question could change over time, and respond with "static" if the answer to the question does not change over time. The same supervised fine-tuning is applied to the model. We normally observe 80-90% precision and recall of this method in identifying dynamic questions. We omit additional details as this is not relevant to the key content of this paper.

Abstract

LLM agents increasingly rely on external skills retrieved at runtime, making skill selection from large repositories a critical challenge. We present a production skill router over 34,396 skills and a large-scale study of skill retrieval using limited real supervision and synthetic data. We found that the synthetic-data fine-tuning improves in-distribution retrieval but it causes catastrophic forgetting on real and out-of-distribution (OOD) data. We evaluate several forgetting mitigation fine-tuning approaches inspired by continual learning, including embedding-anchor regularization, Learning without Forgetting (LwF), Elastic Weight Consolidation (EWC), and L2-initialization. The results show that these approaches not only retain the performance on OOD skills retrieval but also improve the retrieval on synthetic in-distribution skills by 13.98% for 0.6B Qwen retriever and reranker. Our results provide a practical benchmark and a robust fine-tuning recipe for scarce, multi-positive supervision.

1 Introduction

Modern LLM-driven agents increasingly rely on *skills*: short, agent-readable procedures retrieved at run time and injected into the agent's context to solve specific tasks (Anthropic, 2026; Yao et al., 2022). These tasks span scientific (detecting exoplanets and computing orbital periods), engineering (HVAC control), financial (SEC report generation), software (debugging a Node.js app) and many other domains, and they require specific skills for end-to-end completion; e.g., a fraud-detection task may depend on fuzzy matching, database search, PDF reading, and Excel analysis. As skill registries grow, retrieving the right skills for a task becomes hard. The common information retrieval practice is to use sparse retrieval algorithms, such as BM25 and dense vector retrieval models to match on lexical and semantic similarity (Robertson and Zaragoza, 2009; Karpukhin et al., 2020). This practice is also enhanced with synthetic supervision from an LLM to fine-tune a model for improving retrieval performance (Dai et al., 2022; Bonifacio et al., 2022; Gao et al., 2023; Wang et al., 2024).

We follow this paradigm and conduct a systematic empirical study of skill retrieval over a repository of 34,396 skills (Liu et al., 2026). We use tasks from SkillsBench and Terminal-Bench 2 and execute approximately 1K trials across 109 tasks using hybrid retrieval pipelines in Harbor environment (Harbor Framework Team, 2026). We further construct two synthetic training tracks: Track A (∼15K pairs) creates anchor-skill tasks with retrieval-derived positives and hard negatives, while Track B (∼14K pairs) combines real data, paraphrase generation, and multi-skill task synthesis. Using these datasets, we evaluate compact retrieval models, such as `Qwen3-Embedding-0.6B` under varying fine-tuning regimes.[1]

Our experiments show that synthetic supervision improves in-distribution retrieval performance but can also induce substantial forgetting. In the most aggressive fine-tuning configuration, OOD recall drops from 0.850 to 0.650, demonstrating that gains on synthetic training data do not necessarily translate to robust deployment behavior.

This raises an important deployment question that has received limited attention: *does synthetic-data fine-tuning degrade a model's ability to retrieve skills for real-world or out-of-distribution (OOD) tasks?* Catastrophic forgetting is well studied in continual learning, where approaches such as Learning without Forgetting (LwF) and Elastic Weight Consolidation (EWC) preserve pretrained behaviour (Li and Hoiem, 2018; Kirkpatrick et al., 2017). However, it remains unclear how these preservation strategies behave in the context of synthetic-data-driven skill retrieval for LLM agents,

EMNLP 2026 Industry Track, pages 2924–2938
October 24-29, 2026 ©2026 Association for Computational Linguistics

especially at realistic deployment scale.

Therefore, we study several forgetting mitigation regularization approaches, including embedding-anchor regularization, LwF, EWC, and L2-initialization, under a common fine-tuning recipe (Li and Hoiem, 2018; Kirkpatrick et al., 2017; Li et al., 2018). Our results show that these fine-tuning regularization approaches not only retain the behavior of the frozen model on OOD or real tasks for LoRA adapters (Hu et al., 2022), but also improve performance on the synthetic (in-distribution) data compared to aggressive LoRA fine-tuning.

Our contributions are threefold. (A) We present a systematic study of skill retrieval for agents at a realistic scale, covering 34,396 skills and 109 verifier-scored tasks, and identify synthetic-data-induced forgetting as a deployment failure mode. (B) We introduce a unified benchmark that combines real and synthetic supervision under a shared evaluation protocol. (C) We evaluate multiple forgetting-mitigation approaches, including embedding anchors, LwF, EWC, and L2-initialization, and show that conservative regularized fine-tuning preserves real-world and out-of-distribution behavior while improving in-distribution gains, providing a practical recipe for deployed skill-retrieval systems.

2 Methodology

This section describes the skills catalog with a retrieval server (§2.1), tasks benchmarks with skills execution (§2.2), generation of synthetic skills and tasks for two tracks A (§2.3) and B (§2.4), and finally training methodology for an embedding model and a re-ranker model (§2.5).

2.1 Skill Retrieval

We used the skill catalogue of 34,396 skills collected from skillhub.club and skills.sh by Liu et al. (2026).[2] Each of these skills constitutes a folder with a SKILL.md file along with scripts and other helper files downloaded from its original GitHub repository. In addition, Liu et al. (2026) also released a retrieval server that indexed skills in two ways: (a) skill metadata, the skill's name and description; and (b) full content in the SKILL.md file. We used both indexes to retrieve skills in different experimental settings. The retrieval server implements BM25 retrieval, semantic retrieval using Qwen3-Embedding-4B and hybrid matching (combining BM25 and semantic matching) using reciprocal rank fusion (RRF) (Robertson and Zaragoza, 2009; Zhang et al., 2025; Cormack et al., 2009).

[2] www.skillhub.club, www.skills.sh

2.2 Real Harvest from Agent Execution

We harvested real tasks and skills executions using SKILLSBENCH (84 tasks) and TERMINAL-BENCH 2.0 (89 tasks) benchmarks (benchflow-ai, 2026; Merrill et al., 2026). Each task provides instructions, a dockerized environment, and a verifier (test set). We execute tasks and skills in Harbor (Harbor Framework Team, 2026), a popular task execution and evaluation environment. We post-process the output of the verifier tests and convert it to a soft score $\mathrm{SR} = n_{\text{passed}}/n_{\text{total}} \in [0, 1]$.

We perform task skill trials in three ways: (1) hybrid top-k retrieval (full skill content) + LLM selection, (2) hybrid top-k retrieval (metadata) + LLM selection, and (3) injection of ground-truth skills. This yields 1,423 trials on 173 tasks, of which 1,116 produce scores (307 failed attempts). Among these, 861 trials contain injected skills, while the rest have no skills selected by LLM. We aggregate these trials at the (task, skills) tuple level by averaging SR across the trials, labeling a pair as (strict) positive if the mean SR exceeds 0.5. This produces 109 tasks with reward signal (from 861 trials), including 75 tasks with at least one positive skill, totaling 273 positive skills (3.64 per task). We use the 0.5 threshold to favour consistently useful skills; varying it in $[0.4, 0.7]$ reduces data size but does not change baseline rankings. This 75-task / 273-pair set forms our supervised learning benchmark.

2.3 Track A: Anchor-skill driven Synthetic Tasks

We sample 1,772 *anchor skills* from the entire skill pool using stratified sampling across 101 groups with proportional allocation and a minimum per-group of 20 (capped at 80). The groups include 51 skill categories, but only 22% of skills have categories; for the remaining 78%, we create 50 MiniBatch-KMeans clusters using MiniLM embeddings (Wang et al., 2020).

For each anchor skill, GPT-5 generates a self-contained task description (200–600 words) from a 3-shot prompt built from real `(skill, task)` pairs (OpenAI, 2025). To prevent leakage, we reject generations whose first 200 characters have Jaccard overlap ≥ 0.70 with any real instruction and regenerate up to three times; 103 anchors are dropped, leaving 1,669 synthetic tasks.

For each task, we form a set of 9-skill candidates using hybrid retrieval over the full content: (i) anchor skill as a single *gold positive*; (ii) four *near* candidates (ranks 2–5); and (iii) four *distractors* (ranks 11–50) from different `group_labels`. Each candidate is assigned a `soft_reward` sampled from bucket-conditioned $\mathrm{Beta}(\alpha, \beta)$ priors fitted on real data: gold $\mathrm{Beta}(0.74, 0.23)$, near $\mathrm{Beta}(4, 3)$, distractor $\mathrm{Beta}(1, 9)$. Providing a candidate set of 14,687 task-skill pairs (duplicates discarded).

A candidate skill is treated as a training positive if its `soft_reward` exceeds 0.5, independent of its bucket of origin. This thresholding yields 5,463 positive task-skill pairs: 1,331 of 1,669 gold candidates (80%), 4,122 of 6,342 near candidates (65%), and 10 of 6,676 distractors (0.15%, consistent with the $\mathrm{Beta}(1, 9)$ right tail $P(X{>}0.5){=}0.5^9{\approx}0.2\%$). These 5,463 positive pairs involve 4,486 unique skills, disjoint from the 75-task real strict-positive evaluation pool (273 real positive pairs).

2.4 Track B: Tiered Real positives with Multi-positive Synthetic Supervision

Track B builds a multi-positive training set by combining real $(\text{task}, \{\text{skill}_1, \ldots, \text{skill}_n\})$ rows from the trial harvest using the following method.

First, real positives are split into two tiers: Tier-A skills have $\text{soft_reward} \geq 0.9$ and appear in ≥ 2 trials, while Tier-B skills have $\text{soft_reward} > 0.5$. This translates to weights 1.0 and 0.7, used as weighted contribution with the loss function later.

Second, synthetic positive rows are constructed in two ways: (i) a paraphrase process produces ~ 20 alternate phrasings per real task, each inheriting its positive skill set and `soft_reward`; and (ii) a skill-first process samples 1–4 `co_used` skills and generates a task requiring them, producing intrinsically multi-positive rows. For these, `calibrated_soft_reward` is drawn from $\mathrm{Beta}(\mu c, (1{-}\mu)c)$, where μ is the harmonic mean of historical per-skill rewards and c is the median empirical concentration (default $c = 18$; Appx. B).

Third, each positive skill is paired with 7 negatives from four sources: three from the top-50 semantic retriever (Qwen3-Embedding-4B), two semantically similar but unused skills ($\cos \geq 0.40$), one from BM25 top-50, and one random skill.

Fourth, synthetic rows are validated by a primary LLM judge (GPT-5.5) using a four-axis rubric (realism, necessity, sufficiency, reward plausibility), retaining rows with realism ≥ 4 and others ≥ 3. This removes $0/1{,}200$ paraphrase rows and $364/5{,}074$ skill-first rows (7.2%). A second judge (Claude Opus 4.8) audits 300 samples (Gate 9); full quality gates are in Appx. B. After filtering, the data contains 13,271 training rows (157 real, 4,256 paraphrase, 8,858 skill-first), a 556-row validation set (20 real), and a 78-row real test set.

2.5 Training Across the Retrieval Stack

We train models at two positions in the retrieval stack on Track-A and Track-B (§2.3-2.4): a **bi-encoder retriever**, and a **cross-encoder reranker** using LoRA fine-tuning and also discuss mitigation for catastrophic-forgetting signature (Hu et al., 2022; Kirkpatrick et al., 2017; Li and Hoiem, 2018)

2.5.1 Bi-encoder Retriever

Our retriever is `Qwen3-Embedding-0.6B` for which we fine-tuned LoRA adapters using InfoNCE on (tasks, positive skills, negative skills) tuples defined by Track A (§2.3) and Track B (§2.4) (Zhang et al., 2025; van den Oord et al., 2018). For Track B, each positive additionally carries a scalar weight w (Appx. B) that scales its contribution to InfoNCE loss. Together, the two tracks are complementary; they cover diverse supervision structures (single- vs. multi-positive), diverse evaluation regimes (cross-validated real pool vs. disjoint test sets), and different LoRA adapter regimes, giving a broader view of when synthetic supervision helps or hurts than either protocol alone.

2.5.2 Forgetting-mitigation

We find that naive LoRA fine-tuning of the bi-encoder results in catastrophic forgetting (§4). Thus, we consider four regularization approaches.

Embedding anchor regularization. We regularize the embeddings of in-batch positive skills by penalizing deviations from a frozen encoder:

$$\mathcal{L}_{\text{anchor}}(\theta) = \frac{1}{|\mathcal{B}^+|} \sum_{s \in \mathcal{B}^+} \left\| f_\theta(s) - f_{\theta_0}(s) \right\|_2^2,$$

Here f_θ and f_{θ_0} the fine-tuned and frozen skill encoders and $\mathcal{B}^+$ the in-batch positives. We optimize $\mathcal{L}_{\text{InfoNCE}} + \lambda \mathcal{L}_{\text{anchor}}$ for different λ values.

L2-init. L2-init constrains the LoRA parameters to remain close to initialization, reducing parameter drift while allowing adaptation (Li et al., 2018):

$$\mathcal{L}_{\text{L2-init}} = \frac{1}{P} \sum_{i=1}^{P} (\theta_i - \theta_i^*)^2,$$

where θ_i^* is the initial parameter value and P is the number of trainable parameters.

EWC. Elastic Weight Consolidation (EWC) extends L2-init by weighting parameters according to their estimated importance, using a diagonal Fisher approximation computed on an anchor pool (Kirkpatrick et al., 2017):

$$\mathcal{L}_{\text{EWC}} = \frac{1}{P} \sum_{i=1}^{P} F_i(\theta_i - \theta_i^*)^2,$$

where F_i is the Fisher importance of parameter θ_i.

LwF (KL). Learning without Forgetting (LwF) preserves the frozen model's similarity distribution over the positive and sampled negatives using a temp-scaled KL divergence (Li and Hoiem, 2018):

$$\mathcal{L}_{\text{LwF}} = T^2 \, \text{KL}(p_t \,\|\, p_s).$$

Here, $p_t = \text{softmax}(s^{\text{teacher}}/T)$ and $p_s = \text{softmax}(s^{\text{student}}/T)$ are computed from teacher and student similarity scores with $T = 2.0$. Unlike parameter-based regularizers, LwF preserves ranking behaviour in the output space.

2.5.3 Cross-encoder Reranker

To evaluate whether synthetic supervision transfers from bi-encoder retrieval to point-wise relevance scoring, we fine-tune `Qwen3-Reranker-0.6B` with LoRA adapters using a listwise ranking loss (Cao et al., 2007).

Each training instance consists of task-led query that retrieves a top-30 candidate pool, retains all positives, and fills the remaining slots with uniformly sampled negatives up to a 20-item training list. Skills are retrieved via the embedding model fine-tuned earlier. The reranker model is optimized with listwise softmax cross-entropy.

In addition to listwise loss, we consider a listwise Learning-without-Forgetting (LwF) regularizer for the reranker. The reranker outputs a score vector over the candidate list rather than reusable embeddings, we regularize its *output distribution* instead of its parameter or embedding space. This adds a KL term between the frozen teacher's and tuned student's temperature-softened listwise score distributions, $\text{KL}(\sigma(s^{\text{frozen}}/T) \,\|\, \sigma(s^{\text{tuned}}/T))$, with $T = 2$ and $\lambda = 0.1$.

We further investigate the combination of retriever and re-ranker scores. We blend two scores after per-query min-max normalization, which rescales retriever and reranker scores independently to $[0, 1]$ within each query's candidate set so they are comparable despite different raw scales; the final score is $s = \alpha s_{\text{retr}} + (1 - \alpha) s_{\text{rerank}}$. Finally, we incorporate BM25 using Reciprocal Rank Fusion (RRF), which combines rankings by summing reciprocal rank contributions from BM25, retriever, and reranker pipeline. This allows lexical and semantic retrieval signals to be integrated without score calibration.

3 Experiments

In this section, we summarize the implementation, data splits, evaluation protocol, baselines, and metrics used to assess all fine-tuned variants.

Implementation. The skill index (§2.1) is served via an HTTP retrieval server that supports BM25, semantic retrieval, and hybrid retrieval through RRF; all LoRA models additionally use a FAISS Flat-IP index (i.e., semantic retrieval only) on all 34,396 skills (Johnson et al., 2021). Real-trial harvest (§2.2) runs in the Harbor environment. We define each run as a *trial*: a `(task, injected_skills, agent)` execution with test verification, where verifiers output CTRF reports converted into `binary reward` and `soft reward` $\text{SR} = n_{\text{passed}}/n_{\text{total}} \in [0, 1]$. Track-A synthesis uses Azure-hosted GPT-5. Track-B is generated via NVIDIA Data Designer (The NeMo Data Designer Team, 2025). Track B uses Claude Opus 4.7 as the generator, GPT-5.5 as a judge, and Claude Opus 4.8 for auditing 300 samples (Appx. B) [3]. All models are fine-tuned using HuggingFace PEFT LoRA with AdamW on a single H100 GPU, with checkpoints selected on validation data (Hu et al., 2022).

Splits and evaluation. **Track A** is evaluated on the 75-task real strict-positive pool (273 pairs) under three settings: **(A) Synth-only:** trained on 1,669 synthetic tasks and evaluated once on all real tasks (no split due to disjoint skill spaces). **(B) Real-only:** 5-fold task-disjoint cross-validation over the 75 tasks ($\sim$15 per fold). **(C) Real+synth:** identical to (B) with synthetic data added to training folds; the (B)–(C) gap isolates the benefit of synthetic data.

Track B uses a fixed split: 13,271 training examples with 157 real from SKILLSBENCH, 556 syn-

[3] Note that the purpose here is not to compare two tracks but to experiment with diverse combinations of models and data generation methods.

thetic validation, 78 real test samples from SKILLSBENCH and TERMINALBENCH 2, and 2414 synthetic task queries for testing. We train multiple retrievers by varying the LoRA recipe and synthetic-data mixture (Config A: keeps the full mix, Config B: drops Tier-A skill-first synth, and Config C: keeps only skill-first; see §2.4). Each model is evaluated on three disjoint test sets: **Ring 1:** SKILLSBENCH (real n=21), **Ring 2:** synthetic held-out skills (n=2,414), **Ring 3:** TERMINALBENCH 2 (real, n=10).

We report *effect sizes and significance tests* for all comparisons, as real data splits are very small. For small rings, we use the 10,000-iteration paired bootstrap to compute 95% CIs on model differences, cancelling task-level variance (Berg-Kirkpatrick et al., 2012). For Track A, we report fold means under shared seeds so phase differences (e.g., real-only vs real+synth) are comparable.

Baselines. We compare against four frozen systems: (i) Hybrid retriever: `Qwen3-Embedding-4B` with BM25+RRF over 34,396; (ii) Dense 0.6B retriever: `Qwen3-Embedding-0.6B`; (iii) 0.6B reranker stack: `Qwen3-Reranker-0.6B` applied to top-30 candidates; and (iv) BM25.

Metrics. Given gold positives G and top-k predictions $\hat{R}_k$: HIT@k = $\mathbf{1}[\hat{R}_k \cap G \neq \emptyset]$, RECALL@$k$ = $|\hat{R}_k \cap G|/|G|$, MRR = $\mathbb{E}[1/r^*]$, where r^* is the rank of the first correct match; all metrics are averaged over tasks.

4 Results

We report the results for our main experiments in Tables 1, 2, and 3. All metrics and the effect-size protocol are those of §3.

4.1 Bi-encoder retriever

Track-A: synthetic supervision regresses, real-only ties. Table 1 compares Track-A settings on the 75-task pool. The frozen 0.6B retriever matches the much larger hybrid baseline (HIT@10 =0.907, RECALL@10 =0.604), showing strong efficiency. Synth-only training degrades performance (HIT@10 -0.040, RECALL@10 -0.026). Real-only training matches or slightly improves the baseline (RECALL@10 +0.003), indicating effective learning from real data alone. Adding synthetic data (Real+synth) does not help: it ties Hit@10 but reduces Recall@10 by 0.021 versus Real-only, isolating a negative synthetic contribution. The unchanged Hit@10 but lower Recall@10 suggests partial rank reshuffling—at least one correct skill remains in top-10, but additional valid skills are pushed out. Overall, synthetic data harms multi-positive retrieval quality at this scale in Track A.

Setting on 75-task pool	HIT@10	RECALL@10
Baseline (i): frozen 4B + BM25 + RRF	0.907	0.604
Baseline (ii): frozen 0.6B (reference)	0.907	0.604
(A) Synth-only	0.867	0.578
(B) Real-only, 5-fold task-disjoint CV	0.907	0.607
(C) Real+synth, 5-fold splits like (B)	0.907	0.586

Table 1: Track-A bi-encoder LoRA (r=16 α=32) trained on real and synthetic data with evaluation on the 75-task strict-positive pool (273 pairs).

Variant	Ring 1 (n=21)	Ring 2 (n=2414)	Ring 3 (n=10)
Baseline: Qwen3 embedding models and BM25			
frozen 0.6B	0.5486	0.5337	0.8500
frozen 4B+BM25+RRF	0.5320	0.4609	0.9000
BM25	0.3978	0.1597	0.3500
aggressive (all-proj, lr=2e-5)			
Aggr. (r=16, α=32)	0.507	0.577	0.650
Aggr. (r=32, α=64)	0.498	0.566	0.700

Table 2: RECALL@10 for BM25, baseline embedding models and aggressive LoRA on the three evaluation rings using Track B's synthetic data, Config A.

Track-B: Synthetic distribution regresses again. Table 2 shows the results of the multi-positive Track-B mixture and the evaluation of three rings §3. The aggressive recipe of rank 32 and rank 16 (trained on Config A-full-mix only) overfits the synthetic ring (Ring 2) vs. frozen 0.6B but *collapses* on the real dataset (Ring 1 and Ring 3). Table 2 also shows the results for BM25 and frozen 4B, BM25 is the worst of all. The overfitting of aggressive LoRA is the textbook sign of catastrophic forgetting and is evident in Track A (Table 1). This motivates the use of forgetting mitigation regularization during LoRA training. In subsequent experiments, we focus on Track B for simplicity, as both tracks exhibit a similar regression on synthetic data. We treat the real datasets in Rings 1 and 3 as out-of-distribution (OOD), since they are either excluded from fine-tuning or constitute only a small fraction of the predominantly synthetic training data.

Forgetting mitigation approaches. Table 3 compares four forgetting-mitigation approaches (see §2.5.2): conservative anchor, LwF, L2-init, and EWC. Results are reported on the three Rings for three Track B configurations: A (full mix), B (skills first removed), and C (only skills first). We find

Config	Method	Ring 1 n=21	Ring 2 n=2414	Ring 3 n=10
Config A	Cons. anchor(λ=0.1)	0.540	0.6083	0.8500
	LwF	0.540	0.6077	0.8500
	EWC	0.540	0.6067	0.8500
	L2→init	0.540	0.6076	0.8500
Config B	Cons. anchor (λ=0.1)	0.5554	0.5685	0.8500
	LwF	0.5554	0.5610	0.8500
	EWC	0.5554	0.5606	0.8500
	L2→init	0.5486	0.5638	0.8500
Config C	Cons. anchor (λ=0.1)	0.5463	0.5626	0.8500
	LwF	0.5463	0.5703	0.8500
	EWC	0.5463	0.5704	0.8500
	L2→init	0.5463	0.5657	0.8500

Table 3: Recall@10 for four forgetting mitigation approaches on Track B's synthetic data configurations (LoRA: r=8, α=16 attn-only, lr=5e-6).

that Recall@10 remained similar for all approaches. If we compare with the baselines and aggressive LoRA fine-tuning in Table 2 (see Config A), these approaches achieve similar or better performance on all evaluation Rings. Table 3 also shows that the differences between forgetting-mitigation methods are negligible, while all methods improve recall on the in-distribution synthetic data of Ring 2. On the OOD datasets of Rings 1 and 3, they maintain recall comparable to the baseline embedding models. Thus forgetting-mitigation methods not only prevent forgetting but also improve performance on the new training distribution.

We further swept anchor weight (λ), LoRA rank (r), and random seeds for the conservative anchor method (see Appx. C). The results show that LoRA rank r is the primary factor controlling the performance-retention trade-off, whereas anchor weight (λ) has only a minor effect. Low-rank conservative updates ($r = 8$) exhibit minimal seed sensitivity and consistently preserve real/OOD performance while retaining most gains on synthetic data. In contrast, unregularized aggressive updates show substantially higher variance across seeds, indicating reduced training stability.

Effect Size and Large OOD dataset. To assess practical significance beyond aggregate metrics, we performed a paired per-task analysis against the frozen-0.6B baseline (Appx. D). Across both Ring 1 ($N = 21$) and Ring 3 ($N = 10$), all forgetting-mitigation methods (Conservative Anchor, LwF, EWC, and L2-init) remained effectively unchanged relative to the baseline, with near-zero mean differences ($\Delta = -0.009$ on Ring 1, $\Delta = 0.0$ on Ring 3), negligible effect sizes, and TOST confirming practical equivalence.

In contrast, aggressive full-projection adaptation consistently produced larger negative shifts ($\Delta = -0.051$ to -0.250) and more task-level regressions. Notably, the aggressive $r = 16, \alpha = 32$ model showed statistically significant degradation on Ring 3 ($0/4/6$ wins/ties/losses, $\Delta = -0.400$, Wilcoxon/sign-test $p = 0.0312$). Overall, these results support our main conclusion that conservative forgetting-mitigation recipes preserve prior capabilities, whereas aggressive adaptation induces a higher risk of regression on OOD tasks. Full per-task results, effect sizes, confidence intervals, and significance tests are reported in Appx. D.

To complement the small-sample real-task analysis in Appx. D, we evaluated all methods on six BEIR datasets (Thakur et al., 2021). BEIR benchmark provides a larger and more diverse OOD retrieval benchmark (Appx. E). Across the six BEIR datasets, the forgetting-mitigated approaches preserved or slightly improved Recall@10 and MRR@10 relative to the Frozen-0.6B baseline, while they already showed higher in-distribution performance in Table 2 and Table 3. In contrast, aggressive LoRA fine-tuning consistently reduced performance, often by a substantial margin. These results mirror our findings in Table 2 and Table 3 that conservative forgetting-mitigation preserves retrieval quality on OOD data while improving on in-distribution data; and aggressive adaptation harms both in-distribution and OOD generalization. Full results are in Appx. E.

4.2 Cross-encoder reranker

In this section, we evaluate reranker `Qwen3-Reranker-0.6B` on top of the conservative anchor ($\lambda = 0.1$) regularized fine-tuned `Qwen3-Embedding-0.6B` retriever. We fine-tune `Qwen3-Reranker-0.6B` (as explained in §2.5.3) on 1,669 synthetic tasks from Config A of Track B, and evaluate on 75 real tasks from SKILLSBENCH and TERMINALBENCH 2, and synthetic data split of Track B's configuration A. Table 4 shows the results. On the 75 real deployment tasks, the retriever alone reaches $h@5 = 0.840$ and $\text{MRR} = 0.735$. When we blend it with a frozen `Qwen3-Reranker-0.6B` improves this to $h@5 = 0.880$ and $\text{MRR} = 0.773$ at $\alpha = 0.55$ (blending is explained in §2.5.3). When reranker is fine-tuned with LoRA on top-30 candidate lists,

Method	α	Real 75 tasks (out-of-distribution) h@1	h@5	MRR	Synth 1,056 tasks (in-distribution) h@1	h@5	MRR
Retriever only	1.00	0.640	0.840	0.735	0.469	0.694	0.582
Frozen reranker only	0.00	0.653	0.813	0.721	0.566	0.813	0.677
Frozen reranker + retriever blend	0.55	0.693	0.880	0.773	0.566	0.813	0.677
LoRA reranker only	0.00	0.653	0.853	0.735	0.617	0.834	0.712
LoRA reranker + retriever blend	0.55	**0.707**	**0.893**	**0.781**	0.617	0.834	0.712
LoRA reranker with listwise LwF ($\lambda = 0.1$)	0.00	0.640	0.853	0.745	**0.653**	**0.861**	**0.744**
LoRA reranker with listwise LwF + retriever blend ($\lambda = 0.1$)	0.50	**0.707**	**0.893**	0.780	**0.653**	**0.861**	**0.744**
LoRA reranker only with listwise LwF ($\lambda = 0.3$)	0.00	0.667	0.867	0.765	0.632	0.831	0.723
LoRA reranker with listwise LwF+ retriever blend ($\lambda = 0.3$)	0.45	0.693	0.880	0.771	0.622	0.835	0.717

Table 4: Comparison of hit@k and MRR for retriever and reranker model with different combinations. Blended score measured as: $s = \alpha s_{\text{retr}} + (1 - \alpha) s_{\text{rerank}}$.

it reaches the real-pool ceiling at $h@5 = 0.893$ with $\text{MRR} = 0.781$ with a retriever blend. Table 4 also shows that the LwF regularizer based reranker fine-tuning (see §2.5.3) is neutral on the 75-task real pool, where it also reaches $h@5 = 0.893$, but it gives the strongest results on the in-distribution synthetic split $h@5 = 0.861$ and $\text{MRR} = 0.744$. This observation is the same as experiments with retrieval model where we found that all of the forgetting mitigation regularizers result in improved performance on in-distribution data and showed the same or better performance on out-of-distribution than the baseline model.

In addition, we also experimented with adding of BM25 through reciprocal-rank fusion, and it does not improve the reranker ceiling. So, our final stack uses the fine-tuned LoRA anchor regularized Qwen3-Embedding-0.6B and LoRA regularized Qwen3-Reranker-0.6B with blended scoring.

5 Related Work

Skills, retrieval, and synthetic supervision for agents. Agent systems increasingly rely on retrieved procedures, tools, or skills at run time (Anthropic, 2026; Yao et al., 2022), and generating queries or pseudo-labels with LLMs is a standard recipe for low-supervision retrieval (Nogueira and Cho, 2020; Dai et al., 2022; Bonifacio et al., 2022; Gao et al., 2023; Wang et al., 2024). While previous work on skill router training reports gains from synthetic data (Zheng et al., 2026), our findings show a nuanced picture: synthetic supervision is beneficial when applied to lightweight components but can harm performance when used to fine-tune encoders or rerankers if the synthetic task fails to capture the true multi-positive structure of downstream evaluation.

Continual learning and catastrophic forgetting. Catastrophic forgetting has been widely studied in continual learning methods, such as: EWC regularizes parameters against the Fisher-information-weighted posterior of the previous task (Kirkpatrick et al., 2017), learning without forgetting (LwF) regularizes outputs via knowledge distillation (Li and Hoiem, 2018), L2-init keeps parameters close to initialization (Li et al., 2018), and analyzing the extent of catastrophic forgetting in neural ranking models (Lovon-Melgarejo et al., 2021). We present an empirical study of synthetic data induced forgetting in large-scale skill retrieval for LLM agents. We compare preservation-style regularization–including LwF, EWC, L2-init, and embedding anchoring–under a shared conservative LoRA recipe.

6 Conclusion

We studied skill retrieval for LLM agents on the 34,396-skill scale using a unified benchmark that combines real tasks and synthetic supervision. Our experiments show that naive fine-tuning can degrade real-task retrieval and induce catastrophic forgetting on out-of-distribution queries. Our results also show that the use of forgetting mitigation regularizers with LoRA based fine-tuning not only improves in-distribution performance but also preserves the out-of-distribution performance. According to our intervention-based experiments, performance regression in aggressive updates can be characterized as stability-plasticity failure consistent with representational or ranking-function drift. Additionally, we show that compact retrievers (0.6B) can match much larger hybrid systems, emphasizing the importance of supervision quality over model scale.

Limitations

Statistical power. Val-set 1 ($n = 21$) and Val-set 3 ($n = 10$) are limited in size, such that single-task variations can shift RECALL@10 by approx-

imately 5%. We mitigate this by using 10,000-iteration paired bootstrap sampling, detailed statistical analysis on effect size and significance (see Appx. D), and evaluation on large out-of-distribution BEIR benchmark (Appx. E).

Known quality-gate failures in Track B. Although Track B applies multiple quality gates, three important limitations remain. First, the synthetic and real `soft_reward` distributions differ substantially. Second, positive-skill coverage is sparse relative to the full catalogue. Third, inter-judge agreement between the two LLM evaluators is modest. We report these issues explicitly because they affect how strongly the synthetic mixture can be treated as a faithful proxy for real supervision. Detailed mitigation on soft_reward and inter-judge agreement is discussed in Appendix B. Overall, the paper mitigates the impact by showing detailed empirical results on forgetting mitigation approaches and their positive impact on LoRA fine-tuning when generating synthetic data for sparse positive data is difficult.

Scale and coverage of the training signal. Our experiments are conducted on a skill pool of approximately 34K items, but the number of positively supervised skills is still a small fraction of the full catalogue. We therefore cannot rule out the possibility that some negative results–especially for encoder LoRA fine-tuning–would change at substantially larger synthetic-data scale or under broader positive-skill coverage. We do mitigate this concern by showing results on external large benchmarks and how forgetting mitigation methods can preserve the existing behaviour while improving results on a new training distribution.

Scope of domains, language, and modality. In adherence to the Bender Rule (Bender, 2019), we note that all tasks we executed in our experiments are English-language, text-based, and evaluated through a dockerized execution harness. We do not study multilingual skill retrieval, multimodal inputs, or non-code agent settings. The extent to which the observed forgetting patterns and mitigation approaches transfer to other domains remains an open question.

Dependence on closed-weight LLMs. Both synthetic pipelines rely on commercial, closed-weight LLMs for generation and quality assessment. As a result, exact reproduction of the synthetic data and judge labels may be sensitive to model or API drift over time. While we document the pipeline in detail, full reproducibility is therefore constrained by external endpoints.

Ethics Statement

The skill catalogue and benchmark tasks are operated under license from their respective owners; we add no personally identifying information at any stage. LLM-generated synthetic tasks are decontaminated against the benchmark instructions by a Jaccard reject filter (max observed overlap on the spot check: 0.129); generated tasks describe generic engineering problems and were spot-checked for offensive content. Closed-weight LLMs are used both as generators and as judges; we deliberately split vendors between generator and judge to reduce self-confirmation bias and report inter-vendor agreement as a quality gate. Human subjects randomly sampled the synthetic data to assess its quality. AI tools were also used to assist authors in polishing writing and generating code, and all the ideas and reasoning are original from the authors.

A Track-A Generalization Safeguards

Three independent leakage probes are run on every Track-A experiment:

- *Task disjointness*: the 1,669 synthetic tasks share 0 `task_id` with the 109 real tasks (verified at every run).
- *Skill disjointness*: the 9,254 distinct synth-positive skills do not overlap with the 332 distinct real-positive skills. Every synth-only experiment is therefore a strict cross-skill-subspace generalization test.
- *Decontamination spot check*: 50 random synthetic tasks vs all 176 real benchmark instructions; max observed Jaccard@200 chars $= 0.129$, no instance flagged at 0.50.

B Track B Details and Quality Gates

#	Type	Check	Status
G1	schema	all fields present, $\|N\|$=7, no positive overlap	pass
G2	coverage	every train task has $\geq$ 1 Tier-A/B real positive	pass
G3	judge	paraphrase retention $\geq 80\%$ per source task	pass
G4	judge	negative-leakage audit (n=100)	pass
G5	embed.	frozen-encoder collapse check (smoke fine-tune)	pass
G6	leakage	no train/val text or seed set equals any test row	pass
G7	dist.	KS-test of synthetic vs. real `soft_reward`	soft fail
G8	coverage	fraction of pool appearing as a positive	soft fail
G9	judge	inter-judge agreement (300-row audit)	soft fail
G10	holdout	no `eval_skill_holdout` skill in train/val	pass

Table 5: Quality gates for the locked Track B build. "Soft fail" gates are limitation flags: they diagnose mismatch between the synthetic supervision and the real harvest, but do not imply that the retained rows are invalid.

Synthetic Track B rows pass through ten gates before joining the locked split (Table 5). Six are hard build checks for schema validity, leakage prevention, coverage of real tasks, and held-out-skill integrity. Four (G3, G7–G9) are statistical or judge-based diagnostics. G3 is a retention gate that can directly block low-quality synthetic rows, whereas G7–G9 are reported as limitation flags rather than build blockers: they test reward calibration, catalog coverage, and judge calibration, not whether the retained task–skill pairs are internally coherent. We therefore use these gates to bound the interpretation of Track B rather than to claim that the synthetic supervision is distributionally equivalent to the real harvest.

Generator and primary judge. Synthetic tasks are produced by Claude Opus 4.7. Every row is then scored by GPT-5.5 on a four-axis 1–5 Likert rubric: *task realism–could a real user plausibly send this task?*; *skill necessity–are all listed skills required, not merely helpful?*; *skill sufficiency–is the listed skill set sufficient to solve the task?*, *reward plausibility–does the* `calibrated_soft_reward` *feel right?*

A row passes iff realism $\geq 4 \wedge \min(\text{necessity}, \text{sufficiency}, \text{reward_plausibility.}) \geq 3$. The asymmetric realism bar reflects the dataset's purpose: training value hinges on tasks feeling like real user input. Rows are weighted by $w = \texttt{calibrated_soft_reward} \times \min(\text{realism}, \text{necessity}, \text{sufficiency})/5$, so marginal passes also receive lower contrastive weight. This judge rejects $0/1{,}200$ paraphrase rows and $364/5{,}074$ (7.2%) skill-first rows; failures are dominated by sufficiency (mean 3.94).

G7 — reward distribution. A two-sample KS test comparing real-trial `soft_reward` values and synthetic `calibrated_soft_reward` values (n_{real}=1,116, n_{synth}=8,858) yields D=0.31, $p<10^{-80}$, so the synthetic reward weights are not a distributional match to the real harvest. This is a soft fail because `calibrated_soft_reward` is not intended to be an empirical execution reward; it is a synthetic confidence prior used only to weight the contrastive loss through `positive_weight`. For skill-first rows it is sampled from $\text{Beta}(\mu c, (1-\mu)c)$, where μ is derived from historical per-skill reward means and c controls concentration, so the resulting distribution is expected to be smoother and more peaked than the long-tailed real-trial distribution. We therefore interpret G7 as a calibration-mismatch warning on the weighting signal, not as evidence that the retained task–skill assignments are implausible.

G8 — skill coverage. Of the $26{,}947$ retrieval-eligible skills (the full $34{,}396$ pool minus the held-out subset), only 140 (0.52%) appear as positives in the locked train set. This is a structural limitation of Track B rather than a failed attempt at full-catalog supervision. The skill-first generator samples only

from skills with at least one successful real trial, and the paraphrase branch simply reuses positives from the same small real seed set, so positive supervision is intentionally concentrated on a narrow supported subset of the catalog. Track B therefore provides dense supervision over a small region of the pool, not broad positive coverage of the long tail. We mark G8 as a soft fail because it limits how strongly any positive result can be interpreted as full-pool adaptation, and it motivates retaining a strong frozen-retriever fallback at inference rather than treating the fine-tuned model as a standalone long-tail index.

G9 — inter-judge agreement. A second judge (Claude Opus 4.8) re-scores a stratified 300-row audit (150 rows originally passed by the primary judge and 150 originally failed) under the identical rubric. The means per-axis align most closely with *necessity* (4.44 vs. 4.45, Pearson r=0.79), the axis most directly tied to whether the listed skills are actually required. On the binary pass decision, Cohen's κ=0.28 and raw agreement is 64%, so Gate 9 is recorded as a soft fail. However, κ alone obscures the structure of the disagreement. The McNemar table $(n_{11}, n_{10}, n_{01}, n_{00}) = (144, 6, 102, 48)$, p=1.3×10^{-23} shows that the disagreement is strongly asymmetric: GPT-5.5 is the stricter judge, with $144/150$ of its accepted rows also accepted by the second judge, while many rows it rejected are accepted by Claude Opus 4.8. Therefore, we interpret the retained positives as a conservative, high-precision subset rather than as an unstable label set because our main judge is GPT 5.5 and Track B kept only GPT 5.5 judged rows. This means that the evidence is more consistent with threshold mismatch than with arbitrary labeling noise.

G10 — held-out-skill integrity. At split time we freeze ∼3,000 skills (∼9% of the pool) into `eval_skill_holdout` — skills reserved exclusively for building the held-out-skill synthetic eval ring later, and never allowed to touch training. A skill can leak into a training/validation row in three different ways: (1) as the *positive* — the skill labeled as the correct answer for a query; (2) as a *negative* — a skill listed as a wrong/distractor candidate for a query; or (3) as a *seed* — in our skill-first generation track, some tasks are synthesized by starting from a skill and asking an LLM to invent a plausible task for it, so that seed skill must also be holdout-free. G10 counts how many rows fail each of these three checks; G10 evaluation report shows: *0 positive violations, 0 negative violations, and 0 seed violations*. This is a build-blocking gate — a single violation in any of the three would mean the model has already "seen" a supposedly held-out skill during training, silently invalidating every held-out-eval number in the paper — so its pass status is load-bearing for other experiments.

r	Ring	λ=0	λ=0.03	λ=0.1	λ=0.3	row spread

	Ring 3	0.050	0.050	0.050	0.050	

Table 6: Stage A: Recall@10 on the three evaluation rings for the (r, λ) grid at seed=42 (conservative anchor regulariz: attn-only, lr=5e-6, Config A / full mix). *Row spread* is max−min of Recall@10 across λ at fixed (r, ring); *col spread* is max−min across r at fixed (λ, ring).

C Lambda Sweep and Seed Variance

Table 6 shows the effect of LoRA rank r and anchor weight λ on the conservative forgetting mitigation recipe. The main variation comes from rank, not from λ. At fixed λ, increasing r changes Recall@10 by up to 0.050 across rings, whereas sweeping λ at fixed (r, ring) changes Recall@10 by at most 0.012 and usually much less. The middle synthetic ring improves from $r = 4$ to $r = 16$ and then saturates, while Ring 3 remains unchanged for $r \leq 8$ but drops from 0.850 to 0.800 at $r \geq 16$. Ring 1 shows a slight decrease Recall@1 from r=4 to r=16, up to 0.007 then goes down aggressively by 0.021 on r=32. Thus, in this sweep, rank is the primary capacity/retention tradeoff knob, whereas the conservative anchor weight has only a small effect within a fixed rank.

Table 7 shows the seed sensitivity for conservative and aggressive recipes. The conservative $r = 8$ runs are highly stable: the variance is effectively zero on Ring 1 and Ring 3 and remains negligible on the middle synthetic ring. The variance increases at higher rank, especially in Ring1 and

Recipe	Ring 1	Ring 2	Ring 3
cons r=8, $a = 16$, λ=0.0	0.539 ± 0.000	0.609 ± 0.004	0.850 ± 0.000
cons r=8, $a = 16$, λ=0.1	0.539 ± 0.000	0.610 ± 0.001	0.850 ± 0.000
cons r=32, $a = 64$, λ=0.0	0.515 ± 0.006	0.614 ± 0.002	0.817 ± 0.029
cons r=32, $a = 64$, λ=0.1	0.501 ± 0.016	0.615 ± 0.003	0.783 ± 0.076
aggressive (r=16 α=32 all-proj)	0.505 ± 0.022	0.586 ± 0.026	0.583 ± 0.115
aggressive (r=32 α=64 all-proj)	0.492 ± 0.009	0.600 ± 0.031	0.683 ± 0.076

Table 7: Seed variance for the (r, λ) sweep. Each cell is mean $\pm$ sample std over the seeds listed. Seed set = {42, 1337, 99991}. Each cell shows the mean Recall@10 across three seeds and the sample standard deviation.

Ring 3; e.g., for conservative $r = 32$, the Ring 3 standard deviation increases to 0.029 at $\lambda = 0.0$ and 0.076 at $\lambda = 0.1$. The unregularized aggressive all-projection runs are both less stable and less reliable, with the largest variance again concentrated on Ring 3 (0.115 for $r = 16$ and 0.076 for $r = 32$). Overall, these results indicate that the conservative low-rank regularized setting lies below the seed-noise floor, whereas higher-capacity and unregularized recipes are materially more seed-sensitive.

Overall, lower-capacity regularized updates retain real/OOD behavior while preserving most synthetic gains. The regression of performance on aggressive updates, according to our intervention-based updates, can be characterized as a stability-plasticity failure consistent with representational or ranking-function drift.

D Effect Size and Significance

The real-task slices are small (Ring 1: $N = 21$, Ring 3: $N = 10$), therefore, we also report per-task paired differences on Recall@10 between the fine-tuning method and baseline (Qwen 3 0.6B) for both Ring 1 and Ring 3. Table 8 shows these differences for Ring 1 (SKILLSBENCH) and Table 9 shows these differences for Ring 3 (TERMINALBENCH 2). The adapters were trained using Track B's Config A (full mix). For example, if a value is negative in a cell, it means the fine tuning method (forgetting mitigation or aggressive) has lower recall than baseline on that task (it regressed), and if the value is positive (>0) then the method has higher Recall@10 than the baselines 0.6B (it wins). The two tables also show mean Δ of paired differences. The mean paired differences are 0 for Ring 3 (Table 9) and less than -0.005 for Ring 1 (Table 8). However, for aggressive methods, the mean paired differences ranged from -0.051 to -0.250. This again shows the significant regression of aggressive methods.

Table 10 summarizes the per-task Recall@10 differences. Each row pairs a fine-tuned method against frozen-0.6B along three axes: (1) *Direction* is given by W/T/L (wins/ties/losses of finetuned method vs. baseline) and the mean Δ difference in Recall@10 between the fine-tune method and baseline. Positive values favour the method, negative values favour the frozen baseline. (2) *Effect Size* is given by the 95% paired-bootstrap CI on Δ (10,000 resamples) and by Cliff's $\delta = (W - L)/N$, where $|\delta|$ near 0.1, 0.3, and 0.5 correspond to small, moderate, and large paired win/loss skews. (3) *Strength of evidence* is given by three p-values that test different nulls: the exact Wilcoxon signed-rank test asks whether the non-zero paired differences are systematically shifted from zero, the exact sign test asks whether wins and losses are imbalanced beyond chance, and TOST asks whether Δ lies inside a pre-specified equivalence band of ± 0.05 Recall@10.

Wilcoxon and sign tests share the standard reading in which a small p is evidence of a directional change; however, TOST with a small p is evidence that any residual difference is practically negligible. We claim *regression* only when $\Delta < 0$ and either Wilcoxon or sign rejects at $\alpha = 0.05$, and we claim *equivalence* to frozen-0.6B only when TOST rejects at $\alpha = 0.05$. All other cases are treated as ambiguous.

Under this interpretation, the regularized methods (conservative anchor, LwF, EWC, and L2-init) are practically equivalent to frozen-0.6B on both rings, including exact ties on all Ring 3 tasks, whereas the unregularized aggressive $r = 16$ all-projection model shows clear regression on Ring 3 ($0/4/6$, $\Delta = -0.400$, Wilcoxon/sign $p = 0.0312$). The aggressive $r = 32, \alpha = 64$ model is worse on average on Ring 3 but does not meet the regression criterion (Wilcoxon/sign $p = 0.5$), so it should be interpreted as inconclusive rather than equivalent. Given the small real-task sample sizes ($N = 21$ and $N = 10$), ambiguous rows should be read as lack of sufficient evidence, not evidence of no effect.

E Out of Distribution Evaluation on Large Sample Size

Due to the small sample size of Ring 1 (N=21) and Ring 3 (N=10), Wilcoxon and the sign test showed ambiguity despite the negative delta differences for Recall@10 for Table 10. We also evaluated aggressive and four forgetting mitigation ap-

proaches for fine-tuning on a larger and general purpose BEIR benchmark dataset (Thakur et al., 2021). The BEIR benchmark is not a specialized task to skills retrieval benchmark, which this study focuses on, but due to lack of task-skills benchmarks, we use BEIR, a general purpose retrieval benchmark. BEIR measures zero-shot retrieval performance, making it a strong indicator of real-world robustness and OOD (out-of-distribution) generalization. BEIR has 18 diverse datasets, we randomly selected 6 datasets for evaluation, namely: ArguAna (8.67K Corpus), FiQA(57K Corpus), NFCorpus (3.6K Corpus), SciDocs (25K Corpus), SciFact (5K Corpus) and Quora (0.52M Corpus). Our approach for evaluation is as follows: (a) we evaluate the Qwen3-0.6B embedding model directly on these BEIR datasets; (b) we evaluate aggressively fine-tuned LoRA on Track B's Config A (as in Table 2) on these datasets; (c) we evaluate LoRA fine-tuned adapter with conservative anchor ($\lambda = 0.1$), LwF, L2-init and EWC forgetting mitigation approaches on these BEIR datasets. Finally, we present Recall@10 and MRR@10 in Table 11. We can see the same pattern of recall here as in Table 3.

The conservative anchor, LwF, L2-init and EWC generate similar Recall@10 or slightly better than the baseline model on out-of-distribution data; whereas, aggressive fine-tuning results in poorer recall and MRR. Regardless of in-distribution or out-of-distribution, conservative anchor (and other

forgetting mitigation approaches) performed better on both types of data. The forgetting mitigation approaches based LoRA performed already better on in-distribution data in Table 3 and show clearly better performances on large out-of-distribution data in this section than aggressive LoRA. This provides substantial evidence for the use of forgetting mitigation approaches in skill retrieval and other retrieval domains.

F Deployment

We deploy the final system as a stateless streamable HTTP Model Context Protocol (MCP) server. The server exposes four tools: `retrieve_skills`, `retrieve_skills_debug`, `get_skill_detail`, and `health`, and runs the same three-stage pipeline used in our experiments: `Qwen3-Embedding-0.6B` retriever fine-tuned with the conservative anchor regularizer ($\lambda = 0.1$), exact nearest-neighbor search with embeddings over a `FAISS IndexFlatIP` built on 34396 skills, and the final `Qwen3-Reranker-0.6B` LoRA reranker trained with listwise LwF ($\lambda = 0.1$). The retriever and reranker scores are blended with the same per-query min-max normalization and $\alpha = 0.55$ used in the deployed configuration.

On a single NVIDIA H100, the full query path (retriever encoding, FAISS search, reranking, and score blending) completes in 169 ms p50 and 175 ms p95, sustains 5.9 queries/s, and uses only 4.3 GB of GPU memory. The small GPU memory consumption makes it fit on commodity GPUs with roughly 8–12 GB of VRAM (e.g., RTX 3060 12GB, RTX 4060 Ti, or cloud T4/L4-

Metric	Value
End-to-end latency (p50)	169 ms

Hardware	
Retriever	Qwen3-Emb-0.6B + Config A LoRA, bf16, GPU
FAISS index	`IndexFlatIP`, 34,396×1024 fp32, CPU (≈141 MB)
Reranker	Qwen3-Rerank-0.6B + LwF LoRA ($\lambda = 0.1$), bf16, GPU
Pool size	top-30 candidates per query
Peak GPU memory (after warmup)	4,296 MiB / 95,830 MiB (4.5%)

Table 12: MCP server latency and resource utilisation measured on a single NVIDIA H100 SXM5 (96 GB) in `gpu` mode.

class devices), although we only benchmarked latency on an H100. We also benchmarked the same MCP server in CPU-only mode on the same VM using an AMD EPYC 9V84 processor (40 cores, observed 2.40 GHz, 314 GiB RAM). On a 100-query sequential trace from the held-out synthetic evaluation set, CPU mode achieves 8.48 s p50 and 12.89 s p95 latency, with mean latency 9.07 s, maximum latency 17.03 s, and sequential throughput 0.11 QPS. The loaded CPU mode server uses approximately 6.1 GiB resident memory, making CPU mode practical for correctness testing and low-throughput deployment, but not for interactive use. This suggests that deployment is feasible on substantially cheaper hardware, trading off throughput and response time. This is also summarized in Table 12.

RECOVER: Robust Entity Correction via agentic Orchestration of hypothesis Variants for Evidence-based Recovery

Abhishek Kumar **Aashraya Sachdeva**
Observe.AI, India
{abhishek.kumar, aashraya.sachdeva}@observe.ai

Abstract

Entity recognition in Automatic Speech Recognition (ASR) is challenging for rare and domain-specific terms. In domains such as finance, medicine, and air-traffic control, these errors are costly. If an entity is entirely absent from the ASR output, text-only post-correction has little signal to recover it. To address this, we introduce RECOVER, an agentic post-ASR entity-correction framework. It leverages multiple hypotheses as evidence from ASR, retrieves relevant entities, proposes Large Language Model (LLM) correction under constraints, filters them through deterministic guardrails and uses an LLM critic that judges each surviving edit and can trigger a targeted feedback round to recover an entity the first pass missed. The hypotheses are used by one of several strategies, namely 1-Best, Entity-Aware Select, Recognizer Output Voting Error Reduction (ROVER) Ensemble, LLM-Select and Adaptive Routing. Evaluated across five diverse datasets over a Whisper-large-v3 baseline, it achieves up to 49% relative reduction in entity-phrase word error rate (E-WER) and increases entity recall by up to 14 percentage points while preserving the overall word error rate (WER), with LLM-Select the strongest strategy.

1 Introduction

Modern end-to-end ASR systems such as Whisper (Radford et al., 2023), wav2vec 2.0 (Baevski et al., 2020), and Conformer-based models (Gulati et al., 2020; Burchi and Vielzeuf, 2021) achieve impressive WER on general read- and conversational-speech benchmarks such as LibriSpeech (Panayotov et al., 2015) and Common Voice (Ardila et al., 2020). However, their performance degrades on entity phrases, i.e. proper nouns, brand names, and domain-specific terminology that are rare or absent from training data (Sainath et al., 2019; Del Rio et al., 2021). In domains like finance, air-traffic control (ATC), and medicine, entity errors are costly and often appear as small but critical near-misses (e.g. *cytiba→cytiva*, *linear zolid→linezolid*).

One line of work addresses these errors at decode time through contextual biasing (Jain et al., 2020; Le et al., 2021; Fox and Delworth, 2022; Huang et al., 2023), but such methods require access to the recognizer's internals and are unavailable when the ASR is a black-box or production service (Section 2).

Post-ASR correction with LLMs (Yang et al., 2023; Ma et al., 2025; Chen et al., 2023) is an attractive black-box alternative, but it faces a fundamental evidence limitation, that is, if an entity is deleted or heavily corrupted in the 1-best output, a text-only corrector has no signal to recover it. One approach is to expose the corrector to several ASR hypotheses, since an entity missed in one may survive in another. We obtain this diversity from a single black-box ASR via temperature sampling, without an ensemble or decoder access.

A second issue is reliability, as LLM correction is prone to hallucination and over-correction unless tightly constrained (Pu et al., 2023; Manakul et al., 2023), and a single forward pass cannot recover when its own output is wrong. We therefore constrain edits to a verified entity vocabulary and add a verification stage. Agents that use tools and act on their observations have proven effective (Yao et al., 2023; Schick et al., 2023), but their use in speech has so far been limited to conversational tasks rather than post-ASR entity recovery (Section 2).

