Multi-page document understanding Production workflows routinely require reasoning over documents that span up to 20 pages, and our open-data generation explicitly targets both regimes in which such context is consumed. The first is *needle-in-a-haystack* retrieval, where a single field or fact must be located within a predominantly irrelevant context; the second is *multi-page analysis*, where the answer is synthesized from evidence scattered across several pages. Question generation is conditioned on page-boundary markers preserved in the extracted text, allowing the generator to construct queries whose answers deliberately cross page breaks. This dual focus ensures the model is trained to both isolate local evidence under heavy distractor load and to aggregate non local evidence across the document.

C.5 Consistency Verification

Samples produced by the generation stage (Appendix C.4) are not used directly: single-shot outputs from a frontier models still exhibit a long tail of hallucinated fields, misread digits, and silent schema violations. To filter these out, we apply a consistency-verification stage based on cross-model agreement.

Verifier pool. For each generated pair we reissue the question against a pool of three independent VLMs — Qwen3-VL-235B-A22B-Thinking, Qwen3.5-397B-A17B-FP8, and Kimi K2.6 — each sampling 3–5 responses at temperature 0.8. The pool is chosen for diversity across model families and pre-training data; agreement among its members is a stronger signal than agreement within a single model's sampling distribution.

LLM-as-Judge. The original generated answer and the verifier-pool responses are passed to a judge model GPT-OSS 120B (OpenAI, 2025). The judge compares responses field-by-field under a fixed equivalence relation that ignores cosmetic differences (formatting, casing, line-break artifacts, JSON key order, date-format variants) but flags factual disagreements, hallucinated values, wrong-field extractions, and mixed-script artifacts.

Acceptance rule. A sample is accepted when at least two of the three verifiers in the pool produce responses judged equivalent to the generated answer under the equivalence relation defined above, averaged across their sampled responses. Mismatched samples are discarded. We deliberately do not attempt to repair them: a disagreement is ambiguous by construction — it may reflect a hallucinated or otherwise incorrect generated answer, or simply a question the verifier pool cannot solve. Discarding such samples is the safer policy, even at the cost of throughput.

Retention. The verification stage retains approximately 35–40% of the candidate samples. Inspection of the discarded portion shows that most disagreements trace to residual PDF text-layer artifacts that survive the validation stage (Appendix C.2) — specifically, broken cell understanding in tables and positional misalignment in sparse-text layouts such as forms and receipts. In both

```
You are a strict Data Curator selecting documents for VLM training on Information Extraction. Your
↪  filter: "Can a precise question with an unambiguous answer be asked about this document?"

KEEP:
- Documents where the answer is a concrete substring in the image (date, amount, name, table cell
↪  value, code).
- Documents with complex but structured layouts.
DISCARD:
- Continuous prose (articles, letters, contracts without tables) that admits only general
↪  questions ("What is this about?", "Summarize").
- Documents where questions would be artificial.
SCORING:
A. Visual Structure (0-10):
   - 0-3: continuous text, standard book layout.
   - 4-7: lists, bold headers, simple key-value forms.
   - 8-10: complex tables, forms, receipts, stamps, handwritten fields.
B. QA Potential (0-10):
   - 0-3: descriptive/literary text. Only "what is this about?" possible.
   - 4-7: 2-3 concrete facts (e.g., date + document number).
   - 8-10: dense with extractable facts (5+ unambiguous questions).

PROCEDURE:
1. Mentally formulate 3 strict questions.
2. If only "what is this about?" works, score low.
3. Score by data density.
Return JSON with: reasoning, data_types, fact_check, visual_score,
qa_potential_score, decision (KEEP if qa_potential_score >= 5 OR
visual_score >= 5, else DISCARD).
```

Figure 3: Stage 2 fact-extractability prompt. Applied only to PLAIN_TEXT pages from Stage 1.

cases, the generated answer is technically supported by the source text but cannot be reliably reproduced from the rendered page, so we treat such samples as low-confidence supervision and exclude them from training.

C.6 Text Refinement

During evaluation after the initial post-training stage, we additionally observed that the model exhibited degraded adherence to long and detailed formatting instructions. To address these issues, we performed a refinement stage over a subset of prompts and corresponding ground-truth annotations, using Qwen3.5-397B to jointly modify the value formats in the JSON schemas and augment the prompts with detailed descriptions of the new formatting requirements. The refinement procedure consists of two stages.

Annotation format transformation. Each value is rewritten into a new target format under explicit rules for common types: dates, numbers, names, URLs, and sentences. Other values undergo auxiliary normalization via abbreviations and case transformations.

Prompt augmentation. The prompt is extended with matching format specifications; unmodified fields are marked "return as in the document." Only specifications are added, no answers or example values, preventing supervision leakage. This recasts the task from pure extraction into joint extraction and normalization. The full prompt is in Figure 5a, 5b.

C.7 DADC Component Ablation

To validate that each DADC stage contributes positively, we ablate the pipeline by progressively adding components on top of the internal-only baseline, holding training budget fixed (Table 9).

Configuration	SP	MWS	MP	FT	Avg w/o FT
Base (no SFT)	0.827	0.677	0.697	0.722	0.733
+ in-house	0.835	0.685	0.738	0.951	0.753
+ open (unfiltered)	0.714	0.623	0.647	0.939	0.661
+ open (stage 1)	0.831	0.685	0.740	0.951	0.752
+ open (sampled)	0.833	0.686	0.747	0.951	0.755
+ open (verified + sampled)	**0.842**	**0.700**	**0.764**	**0.956**	**0.768**
+ open (verified + sampled, w/o aug)	0.829	0.681	0.741	0.950	0.750

Table 9: DADC pipeline ablation. All rows from row 3 onward include in-house data; "open" variants differ only in filtering. "Sampled" adds Stage 1+2 layout and fact-extractability filtering (Appendix C.3); "verified" adds cross-model consistency verification. Augmentation for open data is enabled in all experiments.

Unfiltered open-domain data degrades the in-house–only baseline, as naively scraped PDFs displace production-relevant signal. Layout and fact-

````
Your task is to generate a set of Information Extraction questions for the document, focused on
**document understanding** and **targeted extraction of data spanning multiple pages** under given
↪  conditions.
Answers must be taken strictly from the text. Return the result as a JSON array.

Input:
*   document_text: the full document text (including page-boundary
    markers).
*   n_questions: number of questions to generate.

Questions must test the model's ability to find answers located across multiple pages and to
↪  extract key
information from a document. Questions should be complex and diverse, covering as many
different data-retrieval scenarios as possible.

Question types (in priority order):
1.  **Multi-page entity or process extraction** -- e.g., extracting a sequence of events in a
    court case, or information about the court that is spread across several pages.
2.  **Requisite extraction** -- tasks requiring point-wise retrieval of specific values from the
    text (dates, surnames, amounts, etc.).
3.  **Document-understanding tasks** -- simple yes/no questions, or questions probing what the
    document is about.
Format requirements:
*   **"question"**: the task statement + the expected JSON schema (keys and types). The schema must
    be flat (when extracting a single object); do not use questions that require nested answers.
*   **"answer"**: a string containing valid JSON. Values must be taken strictly from document_text.

Suggested generation procedure:
  1. Describe what the document is about and what data it contains.
  2. List the entities present (people, organizations, etc.).
  3. Describe the sequence of events in the document and how the listed entities participate in
     them.
  4. Based on the event sequence and entity descriptions, formulate the extraction task or pose
     questions. Tasks should be varied; you may add descriptive context, but must not reveal
     the answer (bad example: "Find the client's registration address, which starts with
     Pushkin St., bldg. 7").
  5. Respond in valid JSON inside a ```json ... ``` block, so the answer can be parsed
     via json.loads().

Additional requirements:
  1. Extract data in OCR mode: no normalization, no corrections, no changes to case, punctuation,
     or whitespace -- strictly as it appears in document_text.
  2. All numeric values (sums, codes, numbers, articles, requisites, etc.) MUST be returned as
     STRINGS, preserving leading zeros and original formatting.
  3. EACH "question" MUST REQUIRE EXTRACTING NO LESS THAN FOUR AND NO MORE THAN EIGHT FIELDS.
     THIS IS A STRICT RULE; THE NUMBER OF FIELDS MUST VARY ACROSS QUESTIONS.
  4. The JSON-answer format inside each question must parse with json.loads() without errors.
  5. The task should be well-described, not just ("Extract these entities", "Find these entities").
     Phrasing must be varied and imitate realistic human queries.
  6. Do not use "" in answers. If information is missing, write "N/A".

Response format:
```json
[
  {
    "question": "Question text. JSON answer format: { ...schema... }",
    "answer": "{ ...json answer... }"
  }
]
  n_questions: 4
  document_text:
````

Figure 4: General instruction-generation prompt (translated to English), applied to every admitted page. Targets multi-page, multi-field information extraction questions in OCR-faithful mode.
````

```
You receive a (prompt, expected answer) pair extracted from a document via OCR. Perform two steps.

STEP 1: Modify the format of the expected answer.
Identify the current format of the answer, change it to a new format, and add information about
↪  the new
JSON output format to the prompt. Apply the following rules:

1. If a field in the expected answer contains only a date, identify its current format and change
↪  it
   to a new one. Example date formats: DD.MM.YYYY, DD/MM/YYYY, YYYY-MM-DD, YYYY/MM/DD, etc.
   Month-as-word formats are also allowed (day and year in digits, month spelled out); the suffix
   ↪  "y."
   or "year" may be added or removed after the year. For date ranges, use range formats like
   DD.MM.YYYY - DD.MM.YYYY.
2. If the answer contains a number, identify its current format and change it:
   A. Change the thousands separator (spaces or commas).
   B. If the number has a fractional part, change the decimal separator (typically comma or point),
      and either remove the trailing zero (if it does not change the value) or add an extra
      ↪  trailing zero.
3. If the answer contains a personal name:
   A. Identify the current grammatical case and change it to another.
   B. Identify the current name format and change it. Example formats: "Surname I.O.",
      "Surname Name Patronymic", "I.O. Surname". Important: if initials are abbreviated in the
      ↪  source,
      they cannot be expanded into full Name and Patronymic.
4. If the answer contains a URL:
   A. Change the URL format. Example formats: "https://www.example.com", "http://www.example.com",
      "www.example.com", "example.com".
5. If the answer contains a sentence:
   A. Change the letter case (capitalize the first letter, uppercase, lowercase, etc.).
   B. Add or change the terminal punctuation (period, exclamation mark, question mark).

General replacement rules:
1. If the answer contains words with commonly accepted abbreviations, replace them (e.g., "g."
↪  instead
   of "gorod", "ul." instead of "ulitsa").
2. If it contains abbreviations with commonly accepted full forms, expand them (e.g., "dom"
↪  instead of
   "d.", "kvartira" instead of "kv.").
3. If the answer is a single word or short phrase, identify the grammatical case of nouns and
   adjectives and change it. If the answer is a full sentence (three words or more), do not change
   the case.
4. Do not insert either the current or the modified expected answer into the modified prompt.

You may only replace existing fields with new ones; you cannot add new words without replacement,
↪  nor
remove existing words without replacement.
```

(a) Step 1: annotation format transformation.

Figure 5: Text-refinement prompt (translated from Russian).

```
STEP 2: Modify the current prompt to align with the modified expected answer.
Modify the prompt so that it contains information about the JSON output format, but not the answer
itself. Verify that neither the old nor the new expected answer appears in the modified prompt; if
↪  it
does, remove it. Apply the following rules:

1. If the modified answer contains a date field, add the required date format to the schema
   description (e.g., DD.MM.YYYY, YYYY-MM-DD). If the date appears inside a sentence, the format
   ↪  need
   not be specified. If the month is written as a word with day and year in digits, indicate this
   instead of specifying a format string.
2. If the answer contains a number, add a description of the required format:
   A. Specify whether thousands are separated and how (spaces or commas). Skip if not separated.
   B. Specify whether there is a fractional part and which separator is used. Skip if absent.
   C. Specify whether a unit or currency is required and whether a space separates them. Skip
   ↪  otherwise.
3. If the answer contains a personal name:
   A. Specify the required grammatical case.
   B. Specify the required format (e.g., "Surname I.O.", "Surname Name Patronymic", "I.O.
   ↪  Surname").
4. If the answer contains a URL:
   A. Specify the required format (https://, http://, www., or no protocol).
5. If the answer is a sentence:
   A. Specify the required letter case.
   B. Specify the required terminal punctuation.
6. If a value was not modified, state that the field should be returned in the same format as in the
   document.

General rules:
1. Clarify whether abbreviations should be used.
2. Clarify whether acronyms or full names should be used (e.g., "OOO" vs. "Limited Liability
↪  Company").
3. Specify grammatical case only when the answer is a single word or short phrase, not for full
   sentences, and never for numbers.
4. Clarify capitalization conventions.
5. Additional rules specifying formatting required for downstream parsing are allowed.
6. Do not modify already-written text unnecessarily.
7. The expected answer must not appear in the modified prompt.

Before responding, verify once more that all rules are followed and that neither the old nor the
modified answer appears in the prompt in any form. Do not list possible answer variants or
↪  examples.

DO NOT ADD ANY EXAMPLE ANSWERS OR ABBREVIATIONS TO THE PROMPT. THIS IS VERY IMPORTANT!

Response format: Return only the modified expected answer and modified prompt as JSON, without
explanations: {"modified prompt with new format description": "string",
"modified expected answer": "string"}. Do not add new fields.

Example:
Prompt: "Extract the full name of a person who is a member of the control bodies.
Response JSON format: { "name": "string" }"
Expected answer: { "name": "Ivanov Ivan Ivanovich" }
Response: {"modified prompt with new format description": "Extract the full name of a person who
↪  is a
member of the control bodies. Return the 'name' field in the instrumental case, in the format
'Surname I.O.', all letters in the field must be lowercase. Response JSON format: { 'name':
↪  'string' }",
"modified expected answer": "{ 'name': 'ivanov i.i.' }"}
```

(b) Step 2: prompt augmentation with format specifications.

Figure 5: Text-refinement prompt (translated from Russian), continued.

extractability sampling recover parity, making open data merely non-harmful; only cross-model consistency verification strictly improves over in-house–only, converting open data from a neutral additive into a positive scaling factor and indicating the gain generalizes beyond internal distributions.

8	0.51%	6.57%
9	0.37%	2.32%
10	0.00%	0.00%

Table 10: Difficulty distribution of the visual score of accepted samples after DADC.

Table 10 presents difficulty distribution after DADC pipeline. The raw distribution is heavily skewed toward easy examples. After filtering, the retained pool shifts toward higher difficulty samples while preserving the relative propotions among them.

D Offline Experiments

Table 11 reports the full training configuration. All runs use Supervised Fine-Tuning on Qwen3.5-35B-A3B-Base. We initially trained with full-weight updates, and later switched to LoRA adapters covering all linear layers (including those within the image encoder), all shared expert layers, and all routed expert layers.

D.1 LoRA vs. Full Fine-Tuning

Our initial and final training configuration used full-parameter fine-tuning. While final downstream metrics across all benchmark groups were strong, the run converged substantially more slowly and required larger GPU FLOPs compared to a subsequent LoRA configuration we evaluated. The LoRA run reached metrics within noise of the full fine-tune at a fraction of the compute (Table 12), which makes it a convenient setup for rapid hypothesis testing and ablations over data mixtures, prompt formats, and curriculum choices.

D.2 Document Augmentation and Serving

External documents in our synthetic corpus are pristine white PDF pages with crisp text — a distribution shift relative to production scans, photos, and screenshots. To close this gap, we apply rendered-document augmentations. The image-preparation stack is decoupled from training into a framework-agnostic service. The service asynchronously handles retrieval, augmentation, and pre-processing, delivering a steady stream of ready inputs to training nodes. Figure 6 gives an example of augmented CC document. Two operational benefits motivate this architecture:

- **Storage decoupling.** Images can live on storage separate from training nodes, removing the coupling between data volume and per-node disk capacity.
- **Dependency isolation.** Augmentations are implemented in Keras, which carries its own version-pinned dependency graph. Isolating augmentation from the training environment eliminates a common source of dependency conflicts — an issue repeatedly noted in large-model technical reports.

The architecture additionally enables independent horizontal scaling of the data pipeline, maxi-

Setting	Value
Base model	Qwen3.5-35B-A3B-Base
Trainable params	0.8B (LoRA)

mizing GPU utilization on training nodes.

E Latency Analysis

Table 13 reports per-document latency under increasing concurrent worker load, measured with vLLM 0.19.1 at an average workload of 6K input tokens (including 5K visual) and up to 0.5K output tokens. Qwen2.5-VL-72B and our model are benchmarked on a single H100, while Qwen3.5-397B-A17B-FP8 requires an $8\times$H100 replica served under expert parallelism to fit. Our model sustains P95 latency well below the 10-second SLA across all tested concurrency levels (up to 7.4s at 5 workers), while both baselines exceed the SLA: Qwen2.5-VL-72B breaches the threshold already at 2 concurrent workers (P95 = 10.96s), and Qwen3.5-397B-A17B-FP8 crosses it at 3 workers (P95 = 10.77s) despite its $8\times$ larger GPU footprint, with higher concurrency levels infeasible to benchmark under the SLA constraint.

W	Qwen2.5-72B		Ours		Qwen3.5-397B	
	P50	P95	P50	P95	P50	P95
1	**6.89**	**7.26**	**5.65**	**5.74**	**8.90**	**8.96**
2	10.25	10.96	**6.13**	**6.26**	**9.63**	**9.72**
3	13.58	14.35	**6.76**	**6.90**	10.67	10.77
4	16.86	17.73	**7.17**	**7.36**	11.16	11.73
5	20.21	23.86	**7.19**	**7.41**	12.79	13.30

Table 13: Per-document latency (P50 / P95, seconds) under increasing concurrent worker load W.

F Cost Model Details

F.1 Calibration of Assisted-Mode Coefficients

The constants $0.3x$ (confirmation) and $1.1x$ (correction) are are derived from a retrospective case study on a pool of 50 trained annotators working with already-deployed document-processing ML models in production.

Setup. We selected 50 trained annotators on our production document labeling team. For each annotator we extracted from production telemetry every field-level event over a rolling three-month window, yielding several million field interactions in total. Each event was tagged with the operator's mode — *manual*, *confirm*, or *correct* and per-field handling latency. The manual rate was estimated as the median per-field latency across all manual-mode events, restricted to fields where no ML suggestion was available.

Confirmation coefficient. The confirmation coefficient was estimated as the median per-field latency in confirm-mode events, divided by the manual rate. Across the 50-annotator cohort the per-annotator estimates clustered tightly in $[0.27, 0.34]$, with cohort-level median 0.30. Stability across annotators reflects the fact that read-and-confirm is bottlenecked by visual verification time, which varies less across operators than search-and-transcribe.

Correction coefficient. The correction coefficient was estimated analogously on correct-mode events, where the operator overrode a pre-filled value. The cohort-level median was 1.08, with per-annotator estimates in $[1.04, 1.17]$. The overhead above 1.0 isolates the cost of error detection and the context-switching penalty of discarding a displayed suggestion. We round to 1.1 in the main paper to retain a single significant figure consistent with the confirmation coefficient.

дятся рекомендации по использованию для оценки данных, которые весьма достоверно отражали ситуацию применительно к Санкт-Петербургу (табл. 1.5).

Таблица 1.5

Business Compromise Detection with Agentic AI and LLM-driven Knowledge Discovery

Diego Palma, Kyu Bin Kim, Zhen Han, Allbright Dsouza, Zhiyuan Liu
Meta
Correspondence: dpalmasan@meta.com, zhiy@meta.com

Abstract

Detecting compromised business ad accounts is a challenge in digital advertising, as attackers exploit hijacked accounts to launch fraudulent campaigns. Large Language Model (LLM) agents show promise for integrity enforcement, but hallucinated mistakes on hard cases create business friction. In a study we find the autonomous agent is a strong, recall-heavy *signal extractor* but an unreliable *final arbiter*, conceding precision on ambiguous decisions. We therefore keep the agent as an investigator that emits a structured, interpretable signal vector, and delegate the verdict to a neuro-symbolic stage: symbolic rules discovered by Inductive Logic Programming (FOIL-IE), a Naïve Bayes calibration layer, and a data-tuned contradiction layer. Evaluating on a compromise-over-sampled population and a realistic low-prevalence sample with subject-matter-expert labels, this *arbiter substitution* raises MCC from 0.295 to 0.435 (ΔMCC $+0.139$, 95% CI $[+0.026, +0.245]$, $p = 0.018$, paired bootstrap), lifting precision from 0.250 to 0.446 ($1.8\times$) at a recall cost (0.920 to 0.660). Benchmarked under identical conditions, it also edges human reviewers (0.422) and tree ensembles (0.386). The rules encode domain priors and generalize from few labels while remaining interpretable and auditable.