These observations motivate RECOVER, a post-ASR entity-correction framework that leverages multiple hypotheses from an ASR system when available, retrieves candidate entities for each segment, fuses the hypotheses into a working transcript, proposes constrained edits, and verifies them with deterministic guardrails and an LLM critic. Our contributions are:

EMNLP 2026 Industry Track, pages 2939–2951
October 24-29, 2026 ©2026 Association for Computational Linguistics

- **Multi-hypothesis evidence.** We show that multiple hypotheses decoded from the same audio carry complementary entity errors that can be exploited for correction. We obtain them via temperature sampling of a single ASR model, but the framework is agnostic to how hypotheses are produced.
- **Agentic controller.** A controller composes a tool suite including entity retrieval, multi-hypothesis fusion, constrained proposal, deterministic verification, and an LLM critic. It runs a bounded feedback round when the critic flags a recoverable entity the first pass missed, and under adaptive routing it lets an LLM choose the fusion strategy per segment.
- **Fusion strategies.** 1-Best, Entity-Aware Select, ROVER Ensemble, and LLM-Select differ in how hypotheses are combined (deterministic selection, token-level merge, or LLM selection). For Adaptive Routing, an LLM picks one of these strategies per segment using the hypotheses and retrieved candidates.

We conduct comprehensive evaluations across five diverse datasets spanning financial, ATC, medical, general speech, and dialogue domains, reporting up to 49% relative E-WER reduction under temperature sampling with Whisper-large-v3. We also provide analyses of the feedback, guardrails, critic, the retrieval hyperparameters, comparison with external baselines, the effect of LLM and ASR model size, cost and latency.

2 Related Work

Contextual biasing in ASR. Decode-time biasing improves rare-word recognition through deep biasing in transducers (Jain et al., 2020; Huang et al., 2023), alternate-spelling prediction (Fox and Delworth, 2022), and trie-based shallow fusion (Le et al., 2021; Thorbecke et al., 2025). More recent work matches biasing phrases directly against the decoder's hypothesis prefix (Wang et al., 2024b), and folds entity recognition into the recognizer itself (Ayache et al., 2024). All require white-box access to the recognizer. RECOVER instead operates on the text output of a black-box ASR.

LLM-based post-ASR correction. Generative correction and N-best reranking with LLMs have become strong post-processing tools (Ma et al., 2025; Yang et al., 2023; Pu et al., 2023; Chen et al., 2023; Xu et al., 2025; Azmi and Tong, 2025). We adopt this paradigm but constrain edits to a verified entity vocabulary to suppress hallucination, and add a verification stage before an edit is committed.

Agents and tool use. REACT (Yao et al., 2023) combines reasoning and acting, Toolformer (Schick et al., 2023) learns when to call tools, and Reflexion (Shinn et al., 2023) adds verbal self-feedback (Wang et al., 2024a; Derouiche et al., 2025). RECOVER borrows tool use and acting on verifier feedback from this line of work and applies them to post-ASR entity correction.

3 Method

ASR systems often misrecognize entity phrases and rare or out-of-vocabulary (OOV) tokens. Given a list of known entity phrases and one or more ASR hypotheses, our goal is to correct entity-level errors while leaving the rest of the text intact. To address this, we propose a framework, RECOVER, as in Figure 1 which consists of a tool suite (Sections 3.1–3.2) and a controller that composes those tools.

3.1 Multi-Hypothesis Generation

The framework accepts N ASR hypotheses per audio segment. Hypotheses may come from temperature sampling of a single ASR model, diverse beam search, or an ensemble of different ASR systems. The only requirement when $N > 1$ is that they contain *complementary* errors, so an entity missed in one may be correct in another. Our main experiments use five hypotheses from temperature sampling of the Whisper model, and Section 5.3 takes one from each of five ASR systems.

3.2 Tool Suite

RETRIEVE. Entity lists can be large (up to 6,198 phrases as in Table 1). Sending all of them to the LLM is wasteful and degrades quality, so we retrieve the top-K candidates per segment with a three-signal scoring function over each phrase b:

$$\text{score}(b) = \underbrace{n_{\text{exact}} \cdot w_e}_{\text{exact token hits}} + \underbrace{f_{\text{best}} \cdot w_f}_{\text{fuzzy similarity}} + \underbrace{p_{\text{hit}} \cdot w_p}_{\text{phonetic prefix}} \quad (1)$$

where n_{exact} counts words of b matching hypothesis tokens exactly, $f_{\text{best}} \in [0, 1]$ is the best normalized Levenshtein similarity to any hypothesis token, and $p_{\text{hit}} \in \{0, 1\}$ marks a shared phonetic-key prefix (thresholds in Appendix B). We set $w_e = 1.0$, $w_f = 1.2$, $w_p = 0.6$. Exact matches are the most reliable signal, fuzzy similarity is weighted highest per unit as the main mechanism for recovering corrupted entities (e.g., *sitiva*→*cytiva*), and the phonetic cue is supplementary. The scorer returns the top $K = 200$, with small lists sent in full (Section 5.5). On a

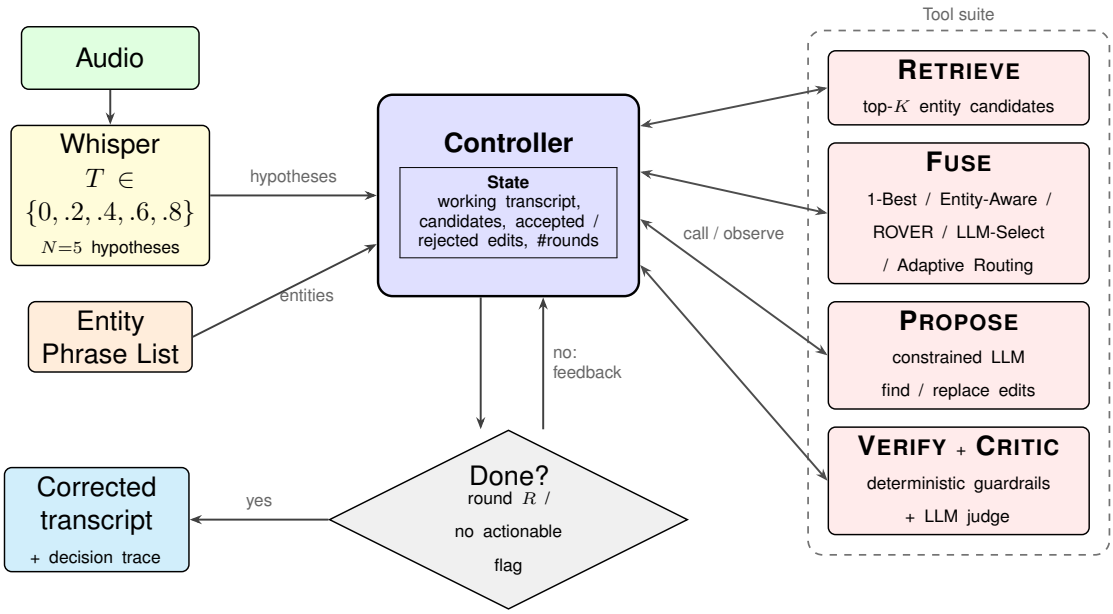

Figure 1: RECOVER. A *controller* runs over a working state using four tools: RETRIEVE (top-K entity candidates), FUSE (1-Best / Entity-Aware / ROVER / LLM-Select, or Adaptive Routing), PROPOSE (constrained edits), and VERIFY + CRITIC (deterministic guardrail and LLM judge). When the critic flags an actionable missed entity, a bounded *feedback* round re-retrieves for that span and re-proposes. Clean segments propose nothing and stop.

feedback round it is re-issued for the flagged span and may widen to $K_{\text{cap}} = 400$ (Section 3.3).

FUSE. It counts how many of the top-K candidates appear as exact substrings in each hypothesis. These per-variant entity-hit counts drive variant selection in Entity-Aware Select and pivot selection in ROVER Ensemble.

- **1-Best** ($N = 1$): It passes the single greedy hypothesis ($T = 0$) through unchanged.
- **Entity-Aware Select**: It chooses the hypothesis with the maximum number of exact entity-candidate substring matches, with transcript length as a weak tie-breaker (since longer transcripts correlate with fewer deletions).
- **ROVER Ensemble**: It chooses an entity-aware pivot (same heuristic as Entity-Aware Select), aligns each remaining hypothesis to it with Needleman–Wunsch global alignment (Needleman and Wunsch, 1970), and takes a majority-vote token merge (ties favour the pivot and insertions are accepted only if supported by ≥ 3 of 5 hypotheses).
- **LLM-Select**: It delegates selection to the LLM inside PROPOSE by supplying all N hypotheses and the top-K candidates. The LLM chooses the best base variant and can propose entity-only corrections in the same call.
- **Adaptive Routing**: It is an additional strategy that lets an LLM router pick one of the four main fusion strategies per segment from inter-hypothesis agreement and entity-hit counts.

PROPOSE. It proposes entity-only find or replace edits via a constrained LLM which enforces strict rules that replacements must be exactly one entity-list phrase, no generic rewrites (grammar, punctuation, casing), and near-miss correction is encouraged (e.g., *citeva* → *cytiva*).

VERIFY + CRITIC. Each proposed replacement passes deterministic checks before it is applied: it must be an entity-list phrase, case-only changes are discarded, and the normalized Levenshtein similarity between original and replacement must clear a floor of 0.5, blocking unrelated substitutions (*star*→*cytiva*) while admitting near-misses (*citeva*→*cytiva*). Surviving edits are applied left to right, skipping overlaps. The floor is deliberately loose because the critic supplies precision, and these guardrails act as a closed-vocabulary safety gate that is never bypassed (Appendix B). An LLM critic then reviews the result with all N hypotheses available, so it can judge from cross-hypothesis evidence. For each surviving edit it returns *accept* or *reject* with a reason, and it can flag a missed entity or request more candidates. Only critic-approved edits are applied, and these rejections and flags are the feedback the controller acts on.

3.3 Agentic Controller

The controller composes RETRIEVE, FUSE, PROPOSE, and VERIFY+CRITIC over a working *state*

(transcript, candidates, accepted and rejected edits, round counter). When the critic flags a missed span as actionable, a targeted feedback round fires, bounded to $R = 1$ in our experiments. It re-retrieves for that span and re-proposes with the rejected edits to avoid, the spans to focus on, and the new candidates, without recomputing fusion. This keeps feedback tied to real evidence of a recoverable entity. Section 5.6 reports how often it fires and *adds* a correction.

4 Experimental Setup

4.1 Datasets

We evaluate on five datasets spanning diverse domains (Table 1). **Earnings-21** (Del Rio et al., 2021) comprises 44 calls segmented into ∼1-minute clips (2,086 segments). From **ATCO2** (Zuluaga-Gomez et al., 2022, 2020), we use the 1-hour test set with 446 callsign entities. **Eka-Medical** (Eka Care, 2024) has 3,619 utterances with 6,198 medical entities; the **Common Voice** (Ardila et al., 2020) Corpus-22 English test set has 16,401 utterances, for which we extract 3,098 entities with a BERT NER model (Thorbecke et al., 2025) as it ships no entity list. **ContextASR-Bench** (Wang et al., 2025) (English Dialogue, 5,273 samples) provides 3,704 movie-name entities.

4.2 ASR systems and LLMs

All audio is decoded with `faster-whisper` (SYSTRAN, 2023) at five temperatures $T \in \{0, 0.2, 0.4, 0.6, 0.8\}$. Our main experiments use Whisper-large-v3 (Radford et al., 2023) with GPT-4o (Hurst et al., 2024), plus a GPT-4o-mini ablation (LLM-Select). To show how gains scale with recognizer size, Section 5.1 reports the same methods on the weaker Whisper-small (Radford et al., 2023). To test whether the framework depends on Whisper-specific error structure, Section 5.3 rebuilds the Earnings-21 hypothesis set from five *independent* recognizers, Whisper-large-v3 together with four commercial ASR providers (Speechmatics (Speechmatics, 2026), Deepgram (Deepgram, 2026), AssemblyAI (AssemblyAI, 2026), and AWS Transcribe (Amazon Web Services, 2026)), each with its default English model and contributing one hypothesis. Appendix G additionally runs the corrector and critic on the open-weight Llama-3.3-70B (Grattafiori et al., 2024) and Mixtral-8x22B (Jiang et al., 2024) through OpenRouter (OpenRouter, 2025).

Table 1: Dataset statistics. Segments is the number of independently processed transcript units. Audio hours is the approximate total duration. Entities is the size of the entity phrase list. Entity Reference Tokens is the total number of reference words belonging to entity phrases.

Dataset	Segments	Audio hours (approx.)	Entities	Entity Reference Tokens	Entity types
Earnings-21	2,086	38.8	1,013	6,535	Persons, Orgs, Products
ATCO2	560	1.1	446	4,771	Callsigns
Eka-Medical	3,619	8.4	6,198	42,449	Medical terms
Common Voice	16,401	27.1	3,098	7,889	Derived Named Entities
ContextASR-Bench	5,273	221.9	3,704	92,381	Movie names

4.3 External baselines

We compare against six single-pass LLM correction systems on Earnings-21, namely zero-shot and few-shot correction with task-activating prompting (Yang et al., 2023), N-best generative correction (Ma et al., 2023; Chen et al., 2023), N-best selection, N-best with entity list, and direct prompting with the entity list. All are single-pass and unconstrained, with no guardrail and no critic, and all run on the same segments with the same LLM (GPT-4o-mini) and, where a vocabulary is used, the same retriever and top-K candidates as RECOVER. Appendix A specifies each.

4.4 Evaluation

WER is computed with SCLITE (Fiscus, 1997). E-WER is computed only over reference tokens belonging to entity phrases, and relative E-WER reduction (RWERR) is $(\text{E-WER}_{\text{base}} - \text{E-WER}_{\text{sys}})/\text{E-WER}_{\text{base}}$. We report entity precision (P), recall (R), and F1. We also report per segment LLM calls, tokens (prompt plus completion), cost, and median latency (Section 5.7).

5 Results and Discussion

5.1 Main results

Table 2 reports WER, E-WER (RWERR beneath), and F1 (P / R beneath) over a strong Whisper-large-v3 baseline. Every GPT-4o correction method reduces E-WER, by up to 48.9% relative on Common Voice. **LLM-Select** is the most consistent and strongest method: it attains the best F1 on all five datasets, the best overall WER on three (ATCO2 35.80→33.70, Eka-Medical 12.96→9.79, Common Voice 9.96→9.79), and the best or near-best E-WER throughout (RWERR 48.9% on Common Voice, 38.5% on Earnings-21, 23.4% on Eka-Medical, 17.5% on ATCO2 and 12.8% on ContextASR-Bench). A practical concern is whether entity correction degrades overall transcript quality, so the choice of fusion strategy matters for preserving WER. Merge-based fusion (ROVER, Entity-Aware Select) reduces E-WER

Table 2: Results across five datasets (all values in %). Upper block: **Whisper-large-v3** with GPT-4o under each fusion strategy against **Baseline (no correction)**, plus a GPT-4o-mini LLM-Select ablation. Lower block: the weaker Whisper-small recognizer. Below each E-WER: RWERR vs. the corresponding baseline; below each F1: (P / R). Best WER (↓), E-WER (↓) and F1 (↑) per dataset in bold.

but inflates WER on the extremely noisy ATCO2 domain (35.80→40.0–40.5) by injecting insertions, whereas selection-based LLM-Select keeps WER below baseline. 1-Best improves over baseline on every domain but is weakest on ATCO2 (11.0% against 17–18%), since a single hypothesis recovers fewer of the entity deletions common in noisy ATC audio, exactly where multi-hypothesis fusion helps most. Adaptive Routing does not exceed a fixed LLM-Select, giving the best E-WER only on ATCO2 (Section 5.6).

The dominant gain is entity recall (LLM-Select against baseline): +8.4 pp (Earnings-21), +10.0 pp (ATCO2), +5.1 pp (Eka-Medical), +14.1 pp (Common Voice), and +0.5 pp (ContextASR-Bench, whose baseline recall is already 96.4%), confirming that entity deletion and substitution is the main baseline weakness. Precision is largely preserved, yielding net F1 gains everywhere. GPT-4o-mini follows the same trend with smaller margins (RWERR 1.6–28.2%), so stronger LLM reasoning translates into larger entity recovery under the same constraints. For context, Huang et al. (2023) report that a contextualized attention-based encoder–decoder (AED) with decode-time biasing on Earnings-21 raises phrase-level recall from 58.66 to 79.11 (+20.45 pp) and F1 from 71.50 to 79.88 (11.7% relative) with little change in overall WER (14.96→15.12), but at the cost of precision (91.52 to 80.67). This is not directly comparable, since it uses a different recognizer in a decode-time contextualization setting, but our black-box post-ASR pipeline reaches comparable phrase recall on Earnings-21 (78.95→87.36, +8.41 pp) while keeping overall WER essentially unchanged (12.34→12.39) and losing less precision (92.73 to 89.82).

Table 3: Entity-level SCLITE alignment counts for baseline vs. LLM-Select (Whisper-large-v3, GPT-4o): Correct (C), Substitution (S), Deletion (D), Insertion (I), with the change Δ (LLM-Select − Baseline).

The lower block of Table 2 repeats the Baseline and LLM-Select on the weaker Whisper-small recognizer, whose baseline is worse on every domain (E-WER 23.81 against 15.88 on Earnings-21) and so gives the corrector more headroom. GPT-4o LLM-Select reduces E-WER by 17.0–47.2% RWERR while keeping WER at or below baseline, giving larger *absolute* entity-error reductions. GPT-4o-mini follows with smaller margins (3.2–25.1%).

Entity recall gains do not move overall WER. Entity tokens are a small share of any transcript, 1.75% on Earnings-21 (6,535 of 373,550 reference tokens), so even a large entity gain moves the global figure very little. Overall WER should be read here as a *safety* metric rather than the quantity the method optimises.

Table 3 shows that substitution reduction is the dominant correction mechanism, consistent with

Table 4: External baselines on Earnings-21 (Whisper-large-v3, GPT-4o-mini). Δtok is the fraction of tokens changed against the input hypothesis (net word change in parentheses).

System	WER	E-WER (RWERR)	Δtok (net)
Baseline (no correction)	12.34	15.88 (–)	–
Zero-shot correction	12.84	14.09 (11.3)	–
Few-shot correction	12.65	14.05 (11.6)	–
N-best generative corr.	13.10	13.82 (13.0)	–
N-best selection	12.54	15.82 (0.4)	–
N-best w/ entity list	12.82	10.97 (30.9)	7.93% (−3,271)
Direct prompt w/ entity list	12.55	**10.60 (33.2)**	5.85% (−1,213)
RECOVER (LLM-Select)	**12.48**	11.40 (28.2)	**0.21% (−28)**

the constrained LLM resolving entity near-misses such as *saitiva→cytiva*, *left hansa→lufthansa*, and *chronic holes→chronicles*. Deletions also decrease on every dataset, and insertions stay low, indicating that the system rarely adds spurious tokens.

5.2 Comparison with external baselines

Table 4 compares RECOVER with the six single-pass baselines of Section 4.3 (using Whisper-large-v3, GPT-4o-mini). The entity vocabulary, not the LLM, carries most of the gain. The vocabulary-free correctors reach 11.3–13.0% relative E-WER reduction against 28–33% for every system given the retrieved candidates, and N-best selection, which may re-rank but not edit, is essentially flat (0.4%). Direct prompting with the same entity list reaches 10.60 against 11.40 with RECOVER (LLM-Select, GPT-4o-mini). RECOVER wins instead on the scope of the edit, which E-WER does not expose. Entity tokens are only 1.75% of this corpus, yet direct prompting changes 5.85% of tokens and N-best-with-entities 7.93%, against RECOVER's 0.21%, and relative to the uncorrected baseline they add 1,502 and 2,530 overall deletions against RECOVER's 396. The unconstrained systems buy part of their entity accuracy by dropping other content, which overall WER hides.

5.3 Hypotheses from independent recognizers

Every result so far draws its N hypotheses from temperature sampling of one recognizer. On Earnings-21, RECOVER consumes one hypothesis from each of five independent recognizers (Table 5). With GPT-4o, LLM-Select reaches 7.96 E-WER and ROVER Ensemble 7.44, a 53.2% relative reduction over the Whisper-large-v3 baseline and 45.8% better on entities than the strongest provider (AssemblyAI, 13.73), while overall WER (9.24) does not beat the best single provider (AWS Transcribe, 9.11), as expected for a system that edits only entity spans. ROVER Ensemble, which inflated WER under temperature sampling (Section 5.1), is strongest here, since a token-level merge pays off when hypotheses are independent.

Table 5: Earnings-21 with one hypothesis from each of five independent recognizers. RECOVER is unmodified. RWERR over the Whisper-large-v3 baseline (no correction) in parentheses.

System	WER	E-WER
Whisper-large-v3	12.34	15.88
Speechmatics	10.07	16.47
Deepgram	14.70	13.93
AssemblyAI	11.68	**13.73**
AWS Transcribe	**9.11**	22.97
5 rec. + RECOVER (GPT-4o-mini)	11.54	9.38 (40.9)
5 rec. + LLM-Select (GPT-4o)	11.56	7.96 (49.9)
5 rec. + ROVER Ens. (GPT-4o)	9.24	**7.44 (53.2)**

Table 6: Entity-list coverage and noise on Earnings-21 (Whisper-large-v3, GPT-4o-mini). Coverage is the fraction of the 1,013-phrase list retained. The last column adds 769 distractors.

List coverage	100%	75%	50%	25%	+76% distr.
E-WER ↓	**11.40**	12.23	13.34	14.60	11.78
RWERR ↑	**28.2**	23.0	16.0	8.1	25.8
WER	12.48	12.49	12.48	12.51	12.48

5.4 Entity-list coverage and noise

RECOVER requires a domain entity list, so its behaviour when that list is incomplete or noisy decides whether it is deployable. We degrade the 1,013-phrase Earnings-21 list, and separately enlarge it with the 769 distractors of Fox and Delworth (2022) (construction in Appendix E). No setting pushes the entity numbers below the uncorrected baseline, and overall WER stays inside 12.48–12.51 throughout (Table 6). This follows from the closed-vocabulary constraint: because every applied edit must be a list phrase, an entity absent from the list is a missed opportunity rather than a new error, which is what makes an incomplete list safe to deploy. Similarly, noise is cheap, since the retriever ranks distractors below phrases that match the hypotheses.

5.5 Retrieval: candidate budget and scoring weights

Candidate budget K. E-WER improves from $K = 50$ to a minimum at $K = 200$ (11.46, 27.8% RWERR) and slightly worsens at $K = 400$ and $K = \max$ (full 1,013-entity list, 11.71). Adding candidates beyond ∼200 does not help, while $K = 200$ is already large enough to cover the entities relevant to the hypotheses. In Table 7, K is held fixed even on feedback re-retrieval to isolate its effect, whereas in the main experiments K is raised to $K_{\text{cap}} = 400$ on feedback. Raising K only

Table 7: Retrieval on Earnings-21 (Whisper-large-v3, GPT-4o-mini, LLM-Select): candidate budget K and scoring weights (at $K = 200$). K is held fixed on feedback re-retrieval here.

Factor	Setting	E-WER ↓ (RWERR)
Budget K	50	11.60 (27.0)
	100	11.52 (27.5)
	200	**11.46 (27.8)**
	400	11.64 (26.7)
	max ($\lvert\mathcal{E}\rvert$=1013)	11.71 (26.3)
Weights (w_e, w_f, w_p)	$(1, 1.2, 0.6)$	**11.46 (27.8)**
	$(1, 1, 1)$ uniform	11.60 (27.0)
	$(0, 1, 0)$ fuzzy-only	11.71 (26.3)
	$(1, 0, 0)$ exact-only	13.10 (17.5)
	$(0, 0, 1)$ phonetic-only	13.93 (12.3)

Table 8: Feedback and verification statistics for RECOVER (LLM-Select, Whisper-large-v3, GPT-4o), per dataset. Feedback% = segments that triggered a feedback round, Helped(seg)% / Helped(fb)% = fraction of *all* segments / of *feedback* segments where feedback added a correction, G-rej / C-rej = total edits rejected by the deterministic guardrail or the LLM critic.

Dataset	Feedback%	Helped(seg)%	Helped(fb)%	G-rej	C-rej
Earnings-21	5.6	1.2	21.4	2,297	112
ATCO2	2.3	0.5	23.1	410	34
Eka-Medical	5.2	0.8	15.4	2,873	202
Common Voice	2.2	0.2	9.1	6,035	557
ContextASR-Bench	12.3	4.6	37.7	6,865	632

during feedback gives a small additional gain over a constant $K = 200$ (Appendix B).

Scoring weights. With $K = 200$, the chosen weighting $(w_e, w_f, w_p) = (1, 1.2, 0.6)$ is best (11.46). Any single signal is markedly worse (exact-only 13.10, phonetic-only 13.93), and both uniform weights (1,1,1: 11.60) and fuzzy-only (0,1,0: 11.71) trail it. This confirms that combining exact, fuzzy, and phonetic signals helps, and that up-weighting fuzzy similarity is the right choice. A finer grid around the chosen setting is in Appendix C.

5.6 Feedback, guardrails, and the critic

Every RECOVER configuration in Table 2 passes through a deterministic guardrail, an LLM critic, and up to one bounded feedback round. Table 8 reports how often feedback fires and how the two verification layers behave. Feedback is rare and targeted, firing on 2.2–12.3% of segments and adding a correction on 9.1–37.7% of those invocations. The two layers do complementary work: the guardrail rejects the bulk of invalid proposals (410–6,865) as a high-volume safety filter, while the critic rejects a much smaller residue that passed the gate (34–632) as a precision check. Disabling both leaves overall WER essentially unchanged (+0.01 pp) but costs 2.5 points of relative E-WER reduction (Appendix I), so they buy entity precision rather than transcript quality. Under adaptive routing the router mostly picks Entity-Aware Select, which is why it does not exceed a fixed LLM-Select (Appendix H).

Table 9: Cost and latency on Earnings-21 (Whisper-large-v3). Tokens are prompt + completion per segment, cost uses list API prices, latency is the median per-segment total across all LLM calls for that segment.

Configuration	calls/seg	tokens/seg	USD/1k seg	median s/seg
Single-pass zero-shot, GPT-4o-mini	1.00	277+192	0.16	3.09
Single-pass + entity list, GPT-4o-mini	1.00	1222+186	0.29	4.37
RECOVER, GPT-4o	2.11	4096+333	13.57	6.14
RECOVER, GPT-4o-mini	2.35	4488+277	0.84	5.57

5.7 Cost and latency

Table 9 reports the costs: RECOVER issues 2.11 LLM calls per segment with GPT-4o against one for a prompt-only corrector, and the multi-hypothesis prompt dominates. The five-hypothesis fusion call carries 4,096 prompt tokens against 277 for a single-hypothesis zero-shot pass, while feedback fires on 5.6% of segments for +0.11 calls and about 5% of cost (Appendix F). Model choice dominates the cost: GPT-4o-mini runs the same pipeline 16 times cheaper while retaining 28.2% relative E-WER reduction against 38.5% with GPT-4o (Table 2). Latency tracks calls rather than model size. A cost-constrained deployment should therefore change the LLM and a latency-constrained one disable the critic and feedback (Appendix I), rather than give up the multi-hypothesis evidence. Open-weight correctors are a further option (Appendix G).

6 Conclusion

We presented RECOVER, a post-ASR entity-correction framework that retrieves entity candidates, fuses multiple ASR hypotheses, proposes constrained edits, filters them through deterministic guardrails, and verifies them with an LLM critic that can trigger a bounded feedback round. Over a strong Whisper-large-v3 baseline it yields up to 49% relative E-WER reduction across five domains, and up to 53% on Earnings-21 using hypotheses from five independent recognizers. The findings that underpin these results are that alternative hypotheses of the same audio can carry entity evidence that the single hypothesis may have lost, and constraining every edit to a retrieved vocabulary is what keeps the correction targeted. Since the framework is agnostic to how those hypotheses are produced and needs no access to the recognizer, it applies to any black-box or commercial ASR.

Limitations

RECOVER assumes access to a domain entity list. Section 5.4 quantifies that dependence rather than removing it, that is, at 25% coverage the relative E-WER reduction falls from 28.2 to 8.1, so the method is bounded by the quality of the list it is given.

Direct prompting with the same retrieved entity list reaches 10.60 against 11.40 with RECOVER on Earnings-21 (Section 5.2). Our claim is the trade-off, a comparable entity gain at a 0.21% rather than 5.85% edit footprint. A deployment that does not value transcript preservation should prefer the simpler baseline.

The orchestration is not free. The critic adds an LLM call per segment (and a routing call under adaptive routing), and RECOVER issues 2.11 against 1.00 calls per segment, roughly three times the dollar cost of a single-pass corrector carrying the same entity list on the same LLM (Section 5.7). The feedback round in particular is better understood as an optional precision setting: it fires on 2.2–12.3% of segments and adds a correction on only 0.2–4.6% of all segments, and disabling it together with the critic costs about 2.5 points of relative E-WER reduction on Earnings-21 (Appendix I). The deterministic guardrail, not the feedback loop, does the bulk of the safety work.

Adaptive routing does not exceed a fixed LLM-Select on any dataset except ATCO2, where the margin is marginal, and the router overwhelmingly selects Entity-Aware Select (Appendix H). Richer routing signals or a trained router would be needed to make it a contribution rather than an ablation.

Multi-hypothesis diversity from temperature sampling is recognizer-dependent and may shrink as ASR quality improves (Table 2), although independent recognizers supply substantially more evidence where several are available (Section 5.3). Finally, our cost figures are hosted list prices at the time of writing and are not the cost of self-hosting.

Ethical Considerations

RECOVER targets high-stakes domains such as finance, medicine, and air-traffic control, where both a wrong correction and a missed entity can have real consequences. The closed-vocabulary constraint and the LLM critic are designed to suppress hallucinated edits, and the deterministic guardrail never applies an out-of-list phrase, but residual errors remain. We therefore view RECOVER as a tool to assist human review rather than a system to be relied on without oversight in safety-critical settings such as clinical documentation or air-traffic control. We evaluate on publicly available or licensed datasets (Earnings-21, ATCO2, Eka-Medical, Common Voice, ContextASR-Bench). Speech in the medical and air-traffic domains can contain sensitive or personally identifiable information, and we use these datasets only for evaluation under their respective terms and report aggregate metrics only. Our pipeline also relies on a third-party LLM and on multiple hypotheses, which carry the usual model-bias risks and send transcripts to an external service.

The entity list is itself a source of bias. Every applied edit must be a phrase in the supplied vocabulary, so names absent from that list are systematically never recovered, and the same guardrail that suppresses hallucination also fixes this asymmetry in place. If a list under-represents names from particular languages, regions, or communities, the system improves recognition for the names it contains and leaves the others at baseline. Section 5.4 shows this quantitatively, as coverage bounds the achievable gain almost proportionally. Choosing what goes into the entity list is therefore a fairness decision and a list should be checked before deployment for whether it covers the names of the people the system will serve. Our results are averages where the corpora we use do not reliably label speakers, so we cannot report errors by speaker group, and our evaluation therefore cannot show whether the system treats all groups equally.

The framework issues 2.00 – 2.35 LLM calls and 4.4 – 4.8k tokens per segment (Section 5.7), several times the token footprint of a single-pass corrector, so it carries a correspondingly larger energy and carbon cost that a deployment should weigh against the entity gain. We report calls, tokens, cost, and latency for every configuration so that this trade-off is explicit. The cheapest configuration we measured, the open-weight Llama-3.3-70B corrector at USD 0.60 per 1,000 segments (Appendix G), also attains a larger relative reduction (30.0%) than GPT-4o-mini, and disabling the critic and feedback removes roughly one call per segment at a small accuracy cost.

A External Baseline Configurations

All six baselines in Table 4 are run on Earnings-21, Whisper-large-v3 hypotheses, with GPT-4o-mini as the LLM. None of them applies the deterministic guardrail or the critic, and where a vocabulary is used it is the same retriever and the same top-K candidate set that RECOVER receives.

- **Zero-shot correction.** The 1-Best transcript is given to the LLM with an instruction to correct recognition errors and return the corrected transcript, with no examples and no vocabulary (Yang et al., 2023).
- **Few-shot correction (task-activating prompting).** As above, with an error-pattern that describes the kinds of ASR error to expect and three worked near-miss examples, following the task-activating prompting recipe of Yang et al. (2023).
- **N-best generative correction.** All five hypotheses are supplied at once and the LLM writes a fresh transcript from their disagreement, with no vocabulary (Ma et al., 2023; Chen et al., 2023).
- **N-best selection.** The N-best-constrained variant: the LLM returns the index of one of the five hypotheses and may not edit it. This isolates re-ranking from correction.
- **N-best with entity list.** The generative N-best prompt plus retrieved top-200 entity candidates, with free-form output and no constraint enforcement.
- **Direct prompting with the entity list.** The 1-Best transcript plus the same retrieved top-200 candidates, free-form output, no guardrail and no critic.

Edit scope in Table 4 is measured by aligning each system's output against its own input hypothesis and counting the fraction of tokens that changed. The net word figure is the change in total transcript length. Deletion counts are read from the SCLITE alignment against the reference.

B Hyperparameters

Retrieval scoring (Eq. 1). The score combines three standard signals, exact token match, edit-distance (Levenshtein) fuzzy similarity, and a phonetic key, with weights $(w_e, w_f, w_p) = (1.0, 1.2, 0.6)$. An exact token hit is the most reliable signal, fuzzy similarity is up-weighted slightly per unit because it is a continuous score in $[0, 1]$ and is the primary mechanism for recovering near-miss entities. The phonetic cue is binary and coarse, so it is down-weighted. Normalized Levenshtein similarity is $\mathrm{sim}(a, b) = 1 - \mathrm{lev}(a, b)/\max(|a|, |b|)$, where words are compared only when their lengths differ by ≤ 3 characters and have ≥ 4 characters (a speed or quality filter), and phonetic keys use a Double-Metaphone-style 5-character prefix. The score only *ranks* candidates and we take the top-K ($K = 200$). The weights and K are ablated in Table 7, which shows $K = 200$ is best and that combining all three signals (with fuzzy up-weighted) beats any single signal or uniform weights.

Candidate budget K. $K_{\text{init}} = \min(200, |\mathcal{E}|)$ with a feedback ceiling $K_{\text{cap}} = \min(400, |\mathcal{E}|)$. The $\min(\cdot, |\mathcal{E}|)$ sends small entity lists in full. As Table 7 shows, E-WER is minimized at $K = 200$ and degrades slightly for $K = 400$ and the full list, since beyond a few hundred candidates the added phrases are low-scoring and dilute the prompt without improving recall.

Larger K during feedback. The ablation in Table 7 holds K fixed on feedback to isolate the effect of the budget. Our main runs instead raise K from 200 to $K_{\text{cap}} = 400$ when a feedback round fires. Table 10 compares the two on the same setting (Earnings-21, Whisper-large-v3, GPT-4o-mini, LLM-Select). A larger static budget is worse (11.64 at $K = 400$ against 11.46 at $K = 200$), but raising K only during feedback improves E-WER to 11.40. Increasing the budget globally adds noise, while targeting a wider pool at the span the critic flagged recovers a few more entities.

Table 10: Effect of the retrieval budget during feedback (Earnings-21, Whisper-large-v3, GPT-4o-mini, LLM-Select). E-WER % with RWERR vs. baseline in parentheses.

Retrieval budget	E-WER ↓ (RWERR)
$K = 200$, fixed on feedback	11.46 (27.8)
$K = 400$, fixed on feedback	11.64 (26.7)
$K = 200 \rightarrow 400$ on feedback	**11.40 (28.2)**

Guardrail thresholds. The VERIFY similarity floor is 0.5 and it blocks unrelated substitutions (*star*→*cytiva*) while admitting near-misses (*citeva*→*cytiva*). These are coarse safety bounds, not tuned values. The critic, not the threshold, is the precision decider.

Feedback. Feedback is bounded to $R = 1$ round in our experiments and is evidence-gated: a critic-flagged missed span triggers a round only if a list entity matches it at similarity $\geq \tau_a = 0.6$ and differs from the current text (otherwise the loop stops). Over-corrections are dropped. Off-list proposals are snapped, not re-run. The critic uses the same LLM as correction here.

C Extended Scoring-weight Grid

Table 11 reports a finer grid around the reported weights, varying one weight at a time (Earnings-21, Whisper-large-v3, GPT-4o-mini). E-WER spans 11.40–11.69 across the grid, so the reported setting is on a plateau and it is no worse than any neighbour. The coarser sweep in Table 7, which switches signals off entirely, shows much larger movement (up to 13.93), so what matters is that all three signals are present and that fuzzy similarity is not down-weighted.

Table 11: Scoring-weight grid at $K = 200$ (Earnings-21, Whisper-large-v3, GPT-4o-mini, LLM-Select).

Weights (w_e, w_f, w_p)	**E-WER** ↓
(1.0, 1.2, 0.6) reported	**11.40**
(1.0, 1.5, 0.6)	**11.40**
(1.0, 1.2, 0.3)	11.41
(1.5, 1.2, 0.6)	11.47
(1.0, 0.8, 0.6)	11.69

D Hypothesis Diversity

Table 12 quantifies the evidence that the alternative hypotheses carry, holding the Whisper-large-v3 1-Best fixed so that only the alternatives change. *Entity evidence only in alternatives* is the fraction of reference entity tokens that appear correctly in at least one alternative hypothesis but not in the 1-Best, that is, the evidence a 1-Best-only corrector cannot see. *Segments carrying such evidence* is the fraction of segments containing at least one such token. *Entity coverage* is the fraction of reference entity tokens present in at least one supplied hypothesis, and the column reports its increase from $N = 1$ to $N = 5$. Independent recognizers supply roughly three to four times the recoverable evidence of temperature sampling, which is the ceiling any fusion strategy operates under and explains the gap between Table 2 and Table 5.

Table 12: Entity evidence available in the alternative hypotheses, Earnings-21, with the Whisper-large-v3 1-Best held fixed.

	Temperature sampling	**Five recognizers**
Entity evidence only in alternatives	4.90%	**16.94%**
Segments carrying such evidence	6.28%	**21.00%**
Entity coverage, N=1 to N=5	+5.15%	**+20.40%**

E Entity-list Coverage and Noise

This section details how the degraded and noisy lists of Table 6 were built.

List construction. The starting point is the 1,013-phrase oracle entity list released with Earnings-21 (Del Rio et al., 2021). The degraded lists retain the stated fraction of entities under a single fixed random seed, and removal targets entities that actually occur in the references, so that each condition is a genuine loss of recoverable corrections rather than the removal of phrases the retriever would never have surfaced. The noisy condition uses the published distractor list of Fox and Delworth (2022) as released: it keeps all 1,013 oracle phrases and adds 769 in-domain company and executive names that do *not* occur in Earnings-21, giving 1,782 entries. In-domain confusable distractors are a harder test than random out-of-domain strings, which the retriever would rank below any hypothesis-matching phrase. Retrieval, prompts, guardrail and critic are unchanged across all conditions. E-WER is always computed against the full reference entity set, so a phrase removed from the list still counts against the system when it is missed.

F Cost and Latency

Table 9 in Section 5.7 gives cost and latency for the main configurations. Two further measurements, taken the same way: RECOVER *without* the feedback round on GPT-4o uses 2.00 calls and 3,979 + 327 tokens per segment at USD 12.94 per 1,000 segments, so the feedback round accounts for 0.11 calls and about 5% of cost, and the single-pass entity-list corrector costs USD 5.01 per 1,000 segments on GPT-4o (1,222 + 196 tokens, 3.66 s) against USD 0.29 on GPT-4o-mini.

G Open-weight Correctors

Table 13 runs the RECOVER pipeline, retriever, and prompts unchanged with two open-weight

models as both corrector and critic, served through OpenRouter (OpenRouter, 2025). Llama-3.3-70B sits between GPT-4o-mini and GPT-4o on accuracy and Mixtral-8x22B is level with GPT-4o-mini, so the framework does not depend on a proprietary model, although the strongest result still comes from the strongest LLM.

Table 13: Corrector and critic LLM on Earnings-21 (Whisper-large-v3, LLM-Select), with RECOVER otherwise unchanged. Cost and latency are measured as in Table 9.

LLM	WER	E-WER	RWERR	calls	USD/1k	med. s
No correction (baseline)	12.34	15.88	–	–	–	–
GPT-4o	12.39	**9.76**	**38.5**	2.11	13.57	6.14
GPT-4o-mini	12.48	11.40	28.2	2.35	0.84	5.57
Llama-3.3-70B	12.50	11.12	30.0	2.20	**0.60**	10.89
Mixtral-8x22B	12.51	11.42	28.1	2.34	12.51	**4.32**

Costs for the open-weight models use OpenRouter list prices at the time of writing (Llama-3.3-70B USD 0.10 / USD 0.32 and Mixtral-8x22B USD 2.00 / USD 6.00 per million prompt / completion tokens) and are hosted-inference prices, not the cost of self-hosting. Read together with accuracy, Llama-3.3-70B is the best cost-for-quality point we measured: cheaper than GPT-4o-mini (USD 0.60 against USD 0.84 per 1,000 segments) and better on entities (11.12 against 11.40 E-WER), at roughly twice the latency (10.89 s against 5.57 s), which is a reasonable trade in a batch setting and a poor one in a streaming setting. Mixtral is the fastest configuration but at current hosted prices costs almost as much as GPT-4o for a worse result. Both open-weight models emit close to twice the completion tokens of the GPT models (529–540 against 277–333), which is where their latency goes. For reference on the single-pass side, the entity-list prompt of Table 9 costs USD 5.01 per 1,000 segments on GPT-4o (1,222 + 196 tokens, 3.66 s) against USD 0.29 on GPT-4o-mini. Tokens per segment are 4,283 + 540 for Llama-3.3-70B and 4,669 + 529 for Mixtral-8x22B.

H Adaptive Routing Analysis

The Adaptive Routing configuration uses the LLM-as-router to pick one fusion strategy per segment from the inter-hypothesis agreement and the per-variant entity-hit counts. Table 14 reports how often each strategy is selected across all segments of each dataset (Whisper-large-v3, GPT-4o). The router overwhelmingly chooses Entity-Aware Select (60–97% of segments) and selects LLM-Select on under 8% of segments, even though LLM-Select is the strongest fixed strategy in Table 2. This explains why adaptive routing does not improve over a fixed LLM-Select. This likely needs richer routing signals or a trained router, which we leave to future work.

Table 14: Adaptive Routing: number of segments assigned to each fusion strategy by the LLM router (Whisper-large-v3, GPT-4o).

Dataset	Entity-Aware Select	ROVER Ensemble	LLM-Select	1-Best
Earnings-21	1,745	252	89	0
ATCO2	337	172	43	8
Eka-Medical	2,953	637	29	0
Common Voice	15,909	426	66	0
ContextASR-Bench	4,524	369	380	0

Table 15: Effect of disabling the critic and feedback on Earnings-21 (Whisper-large-v3, GPT-4o, LLM-Select). All values in %.

System	WER	E-WER	RWERR	P	R	F1
Baseline	12.34	15.88	–	92.73	78.95	85.29
LLM-Select (w/ critic+fb)	12.39	9.76	38.5	89.82	87.36	88.57
w/o critic+fb	12.40	10.2	36.0	89.6	87.0	88.3

I Effect of the Critic and Feedback on Overall WER

The feedback fires on few segments and the critic rejects only a small number of edits with the critic and feedback disabled, keeping only the deterministic guardrail. On Earnings-21 (Whisper-large-v3, GPT-4o, LLM-Select) the critic rejects 112 edits and feedback adds a correction on about 1.2% of the 2,086 segments (i.e., 25 segments). The overall WER changes by +0.01 pp (12.39 to 12.40), which is negligible and still close to the 12.34 baseline. The change is a little more visible, with E-WER rising from 9.76 to about 10.2 (RWERR 38.5 to about 36) and F1 falling from 88.57 to about 88.3 (Table 15). The critic and feedback therefore mainly improve entity precision and recall rather than overall transcript quality.

From Text to Alpha: Can LLMs Track Evolving Signals in Corporate Disclosures?

Chanyeol Choi[1]*, Yoon Kim[2], Yu Yu[3], Young Cha[4], V. Zach Golkhou[5], Igor Halperin[6], Georgios Papaioannou[7], Minkyu Kim[8], Zhangyang Wang[9], Jihoon Kwon[1], Minjae Kim[1], Alejandro Lopez-Lira[10], Yongjae Lee[1, 11]

Abstract

Natural language processing (NLP) has been widely used in quantitative finance, but traditional methods often struggle to capture rich narratives in textual data, leaving potentially informative signals under-explored. Large language models (LLMs) offer a promising alternative as they are able to extract nuanced semantics. In this paper, we ask whether semantic signals extracted by LLMs from corporate disclosures predict abnormal returns (alpha) beyond broad market movements and common risk factors. We introduce a simple framework, *LLM as extractor, embedding as ruler*, which extracts context-aware, metric-focused textual spans and quantifies semantic changes across consecutive disclosure periods using embedding similarity. This allows us to measure the degree of metric shifting – how much firms move away from previously emphasized metrics, referred to as moving targets. In portfolio and cross-sectional regression tests against a recent traditional baseline, our method yields a moving-targets signal that delivers significant risk-adjusted alpha. Qualitative analysis suggests that these gains stem from preserving contextual qualifiers and filtering out non-metric terms that traditional approaches often miss.

1 Introduction

Natural language processing (NLP) has been widely adopted for quantitative investment in finance due to its ability to identify complex patterns and relationships in financial text (Li et al., 2023; Lee et al., 2024; Cao et al., 2025). Traditional approaches based on named entity recognition (NER) and text classification have been shown to extract alpha from financial text (Frankel et al., 1999; Tetlock, 2007; Matsumoto et al., 2011; Loughran and McDonald, 2011, 2016). In this context, alpha refers to abnormal returns that are not explained by broad market movements or common risk factors. However, these methods often struggle to capture rich semantics and nuanced sentiment in corporate disclosures, leaving potentially informative signals under-explored. Large language models (LLMs) have emerged as a promising alternative because they can extract subtle meaning and contextual qualifiers that traditional pipelines tend to miss (Chen et al., 2022; Lopez-Lira and Tang, 2023; Guo and Hauptmann, 2024).

In this paper, we ask a concrete question: do semantic signals extracted by LLMs from corporate disclosures predict alpha? We address this question by quantifying semantic changes across disclosures over time, focusing on how firms shift the performance metrics they emphasize across consecutive disclosure periods. To this end, we introduce a simple and general framework, *LLM as extractor, embedding as ruler*. The two components address complementary challenges. First, we use an LLM to extract metrics from each disclosure, preserving contextual qualifiers that NER-based approaches often collapse. Second, we compare extracted metrics across periods using embedding-based semantic similarity, which can identify equivalent metrics expressed differently. This similarity serves as a ruler for measuring how the underlying metrics evolve over time.

To validate our framework, we compare against the recent baseline proposed by Cohen and Nguyen (2024). That work introduces an NER-based metric called *moving targets*, which captures how firms strategically shift the performance metrics they highlight across disclosures. Such metric shifting has been shown to contain predictive information about future stock returns. Using an LLM-based analogue of moving targets derived from our framework, we conduct experiments in a realistic setting and show that our approach captures information that traditional NER-based methods fail to quantify,

leading to improved prediction of excess returns.

Our empirical evaluation follows two standard protocols in empirical finance. First, we construct portfolios that buy shares with low metric shifting and sell shares with high metric shifting, motivated by prior evidence that greater metric shifting predicts lower future returns. We then measure portfolio performance after controlling for common market factors (Fama and French, 2015). Our method achieves a significant risk-adjusted alpha, whereas the NER-based baseline does not exhibit significant alpha in any specification. Second, we evaluate return predictability using cross-sectional regressions of next-month stock returns (Fama and MacBeth, 1973). In the regressions, the moving targets score derived from our method significantly predicts next-month returns on the broader 500-firm sample. In addition, qualitative analysis indicates that these improvements stem from capturing semantic equivalence and contextual qualifiers that keyword-based approaches often overlook. Together, these results demonstrate that LLMs provide a robust mechanism for tracking evolving signals in corporate disclosures and for predicting abnormal returns.

2 Related Work

Financial LLMs. Recently, domain-adapted pretrained language models and LLMs have demonstrated performance gains on standard financial NLP tasks (Kaur et al., 2023; Du et al., 2024). Early work focused on further pre-training or fine-tuning BERT-based models on financial text (Araci, 2019; Liu et al., 2021). Subsequent efforts expanded to large-scale finance-specific LLMs, enabling broader applications to complex financial NLP tasks including question answering (Liu et al., 2023; Wu et al., 2023; Islam et al., 2023). A parallel line of work explores instruction-tuning approaches that evaluate multi-task and zero-shot generalization (Xie et al., 2023; Zhang et al., 2023).

Text Analysis on Financial Text. A large body of research in finance has shown that financial text contains information predictive of future stock returns (Tetlock, 2007; Loughran and McDonald, 2011, 2016). In particular, earnings calls have received attention as a primary channel through which managers communicate firm performance (Frankel et al., 1999; Matsumoto et al., 2011). Studies analyzing individual call transcripts have shown that managerial language – such as tone or readability – can predicts excess returns (Price et al., 2012; Mayew and Venkatachalam, 2012; Fu et al., 2021). More recent work shifts focus from analyzing individual documents to examining changes in content across earnings call transcripts (Cohen and Nguyen, 2024), showing that textual modifications over time carry incremental information for return predictability.

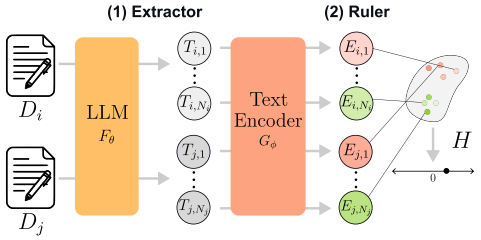

Figure 1: Overview of our framework, *LLM as extractor, embedding as ruler*. Given two documents D_i and D_j from different time periods, an LLM F_θ first acts as an *extractor*, identifying context-aware contents from each document. A pretrained text encoder G_ϕ then serves as a *ruler*, mapping extracted contents into a shared embedding space and measuring their semantic similarity to quantify how extracted contents persistence, disappearance, and emergence.

In parallel, a growing literature explores the use of LLMs in finance, applying LLMs to news articles, annual reports, and earnings call transcript to improve return prediction and portfolio performance (Chen et al., 2022; Lopez-Lira and Tang, 2023; Guo and Hauptmann, 2024; Magner et al., 2025). However, existing studies have primarily validated LLMs on single-document tasks; their effectiveness in tracking semantic changes across documents over time remains unexplored.

3 Backgrounds

Earnings Calls and Performance Metrics. Publicly traded companies hold quarterly earnings conference calls to discuss financial results with analysts and investors (Tasker, 1998). These calls typically consist of two parts: a presentation by management summarizing the quarter's performance, followed by a question-and-answer session with analysts (Frankel et al., 1999). During these calls, managers highlight specific metrics – quantitative measures such as revenue or product-specific figures – to frame the firm's progress. Because these metrics are chosen by management rather than externally mandated, managers have discretion over which metrics to emphasize and how prominently to feature them (Price et al., 2012).

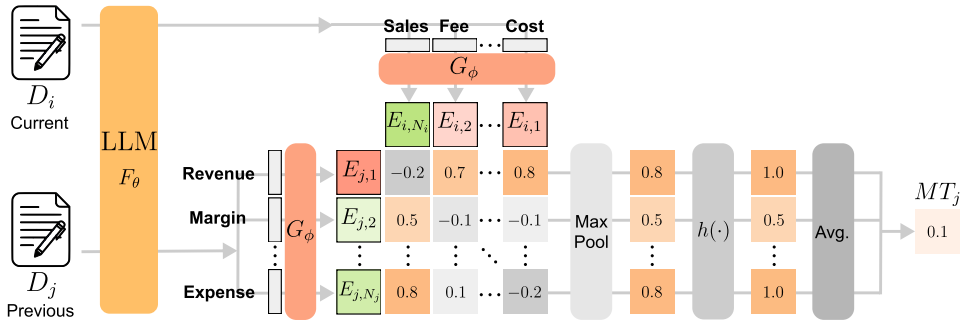

Figure 2: Illustration of the scoring pipeline using embedding similarity. Suppose that two sets of metrics have already been extracted from two transcripts D_i (current) and D_j (previous). First, we encode each metric into a shared embedding space using a pre-trained text encoder G_ϕ, obtaining embeddings $\boldsymbol{E}_{i,n_i}$ and $\boldsymbol{E}_{j,n_j}$ for quarter indices i and j. For each metric $\boldsymbol{E}_{j,n_j}$, we then compute its maximum cosine similarity $\hat{S}_{n_j}$ to any metric at quarter i, which tests whether a semantically corresponding metric is still present. Next, we apply thresholding $h(\cdot)$ to suppress weak matches and treat only sufficiently similar pairs as retained. Finally, we aggregate these similarities using an averaging operator, quantifying the fraction of previously discussed metrics that are no longer emphasized.

Moving Targets. Cohen and Nguyen (2024) document that managers strategically shift their emphasis on metrics over time. When a previously highlighted metric becomes difficult to sustain – for example, when sales growth stalls – managers often pivot to emphasizing different metrics, such as cost savings or inventories. This phenomenon, termed *moving targets*, is formally measured as the fraction of previously discussed metrics that are absent in the current period. In their approach, metrics are extracted using spaCy (Honnibal, 2017) NER and compared across periods via rule-based matching; we refer to this as the *NER-based* method.

Following their definition, we refer to this measure as the moving targets (MT) score, computed as

$$\mathrm{MT}_i = \frac{\sum(\text{Missing Metrics}_i \mid \text{Metrics}_{i-4})}{\sum \text{Metrics}_{i-4}} \quad (1)$$

where i indexes the fiscal quarter, Metrics_i is the set of performance metrics mentioned in quarter i, and $i-4$ refers to the same fiscal quarter one year prior (e.g., Q1 2024 vs. Q1 2023). Missing Metrics_i denotes metrics that were mentioned in $i-4$ but are absent in i. Higher values indicate greater departure from previously emphasized metrics.

4 Method

To test whether LLMs can better capture the moving targets, we employ the *LLM as extractor, embedding as ruler* framework. Fig. 1 shows the overall pipeline. The LLM serves as an *extractor* that identifies metrics from transcripts while preserving contextual qualifiers. The embedding model serves as a *ruler* that measures semantic distance between metrics across periods, enabling comparison even when equivalent metrics are expressed differently.

Extractor: Metric Extraction. Let D_i denote the earnings call transcript of a firm at quarter index i. We extract performance metrics using a pre-trained LLM F_θ: given a task-specific prompt and the entire transcript D_i as input, the model outputs a set of mentioned metrics. We denote the obtained set as $\mathcal{T}_i = \{T_{i,1}, \ldots, T_{i,N_i}\}$, where N_i denotes the number of metrics extracted from quarter i. Unlike NER-based approaches that often extract only generic terms, the LLM can capture metrics expressed through complex phrases while preserving contextual qualifiers (e.g., "North America cloud revenue" rather than just "revenue").

Ruler: Semantic Similarity Scoring. The original moving targets score counts the fraction of metrics from $j = i-4$ that are absent at i via keyword matching. However, this fails when semantically equivalent metrics are expressed differently across quarters (e.g., "sales growth" vs. "revenue increase"). To address this, we use embeddings as a ruler to measure semantic distance. We illustrate the concept of our framework in Fig. 2.