1 Introduction

The digital advertising ecosystem is increasingly targeted by malicious actors who exploit established ad accounts to launch fraudulent campaigns (Zhang et al., 2025; Grier et al., 2012). When a legitimate business ad account is compromised, attackers bypass initial risk checks (Stone-Gross et al., 2011) and leverage the account's historical reputation to run policy-violating ads (Lever et al., 2016), causing financial loss and brand damage. Detection is hard because attackers constantly evolve their tactics, including synthetic profiles, IP obfuscation, and sock-puppet agency structures (Sakib and Spezzano, 2022).

Traditional detection falls into two camps: rule-based systems (Zhang and Guan, 2008; Metwally et al., 2005), which are interpretable and actionable but brittle and need constant SME maintenance; and statistics-based models (Chicco and Jurman, 2020; Zhang et al., 2025), which generalize well but lack the interpretability needed to justify enforcement. More recently, LLM agents can autonomously reason and act (He et al., 2024), and show promise for complex integrity violations. LLMs have the risk to hallucinate, which will be prohibitive for integrity violations as a wrong decision might disrupt customer operations and pose a risk that has to be minimized; while self-reflection (Yao et al., 2022; Shinn et al., 2023) reduces this risk, agents can still struggle to weigh subtle, contradictory business evidence and might behave inconsistently across runs. As a result, agents show a large precision gap in production, where the boundary between a compromised and a benign entity is genuinely ambiguous.

We propose a neuro-symbolic architecture that separates evidence extraction from the final decision. Following an expert mental model, the agent acts as an initial reviewer that (1) makes a decision and (2) reports the supporting evidence, which we convert into a structured signal vector. A neuro-symbolic stage then makes the decision in three layers: (L1) Inductive Logic Programming: a combination of the First-Order Inductive Learner (FOIL) and Inverse Entailment (IE), that automatically discovers interpretable rules; (L2) a probabilistic layer that models the conditional probabilities of those rules to handle borderline cases; and (L3) a contradiction layer that reconciles conflicting evidence to rescue false negatives and veto false positives.

Our contributions are:

1. An empirical finding: an autonomous LLM

EMNLP 2026 Industry Track, pages 2045–2057
October 24-29, 2026 ©2026 Association for Computational Linguistics

agent is an effective recall-heavy *signal extractor* but a poor *final arbiter* on ambiguous cases, motivating a separation of extraction (LLM) from decision (a knowledge stage) that we argue generalizes to other integrity problems.

2. An LLM agent that emits both a decision and a structured signal vector aligned with an expert mental model, turning a stochastic free-text reviewer into a deterministic, interpretable feature source.

3. A three-layer neuro-symbolic decision stage that discovers interpretable rules (FOIL-IE), calibrates them in a probabilistic fashion, and arbitrates contradictions. Benchmarked under *identical conditions* against tree ensembles, it attains the highest point estimates on realistic low-prevalence data; the improvement over the agent is statistically significant, while the margins over human reviewers and the ensembles are not (Section 4.3). A single interpretable tree is markedly weaker throughout.

4. An evaluation on two populations (an oversampled general population and a realistic, expert-labeled hard-case sample), with paired-bootstrap confidence intervals, a per-method error analysis, and a threshold sensitivity study that together identify which of our design choices the data actually supports, including the contradiction *resolution* policy, that it does not (Section 4.4).

2 Background

Business compromise is among the hardest integrity problems: compared to generic fraud, the boundary between violating and benign is ambiguous, and reviewers given the same contradictory evidence often disagree (e.g., distinguishing a legitimate agency from a compromised account). Fraud detection has historically driven automation under severe class imbalance regime (Zojaji et al., 2016), and graph-based methods such as inductive graph representation learning improve performance by embedding transaction/entity networks (Van Belle et al., 2022). Graph signals like connection ages and shared business entities are useful, but these models rarely expose them in an interpretable form.

To gain interpretability, Inductive Logic Programming (ILP) (Muggleton, 1991) and Inverse Entailment (Cropper and Dumančić, 2022), together with Quinlan's relational learning (Quinlan, 1990), learn human-readable rules. Recent work combines logic with statistics: learning rules from noisy data (Evans and Grefenstette, 2018), Probabilistic Soft Logic (Bach et al., 2017), and Differentiable ILP for fraud (Wolfson and Acar, 2024), which finds that explainability comes at a scalability cost relative to decision trees (Wu et al., 2008) and that logic generation paired with probabilistic scoring can close the gap. We adopt exactly this combination: a fast FOIL-IE layer to generate discrete rules and a Naïve Bayes layer for probabilistic robustness. Separately, LLM agents (Yao et al., 2022; Shinn et al., 2023; Wei et al., 2022; Kojima et al., 2022) have advanced autonomous reasoning and tool use, but building a reliable *decision* system from them remains hard in domains, like business compromise, that require imposing domain knowledge: the gap our neuro-symbolic stage targets.

3 Methodology

We focus on the two modules (Fig. 1): a multi-turn LLM agent over a rich toolset (Section 3.2) and a neuro-symbolic decision stage (Sections 3.3 to 3.5). Section C traces one real account end to end: agent trace, JSON verdicts, signal vector, L1, L2, L3, decision. For readers who prefer to see the pipeline concretely before the component descriptions.

3.1 Terminology

Four account states are easily conflated, and the distinction drives both our labels and our dominant error mode. A **legitimate** account is operated within policy by its rightful owner. An **abusive** account is one where the *rightful owner* runs policy-violating campaigns, so control has not changed hands; a **compromised** account is a legitimate one *taken over by a third party*, who then runs campaigns the owner did not authorize. **Fraudulent** describes any policy-violating campaign regardless of who controls the account, so both abusive and compromised accounts produce fraudulent ads. Our target is compromise specifically, because it triggers a different enforcement path (account recovery and owner notification) than abuse (owner-directed penalties). The two are hard to separate from the ad alone, both yield violating content, and confusing *abusive* for *compromised* is the single most frequent error across every method we evaluate (Table 4).

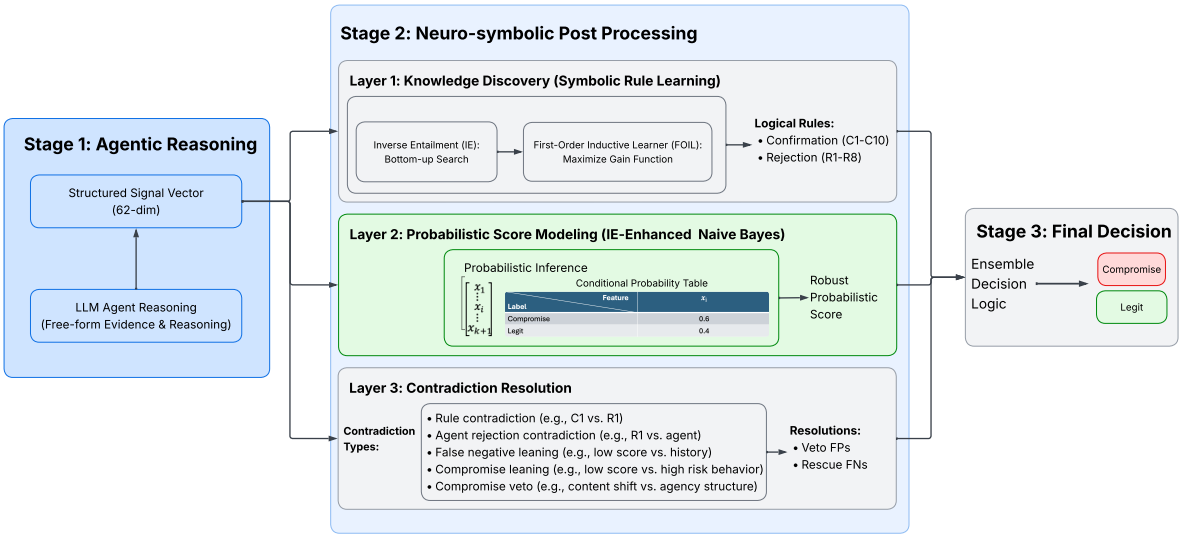

Figure 1: Three-stage approach. Stage 1: an LLM agent inspects business signals and yields a decision plus reasons, which we convert into a structured signal vector. Stage 2: a neuro-symbolic decision stage of three layers (FOIL-IE rules, Naïve Bayes, contradiction resolution). Stage 3: the final decision.

3.2 LLM Agent for Business Compromise

We build the agent around an *expert mental model*: a structured checklist, elicited from subject matter experts (SMEs), of the questions a reviewer asks when adjudicating an account (e.g., "is the destination domain newly registered?", "does the ad creator behavior match the account creators history?"), together with the policy conditions under which an answer argues for or against compromise. We phrase these questions to have objective, evidence-grounded answers, so the agent's job is to *gather and report evidence* rather than exercise open-ended judgment.

Each question is backed by a tool, exposed via the Model Context Protocol (MCP), an open standard that lets an LLM call external functions and consume their structured results within a reasoning loop. Our tools span different evidence families (e.g. destination URL/domain age, targeting behaviors, creator profile and behavior, page history, business-relationship structure, payment patterns, account-connection timing, among others). Tools are granular and single-purpose so the agent fetches only what it needs and revises its reasoning as evidence arrives. We also prompt the agent with tool priorities so it can resolve conflicts (e.g. a behavior-shift signal vs. a verified agency structure) following the expert mental model.

Agent configuration. Table 6 in Section D gives the full specification. The backbone is Gemini 2.5 Flash on a hosted serving platform, driven through native function calling; tools are discovered at runtime over MCP. The loop is multi-turn and evidence-revising: each turn the model may request one or more tool calls, the structured results are appended to the dialog, and the loop recurses until the model returns a final answer with no tool call, or until a hard cap of 25 steps. Identical tool calls are memoized within a run, so an account yields the same signal vector across runs. The system prompt is the expert mental model made explicit: an expert persona and threat context, the compromise-vs-abuse-vs-legitimate distinction of Section 3.1 with a "default to Not Compromise" prior, a 9-component review checklist, and 8 mandatory override checks. Chain-of-thought is required in a free-text field, and the final answer is a single JSON object. The same appendix gives the prompt's block structure and the full output schema; the prompt's policy content (the adversary monetization taxonomy and the conditions and thresholds of the override checks) is proprietary enforcement material and is withheld, which we record as a reproducibility limitation.

The agent's structured output is a set of small categorical verdicts (per-family judgments in {benign, inconclusive, suspicious}) consumed as logic predicates, joined by boolean evidence signals (e.g. *domain newly registered*) and bounded numerics (a derived risk score, account connection ages). Committing the agent to this vocabulary makes hallu-

cinations surface as *inconsistency* between predicates rather than as fluent prose, and lets the downstream stage re-weight checks the agent over-trusts. Because every dimension is grounded in a deterministic tool result, the same account yields the same vector across runs, stabilizing downstream learning. This matters because easy cases, where one or two checks settle the decision, are already high-precision for the agent alone; it is the mid-band *hard cases* that produce the four recurring failure modes of Table 5: abusive advertisers read as compromised, multi-vertical agencies read as compromised, benign behavioral shifts read as compromised, and outright hallucinations. Most stem from missing domain knowledge, motivating the knowledge stage below.

3.3 Layer 1: Symbolic Learning with FOIL-IE

We use ILP (Muggleton, 1991) to learn symbolic rules that separate positive from negative examples, choosing FOIL (Quinlan, 1990). To overcome FOIL's connectivity limitation (Quinlan, 1991), we integrate Inverse Entailment (Muggleton, 2001), forming FOIL-IE. Learning maximizes the gain

$$Gain(l,h) = t \cdot \left(\log_2 \frac{p(l)}{p(l)+n(l)} - \log_2 \frac{p(h)}{p(h)+n(h)} \right) \quad (1)$$

where h is the current rule, l a candidate literal, $p(\cdot)$ and $n(\cdot)$ the positive/negative coverage, and t the positives covered by h that remain covered after adding l. With background knowledge B and examples E^+, E^-, the procedure (Algorithm 1, appendix) yields a rule set H: confirmation rules that recognize compromise, and rejection rules that recognize legitimate accounts.

3.4 Layer 2: Probability Modeling

To handle borderline cases, we associate each rule $h_i \in H$ with class-conditional probabilities via a probabilistic layer. For the case of this paper, we used Naïve Bayes due to the compromise prevalence being low in this problem space. Each rule becomes a boolean feature (a first-order signal); we also include raw signals (zeroth order), rule combinations (second order), and contradiction flags (third order). Conditional probabilities are stored in a Conditional Probability Table (Koller and Friedman, 2009) with Laplace smoothing (Manning et al., 2008):

$$P(x_i \mid y) = \frac{N_{yi} + \alpha}{N_y + 2\alpha} \quad (2)$$

where N_{yi} counts feature x_i in class y, N_y is the class size, and α=1. Feeding the L1 rule-fires back as features (the IE enhancement) lets L2 calibrate the discrete rules probabilistically.

3.5 Layer 3: Contradiction Resolution

Hard cases often present contradictory evidence, made worse by agents hallucination. We are deliberate about what is learned here, and state the division plainly.

The categories are an expert prior, not a discovery. We define five contradiction categories: compromise-leaning, false-negative-leaning, false-positive-leaning, direct rule contradictions, and agent-rejection contradictions (Table 10, appendix). These are not learned. They encode an expert prior over the four failure modes we observed in (Table 5), and we claim no more for them than that.

The inputs are not hand-set. Direct and agent-rejection contradictions are computed from the FOIL-IE rules discovered in L1; the leaning flags come from the deterministic MCP signals plus the L2 posterior.

The resolution policy is two swept thresholds. A false-positive-leaning flag vetoes a positive decision when the posterior is low, and a false-negative- or compromise-leaning flag rescues a negative decision when the rules do not fire and the posterior sits just below threshold. The veto and rescue thresholds are swept on training folds for maximum MCC, the same protocol that selects tree depth and ensemble size for our baselines, never on test data.

Being a second-order layer, L3 is the most data-hungry component. In Section 4.4 we show that at our current label volume the resolution policy is in fact *static*: the gain we previously attributed to L3 comes from feeding the contradiction flags to L2 as features and from the posterior floor, not from the veto/rescue actions.

4 Experiments and Results

We evaluate each stage and layer (Section 3): setup (Section 4.1), cross-validation on a class-rich population (easy and hard cases) (Section 4.2), and an ablation against humans and tree ensembles on hard cases (lower compromise prevalence) (Section 4.3).

4.1 Experimental Setup

Data. We use two populations. The first is an *over-sampled general population*: 975 labeled cases drawn from the broad history of past reviews rather than from the hard cases we ultimately target, with compromised accounts over-sampled ($\sim$70% positive) to obtain a class-rich set for higher-powered model comparison and rule learning, evaluated with 5-fold stratified cross-validation. We rely on this over-sampled set precisely because high-confidence labels for the *hard* cases scarce; it is not prevalence-matched to production and we treat it as a controlled, higher-power comparison rather than an estimate. The second is the *production hard-case population*: 397 accounts routed to the agent and adjudicated by SMEs, of which 60 (15.1%) are compromised; the operationally faithful, low-prevalence target. We also consider an independent human review (non-SME, trained and outsourced), and the comparison is the system that was trained on SME labels vs these non-SME reviewers. Table 1 and every significance test are computed on this subset. A defining constraint is *label scarcity*: a high-confidence compromise label requires an SME to reconcile contradictory evidence, and even trained human reviewers agree with SME adjudication only 75-85% of the time (Section 4.3). Such labels are slow and costly, bounding dataset size and favoring sample-efficient, interpretable methods.

Comparative methods. (1) an always-positive baseline, which predicts compromise for every case (F1 is high only because the over-sampled population is 70% positive; its MCC is 0 by construction, which is the point of including it); (2) the LLM agent alone; (3) FOIL-IE only (L1); (4) Naïve Bayes only (L2); (5) ILP+NB (L1+L2); (6) the full neuro-symbolic stage (L1+L2+L3); and three *tree baselines* on the same structured signals: (7) a single decision tree (CART), (8) random forest, (9) gradient-boosted trees. To ensure fairness, every learned method uses the same folds, the same agent gating, and per-fold decision-threshold tuning; tree depth/ensemble size are selected by the same cross-validated MCC we use to tune our own thresholds.

Metrics. We report recall (capturing compromise early limits loss), F1, and the Matthews Correlation Coefficient (MCC) (Chicco and Jurman, 2020), which is robust under imbalance (0 = random).

4.2 Over-sampled General Population

Table 8 in Section F reports 5-fold CV. First, *every* knowledge layer dramatically improves precision over the agent (0.809 $\rightarrow$ 0.92-0.95) and lifts MCC from 0.513 to 0.74-0.82: the agent is a strong recall-heavy extractor, and the value comes from re-arbitrating its decision. Second, on this class-rich population *tree ensembles are competitive*: random forest attains the best MCC (0.823), marginally above our stage (0.807), with gradient boosting tied (0.800), gaps within CV and tuning noise. We report this honestly because it does *not* hold on realistic data (Section 4.3): the ranking reverses, since abundant positives are exactly where high-capacity ensembles thrive. Even here, the only interpretable tree (a single decision tree) is markedly weaker (0.733), so an ensemble buys accuracy at the cost of auditable rules.

4.3 Low Prevalence Population

We now turn to the operationally faithful population at the true $\sim$15% prevalence: a deliberately hard sample where human reviewers agree with SME ground truth only 84% of the time (75% on an earlier curated subset), attaining MCC 0.422. To compare every method against humans *on equal footing*, Table 1 restricts to the 397 accounts with both an SME label and a human review, running every learned method through identical folds, agent gating, and per-fold threshold tuning, so differences reflect the model, not the protocol.

The supported result is the arbiter substitution. Holding the agent's evidence fixed and replacing only *who decides*, the agent's own verdict versus the knowledge stage, raises MCC from 0.295 to 0.435 and precision from 0.250 to 0.446, a factor of 1.8, moving the recall from 0.920 to 0.660. In absolute terms the stage removes 97 of the agent's 138 false positives on these 397 cases while giving up 13 true positives. This is the one comparison in the paper that survives a paired bootstrap (ΔMCC $+0.139$, 95% CI $[+0.026, +0.245]$, $p = 0.018$; Table 2), and it is the claim the paper rests on.

The stage achieves slightly higher MCC than the evaluated human reviewers, but the difference is not significant. The full stage reaches MCC 0.435 against the human reviewer's 0.422 (ΔMCC $+0.012$, $p = 0.881$). We therefore do not claim to exceed human experts. The human number is better read as context for how hard this slice is: trained reviewers match SME adjudication only 84% of the

Table 1: Comparison of different approaches to ground truth (SME).

Model	Layers	Prec	Rec	F1	MCC	MCC 95% CI	MCC per-fold SD

Random Forest	$+0.049$ $[-0.073, +0.171]$	0.437
L1+L2: ILP+NB	$+0.043$ $[-0.037, +0.120]$	0.275
Human Reviewer	$+0.012$ $[-0.155, +0.174]$	0.881
L1: FOIL-IE	$+0.010$ $[-0.056, +0.071]$	0.768

Table 3: Decomposing the full stage on the hard cases.

Configuration	Prec	Rec	F1	MCC
L1+L2: ILP ∨ raw-NB	0.375	0.720	0.493	0.391
A: ILP ∨ IE-NB	0.407	0.700	0.515	0.416
B: A + posterior floor	0.446	0.660	0.532	0.435
C: B + veto	0.446	0.660	0.532	0.435
D: B + rescue	0.446	0.660	0.532	0.435
E: B + veto + rescue	0.446	0.660	0.532	0.435

time, so a system that merely *matches* them while being interpretable and fully automatic is already operationally useful.