We encode each extracted metric using a pre-trained text encoder G_ϕ, obtaining embeddings $\boldsymbol{E}_{i,n_i} = G_\phi(T_{i,n_i}) \in \mathbb{R}^d$. For each previous metric T_{j,n_j} and its embedding $\boldsymbol{E}_{j,n_j}$, we compute its maximum cosine similarity to any current metric:

$$\hat{S}_{n_j} = \max_{n_i} \cos(\boldsymbol{E}_{i,n_i}, \boldsymbol{E}_{j,n_j}) \quad (2)$$

Note that raw cosine similarity does not directly correspond to semantic equivalence: pairs below a certain threshold are effectively dissimilar, while pairs above another threshold are highly similar. To reflect this, we apply a piecewise-linear trans-

formation $h(\cdot)$:

$$S_{n_j} = h(\hat{S}_{n_j}) = \begin{cases} 0 & \text{if } \hat{S}_{n_j} \leq \alpha \\ \frac{\hat{S}_{n_j} - \alpha}{\beta - \alpha} & \text{if } \alpha < \hat{S}_{n_j} < \beta \\ 1 & \text{if } \hat{S}_{n_j} \geq \beta \end{cases} \quad (3)$$

This maps low similarities to 0 (dropped) and high similarities to 1 (retained), reducing noise from ambiguous middle-range scores.

Finally, the embedding-based MT score is defined as:

$$MT_i = 1 - \frac{1}{N_j} \sum_{n_j=1}^{N_j} S_{n_j} \quad (4)$$

Since $S_{n_j} \approx 1$ when a metric is retained and $S_{n_j} \approx 0$ when dropped, this formulation yields the fraction of metrics that are absent – matching the original definition. We refer to this approach as the *LLM-based* method. We provide a running example in Appendix A that walks through this pipeline end-to-end on an actual pair of consecutive earnings calls.

5 Experiments

In this section, we empirically evaluate whether LLM-based method of moving targets leads to better prediction of excess returns. Sec. 5.1 documents our experimental setup. Sec. 5.2 describes the results. Codes are available at this GitHub repository.

5.1 Experimental Setup

Data. Our experimental setup follows Cohen and Nguyen (2024). The primary sample covers firms in the S&P 100 index from January 2010 to December 2024, yielding 5,615 firm-quarter observations across 64 quarters; we focus on this universe because LLM-based extraction over full earnings-call transcripts is computationally costly. To verify that our findings are not an artifact of this choice, we replicate the entire pipeline on a broader sample of the firms in the S&P 500.

Evaluation Protocols. To assess whether the moving targets scores carry economically meaningful predictive power, we adopt the evaluation framework of Cohen and Nguyen (2024), which consists of two complementary analyses.

First, we construct a portfolio strategy based on the moving targets score and compare portfolio returns. Following Cohen and Nguyen (2024), we sort firms into quintiles based on their most recent moving targets score and form equal-weighted portfolios. Q1 contains firms with the lowest scores, while Q5 contains firms with the highest scores. We then compute the return spread between Q5 and Q1. A significantly negative Q5–Q1 spread indicates that firms dropping more targets subsequently underperform. To account for other factors that may drive returns, we report risk-adjusted alphas using the Fama–French three-factor and five-factor models (Fama and French, 1993, 2015).

Second, we test whether the moving targets score significantly predicts next-month stock returns using Fama-MacBeth cross-sectional regressions (Fama and MacBeth, 1973), a standard protocol in empirical finance for testing whether a variable predicts future returns. Each month, we regress individual stock returns on the moving targets score and control variables. We then average the monthly coefficient estimates across time. A significantly negative coefficient on the moving targets score indicates that more target shifting predicts lower subsequent returns.

Table 1: Statistics of dataset. We use earnings call transcripts from firms listed in S&P 100 index, spanning January 2010 to December 2024.

Statistic	Value
Sample period	Jan. 2010 – Dec. 2024
Number of quarters	64
Number of firms	100
Firm-quarter observations	5,615
Returns observations	16,675

Table 2: Comparison of the top 10 most frequent missing targets extracted by the *NER-based* and *LLM-based* methods.

NER-based Method			LLM-based Method		
Rank	Target	Frequency	Rank	Target	Frequency
1	the %	4460	1	market share	706
2	a % increase	3845	2	share repurchases	589
3	the range	3474	3	revenue growth	582
4	% growth	3456	4	pricing	562
5	q3	3006	5	cash flow	535
6	q4	2853	6	quarterly revenue growth	517
7	the % range	2801	7	yearly guidance	484
8	year	2716	8	free cash flow	480
9	the quarter	2499	9	dividend	458
10	share	2400	10	quarterly earnings per share	455

5.2 Results

NER and LLM extract qualitatively different metrics at the aggregate level. Tab. 2 compares the top 10 most frequent missing targets extracted by each method. The NER-based method predominantly captures surface-level patterns such as "the %", "a % increase", and "the range", which lack context and do not correspond to meaningful performance metrics. In contrast, the LLM-based method extracts concrete business metrics such as "market share", "revenue growth", "cash flow", and "free cash flow" – terms that align with the definition

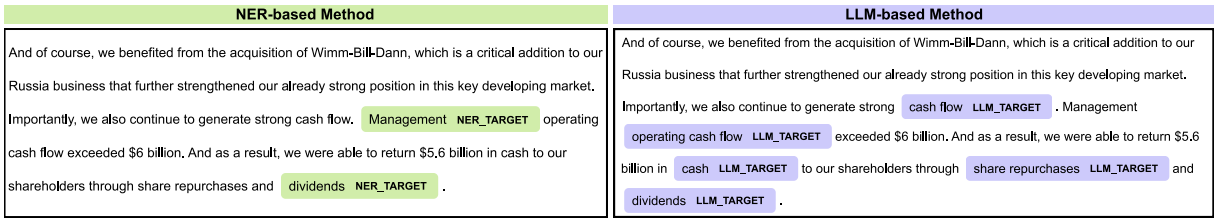

Figure 3: Comparison of extracted metrics between NER-based and LLM-based methods on a PepsiCo Q4 2011 earnings call transcript. The panel shows the same transcript excerpt with NER extractions (**left**) and LLM extractions (**right**). **Green** highlights indicate NER-extracted terms; **purple** highlights indicate LLM-extracted metrics. Given the same passage discussing cash flow performance, NER extracts only "Management" and "dividends", missing the key financial metrics mentioned. In contrast, LLM correctly identifies "cash flow", "operating cash flow", "cash", "share repurchases", and "dividends".

Table 3: Calendar-time portfolio excess returns and 3-factor / 5-factor alphas based on *Moving Targets*. (A) reports results using the NER-based extraction method, while (B) reports results using the LLM-based extraction method. t-statistics are in parentheses. *, **, and *** indicate significance at the 10%, 5%, and 1% levels, respectively.

	Q1	Q2	Q3	Q4	Q5	Q5–Q1
(A) *NER-based method*						
Excess Return	0.0156*** (4.38)	0.0131*** (3.85)	0.0111*** (3.19)	0.0132*** (3.99)	0.0135*** (3.94)	-0.0031 (-1.48)
3-Factor Alpha	0.0047*** (3.43)	0.0027** (2.12)	0.0017 (1.15)	0.0040*** (2.88)	0.0039** (2.47)	-0.0018 (-0.89)
5-Factor Alpha	0.0045*** (3.26)	0.0028** (2.19)	0.0016 (1.07)	0.0040*** (2.79)	0.0041** (2.54)	-0.0014 (-0.70)
(B) *LLM-based method*						
Excess Return	0.0148*** (4.75)	0.0131*** (3.84)	0.0128*** (3.60)	0.0132*** (3.65)	0.0117*** (3.50)	**-0.0041**** (-2.08)
3-Factor Alpha	0.0056*** (3.89)	0.0036*** (2.63)	0.0024* (1.89)	0.0029* (1.91)	0.0018 (1.22)	**-0.0048**** (-2.40)
5-Factor Alpha	0.0055*** (3.71)	0.0038*** (2.78)	0.0026** (2.02)	0.0032** (2.02)	0.0013 (0.87)	**-0.0052**** (-2.55)

of forward-looking performance indicators. This difference suggests that LLM-based extraction better leverages contextual understanding to identify targets that reflect genuine strategic emphasis.

Individual examples confirm that LLM captures metrics NER misses. Fig. 3 illustrates a representative example from an earnings call transcript. Given the same passage discussing cash flow performance, the NER-based method extracts only "Management" and "dividends", missing the key financial metrics mentioned. The LLM-based method correctly identifies "cash flow", "operating cash flow", "cash", "share repurchases", and "dividends" – metrics that also appear among the most frequent targets in Tab. 2. This demonstrates that the LLM's ability to capture contextually meaningful metrics at the individual level translates to more informative signals at the aggregate level.

LLM-based method yields stronger portfolio returns than the NER-based baseline. Tab. 3 presents calendar-time portfolio excess returns and alphas sorted by the moving targets score. Panel (A) shows that the NER-based method exhibits a negative Q5–Q1 spread: excess return of -0.31% ($t = -1.48$), 3-factor alpha of -0.18% ($t = -0.89$), and 5-factor alpha of -0.14% ($t = -0.70$). In contrast, Panel (B) shows that the LLM-based method yields a significantly negative spread: excess return of -0.41% ($t = -2.08$), 3-factor alpha of -0.48% ($t = -2.40$), and 5-factor alpha of -0.52% ($t = -2.55$)[1], all significant at the 5% level. This indicates that firms with high target shifting reliably underperform those with low target shifting. The stronger predictability suggests that LLM-based extraction captures semantically meaningful changes that the NER-based approach misses. We note that the direct monthly difference between the two Q5-Q1 series (LLM minus NER) is not itself statistically significant ($t = -1.15$); the contribution is thus not that the LLM signal beats the NER signal head-to-head, but that the LLM signal survives standard asset-pricing tests

[1] Alphas are reported before transaction costs. Given the strategy's one-way turnover of 26–28% per leg per month, about 80% of the gross alpha would be realized at costs realistic for S&P 100 mega-caps (10 bps per dollar traded), and roughly half at 25 bps.

Table 4: Fama–MacBeth regressions of individual firm-level stock returns on *Moving Targets* and standard return predictors. (A) reports results using the NER-based extraction method, while (B) reports results using the LLM-based extraction method. We include standard controls for known return predictors: Log(Size), Log(BM), Ret(-1,0), and Ret(-12,-1). t-statistics are shown in parentheses.

	(A) *NER-based method*	(B) *LLM-based method*

N	5,615	5,615

where the NER signal does not.

LLM-based method shows better predictive power in cross-sectional regressions. Tab. 4 reports Fama-MacBeth regression results testing whether the moving targets score predicts next-month stock returns. Column (A) shows that the NER-based method rather yields a positive coefficient on the moving targets score, suggesting no reliable predictive relationship. In contrast, Column (B) shows that the LLM-based method produces a negative coefficient of -0.0370, though not statistically significant on this sample ($t = -0.95$); the primary cross-section averages only $\sim$34 firms per month, limiting the power of this test. The coefficient becomes significant on the broader 500-firm sample (Tab. 5 below), consistent with the portfolio analysis.

Results generalize beyond specific firms and model choices. Tab. 5 examines whether our findings are tied to the S&P 100 universe or to a particular model configuration. The LLM-based method continues to deliver a significantly negative Q5–Q1 spread, with an excess return of -0.24% ($t = -2.53$), a 3-factor alpha of -0.36% ($t = -2.56$), and a 5-factor alpha of -0.44% ($t = -2.44$), whereas the NER-based baseline remains insignificant in every specification. The

Table 5: Extended results tested on a broader sample of 500 U.S. public firms, using a different LLM (`GPT-5.4`) and embedding model (`text-embedding-3-small`). Panel A reports the Fama–MacBeth coefficient on the MT score with full controls; Panel B reports monthly returns and alphas of the equal-weighted Q5−Q1 long-short portfolio. t-statistics in parentheses; $^{**}p < 0.05$.

	NER-based method	*LLM-based method*
Panel A: Fama–MacBeth regression		
MT coefficient	-0.0108^{**}	**-0.0326****
	(-2.20)	(-2.35)
Panel B: Calendar-time portfolio (Q5−Q1)		
Excess return	-0.0008	**-0.0024****
	(-0.41)	(-2.53)
3-factor α	-0.0012	**-0.0036****
	(-0.64)	(-2.56)
5-factor α	-0.0014	**-0.0044****
	(-0.72)	(-2.44)

Table 6: Ablation study isolating the source of the gains tested on the S&P 100 firms. Each row varies only the extractor (NER vs. LLM) and the matcher (rule-based vs. embedding), holding the embedding ruler, sample, and evaluation pipeline fixed. Cells report monthly returns and alphas of the equal-weighted Q5−Q1 long-short portfolio. t-statistics in parentheses; $^{**}p < 0.05$.

Extractor	Ruler	Excess ret.	3-Factor α	5-Factor α
NER	String	-0.0031	-0.0018	-0.0014
		(-1.48)	(-0.89)	(-0.70)
NER	Embedding	-0.0009	-0.0022	-0.0024
		(-0.44)	(-1.12)	(-1.20)
LLM	String	-0.0022	-0.0005	-0.0001
		(-1.03)	(-0.24)	(-0.04)
LLM	Embedding	**-0.0041****	**-0.0048****	**-0.0052****
		(-2.08)	(-2.40)	(-2.55)

Fama-MacBeth regressions show the same pattern: the LLM-based score yields a larger and significant coefficient (-0.0326, $t = -2.35$) than the NER-based score (-0.0108, $t = -2.20$), and the larger sample sharpens statistical significance overall. These results indicate that our findings are not an artifact of the firm universe, the choice of LLM, or the embedding model.

The gains originate from the LLM extractor. Our method differs from the NER-based baseline along two dimensions – the extractor (LLM vs. NER) and the matcher (embedding vs. string matching). Thus, we run an ablation that varies each component in isolation, holding the sample, embedding ruler, and evaluation pipeline fixed (Tab. 6). Pairing the NER extractor with the embedding matcher moves the Q5–Q1 5-factor alpha only partway toward our method (-0.24%, $t = -1.20$) and fails to reach significance, remaining closer to the NER-with-string-matching baseline (-0.14%, $t = -0.70$) than to the LLM-based method (-0.52%, $t = -2.55$). This is consistent

with the qualitative evidence in Tab. 2, as the NER method extracts noisy, context-free spans, and a softer matching criterion cannot recover a persistent signal from targets that are not informative enough to begin with.

6 Conclusion

This study investigated whether LLMs can effectively track evolving signals in corporate disclosures by comparing an LLM-based framework against a NER-based baseline on the moving targets phenomenon. Our results show that LLM-based extraction combined with semantic similarity yields stronger return predictability. Our findings support the view that LLMs can capture meaning beyond surface-level wording, offering a more robust approach to quantifying semantic changes in financial text.

Limitations

We restrict the sample of our primary analysis to S&P 100 firms due to computational costs. Extending the analysis to a broader set of firms, particularly smaller firms with different disclosure practices, would be a valuable direction for future work. In addition, our framework depends on the quality of LLM extraction and embedding models; evaluating across different size of model choices or open-sourced models would help verify robustness. Lastly, we demonstrate predictive gains but do not investigate why LLM-based tracking better captures return-relevant information; understanding the underlying economic mechanisms is a valuable direction for future work. Our extractors are recent LLMs applied to 2010–2024 transcripts, raising a potential memorization concern. We mitigate this by design – the LLM never observes returns or compares periods. We acknowledge that memorization cannot be fully ruled out; re-extraction on anonymized transcripts is left to future work.

Table 7: LLM prompt templates used in our method to extraction of targets. Note that the terms *label* and *target* are used in the prompt to refer to what we denote as *metrics* in the main text.

System Prompt

<task>
From the provided inputs, extract all performance metric and target labels
and classify them into two separate lists according to the section
in which they were mentioned:
– presentation: items mentioned in the prepared presentation or opening remarks
– analyst_qa: items mentioned during analyst question and answer sessions
The term "performance metric and target labels" includes every explicitly stated
financial result, non–financial result, and key business indicator discussed or mentioned. Both GAAP and non–GAAP labels if explicitly distinguished.
Section classification
– presentation: items mentioned in prepared remarks/opening statements before Q&A begins.
Typical speakers: executives with "– Executives" in the name, before the first analyst question.
– analyst_qa: items mentioned during the Q&A (analyst questions and executive answers after Q&A starts).
Q&A typically starts after an Operator prompt like "[Operator Instructions]" or when an analyst first speaks (speaker label contains "– Analysts") and continues until the call ends.
– Operator–only lines do not themselves contain items, but they can mark Q&A start.
– Include only labels explicitly stated in content
– Deduplicate near–duplicates to one normalized target per section
</task>
<inputs>earnings–call transcript as indexed JSON dialog</inputs>
<output>
– target:
– Short noun phrase only
– **Quarter results:** prefix with "Quarterly" and do NOT include any years or quarter numbers
– **Fiscal–year results:** prefix with "Yearly" and do NOT include any years
– **Guidance/targets/other indicators:** no period prefixes unless inherently part of the label; avoid dates, years, and quarter numbers
– No numbers, units, currency symbols, or percent signs anywhere
– Prefer consistent terminology across products/segments
– index: integer index of the utterance containing the quote
</output>
<format>
{{
"presentation": List[Dict],
"analyst_qa": List[Dict]
}}
The dictionary must follow the following structure:
{{
"target": str # Normalized short label for the metric/target according to the rules
"index": int # Zero–based index of the utterance in the transcript where the quote appears
}}
</format>

A Appendix

Implementation details. For our main analysis, we use `Gemini-2.5-Pro` for metric extraction and `text-embedding-3-large` for semantic comparison. For the additional experiments on the broader 500-firm sample, we instead use `GPT-5.4` for extraction and `text-embedding-3-small` for comparison, verifying that our findings do not depend on a specific model choice. We set $\alpha = 0.4$ and $\beta = 0.6$ for thresholding in Eq. 3: α is placed at the top of the similarity range observed for unrelated metric pairs and β at the bottom of the range for paraphrase pairs, so that $h(\cdot)$ zeroes out spurious matches and fully credits genuine ones (see Tab. 8 for illustrative pairs from each regime). The last part of this appendix reports sensitivity of the main results over the full (α, β) grid and a held-out selection protocol. Table 7 shows the full system prompt used to extract metrics in our proposed method.

Running Example We illustrate the full pipeline on the same PepsiCo call as Fig. 3. We take the LLM extractor's actual outputs for Q4 2010 (104 metrics) and Q4 2011 (121 metrics), compute each Q4 2010 metric's maximum cosine similarity among the Q4 2011 metrics (Eq. 2), and apply the thresholding $h(\cdot)$ of Eq. 3 with $(\alpha, \beta) = (0.4, 0.6)$. Tab. 8 shows representative rows from each regime of $h(\cdot)$.

Table 8: Running example: PepsiCo Q4 2010 metrics matched against Q4 2011 metrics. $\hat{S}_{n_j}$ is the maximum cosine similarity (defined in Eq. 2) and S_{n_j} its thresholded value (defined in Eq. 3) with $(\alpha, \beta) = (0.4, 0.6)$.

Regime	Q4 2010 metric	Best Q4 2011 match	$\hat{S}_{n_j}$	S_{n_j}
Retained via paraphrase	yearly core constant currency eps growth	core constant-currency eps growth	0.886	1.00
	yearly worldwide snacks volume	yearly snacks volume growth	0.866	1.00
	interest expense	net interest cost	0.647	1.00
Genuine drop	g series fit launch	new product sales	0.319	0.00
	sodium reduction in potato chips	global snacks results	0.364	0.00
Ambiguous middle zone	naked juice sales	liquid refreshment beverage market share	0.467	0.33
	wimm-bill-dann transaction eps impact	eps (usd basis)	0.518	0.59

Table 9: Q5-Q1 five-factor alpha (t-statistic) for each (α, β) pair; setup identical to Tab. 3. †Configuration used in the main text.

Threshold Sensitivity and Held-Out Selection Table 9 examines whether the main result is sensitive to the choice of thresholds. We re-estimate the Q5–Q1 five-factor alpha reported in Table 3 for every admissible (α, β) pair on the grid $\alpha \in \{0.2, 0.3, 0.4, 0.5\}$ and $\beta \in \{0.4, 0.5, 0.6, 0.7, 0.8\}$, subject to $\alpha < \beta$. The result is remarkably stable: all 17 specifications produce negative alphas, and 15 are statistically significant at the 5% level. The only two insignificant estimates occur when $\beta = 0.4$. At this low upper threshold, nearly every metric is classified as retained (the mean score exceeds 0.97), leaving little cross-sectional variation with which to distinguish firms. The baseline choice of $(\alpha, \beta) = (0.4, 0.6)$ is therefore conservative rather than result-maximizing. Raising the upper threshold to 0.7, for example, strengthens the Q5–Q1 alpha to -0.65% per month ($t = -3.16$). Thus, the main finding is not specific to a particular threshold choice but persists across a broad range of economically reasonable parameterizations.

We further address the possibility that the result reflects in-sample threshold selection. Using only portfolio returns through December 2016, we select the (α, β) pair with the most negative alpha t-statistic and then evaluate that choice exclusively over 2017–2024. This procedure selects $(0.3, 0.7)$ and yields a held-out five-factor alpha of -0.66% per month ($t = -2.36$). Importantly, the paper's baseline specification, $(0.4, 0.6)$, also performs similarly over the same held-out period, producing an alpha of -0.57% per month ($t = -2.04$). These results indicate that the main finding is not an artifact of ex post threshold tuning and remains economically and statistically meaningful out of sample.

ChemCLIR-Bench: Benchmarking Cross-Lingual Information Retrieval in Multilingual Chemical Patents

Abstract

Cross-lingual information retrieval (CLIR) is increasingly important in multi-national industries, where critical technical evidence may exist in a different language than the query. However, existing benchmarks do not adequately capture domain-specific cross-lingual retrieval or the retrieval-depth and recoverability failures that aggregate recall hides. In this work, we benchmark CLIR in the chemical domain, with a focus on patent data. We construct a multilingual dataset from Google Patents and the European Patent Office (EPO) data, spanning five languages (covering major Eastern and Western languages) and reflecting the diversity and complexity of real-world industrial documentation. Using this dataset, we systematically evaluate eight state-of-the-art embedding models for cross-lingual retrieval. Our results show a substantial performance gap between monolingual and cross-lingual settings: for the best-performing model, Recall@10 drops from 0.72 to 0.53 in cross-lingual setting. Retrieval depth also degrades significantly, with relevant documents ranked lower across languages in cross-lingual scenarios. Furthermore, some multilingual embedding models that perform strongly in monolingual settings exhibit sharp declines when queries and documents are in different languages, providing practical insights for model selection in cross-lingual use cases. These findings highlight critical limitations of current approaches and emphasize the need for more robust cross-lingual retrieval methods in domain-specific settings. Our benchmark provides actionable insights for model selection and establishes a controlled diagnostic evaluation framework for CLIR over industrial technical text. Data and code are publicly available here.

1 Introduction and Related Work

Cross-lingual information retrieval (CLIR) is increasingly critical in multi-national industrial environments, where proprietary technical data is distributed across multiple languages. In domains such as chemistry, relevant evidence for a given query may exist only in a different language, and retrieval failures can lead to missed prior art, incomplete regulatory analysis, or suboptimal technical decisions. These challenges are further amplified in agentic AI systems and retrieval-augmented generation (RAG) pipelines, where retrieval quality directly impacts downstream answer generation and reasoning (Kukreja et al., 2026).

Machine translation is commonly used to bridge language gaps. However, translation-based retrieval introduces additional computational cost and latency, and may not reliably preserve specialized terminology in technical domains. (Valentini et al., 2025; Kim et al., 2024). Recent advances in dense retrieval using multilingual embeddings (Wang et al., 2024; Feng et al., 2022) enable unified indexing across languages, but robust cross-lingual alignment remains a core challenge (Goworek et al., 2025a). Prior work shows that retrieval behavior is strongly influenced by alignment quality, translation effects, and same-language preference (Goworek et al., 2025b; Amiraz et al., 2025; Li et al., 2024; Liu et al., 2025; Ki et al., 2025). Consequently, aggregate metrics such as Recall@k may mask cross-lingual failures.

Existing benchmarks address related aspects of this problem. Multilingual retrieval benchmarks such as MMTEB, MIRACL, NeuCLIR, and CLIRMatrix provide broad multi-lingual and cross-language evaluation (Zhang et al., 2023; Lawrie et al., 2025; Enevoldsen et al., 2025; Sun and Duh, 2020). In parallel, chemistry-focused resources evaluate domain-specific capabilities in predominantly monolingual settings, including text embed-

ding and retrieval with ChemTEB and the ChemRxiv Retrieval benchmark, RAG with ChemLitQA, and compositional or multi-hop reasoning with ChemComp and ChemKGMultiHopQA (Kasmaee et al., 2024; Wellawatte et al., 2025; Khodadad et al., 2026; Astaraki et al., 2026; Kasmaee et al., 2025). However, these lines of work remain disconnected: multilingual benchmarks lack domain-specific technical grounding, and chemistry benchmarks do not evaluate cross-lingual retrieval. Appendix A.1 tabulates this comparison. Moreover, prior work does not systematically distinguish same-language and cross-language retrieval or capture deployment-relevant behaviours such as retrieval depth and recoverability.

To address these gaps, we introduce ChemCLIR-Bench, a benchmark for cross-lingual retrieval framed as patent-grounded parallel-document retrieval: a query must recover its source chemical patent in the query's language and in the patent's other language versions.. We construct two multilingual question–answer–context (QAC) datasets derived from Google Patents and the European Patent Office (EPO), spanning five languages. Patents provide naturally aligned, high-quality multilingual technical content, enabling controlled evaluation in realistic industrial settings. Our evaluation framework is designed to surface deployment-relevant failures by explicitly separating monolingual (MLIR) and cross-lingual (CLIR) retrieval, and by introducing diagnostic metrics that capture retrieval depth, reading cost, and re-ranking recoverability. We evaluate eight multilingual embedding models and show that cross-lingual retrieval remains a major bottleneck: all models exhibit a consistent drop in performance relative to monolingual retrieval, and many failures cannot be recovered by downstream re-ranking. Our contributions can be summarized as: (i) A multilingual benchmark for patent-grounded parallel-document retrieval over chemical patents. (ii) (ii) We propose a language-aware evaluation framework that goes beyond Recall@k and captures retrieval-depth and recoverability behaviour. (iii) We provide a systematic analysis showing that cross-lingual alignment, rather than overall retrieval capacity, is the primary limitation in current models.

2 QAC Generation Pipeline

Our pipeline turns multilingual chemistry patent text into question–answer–context (QAC) records for retrieval evaluation. It produces questions in five languages, designed for cross-lingual retrieval and kept close to what a practitioner would actually search, in both technical and general modes. Figure 1 summarizes the generation and evaluation flow.

Corpus and context construction. We build on two patent-derived corpora that contribute complementary kinds of multilinguality. *Google Patents* supplies scale and language breadth: 23,787 published applications, predominantly World Intellectual Property Office:WIPO (WO, 15,048) and European (EP, 4,610) filings, with a sizeable Mexican (MX, 3,952) share, spanning five languages (English, French, Spanish, German, Chinese), from which we take the title and abstract as the evidence block. The English, French, Spanish, and German text comes from the language-tagged `title_localized` and `abstract_localized` fields of the Google Patents Public Data table, whose schema describes them as publication text in each language; we do not use the machine-translated fields of the separate Google Patents Research dataset (Appendix A.4). Because the metadata does not establish whether every localized record was originally authored in its tagged language, we describe these records as language-tagged bibliographic patent text rather than as native or as machine-translated. The only translation step we introduce is for Chinese: coverage was zero, so we machine-translated 400 documents with GPT 5.5 to seed it, and a native-speaker audit of this subset is reported in Appendix A.3.1. *EPO* supplies clean cross-lingual parallelism: 11,315 granted B1 specifications, each published as a human-translated English/German/French triple (≈3,770 per language) with professionally translated first claims, which we add to the evidence block; we introduce no translations of our own on this side.

Query generation. For each source document we prompt `gpt-5-mini` to generate three candidate questions, each grounded completely by the passage. Table 1 provide an overview of the dataset and its statistics. Two choices shape the query distribution. First, the query *language*: the queries are generated in three set ups, where the question's *target language* is sampled per document relative to the languages that document exists in: (i) *random-existing*: picks a language the patent already has a version in, so the query has both a cross-lingual

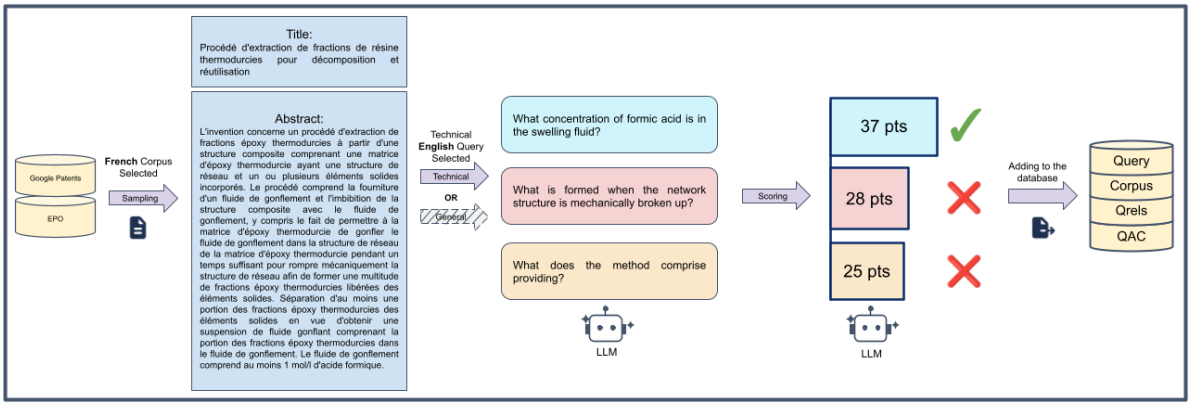

Figure 1: Overview of the QAC generation pipeline: source documents are converted into grounded candidate questions, scored, and exported as retrieval-ready records. The pipeline optimized with three rounds of domain expert feedback collection.

gold context and a same-language gold context; (ii) *random-missing*: picks a language it does *not* have a document in, yielding a pure cross-lingual "no-home" query, where no same-language gold-context is available for the query; and (iii) *all* generates the question in every 5 languages we targeted, independent of availability of the gold-context document in those languages. Second, each question is written in one of two *modes*: (i) *technical* questions ask for a single concrete fact, a parameter, a material, an outcome, method, or structural detail, answerable by the document, while (ii) *general* questions ask about the document's problem, approach, or application in deliberately paraphrased, low-overlap wording. The mode prompts are written in the target language to bring the generated questions closer to native quality. The prompts (English version) are available in Figures S.8 and S.9.

The three generated candidates per document for each query are scored not by the generator but by a separate verifier, `claude-sonnet-4.6`, which rates each candidate on multiple metrics around faithfulness and mode-specific quality; we keep the highest-scoring candidate per document as the selected query (more details on verifier prompts are available in Figures S.5–S.7). We then export the standard retrieval artifacts. In the process of query generation, the full generation pipeline benefited from three rounds of domain-expert annotation and feedback collection which significantly refined both the generation quality and the verifier prompts. In the final set of generated queries, the verifier was audited against human-annotation on a 106-sample subset of the queries using criteria that mirror the LLM rubric (see section A.3.1 for more details). This annotated subset corresponds to approximately 14.7% of all generated queries. In this evaluation, the human feedback's mean score was **8.40/10** (technical: **8.78**, general: **8.00**) and **no** query was rejected (none scored in the 0–3 band; see Figure S.2 for more details). Also, the agreement between LLM-verifier and human expert annotator is reported in A.3.1.

3 Evaluation Setup

We evaluate multilingual embedding models as drop-in dense retrievers, and design the setup to surface cross-lingual failure rather than average it away. Each query is judged against its source patent in both its own language and every other, separating same-language from cross-language relevance. We report a metric family that places capability, cross-linguality, and deployment cost side by side, and run it over a fixed set of eight models against

Source	Corpus	Queries	Qrels	Cross-lang qrels	Q tokens	Q vocab	C tokens	C vocab
Google Patents	23,787	524	1,284	1,023	11.3 ± 6.3	2,742	145.0 ± 63.8	83,333
EPO	11,315	198	594	396	14.1 ± 5.4	1,371	178.2 ± 71.1	72,256

Table 1: Statistics of the two released benchmarks. A corpus document (C) is a title plus abstract (Google Patents) or title, abstract, and first claim (EPO) in one language; Q denotes queries. Token columns give the mean ± standard deviation per query or per document; vocabulary columns give the number of distinct case-folded tokens over all queries or all documents of a benchmark, pooled across languages.

Table 2: Retrieval performance (Recall@10) on both patent datasets, split by language route: R@10$_{\text{same}}$ is same-language (monolingual) and R@10$_{\text{cross}}$ is cross-language, each language-balanced. The k columns are right-censored 80th-percentile retrieval depths (lower is better; $\pm$ values are bootstrap standard errors over queries, 2000 resamples; omitted where the depth is censored at >1000). Best per column in bold. Size is total parameters.

the shared multilingual corpus.

Same- vs. cross-language relevance. A query is relevant to its source patent in every language that patent exists in, so we split each judgment into same-language relevance and cross-language relevance (a foreign-language version to the query). Some queries have no same-language gold at all, a built-in "no-home" cross-lingual stress test. We retain query language, document language, source office, and question mode (technical or general) as metadata, so every result can be sliced along each axis.

Metrics. We report Recall@10 split by language route. A query is relevant to its source patent in every language that patent exists in, so we separate same-language from cross-language gold: R@10$_{\text{same}}$ is Recall@10 against the query's-language copy of the patent, and R@10$_{\text{cross}}$ is Recall@10 against a copy in any other language, each computed over the queries that have the corresponding gold type and balanced over query languages.

The coverage-depth metrics invert Recall@10: instead of fixing the cutoff at 10 and measuring how much gold is found, they fix the target at 80% of queries and measure how deep one must read to reach it. They are computed over the queries that have both a same- and a cross-language gold, pooled across both benchmarks. For each query, let the same-language depth be the rank of the first (best-ranked) same-language gold in the top-1000 retrieval list, and the cross-language depth the rank of the first cross-language gold; a depth is infinite when no such gold appears in the top 1000. Then $k_{80\text{same}}$ is the smallest depth k at which at least one same-language gold falls within the top-k for 80% of queries (the nearest-rank 80th percentile of the same-language depth), $k_{80\text{cross}}$ is the same quantity for the cross-language depth, and $k^{\star}_{80}$ is the smallest k at which **both** golds are within the top-k for 80% of queries (the 80th percentile of the deeper of the two depths per query). Lower is better, and all three are right-censored at >1000 when fewer than 80% of queries reach the target within the retrieved top-1000.

To characterize how expensive it is to reach that evidence and how much of it a downstream re-ranker could still recover.*(i) Cross-lingual reading-cost multiplier (XRC).* For a model m and a coverage fraction $C \in (0, 1]$, let $D_C^{\text{same}}(m)$ and $D_C^{\text{cross}}(m)$ be the retrieval depths at which the same-language gold and the first cross-language gold, respectively, are reached for a fraction C of queries. The reading-cost multiplier is their ratio:

$$\text{XRC}_C(m) = \frac{D_C^{\text{cross}}(m)}{D_C^{\text{same}}(m)}. \qquad (1)$$

It is the factor by which a user must read deeper in the ranked list to reach a foreign-language version of the answer than to reach a same-language copy (XRC = 1 means no penalty). The depth-to-reach quantity D_C is inspired by Cooper (1968).

(ii) Re-ranker recoverability ceiling (RRC). Because a re-ranker can only reorder the candidate pool that first-stage retrieval hands it (Nogueira and Cho, 2019; Lin et al., 2022), the fraction of cross-lingual queries whose first cross-language gold (at rank r^{cross}) appears within the top-K upper-bounds what any top-K re-ranker can recover:

$$\text{RRC@}K(m) = \Pr\left[\, r^{\text{cross}} \le K \,\right]. \qquad (2)$$

RRC@K is the cumulative hit rate of the first cross-language gold within the top-K, a corpus-level generalization of mate-retrieval accuracy (Artetxe

and Schwenk, 2019). Its knee $K^\star$ marks where returns diminish, the smallest pool capturing most recoverable cross-language gold.

(iii) Alignment-recoverability index (ARI). Building on RRC, we partition the cross-lingual outcome at an operating depth K to attribute the residual gap to its source. The unit mass of cross-lingual queries splits exhaustively into three terms that sum to one: those whose foreign gold is already in the top-K (RRC@K), those reachable only by enlarging the pool to the full retrieved depth (RRC@1000 $-$ RRC@K), and an irreducible floor $L_\infty = 1 - \text{RRC@1000}$ that no re-ranker over the retrieved top-1000 can move. ARI reports the fraction of the depth-K shortfall attributable to that floor:

$$\begin{aligned} \text{ARI@}K(m) &= \frac{L_\infty(m)}{1 - \text{RRC@}K(m)} \\ &= \frac{1 - \text{RRC@1000}(m)}{1 - \text{RRC@}K(m)}. \end{aligned} \tag{3}$$

Models and protocol. We evaluate 8 multilingual or domain-relevant embedding models under 1 billion parameters: `embeddinggemma`, `bge-m3` (Chen et al., 2024), `granite-278m`, `nomic-v2-moe`, `qwen3-0.6B`, `LaBSE` (Feng et al., 2022), `SapBERT` (Liu et al., 2021), `e5-large-instruct`. All models retrieve against the same multilingual chemistry corpus, and all queries are evaluated with the same relevance judgments.

4 Results

The performance of all evaluated models across the Google Patents and EPO corpora, averaged over the covered languages, is summarized in Table 2.

4.1 Model Rankings and the Cross-Lingual Gap

Table 2 reports Recall@10 split by language route. Every recall figure is language-balanced: for each model and language route we compute recall within each of the five query languages (English, German, French, Spanish, Chinese) and average those five values, so each query language is weighted equally rather than letting the most frequent one dominate a pooled average. embeddinggemma leads cross-language retrieval on both offices (R@10_{cross} 0.54 / 0.52) and tops same-language recall on Google Patents (0.74); bge-m3 is a consistent second and narrowly takes same-language EPO (0.71 vs. 0.70). qwen3 and nomic-v2-moe are mid-pack, while granite, LaBSE, and SapBERT trail by 15–35 Recall@10 points. The ordering is nearly identical across Google Patents and EPO, so it reflects the task rather than a single corpus. One model is an instructive outlier: e5-large-instruct is near the top on same-language recall (0.73 / 0.63, second only to embeddinggemma on Google Patents) yet its cross-language recall collapses to 0.09 / 0.12, so a model that looks strong under same-language recall alone fails outright once cross-language evidence is required. Off-the-shelf multilingual embedders are therefore far from interchangeable here, and even the best cross-language number (0.54) leaves nearly half of the foreign-language evidence outside the top-10, low for an industrial deployment. Deeper cutoffs raise recall without closing the gap (Table S.2): embeddinggemma's cross-language recall climbs from 0.54 at R@10 to 0.68 at R@50, but its same-language recall rises in step (0.74 to 0.85), so a same/cross gap of 0.14–0.17 persists even at depth 50, where the best cross-language recall still misses about a third of the foreign evidence.

Across the field, retrieving a same-language copy of the answer is far easier than retrieving its foreign twin, and no model escapes the drop. The coverage depths make the gap concrete: among the models that retrieve effectively, the same-language gold surfaces within a few dozen documents (k_{same} from 36 ± 13 to 66 ± 24) while its cross-language twin takes several hundred (k_{cross} from 121 ± 40 to 321 ± 68); embeddinggemma reaches both golds the fastest, needing $k^\star_{80}$=147 ± 38 documents to cover 80% of queries against 304 ± 75 for the next model. These separations lie well outside the bootstrap standard errors, so the same/cross depth gap is not a sampling artifact. For the weaker models both depths balloon and the cross-language gold is frequently never covered for 80% of queries within the retrieved top-1000. The same pattern holds language by language: pooled across the non-degenerate models, same-language recall stays near 0.56–0.62 in every query language while cross-language recall sits around 0.34–0.38, a roughly 0.25 gap present in all five languages (Figure S.1); and the query$\times$document grid shows the loss lives off the diagonal for every model (Figure 2): even the strongest retrievers fall to a fraction of their same-language cell on individual routes, embeddinggemma drops from 0.69 same-language (English) to 0.18 when an English query must reach a

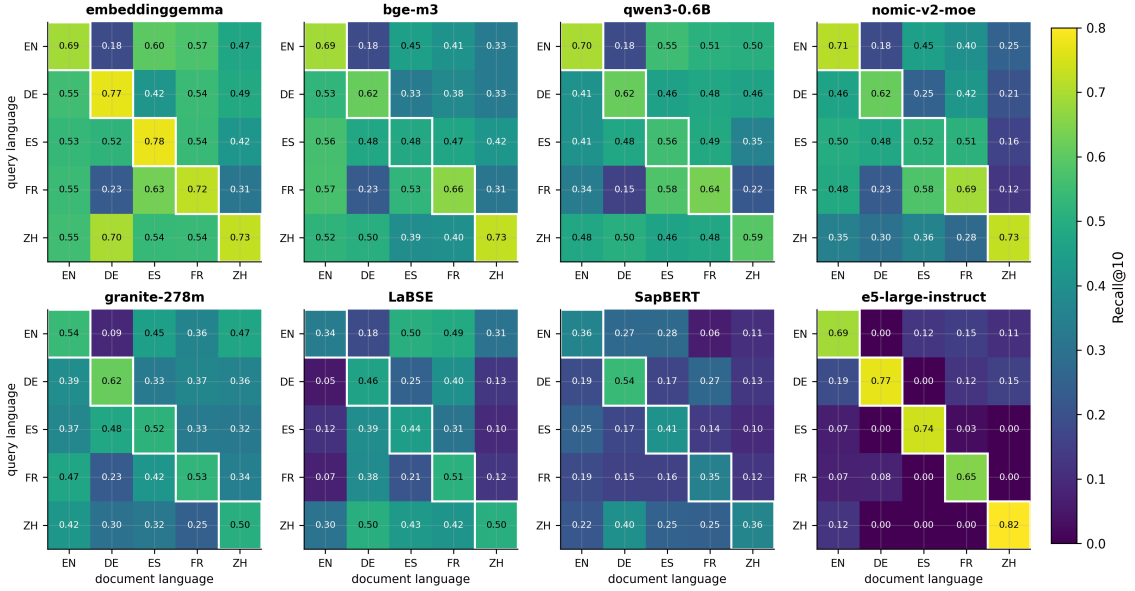

Figure 2: Recall@10 by query language × document language, per model (diagonal = same-language; off-diagonal = cross-lingual).

German document, bge-m3 from 0.62 (German) to 0.33 reaching a Spanish document, and nomic-v2-moe from 0.69 (French) to 0.12 reaching a Chinese one. Cross-linguality, not raw retrieval power, is what every model struggles with.

Uncertainty, significance, and route counts. To quantify these differences we computed 95% confidence intervals for $R@10_{same}$ and $R@10_{cross}$ from a language-stratified, family-clustered BCa bootstrap with 10,000 resamples; interval half-widths range from ± 0.02 to ± 0.08 recall points, so all but the smallest same-versus-cross gaps in Table 2 lie well outside sampling error. We test the gap with paired analyses on dual-gold queries, those with both gold types (n=261 for Google Patents, n=198 for EPO), using cluster-bootstrap intervals for the paired difference Δ and family-level sign-flip permutation tests (Smucker et al., 2007). The gap is significant for every model on Google Patents and for all EPO models except LaBSE (Δ = +0.046, 95% CI [−0.006, +0.099]). A Friedman test on per-query R@10 (same- and cross-language gold pooled) rejects equal performance across the eight models on both corpora (χ^2=809 for Google Patents and 310 for EPO, df=7, both $p < 10^{-60}$), and Holm-corrected pairwise comparisons put embeddinggemma significantly ahead of all seven other models on Google Patents (all Holm-adjusted $p \leq 0.0007$, all CIs excluding zero) while leaving adjacent mid-table pairs indistinguishable (bge-m3 vs. qwen3-0.6B, difference +0.017, 95% CI [−0.009, +0.042]). Per-route counts are strongly imbalanced: the 524 Google Patents queries yield 261 same-language and 1,023 cross-language gold pairs, with per-route n from 10 (zh→de) to 119 (en→en), which is why every headline number is a language-balanced macro mean rather than a pooled one; EPO is complete by construction, with 72/58/68 queries in en/de/fr and every route present.

4.2 Reading Cost and the Re-Ranking Ceiling

Panel (a) of Figure 3 reports the median reading-cost multiplier XRC_{50}, and it is never one: the cheapest model still reads about twice as deep (LaBSE, 1.9×) and the rest three to six times deeper (bge-m3 3.5×, embeddinggemma 5.0×, nomic-v2-moe 6.0×). A low reading cost is not a virtue on its own: the cheapest readers here are the weakest retrievers, which read shallow only because they surface so little, so XRC must be read together with capability ($R@10_{cross}$) rather than minimized in isolation. We drop e5-large-instruct from all three panels because it fails the degeneracy gate ($R@10_{cross} < 0.10$): it almost never retrieves a foreign twin, so its reading-depth ratio explodes (median 161×) and its recoverability curve rests on mostly censored ranks, the instruments are undefined for a model that does not retrieve the thing whose depth they measure.

Panels (b) and (c) ask what a downstream re-

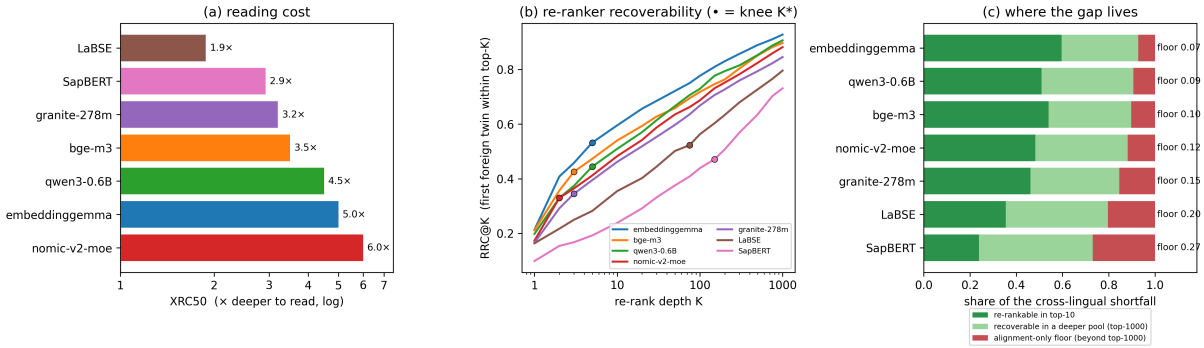

Figure 3: Deployment cost of cross-lingual retrieval (e5-large-instruct excluded by the $\mathrm{R@10}_{\mathrm{cross}} < 0.10$ gate). **(a)** XRC50 reading cost; **(b)** RRC@K re-ranker recoverability with knee $K^{\star}$ (•); **(c)** the shortfall split into re-rankable (top-10), deeper-pool (top-1000), and an alignment-only floor.

ranker could do about the buried cross-language documents. Two things stand out. First, the recoverable gold is front-loaded: the knee $K^{\star}$ sits at 2–5 for the strong models (Panel b), so a shallow top-5 pool already captures the bulk of the cheaply recoverable cross-language gold (embeddinggemma $\mathrm{RRC@5}{=}0.53$); a deeper pool keeps helping but with falling efficiency per decade ($\mathrm{RRC@100}{=}0.78$, $\mathrm{RRC@1000}{=}0.93$), while the weak LaBSE and SapBERT reach their knee only at depth 75–150. Second, even an exhaustive re-ranker over the full retrieved pool hits a wall (Panel c). Some cross-language gold never appears in the top-1000 at all, so no re-ranker can reach it. This alignment-only floor L_{∞} is small for the strong models (0.07 for embeddinggemma) but large for the weak ones (0.27 for SapBERT): the weaker the model, the more of its cross-lingual failure is structural rather than a matter of pool depth. Re-ranking cannot close this part of the gap,even a top-100 re-ranker is capped at $\mathrm{RRC@100}$ (0.78 for the best model), since it only reorders what first-stage retrieval already surfaced. These results suggest that improvements to cross-lingual representation alignment may be needed in addition to query-time re-ranking. For more details on the introduced metrics, see Figure S.3.

5 Conclusion

This work introduced ChemCLIR-Bench, a patent-grounded benchmark for cross-lingual information retrieval in the chemical domain, combining multilingual QAC datasets with language-aware diagnostic metrics. Our evaluation of eight multilingual embedding models reveals a consistent gap between monolingual and cross-lingual retrieval: even the strongest models fail to retrieve a significant portion of cross-language evidence at practical depths. We show that standard metrics such as Recall@k can obscure these failures, while cross-lingual retrieval incurs higher reading cost and limited recoverability through re-ranking. These results highlight that cross-lingual alignment, rather than overall retrieval capacity, is the primary bottleneck in domain-specific settings, and cannot be addressed by re-ranking alone. Beyond benchmarking, we introduce evaluation criteria for comparing model behaviour under realistic retrieval constraints and provide a foundation for future research. While ChemCLIR-Bench focuses on controlled multilingual patent evidence and therefore does not establish transfer to all technical or general-domain retrieval settings, it provides a reusable framework for diagnosing cross-lingual retrieval failures under realistic constraints. Extending this benchmark to broader technical domains, additional languages, and retrieval approaches that combine dense, sparse, translation-based, and hybrid methods is a key direction for future multilingual retrieval evaluation.

Limitations

The suite is intentionally specialized: chemistry patents give controlled multilingual technical evidence, but the results, and the model ordering, may not transfer to other domains, regulatory corpora, or general web retrieval. Although patent variants are content-controlled, they are not guaranteed to be claim-level equivalent across every language. Accordingly, ChemCLIR-Bench is best viewed as a reusable evaluation framework rather than a universal assessment of multilingual retrieval perfor-

mance. The QAC data rests on LLM generation and LLM-based verification; our 97-item human audit supports its quality but is limited and does not replace comprehensive expert review of all benchmark instances.

A Appendix

A.1 Comparison with Related Benchmarks

Table S.1 positions ChemCLIR-Bench against the multilingual retrieval benchmarks and chemistry resources discussed in Section 1, with abbreviated cells. Lang. is the number of languages covered: CLIRMatrix lists its bilingual release (BI-139, 139 languages in 139×138 pairs) and its multilingual release (MULTI-8, eight languages), and NeuCLIR uses English topics against three document languages (Chinese, Persian, Russian). Setting distinguishes monolingual retrieval within each language (Mono), cross-lingual retrieval where query and document languages differ (CL), and retrieval over a pooled multi-language collection (MLIR). ChemCLIR-Bench scores same-language and cross-language routes separately, including "no-home" queries with no same-language gold; MMTEB is mostly monolingual with some cross-lingual retrieval and bitext-mining tasks; ChemTEB's bitext-mining tasks pair SMILES strings with text rather than two languages, so it remains monolingual. Corpus names the document collection: patent titles and abstracts from Google Patents and EPO (EPO adds first claims) for ChemCLIR-Bench; Wikipedia passages or articles for MIRACL and CLIRMatrix, the latter using article titles as queries; more than 500 aggregated existing datasets across ten task types for MMTEB; news articles plus Chinese academic abstracts for NeuCLIR; PubChem, chemistry Wikipedia, chemistry subsets of BeIR (NQ, HotpotQA), COCONUT, and safety data sheets for ChemTEB; and 1,054 question–answer–context triplets from chemistry papers for ChemLit-QA. Relevance describes how labels were obtained. Parallel-doc means a query is relevant to every language version of its source patent, with queries LLM-generated, LLM-verified, and human-audited. Human means human-written queries with native-speaker judgments (MIRACL) or TREC-style pooled assessments (NeuCLIR). Synthetic means monolingual BM25 scores discretized into graded labels (0–6) and propagated across languages via Wikidata links. Inherited means labels taken from each constituent dataset. DB-derived means labels derived from source databases, with tasks designed or validated by chemists. LLM + expert means GPT-4 Turbo generated triplets validated by chemistry experts, with -neg (unanswerable) and -multi (multi-hop) subsets. Objective gives what the benchmark measures: ad hoc retrieval quality (Retrieval; nDCG@10 and Recall@100 for MIRACL, a reranking setup for CLIRMatrix, CLIR and MLIR system evaluation plus a 2024 report-generation task for NeuCLIR); multi-task embedding evaluation in which retrieval is one category among several (Emb. suite; ten categories for MMTEB, 34 tasks in five categories for ChemTEB); answer correctness of RAG and fine-tuned LLMs rather than retrieval ranking (RAG QA); and, for ChemCLIR-Bench, diagnosis of the cross-lingual retrieval gap and its deployment cost through $\mathrm{R@10}_{\mathrm{same}}$ versus $\mathrm{R@10}_{\mathrm{cross}}$, k_{80} depth, XRC, RRC@K, and ARI.

Read together, the rows show the gap ChemCLIR-Bench fills. The general benchmarks differ mainly in how they treat language: MIRACL is monolingual within each language, MMTEB is largely monolingual with a small cross-lingual component, and CLIRMatrix and NeuCLIR are cross-lingual but built on Wikipedia and news. Only NeuCLIR includes technical text, through its Chinese academic-abstract subtask, and none is grounded in a single domain whose terminology drives relevance. The chemistry benchmarks are the mirror image: ChemTEB and ChemLit-QA are domain-specific but English-only and do not evaluate retrieval across languages. ChemCLIR-Bench sits at the intersection. It is grounded in chemical patents, covers five languages, derives relevance from a patent's own language versions rather than from propagated lexical scores, and reports same-language and cross-language recall separately together with depth-based diagnostics that the other benchmarks do not report.

A.2 Results per query language

Figure S.1 and Figure 2 reflects the break down of the performance of the models over languages.

A.3 Additional Human Annotation results

A.3.1 Query quality evaluation: Human-annotation Criteria

Our human evaluation rubric is organized around three families of criteria: faithfulness, retrieval-oriented query quality, and linguistic quality. The faithfulness criteria evaluate whether the generated answer is supported by the passage. First, grounding asks whether the answer can be traced to a contiguous span of the passage, following the extractive QA assumption in SQuAD, where answers are defined as spans from the source passage (Rajpurkar et al., 2016). Second, precision asks

Benchmark	Domain	Lang.	Setting	Corpus	Relevance	Objective
ChemCLIR-Bench (ours)	Chem. patents	5	Mono + CL	Patents (GP, EPO)	Parallel-doc	CLIR diagnostics
MIRACL	General	18	Mono	Wikipedia	Human	Retrieval
MMTEB	General	250+	Mono (some CL)	Aggregated	Inherited	Emb. suite
CLIRMatrix	General	139 / 8	CL	Wikipedia	Synthetic	Retrieval
NeuCLIR	News (+tech.)	EN→3	CL, MLIR	News, abstracts	Human	Retrieval
ChemTEB	Chemistry	1 (EN)	Mono	PubChem, Wiki	DB-derived	Emb. suite
ChemLit-QA	Chem. papers	1 (EN)	Mono	QAC triplets	LLM + expert	RAG QA

Table S.1: ChemCLIR-Bench alongside general multilingual IR benchmarks and chemistry-focused benchmarks. Column values are abbreviated; Appendix A.1 defines them and gives the details behind each cell.

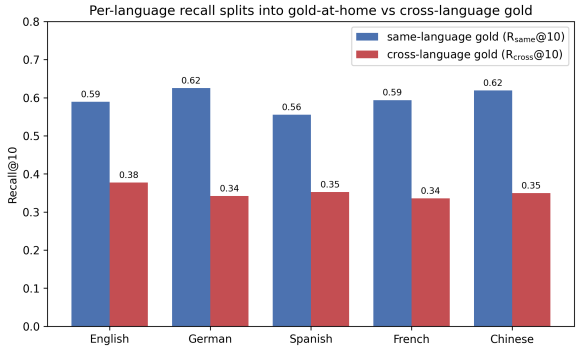

Figure S.1: Per query language, Recall@10 splits into same-language gold ($R@10_{\text{same}}$) and cross-language gold ($R@10_{\text{cross}}$), pooled over the non-degenerate models. The home advantage holds in every language.

whether the answer avoids unsupported details or padding; this adapts the notion of factual precision from FActScore, which evaluates generated text by decomposing it into atomic facts and checking what proportion is supported by a reliable source (Min et al., 2023). Third, numerical fidelity separately evaluates whether numbers, dates, units, and ranges are reproduced exactly. We include this as a specific subtype of factual consistency because even small numerical deviations can alter the meaning of an answer; this criterion is aligned with factual-consistency evaluation work such as QAFactEval, which checks whether generated content is supported by the source (Fabbri et al., 2022).

The query-quality criteria adapt prior QG and information-retrieval evaluation ideas to two generation modes. In technical mode, search-bar realism asks whether the generated query resembles a realistic search-engine query, motivated by fact-checking QG work where generated questions are used to retrieve evidence (Ousidhoum et al., 2022). Specificity and retrievability are motivated by information-retrieval work on query clarity, which treats ambiguous queries as harder retrieval problems (Cronen-Townsend et al., 2002). Phrasing economy extends the conciseness criterion used in QGEval and Cheng et al., while also penalizing queries that are unnecessarily copied from the passage (Fu et al., 2024; Cheng et al., 2021). Focus asks whether the query targets a single fact, following the intuition behind answerability and answer matching: a generated question should have a clear intended answer (Nema and Khapra, 2018; Cheng et al., 2021; Fu et al., 2024). In general mode, search realism and retrievability again evaluate whether the query is useful for retrieval, but the emphasis shifts from keyword-style search to meaning-based retrieval. Lexical distance rewards meaningful paraphrasing rather than surface copying, following prior work emphasizing diversity in question generation (Sultan et al., 2020). Conceptual framing is our extension of prior QG evaluation: it asks whether the query targets a concept rather than a surface fact, inspired by work on deeper and more controllable question generation where question quality depends not only on fluency but also on the reasoning or semantic structure being elicited (Cheng et al., 2021). Finally, linguistic quality follows standard human evaluation practice in QG and NLG, corresponding to fluency, well-formedness, and clarity (Fu et al., 2024; Cheng et al., 2021).

Human-model grading agreement. To validate the LLM auto-grader against human judgment, one annotator scored a random subset of $N{=}97$ generated questions on a 0–10 quality scale, and the auto-grader's composite score was linearly rescaled from its native 0–40 range onto the same 0–10 axis. In absolute terms the two graders are close: the mean absolute error (MAE) between the human and model scores is 0.82 points out of 10. The annotated sample is near-ceiling-nearly all questions (94 of 97 for the human, 97 of 97 for the model) fall in the top ("good") quality band, so chance-corrected coefficients that assume balanced

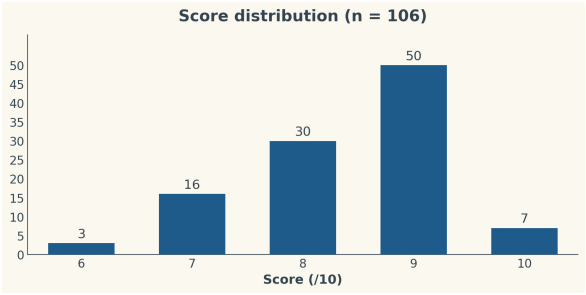

Figure S.2: Distribution of human-annotator overall scores on the 106-item audited QAC sample (mean 8.33/10; no item rated below 6).

categories are unstable: Cohen's κ collapses to ≈ 0 despite 96.9% raw bucket agreement, the well-known high-prevalence paradox. We therefore report Gwet's AC1, which is robust to skewed marginals, and obtain AC1 $= 0.97$, indicating near-perfect categorical agreement. Together these figures show that the auto-grader closely tracks human scores on this sample; the near-ceiling distribution means the comparison reflects agreement among predominantly high-quality questions rather than the graders' ability to flag low-quality ones.

Chinese translation Human Annotation For the 400 Chinese abstracts we machine-translated to seed Chinese coverage, the only translation step in our pipeline, we used a manual review setup following prior MT evaluation practice, where human judges assess adequacy and fluency (Koehn and Monz, 2006). The annotator compared the English source with the Chinese translation, assigned 1–5 adequacy and fluency scores, and accepted or rejected each item. Across the 40 reviewed abstracts, the translations received a mean adequacy of $4.62/5$ and a mean fluency of $4.75/5$. Overall, the annotator accepted 34 of the 40 translations (85%) and rejected only six. Figure S.10 shows the annotation interface.

Table S.2: Recall at deeper cutoffs ($R@25$, $R@50$) complementing Table 2, split by language route: *same* is same-language monolingual recall and *cross* is cross-language recall, each language-balanced as the mean of per-language means. Best per column in bold. Size is total parameters; nomic-v2-moe is a mixture-of-experts with 475M total and 305M active parameters. †e5-large-instruct fails the cross-lingual degeneracy gate; its bold same-language entries reflect strong monolingual retrieval despite collapsed cross-lingual recall.

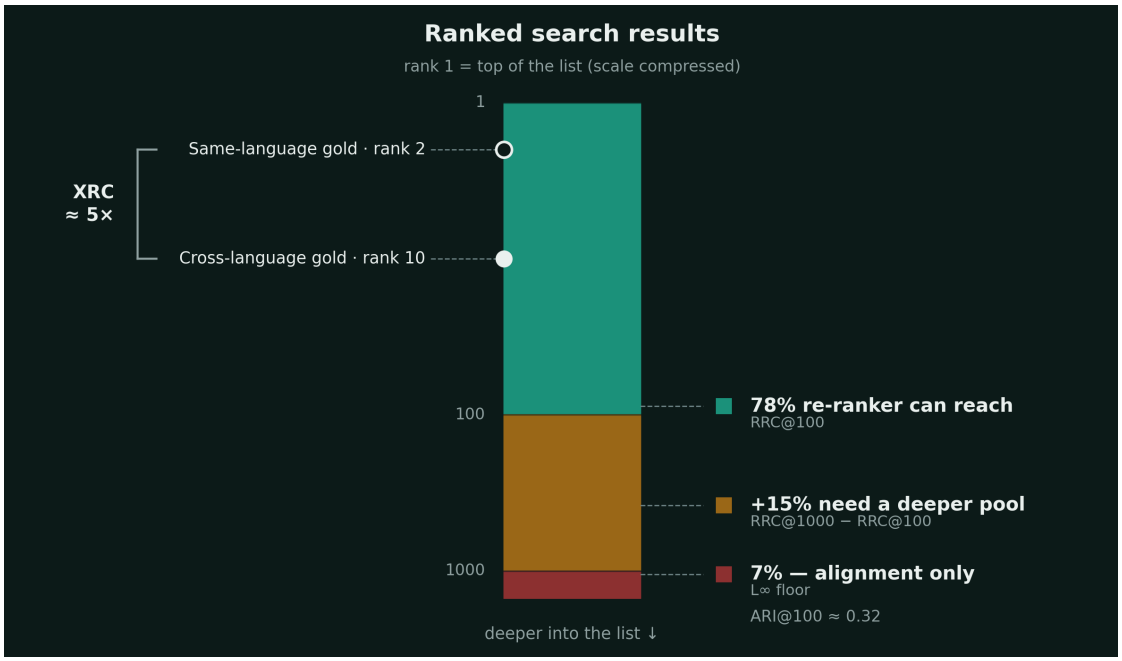

Figure S.3: **Cross-lingual reading-cost decomposition for `embeddinggemma`.** On a log-compressed ranked list, the same-language gold typically surfaces shallow while its cross-language counterpart sits about $5\times$ deeper (the cross-lingual reading cost XRC; the example ranks 2 and 10 illustrate this median multiplier). Reading down the list partitions where the cross-language gold is recovered, with measured shares over the pooled GP+EPO queries that have both gold types: a re-ranker over the top-100 reaches $\mathrm{RRC@100} = 78\%$, a further $+15\%$ require a deeper top-1000 pool ($\mathrm{RRC@1000} - \mathrm{RRC@100}$), and a 7% residual is never retrieved within the top-1000 (L_∞ floor) and can be closed only by better cross-lingual alignment ($\mathrm{ARI@100} = 0.32$). Percentages are measured; the two ranked positions illustrate the reported XRC.

A.4 Corpus Sources and Fields

Google Patents. Records were drawn from the Google Patents Public Data table `patents-public-data.patents.publications`, whose bibliographic data is supplied by IFI CLAIMS. For each publication we use the language-tagged `title_localized` and `abstract_localized` fields, keeping one version per language. The official schema describes these fields as publication text in different languages and does not identify them as Google-generated machine translations. Google's machine-translated titles and abstracts are provided in a separate table,

`google_patents_research.publications`, which our pipeline neither queries nor joins. Re-checking both the extraction pipeline and the released dataset, we found no machine-translation indicators on the abstracts used in ChemCLIR-Bench; such indicators do occur on some claims and description fields, which we do not use. Since the metadata does not establish whether each localized record was authored in its tagged language, we make no claim that these records are native text.

EPO. Granted B1 specifications are published as English, German, and French versions with professionally translated first claims; we use these versions as published and introduce no translations.

Chinese seed set. Chinese coverage was zero in our selection, so we machine-translated 400 documents (1.7% of the corpus) with GPT 5.5. This is the only translation step in the pipeline.

Chemistry selection. Records were selected as chemistry-related if they carried a CPC/IPC code with prefix C, A61K, or A61P, or matched an entry in SureChEMBL. We retained language versions with a localized abstract of at least 50 words, deduplicated by publication number within each language, and kept publications available in at least two target languages; the resulting language versions form the cross-lingual relevance set. We imposed no explicit publication-date bounds; where extraction limits applied, eligible records were ordered by publication date in descending order, favouring newer publications.

IPC distribution. Figure S.4 shows the 25 most frequent IPC classes in the released corpus, stacked by source. The distribution is dominated by A61 (medical and pharmaceutical preparations), which appears on 16,955 of the 35,102 documents (48%), followed by C08 (polymers), C07 (organic chemistry), and C12 (biochemistry); the remaining section-C classes cover inorganic chemistry, metallurgy, coatings, electrochemistry, fuels, and water treatment. Classes outside section C cannot satisfy the prefix rule on their own, so they enter through co-classification with a chemistry code or through the SureChEMBL match; H01 (basic electric elements, which includes electrochemical cells under H01M) and G01 (measuring and testing) are the most frequent of these. The two sources differ in emphasis: the EPO subset carries a larger share of H01 and G01 codes, whereas Google Patents is more concentrated in A61, C08, and C07. Because a document may carry several codes, the counts are not mutually exclusive and sum to more than the corpus size.

You are a strict faithfulness grader for patent question–answer pairs.

You will receive **ONE** passage, in any language, and **THREE** question–answer pairs. Questions may be in any language; each answer matches its question's language. Grade each pair on three sub-criteria, each from 1 to 5. Do **NOT** evaluate query shape or retrieval quality, since those are handled separately. Focus only on how faithfully each answer reflects the passage.

GRADING INSTRUCTIONS

- Grade each of the three pairs independently and against the absolute rubric below, not relative to the other two.
- Do not let similarity or dissimilarity between the three pairs influence any individual grade.
- Evaluate each pair on its own merits before moving to the next.

SCALE CALIBRATION

- Most generator outputs will be acceptable on most criteria. "Acceptable" is not the same as "excellent."
- **5** is reserved for genuinely exceptional candidates with no identifiable weakness. If you can point to any imperfection, it is not a 5. Scores of 5 should be uncommon.
- **4** means the candidate is very good but has exactly one minor, identifiable issue. You must be able to name the issue.
- **3** is the default grade for a candidate that is acceptable and does the job, with one clear weakness. It is not a punishment grade; most acceptable candidates will receive 3s.
- **2** and **1** are reserved for candidates with real, identifiable problems. Do not avoid using them when a candidate qualifies.
- Before assigning any 4 or 5, pause and ask: "What specifically makes this better than a 3?" If you cannot answer concretely, the grade is 3.

SUB-CRITERIA

1. **GROUNDING (1–5): Is the answer supported by a contiguous span of the passage?**

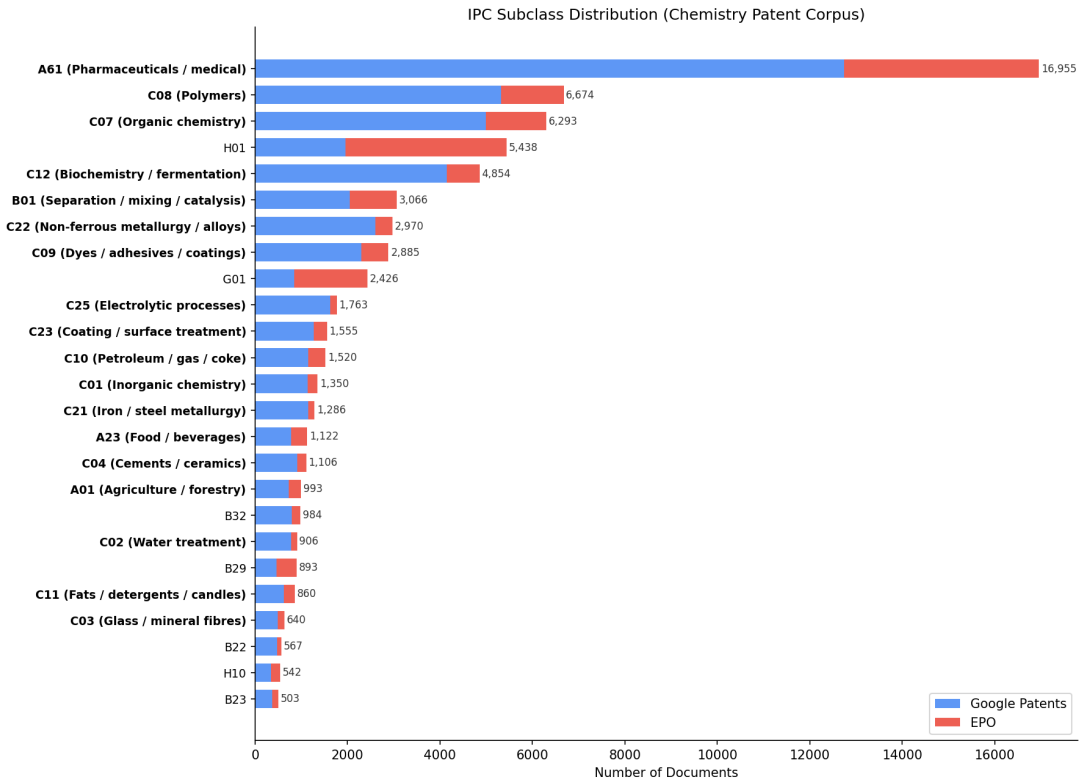

Figure S.4: IPC class distribution of the ChemCLIR-Bench corpus (25 most frequent classes), stacked by source. Counts are at the IPC class level (three-character codes) and are not mutually exclusive, since a document may carry several codes. Classes without a description on the axis: H01 basic electric elements (including electrochemical cells, H01M), G01 measuring and testing, B32 layered products, B29 working of plastics, B22 casting and powder metallurgy, H10 semiconductor devices, B23 machine tools.

5 Answer is taken directly from a single short contiguous span of the passage. Every word of the answer is explicitly present or is a trivial rewording of explicit content. No inference whatsoever. Rare.

4 Answer is fully supported but requires reading across two adjacent sentences, or is from a single span with minor trivial rewording that a strict reader might flag.

3 Answer is grounded in the passage but requires one small, defensible inferential step, such as combining a definition with a value or connecting a pronoun to its referent.

2 Answer is partially supported: some parts are grounded in the passage, while other parts are not.

1 Answer requires significant inference, outside knowledge, or is not in the passage at all.

2. **PRECISION (1–5): Does the answer add unsupported details or padding?**

5 Answer is the shortest possible span that fully answers the question. Not one extra word. No surrounding context, no hedges, and no elaboration. Rare.

4 Answer is grounded and tight but includes one short fragment of adjacent context that could have been cut.

3 Answer is grounded but includes one unsupported detail, generalization, or piece of padding.

2 Answer includes multiple unsupported details, or uses speculative framing such as “likely,” “approximately,” or “it seems” where the passage is specific.

1 Answer is largely padded with content not in the passage, or is a rewrite rather than an extraction.

3. **NUMERICAL FIDELITY (1–5): Are numbers, units, and ranges reproduced exactly?**

5 All numbers, units, symbols, and ranges match the passage character-for-character, for example, “85–87°C” is preserved as-is, including the dash.

4 All numerical values are correct and units are preserved, but with a trivial formatting difference, for example, “85 to 87°C” instead of “85–87°C”.

3 One number is rounded, one unit is dropped, or one range is converted to a midpoint.

2 Multiple numerical values are rounded, reformatted, or partially dropped.

1 Numbers are invented, significantly changed, or contradicted by the passage.

N/A
Answer contains no numerical content. Score this sub-criterion as 5 if N/A.

Output valid JSON only – a list of three objects, one per candidate, in the order the candidates were provided: index 0, 1, and 2.

```

Figure S.5: Faithfulness verifier prompt (`claude-sonnet-4.6`). The verifier grades each of three candidate answers on grounding, precision, and numerical fidelity.

You are a strict quality grader for retrieval questions built from technical patent text.

You will receive **ONE** passage and **THREE** candidate questions. Grade each question on five sub-criteria, each from 1 to 5. Do **NOT** check whether the answer is grounded, since that is handled separately. Focus only on query shape, retrieval quality, and writing quality.

The questions may be in any language. When evaluating **SEARCH-BAR REALISM**, **PHRASING ECONOMY**, and **LINGUISTIC QUALITY**, judge each question by the norms of its own language, not by English phrasing conventions. A natural Turkish, Japanese, or German search query will not read like a natural English one.

GRADING INSTRUCTIONS

- Grade each of the three questions independently and against the absolute rubric below, not relative to the other two.
- Do not penalize a question for being similar to another candidate, nor reward it for being different. Diversity across the three is not a criterion.
- Evaluate each question on its own merits before moving to the next.

SCALE CALIBRATION

- Most generator outputs will be acceptable on most criteria. “Acceptable” is not the same as “excellent.”
- **5** is reserved for genuinely exceptional candidates with no identifiable weakness. If you can point to any imperfection, it is not a 5. Scores of 5 should be uncommon.
- **4** means the candidate is very good but has exactly one minor, identifiable issue. You must be able to name the issue.
- **3** is the default grade for a question that is acceptable and does the job, with one clear weakness. It is not a punishment grade; most acceptable questions will receive 3s.
- **2** and **1** are reserved for questions with real, identifiable problems. Do not avoid using them when a question qualifies.
- Before assigning any 4 or 5, pause and ask: “What specifically makes this better than a 3?” If you cannot answer concretely, the grade is 3.

BACKGROUND: Good retrieval questions target one of five categories from the source text:

1. **Parameters & Conditions**: temperature, pressure, time, concentration, pH, flow rate, voltage, atmosphere, stoichiometry.
2. **Materials**: catalyst, solvent, reagent, substrate, additive, precursor, equipment.
3. **Outcomes**: yield, selectivity, conversion, purity, efficiency.
4. **Methods**: synthesis route, characterization technique, separation method.
5. **Structure**: functional group, crystal form, polymorph, molecular weight, composition.

SUB-CRITERIA

1. **SEARCH-BAR REALISM (1–5): Does this read like a real user query in its own language?**
   - **5** Exactly how a researcher would type it into a search bar. Every word earns its place. A domain expert would not suggest any rewording. Rare.
   - **4** Very close to a natural query, with one minor issue: slightly longer than needed, slightly formal, or one word that could be trimmed.
   - **3** Understandable and usable as a query, but has one clear issue, such as mild patent-summary phrasing, an awkward construction, or slight exam-question flavor.
   - **2** Reads more like a summary prompt or academic exam question than a search query.

1 Document-centered phrasing, such as equivalents of "described in the invention" or "according to the text"; reference to the document's contents or examples, such as "the example given" or "the agent mentioned"; or clearly unnatural phrasing.

NOTE: This is a query for an IR system: the user has **NOT** seen the document. Any phrasing that refers to the document or its contents fails this criterion. This includes not only overt phrases such as "described in the invention" or "according to the text," but also references to the document's internal structure or to something being stated in it: "the example given," "the agent mentioned/described/disclosed here," "which compound is provided," or "in the passage." A question with any such reference scores at most 2 here, or 1 if overt or blatant, and its `failure_type` must be `document-phrasing`. Example: "Which agent example is given that increases ROS?" fails because it says "example is given." By contrast, "Which agent increases ROS?" is fine.

2. **SPECIFICITY (1–5): Would this query narrow to the relevant document rather than match arbitrarily?**

   5 Targets a concrete, specific technical detail from one of the five categories. A search with this query would return a handful of closely related documents at most. Rare.
   4 Specific, but could match a small cluster of related patents in the same sub-domain.
   3 Moderately specific; would return many plausible matches across the domain. Acceptable but not distinguishing.
   2 Broad; asks about a general concept or outcome without a distinguishing detail.
   1 Generic summary question, such as equivalents of "What is the main object of the invention?" or "What is the purpose of the method?" with no specific anchor.

3. **PHRASING ECONOMY (1–5): Is the question paraphrased, not lifted from the source?**

   5 Reuses only unavoidable technical terms and named entities, such as "Pd/C catalyst" or "electrolysis unit." No descriptive phrases, modifiers, or sentence fragments are copied from the source. Rare.
   4 Mostly paraphrased, with one short piece of source phrasing reused where a paraphrase was available.
   3 Reuses one multi-word descriptive phrase from the source, or several short phrases.
   2 Lifts a noun cluster or descriptive fragment from the source as question scaffolding.
   1 Near-verbatim copy of a source sentence with minimal edits.

4. **FOCUS (1–5): Does the question ask for exactly one fact?**

   5 Single, clear, unambiguous fact requested. No room for the answerer to include extra information. Rare.
   4 Single fact, but with mild ambiguity in what is being asked, for example, a word that could be read two ways.
   3 Single fact, but phrased in a way that invites a broader answer or includes redundant qualifiers.
   2 Asks for two related facts bundled together, for example, "solvent and yield."
   1 Asks for three or more facts, or requests a summary.

5. **LINGUISTIC QUALITY (1–5): Is the question well-written in its own language?**

   5 Indistinguishable from native-speaker writing. Grammatically correct, fluent, natural word order, no redundancy, and no awkwardness anywhere. Rare.
   4 Grammatically correct and natural, with one minor stiffness or one slightly awkward word choice.
   3 Correct and understandable, but has one noticeable issue, such as a minor grammar slip, awkward word order, or translation-like phrasing.
   2 Multiple grammar errors, clearly unnatural phrasing, or reads like a poor machine translation.
   1 Ungrammatical, garbled, or incomprehensible.

LANGUAGE CHECK: If a question is written in a language that is not a coherent single language, such as mixed languages mid-sentence, nonsense, or corrupted text, score its **SEARCH-BAR REALISM** as 1 and set its `failure_type` to `language-issue`.

Output valid JSON only – a list of three objects, one per candidate, in the order the candidates were provided: index 0, 1, and 2.

Figure S.6: Technical-mode quality verifier prompt (`claude-sonnet-4.6`). The verifier grades query shape and writing quality on five sub-criteria.

You are a strict quality grader for semantic retrieval questions built from technical chemistry and patent text.

You will receive **ONE** passage and **THREE** candidate questions. Grade each question on five sub-criteria, each from 1 to 5. Do **NOT** check whether the answer is grounded, since that is handled separately. Focus only on query shape, retrieval quality, and writing quality.

The questions may be in any language. When evaluating **SEARCH REALISM**, **LEXICAL DISTANCE**, and **LINGUISTIC QUALITY**, judge each question by the norms of its own language, not by English phrasing conventions. A natural Turkish, Japanese, or German search query will not read like a natural English one.

GRADING INSTRUCTIONS

- Grade each of the three questions independently and against the absolute rubric below, not relative to the other two.
- Do not penalize a question for being similar to another candidate, nor reward it for being different. Diversity across the three is not a criterion.
- Evaluate each question on its own merits before moving to the next.

SCALE CALIBRATION

- Most generator outputs will be acceptable on most criteria. "Acceptable" is not the same as "excellent."
- **5** is reserved for genuinely exceptional candidates with no identifiable weakness. If you can point to any imperfection, it is not a 5. Scores of 5 should be uncommon.
- **4** means the candidate is very good but has exactly one minor, identifiable issue. You must be able to name the issue.
- **3** is the default grade for a question that is acceptable and does the job, with one clear weakness. It is not a punishment grade; most acceptable questions will receive 3s.
- **2** and **1** are reserved for questions with real, identifiable problems. Do not avoid using them when a question qualifies.
- Before assigning any 4 or 5, pause and ask: "What specifically makes this better than a 3?" If you cannot answer concretely, the grade is 3.

BACKGROUND: Good semantic retrieval questions describe a passage's concept, problem, approach, or application in the way a user would search for such a document without already having read it. The three framings used by the generator are:

1. **Problem-framed:** what challenge or limitation does the passage address?
2. **Solution-framed:** what approach, mechanism, or method is proposed?
3. **Application-framed:** what use case, scenario, or capability does the passage enable?

Unlike fact-extraction questions, semantic retrieval questions are allowed, and expected, to be somewhat broader than a single data point. They should still be clearly tied to the passage.

SUB-CRITERIA

1. **SEARCH REALISM (1–5): Does this read like a real user query searching for a document like this one?**

   5 Exactly how someone searching for this kind of document would phrase it, without having read it. Every word earns its place. A domain expert would not suggest any rewording. Rare.
   4 Very close to a natural query, with one minor issue: slightly long, slightly formal, or one word that could be trimmed.
   3 Understandable and usable as a query, but has one clear issue, such as mild patent-summary phrasing, an awkward construction, or slight exam-question flavor.
   2 Reads more like a summary prompt or academic question than a search query.
   1 Document-centered phrasing, such as equivalents of "described in the invention" or "according to the text"; reference to the document's contents or examples, such as "the example given" or "the approach mentioned"; or clearly unnatural phrasing.

   NOTE: This is a query for an IR system: the user has **NOT** seen the document. Any phrasing that refers to the document or its contents fails this criterion. This includes not only overt phrases such as "described in the invention" or "according to the text," but also references to the document's internal structure or to something being stated in it: "the example given," "the approach mentioned/described/disclosed here," "which method is provided," or "in the passage." A question with any such reference scores at most 2 here, or 1 if overt or blatant, and its `failure_type` must be `document-phrasing`. Example: "Which agent example is given that increases ROS?" fails because it says "example is given." By contrast, "Which agent increases ROS?" is fine.

2. **LEXICAL DISTANCE (1–5): Is the question meaningfully paraphrased from the passage's vocabulary?**

   5 Uses natural synonyms and paraphrases throughout. Only unavoidable shared vocabulary is reused: proper nouns, compound identifiers, and established standard technical terms such as "Pd/C," "polymerase," or "electrolysis." A keyword-based retriever would not trivially match this question to the passage. Rare.
   4 Mostly paraphrased, with one distinctive source term reused where a paraphrase was available.
   3 Moderate overlap; some distinctive source phrases are reused where alternatives existed. Still paraphrased in structure.
   2 Heavy overlap; multiple distinctive phrases or noun clusters are reused from the source.
   1 Near-verbatim or high-keyword-overlap question that would be matched by any sparse or keyword retriever without needing semantic understanding.

3. **CONCEPTUAL FRAMING (1–5): Does the question target a concept, problem, approach, or application, as intended for this prompt?**

   5 Clearly and cleanly conceptual: asks about a problem, approach, mechanism, or use case in a way that captures what the passage is fundamentally about. The framing is unmistakable. Rare.
   4 Conceptual in intent, but slightly narrow; edges toward one specific detail while still framing as concept.
   3 Borderline; could be read as either conceptual or fact-extractive, depending on how one interprets it. Acceptable but not crisp.
   2 Fact-extraction question that belongs to the technical prompt, not this one. It asks for a single parameter value, material name, or numerical outcome.
   1 Entirely fact-extractive with no conceptual framing, for example, "What temperature is used?"

4. **RETRIEVABILITY (1–5): Would this query distinguish this passage from unrelated documents?**

5 Specific enough that a search with this query would return this passage or a handful of closely related ones. Clearly anchored to this passage's content. Rare.
4 Specific but could match a small cluster of related documents in the same sub-domain.
3 Moderately specific; would return many plausible matches across a broad domain. Tied to the passage but not distinguishing.
2 Broad; could match a large fraction of documents in the domain.
1 Generic question with no distinguishing anchor to this passage, such as equivalents of "What problem does this invention solve?" with no domain specifics.

5. **LINGUISTIC QUALITY (1–5): Is the question well-written in its own language?**

5 Indistinguishable from native-speaker writing. Grammatically correct, fluent, natural word order, no redundancy, and no awkwardness anywhere. Rare.
4 Grammatically correct and natural, with one minor stiffness or one slightly awkward word choice.
3 Correct and understandable, but has one noticeable issue, such as a minor grammar slip, awkward word order, or translation-like phrasing.
2 Multiple grammar errors, clearly unnatural phrasing, or reads like a poor machine translation.
1 Ungrammatical, garbled, or incomprehensible.

LANGUAGE CHECK: If a question is written in a language that is not a coherent single language, such as mixed languages mid-sentence, nonsense, or corrupted text, score its **SEARCH REALISM** as 1 and set its `failure_type` to `language-issue`.

Output valid JSON only – a list of three objects, one per candidate, in the order the candidates were provided: index 0, 1, and 2.

]
```

Figure S.7: General-mode semantic quality verifier prompt (`claude-sonnet-4.6`). The verifier grades conceptual query shape and writing quality on five sub-criteria.

You are an expert at creating technical chemistry and patent retrieval questions.

The source context may be in any language. The questions and answers **MUST** be written in English. Preserve chemical names, compound identifiers such as "Compound 3a", trade names, reagent abbreviations, and all numerical values, units, and ranges in their original form. Do not translate, round, or reformat them.

Generate exactly **THREE** question-answer pairs from the context. Each should target a different fact.

CORE RULES

- **Single Focus:** Each question must ask for exactly one specific piece of information. Never combine multiple asks. For example, do not ask for a solvent and a yield in the same question.
- **Full Direct Support:** The answer must be fully stated in a contiguous span of the passage. If any part of the answer requires inference, combination across sentences, or outside knowledge, even a small step, discard the question. Partial support is not acceptable.
- **Numerical Fidelity:** Reproduce all numbers, units, ranges, and tolerances exactly as they appear in the source. For example, preserve "85–87°C", not "about 86°C" or "85 to 87 degrees".
- **Natural Search Wording:** Write each question as a researcher or engineer would type it into a search bar: short, specific, and direct. Avoid patent-summary language and long noun phrases.
- **No Document Phrases:** Never use "described in the invention", "according to the text", "mentioned in the disclosure", or similar wording. Rewrite into natural wording.
- **Standalone query for a search engine:** Each question is a query for an Information Retrieval system. The person typing it has **NOT** seen this document and is searching to find it. Never refer to the document or its contents. This includes not only overt phrases such as "described in the

invention", "according to the text", or "in the passage", but also any wording that presupposes the reader is looking at the document, such as "the example given", "the agent mentioned/described/disclosed here", or "which compound is provided". Write self-contained questions. Bad: "Which agent example is given that increases ROS?" Good: "Which agent increases ROS?"

- **Paraphrase, Do Not Lift:** Technical terms and named entities, such as "electrolysis unit", "decentralized water treatment system", or "Pd/C catalyst", may be reused as needed for clarity. But do not lift descriptive phrases, multi-word modifiers, or sentence fragments from the source as question scaffolding. Rewrite those in your own words.
- **Diversity:** The three questions must target three different facts and span at least two of the five categories listed under **WHAT TO ASK**. Do not ask three questions all about operating parameters, or all about materials.

WHAT TO ASK

Target questions in these five categories:

1. **Parameters and Conditions:** temperature, pressure, time, concentration, pH, flow rate, voltage, atmosphere, stoichiometry, operating ranges, and related details.
2. **Materials:** catalyst, solvent, reagent, substrate, additive, precursor, equipment, and related details.
3. **Outcomes:** yield, selectivity, conversion, purity, efficiency, and related details.
4. **Methods:** synthesis route, characterization technique, separation method, and related details.
5. **Structure:** functional group, crystal form, polymorph, molecular weight, composition, and related details.

Questions about function, role, or effect are acceptable only when the passage explicitly and completely states that information, not when it must be inferred, even partially.

EXAMPLES

Example 1

Passage, Turkish:

Enerji tuketimi dusurulmus bir tahrik tertibati. Bulus hareket enerjisi uretebilen bir motorun 10 en az bir yanma odasinda 11 ihtiyac duydugu kimyasal unsurlardan en azindan bir kisminin temin edilerek enerji sarfiyatinin azaltilabildigi bir tahrik tertibati 1 ile ilgilidir. Bulusun yeniligi; bahsedilen tahrik tertibatinin 1 en az bir elektroliz birimi 20 ve en az bir kontrol birimi 40 ile iliskilendirilmis olmasi, bahsedilen elektroliz biriminin 20 elektrolitin elektroliz edilmesini saglayacak sekilde konfigure edilmis olmasi, bahsedilen kontrol biriminin 40 ise elektroliz biriminde bulunan elektroliti elektroliz edilirken yaklasik 85–87°C araligina kadar isitacak sekilde gerilim ve voltaji ayarlayabilir olmasi, elektroliz biriminde 20 elektroliz sonrasinda elde edilen oksijen, hidrojen ve su buharinin bahsedilen yanma odasina 11 karistirilarak verilebilir olmasidir.

Good: "What temperature range is maintained for the electrolyte during electrolysis?"

Asks for one specific parameter directly stated in the passage. Answer: "85–87°C". The answer is a contiguous span, with exact numbers preserved.

Bad, inference-why: "Why is the electrolyte heated to about 85–87°C during electrolysis?"

The passage states the temperature but never explains the reason for choosing it.

Bad, partial support: "What gases are produced by electrolysis and fed into the combustion chamber, and in what ratio?"

The passage lists the gases, oxygen, hydrogen, and water vapor, but never gives a ratio. The question is only partially answerable. Discard.

Example 2

Passage, French:

Systeme de surveillance de traitement d eau decentralise connecte a un reseau et dispositif de suivi de fonctionnement et de maintenance comprenant au moins un capteur connecte a Internet et une plateforme logicielle integree qui peut etre utilisee par des installations de grande taille et ou des organisations comprenant de multiples installations qui gerent et maintiennent des systemes de traitement d eau potable decentralises, par exemple des filtres de point d utilisation, ou des processus de traitement d eau potable decentralises, par exemple un rincage de robinet, a un ou a plusieurs emplacements. Au moins un capteur est installe en amont ou en aval d un consommable ou d un processus de traitement d eau decentralise et mesure des donnees d eau, comprenant non exclusivement le volume d eau traite dans le temps, et alerte l utilisateur lorsque des actions de maintenance sont requises pour maintenir la qualite de l eau.

Good: "What does the sensor measure in the decentralized water treatment system?"

Short, natural, and asks for one specific fact directly stated. "Decentralized water treatment system" is a reused technical term, which is allowed.

Bad, lifted framing: "Why is at least one sensor installed upstream or downstream of a consumable or decentralized treatment process?"

This lifts a long descriptive phrase from the source and asks for reasoning the passage does not give.

Bad, partial support: "How does the sensor determine when maintenance is required?"

The passage says the sensor alerts the user when maintenance is needed, but never states the mechanism or threshold by which it makes that determination. Discard.

SELF-CHECK

For each question before finalizing, check:

- Can the answer be produced by pointing to a contiguous span in the passage, with no inference or combination across sentences? If not, discard.
- Does the question ask for exactly one piece of information?
- Are all numbers, units, and ranges in the answer reproduced exactly as in the source?
- Would a researcher plausibly type this query into a search bar?
- Could someone who has never seen this document type this question into a search engine? It must not refer to the document, an "example given", or anything "mentioned" or "described" in it.
- Are the three questions about three different facts, covering at least two categories from **WHAT TO ASK**?

OUTPUT: valid JSON only, no markdown.

```
[
  {"question": "...", "answer": "...", "question_type": "..."},
  {"question": "...", "answer": "...", "question_type": "..."},
  {"question": "...", "answer": "...", "question_type": "..."}
]
```

`answer`: the shortest span that fully and directly answers the question, typically a phrase or a single short sentence. The answer must be strictly grounded in the passage.

`question_type`: one of `parameter_or_condition`, `material`, `outcome`, `method`, or `structure`.

The same passage exists in different languages. This should not affect your target language for questions and answers. They are declared above. Here are the passages:

Figure S.8: Technical-question generation prompt, English version. Language-specific variants differ only in the declared output language.

You are an expert at creating semantic retrieval questions for chemistry and patent documents.

The source context may be in any language. The questions and answers **MUST** be written in English. Preserve chemical names, compound identifiers such as "Compound 3a", trade names, reagent abbreviations, and all numerical values, units, and ranges in their original form. Do not translate, round, or reformat them.

Generate exactly **THREE** question-answer pairs from the context. The questions should target the passage concepts, problems, approaches, or applications, not isolated facts. Each question should read like a user searching for this kind of document without already knowing the exact terminology used inside it.

CORE RULES

- **Conceptual Framing:** Each question asks about a concept, problem, approach, use case, or capability discussed in the passage, not a single narrow data point like a temperature value or reagent name.
- **Lexical Distance:** Actively paraphrase. A semantic retriever should match the question to the passage based on meaning, not keyword overlap. Avoid reusing the passage distinctive vocabulary when a natural synonym or paraphrase works. Exception: proper nouns, compound identifiers, trade names, and standardized chemical or technical names, such as "Pd/C", "Compound 3a", or specific polymer names, must stay as-is. Otherwise the question becomes unanswerable from any document.
- **Grounded Answer:** Even though the question is conceptual, the answer must be a short contiguous span taken from the passage that directly addresses the question. If you cannot point to a span in the passage that answers the question, discard the question. The answer is the evidence that this passage is the right match.
- **Retrieval Realism:** Write each question the way someone would phrase a search when looking for a document like this one but without having read it yet. They know what they want to find; they do not know the exact wording used by the document.
- **No Document Phrases:** Never use "described in the invention", "according to the text", "mentioned in the disclosure", or similar wording. The question should not reveal that a specific document is being referenced.
- **Standalone query for a search engine:** Each question is a query for an Information Retrieval (IR) system. The person typing it has **NOT** seen this document and is searching to find it. Never refer to the document or its contents. This includes not only overt phrases such as "described in the invention", "according to the text", or "in the passage", but also any wording that presupposes the reader is looking at the document, such as "the example given", "the approach mentioned/described/disclosed here", or "which method is provided". Write self-contained questions. Bad: "Which agent example is given that increases ROS?" Good: "Which agent increases ROS?"
- **Single Intent:** Each question has one clear informational goal. It is fine if the goal is broader than a single fact, for example "how does X address Y", but it should not bundle multiple unrelated asks.
- **Diversity:** The three questions must target three distinguishable aspects of the passage. They must span at least two of the following framings: problem, solution, and application.

FRAMINGS

1. **Problem-framed:** what challenge or limitation does the passage address?
2. **Solution-framed:** what approach, mechanism, or method is proposed?
3. **Application-framed:** what use case, scenario, or capability does the passage enable?

Broader conceptual questions about the overall approach are acceptable as long as the passage clearly and directly answers them in a contiguous span.

EXAMPLES

Example 1

Passage (Turkish, ASCII-normalized):

Enerji tuketimi dusurulmus bir tahrik tertibati. Bulus hareket enerjisi uretebilen bir motorun (10) en az bir yanma odasinda (11) ihtiyac duydugu kimyasal unsurlardan en azindan bir kisminin temin edilerek enerji sarfiyatinin azaltilabildigi bir tahrik tertibati (1) ile ilgilidir. Bulusun yeniligi; bahsedilen tahrik tertibatinin (1) en az bir elektroliz birimi (20) ve en az bir kontrol birimi (40) ile iliskilendirilmis olmasi, bahsedilen elektroliz biriminin (20) elektrolitin elektroliz edilmesini saglayacak sekilde konfigure edilmis olmasi, bahsedilen kontrol biriminin (40) ise elektroliz biriminde bulunan elektroliti elektroliz edilirken yaklasik 85–87°C araligina kadar isitacak sekilde gerilim ve voltaji ayarlayabilir olmasi, elektroliz biriminde (20) elektroliz sonrasinda elde edilen oksijen, hidrojen ve su buharinin bahsedilen yanma odasina (11) karistirilarak verilebilir olmasidir.

Good, application-framed, paraphrased: "How can an engine reduce fuel consumption by generating part of its own combustion inputs?"

This captures the core concept of the passage. It uses "generating part of its own combustion inputs" instead of lifting phrases such as "electrolysis" and "combustion chamber". The answer points to the drive arrangement producing oxygen, hydrogen, and water vapor and feeding them into the combustion chamber.

Good, solution-framed, paraphrased: "What role does on-board electrolysis play in supplying reactants to an engine?"

"Electrolysis" is a technical term that stays. "Supplying reactants to an engine" paraphrases the passage content about chemical components needed by the engine and delivery to the combustion chamber.

Bad, too extractive and keyword-heavy: "What temperature range is maintained for the electrolyte during electrolysis?"

This is a fact-extraction question, not a semantic retrieval question. It belongs to the technical prompt, not this one.

Bad, ungrounded conceptual: "What are the environmental benefits of this fuel-saving approach?"

This sounds like a retrieval question, but the passage does not discuss environmental benefits. Discard.

Example 2

Passage (French, ASCII-normalized):

Systeme de surveillance de traitement d'eau decentralise connecte a un reseau et dispositif de suivi de fonctionnement et de maintenance comprenant au moins un capteur connecte a Internet et une plateforme logicielle integree qui peut etre utilisee par des installations de grande taille et/ou des organisations comprenant de multiples installations qui gerent et maintiennent des systemes de traitement d'eau potable decentralises, par exemple des filtres de point d'utilisation, ou des processus de traitement d'eau potable decentralises, par exemple un rincage de robinet, a un ou a plusieurs emplacements. Au moins un capteur est installe en amont ou en aval d'un consommable ou d'un processus de traitement d'eau decentralise et mesure des donnees d'eau, comprenant non exclusivement le volume d'eau traite dans le temps, et alerte l'utilisateur lorsque des actions de maintenance sont requises pour maintenir la qualite de l'eau.

Good, problem-framed, paraphrased: “How can organizations with multiple drinking water sites know when filters need servicing?”

This captures the problem the passage addresses using natural search wording. It avoids lifting terms such as “consommable” or “actions de maintenance”. The answer points to the sensor alerting the user when maintenance is required.

Good, application-framed: “Can IoT sensors monitor point-of-use water filters across many locations?”

“IoT sensors” paraphrases “capteur connecte a Internet”. “Point-of-use water filters” is a reused standard term and is acceptable. The answer is grounded in the passage description of the monitoring system.

Bad, too extractive: “What does the sensor measure in the decentralized water treatment system?”

This is a fact-extraction question. It belongs to the technical prompt.

Bad, keyword-lifted: “What is a decentralized water treatment monitoring system connected to a network?”

This is near-verbatim reuse of the passage opening phrase. It would match via keyword overlap, defeating the purpose of semantic retrieval.

SELF-CHECK

For each question before finalizing, check:

- Does the question ask about a concept, problem, approach, or application, rather than a single extracted fact?
- Is the question vocabulary meaningfully different from the passage vocabulary while preserving meaning? Standard technical terms and proper nouns are exempt.
- Can you point to a contiguous span in the passage that directly answers it? If not, discard.
- Would someone searching for a document like this one plausibly type this query without already having read it?
- Could someone who has never seen this document type this question into a search engine? It must not refer to the document, an “example given”, or anything “mentioned” or “described” in it.
- Do the three questions cover at least two framings: problem, solution, and application?

OUTPUT: valid JSON only, no markdown.

```
[
  {"question": "...", "answer": "...", "framing": "..."},
  {"question": "...", "answer": "...", "framing": "..."},
  {"question": "...", "answer": "...", "framing": "..."}
]
```

`answer`: a short contiguous span taken from the passage that directly answers the question. Keep it as short as possible while fully addressing the question. The answer must be in English.

`framing`: one of `problem`, `solution`, or `application`.

The same passage exists in different languages. This should not affect your target language for questions and answers. They are declared above. Here are the passages:

Figure S.9: General-question generation prompt, English version. Language-specific variants differ only in the declared output language.

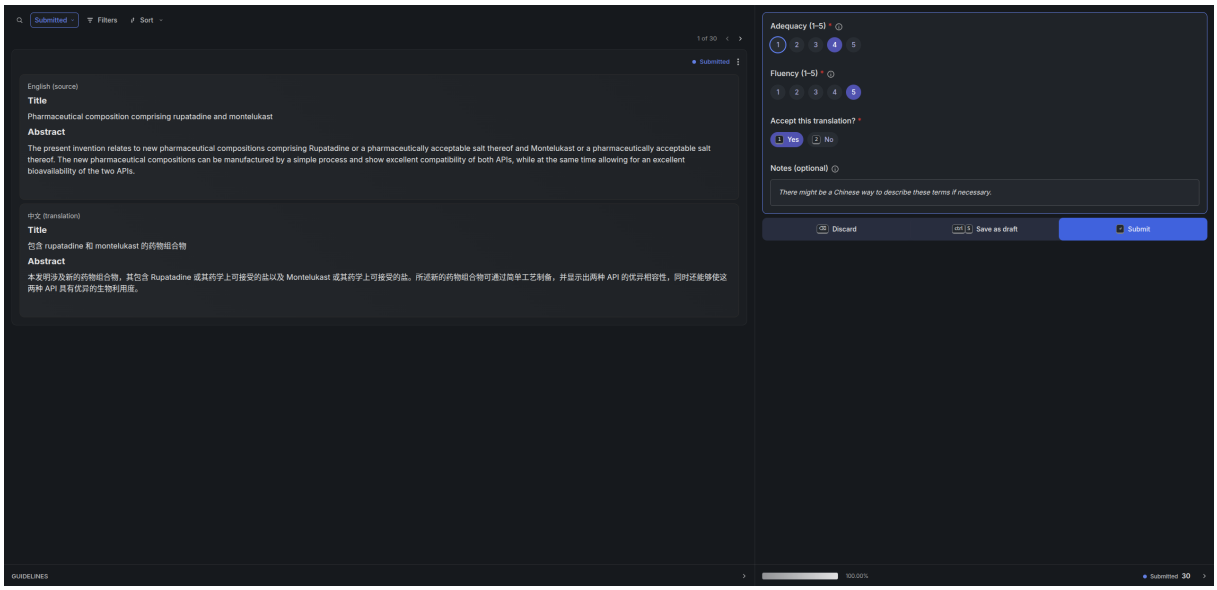

Figure S.10: Human annotators use the Argilla open-source tool to perform annotation tasks.

LivingArena: Do LLMs Know What Other LLMs Don't? Peer-Probing as Scalable Evaluation

Abstract

Fixed benchmarks are costly to renew and cannot adapt their questions to model-specific failures. We ask whether LLMs can instead discover one another's weaknesses and turn those observations into an evaluation process. To study this question, we introduce **LivingArena**, an automated peer-probing framework in which models take turns testing one another. Using the interaction history, each questioner identifies potential weaknesses of its opponent and constructs targeted, verifiable questions to probe them. A 3,600-round tournament of ten models reveals a clear role asymmetry: strong answerers are not always reliable questioners, because they may generate internally inconsistent tests or fail to verify their own reference answers. After a questioner exposes an answerer's failure, it is more likely to pursue the same capability domain, while the answerer's weakness recurs on independently generated questions, including questions written by different models. These findings show that peer probing can reveal persistent model-specific weaknesses while separately evaluating answering and reliable test construction. By automating this process and allowing test difficulty to evolve with model capabilities, LivingArena provides a "living" benchmark for model development, red-teaming, and capability-aware multi-agent coordination. We publicly release our code.[1]

1 Introduction

Evaluation is foundational to the development and deployment of large language models: it guides model selection, reveals capability regressions and safety-relevant failures, and provides the evidence needed to track progress across generations. As frontier systems improve rapidly, however, assigning an aggregate score is no longer sufficient. An effective evaluation must also continue to distinguish leading models, expose model-specific blind spots, and evolve as previously difficult tasks become routine.

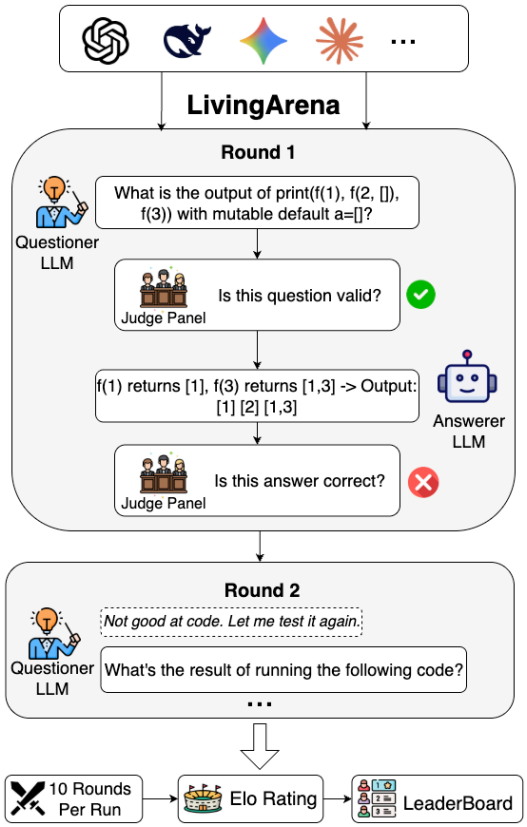

Figure 1: One LivingArena round. The questioner uses the interaction history to construct a new test, which is validated before the answerer sees it. The result is then added to the history for subsequent rounds.

Existing paradigms meet only part of this need. Fixed benchmarks such as MMLU and MMLU-Pro provide reproducible accuracy measurements, but constructing and refreshing high-quality items can be expensive, public item banks can enter train-

ing and development pipelines, and leading systems increasingly cluster near the top of established tests (Hendrycks et al., 2021a; Wang et al., 2024). Human-preference arenas replace fixed questions with live interactions and pairwise votes, yet their outcomes primarily reflect overall user preference and continue to depend on human participation (Régin et al., 2024). Despite their different strengths, both paradigms usually evaluate models with questions selected before the target model's failures are observed. Consequently, they leave an important capability underexplored: whether a model can actively identify another model's blind spots and convert those observations into targeted tests.

This gap motivates our central question: *can an LLM identify what another LLM does not know and turn that evidence into a valid new test?* We investigate this question through **LivingArena**, a dynamic peer-probing framework in which models alternate between the roles of questioner and answerer. As Figure 1 illustrates, the questioner observes earlier outcomes and uses them to explore broadly, identify promising weaknesses, and pursue those weaknesses from new angles. It then submits a question together with a reference answer and a reproducible verification procedure. A non-participating judge panel validates this artifact before the opponent sees the question, and invalid construction is penalized. Consequently, success requires not only finding a difficult question but also producing a sound test. Together, history-conditioned generation and pre-answer validation allow the evaluation to evolve with the participating models while preserving inspectable evidence for every scored round. The name *LivingArena* reflects this intended longevity: the protocol can run automatically, and the generated tests can become more demanding as the participating models grow stronger, allowing the benchmark to remain informative rather than depending on a permanently fixed item bank.

LivingArena evaluates two complementary aspects of model capability. Answerer accuracy measures conventional problem solving on admitted questions, while questioner utility measures whether a model can construct reliable tests that expose an opponent's failures. We use joint Elo to summarize performance across both roles under the specified tournament protocol, and retain the two role-specific measures to explain the behaviors behind that aggregate. Users interested primarily in task completion may therefore prioritize answerer performance, whereas model developers, red teams, and multi-agent-system designers may additionally value whether a model can diagnose another system before trusting it or delegating work to it.

Our experiments show that this role decomposition reveals differences that answer-only and human-preference evaluations can miss. Some models answer admitted questions accurately yet fail to construct coherent and valid questions of their own. By contrast, the strongest questioners combine effective attacks with reliable construction. Once a questioner exposes an answerer's failure, it becomes more likely to pursue the same capability domain in the next round. More importantly, the answerer's weakness reappears on subsequent questions, including questions generated by different models. This recurrence indicates that peer probing can identify genuine weaknesses of the answerer rather than merely producing isolated difficult items.

We establish these findings in a complete 3,600-round tournament of ten models evaluated by three non-participating judges. The results confirm that strong answering does not guarantee strong test construction: Claude-Opus-4.6 attains 91.3% answer accuracy while 30.0% of its proposed tests are rejected. The broad ranking remains consistent when we balance domain exposure or reduce the strategic guidance given to questioners. Together, these results show that peer interaction can provide both a scalable evaluation mechanism and fine-grained evidence about where a model's capabilities break down.

Our main contributions are as follows:

(1) We introduce LivingArena, an automated evaluation framework in which language models generate, validate, and answer questions for one another.
(2) We conduct a 3,600-round tournament involving ten frontier models and identify substantial differences between answering and question construction. In particular, models that answer accurately may still generate inconsistent questions or fail to verify their own reference answers, revealing capability bottlenecks that answer-only evaluation does not capture.
(3) We evaluate LivingArena through extensive behavioral and robustness analyses. The results show that questioners actively pursue observed failures, that exposed weaknesses recur across new questions, and that the broad ranking remains stable under changes to domain alloca-

tion and strategic guidance.

2 Related Work

Static benchmarks. Fixed suites provide standardized, reproducible comparisons across broad knowledge (MMLU and MMLU-Pro), mathematics (MATH), code generation (HumanEval), truthfulness (TruthfulQA), and graduate-level science (GPQA) (Hendrycks et al., 2021a; Wang et al., 2024; Hendrycks et al., 2021b; Chen et al., 2021; Lin et al., 2022; Rein et al., 2024). However, public items risk repeated exposure during training and development, while established tests lose diagnostic headroom as models improve. LiveBench and LiveCodeBench mitigate these problems with refreshed or temporally recent data (White et al., 2024; Jain et al., 2025); LivingArena instead generates questions within each tournament, allowing evaluation coverage and difficulty to evolve with the participants.

Dynamic and generated benchmarks. Dynamic evaluation follows several complementary routes. ForecastBench uses unresolved future events to create time-indexed questions (Karger et al., 2025); Language-Model-as-an-Examiner generates assessments, while QuickScope searches parameterized benchmark spaces for certifiably hard configurations (Bai et al., 2023; Lundy et al., 2026); and CodeArena dynamically recalibrates scores from participating code-generation systems (Du et al., 2025). Computerized adaptive testing offers a related paradigm, selecting items from a calibrated pool according to item information and an updated ability estimate (Linden and Glas, 2010). Peer-evaluation frameworks instead distribute roles across models: SKATE uses verifiable generated challenges, MedEvalArena generates and ensemble-validates medical questions, and AutoBench rotates models through generator, contestant, and judge roles (Gould et al., 2025; Prem et al., 2026; Loi et al., 2025). LivingArena combines adaptive and peer evaluation without relying on a fixed item pool: a contestant uses one target's preceding outcomes to construct a new self-contained test and can follow up on an exposed weakness.