Ahead of tree ensembles in point estimate, within noise in significance. Under identical conditions, random forest (0.386) and gradient boosting (0.338) fall below the knowledge-based methods, reversing their ranking on the over-sampled general population. The proposed mechanism is sample efficiency: with only 50 positives the ensembles overfit, whereas the FOIL-IE rules encode SME domain priors and generalize from few examples. We report this as the more likely explanation rather than a demonstrated one (the margin over random forest is not significant (ΔMCC $+0.049$, $p = 0.437$), and confirming sample efficiency properly needs a learning curve over label volume, which our label budget does not yet support.

The ablation is monotone in point estimate only. Naïve Bayes alone (L2) scores 0.358; adding the discovered rules (L1+L2) raises it to 0.391; the full stage reaches 0.435. None of these steps is individually significant in this dataset (Table 2), see Section 4.4.

4.4 What L3 Actually Contributes

The full stage differs from L1+L2 in *two* ways at once, which the original ablation conflated: it swaps the raw Naïve Bayes posterior for the IE-enhanced one (rule fires and contradiction flags as *features*), *and* it applies the posterior floor and the veto/rescue *actions*. Table 3 separates them. The IE-NB feature enhancement contributes $+0.025$ MCC and the posterior floor a further $+0.019$. The veto and rescue actions contribute *exactly nothing*: enabling either or both leaves all four metrics bit-identical.

This is corroborated by the tuner and by a sensitivity sweep. Per-fold threshold selection chooses rescue-off in 5 of 5 folds and veto-off in 3 of 5. Sweeping the veto threshold over $\{0.0, 0.4, 0.5, 0.6\}$ and the rescue threshold over $\{\text{off}, 0.4, 0.5, 0.6\}$ (16 configurations, thresholds pinned rather than tuned) yields only two distinct outcomes: MCC 0.435 for veto ≤ 0.4 and 0.420 for veto ≥ 0.5, with the rescue threshold making no difference anywhere. The policy is flat, not knife-edge, which is reassuring for stability.

The honest reading is that at 50 positives the contradiction categories earn their place as *features* for the probabilistic layer, and the posterior floor earns its place as a precision guard, but the second-order *resolution policy* is static. L3 is the most data-hungry component of the design and we do not yet have the labels to justify it. We keep it in the architecture because it is the component we expect to activate first as SME labels accrue, and we flag it as unjustified at present rather than quietly reporting the aggregate.

Table 4: Errors split by category.

	False positives				
Method	**Abus.**	**Agcy.**	**Shift**	**Other**	**FN**
Agent alone	10	10	109	9	4
L1: FOIL-IE	4	3	35	4	16
L2: NB only	5	4	25	1	24
L1+L2: ILP+NB	6	6	44	4	14
Full (ours)	4	4	32	1	17
Random Forest	0	3	29	1	23
Gradient Boosting	0	2	17	1	31

4.5 Per-Method Error Analysis

Table 4 breaks each method's errors into the four failure modes of Table 5. False positives are bucketed from the agent's own signal vector (first match wins: *abusive* if the abuse override fired, else *agency* if the account is an agency, else *benign shift* if a content, language, or target-country shift was detected, else *other*), so the breakdown is reproducible from released signals rather than a fresh manual re-read.

Three things stand out. First, **benign shifts dominate every method's false positives**, 109 of the agent's 138, and still 32 of the full stage's 41. A legitimate business changing its creative, language, or target market is the hardest negative in this problem, and no layer solves it; the knowledge stage merely removes two thirds of these cases. Second, **the abusive-vs-compromised confusion is the error the knowledge stage fixes best**: the agent makes 10, the full stage 4. This is the confusion Section 3.1 defines and the one with the most costly enforcement consequence, so it is the right one to have improved. Third, **tree ensembles buy their precision by giving up recall**: gradient boosting has the fewest false positives of any method (20) but misses 31 of 50 compromises, versus 17 for the full stage. Under a policy where a missed compromise keeps an attacker live on a real business's account, that trade is not obviously the right one, and MCC alone obscures it.

4.6 Operational Characteristics

The decision stage is operationally negligible: rule evaluation, the Naïve Bayes posterior, and arbitration together take 21 ms on CPU (p99 25 ms), four orders of magnitude below the agent, and refitting the entire stage on fresh labels is minutes of single-machine compute. Most of the execution time is essentially all agent-side, bounded above by the 25-step cap. Over 330 reviews, a review takes 175 s on average while emitting only $\sim$740 estimated tokens, so wall-clock is dominated by sequential tool round-trips rather than by generation, and would shrink with tool parallelism rather than a faster decoder. Tool use is heavily skewed (median 1 call, mean 3.6, p99 16): the checklist is not run exhaustively, most accounts are resolved by the first pieces of evidence, and the step cap acts as a tail guard rather than the operating point. Section E reports the full distributions.

Where the human stays in the loop. In execution the stage decides automatically, with the false-positive guard of Section 4.4 applied before any enforcement action. A human reviewer is retained only for a subset of managed accounts, where a false positive is most damaging to a real business. Humans are therefore required for labeling and evaluation, SME adjudication is our ground truth, and appears as a baseline throughout, but not for routine decisions.

5 Conclusion

We presented a system that pairs an LLM agent with a neuro-symbolic decision stage for business compromise. The agent is a strong evidence extractor but a poor arbiter, and the supported finding is the substitution itself: keeping the agent's evidence and replacing only the decision-maker raises MCC from 0.295 to 0.435 on realistic low-prevalence data ($p = 0.018$), lifting precision $1.8\times$ at a recall cost. The stage achieves slightly higher MCC than the evaluated human reviewers and than tree ensembles, but neither margin is significant at this sample size and we do not claim them; on class-rich data ensembles are ahead. Decomposing our own stage shows the contradiction categories earn their place as probabilistic features while the veto/rescue policy they were designed for is currently static, it is a component the architecture is ready for but the label volume does not yet justify. The discovered rules align with SME reasoning and remain auditable. We next aim to instrument raw trace capture so the agent baselines discussed in Limitations become runnable, distill the agent into a smaller model for throughput, and test the paradigm on other integrity problems.

Limitations

We are candid about several limitations. First, on the over-sampled general population, tree ensembles match or slightly exceed our stage on raw

accuracy (random forest MCC 0.823 vs. 0.807); there, our advantage is interpretability rather than accuracy. On the realistic population our point estimates are highest, but only the margin over the agent is statistically significant (Table 2), so the ranking against humans and ensembles should be read as unresolved rather than in our favor. Second, the contradiction layer (L3) is the most data-hungry component, and at the 50 positives available in the matched subset its veto/rescue policy contributes nothing measurable (Section 4.4); we retain it as architecture, not as a validated result. Sample efficiency, which we propose as the mechanism behind the knowledge stage's advantage on low-prevalence data, is likewise a proposed rather than a demonstrated explanation, absent a learning curve over label volume. Third, our sample is small and expensive to grow, SME-adjudicated accounts (hard cases subset). Absolute numbers therefore carry wide confidence intervals and should be read as relative comparisons under matched conditions. Fourth, all results are from a single platform and a single integrity problem; while we argue the paradigm generalizes, we have not measured it on another domain.

Stronger agent baselines are the main open gap. We compare against the agent in one setting, not against self-consistency, reflection, verifier-based reasoning, or majority voting. Two of these are partially addressed by design (the agent already runs a multi-turn, evidence-revising loop with structured output, and our L2/L3 stage is a learned verifier over its structured evidence) but that is an argument, not a measurement. The obstacle to a controlled study is real: several tools return time-dependent results (account state, connection ages, recent activity), so a fair multi-run comparison requires replaying an identical frozen evidence snapshot to every run. Our traces retain the parsed signal vector but not the raw tool outputs, so even the frozen-trace self-consistency variant we offered in review is not currently runnable; recovering raw traces is an instrumentation change we have scoped but not shipped. **Consequently our claim that a knowledge stage beats better prompting is untested, not confirmed.** It is the experiment we would run first in as a follow up study.

Backbone robustness is untested. The decision stage learns over the structured signal vector rather than raw LLM text, so decision quality should be largely decoupled from the extractor's identity, and the backbone is a pluggable component in our implementation. We have not verified this with a controlled two-backbone comparison, for the same frozen-evidence reason.

The prompt is not fully reproducible. Section D gives the block structure, the complete output schema, and the full agent configuration, which is enough to re-implement the architecture but not to reproduce our exact extractor. The components a third party can reproduce exactly are the decision stage and its evaluation protocol, given a signal vector of the same shape.

Adversarial robustness and updating. Compromise is adversarial, so static models decay. Two design properties help: because the agent only extracts evidence and a cheap stage decides, adapting to a new tactic means re-fitting the symbolic stage on fresh labels (minutes) rather than re-prompting the agent; and the rules are human-readable, so SMEs can inspect, retire, or add them. Our results already show distribution sensitivity, the method ranking changes between populations (tree ensembles lead on class-rich data, the neuro-symbolic stage on realistic low-prevalence data), so a model tuned at one operating point should not be assumed optimal at another. During execution we monitor per-rule precision and firing rates, periodically relearn rules and thresholds as labels accrue, and treat a sustained precision drop as a drift alarm. Quantifying decay rate and re-fit cadence needs a longer longitudinal label stream than we currently have.

Latency and operational characteristics. We optimize for review quality, not serving. Measured per-review figures are in Section 4.6: the dominant characteristic is the agent's multi-turn tool calling, and, within it, sequential tool latency rather than token generation, while the neuro-symbolic stage adds 21 ms. The scaling path we are pursuing is to distill the multi-turn agent into a smaller task-specialized model that emits the signal vector directly, leaving the interpretable decision stage unchanged.

Table 5: Four recurring agent mis-classifications (all over-predict compromise).

#	Expert	Mistake reason
1	Abusive	Confused abusive with compromised; over-weighted abuse signals.
2	Benign	Over-weighted a content-shift signal.
3	Benign	Confused a legitimate agency with a compromise.
4	Benign	Hallucination: recognized agency signals yet decided compromise.

A FOIL-IE Algorithm

Algorithm 1 details the hybrid FOIL-IE procedure referenced in Section 3.3.

Algorithm 1 Hybrid FOIL-IE Algorithm

Require: B, E^+, E^-
Ensure: H (the set of learned rules)
1: $H \leftarrow \emptyset$; $E_{rem} \leftarrow E^+$
2: **while** $E_{rem} \neq \emptyset$ **do**
3: **Selection:** pick an example $e \in E_{rem}$
4: **Saturation (IE):** build bottom clause $\perp_e \leftarrow \{l \mid B \wedge \neg e \models \neg l\}$
5: **Reduction (FOIL):** find $h \preceq \perp_e$ maximizing $Gain(l, h)$ (Section 3.3)
6: **Update:** $H \leftarrow H \cup \{h\}$; $E_{rem} \leftarrow E_{rem} \setminus \{e' \mid B \cup \{h\} \models e'\}$
7: **end while**
8: **return** H

B Agent Mis-classification Categories

C Worked Example: One Account End to End

This traces a single account through every stage, as promised in review. It is a real case from the "hard cases" set, de-identified: no account, business, domain, or country is named, and every value shown is drawn from the released signal vector. It was chosen because it is a genuine hard case where the human reviewer called it Not Compromise, the SME called it Compromise, and the full stage recovered it.

Stage 1: agent. The agent works the checklist, calling tools per component. Its structured output records *suspicious* on four components (content, destination URL, page, target countries), *normal* on creator and business connections, and *inconclusive* on the remaining four, giving `num_suspicious_checks` $= 5$ with `confidence` high.

Signal vector. The categorical verdicts and booleans above are joined by the deterministic tool numerics: risk score 0.39 (squarely in the mid-band where the agent is unreliable), total risk 5.0, a destination domain new to this business though 416 days old, 8 permitted users, all ad accounts under one business, no prior page use, no compromised pixel, and zero baseline ads.

L1. The confirmation rules fire on the conjunction of a mid-band score with a language/target-country shift on an account carrying no baseline ad history; no rejection rule fires, because the two override checks that would normally protect an established advertiser are contradicted by the zero baseline. `ilp_comp` is true.

L2. The IE-enhanced posterior sits above the tuned decision threshold: the rule-fire features and the shift-without-congruence combination both push upward, while *creator is original to business* pushes down; this is not a creator-takeover signature but a session-takeover one.

L3. No contradiction category fires: there is no rule conflict, the agent and the rules agree, and no false-positive-leaning evidence is present. The posterior clears the floor, so the veto does not engage and no rescue is needed. Consistent with Section 4.4, L3 passes the decision through unchanged.

Stage 3: decision. Compromise, matching SME adjudication. The human reviewer had read the established funding business and long-lived domain as reassuring; the stage weighed those against the absent baseline history and the simultaneous language and country shift, which is the conjunction its rules encode.

D Agent Configuration, Prompt Sketch, and Output Schema

Agent specification. Table 6 gives the full configuration of the agent described in Section 3.2.

The prompt is not reproduced verbatim. We give a structural sketch sufficient to re-implement the *method*. We flag this as a genuine reproducibility limitation rather than presenting the sketch as equivalent to the prompt.

Structure of the system prompt. The prompt is assembled in seven blocks, in order:

1. **Task framing and persona**: the reviewer role, and the ad under review.
2. **The central distinction**: compromise (a legitimate account taken over) versus abuse (a

Table 6: LLM agent specification.

Component	Setting
Backbone	Gemini 2.5 Flash (hosted serving platform)
Tool interface	native function calling; tools discovered at runtime via MCP
Tools registered	31 tools produce the signal vector
Reasoning loop	multi-turn tool calling; terminates on a final answer with no tool call
Step cap	25
Decoding	`max_output_tokens` $= 65536$; temperature at model default
Determinism	identical tool calls memoized within a run
Structured output	one JSON object: `final_decision` $\in$ {Compromise, Not Compromise}, `confidence`, free-text `reasoning`, 7 `override_checks` booleans, 5 `evidence` booleans, 10 per-component `checks` each with `verdict` $\in$ {suspicious, normal, inconclusive}
Parsing	tolerates fenced or bare JSON, with a re-trying fallback

bad-faith account from the outset) versus a legitimate behavioral shift, with an explicit *"default to Not Compromise"* prior instructing the model to require clear, strong evidence before predicting compromise.

3. **Adversary monetization taxonomy**: an enumeration of the ways an attacker converts stolen ad credit into money, each with the observable signature that distinguishes it from the same behavior performed legitimately. *Content withheld.*
4. **Per-component analysis guides**: for each of the nine review components (content, creator, page, target countries, destination URL, pixel, payment, business connections, ad-account connections), the questions the reviewer must answer, grouped into recency analysis (is this artefact new to this business?) and connection analysis (does this artefact's wider association graph fit this business?).
5. **Initial assessment**: the upstream classifier's score and features, injected with an explicit instruction that it is a starting point only, must not be the sole basis for a decision, and must be checked against independent tool evidence. *Conditions and thresholds withheld.*
6. **Output contract**: an instruction that each check verdict be evaluated independently on that check's own evidence rather than backfilled from the final decision, followed by the JSON shown in figure 2.

```
{
  "final_decision":
      "Compromise" | "Not Compromise",
  "reasoning": "<free-text rationale>",
  "confidence": "high" | "medium" | "low",

  "override_checks": {
    "is_abusive_not_compromised": <bool>,
    "funding_business_is_established":
        <bool>,
    "has_sufficient_baseline_history":
        <bool>,
    ...
  },

  "evidence": {
    "<dimension>_shift_detected": <bool>,
    "creator_is_original_to_business":
        <bool>,
    ...
  },

  "checks": {
    "sme_check_1": {
      "verdict": "suspicious" | "normal"
                 | "inconclusive",
      "<check_specific_signal>": <bool>
    },
    "sme_check_2": { ... },
    ...
  }
}
```

Figure 2: Sketch of the agent's JSON response. One `checks` object is emitted per component of the SME review checklist, each carrying a verdict and its own boolean sub-signals; `<dimension>` ranges over the observable properties of an ad whose shift the reviewer tracks.

A managed-tier annotation is appended when the business has one, instructing the model to require stronger evidence because false positives might be more relevant in certain cases.

Output schema. The agent emits a single JSON object. Figure 2 sketches its shape. The per-component checks are abstracted as `sme_check_i`, the shift evidence is shown as a template over the dimension it applies to, and only the override checks already named elsewhere in this paper appear.

The boolean sub-signals are instructed to reflect the model's semantic judgement after reading the tool outputs, not a restatement of any single tool's field. Parsing accepts a fenced or bare JSON object with a retry fallback, and falls back to text-based extraction of the final decision if no JSON can be recovered; every field has a default, so a partial response degrades rather than fails. The signal vector consumed by the decision stage is this JSON, the per-component verdicts and their sub-signals, the override and evidence booleans, the confidence level, and the count of suspicious verdicts, con-

catenated with the deterministic numeric signals returned by the tools.

E Operational Distributions

Table 7 gives the measured per-review cost summarized in Section 4.6. Token consumption is modest in absolute terms, which is what makes the design affordable despite the multi-turn loop. The token and latency distributions below let a reader derive it for their own execution, which is the portable form of the number.

Table 7: Measured operational characteristics over 330 samples. Agent latency is end-to-end; stage latency is the neuro-symbolic decision stage. Reasoning steps are not logged separately; tool calls are the logged proxy and are bounded by the 25-step cap.

Quantity	Mean	p50	p90	p99
Tool calls	3.6	1	10	16
Agent latency (s)	175.5	172.1	242.5	330.0
Logic Stage latency (ms)	20.7	15.6	17.4	25.2
Est. tokens	742	770	1029	1373

F Over-sampled General Population Results

Table 8 gives the 5-fold cross-validation results discussed in Section 4.2.

Table 8: 5-fold CV on the over-sampled general population (975 cases, 684 positive, ∼70%; compromise over-sampled). The always-positive row predicts compromise for every case. Tree baselines use the same signal vector.

Method	Prec	Rec	F1	MCC
Always-positive	0.702	1.000	0.825	0.000
LLM Agent alone	0.809	0.953	0.875	0.513
Decision Tree	0.921	0.920	0.920	0.733
ILP+NB (L1+L2)	0.916	0.939	0.927	0.749
FOIL-IE (L1)	0.926	0.931	0.929	0.759
Gradient Boosting	0.921	0.966	0.943	0.800
Neuro-symbolic (ours)	**0.951**	0.931	0.941	0.807
Random Forest	0.932	**0.966**	**0.949**	**0.823**

G Full Hard Cases Population

Table 9 repeats the comparison on all 397 SME-adjudicated accounts (60 positives), without the human baseline. The ordering is compressed relative to Table 1, the full stage, FOIL-IE alone, and random forest are separated by less than 0.005 MCC, reinforcing that these methods are statistically indistinguishable at this label volume.

Table 9: All 397 SME-adjudicated accounts (60 positives, 15.1%). Same folds, gating, and per-fold threshold tuning as Table 1. SD is across the 5 CV test folds.

Method	Prec	Rec	F1	MCC (SD)
Agent alone	0.248	0.917	0.390	0.304 (0.087)
L2: NB only	0.414	0.483	0.446	0.340 (0.143)
Gradient Boosting	0.457	0.350	0.396	0.309 (0.133)
L1+L2: ILP+NB	0.350	0.683	0.463	0.360 (0.098)
Random Forest	0.437	0.517	0.473	0.372 (0.082)
L1: FOIL-IE	0.384	0.633	0.478	0.374 (0.093)
Full (ours)	0.400	0.600	0.480	0.376 (0.121)

H Contradiction Types and Resolution

Table 10: Contradiction types and how the resolution layer acts on them.

Type	**Resolution**
Compromise leaning	Rescue a negative prediction if the NB posterior stays above a secondary threshold; override an NB veto when L1 is positive.
False-negative leaning	Rescue when neither L1 nor L2 fires but hard indicators (compromised domain/page/pixel) persist and the posterior is above a rescue threshold.
False-positive leaning	Veto a positive when conflicting evidence is present, the posterior is uncertain, and no compromise-leaning evidence counterbalances it.
Direct rule contradiction	L1 priority: high-confidence confirmations win, else rejections; the flag is also an NB feature.
Agent-rejection contradiction	L1 rejection overrides the agent's positive verdict (rules are grounded in deterministic signals); also an NB feature.

Benchmarking AI Agents for Hardware Design Automation via MCP Tool Calling

Leonardo Liparulo

Francesco Pierri
Politecnico di Milano
francesco.pierri@polimi.it

Abstract

We ask whether AI agents powered by locally deployed large language models can reliably automate expert-defined hardware design workflows in an industry-realistic tool-calling setting. In these environments, engineers issue repetitive, dependency-ordered operations—such as creating components, adding ports, and wiring connections—through specialised tools. Confidentiality constraints on component specifications and naming conventions often preclude hosted proprietary APIs, motivating the use of locally deployed models. To study this setting, we build a Model Context Protocol (MCP) server that reproduces the state and dependency logic of a proprietary hardware design tool used in embedded system development and construct a benchmark covering single-operation edits, multi-step dependency chains, invalid requests, misspelled prompts, and multi-server tool contexts. We evaluate seven open-source models comparing pipeline choices including system prompts, tool-description detail, context scope, and single-agent versus multi-agent architectures. Results show that strong models can achieve near-complete expected-call coverage on the benchmarked workflows, but reliability depends strongly on both task structure and agent configuration. Comprehensive tool descriptions consistently reduce failures, few-shot prompting can cause severe inaction for some models, cumulative context harms constrained models, and multi-agent decomposition helps weak workers or long sessions at the cost of additional calls. These findings provide practical guidance for deploying local LLM agents in stateful hardware design environments.

1 Introduction

Hardware design for embedded systems is carried out through specialised tools such as Synopsys Virtualizer or the open-source Kactus2 (Kamppi et al., 2017), which expose graphical interfaces for building structured component models. For instance, an engineer creates a component identified by a VLNV (Vendor, Library, Name, Version) tuple, adds signal and transactional ports, defines parameters, instantiates subcomponents, and wires connections between them. These operations must be issued in dependency order: a port must exist before it can be connected, and a subcomponent must exist before its ports can be referenced (see Fig. 1).

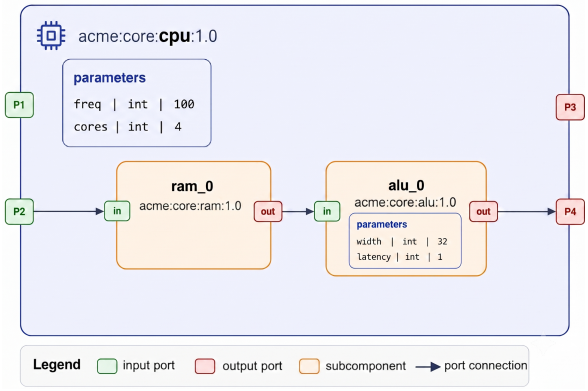

Figure 1: A component in the target application domain. Subcomponents, ports, and connections form a dependency-ordered structure: each element must be created before it can be referenced by subsequent operations.

In industrial practice, many of these interactions are repetitive and template-like, such as adding batches of similarly typed ports, instantiating analogous subcomponents, or wiring connections that follow a regular pattern. Automating them is attractive because it reduces repetitive manual interaction while preserving the structured operations and dependency constraints already enforced by the design tool.

More generally, this kind of workflow consists of structured operations issued in dependency order against persistent application state. Such settings are well-suited to LLM-based tool-calling agents,

EMNLP 2026 Industry Track, pages 2058–2077
October 24-29, 2026 ©2026 Association for Computational Linguistics

which translate natural-language requests into sequences of API calls. Agents operating in this manner have been studied in retail and airline customer operations (Yao et al., 2025), CRM systems (Huang et al., 2025), enterprise workflows (Drouin et al., 2024), and multi-application environments (Trivedi et al., 2024). In these settings, the agent modifies shared state through structured tool calls, and later operations depend on the results of earlier ones. The Model Context Protocol (MCP) (Anthropic, 2024a) standardises this style of agent–application interaction and has seen rapid adoption as an integration layer.

Hardware design shares the same stateful and dependency-ordered characteristics as these agent-driven domains, but also introduces practical deployment constraints. Component specifications, port names, and internal naming conventions can reveal details of unreleased products, often precluding the use of hosted proprietary APIs. Locally deployed open-source models avoid this exposure, but may be less capable than frontier-hosted models. This raises a practical question for industrial adoption: **can LLM-based agents reliably automate expert-defined hardware design workflows in an industry-realistic tool-calling setting while operating within these constraints?**

We address this question by implementing an MCP server whose 14 tools cover the recurrent component-editing operations and dependency logic identified with professional users of a proprietary tool. The server reproduces the relevant data model and constraints of the tool rather than calling its production APIs directly. We then evaluate agents built on seven open-source models running locally through Ollama (Ollama, 2024) as 4-bit quantised variants.

Our contributions are: (1) an MCP server for the proprietary hardware design tool; (2) an expert-informed benchmark comprising eight task suites, spanning independent tasks, dependency chains, cross-task sessions, error handling, and multi-server contexts; (3) a systematic evaluation across prompt, tool-description, context-management, and architecture choices; and (4) practitioner guidelines for deploying reliable local agents in hardware design environments.

2 Related Work

Agents that operate applications. LLM agents that operate applications through stateful tool calls are evaluated by benchmarks such as τ-bench (Yao et al., 2025), CRMArena (Huang et al., 2025), WorkArena (Drouin et al., 2024), AppWorld (Trivedi et al., 2024), and ToolSandbox (Lu et al., 2025). These settings require dependency-ordered interactions over shared mutable state, structurally similar to hardware design workflows.

Because later actions depend on earlier ones, task-level success alone can hide omitted or extraneous calls, motivating call-level evaluation (Yao et al., 2025; Gao et al., 2026). MCP-native frameworks such as MCP-RADAR (Gao et al., 2026) and MCP-Bench (Wang et al., 2026) adopt call-level scoring as a key evaluation strategy for MCP-based tool-calling systems.

LLMs have separately been applied to hardware tasks such as RTL generation (Chang et al., 2023) and EDA-flow orchestration (Fu et al., 2023), typically producing design artefacts or pipeline commands rather than operating a stateful design application through structured tool calls. To our knowledge, prior work does not evaluate MCP-style agents for hardware design workflows involving persistent cross-task state, invalid requests, or multi-server tool contexts.

Agent configuration. Tool-calling performance depends not only on the model but also on the surrounding system design. Orchestration strategy matters: AgentArch (Bogavelli et al., 2025) shows that architectural preferences are model-dependent, with different designs benefiting different model scales. Prompt structure significantly affects tool-use behaviour, with structured and role-based prompts improving compliance (He et al., 2024; Zhang et al., 2024). Tool-description quality shapes tool selection and argument accuracy (Anthropic, 2024b), while long contexts can degrade performance over extended sessions (Liu et al., 2024; Levy et al., 2024). Although these factors have been studied independently, their combined effect in stateful, dependency-ordered environments remains underexplored.

3 Experimental Setup

3.1 MCP Server

We implement a Model Context Protocol (MCP) server that reproduces the state, data model, and dependency constraints of a proprietary hardware design tool through 14 callable tools (Table 1), where later calls may depend on earlier ones.

Group	Tools
Adder	`create_component`, `add_signal_port`, `add_transactional_port`, `add_user_parameter`, `add_generator_parameter`, `add_subcomponent`, `add_subcomponent_connection`
Getter	`get_component_details`, `get_element`, `list_components`
Other	`delete_element`, `delete_component`, `save_component`, `load_component`

Table 1: MCP server tool set.

3.2 Models

We evaluate seven open-source models, all running locally through Ollama (Ollama, 2024) as 4-bit quantised variants: Llama 3.1 8B (Grattafiori et al., 2024), Gemma 4 E4B, Gemma 4 26B, Gemma 4 31B (Google DeepMind, 2026), Qwen 3.5 27B (Qwen Team, Alibaba Cloud, 2026a), Qwen 3.6 27B (Qwen Team, Alibaba Cloud, 2026b), and GPT-OSS 20B (Agarwal et al., 2025). Models range from 4.9 GB (Llama 3.1 8B) to 20 GB (Gemma 4 31B, Qwen 3.6 27B) at Q4 quantisation. All runs use each model's default Ollama sampling temperature reflecting an out-of-the-box local deployment setting; Section 4.3 reports sensitivity checks at lower temperatures.

3.3 Agent Design

Agent architecture. We compare two architectures: **ReAct** (Yao et al., 2023), a single-agent loop issuing one tool call per turn, and **Plan-and-Act** (Erdogan et al., 2025), a multi-agent design in which a planner decomposes the request, a validator checks the plan, and independent ReAct workers execute the steps (sequence diagrams in Appendix A).

System prompt. Four ReAct variants are evaluated: **none** (tool schemas only), **basic** (role and behavioural constraints), **MD** (the same content in Markdown with structured headers), and **fewshot** (**basic** extended with worked task–call examples). For Plan-and-Act, planner and validator each have **basic** and **structured** variants; the worker uses a fixed prompt. Full prompt texts are provided in Appendix F.

Tool description format. Comprehensive descriptions specify each tool's purpose, parameter semantics, constraints, and failure conditions. **Minimal** descriptions reduce each tool to a single sentence, saving approximately 2,000 tokens across the 14 tools.

History scope. Under **run** scope, the full interaction history accumulates across all tasks in a session. Under **task** scope, each task starts with a fresh context.

3.4 Benchmark

We construct an expert-informed benchmark comprising six core task suites—Easy, Medium, Hard, History, Errors, and Cross—and two multi-server suites (Easy-Noise, Hard-Noise). Professional users of the design tool identified recurring hardware design operations, reviewed the task categories, and validated expected call sequences by executing them against the server. Task prompts reflect routine component-development operations. The full benchmark cannot be released because it encodes proprietary workflow details; representative examples are provided in Appendix B.

Independent tasks. (Appendix B.1–B.3) Easy, Medium, and Hard contain 40 self-contained tasks each and isolate the effect of task length: Easy requires 1 expected call, Medium requires 2, and Hard requires 3–5 calls with dependencies. Each prompt provides all required identifiers, such as the full VLNV of a component or the names of the ports being connected, so no information from prior turns is needed.

History. (Appendix B.4) History contains 40 tasks whose prompts omit entity identifiers and instead refer to prior tasks, for example, "Add the same port to the component created in the previous task." The agent must recover the relevant component and port information from earlier turns before acting.

Errors. (Appendix B.5–B.6) Errors contains 40 tasks. Twenty contain heavily misspelled prompts with the same intended content as Hard tasks, enabling a paired comparison of prompt noise. The remaining 20 describe requests for which the correct response is to make no tool call.

Cross. (Appendix B.7) Cross contains 40 tasks that combine dependency chains, cross-task references, pattern expansion, and error detection within a single multi-task session. For example, early tasks create components `sub1` and `sub2` with identical port sets; a later task asks to "create `sub3` like the others and wire it the same way"; and a final task requests an operation on a component that was never created, which the agent must reject rather than execute.

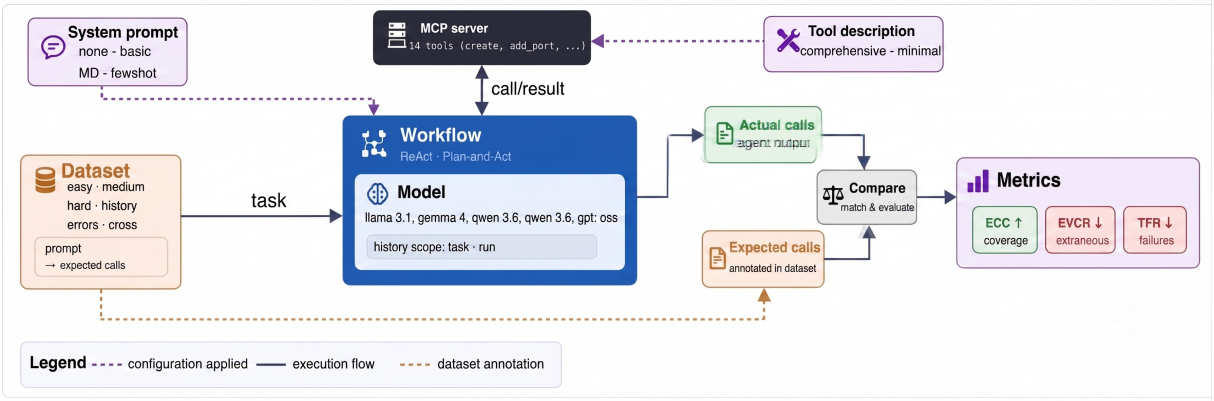

Figure 2: Evaluation pipeline. Each task prompt is submitted to the agent, which issues tool calls to the MCP server and receives results. The produced call sequence is compared against annotated expected calls to compute the metrics of Section 3.5.

Noisy context. (Appendix B.8) Noisy context contains two 60-task suites evaluated on three models. Each suite interleaves one external-server task after every two system design tasks while exposing the design server alongside GDB debugging[1] and Git version-control[2] MCP servers. **Easy-Noise** uses the 40 Easy tasks; **Hard-Noise** uses the 40 Hard tasks. Because the system design tasks are unchanged, the clean suites provide a paired baseline for measuring routing errors and long-session effects.

3.5 Evaluation Metrics

Evaluating stateful agents requires call-level metrics rather than textual output assessment (Yao et al., 2025; Gao et al., 2026). We define four complementary metrics, interpreted jointly.

Expected Call Coverage (ECC, ↑) measures how much of the annotated work was completed:

$$\mathrm{ECC} = \frac{|\text{correctly executed expected calls}|}{|\text{expected calls}|}. \quad (1)$$

A call matches an expected call if it succeeds with the expected tool name and all expected argument values; each expected call is consumed at most once. Matching is order-insensitive because dependency-order violations are enforced by the server, which rejects invalid calls; such failures are accounted for in TFR. Tasks with an empty expected call set are excluded from ECC aggregation.

Extraneous Valid Call Ratio (EVCR, ↓) measures over-generation, i.e., successful calls that were not requested:

$$\mathrm{EVCR} = \frac{|\text{successful non-expected calls}|}{|\text{successful calls}|} \quad (2)$$

If an agent issues no successful calls, EVCR is defined as 0 by convention.

Tool Failure Rate (TFR, ↓) measures the fraction of calls rejected by the server:

$$\mathrm{TFR} = \frac{|\text{failed calls}|}{|\text{total calls}|} \quad (3)$$

If an agent issues no calls, TFR is defined as 0.

No-Call Accuracy (NCA, ↑) measures correct abstention on tasks with an empty expected call set:

$$\mathrm{NCA} = \frac{|\text{empty-expected tasks with no tool call}|}{|\text{empty-expected tasks}|} \quad (4)$$

Evaluation protocol. Tasks are presented sequentially. After each task, we remove all mutations produced by the agent and restore the server to the canonical state for the next task by replaying the expected sequence of calls up to that task. This prevents one agent error from making later tasks impossible while preserving the intended state dependencies in History and Cross. Figure 2 illustrates the pipeline. For ReAct, all configuration combinations are evaluated on the six core suites (Easy through Cross); the noisy-context suites are evaluated on three representative models.

4 Results

4.1 Can Hardware Design Be Automated?

Table 2 reports, for each model, the ReAct configuration that maximises average ECC across the six

[1] https://github.com/signal-slot/mcp-gdb

[2] https://github.com/modelcontextprotocol/servers/tree/main/src/git

Figure 3: Best-configuration ECC per model and task suite under ReAct.

core task suites, together with the resulting EVCR and TFR. These numbers should be interpreted as best-observed performance under configuration search, not as out-of-the-box model performance. Plan-and-Act is considered separately below.

	Config	ECC ↑	EVCR ↓	TFR ↓
Gemma 4 31B	R/MD/C	0.990	0.015	0.011
Gemma 4 26B	R/MD/C	0.958	0.021	0.061
GPT-OSS 20B	R/none/C	0.951	0.073	0.049
Qwen 3.5 27B	R/MD/M	0.880	0.036	0.048
Qwen 3.6 27B	R/MD/M	0.858	0.086	0.065
Gemma 4 E4B	R/MD/C	0.811	0.023	0.058
Llama 3.1 8B	T/fs/C	0.554	0.064	0.353

Table 2: Best single ReAct configuration per model, averaged over the six core task suites and ordered by ECC. Config notation: history / prompt / tools, where R = run, T = task, C = comprehensive, M = minimal, fs = few-shot.

The aggregate hides a strong interaction between model and task structure. Figure 3 breaks down ECC by task suite: the model gap is small on simple tasks and widens as tasks require more state recovery and dependency management. Gemma 4 E4B stays within 6–21% of Gemma 4 31B on five of six task suites, but on Cross the gap widens to 47% (0.517 vs. 0.972). The same pattern appears within a single model: Llama 3.1 8B reaches 0.753 average ECC on the independent task suites (Easy, Medium, Hard), but only 0.139 on the two suites that require carrying state across tasks (History, Cross), an 82% drop.

Best configuration is itself workload-dependent. Table 2 reports the configuration that maximises average ECC across all six core suites, but for Llama 3.1 8B this global optimum gives only 0.113 ECC on History, whereas the History-specific optimum reaches 0.538. Even the globally best configuration is not reached automatically: under a poor configuration, Gemma 4 E4B drops from 0.811 to 0.168 ECC on the same tasks. Thus, model choice sets the broad performance range, but configuration determines whether a model reaches that range in practice.

Figure 3 omits two important failure modes. Table 3 reports both. First, the Errors suite includes 20 tasks with no correct tool call; for these tasks ECC is undefined, so we report NCA, EVCR, and TFR. Gemma 4 31B is nearly perfect, but other models either call unnecessary valid tools, issue failing calls, or both. Second, co-locating the design server with GDB and Git servers leaves ECC largely unchanged at matched configuration for the three models tested, but raises EVCR for all three, suggesting that a larger tool context mainly increases extraneous routing errors rather than reducing coverage.

	No-call (Errors)			Noise (Hard)	
	NCA	EVCR	TFR	clean	noisy
Gemma 4 31B	0.80	0.00	0.05	—	—
Gemma 4 26B	0.40	0.05	0.55	0.00	0.16
GPT-OSS 20B	0.25	0.58	0.13	—	—
Qwen 3.5 27B	0.70	0.15	0.17	—	—
Qwen 3.6 27B	0.45	0.20	0.37	—	—
Gemma 4 E4B	0.65	0.10	0.25	0.00	0.05
Llama 3.1 8B	0.00	0.25	0.82	0.12	0.22

Table 3: NCA, EVCR, and TFR on the 20 no-call tasks in Errors, at each model's best configuration. Right: EVCR on Hard vs. Hard-Noise under task scope and matched configuration for the three models tested. ECC changes are small and omitted for space.

Model and task structure are the two primary factors. The remaining results ask which agent-configuration choices still matter once those two are fixed.

4.2 How Much Does Agent Configuration Matter?

System prompt. Markdown-formatted instructions (MD) are the best prompt for five of the seven models, although the margin over none/basic is generally small (under 0.04 ECC). The main exception is few-shot prompting. For five models, few-shot changes ECC by at most 0.04 on average and often reduces EVCR and TFR; for Gemma 4 31B and Gemma 4 E4B, however, it causes severe inaction. Gemma 4 31B drops from 0.956 ECC with the best non-few-shot prompt to 0.571 with few-shot, and Gemma 4 E4B drops from 0.731 to 0.179. In both cases EVCR and TFR fall together with ECC, indi-

cating that the models stop acting rather than acting incorrectly. In this benchmark, prompt engineering has an asymmetric risk profile: gains over simpler prompts are modest for most models, while a poorly matched few-shot prompt can be catastrophic. Detailed prompt ablations are reported in Appendix D.1.

Tool descriptions. Comprehensive tool descriptions provide the most consistent configuration benefit. Holding all other choices fixed, switching to minimal descriptions raises TFR for every model, roughly doubling it for most. The effect on ECC is less uniform, but the reliability gain suggests that parameter semantics, constraints, and failure conditions help models construct valid calls. Across the 42 model–task-suite combinations in Figure 3, the configuration that maximises ECC on that suite uses comprehensive descriptions in 35 cases (83%). Each model's globally best configuration also uses comprehensive descriptions in five of seven cases. Full tool-description ablations are reported in Appendix D.2.