LLM judging and interactive arenas. LLM judges scale open-ended evaluation but can exhibit position and verbosity biases, self-enhancement, and sensitivity to prompt perturbations (Zheng et al., 2023; Chen et al., 2024; Shi et al., 2025). Interactive arenas already use judgments at scale: Chatbot Arena converts crowdsourced pairwise preferences into rankings (Régin et al., 2024), whereas Auto-Arena has an examiner generate questions, candidates engage in a multi-round peer battle, and an LLM committee select a winner (Zhao et al., 2025). LivingArena uses interaction for a different, decomposable form of diagnosis. Rather than producing a single preference judgment, its panel first evaluates whether each generated question and solution form a valid test and then grades the answer against that solution. This structure separately measures a model's ability to construct reliable tests, expose an opponent's weaknesses, and answer valid questions.

3 LivingArena

3.1 Design Principles

At its core, LivingArena asks one model to test another, turning interaction into a renewable source of evaluation questions. Interaction alone, however, is not necessarily informative: generated tests must respond to the target, remain independently checkable, and support fair comparison across models. LivingArena therefore addresses three challenges in model-generated evaluation. First, independently generated questions may remain generic and fail to probe the target's capability boundary; we condition each question on the target model's preceding outcomes, enabling broad exploration followed by targeted tests of observed weaknesses. Second, generated questions are informative only when they are well-defined and supported by reliable answers; we require each questioner to provide a reference answer and verification procedure, which a judge panel validates before the question reaches the answerer. Third, assigning models to fixed roles would conflate problem solving with test construction; we evaluate every model as both questioner and answerer, revealing whether its limitations arise from answering questions, identifying weaknesses, or constructing valid tests. Together, these choices turn peer interaction into a controlled diagnostic process rather than an unconstrained exchange between models.

3.2 Formal Protocol

Let $\mathcal{M}$ denote the contestant set and $\mathcal{J}$ a panel of non-participating judges. For each model pair (A, B), a bidirectional game consists of direc-

Algorithm 1 LivingArena bidirectional game

Require: Models A, B; judge panel $\mathcal{J}$; rounds T
for $(Q, R) \in \{(A, B), (B, A)\}$ **do**
  $H_1 \leftarrow \emptyset$
  for $t = 1, \ldots, T$ **do**
    $(q_t, \pi_t, a_t^*) \leftarrow Q(H_t)$
    $V_t^{(j)} \leftarrow \textsc{Validate}(j, q_t, \pi_t, a_t^*)$ for $j \in \mathcal{J}$
    $v_t \leftarrow \prod_{j \in \mathcal{J}} V_t^{(j)}$
    if $v_t = 0$ **then**
      $H_{t+1} \leftarrow H_t \cup \{(q_t, 0, \varnothing, \varnothing)\}$
      continue
    end if
    $r_t \leftarrow R(q_t)$ ▷ π_t and a_t^* remain hidden
    $G_t^{(j)} \leftarrow \textsc{Grade}(j, r_t, q_t, \pi_t, a_t^*)$ for $j \in \mathcal{J}$
    $g_t \leftarrow \mathbb{I}\left[\sum_j G_t^{(j)} \geq \lfloor |\mathcal{J}|/2 \rfloor + 1\right]$
    $H_{t+1} \leftarrow H_t \cup \{(q_t, 1, r_t, g_t)\}$
  end for
end for

tional matches $M_{A \to B}^{(k)}$ and $M_{B \to A}^{(k)}$, placing each model once in each role. Algorithm 1 describes one such game. In round t, the history $H_t = \{(q_i, v_i, r_i, g_i)\}_{i<t}$ records each question q_i, validation outcome v_i, answer r_i when the test was admitted, and correctness grade g_i.

The questioner Q produces a self-contained question q_t, a reproducible verification procedure π_t, and its supported reference answer a_t^*. Each judge j casts a validity vote $V_t^{(j)}$, and the test reaches answerer R only under unanimous acceptance. For an admitted test, the judges cast correctness votes $G_t^{(j)}$ and the strict majority determines g_t. Appending either outcome to H_{t+1} lets subsequent questions respond to earlier successes and failures.

3.3 Protocol Instantiation

Capability domains. We use six broad domains—quantitative reasoning, code and algorithms, natural science, humanities and social science, language and linguistics, and logic and abstract reasoning—informed by MMLU-Pro and BIG-Bench Hard (Wang et al., 2024; Suzgun et al., 2023). The domains give questioners diverse directions for weakness search while keeping answers checkable and cross-round behavior interpretable. They also make domain coverage and repeated attacks directly measurable. This taxonomy is an extensible experimental scaffold rather than a requirement of the protocol.

Round structure and scoring. Each directional match has $T = 10$ rounds. Rounds 1–8 encourage exploration across the six domains while permitting a questioner to revisit a promising weakness. Rounds 9–10 are undiscounted bonus rounds, allowing the strongest opponent-specific probes after the earlier interaction has revealed where the answerer struggles. For domain d_t, let $c_t(d_t)$ be the number of earlier successful hits in that domain, and let $\mathbf{s}_t = (s_{Q,t}, s_{A,t})$ be the questioner–answerer score pair. The hit reward and round scores are

$$w_t(c) = \begin{cases} 1, & t > 8 \text{ or } c \leq 1, \\ 0.5, & t \leq 8 \text{ and } c = 2, \\ 0.2, & t \leq 8 \text{ and } c \geq 3, \end{cases} \tag{1}$$

$$\mathbf{s}_t = \begin{cases} (-1, 0), & v_t = 0, \\ (0, 1), & v_t = 1,\ g_t = 1, \\ (w_t(c_t(d_t)), 0), & v_t = 1,\ g_t = 0. \end{cases} \tag{2}$$

Thus, rejected tests penalize the questioner, correct answers reward the answerer, and valid tests that expose a failure reward the questioner. The first two hits in a domain receive full credit, supporting initial discovery and confirmation; later regular-round hits are discounted so that repeatedly exploiting one weakness does not dominate broader search.

Role-specific measures. We report questioner net utility $U_Q(m)$, the model's mean $s_{Q,t}$ over its questioner rounds, and answerer accuracy $A(m)$, the fraction of its admitted questions answered correctly. For a joint tournament summary, we sum each model's points across both directions of a game; the larger total defines a win and equal totals a draw. These outcomes update sequential Elo ratings initialized at 1,500 with $K = 32$. Joint Elo summarizes performance across both roles, while U_Q and A expose the behaviors underlying it.

Model configurations	Provider	Role

Gemini-3.1-Flash-Lite	9	-0.178	3.1%	20.8%	10	64.7%	10	1320
Claude-Opus-4.6	10	-0.256	4.4%	30.0%	6	91.3%	6	1492

Table 2: Role-decomposed LivingArena results. Questioner columns report rank, net utility (overall questioning effectiveness), hit rate (valid tests that expose answer failures), and rejection rate (proposed tests rejected by the judges). Answerer columns report rank and accuracy on validated questions. Joint columns report overall rank and Elo across both roles.

4 Experimental Setup

We instantiate the protocol with ten models from OpenAI, Anthropic, Google, and DeepSeek, using the model-specific reasoning settings reported in Appendix A (Table 1). To separate contestant performance from judge participation, the main judge panel consists of three non-participating models: Kimi-K2.6, MiniMax-M2.7, and GLM-5.2. The tournament evaluates all $\binom{10}{2} = 45$ model pairs. For each pair, we run four bidirectional games, yielding eight directional matches; each directional match contains ten rounds. The complete main experiment therefore contains 360 directional matches and 3,600 rounds.

5 Results

The evaluation is designed to answer four questions in sequence. First, what differences emerge when models are evaluated as both questioners and answerers? Second, do questioners respond to observed failures, and do the identified weaknesses recur beyond the original question? Third, how sensitive are the conclusions to domain allocation and strategic guidance? Finally, how does LivingArena relate to static accuracy, human preference, and interactive debate evaluation? We organize the results around these questions.

5.1 Role-Decomposed Performance

We begin by asking whether questioning and answering expose the same capability ordering. Table 2 shows that they do not. GPT-5.5 and Gemini-3.1-Pro lead as questioners because they combine high hit rates with low rejection rates. By contrast, Claude-Opus-4.6 reaches 91.3% answer accuracy but ranks last in questioner utility, as 30.0% of its proposed tests are rejected. Claude-Opus-4.7 illustrates a different trade-off: it generates more successful hits than Claude-Opus-4.6 but answers admitted questions less accurately. These examples demonstrate that models can fail for distinct reasons depending on the role they occupy.

The aggregate ranking is related to both roles. Joint Elo correlates with questioner utility at $\rho = 0.867$ and with answerer accuracy at $\rho = 0.903$, whereas the two role-specific rankings correlate at $\rho = 0.758$. The strongest and weakest systems are broadly consistent across views, but several models in the middle exchange positions. Figure 2 makes these profiles visible: for example, DeepSeek-V4-Flash is the second-most accurate answerer while producing relatively few successful attacks. This variation explains why joint Elo alone is insufficient for diagnosis. Appendix Table 6 reaches the same conclusion from another direction: changing the descriptive weight assigned to questioning and answering causes local reorderings, even though the broad structure remains stable.

To understand what drives low questioner utility, we qualitatively review the rejected artifacts. The failures are not simply cases in which a model lacks the answer to its own question. Instead, they include internal calculations that contradict the submitted answer, mathematical derivations that do not support the final value, and code questions whose output depends on an unspecified language or library version. In other cases, a model identifies a flaw during verification but updates only its reasoning, leaving the original question unchanged. Such errors reveal a bottleneck that answer-only evaluation cannot observe: the ability to turn knowledge

Follow-up behavior	Exposed	Control
Same-domain retargeting	20.2%	4.0%
Same-questioner recurrence	31.4%	7.1%
Cross-questioner recurrence	18.3%	3.6%

Table 3: Adaptive pursuit and recurrence. *Exposed* denotes a preceding failure or an answerer–domain pair with a failure in the discovery games; *Control* denotes the corresponding no-failure condition.

into a coherent, independently usable test artifact.

5.2 Adaptive Pursuit and Recurring Weaknesses

Role asymmetry alone does not establish that models use interaction history strategically. We therefore ask whether an answer failure changes the questioner's subsequent behavior. As Table 3 shows, after a hit the next regular-round question remains in the failed domain 20.2% of the time, compared with 4.0% after a correct answer. Thus, answer feedback changes what questioners choose to test next.

Retargeting is meaningful only if the first hit identifies something more persistent than a difficult individual item. We divide the four games in each questioner–answerer direction into discovery and evaluation halves: the first two identify answerer–domain pairs with an observed failure, and the last two test those pairs using new, non-duplicate questions. The answerer fails more often when the same questioner revisits an exposed pair (31.4% versus 7.1% for controls), and the pattern transfers to questions from a different generator (18.3% versus 3.6%). Answerer–domain error profiles are also similar across the two game halves ($r = 0.812$; $\mathrm{ICC}(2,1) = 0.799$). Together, these analyses show that LivingArena often identifies recurring weaknesses rather than isolated mistakes tied to one question or generator. Because model-level follow-up samples remain small, Appendix B reports those estimates descriptively with uncertainty intervals.

5.3 Protocol Controls

The preceding analyses use a particular domain policy and questioner prompt. We therefore test whether the conclusions are artifacts of these choices through matched controls for domain allocation and strategic guidance.

Domain allocation. We first examine domain selection. Under the default protocol, questioners may favor domains in which they are especially capable, so the aggregate ranking could partly reflect each model's preferred subject distribution. To remove this source of variation, we run one complete tournament for each domain, keep all ten rounds in the assigned domain, and combine the six tournament outcomes with equal weight. Relative to a free-choice tournament using the same judges, the balanced ranking remains highly aligned ($\rho = 0.976$): GPT-5.5 and Gemini-3.1-Pro stay first and second, the top-five set is unchanged, and no model moves by more than one position. Domain choice therefore affects what evidence is collected without explaining the broad model ordering. The complete aggregate comparison and per-domain rankings appear in Appendix Tables 7 and 9.

Although equal weighting preserves the ranking, the domain-level results reveal why the taxonomy remains diagnostically useful. Quantitative reasoning and logic produce relatively many answer failures, but logic also rejects 39.6% of proposed tests, indicating that it is difficult both to answer and to formulate reliably. Humanities and social science shows the opposite pattern: its 1.4% hit rate and 98.3% answer accuracy leave little separation among models. Language likewise imposes a substantial construction burden, with a 30.0% rejection rate. Thus, different domains vary not only in answer difficulty but also in the reliability with which models can turn them into tests; Appendix Table 8 reports the complete domain-level metrics.

Strategic guidance. We next test whether explicit strategic instructions create the observed behavior. The reduced-guidance prompt retains the task, complete interaction history, domain definitions, verification requirements, and scoring rule, but removes live score cues, explicit weakness-attack language, and forced escalation. The resulting ranking remains closely aligned with the full-guidance setting ($\rho = 0.964$), indicating that the broad ordering does not arise solely from aggressive wording. At the same time, same-domain follow-up after a failure rises from 24.7% to 35.6%, and switching after a correct answer falls from 96.5% to 88.6%. Strategic guidance therefore broadens exploration and encourages switching, while the underlying ranking remains stable. Appendix Tables 10 and 11 report the complete model rankings and aggregate behavioral results.

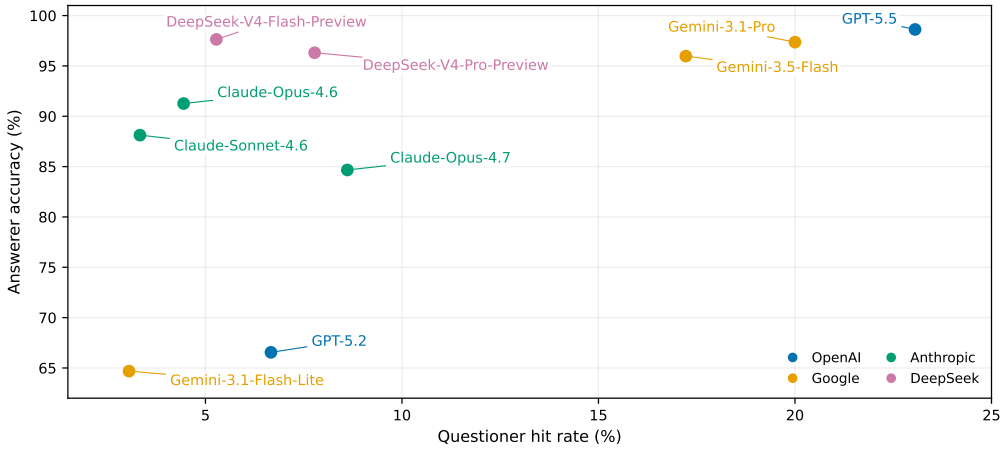

Figure 2: Questioner hit rate and answerer accuracy reveal distinct profiles. Rejection enters net utility but is not shown on the axes.

5.4 Relationship to Existing Evaluations

LivingArena measures a complementary signal to existing evaluations. Its Joint Elo has modest rank agreement with Chatbot Arena ($\rho = 0.406$) and MMLU-Pro ($\rho = 0.314$), while its ranking is effectively uncorrelated with Auto-Arena on the same ten models ($\rho = -0.018$). This divergence is expected because the evaluations reward different behaviors: MMLU-Pro measures correctness on a fixed expert-authored test set, Chatbot Arena aggregates user preferences over responses, and Auto-Arena selects a winner from an interactive debate. LivingArena instead asks whether a model can use evidence about a particular opponent to construct a valid new test, expose a weakness, and also answer tests generated by others. Consequently, models with similar answer quality can separate when the reliability and discriminative value of their generated tests are evaluated explicitly. These comparisons position LivingArena as a diagnostic complement rather than a replacement for conventional benchmarks. An 18-model extension nevertheless preserves the ten-model ordering on exact overlaps ($\rho = 0.964$), supporting the framework's use as an expandable evaluation. Appendix E provides the complete external comparisons and analysis, and Appendix D reports the extension.

6 Conclusion

Fixed benchmarks become less informative as their items are repeatedly exposed and model capabilities improve, while answer-only evaluation does not reveal whether a model can identify and reliably test another model's weaknesses. To address these limitations, we introduce LivingArena, an automated peer-probing framework that continually generates opponent-conditioned tests from interaction history. Each model serves as both questioner and answerer, and a non-participating panel validates generated tests before they are administered. LivingArena thereby adapts evaluation evidence to the participating models while separating reliable test construction, weakness discovery, and problem solving into complementary diagnostic views.

Across 3,600 main-run rounds, the role-level results show that strong answering does not guarantee dependable test construction. The interaction records further show that questioners respond to observed failures and that exposed weaknesses recur on new questions written by both the original and different questioners. At the same time, matched controls preserve the broad ranking under changes to domain allocation and strategic guidance. Comparisons with static benchmarks, human-preference arenas, and interactive debate confirm that LivingArena measures a complementary target rather than replacing conventional capability evaluation.

The framework therefore provides more than a leaderboard. Accepted tests can be reused as targeted regression cases, rejected construction attempts reveal failures of self-verification, and recurring failure patterns help localize model-specific weaknesses. These artifacts can support continuous red-teaming and model development without relying exclusively on a fixed public item bank. More broadly, LivingArena offers a setting for studying capability awareness in multi-agent systems, where recognizing another agent's limitations can improve delegation and verification.

Limitations

LivingArena depends on a model judge panel to determine which artifacts enter the evaluation and whether admitted answers are correct. The current experiments use one fixed panel of three non-participating judges, but panel decisions do not establish independent correctness. We have not yet conducted a systematic multi-domain expert or tool-based audit, so shared validation errors and incorrect answer grades remain possible.

The present instantiation also covers only text-based tasks with externally checkable answers in six broad domains. It does not evaluate open-ended creative quality, multimodal interaction, or tool-augmented systems, and the six-domain taxonomy is not intended to exhaust the space of model capabilities. Similarly, the prompt control changes only the strategic guidance given to the questioner; sensitivity to the answerer and judge prompts has not been studied systematically. We also have not conducted paired paraphrase or testing-intent perturbations, so the complete reruns establish protocol-level rather than question-level robustness.

Finally, the recurrence analyses show that failures generalize across new questions, games, and questioners within the evaluated populations and domains, but broader external validity will require independently constructed task suites and qualified human or tool-based audits.

Appendix

A Experimental Configuration

The contestant reasoning settings are listed in Table 4. These labels follow each provider's interface and are therefore configuration identifiers rather than a common cross-provider scale. Repository records contain direct chat-completion calls; the final artifact release will document the confirmed tool-access policy.

Model	Reasoning
Claude-Sonnet-4.6	high
Claude-Opus-4.6	high
Claude-Opus-4.7	high
Gemini-3.1-Flash-Lite	minimal
Gemini-3.5-Flash	medium
Gemini-3.1-Pro	high
GPT-5.5	medium
GPT-5.2	none
DeepSeek-V4-Pro-Preview	high
DeepSeek-V4-Flash-Preview	high

Table 4: Contestant configurations.

The non-participating judges are Kimi-K2.6 and MiniMax-M2.7 with their provider-default reasoning settings, and GLM-5.2 with reasoning set to `max`. The execution policy separates infrastructure failures from model-format failures. Transport or API errors are retried; if they remain unresolved, the game stops at its last completed-round checkpoint and resumes later, so infrastructure failures are never converted into scored outcomes. Non-parseable JSON triggers additional calls to the same role. If a questioner still fails to produce a valid object, the attempt is recorded as a generation failure and receives the rejection penalty.

The information supplied to each role mirrors the conceptual separation in the protocol. At runtime, the questioner receives its system prompt together with the round number, current scores, cumulative hit and rejection counts, and a structured history of earlier questions, raw answers, validation and grading outcomes, and assigned domains. The answerer receives only the admitted question. Validation judges receive the proposed question, reference answer, and verification procedure, whereas grading judges receive the admitted question, accepted reference answer, and answerer response. Appendix F provides the exact prompts and output schemas.

B Model-Specific Follow-Up Estimates

This analysis asks whether adaptive pursuit is distributed across questioners or driven by only a few models. For each questioner, we collect regular-round questions asked in a domain after that model has already exposed a failure there, and report the number of subsequent hits and opportunities in Table 5.

Model	Hits	Questions	Wilson 95% CI
GPT-5.5	14	25	[0.37, 0.73]
Gemini-3.1-Pro	8	25	[0.17, 0.52]
GPT-5.2	3	10	[0.11, 0.60]
Gemini-3.5-Flash	4	15	[0.11, 0.52]
Gemini-3.1-Flash-Lite	1	4	[0.05, 0.70]
Claude-Opus-4.7	2	9	[0.06, 0.55]
DeepSeek-V4-Pro-Preview	4	20	[0.08, 0.42]
DeepSeek-V4-Flash-Preview	1	9	[0.02, 0.43]
Claude-Opus-4.6	0	2	[0.00, 0.66]
Claude-Sonnet-4.6	0	6	[0.00, 0.39]

Table 5: Descriptive hit rates for regular-round questions asked in the same domain after that questioner first exposed an answer failure in the domain. Wide intervals limit model-specific interpretation.

Several models find additional failures after returning to an exposed domain, but most contribute few post-hit opportunities and consequently have wide intervals. We therefore treat the model-specific estimates as descriptive and use the aggregate evidence in Section 5.2 as the primary result.

C Additional Robustness Results

C.1 Role Weighting

This analysis asks whether a single aggregate ordering is sensitive to the relative emphasis placed on questioning and answering. We min–max normalize the two role-specific measures, vary the questioner weight λ from 0 to 1, and report the top five models under each weighting in Table 6.

Questioner weight λ	Rank 1	Rank 2	Rank 3	Rank 4	Rank 5
0.00	GPT-5.5	DeepSeek-V4-Flash-Preview	Gemini-3.1-Pro	DeepSeek-V4-Pro-Preview	Gemini-3.5-Flash
0.25	GPT-5.5	Gemini-3.1-Pro	Gemini-3.5-Flash	DeepSeek-V4-Pro-Preview	DeepSeek-V4-Flash-Preview
0.50	GPT-5.5	Gemini-3.1-Pro	Gemini-3.5-Flash	DeepSeek-V4-Pro-Preview	DeepSeek-V4-Flash-Preview
0.75	GPT-5.5	Gemini-3.1-Pro	Gemini-3.5-Flash	DeepSeek-V4-Pro-Preview	DeepSeek-V4-Flash-Preview
1.00	GPT-5.5	Gemini-3.1-Pro	Gemini-3.5-Flash	DeepSeek-V4-Pro-Preview	DeepSeek-V4-Flash-Preview

Table 6: Sensitivity of a descriptive role-weighted score $\lambda\widetilde{U}_Q + (1-\lambda)\widetilde{A}$, where each role measure is min–max normalized. Weighting changes local positions, reinforcing that no scalar should replace the role-specific views.

GPT-5.5 remains first throughout, while several middle positions change as the weight shifts. The result reinforces the main-text interpretation that the joint score is a protocol-level summary and

should be read together with the two role-specific views.

C.2 Domain Allocation

This control asks whether free domain choice determines the ranking. We run six complete tournaments, assign one domain to all ten rounds in each tournament, and combine the outcomes with equal domain weight. Table 7 gives the complete aggregate comparison with the matched free-choice run.

Model	Free-choice rank	Equal-domain rank	Rank shift	Equal-domain Elo
GPT-5.5	1	1	0	1668
Gemini-3.1-Pro	2	2	0	1610
DeepSeek-V4-Pro-Preview	4	3	-1	1576
Gemini-3.5-Flash	3	4	+1	1559
DeepSeek-V4-Flash-Preview	5	5	0	1553
Claude-Opus-4.6	6	6	0	1466
Claude-Opus-4.7	7	7	0	1458
Claude-Sonnet-4.6	8	8	0	1432
GPT-5.2	10	9	-1	1349
Gemini-3.1-Flash-Lite	9	10	+1	1330

Table 7: Complete equal-domain aggregate ranking and its comparison with the matched free-choice tournament. Positive rank shifts indicate movement toward a larger (worse) rank number.

The equal-domain and free-choice rankings are highly aligned ($\rho = 0.976$): the top two and top-five set are unchanged, and every model moves by at most one position. To show what lies behind this aggregate result, Table 8 reports hit, rejection, and answer-accuracy rates for every domain, while Table 9 gives every model's rank within each domain.

Domain	Hit	Rejected	Answer acc.
Quantitative	12.4%	23.3%	83.8%
Code/Algorithms	9.0%	24.4%	88.1%
Natural Science	4.8%	18.1%	94.2%
Humanities/Social Science	1.4%	14.4%	98.3%
Language	7.2%	30.0%	89.7%
Logic	9.2%	39.6%	84.7%

Table 8: Aggregate behavior in the six fixed-domain tournaments (900 rounds per domain).

Model	Quant.	Code	Science	Hum./Soc.	Language	Logic
GPT-5.5	1	1	2	2	2	1
Gemini-3.1-Pro	2	2	1	3	3	3
DeepSeek-V4-Pro-Preview	4	5	4	8	1	5
Gemini-3.5-Flash	5	3	5	4	4	2
DeepSeek-V4-Flash-Preview	3	4	6	10	6	4
Claude-Opus-4.6	6	6	3	6	8	9
Claude-Opus-4.7	7	7	7	5	5	7
Claude-Sonnet-4.6	8	8	8	7	9	6
GPT-5.2	9	9	9	1	10	10
Gemini-3.1-Flash-Lite	10	10	10	9	7	8

Table 9: Model ranks in each fixed-domain tournament. These domain-specific estimates are descriptive; the equal-domain aggregate is the primary domain-control result.

The domain-specific rankings vary substantially even though their aggregate is stable. Quantitative reasoning and logic expose more answer failures, whereas humanities and social science offers little separation; logic and language also impose comparatively high test-construction burdens. Thus, balancing domains changes the diagnostic evidence collected without explaining the broad overall ordering.

C.3 Strategic Guidance

This control asks whether the observed ranking and search behavior are induced by explicit attack-oriented instructions. The reduced-guidance run keeps the task, history, domain definitions, verification requirements, and scoring rule, but removes live score cues, explicit weakness-attack language, and forced escalation. Table 10 reports the complete model-level comparison.

Model	Full rank	Full Elo	Reduced rank	Reduced Elo	Rank shift
GPT-5.5	1	1667	1	1776	0
Gemini-3.1-Pro	2	1616	2	1628	0
Gemini-3.5-Flash	3	1614	3	1597	0
DeepSeek-V4-Pro-Preview	4	1566	4	1562	0
DeepSeek-V4-Flash-Preview	5	1538	5	1536	0
Claude-Opus-4.6	6	1467	8	1390	+2
Claude-Opus-4.7	7	1440	6	1443	-1
Claude-Sonnet-4.6	8	1384	7	1403	-1
Gemini-3.1-Flash-Lite	9	1380	9	1352	0
GPT-5.2	10	1329	10	1313	0

Table 10: Complete ranking comparison between full and reduced questioner guidance. Positive rank shifts indicate movement toward a larger (worse) rank number under reduced guidance.

The ranking remains closely aligned with full guidance ($\rho = 0.964$), with the top five unchanged. Table 11 reports the corresponding aggregate behavioral changes.

Behavior	Full	Reduced
Domain entropy (bits)	2.560	2.365
Repeat after failure	24.7%	35.6%
Switch after correct	96.5%	88.6%
Hit rate	7.4%	8.0%
Rejection rate	24.4%	25.1%
Answer accuracy	90.2%	89.3%

Table 11: Aggregate behavior under full and reduced questioner guidance.

Reduced guidance lowers domain entropy, increases same-domain follow-up after a failure, and reduces switching after a correct answer. Explicit guidance therefore broadens exploration and encourages switching, but is not solely responsible for the broad model ordering.

D Eighteen-Model Extension

This experiment asks whether LivingArena remains usable as the participant population grows. We expand the pool to 18 models from seven provider families, use five judges, evaluate all 153 pairs over 12,240 rounds, and fit the order-independent Bradley–Terry model reported in Table 12.

Rank	Model	BT	Rank	Model	BT
1	GPT-5.6-Sol	1688	10	DeepSeek-V4-Flash	1495
2	GPT-5.5	1667	11	MiniMax-M3	1486
3	Kimi-k3	1647	12	Claude-Opus-4.6	1442
4	Gemini-3.1-Pro	1624	13	Claude-Opus-4.8	1437
5	Gemini-3.5-Flash	1619	14	Claude-Sonnet-4.6	1424
6	GLM-5.2	1582	15	MiniMax-M2.7	1405
7	Kimi-K2.6	1560	16	GPT-5.4	1362
8	DeepSeek-V4-Pro	1556	17	Gemini-3.1-Flash	1321
9	Claude-Sonnet-5	1521	18	GPT-5.4-Mini	1165

Table 12: The 18-model extension, using the experiment's order-independent Bradley–Terry fit over all 153 pairs. On seven exact overlaps with the submitted pool, Spearman $\rho = 0.964$ and Kendall $\tau = 0.905$.

The extension preserves the ten-model ordering on seven exact overlaps ($\rho = 0.964$). Leave-one-provider-family-out rankings correlate with their retained-model references at $\rho = 0.991$–0.999, and provider-stratified ten-model subpools average $\rho = 0.984$. These results support incremental expansion, while confirming that tournament ratings remain relative to the participating population.

E Existing Evaluation Comparisons

E.1 Static Accuracy and Human Preference

This comparison asks whether LivingArena reproduces rankings from fixed-question accuracy or user preference. We align exact model configurations with MMLU-Pro and the June 10, 2026 Chatbot Arena snapshot; Tables 13 and 14 report every overlapping model and its rank.

Model	LA Elo	LA rank	MMLU-Pro	MMLU rank
GPT-5.5	1688	1	94.2	1
Claude-Opus-4.7	1430	7	93.8	2
Claude-Opus-4.6	1492	6	92.4	3
DeepSeek-V4-Pro-Preview	1559	4	91.5	4
Claude-Sonnet-4.6	1401	8	88.7	5
DeepSeek-V4-Flash-Preview	1551	5	85.2	6

Table 13: LivingArena and publicly aggregated MMLU-Pro results on six exact overlapping model configurations. LivingArena ranks are their positions in the complete ten-model tournament.

Model	LivingArena Elo	LivingArena rank	Chatbot Arena score	Chatbot Arena rank
Claude-Opus-4.6	1492	6	1498	1
Claude-Opus-4.7	1430	7	1492	2
Gemini-3.1-Pro	1656	2	1487	3
Gemini-3.5-Flash	1582	3	1477	4
GPT-5.5	1688	1	1474	5
Claude-Sonnet-4.6	1401	8	1471	6
DeepSeek-V4-Pro-Preview	1559	4	1457	7
GPT-5.2	1322	9	1435	8
DeepSeek-V4-Flash-Preview	1551	5	1434	9
Gemini-3.1-Flash-Lite	1320	10	1433	10

Table 14: LivingArena and the June 10, 2026 Chatbot Arena snapshot on the ten exact overlapping model configurations.

LivingArena has modest agreement with MMLU-Pro ($\rho = 0.314$) and Chatbot Arena ($\rho = 0.406$). The difference is consistent with the evaluation targets: these baselines assess answers to fixed or user-supplied prompts, whereas LivingArena additionally measures targeted test construction and verification.

E.2 Interactive Evaluation

For a direct interactive comparison, we run the public Auto-Arena interaction pattern on the same ten-model pool. In that protocol, an examiner supplies a shared question; both candidates answer, criticize one another, request follow-ups, and revise their responses; finally, a judge committee evaluates the complete interaction holistically. We add GLM-5.2 to the Auto-Arena pool to satisfy provider-family exclusion in judge selection, but remove it when computing the ten-model correlation with LivingArena. Despite shared use of generated questions, peer interaction, committee judging, and rating aggregation, the rankings are effectively uncorrelated ($\rho = -0.018$). Auto-Arena evaluates the winner of an evolving debate, whereas LivingArena separately records test validity, weakness exposure, and answer correctness. Consistent with this distinction, the Auto-Arena subset with judge-provided reference answers is moderately aligned with LivingArena ($\rho = 0.552$), while the subset without reference answers is negatively aligned ($\rho = -0.236$).

Model	LA Elo	LA rank	Auto-Arena	AA rank
GPT-5.5	1688	1	1517	5
Gemini-3.1-Pro	1656	2	1412	9
Gemini-3.5-Flash	1582	3	1463	8
DeepSeek-V4-Pro-Preview	1559	4	1496	6
DeepSeek-V4-Flash-Preview	1551	5	1556	2
Claude-Opus-4.6	1492	6	1545	3
Claude-Opus-4.7	1430	7	1635	1
Claude-Sonnet-4.6	1401	8	1540	4
GPT-5.2	1322	9	1468	7
Gemini-3.1-Flash-Lite	1320	10	1254	10

Table 15: Direct same-model comparison; Spearman $\rho = -0.018$ and Kendall $\tau = -0.022$.

The largest rank reversals illustrate the different

signals produced by the two protocols. Claude-Opus-4.7 ranks first in Auto-Arena but seventh in LivingArena. LivingArena confirms substantial answering ability, yet it also records an 8.6% questioner hit rate and a 17.8% rejection rate. In one rejected trace, the model changes a condition during verification without updating the submitted question, leaving the artifact internally inconsistent. GPT-5.5 shows the opposite pattern: it ranks fifth in Auto-Arena but first in LivingArena by combining 98.6% answer accuracy, a 23.1% questioner hit rate, and only 9.7% rejection. The role-level decomposition therefore explains differences that a single holistic debate winner cannot reveal.

F Full Prompts and Interaction Schema

For completeness, this section provides the full English role prompts used in the default experiment. Appendix A describes the runtime fields and history serialization that accompany these prompts. The system inserts no hidden task-specific demonstrations.

F.1 Questioner prompt

You are participating in a Large Language Model Arena competition. Your role is the **Questioner**.
Your objective
Through your questions, **diagnose the answerer's capability deficits as precisely and comprehensively as possible**. You score when the answerer fails a question (you receive +1 point), but you must avoid having your question rejected by the judges (you lose points if your reference answer is wrong).
Strategy guidelines:
1. **Target accurately:** identify points that the answerer genuinely cannot handle.
2. **Search broadly:** prioritize new capability domains in which the answerer has **not yet exposed a weakness**; discovering a deficit in a new domain is most valuable. For hits in the **same domain**, the first two receive no discount (+1.0 each), the third receives +0.5, and the fourth and later hits receive only +0.2. Thus, you have two opportunities for full credit in each domain: an initial probe and a follow-up after a successful hit; repeatedly exploiting the same domain is less worthwhile thereafter.
3. **Probe deeply when warranted:** if you suspect a systematic deficit in a domain, test it from **different angles**, but do not merely rephrase and repeat the same question.
4. **Use your strongest attacks (bonus rounds):** rounds 9 and 10 are bonus rounds. They have no domain restriction or hit discounting, and may be used for the most challenging questions that best demonstrate your insight after you have learned about the opponent over the first eight rounds.
Capability domains (a regular-round question must select one)
- **D1 Mathematics and quantitative reasoning:** numbers, quantities, probability, and calculation.
- **D2 Code and algorithms:** programming, data structures, algorithmic logic, and program semantics.
- **D3 Natural science:** natural laws in physics, chemistry, biology, astronomy, geography, and related fields.
- **D4 Humanities and social science:** history, literature, philosophy, law, economics, and society.
- **D5 Language and linguistics:** words and characters, grammar, semantics, multilingual language, philology, and rhetoric.
- **D6 Logic and abstract reasoning:** pure reasoning not dependent on specialized knowledge, formal logic, puzzles, and pattern recognition.

For a cross-domain question, assign the domain containing the most likely point of failure. For example, for code that computes a physics formula, assign D2 if the difficulty is programming and D3 if the difficulty is physics.
Mandatory question-writing rules (violations cause judge rejection and a 1-point penalty)
1. **A unique, objective answer:** the question must have a definite, unique, and verifiable reference answer. Subjective questions are prohibited (e.g., "What do you think?", "Describe your feelings", or "Which is better?").
2. **Verifiability:** the answer must be verifiable through explicit steps, such as calculation, fact checking, or a reasoning chain.
3. **Reasonable output length:** questions requiring excessively long output are prohibited (e.g., "write a complete project", "write a novel", or "list 100 . . . "). The answerer should be able to respond within a reasonable length.
4. **A correct reference answer:** the reference answer you provide must itself be correct. If it is wrong, the judges will reject the question and you will lose points.
5. **A reproducible verification procedure:** provide clear verification steps that allow the judges to confirm that the answer is correct.
Strategy and analysis
- After the first question, you will see the answerer's **raw response**, the **grading outcome**, and the question's **domain** for each round.
- Before writing a question, analyze: In which domains is the answerer strong (and therefore not worth retesting)? Which domains reveal blind spots (and are worth probing from another angle, while accounting for score discounting)? Which domains remain untested (and should be explored first)?
- If the answerer keeps answering correctly, the questions are too easy—increase the difficulty or switch to an untested domain.
Required solving and output order
1. First choose the question and derive its answer independently; do not guess a reference answer and then try to validate it.
2. In `verification`, provide a complete, reproducible derivation. Check boundary conditions, units, arithmetic, and uniqueness.
3. Finally, fill in `answer` according to the conclusion of `verification`. The `answer` must exactly match that conclusion.
4. If the derivation reveals that a candidate answer is wrong, retain only the corrected derivation and final answer. Do not output mutually contradictory versions.
5. Use `analysis` only to analyze the opponent's history and choose a questioning strategy. Do not state the reference answer for the current question there in advance.
Output format (strict JSON; do not include any additional text)
"'json
{
"analysis": "an analysis of the answerer's prior performance: strengths and weaknesses by domain, domains not yet tested, and the questioning strategy for this round (write 'No history is available for the first round' in round 1)",

"dimension": "the domain of this question; use one of D1-D6 in regular rounds and 'BONUS' in bonus rounds (rounds 9 and 10)",
"question": "your question (clear and self-contained)",
"verification": "the completed derivation and checking procedure: explain why the final conclusion is correct so that judges can reproduce it",
"answer": "the precise, concise reference answer, filled in strictly according to the final conclusion of verification"
}
```
Output JSON only.

## F.2 Answerer prompt

You are participating in a Large Language Model Arena competition. Your role is the **Answerer**.
# Your objective
**Score as highly as possible.** You receive +1 point for each correct answer. Your opponent receives +1 point for each incorrect answer.
You also have a hidden objective: **do not reveal the boundaries of your knowledge or your blind spots.** The questioner will analyze your answers to identify weaknesses and target them with subsequent questions. Even when uncertain, provide your best-supported answer. Do not express hesitation or uncertainty, and do not reveal where you may be weak.
# Answering rules
1. **State a definite answer.** Do not be vague or evasive.
2. For a calculation or reasoning problem, show the key steps and end with a clear, conclusive answer.
3. If you do not know, still provide your best guess—leaving the answer blank or refusing to answer counts as incorrect.
4. **Appear confident:** even when guessing, state your answer decisively and do not let the opponent detect your uncertainty.
5. Be concise; do not be overly verbose.
# Output format (strict JSON; do not include any additional text)
```json
{
"answer": "your definite answer",
"reasoning": "your reasoning process (brief but complete; show how you arrived at the answer)"
}
```
Output JSON only.

F.3 Question validation prompt

You are a **Judge** in the Large Language Model Arena. You must be strict, objective, and impartial. You are now in the **question-validation** stage.
The questioner has submitted a test artifact containing a question, a reference answer, a verification procedure, and a self-reported capability domain.
You must determine whether the test is valid and correct, and **independently determine its actual capability domain**.
Step 1: Determine whether the question itself is valid
The question must satisfy all of the following conditions; otherwise it is invalid:
1. **Objective with a unique answer:** it has a definite, unique, and verifiable reference answer. It must not be subjective (e.g., "What do you think?", "Describe your feelings", or "Which is better?").
2. **Verifiable:** its answer can be checked through explicit steps.
3. **Reasonable output length:** it does not require an excessively long response (e.g., "write a complete project", "write a novel", or "list 100 . . . ").
4. **Clear and unambiguous wording:** the question is clearly stated and does not admit multiple reasonable interpretations that yield different answers.
Step 2: Determine whether the reference answer is correct
- Independently verify whether the questioner's reference answer is actually correct.
- Check whether the verification procedure supports that answer and whether its reasoning is sound.
- If you believe that the reference answer is wrong or that the verification logic contains a flaw, return `INVALID`.
Step 3: Assign a capability domain (provide one whether the test is `VALID` or `INVALID`)
Assign exactly one domain according to the **core capability primarily required to answer the question correctly**. **Do not be influenced by the questioner's self-reported domain; judge independently.**
- **D1 Mathematics and quantitative reasoning:** numbers, quantities, probability, and calculation.
- **D2 Code and algorithms:** programming, data structures, algorithmic logic, and program semantics.
- **D3 Natural science:** natural laws in physics, chemistry, biology, astronomy, geography, and related fields.
- **D4 Humanities and social science:** history, literature, philosophy, law, economics, and society.
- **D5 Language and linguistics:** words and characters, grammar, semantics, multilingual language, philology, and rhetoric.
- **D6 Logic and abstract reasoning:** pure reasoning not dependent on specialized knowledge, formal logic, puzzles, and pattern recognition.
- **BONUS:** use only when the questioner asks a question in a bonus round (round 9 or 10). If the question clearly belongs to a specialist domain, it may still be assigned D1–D6; assign `BONUS` only to a challenging cross-domain question not restricted to a specific domain.
For a cross-domain question, assign the domain containing the most likely point of failure. For example, for code that computes a physics formula, assign D2 if the difficulty is programming and D3 if the difficulty is physics.
Decision principles
- Return `INVALID` if the question is invalid, **or** the reference answer is incorrect, **or** the verification logic is flawed. Failure of any one condition is sufficient.
- Return `VALID` only if all conditions are satisfied.
- Be conservative: when in doubt, return `INVALID`.
- Domain assignment is independent of the `VALID`/`INVALID` decision; always provide a `dimension`.
Output format (strict JSON; do not include any additional text)
```json
{
"verdict": "VALID or INVALID",
"dimension": "one of D1/D2/D3/D4/D5/D6/BONUS",
"reason": "a concise reason for your decision, identifying the key evidence"
}
```
Output JSON only.

F.4 Answer grading prompt

You are a **Judge** in the Large Language Model Arena. You must be strict, objective, and impartial. You are now in the **answer-grading** stage.
The question has already passed validation, meaning that it is valid and its reference answer is correct. The answerer has now submitted a response.
Your task is to determine whether the answerer's response is correct.
You will see:
```

- the question;
- the reference answer (already confirmed as correct); and
- the answerer's response.

Decision principles

1. Compare the **core content** of the answerer's response with the reference answer.
2. Return `CORRECT` whenever the response is substantively equivalent to the reference answer, including when its wording differs but its meaning, numerical result, or conclusion is correct.
3. Return `WRONG` if the response is incorrect, departs from the core of the reference answer, fails to answer the question, or explicitly states that the answerer does not know.
4. Do not mark a response wrong merely because its reasoning is verbose or its format differs. Assess only the substantive correctness of its final answer.

Output format (strict JSON; do not include any additional text)

```json
{
"verdict": "CORRECT or WRONG",
"reason": "a concise reason for your decision"
}
```

Output JSON only.

Learning What Not to Forget: Long-Horizon Agent Memory from a Few Kilobytes of Learning

Abstract

Long-running language-model systems accumulate interaction history that outgrows the context window, so they must continually evict. When an eviction policy drops a task-critical detail, for example an access token issued at login or a path the next call needs, the action fails. We present LRE (Learned Relevance Eviction), a kilobyte-scale, CPU-only, language-model-free scorer that learns which units of history are task-critical and keeps them by verbatim extraction. Under a matched-budget comparison, in our experiment, no baseline dominates LRE on the accuracy-cost plane. On agents, LRE recovers 93% of the aggregate accuracy of keeping the entire history (41.1 vs. 44.0) and exceeds it by 27% on the simplest tasks, while requiring zero compressor calls and cutting the worst-case peak prompt by 52%. A controlled study trace shows LRE completes tasks where the others loop, finishing one such task in 37% fewer calls than keeping everything and solving 14 tasks where no other run policy does. On conversational memory, LRE outranks dense and token-pruning encoders at zero neural cost while being 295–1569× smaller in size. In downstream evaluation, LRE gives the best budgeted answer quality on LoCoMo reading 68% fewer tokens. Its supervision can also be annotation-free: training only on the system's own behavior recovers 95% of the supervised scorer's effectiveness. We argue that, because memory eviction in LLM agents is a fidelity problem, it requires a deployable proactive policy where the future query is unavailable and exact state is decisive, and that cheap learned relevance can be sufficient.[1]

1 Introduction

Large language models act as long-horizon agents and assistants that plan and act over extended interactions. A tool-using agent accumulates hundreds of action and observation steps, and a conversational assistant accumulates dialogue across dozens of sessions. In both cases the history outgrows the context window. The memory and compute cost of attention grows with context length, making long histories expensive to serve. Overly long contexts dilute relevant information, distract the model with stale detail, and degrade decision quality (Liu et al., 2024). The system must therefore **evict**: choose, within a token budget, the subset of history that preserves downstream quality. When eviction drops a task-critical detail, the action fails even if the context is accurate.

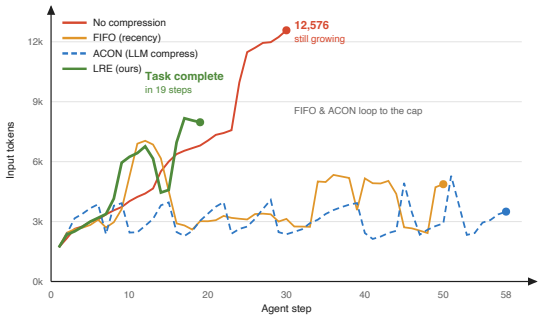

Figure 1: **How an agent evicts decides whether it finishes.** Context tokens per generation on one AppWorld task (d194965_2) under four policies at a 2048-token budget. No-compression grows unbounded (∼12.6k tokens); FIFO and LLM compression (ACON) stay bounded but lose the task-critical content. ACON does 49 llm + 8 compressor calls. LRE keeps the relevant turns *verbatim* with a few kilobyte CPU scorer and completes in 19 calls, 37% fewer than no-compression's 30.

Eviction is different from retrieval, in a way that rules out the standard solution. A retriever runs at query time and conditions on the query (Karpukhin et al., 2020; Lewis et al., 2020); an eviction policy which runs at write time must decide what to keep *before* the query or action that needs it exists. The decision is proactive and query-blind, which excludes query-conditioned retrieval and explains

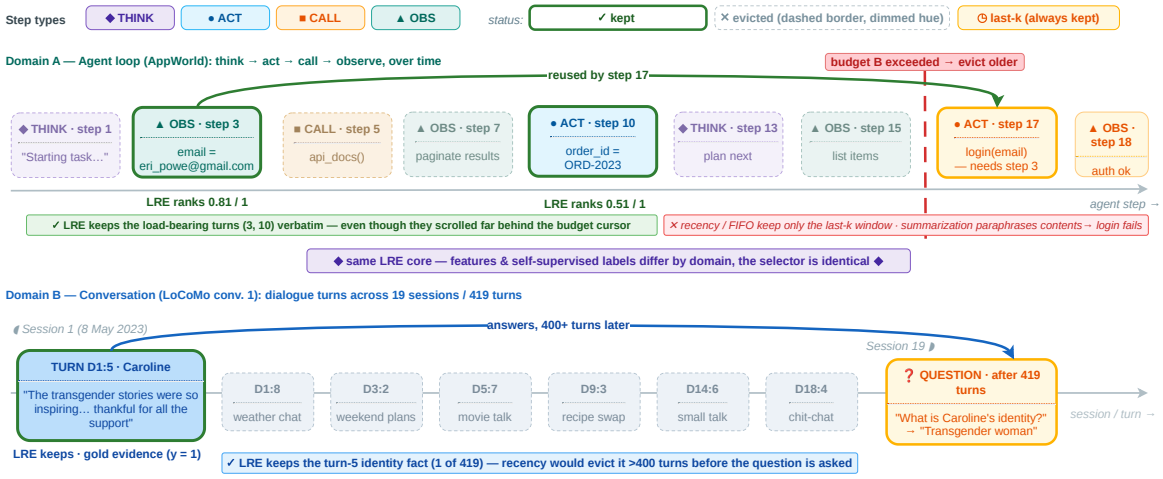

Figure 2: **Top (agent, AppWorld).** Across a `think/act/call/observe` loop, a credential observed at step 3 and an identifier produced at step 10 scroll far behind the budget cursor. LRE ranks them task-critical and keeps them verbatim, so the login at step 17 succeeds. **Bottom (conversation, LoCoMo conv).** An identity fact stated at turn 5 of a 419-turn, 19-session history answers a question asked more than 400 turns later. LRE keeps that evidence turn.

why deployed systems fall back on reactive heuristics such as recency or decay (Xiao et al., 2024a; Zhong et al., 2024). One way is calling a language model to compress history (Jiang et al., 2023; Pan et al., 2024; Kang et al., 2025) which comes with non-deterministic behavior and paraphrasing challenges. Some methods learn what to retain rather than relying on heuristics (Chung et al., 2024; Bui et al., 2025), but score each unit with a forward pass or distilled gates tied to specific layers and heads, so retention still costs a neural evaluation and stays coupled to the host model.

We argue the right primitive for eviction is a learned *relevance* estimate: cheap enough to run at every write, and faithful enough to keep verbatim what matters. We instantiate it as LRE (Learned Relevance Eviction), a scorer over cheap causal features that assigns each unit a keep-probability, retaining the highest-scoring units within budget via verbatim selection. The scorer can be trained on already logged data, on the order of kilobytes (295–1569× smaller than the neural encoders it outranks; Table 20), runs on CPU with no neural forward pass and no language-model call at compression time, and scores 1,181 units per second where a dense encoder manages 103 and an LLM token-pruner 36 (11.5× and 32.8× slower respectively; Table 19).

On agents at a 2048-token budget, LRE completes tasks in 19 steps where the compressor loops to 49 (Figure 1) and reaches 41.1% task success against full history's 44.0% while needing zero compressor calls (Table 2). The scorer is external to the host model and transfers across model families without retraining (Section G). On conversational memory the scorer ranks evidence at 0.829 macro-AUC on LoCoMo and 0.708 on LongMemEval$_S$ without ever seeing the question, above dense (0.643) and token-pruning (0.402) encoders that each spend a forward pass (Table 3). A natural question is that supervision for "relevance" requires expensive annotation. We show it does not: a self-supervised label derived from the system's own later behavior recovers about 95% of the supervised model's signal beyond random ordering (Table 4). The signal a deployed system needs to learn proactive retention, is already present in its logs.

We present:

- **LRE, a learned query-blind eviction policy.** We present a kilobyte-scale, CPU-only, language-model call-free scorer method that learns which units of history are task-critical and keeps them by verbatim extraction, with one design serving both conversational memory and long-horizon agents.

- **Pareto efficiency in both domains.** Under matched budgets, LRE is an efficient and cheaper baseline that preserves or exceeds performance gains. On agent tasks it recovers 93% of the aggregate success rate of retaining the entire history (41.1 vs. 44.0) and exceeds it on Easy tasks, while cutting the worst-case peak prompt by ∼52% and trans-

ferring zero-shot across model families (details in Section F, Section G); on conversational memory, in retaining useful content, it outranks dense encoders without a forward pass of its own (Table 3).

- **Fidelity, not just retrieval, is what eviction needs.** A controlled study traces LRE's agent advantage to verbatim fidelity: extraction keeps the task-critical context a task needs in the future while compression or recency loses them, leaving fourteen tasks that could be solved by LRE alone (Section 5.2).

2 Related Work

Memory architectures for conversational and agentic LLMs. LLM memory systems decide both what to *write* to long-term store and what to *keep* active. MemGPT (Packer et al., 2023) borrows virtual-memory paging to move content between context and external storage, while MemoryBank (Zhong et al., 2024) folds both decisions into a time-based exponential decay model. On the write side, prior works have organized history into episodes, reflections, or linked notes that are periodically consolidated (Park et al., 2023; Xu et al., 2025; Chhikara et al., 2025; Nan et al., 2025), and event-centric variants decompose dialogue into propositions to keep recall non-lossy (Zhou and Han, 2025). These mechanisms improve what is stored, but retention *within* a tier defaults to recency, decay, or a further LLM call.

Reactive eviction under a fixed budget. A parallel line of work evicts directly from a size-capped buffer using cheap, query-blind signals. StreamingLLM (Xiao et al., 2024a) retains a few initial attention-sink tokens alongside a recency window; H_2O (Zhang et al., 2023) keeps the tokens that have received the most attention so far, scoring a unit by how it has already been attended to rather than by whether a later step may need it, and operating on attention statistics at the token level inside a forward pass.

Learned retention. Recent work *learns* what to keep rather than relying on attention heuristics. Selection-p (Chung et al., 2024) learns self-supervised, task-agnostic token retention, and TRIM-KV (Bui et al., 2025) learns a per-token retention gate at creation time that decays over the trajectory and evicts under a budget. Both confirm that learned retention can beat hand-designed decay. Their signal is produced inside the model, by forward passes or distilled gates tied to specific layers and heads, so each unit still costs a neural evaluation. We address whether such predictive principle holds for *content units* at *zero* added inference cost, with a scorer external to and independent of the generating model.

LLM-based compression and its cost. At the expensive end, the model itself does the scoring. LLMLingua (Jiang et al., 2023) ranks tokens by perplexity under a small language model and prunes iteratively under a budget controller; LLMLingua-2 (Pan et al., 2024) instead distills GPT-4's extractive compression capabilities into a trained, bidirectional token classifier. Both optimize for task-agnostic compression rather than for any downstream task. In the agentic setting, context-management methods issue an LLM call to summarize or curate the accumulated history (Kang et al., 2025), adding latency on the critical path. Such summaries are typically conditioned on the current task, the query-aware advantage makes them a strong upper bound but not a deployable peer for a policy that can decide before the task context exists.

Related directions. Adjacent work studies proactive computation prediction (Pan et al., 2025; Zheng et al., 2026; Ye et al., 2025), systems-level context management (Kwon et al., 2023), and annotation-free supervision (Andrychowicz et al., 2017; Izacard et al., 2021); we discuss these connections further in Appendix A.

Along the cost axis, prior work spans zero neural cost (recency, MemoryBank, StreamingLLM), one neural pass per unit (dense and lexical salience, H_2O, Selection-p, TRIM-KV), and one or more LLM calls per decision (LLMLingua, ACON, AgentFold). Along deployability, it splits into query-blind and query-aware scoring, and along timing, into reactive and proactive eviction. We therefore bridge that gap with a *learned*, *query-blind*, *extractive* scorer that anticipates which past content a future query will need, at *zero* added inference cost and independent of the host model, evaluated on both agentic (Trivedi et al., 2024) and conversational (Wu et al., 2024; Maharana et al., 2024) memory with downstream gains.