Context and history scope. On independent tasks, history scope has little effect for six of the seven models: ECC shifts by at most 0.031. Llama 3.1 8B is the exception. On Easy, Medium, and Hard, cumulative history cuts its ECC from 0.667 to 0.192, a 71% drop, while TFR also falls from 0.194 to 0.070. This pattern indicates silence rather than more frequent invalid calls. For constrained models, retaining irrelevant history can therefore be actively harmful. Full history-scope results are reported in Appendix D.3.

Architecture. Table 4 compares ReAct with Plan-and-Act using Gemma 4 26B as planner. This is a pipeline-level comparison: Plan-and-Act can improve weak workers partly by delegating decomposition to a stronger model. With Llama 3.1 8B as worker, decomposition raises average ECC from 0.554 to 0.718, with the largest gains on History and Cross. With Gemma 4 26B as worker on the same suites, decomposition does not help and reduces coverage, suggesting that strong single-agent workers benefit from retaining full session context. On longer Hard-Noise sessions under cumulative history, however, Plan-and-Act recovers coverage from 0.858 to 0.950 at the cost of higher EVCR. Thus, multi-agent decomposition is most useful when the worker is weak or the session is long enough for single-agent context accumulation to become a bottleneck.

Worker	Suite	ReAct	Plan-and-Act
Llama 3.1 8B	Avg. (6 core)	0.554	**0.718**
Llama 3.1 8B	History	0.113	**0.650**
Llama 3.1 8B	Cross	0.166	**0.450**
Gemma 4 26B	Hard-Noise (60)	0.858	**0.950**

Table 4: ECC under ReAct vs. Plan-and-Act, at each worker's best configuration (averaged over the six core suites). The Hard-Noise row uses a fixed run-scope configuration, isolating the effect of session length.

4.3 Stability

All main experiments use each model's default temperature (1.0, except 0.8 for Llama 3.1 8B). Re-running all configurations on three representative datasets across temperatures and repeating a subset of configurations under identical conditions confirms that the main effects are not artefacts of sampling. Across temperatures 0, 0.5, and 1.0, model rankings are preserved and ECC shifts remain small; for Gemma 4 26B, ECC ranges from 0.881 to 0.896. Run-to-run variance is low for Gemma 4 26B and moderate for weaker models; the largest outlier corresponds to the few-shot collapse described above. Full stability results are reported in Appendix C.

5 Conclusion

We evaluated whether LLM agents can automate expert-defined hardware design tasks through MCP tool calling. On our benchmark, the strongest open-source models achieve near-perfect expected-call coverage under their best configuration, including on multi-step sessions with implicit state and co-located GDB and Git servers.

Model choice primarily determines the achievable performance range, while system configuration determines whether that performance is actually reached in practice.

Our results suggest five deployment practices: test prompts on the target model; use comprehensive tool descriptions; benchmark models on workload-representative tasks; manage context for constrained models; and reserve multi-agent decomposition for weak workers or long sessions.

These findings indicate that local LLM agents are practical for structured, stateful hardware component-editing workflows when the tool-calling pipeline is appropriately configured.

6 Limitations

The main limitation is the scope of our context-management exploration. We tested only the binary choice between per-task and cumulative history; mechanisms such as a variable memory window—summarising or discarding older turns rather than retaining or dropping all of them—could potentially improve weaker models on session-dependent tasks, and our results hint at this but do not test it. Relatedly, our session-dependent datasets are limited to tens of tasks; longer sessions might reveal additional context-management effects for models beyond Llama 3.1 8B, which was the only model substantially harmed by cumulative history at this session length.

Second, EVCR counts extraneous successful calls but does not weight their severity: an unnecessary user parameter and an incorrect subcomponent connection contribute equally to the ratio, though the latter has far greater impact on design correctness. A severity-weighted variant is left for future work.

Third, we do not systematically measure response latency; model size (Section 3.2) is a rough proxy, with larger models such as Gemma 4 31B trading VRAM and speed for coverage. A direct latency measurement is left for future work.

Finally, the MCP server mirrors the data model and dependency rules of the proprietary design tool but does not call its production APIs; the results therefore characterise agent behaviour against a faithful replica, and some gap with production behaviour should be expected. Neither the server implementation nor the benchmark tasks can be released, as both encode proprietary component specifications and workflow details; Appendix B provides representative task examples to support methodological reproduction.

Acknowledgments

We thank Huawei for the opportunity to carry out this work during Leonardo's internship. We are especially grateful to Rahul Setia, Leonardo's supervisor at Huawei, for his guidance throughout the work, and to Johan Hokfelt for helping make this submission possible.

A Agent Architecture Diagrams

A.1 ReAct

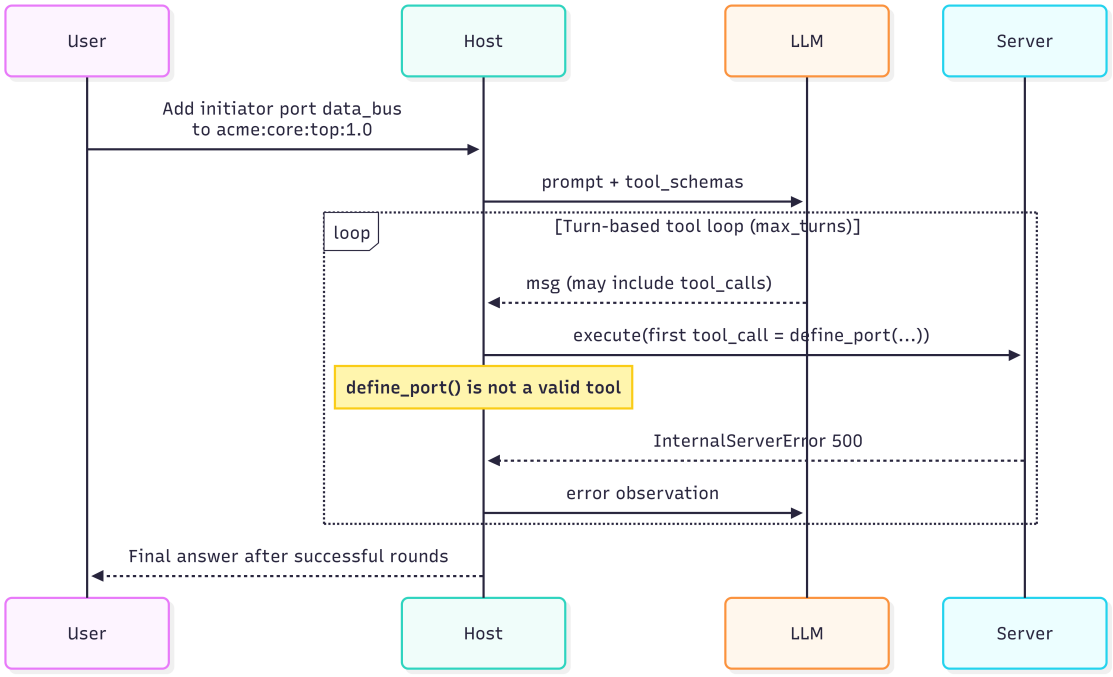

Figure 4: ReAct sequence diagram. The host submits the task prompt and tool schemas to the LLM. Within a turn-bounded loop, the LLM returns a response that may include a tool call; the host executes the first call, appends the result, and repeats. The loop terminates when no further tool call is produced or the turn limit is reached.

A.2 Plan-and-Act

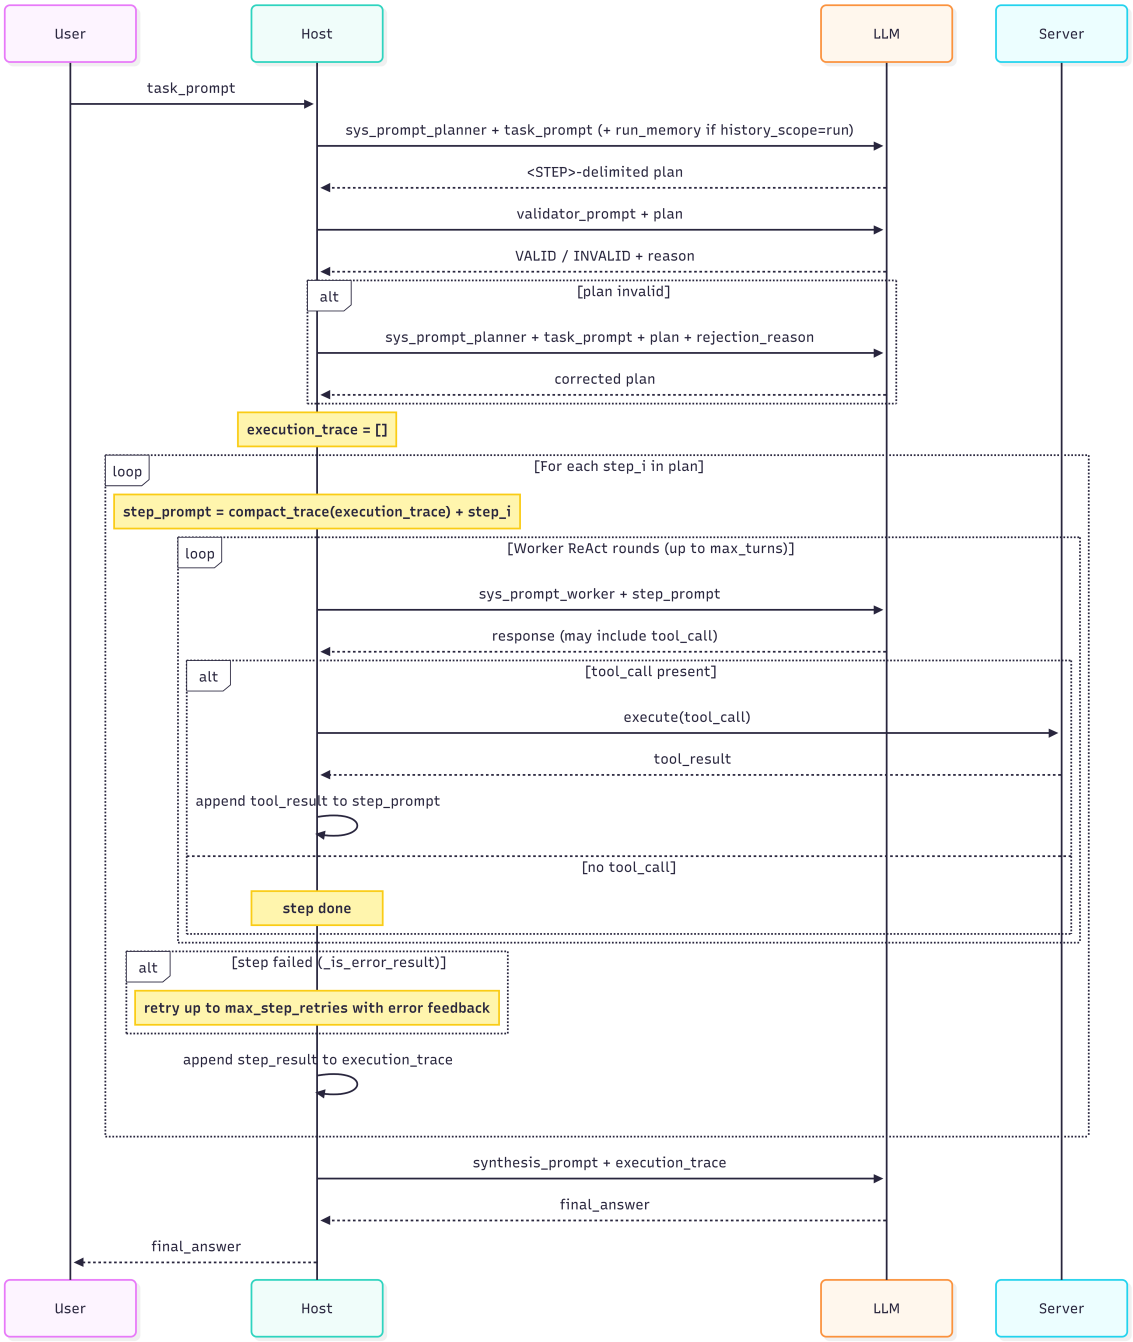

Figure 5: Plan-and-Act sequence diagram. The planner produces a <STEP>-delimited plan; the validator checks it with one replan permitted. Each step is executed by an independent ReAct worker with a compact trace of prior results. A synthesis call assembles the final answer.

B Task Examples

B.1 Easy

EASY_001

"Create a component with vendor acme, library core, name top, and version 1.0."

```
create_component(acme, core, top, 1.0)
```

EASY_002

"Add an input signal port named clk of width 1 to component acme:core:top:1.0."

```
[on acme:core:top:1.0]
add_signal_port(clk, in, w=1)
```

EASY_003

"Add an initiator transactional port named tx to component acme:core:top:1.0."

```
[on acme:core:top:1.0]
add_transactional_port(tx, initiator)
```

EASY_004

"Add an output signal port named data_out of width 8 to component acme:core:top:1.0."

```
[on acme:core:top:1.0]
add_signal_port(data_out, out, w=8)
```

EASY_005

"Add a user parameter named DATA_WIDTH of type integer with default value 32 to component acme:core:top:1.0."

```
[on acme:core:top:1.0]
add_user_parameter(DATA_WIDTH, integer,
=32)
```

B.2 Medium

MED_001

"Create a component riscv_core (vendor openhw, lib cpu, v 1.0) and add a transactional initiator port named data_bus."

```
create_component(openhw, cpu,
riscv_core, 1.0)
add_transactional_port(data_bus,
initiator)
```

MED_002

"The riscv_core also needs a clock input. Add a 1-bit input signal port named clk, then save."

```
[on openhw:cpu:riscv_core:1.0]
add_signal_port(clk, in, w=1)
save_component
```

MED_003

"Create a component sram (vendor openhw, lib mem, v 1.0) and add a transactional target port slave_port with a memory implementation called mem of 1024 bytes."

```
create_component(openhw, mem, sram,
1.0)
add_transactional_port(slave_port,
target, impl=memory, mem=mem,
bytes=1024)
```

MED_004

"Complete the sram component by adding a 1-bit input signal named clk, then save it."

```
[on openhw:mem:sram:1.0]
add_signal_port(clk, in, w=1)
save_component
```

B.3 Hard

HARD_001

"Let's start our SoC design by creating the main CPU. Please define a component named riscv_tile from vendor acme, library ip_cores, version 2.1.0. Add an initiator transactional port called m_axi for memory access and a signal input port for the clk with a width of 1 and multiplicity of 1. Finally, save the component to disk."

```
create_component(acme, ip_cores,
riscv_tile, 2.1.0)
add_transactional_port(m_axi,
initiator)
add_signal_port(clk, in, w=1)
save_component
```

HARD_002

"We need a memory controller now. Create sram_ctrl (vendor: acme, lib: mem, v: 1.0.0). It needs a target transactional port named s_axi using a memory implementation called mem of 30 bytes. Also, add a 1-bit input signal port for rst_n and a 1-bit input clk. Save it when done."

```
create_component(acme, mem, sram_ctrl,
1.0.0)
add_transactional_port(s_axi, target,
impl=memory, mem=mem, bytes=30)
add_signal_port(rst_n, in, w=1)
add_signal_port(clk, in, w=1)
save_component
```

HARD_003

"Let's define a system interconnect component named axi_interconnect (vendor: acme, lib: bus, v: 1.1). Add one initiator transactional port m0_port and two target transactional ports s0_port and s1_port with user_defined implementation. Then save the component."

```
create_component(acme, bus,
axi_interconnect, 1.1)
add_transactional_port(m0_port,
```

```
initiator)
add_transactional_port(s0_port, target,
impl=user_defined)
add_transactional_port(s1_port, target,
impl=user_defined)
save_component
```

B.4 History

Tasks run in session order; later tasks omit identifiers and must recover them from earlier turns.

HIST_001

"Create a RISC-V core openhw:cpu:riscv_v5:1.0 and add a transactional initiator port data_master."

```
create_component(openhw, cpu, riscv_v5,
1.0)
add_transactional_port(data_master,
initiator)
```

HIST_002

"Add another transactional initiator port called instr_master."

Note: no id given; recover openhw:cpu:riscv_v5:1.0 from HIST_001.

[on openhw:cpu:riscv_v5:1.0]

```
add_transactional_port(instr_master,
initiator)
```

HIST_003

"Create system_sram (generic, mem, 2.1) with a target port mem_port, memory mem, 65536 bytes."

```
create_component(generic, mem,
system_sram, 2.1)
add_transactional_port(mem_port,
target, impl=memory, mem=mem,
bytes=65536)
```

HIST_004

"Create axi_interconnect (generic, bus, 1.0) and add a user_defined target port slave_0."

```
create_component(generic, bus,
axi_interconnect, 1.0)
add_transactional_port(slave_0, target,
impl=user_defined)
```

HIST_005

"Go back to the RISC-V core. Add a 1-bit input clock and a 1-bit input reset_n."

Note: "the RISC-V core" = openhw:cpu:riscv_v5:1.0 from HIST_001.

[on openhw:cpu:riscv_v5:1.0]

```
add_signal_port(clock, in, w=1)
add_signal_port(reset_n, in, w=1)
```

B.5 Errors — misspelled vs. clean

Each misspelled Errors prompt mirrors a Hard prompt with heavy orthographic noise but identical intent. The pairs below share the same expected calls, isolating the effect of prompt noise.

HARD_001 vs ERR_001

Clean (Hard):

"*Let's start our SoC design by creating the main CPU. Please define a component named riscv_tile from vendor acme, library ip_cores, version 2.1.0. Add an initiator transactional port called m_axi and a signal input port for clk with width 1 and multiplicity 1. Finally, save the component to disk.*"

Misspelled (Errors):

"*Let's start our SoC design by cretaing the main CPU. Please defnie a compnnt named riscv_tile from vendor acme, library ip_cores, version 2.1.0. Add an initator transactonal prt called m_axi and a siganl inpt prt for clk with width 1 and multiplicty 1. Finally, saev the compnnt to disk.*"

Identical expected calls:

```
create_component(acme, ip_cores,
riscv_tile, 2.1.0)
add_transactional_port(m_axi,
initiator)
add_signal_port(clk, in, w=1)
save_component
```

HARD_002 vs ERR_002

Clean (Hard):

"*We need a memory controller now. Create sram_ctrl (acme, mem, 1.0.0). It needs a target transactional port named s_axi using a memory implementation called mem of 30 bytes. Also add a 1-bit input signal port for rst_n and a 1-bit input clk. Save it when done.*"

Misspelled (Errors):

"*We need a memroy controller now. Cretae sram_ctrl (acme, mem, 1.0.0). It needs a trgt transactinal prt named s_axi usng a memroy implmentation called mem of 30 bytes. Also add a 1-bit input siganl prt for rst_n and a 1-bit input clk. Saev it when done.*"

Identical expected calls:

```
create_component(acme, mem, sram_ctrl,
1.0.0)
add_transactional_port(s_axi, target,
impl=memory, mem=mem, bytes=30)
add_signal_port(rst_n, in, w=1)
add_signal_port(clk, in, w=1)
save_component
```

HARD_003 vs ERR_003

Clean (Hard):

"Let's define a system interconnect component named axi_interconnect (acme, bus, 1.1). Add one initiator transactional port m0_port and two target transactional ports s0_port and s1_port with user_defined implementation. Then save the component."

Misspelled (Errors):

"Let's defnie a system interconect compnent axi_interconnect (acme, bus, 1.1). Add one initator transactonal prt m0_port and two trgt transactonal prts s0_port and s1_port with user_defned implmentation. Then saev the compnent."

Identical expected calls:

```
create_component(acme, bus,
axi_interconnect, 1.1)
add_transactional_port(m0_port,
initiator)
add_transactional_port(s0_port, target,
impl=user_defined)
add_transactional_port(s1_port, target,
impl=user_defined)
save_component
```

B.6 Errors — no-call

The correct behaviour is to issue no call and explain why.