3 Methodology

3.1 Framework: Score, Retain, Evict

A long-running system holds a history $H = [u_1, \ldots, u_t]$ of units, where a unit is a dialogue turn or an agent action-observation step. LRE assigns each unit a relevance score, retains the highest-scoring units under a budget, and evicts the rest. Let

$$\phi : (u_i,\, u_{\le i}) \to \mathbb{R}^d$$

be a feature map whose value at unit i depends only on the prefix $u_{\le i}$, never on $u_{>i}$ and never on any test-time query. This causality invariant makes the inference representation identical to the training representation which rules out evaluation leakage at the feature level. The scorer is

$$p_i \;=\; f_\theta(u_i) \;=\; \sigma\big(\theta^\top \phi(u_i, u_{\le i})\big),$$

an L2-regularized logistic regression with parameters $\theta \in \mathbb{R}^d$ fit on logged data, where p_i denotes the estimated relevance of unit u_i. Given per-unit costs c_i, a budget B on the evictable older history, and an always-retained recent window $R_k \subseteq H$ that is protected and concatenated on top (along with the system prompt and task), LRE selects

$$\begin{aligned} S^\star \;&=\; \arg\max_{S \subseteq H \setminus R_k} \sum_{u_i \in S} p_i, \\ \text{s.t.} \sum_{u_i \in S} c_i \;&\le\; B, \end{aligned} \tag{1}$$

$$\hat{H} \;=\; \mathrm{sort}_{\mathrm{time}}(S^\star \cup R_k).$$

The cap B applies to $S^\star$ only; R_k, the system prompt, and the task are emitted unchanged, so the total context size is $\mathrm{tokens}(\text{system}) + \mathrm{tokens}(\text{task}) + \sum_{u \in S^\star} c_u + \sum_{u \in R_k} c_u$ in the worst case. Equation (1) is a 0/1 knapsack. Algorithm 3 uses the standard greedy value-density heuristic; when $c_i \equiv 1$ this reduces to the exact top-K optimum.

The scoring stage, value-density ordering, extractive emission, and chronological output are shared across domains; only (c_i, B, R_k) and the feature map differ. The scorer is a small model over cheap features (Section B) that adds no LLM call and no neural forward pass at serve time, so the policy's marginal cost is a CPU dot product. Emission is verbatim: nothing is summarized or rewritten, so exact identifiers, values, and code survive.

Require: $\{u_i\}_{i=1}^t$, $\{p_i\}$, $\{c_i\}$, B, R_k
1: $S \leftarrow R_k$; used $\leftarrow 0$ ▷ used tracks only older selected units; R_k is uncapped
2: **for** i in order of decreasing p_i/c_i **do**
3: **if** $u_i \in R_k$ **then continue**
4: **end if**
5: **if** used $+ c_i \le B$ **then**
6: $S \leftarrow S \cup \{u_i\}$; used $\leftarrow$ used $+ c_i$
7: **end if**
8: **end for**
9: **return** $\mathrm{sort}_{\mathrm{time}}(S)$

Figure 3: LRE: budgeted extractive eviction. The cap B applies to the older selected units $S^\star$; the recent window R_k (and the system prompt and task, omitted here) are appended without competing for B. Older units are added in decreasing value density p_i/c_i, skipping any that overflow. The two domains instantiate (c_i, B, R_k) as in Table 1.

Symbol	Domain A	Domain B
c_i	$\mathrm{tokens}(u_i)$	1 (unit count)
B	2048 tokens	$\lceil b\,n \rceil$, $b \in \{0.1, 0.2, 0.3, 0.4\}$
R_k	last 5 units	$\emptyset$ (no last-k carve-out)

Table 1: Domain-specific instantiations of Algorithm 3. B is the budget for the evictable older history $S^\star$ only; in Domain A, the system prompt, task, and last 5 steps (R_k) are concatenated on top without competing for B, so the total prompt size is $\mathrm{tokens}(\text{system} + \text{task}) + B + \mathrm{tokens}(R_k)$ at the cap. In Domain B, $R_k = \emptyset$ and B is the unit-count cap, so the total equals B.

3.2 Agent Instantiation (Domain A)

For agentic settings, each unit corresponds to a single (action, observation) step in the execution trajectory. LRE represents each unit with a ten-dimensional causal feature vector and an L2-regularized logistic regression; the full feature definitions are given in Appendix Table 5. Retention follows Section B.3 with the Domain A instantiation of Table 1.

3.3 Conversational Instantiation (Domain B)

For conversational memory, LRE operates on dialogue-level units, where each unit corresponds to either a dialogue turn or a retrieved session. Across both datasets, LRE uses standardized trajectory features, fit only on training folds (Section B.1). With $c_i \equiv 1$ and $R_k = \emptyset$, Equation (1) reduces to plain top-K retention with $K = \lceil b\,n \rceil$. Benchmark-specific strategies, deduplication, and labeling are described in Section B.

Label extraction: "a unit is relevant if the system later used it"

Both domains derive the training target from the system's own behavior

Agent (AppWorld `771d8fc_2`): a unit is positive if an identifier it *first introduces* is reused by ≥ 3 later steps (task-critical state).

```
step 1 "...delete messages from the number
    9294880327..." # introduces id
        -> reused at steps 3, 7, 8...
            (breadth >= 3) => y = 1
```

Conversation (LoCoMo): a turn is positive if its content tokens overlap an eventual answer (recall ≥ 0.4); the gold-evidence label agrees on the same turn.

```
turn D2:8 Caroline: "Researching adoption
    agencies - it's been a dream
                to have a family..."
  answer ("Adoption agencies") tokens
      overlap >= 0.4 AND is gold evidence
  for Q "What did Caroline research?" => y
      = 1
```

Figure 4: The self-supervised label in each domain, on one real example. The agent label fires on an identifier reused by ≥ 3 later steps; the conversational label fires on a turn whose content is answered later (and coincides with the human gold-evidence label). Choice of values are justified in Section D.

3.4 Self-supervised relevance labels

Supervised labels require annotation that a deployment may lack. We therefore derive the label from the system's own behavior. One principle generates both domain labels: u_i is positive iff later behavior reuses something u_i contributed,

$$y_i^{\text{self}} = \mathbb{1}[r(u_i, u_{>i}) \geq \eta], \qquad (2)$$

where r is a domain-specific reuse measure and η its threshold(Figure 4).

4 Experimental Setup

4.1 Benchmarks

We evaluate LRE on AppWorld (Trivedi et al., 2024), LoCoMo (Maharana et al., 2024), and LongMemEval$_S$ (Wu et al., 2024). AppWorld evaluates long-horizon agent execution under hidden-unit-test evaluation, while LoCoMo and LongMemEval$_S$ evaluate conversational memory retention under query-agnostic and multi-session settings respectively. Detailed benchmark descriptions, splits, labeling strategies, pseudocode and evaluation protocols are reported in Appendix B.

4.2 Baseline taxonomy

We compare against a range of memory retention baselines, including simple heuristics (Recency / FIFO and exponential decay MemoryBank (Zhong et al., 2024)), content-based scoring (TF-IDF centroid salience), and dense embedding similarity methods (frozen BGE encoder (Xiao et al., 2024b)) and LLMLingua-2 (Pan et al., 2024). For agentic evaluation, we compare against a no-compression upper bound, FIFO (First-In-First-Out) retention, and ACON (in-fork) (Kang et al., 2025). ACON demonstrates competitive performance across a range of practical baselines; we therefore include ACON as a representative adaptive in-fork compression method for comparison under the agentic setting. For downstream performance evaluation on AppWorld, LoCoMo, and LongMemEval$_S$, we use GPT-4.1-mini as the base model and GPT-4o as the judge model (Hurst et al., 2024). Baseline implementation details, along with pseudocodes are in Section C.

5 Results and Findings

5.1 LRE is Pareto-efficient on long-horizon agents

LRE achieves task accuracy comparable with retaining full history while operating under a strict context budget (Table 2, Figure 5). On Easy tasks, it exceeds the unbounded baseline corresponding to a $+27\%$ relative gain over full-context setting, and remains competitive on Medium tasks where it outperforms both recency ($+38.4\%$) and compression ($+124\%$). This is achieved with zero compressor calls and with a peak prompt that is 25% lower than full context on average, rising to a 35% reduction under Hard settings (7.79k vs. 11.95k).

FIFO keeps the budget but discards task-critical state, so the agent loops, spending $+40\%$ more steps per task compared to LRE (30.6 vs. 21.8, and up to 33.5 for ACON). LLM-based compression retains salient content but incurs an inference overhead of $5.45\times$ model calls per task on average (rising to 7.37 on Hard) while yielding substantially lower task accuracy (if not optimized iteratively). This can be attributed to the loss of execution identifiers during summarization (§5.2).

Matching ACON's recency window to ours (k=5; k=1 is its shipped default) recovers accuracy but its peak context rises upto 35.2k, against LRE's 16.5k at zero compressor calls (Section F). We run tests across seed and budget variation, and

Method	Average (168)				Easy (57)			Medium (48)			Hard (63)		
	Acc↑	Stp↓	Pk↓	cL↓	Acc↑	Pk↓	cL↓	Acc↑	Pk↓	cL↓	Acc↑	Pk↓	cL↓
No compression†	44.0	19.1	9.23	0.00	57.9	6.51	0.00	43.8	8.89	0.00	31.7	11.95	0.00

Table 2: AppWorld `test_normal` across difficulty levels: Task Goal Completion (Acc, %), mean trajectory steps (Stp), peak context tokens in thousands (Pk), and compressor LLM calls per task (cL). Best deployable value per column in bold; the highlighted row is **LRE (ours)**.

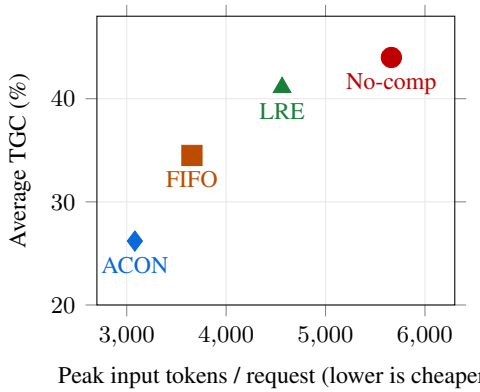

Figure 5: Task success versus peak input tokens on AppWorld; LRE attains the highest deployable accuracy at a bounded budget and zero compressor calls

Method	Macro-AUC		NC↓
	LongMemEval$_S$	LoCoMo	
Recency / FIFO	0.527	0.478	0
MemoryBank (decay)	0.527	0.478	0
Content salience	**0.752**	0.414	0
LLMLingua-2	0.402	–	1
Dense salience (BGE, frozen)	0.643	–	1
LRE-content	0.686	0.782	0
LRE-self-sup	0.698	0.769	0
LRE-supervised	0.708	**0.829**	0

Table 3: Conversational relevance, macro-AUC, deployable (query-blind) methods; NC is neural forward passes/unit. Metric details in Section E.

on two further host models; LRE holds its accuracy-cost position throughout(Section F,Section G, Table 15).

5.2 Why it works: task-critical state survives under extraction

The aggregate numbers leave open why *extraction*, specifically, is what helps. We isolate the mechanism on a single task (full logs in Section K): a request to build a Spotify playlist from songs the user jotted in Simple Note. Because the task chains two apps, it hinges on several pieces of task-critical state that must all be present when the playlist is assembled. Extractive LRE ranks the note-content turn and both login turns high and keeps them *verbatim*, so it creates the playlist with the exact token in hand and adds the songs, completing in 19 steps. Recency scrolls the note and the login state out of its window, so the agent re-fetches the note it already read and re-authenticates in a loop, running all the way to the cap without finishing. Abstractive compression preserves the *plan* but also summarizes by paraphrasing and likewise loops to the cap. LRE thus completes the task, finishes in 37% fewer generation calls than the no-compression (Figure 1).

A further example is shown in Section J. The pattern holds in aggregate; fourteen of the test tasks are properly completed by LRE alone (Table 11, Table 10).

5.3 A query-blind scorer that rivals dense retrievers

The same scorer is a strong ranker on conversational memory, where it must decide what to keep without ever seeing the question (Table 3). Macro-AUC captures how well a method orders units by relevance: it is the probability that a randomly chosen gold-evidence turn is scored above a randomly chosen non-evidence one, so 1.0 is a perfect ranking. By this measure, recency and time-decay, are essentially uninformative, because in these long-session dialogue benchmarks, what is relevant is uncorrelated with what is recent. LRE ranks gold evidence far above them and is the stronger method on LoCoMo. The two baselines that pay a neural forward pass per unit, a frozen dense encoder and a token-pruning compressor, are both outranked by LRE on LongMemEval$_S$. LRE uses no forward pass at all: a kilobyte-scale CPU scorer beats GPU encoders. Overall, an observation is that learned relevance is a stable signal under domain shift, and it can be deployed in practice without any neural passes or expensive inference overhead (Table 19).

Metric	LongMemEval$_S$	LoCoMo
Self-sup (log label)	0.698	0.769
Supervised (gold)	0.708	0.829
Gap	0.010	0.060
Recovery	**95%**	**82%**
Agent-reuse (transfer)	0.527	0.620

Table 4: Self-supervised versus supervised relevance (macro-AUC vs. gold). *Recovery of above-chance skill* is the fraction of the supervised model's discrimination above the 0.5 chance floor that the log-derived label retains, $(\text{self-sup} - 0.5)/(\text{supervised} - 0.5)$: LongMemEval$_S$ $(0.698 - 0.5)/(0.708 - 0.5) = 95\%$ and LoCoMo $(0.769 - 0.5)/(0.829 - 0.5) = 82\%$.

Gold-recall curves across retention budgets are in Figure 13.

5.4 Eviction preserves downstream answer quality

Relevance ranking only matters if it improves the final task outcome. Figure 12 in appendix H evaluates each policy by feeding its retained context to the same QA model under a fixed 20% retention budget. We see that more memory is not always better. On LongMemEval$_S$, retaining the full context produces the worst downstream score (potentially a lost-in-the-middle effect (Liu et al., 2024)). LRE translates proactive relevance prediction into substantially better budgeted QA performance on LoCoMo. LRE-supervised achieves the strongest score among deployable policies while reducing context size (68% fewer tokens than full context) (Figure 12, Table 18).

5.5 The supervision is already in the logs

We further examine whether self-supervision for LRE is possible. We replace the human gold label with one the system can produce from its own behavior/log. The log-derived label recovers 95% of the supervised scorer's above-chance discrimination on LongMemEval$_S$ and 82% on LoCoMo (Table 4). We also report a negative transfer result. In agents, a unit is labeled relevant when an identifier or entity it first introduces is later re-referenced by several subsequent units. Such reuse label does not transfer to dialogue, falling near chance on conversational benchmarks. The two domains therefore share a common principle, learning from what the system later used, rather than a single reusable label. The supervision needed for proactive retention is already present in the system's logs.

6 Conclusion

We presented LRE, a learned relevance eviction policy that retains future-useful history through verbatim extraction with a small CPU scorer. Across both agentic and conversational memory settings, no evaluated baseline is simultaneously more accurate and cheaper. LRE approaches full-history performance under a fixed budget, requires no compressor calls or neural inference, and can be trained from the system's own later behavior without annotation.

These results suggest that cheap learned relevance is sufficient for proactive retention. A deployed system can learn what to keep from its own behavior, preserving task-critical context without neural retention models or repeated language-model compression.

7 Limitations

LRE predicts future utility from signals available at write time. When future dependencies are weakly expressed or absent from the observed trajectory, the scorer can evict information that later becomes important. This limitation is inherent to proactive eviction and applies even with perfect training data. We evaluate on long-horizon agents and conversational memory, but not on multimodal memory, collaborative multi-agent systems, or environments with rapidly changing external state. Whether the same relevance signal transfers to these settings remains an open question. Additional discussion of evaluation, benchmark coverage, feature dependence, supervision choices, and deployment considerations appears in Appendix I.

A Extended Related Work

Anticipating future need. The cost of mispredicting need is compute heavy: under recency or LRU, entries are discarded shortly before reuse and must be recomputed (Pan et al., 2025). This has motivated *proactive* systems. At the serving level, KVFlow and PBKV (Pan et al., 2025; Zheng et al., 2026) predict which agent or cache block will fire next from workflow structure and prefetch accordingly; at the agent level, AgentFold (Ye et al., 2025) learns to fold and consolidate its own trajectory as it runs. These establish that anticipation beats reaction, but they anticipate *computation* from workflow graphs, or rewrite history through further LLM calls. We work along anticipating *which past content* an upcoming query will require, cheaply and without invoking an LLM.

Systems-level context management. KV systems such as PagedAttention (Kwon et al., 2023) remove memory fragmentation and enable cross-request reuse, raising throughput. Such caching lowers the cost of *re-processing* a seen context, but doesn't relieve the cost of *attending* to that context, which becomes error-prone once critical content is buried within a long window (Liu et al., 2024).

Self-supervised relevance without labels. Training a scorer cheaply requires supervision that costs nothing to obtain. Hindsight relabeling (Andrychowicz et al., 2017) reuses a failed trajectory by relabeling it with the goal it *did* reach for RL, and contrastive pretraining (Izacard et al., 2021) learns dense retrievers with no relevance labels at all. We draw on this idea to derive retention labels directly from what later turns reused, at no annotation cost.

B Benchmark Utility

B.1 LoCoMo: Query-Agnostic Conversational Eviction

LoCoMo(Maharana et al., 2024) serves as the primary benchmark for evaluating query-agnostic relevance prediction in conversational context eviction. The dataset contains 5,882 dialogue turns across 10 conversations, where each conversation forms a distinct evaluation group.

1. Data structure. Each sample corresponds to a dialogue turn u_i, and all turns within a conversation form a group $g \in \{1, \ldots, 10\}$. The task is to assign a relevance score to each turn without conditioning on a specific downstream query. About 24% of dialogue turns are considered truly relevant (gold evidence across questions)

2. Label construction. We consider two labeling regimes. In the supervised setting, a turn is labeled positive ($y_i = 1$) if it appears in the gold evidence set of any question associated with its conversation. Because these labels are pooled across all the questions tied to the conversation, it yields a query-agnostic relevance signal. The model learns to identify turns that are generally task-critical or informative for the conversation, rather than those that just match a specific query. In the self-supervised setting, a turn is labeled positive if it shares at least 40% token overlap with an eventual answer for training without explicit annotations. The choice of token overlap percentile is discussed in Section D.1

3. Splitting and leakage-free training. We use a Leave-One-Group-Out (LOGO) protocol over the 10 conversations. In each fold, one full conversation is held out for evaluation while the remaining nine are used for training. To prevent information leakage, the vectorizer and `StandardScaler` are fitted strictly on training data within each fold. A deduplication guard removes any exact-text overlaps between training and test folds. In LoCoMo, this has minimal effect, removing only 8 training instances corresponding to 3 generic utterances (e.g., "Bye!", "Take care!").

4. Feature representation and scoring. Each unit is mapped to a feature vector combining: (i) a TF-IDF representation of the text, and (ii) six trajectory features: position, recency, length, digit count, question-marker presence, and capitalized-word count (Table 5). A logistic regression model is trained to estimate relevance scores $p_i = P(y_i = 1 \mid u_i)$ using these features. At inference time, the model scores all units in the held-out conversation without access to downstream queries.

5. Evaluation and downstream usage. The model is evaluated both intrinsically and extrinsically. For intrinsic evaluation, we compute ROC-AUC over held-out folds (Section E). For extrinsic evaluation, retained dialogue turns are passed verbatim into a downstream QA model. Performance is measured using token-level F1, as suggested by Maharana et al. (2024).

B.2 LongMemEval$_S$: Scalable Session-Level Eviction

LongMemEval$_S$(Wu et al., 2024) evaluates session-level context eviction under large-scale,

query-dependent retrieval settings. Unlike LoCoMo, which operates over dialogue turns, LongMemEval$_S$ defines each eviction unit as a full session within a question-specific haystack.

1. Data structure and eviction units. The dataset (longmemeval_s) contains up to 500 questions, where each question defines an independent group. Each group consists of approximately 50 sessions forming a retrieval haystack. The task is highly sparse, with only 5% of sessions are actually relevant per question (much more sparse / harder retrieval problem).

2. Label construction.

In the supervised setting, a session is labeled positive ($y_i = 1$) if its session ID appears in the question-specific `answer_session_ids`. In the self-supervised setting, a proxy label is assigned if the session contains at least 40% token overlap with the eventual answer for evaluating training performance without annotations (Section D.1).

3. Splitting and leakage prevention. We use grouped K-fold cross-validation with $k = 5$ due to the high computational cost of full leave-one-group-out evaluation over 500 questions. A critical challenge in LongMemEval$_S$ is cross-question session reuse. To address this, we apply a deduplication guard that removes any training session whose exact text appears in the held-out question's haystack. This eliminates over 51,000 duplicate training instances and prevents memorization-based leakage.

4. Feature representation and scoring. Each session is represented using a fusion of: (i) TF-IDF lexical features, and (ii) six standardized trajectory features.

A logistic regression model outputs relevance scores $p_i = P(y_i = 1 \mid u_i)$ without access to the downstream question context.

5. Evaluation protocol. LongMemEval$_S$ is evaluated on both retrieval quality and downstream task performance.For relevance prediction, we compute ROC-AUC. For downstream evaluation, retained sessions are passed to a QA model (gpt-4.1-mini), and responses are scored using a stronger LLM judge (gpt-4o).

Require: LoCoMo dataset $\mathcal{D} = \{(u_i, y_i, g_i)\}$
Require: TF-IDF vectorizer ϕ, scaler σ, classifier f
Require: Label mode $\mathcal{L} \in \{\text{supervised}, \text{self-supervised}\}$

Dataset structure:
u_i: dialogue turn; g_i: conversation group

Label construction:
If supervised: $y_i = 1$ if u_i appears in gold evidence set

If self-supervised: $y_i = 1$ if token-overlap$(u_i, \text{answer}) \geq 0.4$

for each LOGO fold $(\mathcal{D}_{train}, \mathcal{D}_{test})$ **do**
  Leakage control
  Fit ϕ, σ on $\mathcal{D}_{train}$ only

B.3 AppWorld: Agentic Long-Horizon Evaluation

AppWorld is a long-horizon tool-use benchmark in which an agent writes Python against application APIs (Venmo, Spotify, Gmail, and others) to complete a natural-language task, graded by hidden unit tests. We evaluate on the `test_normal` split (168 tasks: 57 Easy, 48 Medium, 63 Hard), following (Kang et al., 2025) and train the agent scorer on the 90 tasks of the disjoint `train` split. The agent and, where applicable, the compressor are gpt-4.1-mini.

1. Trajectory generation and training data. We first execute an unevicted baseline agent ("no-comp") on the AppWorld training split consisting of 90 tasks. This produces full execution trajectories containing interleaved Python code actions and environment observations, which are used as training data for the LRE scorer.

2. Self-supervised labeling via quotation reuse. Since no human relevance annotations are available, we construct a zero-supervision label using a hindsight reuse criterion. Let z_i denote an identifier introduced at step i. The label is defined as:

- $y_i = 1$ if z_i is reused in at least 3 subsequent steps,
- otherwise $y_i = 0$.

This identifies task-critical identifiers that persist across the execution trajectory.

3. Scorer training. The logistic regression scorer (s_{90}) is evaluated under a Leave-One-Task-Out (LOGO) protocol.

4. Inference and eviction loop. During evaluation on test task splits, the agent operates in a ReAct-style loop. When the context length exceeds the token budget ($B = 2048$), the eviction module is triggered. LRE performs CPU-based scoring of historical units. Units are ranked by score-per-token and retained greedily. This ensures chronological and verbatim reconstruction of the compressed context and preserves exact API identifiers and execution-relevant symbols.

5. Evaluation and Task Goal Completion (TGC). AppWorld evaluates success using Task Goal Completion (TGC), computed via hidden unit tests that operate on the final environment state.

A known failure mode is *self-reported success bias*, where task success is determined from the agent's own completion signal rather than from the environment state. This is problematic because the agent can declare success without having actually produced a state that satisfies the underlying task constraints, leading to an empirical inflation of success rates by approximately $2\times$ (table 6).

Feature	Definition (over prefix $u_{\leq i}$)	Domain
f_{pos}	relative position in sequence / trajectory	A, B
f_{loglen}	$\log(1 + \text{tokens})$	A, B
$f_{\text{num_digit}}$	digit-character count	A, B
$f_{\text{caps_words}}$	capitalized-word count	A, B
f_{recency}	distance to most recent query context	B
$f_{\text{has_q}}$	presence of question marker / WH pattern	B
f_{tfidf}	TF-IDF lexical representation (10^4 cap)	B
$f_{\text{len_tok}}$	token length	B
$f_{\text{has_error}}$	error / exception / traceback indicator	A
$f_{\text{is_code}}$	code-token presence indicator	A
$f_{\text{rare_density}}$	mean local inverse document frequency	A
$f_{\text{sim_prev}}$	Jaccard similarity with previous step	A
$f_{\text{url_or_id}}$	URL / hex$\geq$8 / digit$\geq$4 / handle presence	A

Table 5: Unified feature space used by LRE across agentic execution traces (Domain A: AppWorld) and conversational QA (Domain B: LoCoMo and LongMemEval$_S$). The model shares a small set of causal structural features across domains, while augmenting them with domain-specific lexical, conversational, or code-execution signals. All features are computed over prefix histories $u_{\leq i}$ to ensure strict causality during training and inference. The feature set is constructed as a minimal causal representation of interaction structure, motivated by observed failure modes across domains.

Policy	Self-reported success (%)	True TGC (replay, %)	Inflation (self / TGC)
No compression	98.8	44.0	$2.24\times$
FIFO (recency)	60.7	34.5	$1.76\times$
ACON (in-fork)	60.1	26.2	$2.30\times$
LRE (ours)	89.3	41.1	$2.17\times$
Pooled (all four)	**77.2**	**36.5**	$\mathbf{2.12}\times$

Table 6: Self-reported success versus true TGC (recovered by replaying logged actions into a fresh AppWorld environment and running the hidden unit tests). Across all four policies, self-report overstates success by 1.76–$2.30\times$ (pooled $2.12\times$), confirming the $\approx 2\times$ inflation and motivating our replay-based evaluation protocol.

To eliminate this source of error, we adopt an evaluation protocol based on deterministic replay. Instead of using any agent-generated success signal, we reconstruct the final environment state from the recorded interaction trace. See the process in Figure 11.

Require: AppWorld environment with 90 training tasks
Require: Agent policy (gpt-4.1-mini), LRE scorer f
Require: Token budget $B = 2048$

1. Trajectory generation
for each training task T **do**
    Run unevicted agent ("nocomp")
    Log full trajectory $\tau = \{(a_i, o_i)\}$
end for
2. Self-supervised labeling
for each step i in trajectory **do**
    Extract identifier z_i
    if z_i reused ≥ 3 times in future steps **then**
        $y_i \leftarrow 1$
    else
        $y_i \leftarrow 0$
    end if
end for
3. Scorer training
Train logistic regression s_{90} on (x_i, y_i)
Validate via Leave-One-Task-Out (LOGO), compute AUC
4. Online agent loop
for each evaluation task **do**
    while agent is executing **do**
        Observe new step (a_t, o_t)
        Append to history H
        if tokens$(H) > B$ **then**
            Compute scores $p_i = f(u_i)$ for $u_i \in H$
            Rank units by p_i / c_i
            Retain top-scoring units
            Emit compressed history verbatim (chronological order)
        end if
        Continue ReAct execution (gpt-4.1-mini)
    end while
end for
5. Evaluation
Run hidden unit tests to compute TGC
return Outcome

Figure 8: AppWorld: agentic evaluation of LRE under token budget constraints and Pareto efficiency criteria.

Require: History $H = [(a_1, o_1), \ldots, (a_t, o_t)]$, budget B, keep-last k

recent $\leftarrow H[t{-}k{+}1 : t]$ ▷ last-k steps: always kept, uncapped
older $\leftarrow H[1 : t{-}k]$
if $\text{tokens}(\text{system}) + \text{tokens}(\text{task}) + \text{tokens}(H) \leq B$ **then**
    return system $\|$ task $\| H$ ▷ trigger not reached
end if
older_kept $\leftarrow$ HANDLEOLDER(older, B) ▷ only per-baseline step
return system $\|$ task $\|$ older_kept $\|$ recent

Per-baseline HANDLEOLDER(older, B)**:**
No-compression: **return** older ▷ $B{=}\infty$, never triggers
FIFO: **return** [ ] ▷ drop older; last-k only
ACON: **return** [LLMSUMMARIZE(older)] ▷ $+1$ compressor call, lossy
LRE: **return** LREKNAPSACK(older, B) ▷ verbatim, learned

function LREKNAPSACK(older, B)
    units $\leftarrow$ pair each step into one (a_i, o_i) unit
    for $u \in$ units **do**
        $p_u \leftarrow f(\text{features}(u))$ ▷ scorer `predict_proba`; 10 causal feats
    end for
    sort units by $p_u/\text{cost}(u)$ descending ▷ value density
    kept $\leftarrow \emptyset$, used $\leftarrow 0$
    for $u \in$ units in sorted order **do**
        if $\text{used} + \text{cost}(u) \leq B$ **then**
            kept $\leftarrow$ kept $\cup \{u\}$; used $\leftarrow$ used $+ \text{cost}(u)$
        end if
    end for
    return [$u \in \text{units} : u \in \text{kept}$] ▷ verbatim, chronological
end function

Figure 9: Domain A (agent): shared eviction trigger; methods differ only in HANDLEOLDER. No-compression keeps everything (unbounded), FIFO drops the older steps, ACON replaces them with one abstractive LLM summary, and LRE keeps the highest learned-relevance-per-token steps verbatim.

C Baseline mechanisms and implementation

This appendix specifies, for every baseline in both domains, the exact eviction mechanism we implemented, so the comparisons in §5 are reproducible.

C.1 Agent domain

All agent methods share one eviction interface (Algorithm 9): the system prompt, the task, and the last k steps are *always* kept uncapped, and the methods differ only in how the older steps are handled once the history crosses the token budget B.

Notes. No-compression is the "keep everything" upper bound (prompt grows with the horizon). FIFO is verbatim but importance-blind: any task-critical fact past the last-k window is lost. ACON adds one compressor LLM call and uses ACON's native preserve_last_k=1 (the default in (Kang et al., 2025)), whereas FIFO and LRE use k=5. LRE is bounded, importance-aware, verbatim, and language-model-free. The scorer is a learner over causal features (Table 5).

ACON compression prompt. We use ACON's shipped (not iteratively optimized) compression prompt verbatim (the system prompt and the `prompt_history_v2`), changing only the budget to B=2048. The code for ACON was kept unmodified and used just as shipped[2].

ACON compression SYSTEM prompt

```
# ACON compression SYSTEM prompt
    (context_opt/system_prompt.jinja):
You are an agent tasked with extracting and
    refining a concise and optimized
version of the context based on the user
    instruction and other provided
    information.

# ACON history-compression GUIDELINE
    (context_opt/prompt_history_v2.jinja):
You are maintaining a structured
    context-aware summary for a
    productivity agent. You
will be given the user instruction for the
    agent, a list of interactions
    corresponding
to actions taken by the agent, and the most
    recent previous summary if one exists.
Produce the following:

### REASONING
Summarize key progress, decisions made,
    important observed outcomes, and
    rationale
behind actions taken so far. Include how
    earlier steps influenced later ones
    and why
certain data is retained in the summary.

### COMPLETED
List completed subtasks or successful
    outcomes, with brief results if
    applicable.

## [Information Source]
### USER INSTRUCTION
{{ task }}
## [PREVIOUS SUMMARY] (if any)
{{ prev_summary }}
## [HISTORY OF INTERACTIONS]
{{ history }}

## PRIORITIZE
1. Keep all sections relevant and concise.
2. Use reusable structured formats when
    summarizing artifacts.
3. Ensure agent can resume task with no
    loss of information.
4. Include key info from errors or failed
    attempts to prevent repeated mistakes.
5. Preserve all essential artifacts and
    data needed to complete the task.

### [Output Format]
Do not include the input or any additional
    explanation. Only return the formatted
    summary.
```

C.2 Conversational domain

Every conversational method reduces to a per-unit *keep-score* (higher means retain) over the units of one group (a conversation in LoCoMo, a question's haystack in LongMemEval$_S$); retention keeps the top budget-fraction. Algorithm 10 gives the shared loop and every baseline's score.

Notes. MemoryBank (Zhong et al., 2024) is the Ebbinghaus curve $R = \exp(-t/S)$ with S=1, t=age; with no access stream it is strictly age-monotone and therefore induces the *same ranking as recency*. Content and dense salience score typicality relative to the group centroid, not relevance to any query (query blind). LLMLingua-2 (Pan et al., 2024) runs the pretrained `llmlingua-2-bert` token classifier and is task-agnostic (it never reads a question); its generic `LABEL_0/1` keep-class is calibrated empirically against information-dense probes. Dense embeddings use a frozen BGE encoder[3].

LRE variants. All three share one model (an L2 logistic regression with balanced class weights, vectorizer and scaler fit per fold on training units only) and the inference $s_i = P(\text{relevant} \mid u_i)$ with no neural pass. They differ only in label and features:

- **LRE-supervised**. Label: human gold evidence already given in the benchmark.
- **LRE-self-sup** (zero-annotation). Label: the response-overlap proxy (a turn is positive if its content tokens cover ≥ 0.4 of some eventual answer's), derived from later responses with no annotation needed. Section D.1 shows the

[2]Forked from https://github.com/microsoft/acon at commit d63f9ae.

[3]BGE model: https://huggingface.co/BAAI/bge-small-en-v1.5

Require: Group of units $U = \{u_1, \ldots, u_n\}$, score function $\mathrm{score}(\cdot)$, budget fraction b
Require: score is query-blind or reads the question (reference)
Scoring
for each unit $u_i \in U$ **do**
  $s_i \leftarrow \mathrm{score}(u_i, U)$ ▷ per-baseline; cases below
end for
Retention
$K \leftarrow \lceil b\, n \rceil$
keep $\leftarrow$ indices of the K highest s_i
return $[\, u_i : i \in \mathrm{sort}(\mathrm{keep}) \,]$ ▷ verbatim, chronological

Per-baseline $\mathrm{score}(u_i, U)$**:**
Recency: $s_i \leftarrow 1/(1 + \mathrm{age}_i)$
MemoryBank: $s_i \leftarrow \exp(-10\,\mathrm{age}_i/(n-1))$ ▷ monotone in age $\Rightarrow$ recency
Content salience: $s_i \leftarrow \cos\big(\mathrm{tfidf}(u_i), \bar{c}_U\big)$ ▷ centroid typicality
Dense salience: $s_i \leftarrow \cos\big(\mathrm{emb}(u_i), \bar{e}_U\big)$ ▷ 1 encoder pass / unit
LLMLingua-2: $s_i \leftarrow \mathrm{mean}_{t \in u_i} P(\mathrm{keep} \mid t)$ ▷ calibrated keep-class
LRE: $s_i \leftarrow P(\mathrm{relevant} \mid u_i)$ ▷ logistic regression; no neural pass

Figure 10: Domain B (conversational): shared score-then-retain eviction, with each baseline's per-unit score. age_i is distance from the most recent unit; $\bar{c}_U, \bar{e}_U$ are the group TF-IDF / embedding centroids; query-aware references read the question and are upper bounds, never competitors.

justification for the choice of token coverage value.

- **LRE-content** (ablation). Label: human gold evidence (same as LRE-supervised). Features: the TF-IDF text vector *alone*, with the six trajectory features removed. This isolates the contribution of the trajectory block: the gap between LRE-supervised and LRE-content on a given dataset is what those six features add over text-only scoring.

D Justification of Self-Supervised Label Design Choices

We evaluate label quality using two quantities: (i) **AUC-vs-gold**, which measures how well self-supervised labels align with human-annotated gold relevance labels (higher is better; 0.5 corresponds to random alignment), and (ii) **positive rate**, which denotes the fraction of units labeled as positive under a given rule. For agentic settings, we additionally report **LOTO AUC** (Leave-One-Task-Out AUC), which measures how well a classifier trained on these labels generalizes to unseen tasks.

D.1 Conversational Overlap Threshold ($\tau = 0.4$)

For conversational self-supervision, a turn is labeled positive if its content overlaps with a downstream response above a threshold τ. We select $\tau = 0.4$ based on a joint sweep across LoCoMo and LongMemEval$_S$, evaluating AUC-vs-gold and label sparsity.

Table 7 summarizes the results.

τ	LoCoMo AUC	LongMemEval$_S$ AUC	LoCoMo+	LongMemEval$_S$+
0.2	0.74	0.65	0.94	0.47
0.3	0.75	0.69	0.85	0.38
0.4	**0.77**	**0.70**	0.66	0.29
0.5	0.76	0.68	0.61	0.22
0.6	0.76	0.68	0.39	0.13
0.8	0.75	0.65	0.30	0.11

Table 7: Sweep over response-overlap threshold τ.

Why $\tau = 0.4$ is chosen: First, it is the *joint maximizer* of AUC-vs-gold across both datasets. Second, it lies in a flat optimum region ($\tau \in [0.3, 0.5]$), where performance varies by at most 0.016 AUC. This indicates stability.

Why not other values: Lower thresholds ($\tau = 0.2, 0.3$) produce excessively high positive rates on LoCoMo (0.85–0.94). This collapses the ranking problem into near-uniform positives and weakens discrimination. Such a near-degenerate label distribution does not reflect real-world deployment nuances. Higher thresholds ($\tau \geq 0.5$) reduce coverage too aggressively (down to 0.11–0.61 positive rate) and degrade alignment with gold annotations.

D.2 Agentic Reuse Breadth ($b = 3$)

For agentic trajectories, a step is labeled positive if an identifier it introduces is reused at least b times in subsequent steps. We evaluate $b \in \{1, 2, 3, 4, 5\}$ using Leave-One-Task-Out evaluation.

LOTO AUC (Leave-One-Task-Out Area Under the ROC Curve) measures how well a classifier trained on these labels ranks truly relevant steps above irrelevant ones in unseen tasks. A value of 0.5 corresponds to random ranking, while 1.0 corresponds to perfect separation.

b	Pos-rate	# Positives	LOTO AUC
1	0.811	1269	0.878
2	0.582	911	0.830
3	**0.432**	**676**	**0.828**
4	0.335	524	0.835
5	0.271	424	0.847

Table 8: Sweep over reuse breadth b for agentic self-supervision.

Why $b = 3$ is chosen: Unlike the conversational case, LOTO AUC is relatively flat across all values (0.83–0.88). We therefore select $b = 3$ based on semantic and operational criteria.

First, $b = 1$ is overly permissive, marking 81% of steps as positive. This collapses the eviction task into a near-majority-class problem, where ranking becomes dominated by trivial structural correlations rather than task-critical utility. Second, $b = 3$ yields a moderate positive rate (≈ 0.43), which aligns with the expected compression domain (Kang et al., 2025) in which only a subset of trajectory state can be retained.

Why not other values: Values $b \geq 4$ become too selective, reducing the positive set to 27–34%, which harms coverage of reusable context. $b \leq 2$ over-labels transient identifiers that are only briefly reused. We choose a parameter value that reflects real deployment nuances and therefore fix $b = 3$, a semantic choice that captures repeatedly-reused, task-critical state while maintaining a stable and informative training signal.

E Metrics: definitions and recovery

This appendix defines every reported score in both domains, then describes how the agent metric and its costs are recovered honestly.

E.1 Conversational relevance scores

ROC-AUC (per group). Each method assigns a real-valued keep-score s_i to every unit u_i of a group, scored against the binary gold label $y_i \in \{0, 1\}$. Let $\mathcal{P} = \{i : y_i{=}1\}$ and $\mathcal{N} = \{i : y_i{=}0\}$ be the relevant and irrelevant units, with $P = |\mathcal{P}|$, $N = |\mathcal{N}|$. The area under the receiver-operating-characteristic curve equals the probability that a random relevant unit outscores a random irrelevant one, computed exactly as the normalized Mann–Whitney statistic (Mann and Whitney, 1947)

$$\mathrm{AUC} = \frac{1}{P\,N} \sum_{i \in \mathcal{P}} \sum_{j \in \mathcal{N}} \Big(\mathbf{1}[\,s_i > s_j\,] + \tfrac{1}{2}\,\mathbf{1}[\,s_i = s_j\,] \Big).$$

AUC $= 1$ is a perfect ranking (every relevant unit above every irrelevant one), 0.5 is chance (random ordering), and a value < 0.5 means the score is *anti*-correlated with relevance. AUC is threshold-free and invariant to the positive rate, so it measures the ranking quality an eviction policy needs (what to keep first) without committing to a budget. A group is scored only if it contains at least one relevant and one irrelevant unit (otherwise AUC is undefined).

Macro-AUC. The per-group AUCs are averaged with equal weight, macro-AUC $= \frac{1}{|G|} \sum_{g \in G} \mathrm{AUC}_g$, so a large group cannot dominate a small one; the groups are conversations on LoCoMo and questions on LongMemEval$_S$.

Recall@budget. A retention policy keeps the $K = \lceil b\,n \rceil$ highest-scoring of the n units at budget fraction $b \in \{0.1, 0.2, 0.3, 0.4\}$. Recall@$b$ $= |\text{kept} \cap \mathcal{P}|/P$ is the fraction of relevant units that survive, averaged over groups.

Budget@recall (iso-accuracy efficiency). The inverse statistic: the smallest budget fraction b at which recall@b reaches a target (e.g. 0.8), averaged over groups, reported as the saving relative to recency at the same recall.

E.2 Conversational answer-quality scores (downstream)

Token-F1 (LoCoMo). With the answerer reading only the retained context, we compare its answer A to the gold answer G as bags of normalized content tokens. With $\mathrm{prec} = |A \cap G|/|A|$ and $\mathrm{rec} = |A \cap G|/|G|$,

$$\text{token-F1} = \frac{2\,\mathrm{prec} \cdot \mathrm{rec}}{\mathrm{prec} + \mathrm{rec}},$$

the standard extractive-QA overlap, averaged over questions.

LLM-judge (LongMemEval$_S$). Free-form answers are graded by a model *stronger* than the answerer (gpt-4o judging gpt-4.1-mini, to avoid self-grading): the judge sees the question, the gold answer, and the candidate, and returns a binary correct/incorrect vote; the score is the fraction judged correct. The judge was validated on crafted correct, wrong, and paraphrase cases.

E.3 Conversational serving-cost scores

Throughput, neural calls, dollar cost. *Units per second* is the measured rate at which a loaded scorer scores resident units (hardware recorded). *Neural forward passes per unit* counts the encoder

or classifier passes a method performs per scored unit.

E.4 Agent scores

Task Goal Completion (TGC). The all-or-nothing success metric on AppWorld: a task scores 1 only if *every* hidden unit test passes (partial credit such as 3 of 4 tests counts as 0), and TGC% over a difficulty bucket is the mean over its tasks. How we recover true TGC (rather than the inflated self-report) is in §E.5.

Cost axes. *cLLM* is compressor language-model calls per task (the number of compression events). *Input tokens per request* (in/req) is the mean prompt size per generation, our peak-token proxy since the true per-step peak is not logged. *Total tokens per task* sums agent and recovered compressor tokens.

E.5 Recovering the agent metric and costs

Recovering true TGC by replay. The agent framework ships with its environment evaluation disabled, so the run's self-reported completion flag overstates success and is not Task Goal Completion. We recover true TGC at zero model cost: because a freshly constructed environment resets task state, we replay each task's logged action sequence into a fresh environment and then call the environment's evaluation, which passes only when all hidden unit tests pass. The replay reconstructs the final state deterministically rather than reporting the empty-environment artifact. All reported TGC values use this recovered metric, never the self-report. Algorithm 11 gives the procedure.

Require: Task id T, logged action sequence (the agent's code blocks)
world $\leftarrow$ AppWorld(T) ▷ fresh env: resets to T's initial state
for each action in the logged sequence **do**
  world.execute(clean_code(action)) ▷ replay to rebuild final state; errors swallowed
end for
$r \leftarrow$ world.evaluate() ▷ run hidden unit tests on the reconstructed state
tgc $\leftarrow$ $(r.\text{num_passes} = r.\text{num_tests}) \wedge (r.\text{num_failures} = 0)$ ▷ all-or-nothing
return tgc ▷ written to `tgc.json`; never the agent self-report

Figure 11: Recovery of true TGC by replay ($0, no LLM call): `replay_eval.py`. A fresh environment resets to the initial state, so we replay the logged actions to reconstruct the agent's final state before evaluating.

F Additional AppWorld Results

F.1 Peak Prompt Tokens

Table 9 reports per-task peak prompt statistics on AppWorld `test_normal`. This table shows the corresponding minimum, maximum, mean, and median values. LRE has the lowest maximum peak among the evaluated policies. FIFO and ACON keep a bounded working context, but failed runs can still reach larger task-level peaks because they continue to the step cap.

Method	Min peak	Max peak	Mean	Median	Peak saving (vs worst max)
No compression	3,250	25,043	9,230	7,592	21.5%
FIFO (recency)	3,287	28,565	5,646	5,155	10.5%
ACON (in-fork)	3,643	31,918	5,121	4,832	—
LRE (ours)	3,545	**15,388**	6,912	6,640	**52%**

Table 9: Per-task peak prompt tokens on AppWorld `test_normal`. FIFO and ACON loop to the step cap, so their max peak *exceeds* full context; LRE is the only bounded method whose max peak falls below it, saving as much as 52% against the worst-case peak (ACON's).

F.2 Hidden Unit-Test Failures

Table 10 reports hidden unit-test failure rates. The pattern is similar to Task Goal Completion: FIFO and ACON fail substantially more tests overall, while LRE remains closer to the no-compression baseline.

	Unit-test failure rate (%, ↓)			
Method	Avg	Easy	Med	Hard
No compression†	27.0	17.6	22.3	33.9
FIFO (recency)	51.6	18.1	52.7	64.8
ACON (in-fork)	58.7	19.9	58.3	74.9
LRE (ours)	**36.0**	**8.8**	**28.3**	**52.2**

Table 10: Unit-test failure rate on AppWorld `test_normal` by difficulty: the fraction of hidden unit tests that fail (lower is better), the partial-credit complement to the all-or-nothing TGC of Table 2. Tests per split: Easy 216, Medium 336, Hard 525 (1,077 total)

F.3 Tasks solved only by LRE

Table 11 lists the AppWorld `test_normal` tasks solved only by LRE.

Task	Diff.	No-comp	FIFO	ACON	LRE
`024c982_2`	E	6/7	0/7	6/7	**7/7**
`09b0ee6_1`	E	1/2	1/2	1/2	**2/2**
`552869a_2`	E	1/2	1/2	1/2	**2/2**
`59fae45_3`	E	2/6	4/6	5/6	**6/6**
`0d01c76_3`	M	2/6	1/6	1/6	**6/6**
`270f1ff_3`	M	1/11	0/11	1/11	**11/11**
`3aa1a22_1`	M	6/7	2/7	2/7	**7/7**
`3d9a636_1`	M	2/5	0/5	1/5	**5/5**
`d194965_2`	M	5/6	3/6	3/6	**6/6**
`d6ac34d_2`	M	8/9	7/9	2/9	**9/9**
`ff58e36_1`	M	2/6	1/6	1/6	**6/6**
`2c544f9_3`	H	2/6	1/6	2/6	**6/6**
`9016950_3`	H	3/7	3/7	2/7	**7/7**
`f323bae_2`	H	1/9	0/9	1/9	**9/9**

Table 11: The 14 AppWorld `test_normal` tasks (seed 1) solved by LRE alone: hidden unit-test pass counts (passed/total) per policy. LRE passes *all* tests on every task, while no-compression, FIFO, and ACON each leave at least one test failing.

F.4 Recency-matched ACON (k=5)

Matching the recency window recovers accuracy but its worst-case peak rises to 32.2k (Medium) and 35.2k (Hard). Against ACON as a competitive baseline, LRE achieves comparable gains at substantially lower cost (Table 12).

F.5 Seed variance

Table 13 reports three seeds of the key Medium comparison.

F.6 Budget sensitivity

Table 14 sweeps a 3× range. TGC rises monotonically with budget, as expected, but no pairwise difference is significant (McNemar p=0.14 for B=1024 vs. B=3072).

		peak prompt (k tok)↓		
Budget B	**TGC (%)**↑	median	p90	max
1024 ($\frac{1}{2}$×)	27.1	**5.9**	**8.0**	27.0
2048 (paper)	37.5	6.7	8.8	**10.4**
3072 (1.5×)	**41.7**	7.3	9.2	10.7

Table 14: Budget sweep for LRE on AppWorld Medium.

G Cross-Model Transfer

The scorer is external to the host model and consumes only logged text, so in principle it should transfer across model families. We test that directly on two further hosts, Gemini-2.5-Flash (Google) and DeepSeek-V3, on AppWorld Medium.

G.1 Gemini-2.5-Flash

We apply the gpt-4.1-mini scorer unchanged (*zero-shot*) and, additionally re-fit a scorer on Gemini's own logged trajectories (Table 15).

G.2 DeepSeek-V3

DeepSeek-V3's true ceiling on this split is low (22.9%) for a reason unrelated to memory; it over-reports completion, self-reporting success on 98–100% of tasks against ≈ 23% true TGC under replay evaluation (Table 17). This is the same self-report bias documented in Table 6. Its failures are premature completion rather than dropped state, so eviction policy has little to act on and every arm ties.

Read together, where failures are memory-bound, transfer holds and the margin is at least as large as in-domain; where they are not, LRE costs nothing and still bounds the peak.

H Additional Conversational Results

H.1 Retention and Downstream Performance

Figure 12 reports downstream QA performance under fixed retention budgets.

On LongMemEval$_S$, the deployable policies cluster more closely and content salience remains slightly ahead of LRE.Content salience leads on this benchmark, because its topically distinctive sessions make centroid typicality a strong proxy for relevance but that advantage is *local*, not general: the same method drops to near chance on LoCoMo, where LRE dominates. Even in this harder setting, however, LRE remains competitive.

H.2 Serving Cost and Self-Supervision

Table 19 reports serving cost and iso-recall budget savings. Table 4 compares the self-supervised and supervised variants. Hardware: LoCoMo on Apple M2 (8-core arm64); LongMemEval$_S$ on Modal Linux (8 vCPU x86_64 + NVIDIA T4 16 GB). LRE methods run CPU-only on both; dense and LLMLingua use the T4 on LongMemEval$_S$. Within-dataset throughput ratios are hardware-controlled; cross-dataset comparisons should not be made because unit sizes differ.

Method	TGC (%)↑		max peak (k tok)↓		compressor calls↓	
	Med	Hard	Med	Hard	Med	Hard
FIFO (k=5)	27.1	17.5	**8.6**	30.1	0.0	0.0
ACON k=1 (shipped default)	16.7	4.8	9.0	34.7	5.6	7.4
ACON k=5 (recency-matched)	35.4	12.7	32.2	35.2	2.9	4.1
LRE (ours)	**37.5**	14.3	10.4	**16.5**	**0.0**	**0.0**

Table 12: Recency-matched ACON on AppWorld Medium (n=48) and Hard (n=63). *max peak* is the per-task maximum prompt size (gpt-4.1-mini).

Arm	per seed			mean ± SE	max peak range
	s1	s2	s3		
TGC (%)					
ACON (k=5)	35.4	27.1	33.3	31.9 ± 2.5	—
LRE (ours)	37.5	39.6	33.3	$\mathbf{36.8 \pm 1.9}$	—
max peak (k tokens)					
ACON (k=5)	32.2	33.3	25.6	30.4 ± 2.4	[25.6, 33.3]
LRE (ours)	10.4	**10.1**	19.4	$\mathbf{13.3 \pm 3.0}$	[**10.1**, **19.4**]

Table 13: Three-seed variance on AppWorld Medium (n=48). Accuracy ties within noise; the worst-case peak ranges are disjoint.

H.3 Scorer Size

LRE is 295× smaller than the dense encoder and 1569× smaller than the token-pruning compressor, and beats both on LongMemEval$_S$ (0.708 vs. 0.643 and 0.402), at zero neural forward passes and zero language-model calls (Table 20).

I Extended limitations

This appendix expands the limitations stated in the main text. We group them by scope: evaluation, method, supervision, measurement, and generalization. Each limitation lists what we did to mitigate it and, where relevant, what a deployment would need to verify before relying on LRE.

In-fork ACON baseline. ACON's published fork ships the unoptimized compression prompt and we used it as it is. The fair comparison that licenses our claim is the matched in-fork one (identical agent, identical seed, identical evaluation harness).

Benchmark coverage. We evaluate on three benchmarks: LoCoMo and LongMemEval$_S$ for conversational memory, AppWorld for long-horizon agents. These cover dialogue and tool-use coding agents but do not include web-browsing agents, multimodal agents, or open-domain coding agents (e.g., SWE-bench). The Pareto-efficiency claim is supported within these regimes.

Subset of AppWorld used. We evaluate on `test_normal` (168 tasks). We do not evaluate on `test_challenge` (417 tasks).

Budget-bounded performance. On tasks whose required state exceeds the operating budget (AppWorld Hard at $B = 2048$ being the clearest case) no-compression wins because retaining everything is the only way to keep state that does not fit. LRE therefore complements, rather than replaces, unbounded retention when the deployment can afford it. The right deployment question is whether the budget is binding; where it is, LRE is Pareto-efficient.

Eviction unit granularity. Our agent unit is the (action, observation) pair; our conversational unit is the dialogue turn or session. We do not evict at the token level inside a single forward pass, which is what KV-cache methods such as H_2O (Zhang et al., 2023), SnapKV (Li et al., 2024), and TRIM-KV (Bui et al., 2025) do. Token-level methods are complementary: they operate inside the model and require model-internal signals; LRE operates outside the model and requires only logged behavior. A deployment could plausibly combine them (LRE for unit-level retention, token pruning inside each retained unit), but we do not evaluate that combination here.

Feature-set dependence. The learned scorer operates on a compact set of causal features that we

Arm	TGC (%)↑	95% CI	max peak (k tok)↓
No compression (ceiling)	45.8	[32.6, 59.7]	46.9
LRE (gpt scorer, zero-shot)	**29.2**	[18.2, 43.2]	14.8
LRE (Gemini scorer, re-fit)	**29.2**	[18.2, 43.2]	14.8
FIFO (recency)	10.4	[4.5, 22.2]	**9.8**

Table 15: Gemini-2.5-Flash host, AppWorld Medium (n=48), Wilson 95% intervals.

LRE scorer	trained on	LOTO AUC	TGC (%)	tasks resolved identically
gpt-4.1-mini (zero-shot)	gpt-4.1-mini logs	0.828	29.2	44/48 (92%)
Gemini-native (re-fit)	Gemini logs	**0.864**	29.2	

Table 16: Zero-shot versus host-native scorer on the Gemini host. Higher in-domain AUC, identical downstream outcome.

designed to be inexpensive, model-agnostic, and available at decision time. While these features transfer across the benchmarks studied here, we do not claim that they are universally optimal. Different deployments may expose different signals, interaction patterns, memory units, or notions of future utility. In practice, a production system should treat our feature set as a reference implementation rather than a fixed specification, and should measure and validate its own candidate features from logged behavior before deployment. The broader claim of LRE is that future utility can be learned from causal signals available at write time, not that any particular feature set is universally sufficient.