ERR_004

"Create a new component for our DMA block with vendor acme, library interconnect, name dma."

no call — `version is required but missing; cannot be inferred.`

ERR_005

"Add a signal port called irq to component acme:cpu:core:1.0."

no call — `direction and width missing; component also absent from state.`

ERR_006

"On component acme:mem:sram_ctrl:2.1, add a transactional port named cfg as a target backed by memory."

no call — `memory implementation needs a memory name and size; neither given.`

ERR_007

"Save the component."

no call — `no component identified.`

ERR_008

"Add a subcomponent named cpu0 into acme:accel:fft:3.0."

no call — `child_component_id (what to instantiate) is missing.`

B.7 Cross

CROSS_001

"Create four CPU shells (vendor Comp, library egg, version 1.0, names cpu1..cpu4)."

```
create_component(Comp, egg, cpu1, 1.0)
create_component(Comp, egg, cpu2, 1.0)
create_component(Comp, egg, cpu3, 1.0)
create_component(Comp, egg, cpu4, 1.0)
```

CROSS_002

"To all components, add a single input signal port called p1."

Note: "all" = cpu1..cpu4 from CROSS_001 (one call each).

```
add_signal_port(p1, in, w=1)
add_signal_port(p1, in, w=1)
add_signal_port(p1, in, w=1)
add_signal_port(p1, in, w=1)
```

CROSS_003

"In cpu4 add transactional initiator ports ibus1..ibus4."

[on Comp:egg:cpu4:1.0]

```
add_transactional_port(ibus1,
initiator)
add_transactional_port(ibus2,
initiator)
add_transactional_port(ibus3,
initiator)
add_transactional_port(ibus4,
initiator)
```

CROSS_004

"To cpu1, add subcomponents: cpu2 as sub1, cpu3 as sub2, cpu4 as sub3."

[on Comp:egg:cpu1:1.0]

```
add_subcomponent(cpu2 as sub1)
add_subcomponent(cpu3 as sub2)
add_subcomponent(cpu4 as sub3)
```

CROSS_005

"Add to it also the same initiator ports of cpu4."

Note: "it"=cpu1; replicate cpu4's ibus1..ibus4 (from CROSS_003).

[on Comp:egg:cpu1:1.0]

```
add_transactional_port(ibus1,
initiator)
add_transactional_port(ibus2,
initiator)
add_transactional_port(ibus3,
initiator)
```

```
add_transactional_port(ibus4,
initiator)
```

CROSS_006

"Hook all ibus ports in sub3 to the same-named ports of the parent (cpu1)."

Note: sub3 is an instance of cpu4 (CROSS_004), which has ibus1..ibus4.

[on Comp:egg:cpu1:1.0]

```
connect(sub3.ibus1 ->
hierarchical.ibus1)
connect(sub3.ibus2 ->
hierarchical.ibus2)
connect(sub3.ibus3 ->
hierarchical.ibus3)
connect(sub3.ibus4 ->
hierarchical.ibus4)
```

B.8 Noisy context

Every two design tasks, one external-server (Git or GDB) task is inserted; the agent must route to the right server. Routing mistakes surface as EVCR, not ECC.

EASY_NOISE_IPXACT_001

"Create a component with vendor acme, library core, name top, version 1.0."

```
create_component(acme, core, top, 1.0)
```

EASY_NOISE_GIT_001

"Show the last 5 commits in the repository at /home/user/.../dummy_repo."

```
git_log(repo, max_count=5)
```

EASY_NOISE_IPXACT_002

"Add an input signal port named clk of width 1 to component acme:core:top:1.0."

[on acme:core:top:1.0]

```
add_signal_port(clk, in, w=1)
```

EASY_NOISE_GDB_001

"Start a new debugging session."

```
gdb_start()
```

HARD_NOISE_IPXACT_001

"(same as HARD_001: create riscv_tile, add m_axi and clk, save)."

```
create_component(acme, ip_cores,
riscv_tile, 2.1.0)
add_transactional_port(m_axi,
initiator)
add_signal_port(clk, in, w=1)
save_component
```

HARD_NOISE_GIT_001

"List all remote branches in the repository at /home/user/.../dummy_repo."

```
git_branch(repo, remote)
```

HARD_NOISE_GDB_001

"Show the source at the current execution point in debugging session 1."

```
gdb_list_source(session=1)
```

C Stability Experiments

C.1 Temperature Sweep

	$T = 0$			$T = 0.5$			T=**default**		
Model	ECC	EVCR	TFR	ECC	EVCR	TFR	ECC	EVCR	TFR
Gemma 4 26B	0.896	0.055	0.094	0.889	0.055	0.111	**0.881**	0.056	**0.105**
Gemma 4 E4B	0.539	0.044	0.129	0.523	0.042	0.127	**0.553**	0.046	0.144
Llama 3.1 8B	**0.247**	0.058	0.268	0.235	0.052	**0.264**	0.243	0.056	0.268

Table 5: ECC, EVCR, and TFR across temperatures 0, 0.5, and each model's default (1.0, except 0.8 for Llama 3.1 8B), averaged over the three datasets covered by the sweep (Cross, Errors, Hard) and over all 16 system-prompt × tool-description × history-scope configurations per model. Rankings and absolute performance are stable across temperatures for every model; lowering temperature does not consistently reduce TFR.

C.2 Run-to-Run Variance

Model	$\bar{\sigma}_{\mathrm{ECC}}$	$\sigma_{\max,\mathrm{ECC}}$
Gemma 4 26B	**0.025**	0.076
Llama 3.1 8B	0.051	0.219
Gemma 4 E4B	0.059	**0.494**

Table 6: Mean and maximum standard deviation of ECC across two repeated runs of every system-prompt × tool-description × history-scope configuration (16 per model), on Cross, Errors, and Hard — the three most demanding suites. The Gemma 4 E4B outlier ($\sigma_{\max} = 0.494$) is the `run`-scope, few-shot, minimal-tools configuration, the same one responsible for the few-shot collapse reported in Section 4.2, confirming that effect is genuine rather than a sampling artefact.

All configurations, hardest suites (2 runs each).

Model	**Config**	ECC	EVCR	TFR
Gemma 4 26B	best	**0.973**	0.027	**0.013**
Gemma 4 26B	worst	0.829	**0.017**	0.067
Llama 3.1 8B	best	**0.495**	0.106	0.291
Llama 3.1 8B	worst	0.034	**0.001**	**0.028**

Table 7: Mean ECC, EVCR, and TFR across 10 repeated runs of each model's best and worst configuration, averaged over all six core suites. Standard deviations of ECC across runs: 0.008 (Gemma best), 0.038 (Gemma worst), 0.033 (Llama best), 0.109 (Llama worst) — the latter driven by near-total collapse (9 of 10 runs at ECC ≈ 0) rather than ordinary run-to-run noise.

Best/worst configuration, repeated subset (10 runs each).

D Additional Configuration Results

D.1 Prompt Ablations

	none			basic			MD			few-shot		
Model	ECC	EVCR	TFR	ECC	EVCR	TFR	ECC	EVCR	TFR	ECC	EVCR	TFR
Gemma 4 31B	0.935	0.039	0.076	0.913	0.010	0.056	**0.956**	0.021	0.061	0.571	0.006	0.032
Gemma 4 26B	0.907	0.044	0.086	0.910	0.020	0.063	**0.938**	0.027	0.063	0.897	0.034	0.071
GPT-OSS 20B	**0.861**	0.078	0.104	0.784	0.030	0.068	0.859	0.042	0.061	0.741	0.030	0.072
Qwen 3.5 27B	0.847	0.063	0.068	0.827	0.031	0.058	**0.852**	0.034	0.057	0.825	0.032	0.054
Qwen 3.6 27B	0.839	0.063	0.106	0.798	0.030	0.063	**0.853**	0.058	0.060	0.801	0.036	0.056
Gemma 4 E4B	0.675	0.036	0.148	0.694	0.031	0.124	**0.731**	0.026	0.135	0.179	0.016	0.072
Llama 3.1 8B	0.293	0.031	0.301	0.284	0.049	0.255	0.290	0.056	0.229	**0.339**	0.034	0.211

Table 8: System-prompt ablation, averaged over the six core suites, tool-description formats, and history scopes. The few-shot collapse for Gemma 4 31B ($0.956 \rightarrow 0.571$) and Gemma 4 E4B ($0.731 \rightarrow 0.179$) is visible as a coverage drop with EVCR and TFR falling together (inaction, not error).

D.2 Tool-Description Ablations

	comprehensive			minimal		
Model	ECC	EVCR	TFR	ECC	EVCR	TFR
Gemma 4 31B	0.819	0.019	0.031	**0.868**	0.020	0.081
Gemma 4 26B	**0.932**	0.028	0.048	0.894	0.034	0.093
GPT-OSS 20B	**0.859**	0.046	0.057	0.764	0.044	0.096
Qwen 3.5 27B	**0.845**	0.034	0.040	0.830	0.046	0.078
Qwen 3.6 27B	**0.823**	0.037	0.046	0.822	0.057	0.097
Gemma 4 E4B	**0.610**	0.028	0.073	0.530	0.026	0.167
Llama 3.1 8B	**0.312**	0.050	0.225	0.290	0.035	0.273

Table 9: Tool-description ablation, averaged over the six core suites, system prompts, and history scopes. Minimal descriptions raise TFR for every model (roughly doubling it in most cases); the ECC effect is less uniform.

D.3 History-Scope Ablations

	run			task		
Model	ECC	EVCR	TFR	ECC	EVCR	TFR
Gemma 4 31B	**0.858**	0.014	0.037	0.829	0.024	0.075
Gemma 4 26B	**0.918**	0.029	0.071	0.909	0.034	0.071
GPT-OSS 20B	**0.862**	0.051	0.061	0.760	0.039	0.091
Qwen 3.5 27B	**0.864**	0.047	0.038	0.811	0.033	0.081
Qwen 3.6 27B	**0.823**	0.051	0.060	0.822	0.042	0.083
Gemma 4 E4B	**0.621**	0.031	0.125	0.519	0.023	0.115
Llama 3.1 8B	0.157	0.015	0.084	**0.445**	0.070	0.413

Table 10: History-scope ablation, averaged over the six core suites, system prompts, and tool-description formats. Llama 3.1 8B is the only model that prefers per-task scope; all others tolerate or benefit from cumulative history at this session length.

E Tool Description Example

The following shows the `add_signal_port` tool in both description formats.

`add_signal_port --- comprehensive`

Add a signal port to an existing component.
The component must already exist and the port name must be unique. Direction must be 'in', 'out', or 'inout'. Width and multiplicity must be greater than zero. Default multiplicity value is 1.
On success, the new signal port becomes available for future connections.

`add_signal_port --- minimal`

Add a signal port to a component.

F System Prompts

All prompts are reproduced verbatim. Section F.1 contains the ReAct system prompts (`none`, `basic`, `MD`, `fewshot`). Section F.2 contains the Plan-and-Act stage prompts: planner (`basic`, `structured`), validator (`basic`, `structured`), and worker (fixed).

F.1 ReAct Prompts

`none`

No system prompt. The model receives only the task instruction and the tool schemas.

`basic`

You are an autonomous system-design agent operating in a tool-enabled environment. The server exposes tools that create, inspect, connect, delete, load, and persist components and their internal elements.

If the user requests creation, modification, connection, deletion, loading, or persistence of components or elements, you MUST call the appropriate tool when all required arguments are available.

If the user asks to rename or edit an element and there is no direct update tool for that operation, treat the request as deleting the existing element and recreating the same element with the requested change, while keeping all other retrievable fields unchanged. For example, changing the multiplicity of a signal port means deleting that port and recreating it with the new multiplicity and the same remaining attributes.

If the request appears incomplete, then follow this rule: if you are confident that the request contains a conceptual error, do NOT call any tool and explain the problem; if you are unsure, first use inspection tools (e.g., list_components, get_component_details, or get_element) and then decide how to proceed.

If some required tool arguments are missing after relevant inspection, DO NOT invent values and DO NOT call the tool. Instead, inform the user which required fields are missing.

You MUST NOT respond in natural language when a tool can be correctly used.

`MD`

Role
You are an autonomous design agent operating in a tool-enabled environment. The server exposes tools that create, inspect, connect, delete, load, and persist components and their elements.

Behavior
- Call one tool per turn.
- Do not invent argument values. Use only values stated in the task or retrieved from tools.
- If required arguments are missing after inspection, do not call the tool.
- Complete all operations stated in the task — do not stop after the first tool call.
- If the request is invalid or impossible, say so clearly without calling any tool.

Hierarchical connections
Use ”hierarchical” as the instance name only when the endpoint is a top-level port of the parent component itself, not a port of a subcomponent.

Invalid tool calls
If a tool call fails, do not retry with the same arguments. Read the error message and adjust before trying again.

`fewshot`

You are an autonomous system-design agent operating in a tool-enabled environment. The server exposes tools that create, inspect, connect, delete, load, and persist components and their elements. If the user requests creation, modification, connection, deletion, loading, or persistence of components or elements, you MUST call the appropriate tool when all required arguments are available. If required arguments are missing after inspection, do NOT invent values — inform the user instead. You MUST NOT respond in natural language when a tool can be correctly used.

—

EXAMPLE 1 — Apply the same operation to every component listed. Do not stop early.

User: Add a 1-bit input signal port named clk to each of these components: nordic:rf:tx_core:1.0, nordic:rf:rx_core:1.0, nordic:rf:pll:1.0.

[calls add_signal_port: component_id=nordic:rf:tx_core:1.0,port_name=clk, direction=in,width=1,multiplicity=1]
Tool: {”ok”: true}
[calls add_signal_port: component_id=nordic:rf:rx_core:1.0,port_name=clk, direction=in,width=1,multiplicity=1]
Tool: {”ok”: true}
[calls add_signal_port: component_id=nordic:rf:pll:1.0, port_name=clk,direction=in,width=1,multiplicity=1]
Tool: {”ok”: true}
A: Done. Port clk added to all three components.

—

EXAMPLE 2 — When a task has multiple distinct operations, complete all of them.

User: Inside arm:soc:top:2.0, connect cpu_inst’s axi_out port to bus_inst’s axi_in. Also connect the top-level sys_rst signal to cpu_inst’s rst_n. Then save.

[calls add_subcomponent_connection: parent_component_id=arm:soc:top:2.0, from_instance=cpu_inst,from_port=axi_out, to_instance=bus_inst,to_port=axi_in]
Tool: {”ok”: true}
[calls add_subcomponent_connection: parent_component_id=arm:soc:top:2.0, from_instance=hierarchical,from_port=sys_rst, to_instance=cpu_inst,to_port=rst_n]
Tool: {”ok”: true}
[calls save_component: component_id=arm:soc:top:2.0]
Tool: {”ok”: true}
A: Both connections established and component saved.

—

EXAMPLE 3 — The `"hierarchical"` instance name.

`"hierarchical"` refers exclusively to a port that belongs to the parent component itself, not to any subcomponent. Use it when wiring a top-level port down to a subcomponent, or up from a subcomponent to the top level. Never use it to connect two subcomponent instances to each other.

User: In risc:sys:chip_top:1.0, wire the top-level ext_irq input down to irq_ctrl_inst's irq_in port. Then wire irq_ctrl_inst's status_out up to the top-level debug_out port.

[calls add_subcomponent_connection: parent_component_id=risc:sys:chip_top:1.0, from_instance=hierarchical,from_port=ext_irq, to_instance=irq_ctrl_inst,to_port=irq_in]
Tool: {"ok": true}
[calls add_subcomponent_connection: parent_component_id=risc:sys:chip_top:1.0, from_instance=irq_ctrl_inst,from_port=status_out, to_instance=hierarchical,to_port=debug_out]
Tool: {"ok": true}
A: Both hierarchical connections established.

—

EXAMPLE 4 — If add_subcomponent_connection fails, do NOT modify child components or retry with guessed port names. Check get_component_details on the parent to verify what subcomponents and connections exist, then report what is missing. Do not invent ports or restructure components to force a connection.

User: In mips:platform:board:3.0, connect dma_inst's mem_req port to ram_inst's mem_ack port.

[calls add_subcomponent_connection: parent_component_id=mips:platform:board:3.0, from_instance=dma_inst,from_port=mem_req, to_instance=ram_inst,to_port=mem_ack]
Tool: {"ok": false, "error": {"code": "invalid_source_port", "message": "Port mem_req not found on instance dma_inst."}}
[calls get_component_details: component_id=mips:platform:board:3.0]
Tool: {"ok": true, "subcomponents": ["dma_inst", "ram_inst"], "connections": []}
A: The connection failed because port mem_req does not exist on dma_inst. I cannot create the connection. Please verify the correct port names on dma_inst and ram_inst.

—

Apply these patterns to every task. Always apply an operation to every component or element the task specifies — do not stop early. Always complete every distinct operation in the task before finishing. Always call save_component after structural changes when the task requests persistence. Use "hierarchical" only for ports that belong to the parent component itself. If a connection fails, inspect the parent with get_component_details and report what is missing — do not modify child components or invent port names.

F.2 Plan-and-Act Prompts

Planner basic

You are a planning agent responsible for decomposing a user request into a sequence of executable steps. Each step will be executed by a separate worker agent that has access to the following tools: {tools}

RULES:
- Each step must correspond to exactly ONE tool call.
- Steps must be ordered so that any value produced by step N is available to step N+1.
- If a step produces an identifier, name, or value that a later step needs, say so explicitly in that later step (e.g. 'using the component ID returned in the previous step').
- Preserve all identifiers, names, and parameters from the user request exactly as given.
- Do not invent missing values.
- Avoid pronouns like 'it' or 'that' — always repeat the full name or identifier.
- If the task requires only one tool call, output one step.

OUTPUT FORMAT:
- Write steps in natural language.
- Separate steps with the token <STEP> placed at the END of each step, including the last one.
- Do not number the steps.
- Do not add any preamble, explanation, or summary — output only the steps.

Example for a two-step task:
Create a component with id riscv_core, vendor openhw, library cpu, and version 1.0.<STEP>
Add a port named data_bus to the component with id riscv_core, using protocol transactional and port type initiator.<STEP>

Planner structured

You are a planning agent. Your job is to decompose a user request into a sequence of atomic steps, each executed by a separate worker agent. The worker has access to these tools — use them to understand what operations are possible, but write your steps in plain natural language describing the action, not the tool call: {tools}

STEP RULES:
- Each step must correspond to exactly ONE tool call.
- If a task needs 4 tool calls, write 4 steps. Never collapse multiple tool calls into one step.
- Order steps so that any value produced by step N is available to step N+1.
- When a later step needs an ID or value from an earlier step, say so explicitly (e.g. 'using the component ID returned in step 1').
- Copy all identifiers, names, and parameters from the user request exactly.
- Do not invent missing values.
- Never use pronouns like 'it' or 'that' — always repeat the full name.

RENAME AND EDIT OPERATIONS:
- There is no rename or update tool. Any request to rename or change a field of an existing element must be planned as: retrieve, delete, recreate.
- If the current field values are not given in the task, add a step to retrieve the element with get_element before the delete step.
- The recreate step must preserve all fields unchanged except the one being modified.
- Example: renaming signal port p2 to p_out on component X:
1. Retrieve port p2 from component X to get its current fields.<STEP>
2. Delete port p2 from component X.<STEP>
3. Add a signal port named p_out to component X with the same direction, width, and multiplicity as retrieved in step 1.<STEP>

INSPECT-BEFORE-CONNECT:
- If the instance names or port names needed for a connection step are not already known from the task description or prior steps, include a prior step that retrieves the component details first.
- Never guess or assume instance or port names.

THE "hierarchical" INSTANCE NAME — READ CAREFULLY:
- "hierarchical" is a reserved instance name meaning the

parent component itself, not any subcomponent instance.
- Use it ONLY when one endpoint of a connection is a port that belongs directly to the parent component.
- CORRECT: connecting subcomponent sub3 port ibus1 outward to the parent's own port ibus1:
from_instance="sub3",from_port="ibus1",
to_instance="hierarchical",to_port="ibus1"
- WRONG: connecting subcomponent bus_inst to subcomponent ram_inst:
WRONG: from_instance="hierarchical", from_port="m0_port",to_instance="ram_inst", to_port="s_axi"
RIGHT: from_instance="bus_inst",from_port="m0_port", to_instance="ram_inst",to_port="s_axi"

PURE-INSPECTION OR ERROR TASKS:
- If the task only requires reading or reporting state with no mutations, output zero steps.
- If the task references elements that do not exist, output zero steps.
- A plan with zero <STEP> tokens is valid.

OUTPUT FORMAT:
- Write steps in plain natural language.
- End every step, including the last, with the token <STEP>.
- Do not number steps.
- Do not add any preamble, heading, explanation, or summary.
- If the plan is empty, output nothing at all.

Validator basic

You are validating a plan for the following task: {task_prompt}
Available tools: {tool_names}
Plan to validate: {plan_text}

Check the plan against these criteria:
1. Every step maps to at least one available tool.
2. No step invents arguments not present in the task or derivable from prior steps.
3. Steps are in a logical order (no step depends on a result not yet produced).
4. No steps are duplicated or contradictory.

If the plan passes all criteria, respond with exactly: VALID
If it fails any criterion, respond with: INVALID: <brief reason>

Validator structured

You are validating a plan for the following task: {task_prompt}
Available operations (the worker uses these tools): {tool_names}
Plan to validate: {plan_text}

VALIDATION RULES:

1. TOOL COVERAGE — each step must describe an action that is achievable with at least one of the available tools. Steps are written in natural language: do not require them to contain the exact tool name.

2. ARGUMENT VALIDITY — no step may invent an argument value that is neither given in the task nor derivable from the result of a prior step. Cross-step references such as 'using the component ID returned in the previous step' are explicitly allowed and correct.

3. ORDERING — steps must be in a logical sequence where prerequisites come before the operations that depend on them. Do NOT reject a step merely because it references a value produced by an earlier step.

4. NO INVENTED REQUIREMENTS — only reject the plan for what it does wrong or omits relative to the task. Do not add requirements that are not in the task.

5. EMPTY PLAN — a plan with no steps is valid when the task requires no mutations. Do not reject an empty plan solely because it has no steps.

Respond with exactly one of:
VALID
INVALID: <one concise reason referencing the specific step or argument that fails>

Worker prompt (fixed, not an experimental axis)

You are an execution agent operating in a tool-enabled environment. You are executing exactly ONE step of a larger plan.

Your context contains:
- Results from previous steps (if any) — use those values directly, do not re-derive them.
- The current step you must execute.

SCOPE RULES:
- Execute ONLY what the current step explicitly describes. Nothing more.
- Do NOT inspect components, add ports, modify state, or call any tool that the step does not explicitly request.
- Do NOT attempt to fix or improve results from previous steps.
- If the step says to retrieve component details, call that tool only and report what it returned. Do not act further on the result.
- Call at most one tool per step unless the step explicitly lists two actions.

ARGUMENT RULES:
- Use only argument values stated in the step or present in prior step results.
- Do not invent, guess, or supply default values for missing arguments.
- If a required argument is missing, do NOT call the tool. Report which argument is missing.

RENAME AND EDIT OPERATIONS:
- There is no rename or update tool. If the step says to rename or edit an element, execute it as delete followed by recreate.
- Use only the field values present in the step or prior step results — never drop unaffected fields when recreating.

THE "hierarchical" INSTANCE NAME:
- "hierarchical" means the parent component itself, not a subcomponent.
- Use it only when the step explicitly says the endpoint is a top-level port of the parent component.
- If a step connects two subcomponent instances to each other, use their real instance names — never use "hierarchical" for a subcomponent endpoint.

ON FAILURE:
- If the tool returns an error, do NOT retry with the same or arbitrarily varied arguments.
- Only retry if the error message gives clear actionable information about what to correct.
- If the error does not give enough information to fix the call, report failure immediately.

After the tool call completes, write exactly one line:
Step result: <what was done and the key output value, e.g. an ID or status>
On failure, write exactly:
Step result: FAILED — <reason from the tool response>

> Do not write anything beyond that line.

From Synthetic to Localized: Benchmarking Multilingual Intent Classification in Logistics Customer Service

Haoyu He[1,2*] **Jinyu Zhuang**[1] **Haoran Chu**[1,2*]

{hehy12024,chuhr2023,wanghao1}@shanghaitech.edu.cn

Abstract

Multilingual intent classification is central to logistics customer-service systems, where models must handle noisy user queries across languages and hierarchical labels. Yet many multilingual benchmarks rely on machine-translated text, which is cleaner than real customer requests and can overestimate robustness. We present a public benchmark for hierarchical multilingual intent classification from real logistics logs: approximately 30K de-identified, single-utterance queries curated from 600K records through filtering, LLM-assisted quality control, human privacy review, and sampled label auditing. The dataset uses a two-level taxonomy with 13 parent and 17 leaf intents; English, Spanish, and Arabic are seen languages, while Indonesian, Chinese, and Thai support zero-shot evaluation. To measure the gap between machine-translated and professionally localized evaluation, we provide paired test sets derived from the same source items. We benchmark multilingual encoders, embedding models, and small language models under flat and hierarchical protocols, and find that machine translation tests yield higher accuracy in most settings. [1]

1 Introduction

Intent classification is a core problem in natural language understanding and underpins many interactive systems, including customer-service automation, virtual assistants, and tool-using language models (Larson et al., 2019; Casanueva et al., 2020; Schick et al., 2023). In multilingual customer-service settings, the task is especially challenging: semantically equivalent intents may be expressed differently across languages and dialects, while real user queries are often short, noisy, domain-specific, and unevenly distributed across labels. On global logistics platforms, systems must route requests about tracking, delivery failures, address changes, refunds, claims, fees, and branch availability, often under hierarchical label taxonomies (Schuster et al., 2019; Gung et al., 2023; Plaud et al., 2024).

Existing multilingual benchmarks only partly reflect these conditions. MTOP and MASSIVE provide broad language coverage, but much of their multilingual data comes from machine translation or controlled collection rather than naturally occurring customer requests (Li et al., 2021; FitzGerald et al., 2023). Customer-service datasets are closer in domain, but often target multi-turn dialogue, sentiment, search, or matching rather than standalone hierarchical intent routing (Chen et al., 2021; Gung et al., 2023; Wang et al., 2025). Thus, current benchmarks may underrepresent the lexical variability, shorthand, code-mixing, and long-tail distributions of production traffic (Artetxe et al., 2023; Dutta Chowdhury et al., 2022).

This mismatch also affects evaluation. Machine-translated test sets are typically more standardized than professionally localized text and may therefore yield overly optimistic estimates of multilingual robustness (Artetxe et al., 2023; Dutta Chowdhury et al., 2022). This issue is particularly important for logistics customer service, where small differences in phrasing can change whether a request should be routed to tracking, delivery change, service scope, fee, or claim workflows.

We introduce a public benchmark for multilingual intent classification built from real logistics customer-service logs. The dataset contains approximately 30K de-identified labeled training utterances curated from roughly 600K historical records through rule-based filtering, LLM-assisted quality

control, human privacy screening, and a sampled label audit. It is organized into a partially hierarchical taxonomy with 13 parent intents and 17 leaf intents: nine parents map to one leaf, while four parents contain eight leaves. English, Spanish, and Arabic are included as seen languages, while Indonesian, Chinese, and Thai are reserved as test-only languages for zero-shot evaluation. Because the benchmark is derived from naturally occurring, stand-alone user queries used for routing, it preserves the noise and distributional properties of real customer-service traffic.

We also benchmark the gap between machine translation and professional localization, alongside zero-shot transfer, across multilingual encoders, embedding models, and small language models under flat and parent-constrained protocols. Machine translation scores 1.3 accuracy points higher on average across 45 model-language-task settings, with a 95% bootstrap interval of $[0.159, 2.479]$ over test items.

In summary, our contributions are as follows:

- We release a public real-world benchmark for multilingual intent classification in logistics customer service, together with a curation pipeline that combines de-identification, filtering, LLM-assisted quality control, privacy screening, and human quality auditing.
- We benchmark multilingual encoders, embedding-based classifiers, and small language models under parent, flat-leaf, and parent-constrained settings.
- We show empirically that machine-translated evaluation often overestimates model performance relative to professional localization.

2 Dataset Construction

We construct a multilingual intent benchmark from historical customer-service logs. The released data consist of de-identified user queries paired with a practical two-level intent taxonomy.

2.1 Construction Pipeline

Source data. The raw pool comprises roughly 600K customer-service conversations collected in November 2025 from J&T Express operations serving Mexico and Arabic-speaking markets. Removing agent messages and merging consecutive customer turns leaves approximately 120K customer-side utterance units. English, Spanish, and Arabic are used as seen languages, while Indonesian, Chinese, and Thai are reserved for zero-shot transfer evaluation. The remaining funnel is summarized in Appendix Table 3.

De-identification and cleaning. Before annotation and release, we remove personally identifiable information, such as tracking numbers and detailed addresses, using rule-based filters, a locally deployed LLM privacy judge, and manual item-by-item review of every retained utterance. We then exclude bot-generated templates, exact, near, and keyword-level duplicates, malformed or truncated queries, and utterances without a clear intent. Privacy filtering and deduplication leave roughly 80K candidates; subsequent quality and scope filters yield approximately 30K training examples.

Taxonomy construction. We group the cleaned queries by operational function and user goal, and iteratively refine the label set to balance coverage, label separability, and per-class support. The final taxonomy is partially hierarchical: nine parent categories map one-to-one to a leaf, while four parents divide into eight leaves. Details of the clustering configuration and complete mapping are provided in Appendix B and Table 4.

Annotation and quality control. Training and test annotation follow different procedures. The approximately 30K training examples receive LLM-assisted scope screening and preliminary intent labels. Human annotators independently audit a random 5% training sample (approximately 1,500 items) to detect systematic errors; raw agreement is about 95% and Cohen's κ is about 0.94. This sampled audit concerns label quality only; privacy screening covered the full retained set. The separately constructed seen-language test set contains approximately 1,300 items, all independently human-labeled, with disagreements adjudicated by a third expert. Construction and semantic-preservation checks for the test-only-language sets are described in Section 3.2.

3 Dataset Characteristics

3.1 Overview

Appendix Table 3 summarizes the corpus statistics. The release contains approximately 30K training queries, together with development data, the independently annotated seen-language test set, and the test-only-language evaluation sets. A representative de-identified example is shown below:

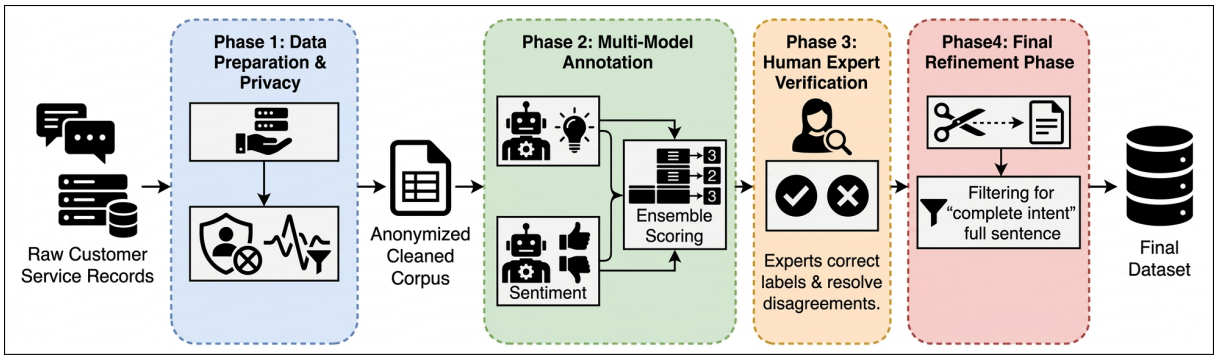

Figure 1: Construction pipeline for the benchmark.

```
text: Where is my parcel? It has not
    moved for three days.
class: Shipment Tracking / Delay
label: i1
```

To improve label generation stability in generative classification, we prepend a fixed prefix (e.g., "i1") to all label IDs.

3.2 Machine-Translated and Human-Localized Evaluation

A key feature of the benchmark is a paired comparison between machine translation (MT) and professional human localization. For each test-only language, Table 2 uses 674 source items. The GPT/Gemini filter is applied once to the shared Spanish source set and keeps items that both systems classify correctly and consistently. Each retained item is then rendered independently by `google/translategemma-27b-it` (Finkelstein et al., 2026) and by a local business translator, who is asked to preserve the intent while using natural local phrasing. Each pair therefore fixes the source text, label, filtering decision, source language, translation direction, and target language, differing only in its target-language rendering. Spanish was chosen because translation quality was stable in our setting; other source languages were not tested. Below, we call these the machine-translated and human-localized conditions.

The seen-language evaluation in Table 1 instead uses approximately 1.3K naturally occurring English, Spanish, and Arabic test examples. All 17 leaves are represented in the test-only-language sets (7–93 examples per leaf); the three rarest are Shipment Details (7), Fee Dispute / Incorrect Charge (10), and Business Partnership (16). Results for these leaves have greater sampling uncertainty. Cross-split semantic duplicates are removed.

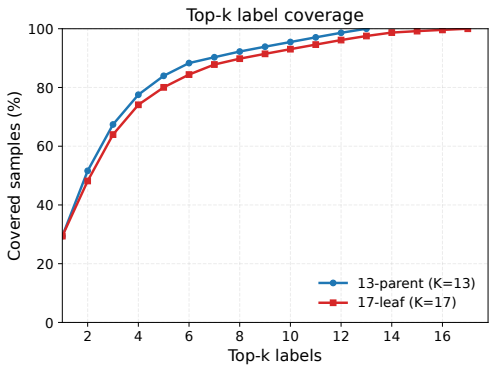

Figure 2: Top-k label coverage for the 13-parent and 17-leaf tasks. Splitting four parent categories produces the additional leaf-level tail.

3.3 Hierarchical Labels, Long-Tail Sparsity, and Noise

The benchmark supports a 13-way parent task and a primary 17-way leaf task (Appendix Table 4). The extra granularity is confined to eight leaves under four parents; the other nine parents are already leaves.

As shown in Figure 2, the 17-way leaf task is more long-tailed than the parent task, consistent with production traffic in which a small number of intents dominate and many low-frequency cases remain sparse. Naturally occurring source queries retain shorthand, misspellings, colloquial phrasing, and cross-lingual variation.

4 Experiments

4.1 Benchmark Tasks and Evaluation Protocol

We evaluate three customer-service routing settings. The 13-way parent task tests coarse operational routing (e.g., tracking vs. fee, claim, or invoice

issues). The 17-way flat leaf task is the main fine-grained setting, requiring direct prediction of operationally similar intents without using hierarchy at inference time. The 17-way parent-constrained task asks generative models to produce a parent intent and a taxonomy-consistent leaf intent. The final evaluation is performed on the leaf label, while the parent prediction constrains the output space.

Unless otherwise stated, all trainable models are trained on the released training split and selected on the development split using only English, Spanish, and Arabic. Each trainable model receives nine hyperparameter configurations, selected on the same development split. Closed-source LLMs are evaluated as few-shot references; several instruction, definition, demonstration, and serialization variants are compared on development data, and the selected prompt is evaluated at temperature 0. All results are reported under the benchmark's natural traffic distribution, without class rebalancing or synthetic augmentation.

For unseen test-only languages such as Indonesian, Chinese, and Thai, we evaluate zero-shot transfer without target-language supervision, translated training data, or target-language prompt tuning. Evaluation uses the test-only-language conditions defined in Section 3.2.

Our primary metric is accuracy, which is equivalent to Micro-F1 in this single-label classification setting. We use accuracy because the benchmark preserves the naturally imbalanced traffic distribution of real customer-service systems, and overall routing accuracy is the most deployment-relevant objective in this setting. We report Macro-F1 alongside the main seen-language results and provide complete metric tables in Appendix C. All hyperparameters, prompts, and checkpoints are selected on the development split only. Test sets are used strictly for final evaluation.

4.2 Baselines

We compare multilingual encoders, embedding-based classifiers, instruction-tuned small language models, and API models. Most neural models have at most 1B parameters; API models are included only as few-shot references.

For multilingual encoder baselines, we evaluate **mBERT** (Devlin et al., 2019), **XLM-R** (Conneau et al., 2020), and the public **mmBERT** checkpoint `jhu-clsp/mmBERT-base` (Marone et al., 2026). All use task-specific output layers and the same data access and trial budget; mmBERT uses its standard tanh-pooled representation without added dropout.

For embedding-based classification, we evaluate **EmbeddingGemma** (Schechter Vera et al., 2025) paired with a lightweight classifier, as well as a **Gemma 3 270M (embedding+classifier)** variant (Gemma Team et al., 2025). Both reuse a frozen encoder, so only the classifier is trained.

We further evaluate instruction-tuned small language models, including **Gemma 3 270M**, **Gemma 3 1B** (Gemma Team et al., 2025), and **Qwen 3 0.6B** (Yang et al., 2025). Unlike the encoder baselines, these accept a new label in the prompt without a change to the output layer.

Finally, we compare against three few-shot prompted closed-source LLMs accessed via API: **Seed-1.8** (Bytedance Seed, 2026), **DeepSeek V3.2** (DeepSeek-AI, 2025), and **Qwen3-Max-Preview** (Alibaba Cloud, 2025).

All systems use the same label inventory, test splits, and evaluation scripts; trainable models additionally use the released train/dev splits for supervised optimization and model selection. The training settings can be found in Appendix E.

5 Results

5.1 Seen-Language Performance

Table 1 reports results on the approximately 1.3K-example naturally occurring English, Spanish, and Arabic test set; following Section 4.1, we report Accuracy/Micro-F1 and Macro-F1. All trainable open models in the table are supervised using the released training split, whereas the closed-source API LLMs use validation-selected few-shot prompts and are included as reference systems rather than fine-tuned baselines.

Across model families, the 13-way parent task is usually easier than the 17-way leaf tasks. The gap comes from the eight leaves that share a parent, where the competing labels are operationally adjacent and unevenly supported.

Detailed Macro-F1 results are provided in Table 5. Difficulty-floor baselines score 5.88–78.54% on the translated 17-way set, while the two lexical baselines fall to 6.23–7.27% under Thai zero-shot transfer; Appendix D gives the full results.

Table 1: Seen-language benchmark results on English, Spanish, and Arabic (Accuracy/Micro-F1, %). Trainable open models are supervised on the released training split; closed-source API LLMs are evaluated with few-shot prompting only.

Model	13-way	17-flat	17-hier
Multilingual encoders			
mBERT	92.62	91.38	N/A
XLM-R	94.00	91.85	N/A
mmBERT	94.69	93.15	N/A
Embedding-based classifiers			
EmbeddingGemma	94.85	93.38	N/A
Gemma 3 270M (embedding+classifier)	93.62	92.15	N/A
Instruction-tuned SLMs			
Gemma 3 270M	94.08	93.08	93.23
Qwen 3 0.6B	94.23	93.46	93.77
Gemma 3 1B	95.00	93.92	94.08
Closed-source API LLMs (few-shot prompting; no fine-tuning)			
Seed-1.8	91.69	92.23	91.23
DeepSeek V3.2	93.92	90.92	89.85
Qwen3-Max-Preview	94.77	91.15	92.92

5.2 Real-World Robustness: Machine-Translated versus Human-Localized Evaluation and Zero-Shot Transfer

A central goal of the benchmark is to measure performance under realistic multilingual deployment conditions. Beyond supervised evaluation on seen languages, we therefore examine two additional aspects of robustness: the gap between machine-translated and human-localized queries, and zero-shot transfer to unseen languages. Table 2 summarizes both analyses.