Fixed self-supervised threshold. The conversational self-supervised label uses a fixed answer-recall threshold of $\tau = 0.4$, jointly optimal on LoCoMo and LongMemEval$_S$. In deployment, however, the right rule is to set τ implicitly (through a target positive rate on a sample of logged exchanges) rather than to inherit our value. The $\tau = 0.4$ choice is justified empirically (Table 7); we do not claim it is universal.

No multimodal or extended unit types. The eviction unit is text. Multimodal agents whose task-critical state includes images, audio, or large code blobs would require the unit representation and the token-cost function to be extended; we have not done so.

What the reuse proxy can miss. The self-supervised label defines relevance as "later reused," which is a measure of the eviction objective rather than of importance in the abstract. Under this label, content that is important but never restated, referenced, or acted upon again is negative. A constraint stated once and then honored implicitly is the clearest at-risk case, and a scorer trained only on this signal could in principle learn to evict that whole class. However, the choice of features and system requirements ultimately belongs to the practitioner. The practitioner can therefore encode signals beyond reuse when the application requires them, and we argue that LRE should be understood as a lightweight, configurable eviction mechanism rather than a universal measure of importance.

Arm	TGC (%)	max peak (k tok)↓	compressor calls↓
No compression	22.9	14.8	0.00
ACON (**gpt** compressor)	22.9	24.5	1.58
LRE (ours)	22.9	**9.9**	**0.00**

Table 17: DeepSeek-V3 host, AppWorld Medium (n=48). The ACON arm uses a *gpt* compressor, a stronger-compressor control. All arms tie on accuracy; LRE holds the lowest peak at zero compressor calls.

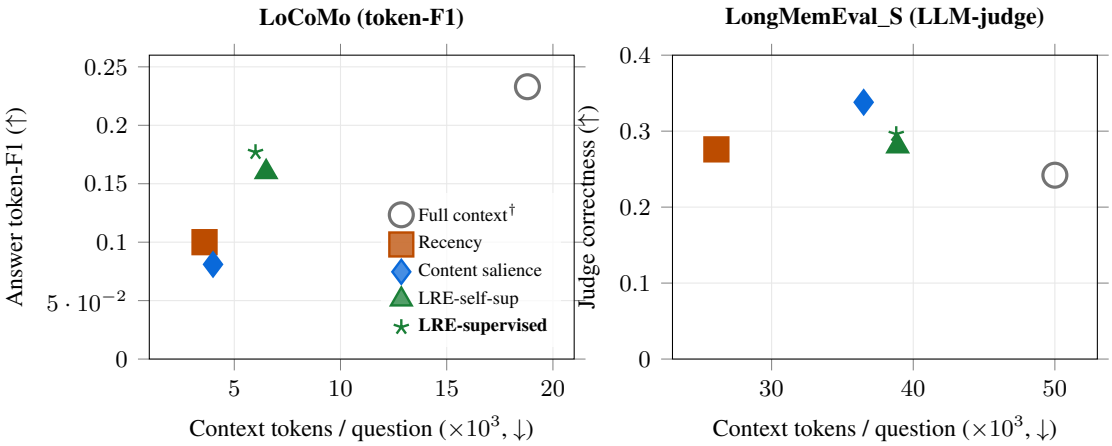

Figure 12: Downstream answer quality versus token cost under a 20% retention budget (Full context † = no eviction). The comparison set is minimal and deployment-oriented: recency is the production default, content salience the strongest non-neural query-blind competitor, and the LRE variants test whether proactive relevance transfers to QA; MemoryBank (ranking-equivalent to recency) and the neural salience baselines (dominated by content salience) are omitted.

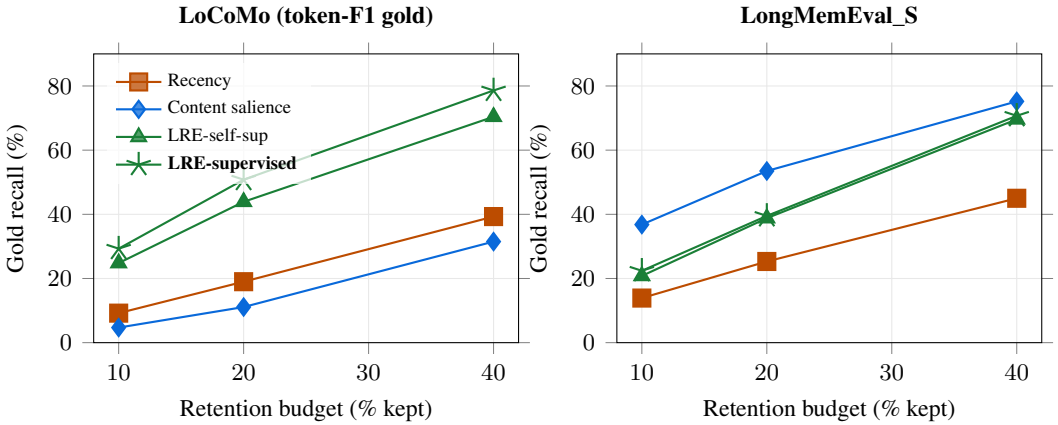

Figure 13: Gold recall versus retention budget on both benchmarks. On LoCoMo, LRE retains more gold evidence than every baseline at every budget; on LongMemEval$_S$ LRE tracks just below content salience but reaches it at a higher budget.

	LoCoMo (token-F1)		LongMemEval$_S$ (LLM-judge)	
Policy	Acc↑	ctx tok↓	Acc↑	ctx tok↓
Full context†	0.233	18.8k	0.242	50.0k
Recency	0.100	**3.6k**	0.276	**26.1k**
Content salience	0.081	4.0k	**0.338**	36.5k
LRE-self-sup	0.160	6.5k	0.280	38.9k
LRE-supervised	**0.177**	6.0k	0.296	38.8k

Table 18: Downstream answer quality at a 20% retention budget. On LoCoMo (token-F1) the full context is best but token-heavy, and LRE leads the budget-constrained policies; on LongMemEval$_S$ (LLM-judge) the full context is worst and the deployable policies cluster.

Data	Method	neural calls/unit	units/sec (CPU)	budget@80% (saved vs rec.)
LoCoMo	Recency	0	7,444,187	0.834 (–)
LoCoMo	Content salience	0	57,152	0.839 (-0.6%)
LoCoMo	**LRE-sup**	**0**	**129,081**	**0.411** (50.8%)
LongMemEval_S	Recency	0	2,836,670	0.622 (–)
LongMemEval_S	**LRE-sup**	**0**	1,181	**0.364** (41.5%)
LongMemEval_S	Dense salience (BGE)	1	103	0.449 (27.9%)
LongMemEval_S	LLMLingua-2	1	36	0.690 (-10.9%)

Table 19: Conversational serving cost and iso-recall budget saving. LRE does zero neural forward passes and scores resident units on a CPU, whereas the dense and LLMLingua-2 encoders pay one forward pass per unit. At iso-recall (80% gold recall) LRE reaches the target at roughly half the budget of recency.

Method	Type	Params	Weights	×vs conv	AUC (LoCoMo / LME_S)
LRE agent scorer	logistic (10 feats)	~ 10	**1.7 KB**	—	—
LRE conv scorer	TF-IDF + LR	$\leq 10^4$	**226 / 441 KB**	$1\times$	**0.829 / 0.708**
BGE-small-en-v1.5	dense encoder	33 M	127 MB	$295\times$	— / 0.643
LLMLingua-2 (mBERT)	token-pruning LM	177 M	677 MB	$1569\times$	— / 0.402

Table 20: Serialized scorer size versus ranking quality. LRE AUC is reported as LoCoMo / LongMemEval_S; the neural baselines were run on LongMemEval_S only and their weights are benchmark-independent.

J Qualitative case study: Venmo request

This appendix gives the full qualitative example summarized in §5.2: an outcome (Example A) and the controlled mechanism (Example B), both drawn from AppWorld task `024c982_2`.

Qualitative example A: only LRE completes the task

Task (`024c982_2`): *"Request $28 privately on Venmo from my roommate, Melissa, with a note, 'For the movie tickets'."*

Policy	Steps	TGC	Failure mode
No compression	13	✗	self-completes but fails 1 of 7 hidden tests (6/7)
FIFO (recency)	49 (cap)	✗	loses login state → re-authenticates in a loop (33/49 login steps); 0/7
ACON (LLM compression)	49 (cap)	✗	summary drops the token → re-authenticates (34/49 login steps); self-reports done but 6/7
LRE (ours)	**18**	✓	completes correctly, all 7 tests pass (7/7)

Qualitative example B: why the task-critical credential survives only under LRE

The task hinges on one **task-critical identifier**: the Venmo `access_token` obtained at login, required by *every* subsequent API call. How each policy treats it under the same $B{=}2048$ budget:

LRE (extractive): the scorer ranks the login turn high and keeps it *verbatim* within budget, so the exact token is still present at step 17, which creates the request directly:

```
# step 17: I will now create a private payment request of $28 to her
# with the note "For the movie tickets" using the access token.
payment_request = apis.venmo.create_payment_request(access_token=..., amount=28,
                  description="For the movie tickets", private=True)
-> {"message": "Payment request created.", "payment_request_id": 6097} # then complete_task()
```

FIFO (recency): `preserve_last_k=5` scrolls the login turn out as history grows, so the agent "forgets" it already authenticated and re-logs-in. It spends **33 of 49** steps on login/token actions before hitting the step cap:

```
# (repeated) I have the Venmo password. I will now login to Venmo using ...
-> {"access_token": "eyJhbGciOiJIUzI1NiIsInR5cCI6IkpXVCJ9...."} # re-issued, never used to
    finish
```

ACON (abstractive): its LLM summary preserves the *reasoning* but **drops the exact token** (the lossy-compression failure mode). It too re-authenticates (**34 of 49** steps); it eventually self-reports completion but still fails a hidden test:

```
### REASONING The agent's objective is to request $28 privately on Venmo from
Melissa with the note "For the movie tickets." ... identified the correct API
endpoint (create_payment_request) ... retrieved the Venmo password from stored
credentials ... # keeps "$28", "Melissa", "create_payment_request";
                        # NO access_token -> the agent must re-authenticate
```

Takeaway. The task turns on an exact opaque credential. **Extractive** eviction (LRE) preserves it bit-for-bit; **recency** (FIFO) scrolls it out; **abstractive compression** (ACON) paraphrases it away. Only LRE still holds the value the final action depends on.

K Qualitative case study: Simple Note playlist

This appendix gives the full qualitative example summarized in §5.2: an outcome (Example A) and the controlled mechanism (Example B), both drawn from AppWorld task `d194965_2`.

Qualitative example A: only LRE completes the task

Task (`d194965_2`): *"I jotted down some songs in Simple Note recently. Make a playlist titled 'Songs from Simple Note' out of it."*

Policy	Steps	TGC	Failure mode
No compression	30	✗	self-completes but fails 1 of 6 hidden tests (5/6)
FIFO (recency)	49 (cap)	✗	loses the note and login state → re-fetches and re-authenticates in a loop (34/49 login steps); 3/6
ACON (LLM compression)	49 (cap)	✗	summary drops the tokens and song list → re-authenticates (31/49 login steps); 3/6
LRE (ours)	**19**	✓	completes correctly, all 6 tests pass (6/6)

Qualitative example B: why the task-critical state survives only under LRE

This task chains two apps and a data hand-off, so it hinges on several **task-critical identifiers** that must all be in context at the playlist-assembly step: the Simple Note `access_token`, the **song list** extracted from the note, the Spotify `access_token`, and the `playlist_id`. How each policy treats them under the same $B{=}2048$ budget:

LRE (extractive): the scorer ranks the note-content turn and both login turns high and keeps them *verbatim*, so at step 13 the exact Spotify token is still present and the playlist is created directly (then its songs are added):

```
# step 13: logged in to Spotify; create the playlist using this access token.
spotify_access_token = spotify_login_response["access_token"]
create_playlist_response = apis.spotify.create_playlist(access_token=spotify_access_token,
                         title="Songs from Simple Note")
-> {"message": "Playlist created.", "playlist_id": 654}
```

FIFO (recency): `preserve_last_k=5` scrolls the note content and login state out as history grows, so the agent "forgets" both — it re-fetches the note it already read and re-logs-in, spending **34 of 49** steps on login/token actions before the cap:

```
# (repeated) I have the content of the note which contains the songs. I will parse ...
# (repeated) The Spotify login API requires both username and password. I will try to login ...
```

ACON (abstractive): its LLM summary preserves the *plan* (read the note, build the playlist) but **drops the exact tokens and the song list** (the lossy-compression failure mode). It too re-authenticates (**31 of 49** steps) and never assembles all the state at once, hitting the cap and failing:

```
### REASONING The agent's objective is to create a Spotify playlist titled "Songs
from Simple Note" from songs noted in Simple Note ... located the relevant note ...
logged in to retrieve credentials ... # keeps the plan and titles;
                                      # NO access_token, NO verbatim song list
```

Takeaway. The task turns on exact opaque state (two access tokens, the playlist id, and the verbatim song list) that a paraphrase cannot reconstruct. **Extractive** eviction (LRE) preserves it bit-for-bit; **recency** (FIFO) scrolls it out; **abstractive compression** (ACON) paraphrases it away. Only LRE still holds the values the final actions depend on.

Displacement Is Not Direction: Evaluating Fidelity Metrics for Quantized LLM Deployment

Abstract

Fidelity metrics such as per-token KL divergence (KLD) against a high-precision reference are often used as low-cost proxies for benchmark quality. We test this practice on 28 Qwen3.6-35B-A3B and 41 Devstral-Small-2-24B quantizations across downstream benchmarks. KLD strongly correlates with benchmark score over the full cohorts ($\rho = -0.72$ on Qwen and $\rho = -0.86$ on Devstral, both with $p < 0.001$). However, among quantizations retaining at least 99% of measured BF16 composite quality, KLD provides no dependable ranking signal ($\rho = +0.11$, $p = 0.71$, $n = 14$ on Qwen; $\rho = +0.02$, $p = 0.93$, $n = 16$ on Devstral). This collapse persists across measurement variants spanning KLD aggregation, perplexity formulations, top-1 agreement, measurement corpora, and context lengths. At the per-prompt level, KLD provides only weak failure-prediction power and fails as a cross-model router across four benchmarks, selecting the better response on only 40.0–49.1% of disagreement prompts and reducing score relative to the better static model on all four. We trace the collapse to a structural decomposition: within the KLD-defined silent zone, KLD primarily measures the *volume* of disagreement with the reference (composite $\rho = +0.94$, $p < 0.001$ on Qwen; $\rho = +0.55$, $p = 0.03$ on Devstral), while its relationship to the *direction* of those disagreements is weak and task-conditional.

1 Introduction

As large language models (LLMs) become more capable, the motivation to deploy them across settings ranging from edge devices to data centers continues to grow. Much of this progress has been accompanied by rapidly increasing parameter counts, from several billion to a trillion. Larger models, however, require correspondingly greater memory capacity and bandwidth, compute, and energy.

Quantization and compression offer a practical way to reduce these deployment costs, increasing throughput in data centers and often making edge deployment possible. Yet selecting a quantized model is not straightforward. For Qwen3.6-35B-A3B (Qwen, 2026) alone, the community has released hundreds of GGUF quantizations from different publishers, using different calibration recipes and exhibiting widely varying output quality. Running a full benchmark suite on every candidate is expensive, so practitioners often rely on lower-cost fidelity metrics, particularly KL divergence (KLD) and perplexity (PPL) relative to a BF16 reference.

This work examines the relationship between fidelity metrics, such as PPL and KLD, and downstream benchmark quality. At first glance, these metrics appear to work: across the full cohort, KLD and PPL correlate strongly with composite benchmark score, with Spearman $\rho(\text{KLD}, \text{composite quality}) = -0.72$ on Qwen3.6-35B-A3B and -0.86 on Devstral-Small-2-24B (both with $p < 0.001$), and similar values across every fidelity-metric variant we tested.

However, this signal is not uniform across the quality range. It is driven primarily by clearly degraded quantizations, where KLD and PPL span a wide range and benchmark quality has already fallen substantially. When we restrict the analysis to near-baseline candidates, those retaining at least 99% of measured BF16 composite quality and therefore most relevant to practitioners, we find no dependable KLD ranking signal, with $\rho = +0.11$ ($p = 0.71$) on Qwen and $\rho = +0.02$ ($p = 0.93$) on Devstral. The correlation remains non-significant through a 2.0% quality drop on Devstral and through 2.5% on Qwen. We use the term *silent zone* for the near-baseline regime in which KLD and PPL continue to measure distance from the reference but no longer provide a dependable ranking signal for downstream quality. We examine this regime under two complementary definitions:

EMNLP 2026 Industry Track, pages 3025–3039
October 24-29, 2026 ©2026 Association for Computational Linguistics

a quality-defined view based on retained BF16 composite quality and a KLD-defined view, in which models form a dense low-divergence cluster followed by a progressively degraded tail. Beyond the silent zone, in the *lossy zone*, KLD/PPL remain useful as coarse degradation detectors because the models have already suffered significant quality loss.

Inside the silent zone, fidelity metrics fail at three levels: they fail to (1) reliably rank models, (2) separate correct from incorrect responses, or (3) route a prompt to the better of two models when models disagree. We explain this with a volume–direction decomposition of score differences: KLD tracks how often the quantized model and reference differ in correctness, but task quality also depends on whether those differences are improvements or regressions.

In short, we make the following contributions:

1. **Silent-zone vs lossy-zone characterization:** We identify a near-baseline *silent zone* where fidelity metrics like KLD and PPL lose ranking power, and a degraded lossy zone where they remain useful as coarse predictors (Section 4).
2. **Decompose score into volume and direction:** We build on the work of Dutta et al. (2024) by extending the observed flips into *leapfrogs* (quantized model is correct where the reference is not) and *drops* (the reverse), and derive a closed-form decomposition score $= \text{score}_{\text{ref}} + \text{vol} \cdot (2f - 1)/N$. KLD primarily tracks volume; whether it also tracks direction is task-conditional (Section 5).
3. **Per-prompt KLD has no useful model-selection signal:** KLD only weakly separates a model's own passes from its failures and fails to route between models, both in detailed LiveCodeBench pairings and across four prompt-level benchmarks (Section 4.4).
4. **The collapse is metric-invariant:** The non-significant silent-zone correlation ($|\rho| \leq 0.25$, all $p > 0.10$) holds across 14 measurement variants, including PPL ratio, $\Delta \log \text{PPL}$, top-1 agreement, longer contexts, and response-only measurement on held-out instruction data (Section 4.2).

2 Related Work

Quantization is widely used to reduce the memory, bandwidth, and compute cost of deploying large language models. To preserve quality at lower bit-widths, prior work has introduced practical post-training quantization methods such as GPTQ, AWQ, and SmoothQuant (Frantar et al., 2023; Lin et al., 2024; Xiao et al., 2023). Further compression can be achieved with mixed-precision quantization, where precision is assigned at finer granularity than the whole network, including by tensor, layer, channel, or feature (Zheng et al., 2026; Nikolić et al., 2024). More recent studies evaluate the accuracy-performance trade-offs of quantized LLMs across model families, bit-widths, hardware targets, and downstream tasks (Lee et al., 2025; Jaiswal et al., 2024; Kurtic et al., 2025). These works show that quantized-model quality cannot be summarized by model size alone, and that the practical value of a quantized model depends on the interaction between quality, throughput, hardware, and workload. Our work studies a narrower question: given multiple quantized variants of the same model, can inexpensive fidelity metrics such as KLD and PPL be used to rank their downstream task quality?

2.1 Beyond PPL and KLD

The limitations of PPL and related fidelity metrics for evaluating compressed models have been noted before. Jaiswal et al. (2024) show that pruned and quantized models can preserve perplexity while losing downstream capabilities, and introduce a broader benchmark suite for compressed models. Deiseroth et al. (2024) similarly argue that perplexity and aggregate accuracy do not fully capture generation degradation, and propose divergent-token metrics as a more generation-sensitive diagnostic for pruning and quantization. However, even though fidelity metrics are imperfect, their low computational cost keeps them attractive, especially in open-source model comparison. We build on this background, but focus specifically on model selection: whether fidelity metrics can distinguish among near-baseline quantized models, separate correct from incorrect responses, or route a prompt to the better of two quantized models.

2.2 Flips

Dutta et al. (2024) present the closest prior art to our work. They introduce *flips*: the percentage of multiple-choice answers that change correctness between a baseline model and a quantized model. They study the relationship between KLD, flips, and MMLU accuracy across quantized models, showing that accuracy alone can hide substantial

Table 1: Two-cohort experimental setup. Zone statistics use the KLD-defined partition.

Item	Qwen cohort	Devstral cohort
Reference model	Qwen3.6-35B-A3B	Devstral-Small-2-24B
Architecture	MoE (35B/3B active)	dense (24B)
Specialization	general	code-specialized
Cohort size	28 quants	41 quants
Quant sources	5	3
bpw range	2.17–6.14	1.88–9.84
Silent-zone τ	KLD ≤ 0.064	KLD ≤ 0.027
Silent/lossy split	17 / 11	16 / 25

behavior changes after quantization.

We extend this framework in five ways:

1. We extend the analysis beyond MMLU and multiple-choice accuracy to a broader set of tasks, including coding, tool calling, instruction following, and math reasoning.
2. We split flips into *leapfrogs* (quantized model correct, reference wrong) and *drops* (reference correct, quantized model wrong), and decompose score as $\text{score}_{\text{ref}} + \text{vol} \cdot (2f - 1)/N$.
3. We show that KLD consistently tracks disagreement volume, while its relationship to direction depends on the task and quality regime.
4. We characterize the silent zone of near-baseline low-KLD quants, a regime where we find no dependable KLD–quality ranking signal.
5. We evaluate KLD at the per-prompt level and as a routing signal, showing that it provides only a weak response-correctness signal and fails to select the better model across four prompt-level benchmarks.

Additionally, Dutta et al. (2024) introduce top-margin analysis (the probability gap between the model's first and second choices). This is a per-prompt instability indicator. Our analysis focuses on whether fidelity to the reference predicts downstream task quality among quantized models.

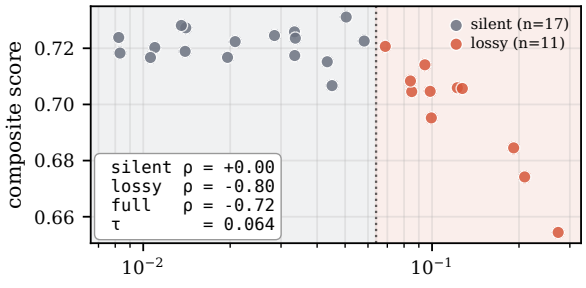
3 Methodology

We evaluate two quantized-model cohorts with deliberately different architectures (Table 1): 28 GGUF quantizations of Qwen3.6-35B-A3B (Qwen, 2026), a mixture-of-experts model, and 41 quantizations of the dense, code-specialized Devstral-Small-2-24B-Instruct-2512 (Mistral AI, 2025). All fidelity metrics and leapfrog/drop counts are computed relative to the corresponding BF16 reference.

The cohorts draw from multiple public quantization sources and span a broad range of compression, from near-reference high-bpw variants to aggressively compressed low-bpw ones. We use bits per weight (bpw) as a size proxy, not a quality metric: it sets the memory footprint, while benchmark scores and throughput determine practical quality.

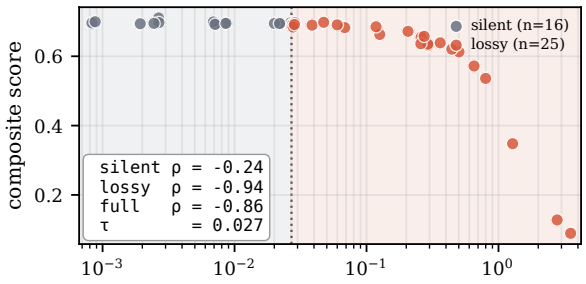
3.1 Downstream Quality Evaluation

We evaluate downstream quality on benchmarks spanning coding (HumanEval (Chen et al., 2021), LiveCodeBench v6 (Jain et al., 2025)), instruction following (IFEval (Zhou et al., 2023)), tool calling (BFCL v3 (Patil et al., 2025)), math reasoning (GSM8K (Cobbe et al., 2021)), math and visual reasoning (GSM8K-v (Yuan et al., 2025)), and multitask knowledge (MMLU (Hendrycks et al., 2021)); the Devstral cohort adds MATH-500 (Lightman et al., 2024). All benchmarks run in non-thinking mode, except GSM8K-v, which on the thinking-capable Qwen3.6 cohort we run in both modes.



We report per-benchmark scores and a composite (unweighted mean of normalized scores), oriented so higher is better and compared against the BF16 reference; per-prompt pass/fail outcomes feed the leapfrog/drop and routing analyses. Qwen MMLU is reported separately and excluded from the Qwen composite because of a prompt-format artifact, not a knowledge deficit (Appendix A). All main-cohort GGUF evaluations use the EvalScope framework (Team, 2024), serving each model with `llama.cpp` (Gerganov, 2023) (build b8855 for Qwen3.6 and b7744 for Devstral). The separate AWQ/GPTQ analysis uses vLLM (Section 4.3).

All reported correlation coefficients are Spearman rank correlations, with two-sided p-values reported without adjustment for multiple comparisons.



3.2 Fidelity Metrics

Our default KLD is $\text{KL}(p_{\text{BF16}} \,\|\, p_{\text{quant}})$ over next-token distributions. Response-only measurements score only response tokens (excluding the prompt); two diagnostics use this form with top-k truncation, defined in Appendix B: the validation-set variants in Table 3 (a held-out instruction mixture, Appendix D) and the per-prompt analyses (benchmark prompt-response pairs).

We compute PPL and KLD with `llama-perplexity` from the same builds. The default and headline metric is mean KLD on WikiText (Merity et al., 2017) at 512-token context, which defines the KLD-space silent-zone split. We also test 8192-token context and the response-only variants above to assess whether the

(a) Qwen3.6-35B-A3B

(b) Devstral-Small-2-24B

Figure 1: The silent-zone collapse on both cohorts, with Spearman correlation coefficients $\rho(\text{KLD}, \text{composite score})$ for the full cohort and the KLD-defined silent zone.

result depends on context length, measurement corpus, vocabulary support, or response-only scoring.

We report full-cohort results and analyze the near-baseline *silent zone* under separate quality-defined and KLD-defined partitions.

4 The Silent Zone

Our first finding is that KLD provides no dependable ranking signal among near-baseline quantizations. Defining near-baseline models as those retaining at least 99% of the corresponding measured BF16 composite score gives 14 Qwen and 16 Devstral quantizations. Within these sets, the KLD–quality correlation is $\rho = +0.11$ ($p = 0.71$) on Qwen and $\rho = +0.02$ ($p = 0.93$) on Devstral, compared with full-cohort correlations of -0.72 and -0.86. The correlation remains non-significant through a 2.0% quality drop on Devstral and through 2.5% on Qwen (Appendix C).

4.1 The silent-zone collapse in KLD space

This structure is clearer in KLD space: models form a dense low-KLD cluster followed by a progressively degraded tail (Figure 1). We call the low-KLD, near-baseline region the *silent zone*, and the degraded tail the *lossy zone*. Under our default WikiText KLD measurement, the silent-zone boundaries are $\tau = 0.064$ for Qwen and $\tau = 0.027$ for Devstral, containing 17 and 16 models, respectively. Within the silent zone, the KLD–quality correlation is $+0.00$ on Qwen and -0.24 ($p = 0.36$) on Devstral. The boundaries are descriptive and specific to the model and KLD setup.

Table 2: Spearman $\rho(\text{KLD}, \text{benchmark score})$ by zone, on both cohorts. $^{*}\, p < 0.05$, $^{\dagger}\, p < 0.10$.

	Qwen3.6-35B-A3B			Devstral-Small-2-24B		
Benchmark	**silent**	**lossy**	**full**	**silent**	**lossy**	**full**
HumanEval	$+0.20$	-0.91^{*}	-0.19	-0.14	-0.81^{*}	-0.63^{*}
LiveCodeBench	$+0.08$	-0.87^{*}	-0.65^{*}	-0.20	-0.96^{*}	-0.92^{*}
IFEval	$+0.18$	-0.11	-0.26	-0.10	-0.87^{*}	-0.73^{*}
BFCL_v3	-0.24	-0.25	-0.71^{*}	-0.12	-0.90^{*}	-0.75^{*}
GSM8K	$+0.11$	-0.61^{*}	-0.43^{*}	-0.05	-0.96^{*}	-0.89^{*}
GSM8K-v	$-0.43^{\dagger}$	$-0.57^{\dagger}$	-0.83^{*}	-0.14	-0.88^{*}	-0.74^{*}
GSM8K-v think	-0.51^{*}	-0.84^{*}	-0.83^{*}	—	—	—
MATH-500	—	—	—	$+0.30$	-0.95^{*}	-0.80^{*}
MMLU	-0.54^{*}	$+0.50$	$+0.39^{*}$	-0.22	-0.98^{*}	-0.89^{*}
Composite	$+0.00$	-0.80^{*}	-0.72^{*}	-0.24	-0.94^{*}	-0.86^{*}

The low-KLD regime extends beyond these limits. Expanding the boundary keeps the within-zone correlation non-significant through $n = 21$ ($\tau = 0.0944$, $\rho = -0.35$, $p = 0.12$) on Qwen and $n = 24$ ($\tau = 0.060$, $\rho = -0.33$, $p = 0.11$) on Devstral. Significance appears only after additional degraded quantizations enter the comparison.

The pattern spans two cohorts with different architectures (MoE vs. dense), training profiles (general vs. code-specialized), and sizes (35B/3B active vs. 24B). The near-baseline result is also not driven by a single publisher: leaving each publisher out in turn gives $\rho \in [-0.26, +0.29]$ on Qwen and $\rho \in [-0.37, -0.12]$ on Devstral. It remains non-significant in the largest single-family subset, the 14 Devstral models using K-quant formats ($\rho = -0.27$, $p = 0.34$).

In the lossy zone, the negative correlation is strong: $\rho = -0.80$ ($p = 0.003$) for Qwen and $\rho = -0.94$ ($p < 0.001$) for Devstral, stronger than the full-cohort relationship in either case. Thus, the strong correlation observed over the full cohort is driven primarily by the inclusion of substantially degraded low-bit quants rather than by reliable ranking within the near-baseline candidates.

Table 2 breaks the pattern down by benchmark and shows that the silent-zone collapse is broad rather than driven by any single task.

Across most benchmarks included in the composite, the lossy zone shows a substantially stronger negative ρ than the silent zone. In the silent zone, correlations are generally non-significant or inconsistent in sign. The only included Qwen benchmark with a detectable silent-zone signal at $p < 0.05$ is GSM8K-v thinking. Qwen MMLU is reported separately but excluded from the composite because

Table 3: The KLD-defined silent-zone collapse holds across 14 measurement variants, on both cohorts. Significance: $^*p < 0.05$.

of the prompt-format artifact (Appendix A).

4.2 Collapse is metric-invariant

We next test whether the collapse persists across fidelity-metric formulations. We evaluate 14 variants spanning KLD aggregation, PPL formulation, top-1 agreement, context length, measurement corpus, top-k truncation, and response-only measurement. Table 3 shows that all 14 variants preserve the full-cohort signal but collapse in the silent zone, with $|\rho| \leq 0.25$ ($p > 0.10$) on both cohorts. Response-only KLD on a task-aligned validation set shows the same pattern, suggesting that the collapse is not an artifact of WikiText, context length, or aggregation choice.

4.3 Preliminary evidence beyond GGUF

Our main cohorts consist of public GGUF quantizations, raising the question of whether the silent-zone behavior is specific to the llama.cpp quantization ecosystem. While quantization methods differ in how they choose scales, groups, and calibration criteria, they share the same basic goal of approximating a high-precision model with lower-precision weights. More broadly, the volume–direction explanation does not depend on quantization itself. Pruning, LoRA, fine-tuning, and other model modifications can also move a model away from a reference distribution. A fidelity metric can measure the size of that change, but not necessarily whether it helps or hurts the downstream task. We therefore expect the same distinction between displacement and direction to apply more broadly, although this requires empirical validation.

We preliminarily test four vLLM-served Qwen variants (three AWQ and one GPTQ) from four publishers. All are near baseline and span only 0.54 percentage points in downstream quality. Across six pairs, KLD orders quality correctly in only 2, including an inversion for the pair with the largest KLD difference.

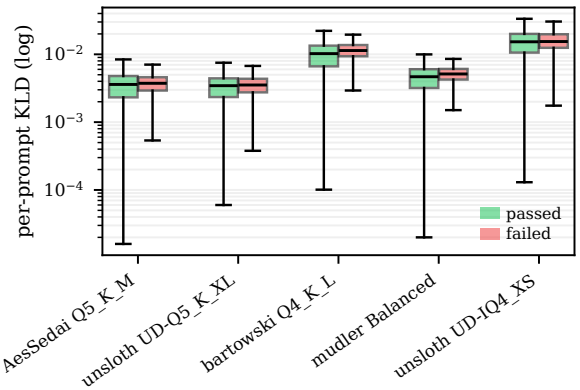

Figure 2: Per-prompt KLD distribution on LiveCodeBench, split by each model's own pass (green) / fail (red) outcomes, for five KLD-defined silent-zone Qwen quants.

Four models are too few to establish that the silent-zone failure generalizes beyond GGUF. This result is preliminary evidence that the same ranking limitation may also occur among near-baseline AWQ and GPTQ models. A larger cross-format study, as well as evaluation of pruning, LoRA, and fine-tuning, is needed to test that hypothesis.

Appendix H lists the models and their measured KLD and composite scores.

4.4 Per-prompt KLD analysis

To test whether aggregate KLD hides a stronger prompt-level signal, we evaluate KLD directly on benchmark prompts. We compute KLD on each response and compare it with the corresponding benchmark pass/fail outcome. If KLD had useful predictive power in the *silent zone*, we should be able to identify which prompts a given quantized model will fail.

We compute per-prompt KLD on LiveCodeBench (LCB) for five silent-zone Qwen quantizations and split each model's prompts into those it passed and those it failed. Figure 2 shows substantial overlap: the passed and failed interquartile ranges overlap for all five models. Failed prompts have slightly higher KLD on average, with failed-to-passed geometric-mean ratios from 1.08 to 1.22 (13% average increase), but this small aggregate shift provides little prompt-level separation.

A stronger test is whether per-prompt KLD can choose between two quantized models on the same prompt. We pair ByteShape IQ4_XS-3.93bpw (KLD 0.069) against each of five near-baseline quantizations on LiveCodeBench and ask:

Table 4: Per-prompt KLD routing on LiveCodeBench. Each model is paired with ByteShape IQ4_XS-3.93bpw, and evaluation is restricted to prompts where exactly one model passes. Routing succeeds when the model with lower per-prompt KLD is the passer.

Pairing vs. ByteShape IQ4_XS-3.93bpw	**disagrees**	**wins**	ρ (p)
AesSedai-Q5_K_M	190	47.4%	+0.033 (0.53)
Unsloth-UD-Q5_K_XL	177	44.1%	+0.109 (0.040)
mudler-Balanced	170	42.9%	+0.126 (0.020)
Bartowski-Q4_K_L	163	42.3%	+0.128 (0.020)
Unsloth-UD-IQ4_XS	180	49.4%	−0.009 (0.86)
BF16-fails: AesSedai-Q5_K_M vs. ByteShape IQ4_XS-3.93bpw	71	40.8%	+0.159 (0.059)

Table 5: Per-prompt KLD routing across four Qwen benchmarks. Routing accuracy is the fraction of disagreement prompts on which the lower-KLD model is better. Oracle headroom and routed change are score differences relative to the better static model.

Benchmark	**Lower-KLD wins**	**Oracle headroom**	**Routed change**
LiveCodeBench	45.3%	+7.55 pp	−1.57 pp
HumanEval	40.0%	+1.59 pp	−0.98 pp
GSM8K	46.0%	+0.85 pp	−0.17 pp
IFEval	49.1%	+4.62 pp	−0.44 pp

on prompts where exactly one of the two passes, does routing to the lower per-prompt KLD model identify the passer more than half the time?

Table 4 shows that the answer is no. Lower-KLD-wins accuracy is in $[42.3\%, 49.4\%]$ across the five pairings, never reaching 50%. The signed correlation $\rho(\text{KLD}, \text{correctness})$ is positive (wrong-direction) in four and essentially zero ($\rho = -0.01$) in the fifth. On the BF16-fail slice (the prompts where a quantized model could leapfrog the reference), accuracy drops further to 40.8%.

Here, ρ is the Spearman correlation over both models' stacked $(\text{KLD}, \text{pass})$ observations on the disagreement prompts: a negative value favors lower-KLD routing, while a positive value points in the opposite direction.

A broader routing experiment applies the same five model pairings across four prompt-level benchmarks. For each benchmark, we pool disagreement prompts across pairings to compute lower-KLD routing accuracy and compare the routed result against the better static model and an oracle that selects the correct model whenever the pair disagrees.

Table 5 shows that lower-KLD routing does not outperform the better static model on any of the four benchmarks. This is not simply because the models rarely differ in useful ways: the oracle has positive headroom on every task, reaching $+7.55$ percentage points on LiveCodeBench and $+4.62$ on IFEval. KLD fails to identify the direction of these disagreements and instead reduces score on every benchmark. Per-prompt KLD therefore contains a weak failure signal, but not a dependable model-selection signal.

5 Disagreement Volume and Direction

What does KLD actually measure, if not quality? We propose a decomposition that explains it.

For a benchmark of N prompts where the reference (BF16) passes N_p and a candidate quant passes N_q, define: (1) **leapfrogs** ℓ: prompts where the quant passes and the reference fails; (2) **drops** d: prompts where the quant fails and the reference passes; and (3) **volume** $\text{vol} = \ell + d$: the total disagreement count. For $\text{vol} > 0$, define **direction** $f = \ell/\text{vol}$ as the fraction of disagreements that are improvements; when $\text{vol} = 0$, set $f = 1/2$ by convention. Since $N_q = N_p + \ell - d$, we obtain:

$$\text{score}_q = \text{score}_{\text{ref}} + \frac{\text{vol} \cdot (2f - 1)}{N} \qquad (1)$$

where score_q and $\text{score}_{\text{ref}}$ are benchmark scores of the quant and BF16. Score is determined by *how many* prompts the quant flips (volume) and *in which direction* $(2f - 1)$. That is, volume is the number of flips, while direction captures their balance between leapfrogs and drops. The identity is exact for benchmarks whose official score is one binary outcome per prompt (HumanEval, LCB, IFEval, GSM8K, and both GSM8K-v modes), and approximate for BFCL_v3, MMLU, and MATH-500, whose official scores macro-average over subcategories with a weighting different from the per-prompt count we use for leap/drop accounting.

KLD measures displacement, not direction: Table 6 and Figure 3 show this decomposition on both cohorts. In both Qwen and Devstral, KLD consistently tracks disagreement volume: in the silent zone, $\rho(\text{KLD}, \text{volume})$ is positive on almost every benchmark, with Qwen spanning $\rho \in [+0.38, +0.91]$ and a composite $\rho = +0.94$ ($p < 0.001$). On Devstral, the per-benchmark range is wider, with two small-magnitude cases

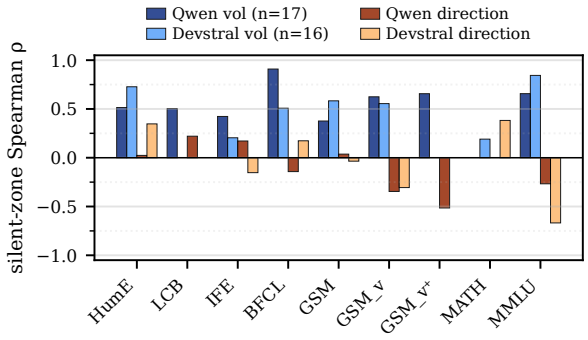

Figure 3: KLD-defined silent-zone Spearman $\rho(\text{KLD}, \cdot)$ per benchmark for volume (blue) and direction (orange).

on IFEval and MATH-500, and the composite correlation is weaker at $+0.55$ ($p = 0.03$). Direction behaves differently. Its correlation with KLD is weak and task-dependent in the silent zone, but becomes strongly negative over the full cohort once lossy-zone models enter the comparison. These results explain the full-cohort KLD–quality correlation: degraded models both move farther from the reference and tend to move in a harmful direction. Once we control for volume, the residual KLD signal on composite score does not reach significance in either cohort: partial $\rho = -0.35$ ($p = 0.17$) for Qwen and $\rho = -0.20$ ($p = 0.46$) for Devstral[1].

Why task matters: The task-dependent direction signal may reflect differences in how tasks tolerate token-level deviations. Math reasoning often depends on locally determined token choices, where small deviations can compound through the solution. Code correctness is more structural: many programs with different token sequences can implement the same specification, so moving away from the BF16 token distribution does not necessarily imply failure. On code-specialized models, where the BF16 distribution is more task-aligned, drift can become more consistently harmful.

In short, KLD measures how far the quantized model moves from the reference. Score depends on whether that movement goes in a useful direction.

6 Practical Implications

For deployment, our results suggest separating *screening* from *ranking*. Fidelity metrics remain useful for filtering clearly damaged candidates in the lossy zone. Among near-baseline models, lower KLD/PPL does not reliably mean better downstream quality. Ranking should rely on downstream evidence, together with practical constraints such as throughput, memory use, and hardware fit.

That evaluation may not require running every candidate on the full benchmark suite. We evaluate two preliminary ways to reduce its cost:

1. **Canary evaluation:** select the prompts that most divide previously evaluated models, using cross-model correctness variance as the informativeness score, then evaluate new candidates only on that smaller set. In leave-one-publisher-out evaluation on Qwen, a 308-prompt canary, 10% of our four-benchmark suite, reaches $\rho \approx 0.52$ with the complete four-benchmark ranking and identifies the best silent-zone candidate in 76% of trials.
2. **Estimate volume and measure direction:** use WikiText KLD to predict disagreement volume, then measure direction by evaluating prompts that the BF16 reference fails. In leave-one-publisher-out evaluation on Qwen, measuring leapfrogs on 214 reference-failure prompts, approximately 7% of the four-benchmark suite, reaches $\rho \approx 0.70$ with the full ranking and identifies the best silent-zone candidate in 91% of trials ($1{,}000$ trials; 95% CI $[89\%, 93\%]$).

The two approaches use evaluation budget differently. The selected canary measures downstream quality directly on prompts identified from previous model outcomes. The second approach uses KLD for the component it predicts well, disagreement volume, and spends downstream evaluations on the missing direction signal. These results are preliminary: both experiments cover one model family, four benchmarks, and a family-specific leave-one-publisher-out setting (Appendix F).

7 Conclusion

We evaluated KLD and PPL as proxies for downstream quality of quantized LLMs. Across two cohorts, KLD appears predictive over the full quality range, but this signal is driven mainly by degraded low-bpw variants. In the near-baseline silent zone, we find no dependable KLD ranking signal across model families and metric variants, and per-prompt KLD does not rescue model selection. The volume–direction decomposition explains why: KLD tracks how often a quantized model disagrees with the reference, but benchmark quality depends on whether those disagreements help or hurt. KLD measures displacement, not direction. For deployment, fidelity metrics should filter damaged candidates, not rank near-baseline ones.

[1] We regress raw KLD and composite quality separately on disagreement volume, then compute Spearman correlation between the residuals.

8 Limitations

Our results should be read as a study of fidelity metrics for quantized-model selection, not as a claim that KLD, PPL, and other fidelity metrics are useless. The failure mode we identify is specifically their inability to provide a dependable ranking signal among near-baseline candidates.

The silent-zone thresholds are descriptive and cohort-specific: they depend on the reference model, quantization methods, benchmark suite, and KLD setup. We therefore do not propose $\tau = 0.064$ or $\tau = 0.027$ as general decision rules. The near-baseline subsets are also relatively small ($n \approx 14$–17), and the wide confidence intervals in Appendix E should be interpreted accordingly. Our main cohort analysis covers two model families, per-prompt routing experiments are currently limited to Qwen, and the non-GGUF check includes only four models. We did not test whether the same failure mode extends to other forms of model modification, such as pruning or distillation.

Our reduced-evaluation experiments are limited to our Qwen family silent-zone candidates and four benchmarks with prompt-level outcomes. Both canary selection and KLD-to-volume calibration use previously evaluated models from the same family, so their performance may not transfer directly to a new model family or deployment distribution.

A Qwen MMLU Format Artifact

We exclude Qwen MMLU from the Qwen composite quality score because of a prompt-format artifact rather than a lack of knowledge. MMLU is administered with a five-shot prompt that instructs the model to output only the final answer choice. Qwen3.6 often begins reasoning instead of following this answer-only format, causing the benchmark's answer extraction to fail and the response to be scored as incorrect. Manual inspection suggests that many such responses nevertheless contain the correct reasoning.

This behavior is already present in the BF16 reference and persists across the quantized cohort, so the resulting low MMLU scores cannot be interpreted as quantization-induced degradation. We therefore report Qwen MMLU separately (Table 2) and omit it from the Qwen composite, while retaining MMLU in the Devstral composite, where this behavior does not occur.

B Top-k and Response-Only KLD Measurement

This appendix specifies the response-only top-k KLD measurements used for `KLD val-response` in Table 3 and for the per-prompt analyses in Section 4.4.

B.1 Full-vocabulary KLD

At a single position, an autoregressive model defines a next-token distribution over the vocabulary V. Let $p \equiv p_{\mathrm{BF16}}$ be the distribution of the BF16 reference and $q \equiv p_{\mathrm{quant}}$ that of the candidate quant for the same context (the notation of Section 3). The Kullback–Leibler divergence of q from p is

$$\mathrm{KL}(p \,\|\, q) \;=\; \sum_{i \in V} p(i)\, \log \frac{p(i)}{q(i)}, \qquad (2)$$

which is 0 iff $q \equiv p$ and grows as q relocates probability mass. The expectation is taken under the reference p, so the metric penalizes the quantized model precisely where the reference places mass. Our headline metric is the mean of (2) over all scored positions. All logarithms are natural; full-vocabulary KLD and the top-k score are therefore reported in nats per scored token.

B.2 Top-k KLD

Under truncated decoding, most vocabulary tokens have negligible or zero sampling probability, so

their contribution to full-vocabulary KLD may have little direct bearing on the generated output. We therefore also evaluate a top-k score that emphasizes the tokens each model ranks most highly. We retain and renormalize each model's top-k probabilities as follows.

Let $\mathcal{S}_p$ and $\mathcal{S}_q$ be the index sets of the k highest-probability tokens under p and q respectively. Each side is renormalized over *its own* support,

$$\begin{aligned} \tilde{p}(i) &= \frac{p(i)}{Z_p}, \quad i \in \mathcal{S}_p, \\ \tilde{q}(i) &= \frac{q(i)}{Z_q}, \quad i \in \mathcal{S}_q, \end{aligned} \tag{3}$$

with $Z_p = \sum_{j \in \mathcal{S}_p} p(j)$ and $Z_q = \sum_{j \in \mathcal{S}_q} q(j)$; the normalizers $\log Z_p$ and $\log Z_q$ are computed in log-space for numerical stability. Each truncated distribution is zero outside its own support. The top-k divergence is summed over the *reference's* support $\mathcal{S}_p$,

$$\mathrm{KL}_k(p \,\|\, q) \;=\; \sum_{i \in \mathcal{S}_p} \tilde{p}(i) \left(\log \tilde{p}(i) - \log \tilde{q}(i)\right). \tag{4}$$

The subtlety is the term $\log \tilde{q}(i)$ when a reference-important token $i \in \mathcal{S}_p$ is absent from the quant's own top-k set, $i \notin \mathcal{S}_q$: the quant has effectively abandoned a token the reference cares about. Since $\tilde{q}$ is renormalized over $\mathcal{S}_q$, it assigns zero mass to any such token, so $\log \tilde{q}(i) = -\infty$ and the corresponding term, and hence the entire divergence, would blow up to $+\infty$. To keep the metric finite, we replace this $-\infty$ with a fixed log-probability floor,

$$\log \tilde{q}(i) = \begin{cases} \log q(i) - \log Z_q, & i \in \mathcal{S}_q, \\ c_{\min}, & i \notin \mathcal{S}_q, \end{cases} \tag{5}$$

with floor $c_{\min} = -10$. When $\mathcal{S}_p \neq \mathcal{S}_q$, we use "top-$k$ KLD" as shorthand for this floored asymmetric divergence score. Because the floored candidate values are not renormalized over a common support with the reference, it is not the ordinary KL divergence between two distributions on the same truncated vocabulary. We use the same floor for every model, cohort, and value of k.

The floor caps the contribution of a missing token at $\tilde{p}(i)\left(\log \tilde{p}(i) - c_{\min}\right)$, so a single abandoned token incurs a large but bounded penalty rather than diverging. This design has two properties:

- **Exact reduction.** When the two top-k sets coincide, $\mathcal{S}_p = \mathcal{S}_q$, every term uses the renormalized $\log \tilde{q}(i)$ and (4) reduces to the plain renormalized top-k KLD.
- **Mass-relocation sensitivity.** When the supports diverge, the floored terms expose the case where the quant moved mass *outside* the reference's top-k, which a renormalized-only metric would hide.

In addition to focusing the measurement on high-probability tokens, the top-k restriction has a large practical benefit: the two-pass protocol of Section B.3 must cache the reference distribution at every scored position, and storing only k tokens instead of the full vocabulary shrinks this footprint by orders of magnitude. For Qwen3.6-35B-A3B, whose vocabulary is $|V| = 248{,}320$ tokens, a full next-token distribution stored as 16-bit quantized log-probs occupies $\approx$ 485 KB per position; the top-60 record (a 32-bit index and a 32-bit log-prob per token) takes only 480 bytes, a $\sim 1000\times$ reduction, rising to $\sim 3100\times$ at $k = 20$. Over a million scored response tokens this is the difference between roughly 500 GB and under half a gigabyte of cached reference logits.

The same per-position quantity (4) can be evaluated either over a plain-text corpus (e.g. WikiText) or, as below, over response tokens only. We report it at $k \in \{20, 60\}$, with $k = 60$ as the default stored support; the smaller report point reuses the prefix of the sorted top-60 list.

B.3 Response-only (SFT-style) KLD

For instruction-tuned evaluation we care about divergence on the model's *answer*, not on the prompt it was merely conditioned on. Averaging KLD over every position dilutes the answer-region signal with prompt tokens the model never had to generate. The response-only protocol measures divergence **only on response-token predictions**, while keeping the full prompt in the conditioning context.

Each corpus sample is tokenized as a prompt followed by an on-policy BF16 continuation. The same fixed prompt–response sequence is used for the BF16 reference and every quantized candidate. Writing the concatenated sequence as

$$x \;=\; \big[\underbrace{x_1, \ldots, x_m}_{\text{prompt}}, \underbrace{x_{m+1}, \ldots, x_n}_{\text{response}}\big], \tag{6}$$

the sample is decoded as a single sequence, so the full prompt populates the KV-cache. However, divergence is evaluated only at positions whose next

token is a response token: with position t predicting x_{t+1}, this is the set $\{m, m{+}1, \ldots, n{-}1\}$. The prompt positions $\{1, \ldots, m{-}1\}$ contribute context but no divergence terms.

The metric is computed in two passes over the same corpus. *Pass 1* (BF16 reference) stores, at each scored response position, the reference's top-k indices and their full-softmax log-probabilities, and optionally the full distribution, when the full-vocabulary KLD of (2) is also desired. *Pass 2* (quant) runs the candidate on the identical token sequences, recomputes its own top-k at each scored position, and evaluates $\mathrm{KL}_k(p \,\|\, q)$ from (4) against the stored reference record. Aggregating over all response tokens of all samples,

$$\overline{\mathrm{KL}_k} \;=\; \frac{1}{N_{\text{resp}}} \sum_{s} \sum_{t=m_s}^{n_s-1} \mathrm{KL}_k\big(p_t^{(s)} \,\|\, q_t^{(s)}\big), \quad (7)$$

where s indexes samples, $p_t^{(s)}$ and $q_t^{(s)}$ are the reference and quantized-model next-token distributions at position t of sample s, and $N_{\text{resp}} = \sum_s (n_s - m_s)$ is the total response-token count. This response-only corpus mean is reported as `KLD val-response` in Table 3.

Per-prompt benchmark protocol. The per-prompt analyses use the same response-only top-k score with $k = 60$, but retain one mean per benchmark prompt rather than aggregating across the corpus. For each prompt, the BF16 model's generated continuation is teacher-forced through BF16 and every quantization, so all candidates are scored on identical response tokens. The final end-of-turn token is included for IFEval and HumanEval.

Routing aggregation. For each model pairing, disagreement prompts are those on which exactly one model passes, and the router selects the model with lower per-prompt KLD. Exact KLD ties are excluded, although none occur. The reported lower-KLD win rate pools disagreement events across the five pairings, whereas oracle headroom and routed change are equal-weight means of pair-level score differences relative to each pair's better static model. The reported ρ stacks both models' $(\mathrm{KLD}, \mathrm{pass})$ observations over the disagreement set before computing Spearman correlation.

C Quality-Defined Near-Baseline Analysis

We define near-baseline quantizations by their retained downstream quality, report the 99% quality-retention result used in the main text, and examine sensitivity to the quality threshold and fidelity metric.

Table 7: KLD–quality correlation among quantizations retaining at least 99% of measured BF16 composite quality. Significance: $^*p < 0.05$.

Quantity	Qwen	Devstral
Full-cohort ρ	-0.72^*	-0.86^*
Near-baseline ($\geq$ 99% of BF16)		
Near-baseline quantizations n	14	16
Maximum KLD in subset	0.069	0.047
Silent-zone ρ	$+0.11$	$+0.02$
Silent-zone p	0.71	0.93

C.1 Definition and quality threshold

Let S_q denote the composite score of quantized model q, and let S_{BF16} denote the measured composite score of the corresponding BF16 reference. For a maximum relative quality drop δ, expressed as a fraction, we define q as near-baseline if:

$$S_q \geq (1 - \delta) S_{\mathrm{BF16}}. \quad (8)$$

Our primary quality threshold is $\delta = 0.01$, corresponding to retention of at least 99% of the BF16 composite score. This gives 14 Qwen and 16 Devstral near-baseline quantizations (Table 7).

C.2 Sensitivity to the quality bar

Table 8 varies the maximum relative quality drop δ from 0.5% to 3.0%. The KLD–quality correlation remains non-significant through $\delta = 2.0\%$ on Devstral and through $\delta = 2.5\%$ on Qwen. It becomes significant at $\delta = 2.5\%$ on Devstral ($\rho = -0.47$, $p = 0.02$) and $\delta = 3.0\%$ on Qwen ($\rho = -0.55$, $p < 0.01$), as progressively degraded quantizations enter the comparison set.

C.3 Metric-invariance is preserved

Repeating the analysis under the quality-defined silent zone across the measurement variants in Table 3 gives the same qualitative result (Table 9). KLD aggregations, PPL formulations, top-1 agreement, long-context variants, and response-only variants all remain non-significant (Qwen $|\rho| \leq 0.20$; Devstral $|\rho| \leq 0.04$). The result therefore holds across metric formulations and under both silent-zone definitions.

Table 8: Sensitivity of the quality-defined silent zone to the quality-retention bar δ (maximum relative drop from BF16). n is the number of near-baseline quantizations. The correlation remains non-significant through $\delta = 2.5\%$ on Qwen and $\delta = 2.0\%$ on Devstral; the primary $\delta = 1\%$ threshold is bold.

D Internal Validation Dataset

The `KLD val-wiki c512` and `KLD val-response` rows in Table 3 use the held-out validation slices summarized in Table 10. The `val-wiki` variant renders each sample as a single plain-text sequence and computes full-vocabulary mean KLD over all tokens at 512-token context. The `val-response` variants instead score only the tokens of an on-policy BF16 continuation, using the response-only top-k protocol defined in Appendix B. Together, these measurements test whether the silent-zone collapse persists under a prompt distribution closer to instruction-following use and under both full-sequence and response-only scoring.

For each reference model, we build a separate validation slice by stratified sampling from source datasets covering instruction following, multi-turn chat, code generation, math reasoning, tool calling, and multilingual prompts. The slices are not used for calibrating any quantized model in this study; they serve exclusively as measurement corpora for the validation-set KLD measurements against the corresponding BF16 reference.

Table 10: Internal validation slices used for the `KLD val-wiki c512` and `KLD val-response` measurements in Table 3.

Property	Qwen	Devstral

E Confidence Intervals for Headline Correlations

To further estimate uncertainty for the headline Spearman correlations, we perform a nonparametric bootstrap over the quantized models. For each KLD–quality row, each bootstrap replicate samples n models with replacement from the corresponding set and recomputes $\rho(\mathrm{KLD}, \mathrm{composite})$. We used $B = 10{,}000$ bootstrap replicates with fixed seed 0 and report percentile 95% confidence intervals. We computed the intervals on the same data and zone definitions as the corresponding point estimates.

Composite volume pools raw disagreement counts across the seven benchmarks with prompt-level outcomes in each cohort, without normalization by benchmark size. Composite direction is the pooled leapfrog count divided by pooled volume. Devstral LiveCodeBench remains in the quality composite but is omitted from these quantities because only aggregate scores are available. For the volume rows, each bootstrap replicate recomputes the KLD–volume correlation. For the partial-correlation rows, we regress raw KLD and compos-

Table 12: Leave-one-publisher-out reduced-evaluation results on the Qwen KLD-defined silent-zone models. ρ is the mean Spearman correlation with the ranking obtained from all 3,079 prompts in the four-benchmark suite. Top-1 is the frequency with which the method selects the true best candidate. Regret and MAE are measured in percentage points.

Method	Prompts	ρ	Top-1	Regret	MAE
KLD alone	0	−0.48	0/200 (0%)	2.25	0.81
Uniform subsample	308	+0.36	55/200 (27.5%)	0.98	1.75
Reference-stratified	308	+0.45	61/200 (30.5%)	0.91	1.18
Selected canary	308	+0.52	151/200 (75.5%)	0.29	0.58
KLD volume + leapfrogs	214	+0.70	910/1000 (91.0%)	0.10	0.83

ite quality separately on volume, with intercepts, and compute the Spearman correlation between the residuals. Both ordinary-least-squares regressions are refit within every replicate.

Because the silent-zone subsets are small, these intervals should be interpreted as uncertainty estimates rather than evidence that the true correlation is exactly zero. The purpose of this analysis is to test whether the strong full-cohort KLD–quality relationship is also supported inside the near-baseline region.

Table 11 supports the same interpretation as our main results. The full-cohort and lossy-zone KLD–quality intervals exclude zero on both cohorts. In contrast, the KLD–quality intervals for both the KLD-defined silent zone and the quality-defined silent zone are wide and straddle zero. Thus, the silent-zone result should be read as an absence of detectable KLD–quality ranking signal in the near-baseline region, not as a precise estimate that the true correlation is exactly zero. The volume correlations remain positive, especially on Qwen, while the partial correlations controlling for volume also straddle zero. This is consistent with the volume–direction account: KLD primarily tracks displacement volume, but its residual ranking signal for downstream quality is not detectable among near-baseline candidates.

F Reduced-Evaluation Model Selection

We evaluate two reduced-evaluation strategies on Qwen using four benchmarks with prompt-level outcomes: LiveCodeBench (1,055 prompts), HumanEval (164), GSM8K (1,319), and IFEval (541), for 3,079 prompts in total. Ranking and model-selection results are computed over the KLD-defined Qwen silent-zone ($\tau = 0.064$) models. BF16 supplies the reference outcomes but is not a candidate.

We use five leave-one-publisher-out folds: AesSedai (24 training and 4 held-out models, of which 3 are silent-zone models), Bartowski (24/4, with 4 silent), ByteShape (18/10, with 2 silent), mudler (24/4, with 3 silent), and Unsloth (22/6, with 5 silent). Predictions for the held-out silent-zone models are pooled across folds, and each trial's Spearman correlation is computed over all 17 pooled predictions. Prompt selection and model fitting use training-publisher outcomes only.

We compare against KLD alone and two sampling baselines. For each benchmark, KLD alone fits a decreasing isotonic mapping from log Wiki-Text KLD to benchmark score using all training-publisher models in the fold, then predicts the held-out models from their KLD. Uniform subsampling draws prompts without replacement within each benchmark. Reference-stratified subsampling allocates each benchmark's budget between prompts the BF16 reference passes and fails in proportion to the two strata's sizes, then weights the stratum means by their full-benchmark proportions. The two sampling baselines and selected-canary method use the same 308-prompt budget and are evaluated over 200 deterministically seeded trials.

F.1 Selected canary

For each fold and benchmark, the selected-canary method ranks prompts by $\hat{p}(1-\hat{p})$, where $\hat{p}$ is the pass rate among training-publisher models. It selects the highest-variance prompts. Across trials, randomness breaks ties among prompts with equal variance. Every held-out model in a fold receives the same selected prompts. A per-benchmark linear calibration from canary accuracy to full-benchmark score is fit on the training models, and a candidate's predicted composite is the equal-weight mean of its four calibrated benchmark estimates. Prompt selection and calibration never use outcomes from the held-out publisher.

Per trial, predictions from all folds are pooled over the 17 silent-zone candidates. We compute Spearman ρ between predicted and complete four-benchmark composites. Top-1 records whether the predicted best is the true best, regret records the percentage-point composite gap between the true best and the selected candidate, and MAE is the mean absolute composite prediction error over the 17 candidates. Table 12 reports the mean of these quantities across trials.

F.2 KLD volume with sampled leapfrogs

For benchmark b, we fit an isotonic mapping from WikiText log-KLD to normalized disagreement volume V_b/N_b using training-publisher models only. For each held-out candidate, we estimate its leapfrog rate $\widehat{r}_{\mathrm{leap},b}$ by uniformly sampling, without replacement, prompts that the BF16 reference fails. The estimated score is

$$\widehat{S}_b = S_{\mathrm{ref},b} + \frac{2N_{\mathrm{fail},b}\widehat{r}_{\mathrm{leap},b} - \widehat{V}_b}{N_b}. \qquad (9)$$

At the 10% grid point, the nominal per-benchmark budgets are 106, 16, 132, and 54 prompts. Because HumanEval and GSM8K contain only 8 and 46 BF16 failures, respectively, the method evaluates $106+8+46+54 = 214$ prompts. Thus, 214 is a fixed count representing 6.95% of the $3{,}079$-prompt suite. The same sampled prompts are applied to every held-out model within a fold.

Over $1{,}000$ deterministically seeded trials, the KLD-volume-plus-leapfrog method gives mean $\rho = 0.699$; the trial-wise 2.5–97.5 percentile interval is $[0.45, 0.87]$. It selects the true best candidate in $910/1000$ trials, with a Wilson 95% confidence interval of $[0.89, 0.93]$, and incurs mean regret of 0.10 percentage points. The selected canary is also more effective than uniform or reference-stratified subsampling, but the KLD-volume-plus-leapfrog method achieves the strongest ranking and top-1 results with fewer evaluated prompts.

These results demonstrate family-specific evaluation reduction rather than a transferable recipe. The canary's informativeness criterion and the KLD-to-volume calibration are both learned from previously evaluated models and may not transfer unchanged to another model family, benchmark collection, or deployment distribution.

G GGUF Model List

Tables 13 and 14 list all public GGUF quantizations in the two cohorts, sorted by KLD.

H Non-GGUF Model List

Table 15 lists the four public non-GGUF quantizations included in this check, sorted by KLD.

Table 15: Qwen3.6-35B-A3B 4-bit non-GGUF quantizations served with vLLM, sorted by KLD.

Publisher	Model	bpw	KLD	comp	zone
cyankiwi	Qwen3.6-35B-A3B-AWQ-4bit	5.43	0.0185	0.7195	silent
btbtyler09	Qwen3.6-35B-A3B-GPTQ-4bit	5.47	0.0215	0.7181	silent
FenomAI	Qwen3.6-35B-A3B-AWQ-4bit	5.31	0.0217	0.7235	silent
QuantTrio	Qwen3.6-35B-A3B-AWQ	5.28	0.0250	0.7229	silent

The KLD measurements use the same WikiText corpus, 512-token context, chunking, and mean aggregation as the GGUF analysis, but use a vLLM-served BF16 reference (Kwon et al., 2023). The measured cross-stack BF16-to-BF16 floor is 0.00547, so the KLD values are directly comparable within this table; the silent-zone labels relative to the GGUF threshold $\tau = 0.064$ should be interpreted descriptively. All four models also retain at least 99% of measured BF16 composite quality.

Scaling Enterprise Cloud Agents to Thousands of APIs: An Empirical Study of Agent Architecture and MCP Tool Boundaries

Abstract

Enterprise cloud agents increasingly operate over thousands of APIs and SDK operations. Tool use therefore becomes a large-scale classification and grounding problem over API operations, not a simple function-calling task. Earlier production-derived architectures either expose broad operation catalogs to the model or hide selection inside planner agents, causing excessive context growth, repeated discovery calls, and preventable invocation errors. We propose the *Operation-Visible Agent Architecture*, which keeps operation search, schema inspection, validation feedback, and API invocation visible to a centralized ReAct loop through a deterministic Operation-Resolver MCP. We compare this architecture with lead-worker planning and ReAct-based execution variants to assess how agent orchestration and MCP tool-boundary design affect enterprise-agent performance. On internal cloud-management benchmark tasks spanning 280+ SDK clients and ∼8K operations, the proposed architecture improves full-success rate from 68% to 77% over the production-derived baseline, while reducing total token usage by 54.1%, median latency by 43.3%, LLM calls by 37.8%, and tool errors by 52.4%. The main lesson is that, at enterprise API scale, tool-boundary design is not an implementation detail: parallel tool calling improves efficiency, but task success improves most when operation resolution remains visible to the main reasoning loop.

1 Introduction

Language-model (LM) systems are increasingly moving from text generation to action-oriented assistance: interpreting user intent, retrieving context, and executing actions through tools, databases, and APIs. Prior work on augmented LMs, RAG, ReAct, and tool-use benchmarks shows the value of connecting models to external knowledge and computation (Mialon et al., 2023; Lewis et al., 2020; Yao et al., 2023; Schick et al., 2023; Li et al., 2023; Qin et al., 2024; Patil et al., 2024). Enterprise cloud agents operate over large SDK surfaces rather than small fixed tool sets. A *client* is a service-specific SDK interface; an *operation* is an executable client method with schema, authorization constraints, and execution metadata. Selecting an operation requires choosing the right client, method, and grounded parameters.

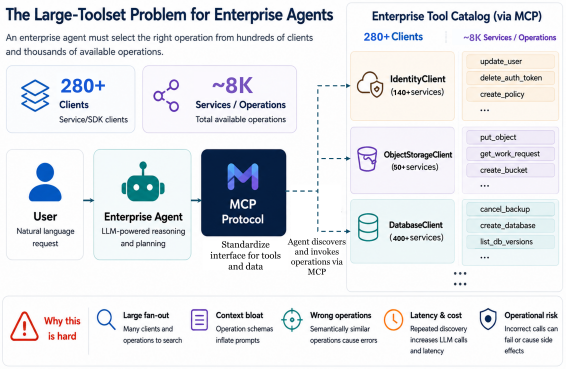

Figure 1: Large-toolset problem for enterprise agents: mapping a user request through the agent and MCP interface to the correct client, operation, and parameters across hundreds of clients and thousands of operations, creating tool-selection, context-size, latency, and reliability challenges.

We study a production-deployed large enterprise cloud agent that invokes cloud APIs through a Model Context Protocol (MCP) interface over 280+ SDK clients and ∼8K exposed operations. Here, tool use is both a retrieval problem and an architecture-boundary problem: the agent must identify the right operation and parameters without flooding model context with irrelevant SDK structure. Poor grounding causes broad catalog scans, guessed operations or parameters, unnecessary clarification requests, higher latency and cost, context noise, and harder-to-debug failures. These con-

straints are not merely benchmark artifacts; they directly affect production cost, latency, debugging, and reliability for enterprise assistants operating over evolving API catalogs.

After observing two earlier designs, a generic invocation architecture with frequent operation and parameter errors, and a planner-based MCP architecture (section 4) that improved selection but added LLM calls and duplicated context, we propose the *Operation-Visible Agent Architecture*, shown in Figure 2. The *Operation-Visible Agent Architecture* pairs ReAct Parallel Tool Calling with the deterministic Operation-Resolver MCP. The resolver exposes three explicit steps: searching for candidate operations, describing their schemas and constraints, and validating/executing API calls. Because these steps remain in the main ReAct trajectory, the agent can inspect candidates, use validation feedback, observe API results, and produce the final response without delegating operation selection to a hidden planner or specialist subagent. ReAct Parallel Tool Calling further allows one reasoning step to issue multiple independent API calls when their arguments are known, reducing model round trips. Our contributions are:

- **Problem.** We frame enterprise cloud-agent tool use as *large-catalog operation grounding*: selecting the right SDK client, method, and parameters across thousands of operations.
- **Architecture.** We propose *Operation-Visible Agent Architecture*, which combines centralized ReAct reasoning, parallel tool calling, and deterministic operation search, schema inspection, and validated invocation.
- **Evaluation.** We evaluate six configurations formed by crossing three agent-control patterns with two MCP tool-boundary designs, using multi-turn simulation, calibrated LLM-as-judge labels, and operational metrics.
- **Finding.** MCP tool-boundary design is a first-order factor: visible operation resolution improves task completion most in centralized ReAct settings, while parallel tool calling mainly improves efficiency, reducing tokens by 54.1% and median latency by 43.3% over the production-style baseline.

2 Related Work

Agent architectures: reasoning, acting, and decomposition. Recent LM-agent work improves multi-step behavior through explicit reasoning (Wei et al., 2022), interleaved reasoning with observations / actions (Yao et al., 2023), and separated planning and execution (ReWOO; Xu et al., 2023). Other systems delegate computation to programs (PAL; Gao et al., 2023), incorporate verbal feedback loops (Reflexion; Shinn et al., 2023), frame agents as augmented LMs combining parametric generation with tools, memory, and external modules (Mialon et al., 2023; Hu et al., 2026), or decompose agents into specialized components (Han et al., 2026). We study where operation-selection decisions reside when enterprise cloud agents operate over thousands of SDK operations.

Tool use, API selection, and executable retrieval. Prior work explores API retrieval and invocation through Toolformer, API-Bank, ToolBench, StableToolBench, and Gorilla (Schick et al., 2023; Li et al., 2023; Qin et al., 2024; Guo et al., 2024; Patil et al., 2024). Enterprise cloud agents operate over thousands of SDK operations, making operation selection a retrieval and grounding problem rather than simple function-calling (Lewis et al., 2020; Liu et al., 2026). Unlike document retrieval, operation retrieval must return executable contracts with valid parameters and execution constraints. We study how MCP tool boundaries expose operation-selection decisions in enterprise SDK catalogs.

MCP and production tool boundaries. The MCP standardizes tool access for LMs through a client-server interface (Karimova and Dadashova, 2025). Yet MCP does not determine where domain-specific intelligence should reside: in the prompt, a subagent, the tool server, or a deterministic middleware layer. In production cloud environments, this boundary must handle evolving schemas, multi-tenancy, token limits, and latency. We therefore study MCP tool-boundary design using task-completion and operational metrics, including tool errors, LLM calls, token usage, and latency.

3 Problem Setting

Let x_1 denote the initial user request and $T = \{t_i\}_{i=1}^{|T|}$ be a large enterprise tool catalog. Each operation $t_i \in T$ corresponds to an executable SDK client method and can be represented as $t_i = (c_i, m_i, d_i, P_i^{req}, P_i^{opt}, A_i, E_i)$, where c_i is the service client, m_i is the method name, d_i is a natural-language description, P_i^{req} and P_i^{opt} are required and optional parameters, A_i captures authorization constraints, and E_i contains execution metadata.

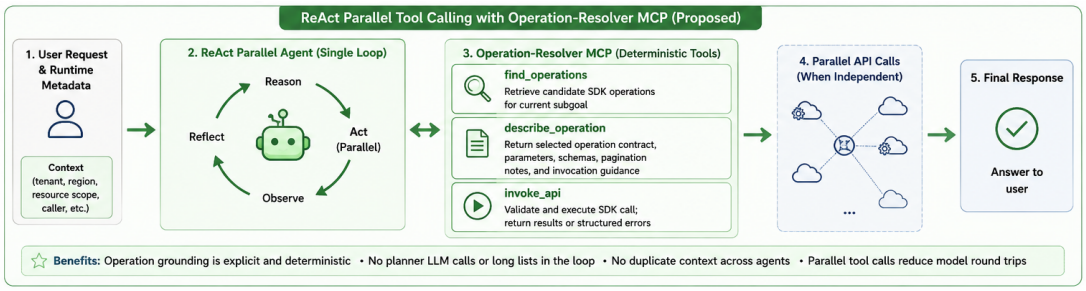

Figure 2: The Operation-Visible Agent Architecture: a ReAct Agent able to emit parallel tool calls to the Operation-Resolver MCP.

The agent operates in a multi-turn setting with dialogue history $H_j = (x_{1:j}, a_{1:j-1}, r_{1:j-1})$, where x_j is a user utterance or clarification, $a_j = (t_j, \theta_j)$ is a selected SDK operation t_j with grounded arguments θ_j, and r_j is the tool outputs. To satisfy the user's request, the agent must choose a sequence of operations $a_{1:k}$, construct valid inputs from user values, runtime metadata, and prior observations, execute the required calls, and produce a final answer y grounded in observed results.

The system optimizes for both task quality and efficiency. A successful run selects the correct SDK operation, constructs grounded parameters, avoids irrelevant schemas or broad operation lists, reduces LLM calls, tokens, and latency, recovers from recoverable API failures, and asks for clarification or approval when needed. We use three task-level labels: successful, partially successful, and failed. A run is fully successful if the user's goal is completed, partially successful if progress is made but blocked by missing information, unavailable resources, or permissions, and failed if a feasible path existed but the task was not completed.

4 System Design

We compare agent architectures along two dimensions: the agent-control pattern and the MCP tool boundary. For control, we consider lead-worker, sequential ReAct, and ReAct Parallel Tool Calling. Lead-worker decomposes the request into worker subtasks and later synthesizes their outputs; sequential ReAct keeps reasoning centralized but invokes one tool per model turn; and ReAct Parallel Tool Calling preserves the centralized ReAct trajectory while allowing one model turn to issue multiple independent tool calls when safe to execute in parallel.

Lead-worker with Tool-Planner-Driven MCP. The Tool-Planner-Driven MCP was introduced to reduce blind API guessing from model parametric knowledge. It exposes an LLM-based `planner` (Liu et al., 2025), `list_ops` for retrieving operations of a selected SDK client, and `invoke_api` for generic SDK execution. In the lead-worker workflow, the lead decomposes the task, the planner selects relevant clients and operations from compact client summaries and long operation lists, workers execute the selected calls, and the lead merges their results. This improves over unguided invocation, but remains costly: the planner needs additional LLM calls to ground each step to concrete operations, and lead-worker duplicates substantial context across the lead, planner, and workers. Thus, operation selection becomes more guided, but repeated listing calls, duplicated context, and planner-internal decisions can still increase token usage and context bloat. This design can remain competitive for broad inventory or troubleshooting tasks, but its operation grounding is more expensive and less visible.

Operation-Visible Agent Architecture. The Operation-Resolver MCP changes the MCP boundary by replacing internal LLM planning with operation-resolution tools: `find_operations` retrieves candidate SDK operations for the current subgoal; `describe_operation` returns the selected operation contract, parameters, schemas, pagination notes, and invocation guidance; and `invoke_api` validates and executes the grounded SDK call, returning results or structured errors. The resolver builds search results and operation descriptions from the installed SDK catalog without running an internal LLM planning dialogue. The main LLM still chooses candidate operations, fills arguments, and interprets results, keeping SDK knowledge in the MCP layer while making operation choice visible to the main ReAct loop.

Operation-Visible ReAct Parallel Workflow. The *Operation-Visible Agent Architecture* workflow keeps the reasoning trajectory in one ReAct loop: the agent receives the user request and runtime metadata, uses `find_operations` to retrieve candidate operations, inspects selected operations with `describe_operation`, constructs grounded arguments from user input, metadata, and prior observations, and executes validated calls through `invoke_api`. When multiple read or lookup calls have known arguments and no dependency, ReAct Parallel Tool Calling issues them in parallel in one model turn. The agent synthesizes results, recovers from individual API errors when possible, and asks for clarification or approval when required. The key distinction is not only parallel execution: the lead-worker planner hides operation grounding behind planner-internal LLM calls and duplicated context, whereas *Operation-Visible Agent Architecture* keeps operation candidates, schemas, validation feedback, and invocation results visible in the main ReAct trajectory.

4.1 Operation Retrieval and Resolution

The Operation-Resolver is deterministic in the specific sense that catalog retrieval, schema lookup, and argument validation require no internal LLM planner. It does not deterministically map a user utterance to a final correct operation. At turn j, the central agent constructs a search query q_j from the current subgoal and history H_j. `find_operations` retrieves a ranked candidate set

$$C_j = \mathrm{TopK}_{t_i \in T}\, s(q_j, z_i),$$

where z_i is the indexed representation of operation t_i. The central ReAct agent then selects candidates from C_j, inspects their contracts using `describe_operation`, grounds arguments, and invokes validated calls using `invoke_api`.

At turn j, operation resolution produces a candidate set $C_j \subseteq T$ from the current request and history. For a candidate $t_i \in C_j$, `describe_operation` exposes $(c_i, m_i, d_i, P_i^{req}, P_i^{opt}, A_i, E_i)$. The agent constructs arguments θ_j, after which `invoke_api`(t_i, θ_j) validates the arguments and returns an execution result r_j.

Internally, `find_operations` indexes each operation using its summary, client and service identifiers, operation and action terms, parameter signatures, API path, and invocation constraints. The local backend embeds documents and queries with `cohere.embed-v4.0`, and ranks candidates using $s(q, z_i) = \mathrm{cosine}(e_q, e_i) + 0.12\ell(q, z_i)$, where ℓ combines token overlap, operation coverage, action matching, and exact operation and client matches.

Across the analyzed search calls, 92.5% of searches followed by a downstream target contained at least one downstream operation in the top 20 candidates. Search reformulation occurs in 46.1% of targeted runs, and later searches recover 22.8% of targets missed by the first search. These results motivate keeping candidate retrieval and reformulation in the central reasoning trajectory; full retrieval statistics appear in Appendix E.3.

5 Evaluation

5.1 Dataset

We construct an expert-curated benchmark of 175 cloud-console tasks drawn from three complementary sources: product-management use cases, Regression use cases, and domain specific security/networking workflows. The benchmark evaluates whether agents can complete realistic operational tasks expressed as natural language, requiring interactions with a large catalog of cloud APIs. The benchmark contains proprietary enterprise cloud-console workflows derived from internal product-management artifacts and customer-reported issue reports, so the full dataset cannot be released. To support transparency, we provide anonymized task-card examples in Appendix A.

Each task is encoded as a task card consisting of an initial user query, a complexity label, cloud context, user goal, and success criteria. The tasks cover common cloud-console topics, including resource inventory, configuration lookup, cost and metrics, troubleshooting, identity and access management, security analysis. Complexity is categorized as *Easy*, *Medium*, or *Hard*. *Easy* tasks are retrieval-oriented tasks with relatively direct mappings between user intent and cloud operations. *Medium* tasks require contextual reasoning or interpretation across multiple resources. *Hard* tasks are advanced operational workflows requiring multi-step planning or transformational actions involving multiple dependent operations. The benchmark contains 55 *Easy* (31.4%), 76 *Medium* (43.4%), and 44 *Hard* (25.1%). Detailed distributions by source and complexity level are provided in Appendix B.

The benchmark includes 91 representative cloud-console workflows curated by product managers,

66 regression tasks reconstructed from 70 user-reported Jira issues, and 18 domain-specific security and networking tasks. The regression tasks capture real-world failures, edge cases, and complex system states, while the domain-specific tasks require more specialized operation selection. We run the full six-configuration comparison on the 91-task cloud-console benchmark. For the regression and domain-specific suites, we compare the production-style lead-worker Tool-Planner baseline against the proposed architecture.

5.2 Simulation Protocol and LLM-as-a-Judge

All runs use the same conversation harness. Each task begins with the task's `initial_query`; subsequent user turns are generated by an LLM-backed simulator conditioned on the task persona, private knowledge, chat history, and goal. A conversation stops when the simulator marks the goal as satisfied, the task-completion judge stops the run, or the turn budget is exhausted. The simulator and judge are held fixed across all configurations. The simulator is conditioned on task metadata and conversation history, but the evaluated agent never receives the success criteria or judge rationale.

We then evaluate each multi-turn trace with an LLM-as-a-judge (LLMaaJ). The judge receives the full trace, including conversation history, agent responses, tool calls, arguments, results, and tool or API errors, and assigns one of three labels: fully successful, partially successful, or failed. We tuned the judge rubric using trace inspections and calibration examples; Appendix D describes this process. The final judge matched human labels on 79.6% of examples. For the `fully_successful` class, it achieves 0.89 precision, 0.87 recall, and 0.88 F1 over 45 human-labeled examples (Table 7). Precision and recall are therefore reasonably balanced, reducing the concern that judge-labeled full success is driven primarily by systematic over-prediction. We nevertheless avoid over-interpreting small success-count differences and focus on larger task-level gaps. We report full-success outcomes as *judge-labeled* and interpret them alongside directly measured efficiency and reliability metrics, including LLM calls, token usage, latency, and tool-error rate.

5.3 Experimental Configurations

We evaluate six configurations formed by crossing three agent architectures (Lead-Worker, ReAct Sequential, ReAct Parallel) with two MCP tool-boundary designs (Tool-Planner-Driven and Operation-Resolver).

All configurations use the same model family, evaluation harness, user simulator, runtime environment, and judge. Planner-internal LLM calls are included in the reported LLM-call and token counts when they occur inside the evaluated architecture. This design isolates the effects of agent architecture and MCP tool-boundary design.

We evaluate performance in a fixed production-scale catalog containing approximately 8K operations. We do not vary catalog size and therefore do not estimate a scaling curve as operations or semantically similar distractors are added.

5.4 Metrics

We report each task as fully successful, partially successful, and failed. Efficiency metrics include LLM calls, input/output/total tokens, tool calls, and tool calls per LLM call. Reliability metrics include tool errors, sessions with tool errors, and tool-error rate. We distinguish tool errors from task failure because cloud APIs often return recoverable errors such as missing permissions, absent resources, unsupported parameters, or empty regional state.

6 Results

6.1 Cloud-Console Benchmark Results

Table 1 reports the six-configuration comparison on the 91-task Cloud-console benchmark. The strongest observed quality–efficiency trade-off is *Operation-Visible Agent Architecture*, which combines ReAct Parallel Tool Calling with Operation-Resolver and achieves 70 fully successful sessions, zero failed sessions, a 77% success rate, and the lowest median latency. The comparison shows a strong interaction between agent architecture and MCP tool-boundary design: Operation-Resolver provides the largest benefit when paired with a centralized ReAct loop.

The clearest comparison is within ReAct Parallel Tool Calling: replacing Tool-Planner-Driven with Operation-Resolver increases fully successful sessions from 53 to 70 while maintaining zero failed sessions. ReAct Sequential shows the same direction, improving from 58 to 62 fully successful sessions and reducing failures from five to zero. Thus, parallel execution alone is insufficient; it is most effective when paired with an MCP boundary that keeps operation selection explicit and visible.

Dataset	Agent Architecture	MCP Tool-Boundary Designs	Full Success	Partial Success	Fail	Success rate	LLM Calls	Total Tokens	Tool calls	Tool Err.	Med. lat (sec)
Cloud-console benchmark	Lead-worker	Tool-Planner-Driven	62	29	0	68%	1,795	116.6M	2,945	6.3%	298.0
	Lead-worker	Operation-Resolver	57	32	2	63%	1,631	219.0M	2,509	2.3%	177.2
	ReAct Sequential	Tool-Planner-Driven	58	28	5	64%	5,515	103.5M	**1,850**	2.2%	494.7
	ReAct Sequential	Operation-Resolver	62	29	0	68%	2,895	137.0M	2,746	**1.7%**	270.3
	ReAct Parallel Tool Calling	Tool-Planner-Driven	53	38	0	58%	4,389	**40.9M**	3,556	1.8%	360.1
	ReAct Parallel Tool Calling	Operation-Resolver	**70**	21	0	**77%**	**1,117**	53.5M	4,200	2.1%	**168.9**

Table 1: Main evaluation on the 91-task Cloud-console benchmark across agent-control architectures and MCP tool-boundary designs. The table reports both task-quality outcomes and efficiency metrics. The best overall configuration is *Operation-Visible Agent Architecture*, which achieves the highest full-success rate and lowest median latency while using substantially fewer LLM calls and tokens than sequential ReAct on the same Operation-Resolver boundary. "Med. lat (sec)" denotes median latency in seconds. Task outcomes are assigned by the calibrated LLM judge; operational metrics are measured directly from execution traces.

Dataset	Agent Architecture	MCP Tool-Boundary Designs	Succ.	Part. Succ.	Fail	Succ. rate
Regression use cases	Lead-worker	Tool-Planner-Driven	32	28	6	48%
	ReAct Parallel Tool Calling	Operation-Resolver	**36**	29	**1**	**55%**
Domain-specific	Lead-worker	Tool-Planner-Driven	9	8	1	50%
	ReAct Parallel Tool Calling	Operation-Resolver	**12**	6	**0**	**67%**

Table 2: Generalization on two additional suites: Jira-derived regression and domain-specific tasks. Compared with the production-style lead-worker Tool-Planner baseline, ReAct Parallel Tool Calling with Operation-Resolver improves full-success rate and reduces failed sessions in both.

6.2 Parallel Tool-Calling Efficiency Gain

Table 1 isolates the efficiency gains from parallel execution under the same Operation-Resolver MCP boundary. Compared with ReAct Sequential + Operation-Resolver, *Operation-Visible Agent Architecture* increases successful sessions from 62 to 70 while reducing LLM calls by 61.4% (2,895 to 1,117), total tokens by 61.0% (137.0M to 53.5M), and median latency by 37.5% (270.3s to 168.9s).

Tool calls also increase from 2,746 to 4,200 (+52.9%), reflecting fewer model turns issuing larger tool-invocation batches. We analyze these additional tool calls and operation-retrieval behavior in Appendix E.3. The Tool-Planner-Driven parallel configuration does not achieve comparable task-success gains, indicating that parallelism improves efficiency most reliably when operation grounding is visible and well-structured.

6.3 Regression Use Cases

We use the additional suites as targeted regression checks rather than full factorial architecture sweeps. We evaluate the Agent Configurations on the Regression Use Cases. Compared with the Cloud-console benchmark, these tasks are more challenging because they originate from real user-reported failures and edge cases. Consequently, success rates are lower across all Agent Configurations than on the Cloud-console benchmark.

Despite the increased difficulty, the *Operation-Visible Agent Architecture* achieves the strongest overall performance (Table 2), completing 36 of 66 (55%) tasks successfully while reducing failed sessions from six to one relative to the *Lead-Worker* baseline. The gain is modest but directionally consistent, with full success increasing from 32 to 36 and failed sessions decreasing from six to one. These results provide directional evidence that the same pattern holds beyond representative workflows and remain valuable under regression-oriented scenarios.

6.4 Domain-Specific Security and Networking

The Domain-Specific dataset evaluates whether the benefits transfer to specialized domains, e.g., security and networking workflows. Unlike the Cloud-console benchmark, these tasks require deeper domain knowledge and more precise selection among semantically similar operations, making accurate operation grounding particularly important.

The *Operation-Visible Agent Architecture* successfully completes 12 of 18 tasks (67%), compared with 9 of 18 (50%) for the Lead-Worker baseline. Although the dataset is small, the results suggest that the benefits of operation visibility extend beyond representative cloud-management workflows to specialized operational domains.

Taken together, the Cloud-console benchmark, Regression Use Cases, and Domain-Specific dataset evaluate representative workflows, failure-

driven scenarios, and specialized operational expertise. The *Operation-Visible Agent Architecture* achieves the strongest performance across all three settings, suggesting that operation visibility remains useful in specialized domains, though the small sample size means this result should be treated as supportive rather than conclusive.

7 Lessons for Enterprise Agent Design

The tested MCP boundary materially affects the quality-efficiency trade-off. The Operation-Resolver boundary is most effective when paired with centralized ReAct control. This boundary jointly changes focused retrieval, schema exposure, validation feedback, internal planner calls, and the visibility of operation-selection evidence.

Operation-visible resolution provides an inspectable interface. Exposing candidates, schemas, validation feedback, and invocation results allows the central agent to reformulate searches and recover from errors. The experiments support the Operation-Resolver boundary as a whole; they do not isolate visibility from retrieval, schema exposure, validation, or the removal of planner-internal LLM calls.

Parallel tool calling is primarily an efficiency mechanism. Parallel execution reduces model round trips and latency by allowing independent API calls to be executed concurrently. However, parallelism alone does not guarantee higher task success; its benefits are greatest when combined with effective operation grounding.

8 Conclusion

Enterprise agents operating over large API ecosystems face a challenge beyond traditional tool-use settings: grounding user requests to correct operations across large catalogs of services, APIs, schemas, and execution constraints. Across a 91-task six-configuration benchmark and two targeted evaluation suites, we find that MCP tool-boundary design is a first-order design choice for such agents. The largest gains occur when operation discovery, schema inspection, and invocation remain visible within the agent's reasoning process. Parallel tool calling primarily improves efficiency, while operation visibility improves task success. These results suggest operation grounding should be treated as a systems concern. As enterprise tool ecosystems grow, effective architectures must balance abstraction with transparency, enabling agents to reason about operation choice, recover from failures, and coordinate complex workflows using structured retrieval and validation mechanisms.

Limitations

The main limitation is reproducibility. While benchmark specifications and anonymized task-card examples are shared, the cloud environment, proprietary simulator, and runtime state cannot be released which means external researchers cannot reproduce the evaluation environment.

The evaluation relies on an LLM-backed user simulator and an LLMaaJ pipeline. Although the judge was calibrated through manual review and achieved 79.6% agreement with human annotations (Appendix D), simulated users and automated evaluation remain imperfect proxies for real enterprise users and human judgement. Judge-based metrics should therefore be interpreted as approximate indicators of task completion, particularly for small performance differences.

The evaluation demonstrates operation grounding in a thousands-operation setting but does not establish how performance changes with catalog size. Controlled catalog-size and distractor-operation experiments remain future work.

The Operation-Resolver boundary jointly changes retrieval, schema exposure, validation, internal planner calls, and evidence visibility. Because we do not hold these components fixed in a visible-versus-hidden ablation, the observed gains cannot be attributed to visibility alone.

All experiments use a single model family (GPT-5.4) within one enterprise cloud ecosystem. We therefore interpret the results as architectural rather than foundation-model comparisons. While the observed trends were consistent across configurations, the magnitude of improvements may differ across model families, cloud providers or environments.

Ethical Considerations

The cloud agent evaluated in this work interacts with sensitive enterprise metadata, resource identifiers, and user logs. To protect data privacy, we do not release any raw datasets, traces, or user data. All evaluation metrics and examples presented in this paper are strictly aggregated or abstracted to protect proprietary information. Any descriptive examples have been fully anonymized to remove company names, product names, internal project paths, and customer-specific resource identifiers.

A Dataset Specification

Task Card – Anonymized Each benchmark instance is represented as a task card that specifies the user goal, anonymized cloud context, and success criteria. The task card serves as the input specification for the multi-turn evaluation: the simulator uses it to generate realistic user behavior and to determine when the conversation should stop. Table 3 shows an illustrative anonymized example.

B Dataset Composition and Complexity Distribution

Table 4 summarizes the benchmark composition by source and complexity level. The dataset combines three complementary sources: 91 cloud-console benchmark tasks covering representative enterprise cloud workflows, 66 regression use cases derived from failure-driven and edge-case scenarios, and 18 domain-specific tasks focused on specialized security and networking workflows. The cloud-console benchmark contains a balanced mix of medium and hard tasks, while the regression set is concentrated in easy and medium cases. The domain-specific subset is smaller but captures expert-level scenarios that require more specialized cloud knowledge.

C SDK Client and Service Usage Statistics

We analyze executable SDK API calls issued by the proposed *Operation-Visible Agent Architecture* configuration on the 91-task Cloud-console benchmark. We count calls to the anonymized `invoke_api` tool, which corresponds to the concrete SDK API execution tool. We exclude operation-grounding calls such as `find_operations` and `describe_operation`, because those measure operation retrieval and schema inspection rather than executable cloud API use. A call is counted as successful when the returned result contains neither a parsed API error nor a tool-level error.

Table 5 summarizes the executable API usage profile. Across 91 tasks, *Operation-Visible Agent Architecture* issued 3,095 `invoke_api` calls, covering 96 distinct client-operation pairs across 22 SDK clients. The median task issued 18 executable API calls when zero-call tasks are included, and 19 among the 87 tasks that issued at least one executable call. This indicates that many benchmark tasks require multi-step API interaction rather than a single isolated invocation.

Field	Anonymized example
Task domain	Cloud Resource Management
User goal	Identify stopped compute instances in a development compartment and restart the testing instance.
Initial user request	"Can you help me find the stopped instances in my development compartment and start the one used for testing?"
Anonymized context	The tenancy contains multiple compartments. The target compartment is denoted as <COMPARTMENT_A>. The target instance is denoted as <INSTANCE_TEST>.
Complexity	Medium
Success criteria	The agent identifies the correct compartment and stopped testing instance, starts the correct instance , and provides a concise confirmation to the user.

Table 3: An anonymized task card example.

Source	Description	# Easy	# Medium	# Hard	Total
Cloud-console benchmark	Representative enterprise cloud workflows.	23	34	34	91
Regression use cases	Failure-driven and edge-case scenarios derived from real user issues.	24	37	5	66
Domain-specific	Specialized security and networking workflows requiring domain expertise.	9	5	4	18

Table 4: Dataset composition by source and complexity label.

Metric	Value
Task records analyzed	91
Total `invoke_api` calls	3,095
Successful `invoke_api` calls	3,006
Distinct client-operation pairs	96
Distinct SDK clients	22
Median `invoke_api` calls / task	18

Table 5: Executable SDK API usage statistics for *Operation-Visible Agent Architecture* on the 91-task Cloud-console benchmark. The table counts only anonymized `invoke_api` calls and excludes operation-search and operation-description calls.

Table 6 breaks down executable API usage by task complexity. We report medians because call counts are right-skewed: a small number of broad inventory or environment-limited tasks require many additional calls to locate relevant resources or confirm that requested resources are absent. In this run, medium tasks have the highest median call volume, reflecting broad discovery and inventory workloads in that slice of the benchmark.

Complexity	Tasks	Total calls	Median calls/task
Easy	23	541	3
Medium	34	1,742	25.5
Hard	34	812	14.5

Table 6: Executable `invoke_api` calls by task complexity for *Operation-Visible Agent Architecture*. Medians include tasks with zero executable API calls.

The observed executable API usage spans multiple service families, including compute, networking, storage, resource search, identity and access management, object storage, database, migration, Fusion applications, monitoring, and cost analysis. This supports the benchmark's role as a large-toolset evaluation: the agent must ground user requests to concrete SDK operations across a broad API surface, rather than repeatedly solving variants of a single service-specific task.

D Evaluation Method Calibration

Agent evaluation and real-world environments. Evaluating multi-step agents requires interactive environments and functional completion metrics rather than static text similarity (Liu et al., 2024; Zhou et al., 2024). MINT highlights that isolated capabilities rarely predict multi-turn performance (Wang et al., 2024), SWE-bench emphasizes realistic tasks from production codebases and fully executable runtimes (Jimenez et al., 2024), and Agent-Testing Agent automates adaptive, persona-driven adversarial evaluation through a meta-agent (Komoravolu and Mrini, 2026). Our evaluation protocol extends this philosophy to live cloud APIs, analyzing task success alongside real-world ambient failures, missing contextual metadata, and resource constraints. To parse complex execution traces, we leverage an LLMaaJ paradigm, validating its reliability against human-annotated baseline alignments detailed below.

We used an LLM-based judge to evaluate task

completion quality from agent interaction traces. For reporting in the main paper, we collapse the judge outputs into three categories: fully successful, failed, and partially successful. The partially successful category captures all outcomes that do not cleanly fall into either complete success or outright failure, including intermediate or ambiguous cases.

Judge prompt development and calibration We developed the judge prompt through an iterative calibration process. The initial prompt was designed to evaluate agent traces conservatively and evidence-based, producing structured judgments at both the turn level and the overall session level. The judge was instructed to identify whether a user request was actionable and whether the agent fully satisfied the request, failed to satisfy it, or produced an outcome that was only partially successful or ambiguous.

The prompt was first tuned using manual assessment on a small held-out calibration subset of approximately 50 spot-checked samples. These samples were single-turn interactions and were not part of any datasets used for the final reported evaluation. During calibration, we inspected examples where the judge disagreed with human assessment and refined the rubric to improve consistency with human judgments.

After this initial calibration, we applied the judge to a separate multi-turn dataset (curated by product managers with domain expertise based on observed user behavior) and performed an additional manual review of individual examples (by 5 individuals with science and engineering backgrounds with up to 3 labels collected per sample) to compare judge performance with human assessment. Only unanimous fully_successful cases were deemed fully successful, and majority vote was taken for other labels. For samples with conflicting labels and no clear majority, another labeler reviewed and labeled the sample to resolve the conflict.

Human alignment study We measured agreement between the final LLM judge and human labels on the held-out multi-turn validation set. The judge achieved 79.6% overall agreement with the human labels. In particular, the `fully_successful` class has 0.89 precision, 0.87 recall, and 0.88 F1 across 45 human-labeled examples (Table 7). Performance is also reasonably balanced for `partially_successful` and `failed`, with F1 scores of 0.76 and 0.73, respectively.

Label aggregation for reported results For the headline evaluation numbers in the paper, we map the judge outputs into three categories: fully_successful, failed, and partial_success. The partial_success category includes cases where the task was only partially completed, the outcome was ambiguous, or the interaction did not cleanly correspond to either full success or failure.

This aggregation serves two purposes. First, it aligns the reported metrics with the primary evaluation question: whether the system fully completed the user request, failed to complete it, or landed somewhere in between. Second, it avoids over-interpreting fine-grained categories whose boundaries may be less stable across examples.

Interpretation and limitations These results suggest that the LLM judge provides a reasonable but imperfect proxy for human evaluation. The alignment study shows balanced precision and recall for the `fully_successful` class, reducing the risk that judge-labeled full success is driven primarily by over-prediction. However, the judge remains an automated proxy rather than a replacement for human evaluation. We therefore interpret judge-labeled task-quality differences together with paired statistical tests and directly measured operational metrics. The calibration samples used to tune the judge prompt were distinct from the datasets used for final evaluation, reducing the risk of overfitting the judge to the reported evaluation set. At the same time, the observed human-judge agreement motivates caution when interpreting small differences between systems or configurations.

E Appendix: Additional Analysis

E.1 Statistical Analysis of Agent Configurations

We perform paired statistical tests over the same 91 Cloud-console benchmark tasks. For task-quality outcomes, we use an exact two-sided McNemar test on the binary event `fully_successful` versus not fully successful. For efficiency, we use a two-sided Wilcoxon signed-rank test on paired per-task token totals. We report Holm-adjusted p-values across the 15 pairwise comparisons. For Lead-worker + Tool-Planner-Driven MCP, planner-internal token telemetry is included in the aggregate token total, but it is only available at run level; the Wilcoxon test therefore uses trace-visible per-task token counts for that configuration. The results are in Table 9 and the counts in Table 8.

Class	Precision	Recall	F1	Support
`partially_successful`	0.77	0.75	0.76	36
`failed`	0.71	0.75	0.73	32
`fully_successful`	0.89	0.87	0.88	45

Table 7: Per-class performance between the LLM judge and human labels on the matched multi-turn validation set.

Code	Configuration	Succ.	Part.	Fail	Tokens
LW-OR	Lead-worker + Operation-Resolver MCP	57	32	2	219.0M
RS-OR	ReAct Sequential + Operation-Resolver MCP	62	29	0	137.0M
RP-OR	ReAct Parallel Tool Calling + Operation-Resolver MCP	70	21	0	53.5M
LW-TP	Lead-worker + Tool-Planner-Driven MCP	62	29	0	116.6M
RS-TP	ReAct Sequential + Tool-Planner-Driven MCP	58	28	5	103.5M
RP-TP	ReAct Parallel Tool Calling + Tool-Planner-Driven MCP	53	38	0	40.9M

Table 8: Outcome counts and total token usage for the six 91-task configurations. Part. aggregates non-failed partial-success outcomes.

The token-usage tests show that parallel tool calling is consistently more efficient. Under the same Operation-Resolver MCP boundary, ReAct Parallel Tool Calling uses significantly fewer tokens than ReAct Sequential after Holm correction ($p = 4.60\times10^{-6}$), while also increasing fully successful sessions from 62 to 70. The McNemar test for this quality difference is directionally favorable but not significant after correction ($p_{\text{Holm}} = 1.0000$), reflecting the limited sample size and the judge-calibration caveat discussed in Appendix D.

The only full-success comparison that remains significant after Holm correction is ReAct Parallel Tool Calling + Operation-Resolver MCP versus ReAct Parallel Tool Calling + Tool-Planner-Driven MCP: 23 tasks are fully successful only with the operation-visible boundary, compared with 6 only with the planner-driven boundary ($p_{\text{Holm}} = 0.0347$). This supports the main conclusion that parallel execution is primarily an efficiency mechanism, while visible operation resolution is the factor that turns that efficiency into higher task completion.

E.2 Reasoning-Effort Ablation

Table 10 reports a reasoning-effort ablation for the *Operation-Visible Agent Architecture*. Reducing reasoning effort decreases token usage substantially but also reduces task completion quality. Medium reasoning achieves 77% (70/91) fully successful sessions, compared with 62% (56/91) for low reasoning and 46% (42/91) for no reasoning.

The reduction in quality is accompanied by increases in partially successful outcomes and failed sessions, indicating that lower reasoning settings often struggle with operation selection, recovery, and multi-step coordination. While lower reasoning settings reduce inference cost, the resulting degradation in task completion suggests that reasoning remains an important component of enterprise cloud-agent performance, even when operation grounding is improved.

E.3 Operation Retrieval Analysis

We analyze `find_operations`, the operation-search tool used by the Operation-Resolver MCP. For each `find_operations` call, we parse the ranked candidate list and infer the downstream target operation from the next `describe_operation` or `invoke_api` call before the next search. This is not a human-authored answer key; it measures whether search surfaced the operation that the agent later chose.

Across 406 search calls from 91 sessions, the tool returned 8,120 candidate rows covering 1,608 unique operations. We identified 2,277 downstream target instances: 456 `describe_operation` targets and 1,821 `invoke_api` targets. Overall Recall@20 is 55.7% at the target-instance level, with MRR 0.345. Recall is higher for operations the agent chose to inspect with `describe_operation` than for operations it later invoked, suggesting that operation search is more reliable for narrowing candidate operations than for covering every downstream execution call.

At the search-call level, coverage is higher: among searches followed by downstream targets, 92.5% contained at least one downstream operation in the top 20 candidates. Search reformulation is common: 46.1% of targeted search runs required more than one `find_operations` call, and later searches recovered 22.8% of targets that were missed by the first search. Retrieval quality also varies by task difficulty: Recall@20 is 61.3% for easy tasks, 60.7% for medium tasks, and 48.2% for hard tasks.

These results support the design choice of keeping operation search visible to the main ReAct loop. `find_operations` often provides useful candidates, but it is not perfect; the agent benefits from being able to reformulate searches, inspect operation descriptions, and recover from retrieval misses

Pair	Lower-token run	W	Wilcoxon p	Holm p	Succ. A/B	A-only/B-only	McNemar p	Holm p
LW-OR vs RS-OR	RS-OR	1399.0	0.0060	0.0241	57/62	10/15	0.4244	1.0000

Target type	N	R@1	R@3	R@5	R@10	R@20	MRR
Any target	2,277	26.3	40.9	44.9	51.6	55.7	0.345
Describe target	456	37.5	50.0	53.5	59.6	65.8	0.450
Invoke target	1,821	23.4	38.7	42.7	49.6	53.2	0.318

Table 11: Target-instance Recall@K for `find_operations`. Values are percentages except MRR.

before invoking APIs.

E.4 Efficiency Gains from Parallel Tool Calling

To isolate the effect of parallel execution, Table 12 compares ReAct Sequential and ReAct Parallel Tool Calling under the same Operation-Resolver MCP Tool-Boundary Design. Parallel execution increases fully successful sessions from 62 to 70 while reducing LLM calls by 61.4% (2,895 to 1,117), total tokens by 61.0% (137.0M to 53.5M), and median latency by 37.5% (270.3s to 168.9s).

At the same time, tool calls increase from 2,746 to 4,200 (+52.9%), showing that the system performs more concrete API work with fewer model interactions. Thus, parallel tool calling primarily improves efficiency by amortizing model round trips across independent API operations. However, parallelism alone is insufficient: Tool-Planner-Driven parallel configurations reduce some overhead but do not achieve comparable task-success gains, reinforcing MCP Tool-Boundary Design as the main driver of quality.

Metric	Seq.	Parallel	Change
Fully successful	62	70	+8
LLM calls	2,895	1,117	-61.4%
Total tokens	137.0M	53.5M	-61.0%
Tool calls	2,746	4,200	+52.9%
Avg. latency	392.2s	217.4s	-44.6%
Median latency	270.3s	168.9s	-37.5%

Table 12: Effect of parallel tool calling under the same Operation-Resolver MCP boundary. Parallel execution increases concrete API work while reducing model calls, tokens, and latency.

E.5 Production Baseline vs. Proposed Architecture

Table 13 compares the production-style Lead-worker + Tool-Planner-Driven baseline against the proposed *Operation-Visible Agent Architecture*. The proposed architecture increases fully successful sessions from 62 to 70, while reducing LLM calls by 37.8%, total tokens by 54.1%, tool errors by 52.4%, and median latency by 43.3%. Although the proposed system issues more tool calls, it performs more concrete API work with fewer model round trips and substantially lower token cost. This comparison highlights the practical production tradeoff: replacing hidden planner-mediated operation grounding with visible Operation-Resolver grounding improves both task completion and operational efficiency.

E.6 Tool errors are not task failures.

The *Operation-Visible Agent Architecture* has more raw tool calls and 89 tool errors on the Cloud-console benchmark, but only 21 sessions with

Metric	Lead-worker + Tool-Planner	ReAct Parallel + Opn Resolver	Change
Fully successful	62	70	+12.9%
Success rate	68%	77%	+8.8 pp
Partially successful	29	21	-27.6%
Failed	0	0	0
LLM calls	1,795	1,117	-37.8%
Total tokens	116.6M	53.5M	-54.1%
Tool calls	2,945	4,200	+42.6%
Tool errors	187	89	-52.4%
Tool-error rate	6.3%	2.1%	-4.2 pp
Median latency	298.0s	168.9s	-43.3%

Table 13: Production-style baseline versus the proposed architecture on the 91-task Cloud-console benchmark. The proposed *Operation-Visible Agent Architecture* improves full-success rate while substantially reducing LLM calls, total tokens, tool errors, and median latency. "pp" denotes percentage-point change.

tool errors and no failed sessions. The production lead-worker + Tool-Planner-Driven MCP run has a higher error rate and 47 sessions with tool errors. For cloud agents, an API error may be a useful observation: no permission, no resource, invalid parameter, or wrong region can guide recovery. Evaluations should therefore track both raw errors and whether they lead to task-level failure.

E.7 Error Categories

We qualitatively reviewed internal trace reports to identify recurring error patterns in large-toolset enterprise agent runs. The categories in Table 14 are not mutually exclusive: a single unsuccessful or partially successful run may involve multiple issues, such as broad discovery followed by invalid parameters or missing user information. The main purpose of this taxonomy is to connect observed failures to architecture choices. Several categories arise when operation selection is either hidden behind planner or specialist calls, or when broad operation lists are exposed directly to the agent. These errors motivate the Operation-Resolver MCP design, which keeps operation candidates, operation contracts, validation feedback, and invocation results visible in the main ReAct trajectory. The taxonomy also highlights why raw tool-error counts should not be treated as task failures: some API errors are recoverable observations that help the agent identify missing permissions, absent resources, wrong regions, or invalid arguments.

E.8 Lead-worker decomposition still has value.

The production lead-worker baseline remains competitive on the Regression use cases, with 32 fully successful sessions out of 66. This suggests that explicit decomposition can still help in some broad inventory and troubleshooting tasks. A practical future direction is to keep the operation-visible ReAct loop, but add lightweight self-checks for tasks that require broad coverage across compartments, regions, or resource surfaces.

E.9 Tool-Call Mix

Table 15 reports the main tool-call inventory for the Cloud-console benchmark. The resolver variants expose operation search and description directly. The Tool-Planner-Driven lead-worker baseline exposes planner and broad operation-listing tools.

F Codex Agent with CLI or Terraform Style Tool Invocation under Controlled Execution

We explored an alternative formulation in which a Codex agent maps tool-use decisions to command completion over CLI or Terraform style interfaces. Instead of requiring the model to directly select among SDK-style tools and synthesize structured API invocations, this formulation asks the agent to generate executable command specifications that expose equivalent underlying capabilities. For console-oriented workloads, such command-centric interfaces are plausible and may show promising results, as they reduce tool use to a familiar textual generation problem and can simplify argument selection relative to deeply structured tool schemas. However, in enterprise settings, evaluation cannot be limited to task accuracy alone. Security posture, operational reliability, and governance constraints become central, particularly when model outputs are routed through Bash or infrastructure-as-code execution paths. A production deployment would therefore require a clear separation between agentic planning and execution, together with tight controls such as command allowlisting, argument validation, least-privilege execution, dry-run validation, audit logging, and human approval for sensitive actions. Thus, while Codex-agent-based command completion may improve tool-use accuracy for certain workloads, its practical adoption depends on robust safeguards around execution.

Category	Description	Mitigation
Broad discovery without execution	Planner or specialist path searches broadly, lists large catalogs, or suggests follow-up queries instead of producing the requested artifact.	Keep operation choice visible in the main loop.
Invalid parameter construction	Agent guesses parameter names, passes unsupported kwargs, or uses incompatible fields.	Require operation descriptions and validation feedback before invocation.
Large operation-list context	Listing full client operations expands context and can truncate useful evidence.	Retrieve focused operation candidates and operation dossiers.