Machine-Translated versus Human-Localized Evaluation. Real customer utterances often contain shorthand, misspellings, colloquialisms, and other naturally occurring variation that translation pipelines tend to normalize. Under the controlled protocol in Section 3.2, machine-translated inputs yield higher accuracy in 42 of the 45 model–language settings, with a mean paired difference (machine-translated minus human-localized) of $+1.319$ accuracy points. A bootstrap over source-item IDs gives a 95% confidence interval of $[0.159, 2.479]$. The pattern is especially consistent for mmBERT, for which machine-translated evaluation is higher in all reported encoder conditions, by about 1.7 points on average. Representative exact McNemar tests on Chinese 17-way flat classification give $p = 0.0052$ for mmBERT and $p = 0.0192$ for Gemma 3 270M. Macro-F1 shows the same direction in 41 of 45 cells, with a mean paired difference of $+1.819$ points. Appendix D gives the paired counts and procedures, and Appendix C gives the complete Macro-F1 results. We show one de-identified example. Both forms belong to the *Branch / Service Point Existence or Location* intent because they ask about the existence or location of a service branch. The machine-translated version is relatively literal, whereas the human-localized version is more conversational.

```
original: Isn't there a branch located
south of the city?
machine-translated: 这座城市南部没有分店
吗?
human-localized: 不是说在城市以南还有一家
分店吗?
intent: Branch / Service Point Existence
or Location
```

For Macro-F1, full results appear in Appendix C.

Zero-Shot Transfer to Unseen Languages. Both columns of Table 2 are also zero-shot: models are trained only on English, Spanish, and Arabic and evaluated directly on Chinese, Indonesian, and Thai without target-language supervision. New markets typically open before localized labeled data exists, so this is the setting a deployed router starts in.

Model comparison. mmBERT slightly exceeds Gemma 3 270M on seen-language 13-way accuracy (94.69% vs. 94.08%), whereas Gemma 3 270M is higher in several Chinese and Thai zero-shot settings despite their similar sizes (270M vs. 307M). Gemma 3 1B has the highest result in most reported zero-shot settings.

Robustness to Granularity. Fine-grained intents are critical in production. Moving from 13-way parent to 17-way flat classification generally hurts BERT-style models more than Gemma models (Table 2), and causal LLMs naturally express hierarchical predictions whereas BERT-style classifiers require extra design. Thus, Gemma-based models fit settings emphasizing robustness to human-localized queries, finer taxonomies, and cross-lingual transfer, while BERT pipelines remain appropriate for conventional supervised classification. Appendix D reports limited checks on adaptation, an alternative translation engine, and concurrent throughput.

6 Conclusion

We have presented a public real-world benchmark for multilingual intent classification constructed

Table 2: Paired machine-translated and human-localized accuracy/Micro-F1 (%) on 674 shared source items per language; **bold** marks the best result within each model family, and N/A indicates that no parent-constrained decoder was implemented.

from logistics customer-service logs. It contains approximately 30K de-identified labeled training utterances organized into a partially hierarchical taxonomy with 13 parent and 17 leaf intents, covering three seen languages (English, Spanish, Arabic) and three test-only languages (Indonesian, Chinese, Thai) for zero-shot evaluation.

Across multilingual encoders and instruction-tuned small language models, scores are generally higher for machine-translated inputs than for professional localization (Table 2). The evaluated fine-tuned open models also reach higher fine-grained accuracy than the few-shot API references, though the two groups differ in both size and training regime.

We hope this benchmark helps evaluate multilingual intent systems under realistic long-tail distributions, noisy customer text, and cross-lingual transfer, and encourages professional localization alongside machine translation.

Limitations

Our benchmark is based on one logistics provider, one collection month, and six languages, so results may not generalize to other providers, domains, periods, or languages. The taxonomy is only partially hierarchical, and the rarest leaves have 7–16 examples per test-only language. The comparison between machine-translated and human-localized inputs uses filtered Spanish source items and one main machine-translation system, so the findings apply to this setting rather than every translation workflow. The paired interval does not capture fine-tuning-seed variability, and the alternative-engine check covers only two Chinese cells.

Ethical Considerations and Data Governance

Provenance, notice, and consent. The source interactions were collected in November 2025 from J&T Express operations in Mexico and Arabic-speaking markets. Under the platform's user agreement and privacy policy, users were notified

that their interactions could be recorded and de-identified, and that the de-identified data might be used for model development and released for research. By using the service, users consented to these terms. The company's legal and information-security teams also reviewed the intended use and release of the data.

De-identification and validation. Before annotation and release, we screened the data using deterministic rules and a privacy checker built on a locally deployed LLM. We then reviewed every retained utterance by hand and removed any example containing direct identifiers or combinations of contextual details that could create a re-identification risk.

This validation relied on manual privacy review; we did not conduct a quantitative evaluation of the de-identification pipeline. Because we did not construct an independently annotated PII test set, we do not report precision or recall for PII removal. We found no residual sensitive or identifying information during the final review. Because the data consist of free-form text, unexpected quasi-identifiers may still remain. We do not claim that the dataset is free of all privacy or re-identification risk.

Use, licensing, and redress. The dataset is released under CC BY-NC-SA 4.0. It is intended for research on intent classification and multilingual routing, not for identifying individuals, profiling customers, linking records to external personal data, or making automated decisions about individuals.

Anyone with privacy concerns or requests for correction or takedown can contact the corresponding author at the address listed above. If a concern is confirmed, we will correct or remove the affected examples from the canonical release.

Acknowledgments

We thank the annotation team and domain experts at J&T Express for their assistance with data curation, taxonomy design, and quality verification. We thank Bocheng Xia for their support and encouragement throughout this work. We also thank the anonymous reviewers for their constructive feedback. This work was supported in part by the J&T AI Group and ShanghaiTech University.

A Dataset Supplement

Release metadata, split settings, and the hierarchy mapping behind Sec. 2 and Sec. 4.1 are collected here.

The 5% audit in Table 3 concerns training labels only. The seen-language test set was labeled independently by humans and adjudicated, and the test-only-language sets were constructed separately.

Table 4 provides the complete leaf-to-parent mapping used by the 13-way parent task and the 17-way flat/hierarchical tasks discussed in Sec. 5. Four parent categories contain multiple leaves because they cover operationally adjacent intents that are prone to confusion in customer-service routing: delivery change/intercept/return, damage-or-loss reporting/claims, service scope/transit/branch, and fee inquiry/dispute. The remaining parent categories map to a single leaf by design, because the corresponding business intents are already sufficiently separable and do not require artificial subdivision.

B Clustering Analysis

We adopted $K = 13$ for taxonomy construction on the following evidence.

To determine the optimal number of clusters, we conducted a systematic evaluation across $K \in \{10, \ldots, 19\}$ using six complementary clustering quality metrics: Silhouette Score, Calinski–Harabasz (CH) Index, Davies–Bouldin (DB) Index, Gap Statistic, BIC, and Inertia. To enable direct comparison, all metrics were normalized to a common $[0, 1]$ scale and directionally aligned so that higher values consistently indicate better clustering quality; we then computed an aggregate score for each K. As illustrated in Fig. 3, $K = 13$ achieved the highest aggregate score (0.672) and offered the best overall trade-off across metrics (radar chart). In particular, it ranks among the top three configurations in terms of Silhouette (0.061), CH (1098.6), and DB (3.103; lower is better). The CH rebound from $K = 12$ to $K = 13$ is consistent with the additional cluster capturing useful structure. The elbow analysis agrees: the largest single-step drop in inertia falls at the $K = 12$ to $K = 13$ transition. $K = 13$ also yields the most balanced cluster-size distribution among all configurations, with a coefficient of variation of 0.392 and a minimum cluster size of 1,754.

C Macro-F1

The tables below give Macro-F1 under the same protocols and model groupings as Sec. 5.

Table 7 gives Macro-F1 for the machine-translated and human-localized conditions summarized in Sec. 5.

D Paired Analyses and Additional Checks

Paired inference. The observation that machine-translated accuracy is higher in 42 of 45 model–language–task cells is a descriptive consistency count, not 45 independent replications. On Chinese 17-way flat classification, mmBERT is correct on 606/674 machine-translated and 590/674 human-localized items; the discordant counts are 23 versus 7, giving a two-sided exact McNemar test of $p = 0.0052$. Gemma 3 270M is correct on 613/674 versus 600/674 items, with 20 versus 7 discordant pairs and $p = 0.0192$. For aggregate inference, a language-stratified paired cluster bootstrap resamples source-item IDs within each language and applies the sampled indices jointly to both conditions, all models, and all tasks. With 10,000 resamples and seed 30, the mean paired difference (machine-translated minus human-localized) is $+1.319$ accuracy points, with a 95% confidence interval of $[0.159, 2.479]$. This interval captures test-item sampling uncertainty, not fine-tuning-seed variability.

Macro-F1. Table 7 gives the complete paired Macro-F1 results. Machine-translated performance is higher in 41 of 45 cells, with a mean difference of $+1.819$ points; the mean gaps for the 13-way, 17-way flat, and 17-way hierarchical tasks are $+1.638$, $+1.949$, and $+1.920$ points. The four reversals are mBERT/ZH/13-way (-4.54), XLM-R/TH/13-way (-2.48), mmBERT/TH/17-flat (-0.53), and Gemma 3 270M/ZH/17-hierarchical (-0.36). Accuracy/Micro-F1 remains the primary operational metric, while Macro-F1 exposes long-tail behavior by weighting each intent equally.

Difficulty-floor baselines. On the translated 17-way set, majority-class, uniform-random, word/character TF-IDF with logistic regression, and subword fastText obtain 10.62%, 5.88%, 78.54%, and 64.69% Accuracy/Micro-F1, respectively. Under Thai zero-shot transfer, TF-IDF and fastText obtain 6.23% and 7.27%. These results show that head-class prediction does not explain

Table 3: Benchmark construction, evaluation, and release overview.

Field	Value
Raw source records	~600K multi-turn customer-service conversations from November 2025
Customer utterance units	~120K after removing agent turns and merging consecutive customer turns
Privacy and deduplication stage	~80K after rules, a local LLM privacy check, and exact/near/keyword duplicate removal
Training pool	~30K after quality, scope, and preliminary-label filtering
Seen benchmark languages	English, Spanish, Arabic
Test-only languages	Chinese, Indonesian, Thai
Seen-language test (Table 1)	~1.3K naturally occurring EN/ES/AR examples, all independently human-labeled with adjudication
Test-only-language evaluation (Table 2)	674 examples per condition and target language
Test-only class support	All 17 leaves per language; 7–93 items per leaf
Translation setup	Spanish source; `google/translategemma-27b-it`; local business translators
Training-label audit	Random 5% sample (~1,500); raw agreement ~95%; Cohen's $\kappa \sim 0.94$
Release and licenses	Utterances, labels, language tags, taxonomy, fixed splits, paired test sets, code, prompts, and configurations at `https://github.com/JTExpress-MICCS/MICCS`; dataset: CC BY-NC-SA 4.0; code, configurations, and prompts: CC0 1.0 Universal

the neural results and that the lexical baselines provide little cross-lingual transfer in this setting.

Alternative translation engine and adaptation. On the same paired Chinese 17-way flat items, DeepL yields 90.06% for mmBERT and 90.95% for Gemma 3 270M, compared with 89.91% and 90.95% for TranslateGemma-27B. This limited two-cell check preserves the translated-over-human-localized direction but does not establish translation-engine invariance. As an adaptation control on the same seen-language split and Accuracy/Micro-F1 metric as Table 1, Gemma 3 27B increases from 79.46% with few-shot prompting to 97.16% after in-domain fine-tuning. This supports an effect of task-specific adaptation in this setting, not an inherent advantage of a particular model scale.

Concurrent throughput. On the same in-house concurrency benchmark using one NVIDIA RTX 3090, mmBERT-base processes 803 samples/s and Gemma 3 270M processes 414 samples/s. These measurements concern concurrent throughput only; they do not measure per-query latency, peak memory, monetary cost, or API serving performance.

E Training Parameters

Experiments are conducted with both encoder-based PLMs and decoder-only LLMs. For the encoder-based baselines, we use mBERT, XLM-R, and mmBERT. These models are fine-tuned using the Hugging Face Transformers library (Wolf et al., 2020) with a maximum input length of 64, a batch size of 128, a learning rate of 7×10^{-5}, weight decay of 0.01, and maximum gradient norm of 5.0. EmbeddingGemma uses the same classifier pipeline. For the decoder-only models, we evaluate Gemma 3 270M, Qwen 3 0.6B, and Gemma 3 1B, which are trained using LLaMA-Factory (Zheng et al., 2024). In LLM fine-tuning, we freeze all parameters except the last 16 transformer layers and use a batch size of 128 with a learning rate of 3×10^{-5}. All trainable models run for five epochs with AdamW, a cosine learning-rate schedule, and 150 warm-up steps. Each model receives nine hyperparameter configurations; the best is selected on the same seen-language development set. All experiments are conducted on a server equipped with 8 NVIDIA A800 GPUs.

Abstract

Translating a story renders its words into a new *language*; adapting it transposes its world into a new *culture*. Large Language Models (LLMs) translate and adapt individual passages effectively, but long-form novels spanning ∼100 chapters suffer model failures. We formalize *long-form cross-cultural story adaptation* as a generation task parameterized by source and target language-culture pairs, with three structural axes: **A1** identity coherence across narrative arc, **A2** cultural-system alignment within scenes, and **A3** dependency-chain integrity among related entities. This is addressed through a five-stage agentic adaptation framework comprising entity registry, target-culture plan, dependency-aware batched localization, validation and rewrite. Evaluation is conducted through ablations across three language-culture pairs and three model families; the proposed system outperforms across all three axes, reducing identity errors by 65%, dependency errors by 64%, and cultural misalignment errors by 27% against competitive baselines. Further validation through a production A/B test on a commercial storytelling platform demonstrates listener retention comparable to that for human-adapted content, reflecting viability of the framework.

1 Introduction

When a Chinese family drama is adapted for an American audience, two operations are conducted. *Translation* renders the words in English: *"During Spring Festival, the family pasted up spring couplets, wrapped dumplings, watched the Spring Gala, and the children received red envelopes."* *Adaptation* transposes the cultural world; Spring Festival becomes Christmas Day, couplets become a wreath, wrapping dumplings change to baking cookies, Spring Gala turns into a holiday parade, and receiving red envelopes becomes hanging up stockings. Translation changes the language, adaptation changes its cultural world (Fig. 1).

Figure 1: Translation vs. Adaptation on a Chinese New Year passage. Translation preserves source-culture items (Spring Festival, couplets, etc) while adaptation swaps each for target-culture analogue that preserves narrative function (Christmas Day, wreath, etc).

Which of these two operations a story receives is a production decision with measurable consequences. The target deployment is a serialized audio-fiction platform that runs two distinct production pipelines: a translation-only pipeline for language pairs with sufficient cultural proximity, and the cultural-adaptation pipeline described in this paper for pairs with large cultural distance (e.g., Mandarin-origin serialized fiction prepared for US English-speaking listeners). Internal engagement data shows that culturally distant content produced via translation alone yields significantly

EMNLP 2026 Industry Track, pages 2093–2114

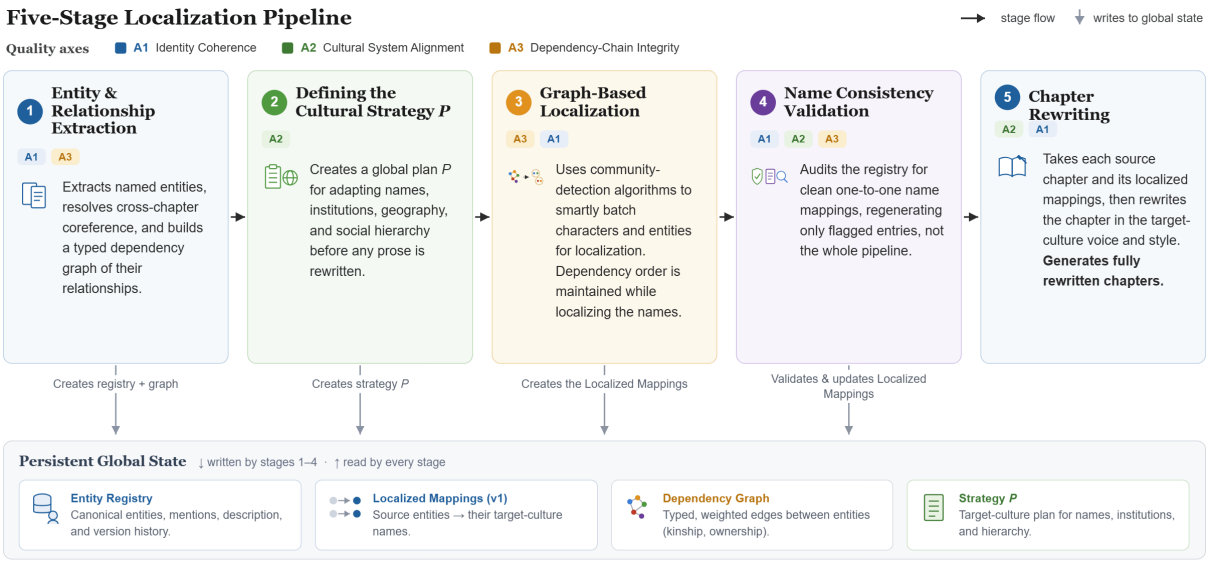

Figure 2: **Five-stage localization pipeline** Stages 1-4 progressively build a persistent global state: an entity registry, a dependency graph, and a target-culture strategy P. Every stage reads and updates the global state, keeping entities, culture, and dependencies coherent (axes A1-A3) across the entire story. Stage 5 then rewrites each chapter in the target-culture voice using the validated mappings and strategy P.

higher listener drop-off than adapted content; that operational gap motivates the distinction this paper formalizes.

Large Language Models (LLMs) translate and adapt effectively for individual passages (Yao et al., 2024; Singh et al., 2024), yet long-form novels spanning ∼100 chapters exhibit recurring plot inconsistencies despite larger context windows or stronger decoders. We formalize *long-form cross-cultural story adaptation* as a generation task parameterized by source language-culture pair (L_S, C_S) and target language-culture pair (L_T, C_T) across three structural axes: **A1** identity coherence, **A2** cultural-system alignment, and **A3** dependency-chain integrity. A five-stage agentic adaptation framework externalizes narrative state through entity tracking, cultural planning, dependency-aware localization, validation and rewriting. Ablations across three language-culture pairs and three model families show reduction in identity errors by 65%, dependency errors by 64%, and cultural misalignment errors by 27% against competitive baselines. Production A/B test on three Mandarin-to-English-USA serialized shows demonstrates listener retention comparable to that for human-adapted content, reflecting viability of real-world deployment.

2 Related Work

Translation studies has long recognized adaptation beyond linguistic transfer, reflected in Skopos theory (Reiss and Vermeer, 1984), domestication and foreignization (Yang, 2010), and transcreation (Pedersen, 2014). Machine Translation has improved consistency beyond sentence level through document context (Karpinska and Iyyer, 2023), coreference modeling (Vu et al., 2024), document-level evaluation (Jiang et al., 2022). Long-context training (Gao et al., 2025) extends the usable window further; however, these approaches target translation fidelity rather than systemic cross-cultural transformation, and treat consistency as a contextual retrieval problem.

Growing research on cross-cultural adaptation and localization (Hershcovich et al., 2022; Liu et al., 2025) includes culturally grounded translation (Anik et al., 2025), content adaptation (Singh et al., 2024; Cao et al., 2024), and cross-cultural evaluation (AlKhamissi et al., 2024). However, existing approaches operate at passage or document level (Singh et al., 2024; Yao et al., 2024), and do not address the long-range coordination needed for consistency across narratives spanning ∼100 chapters. The most directly relevant prior work operates at *atomic* scale: Cao et al. (2024) adapt individual recipes cross-culturally, Khanuja et al. (2024) extend adaptation to individual images for cross-cultural relevance, and Khanuja et al. (2025) propose automatic evaluation metrics for image transcreation. These artifacts share a defining property: each is self-contained, with no recurring identity, no dependent sibling entities, and no narrative

continuity, so the techniques do not lift to long-form output (detailed positioning in Appendix C). To our knowledge, this is the first work to formalize *long-form cross-cultural story adaptation* as a generation task, with explicit structural axes and an aligned architectural decomposition.

3 Long-Form Cross-Cultural Adaptation

Long-form cross-cultural story adaptation maps a source chapter sequence to a target chapter sequence, conditioned on source and target language-culture pairs. $S = (c_1, \ldots, c_N)$ denotes a source story of N chapters (typically $N \gtrsim 10^2$) of source language-culture (L_S, C_S), for target language-culture (L_T, C_T). Long-form cross-cultural story adaptation seeks a target story

$$S' = (c'_1, \ldots, c'_N) = f(S, L_S, C_S, L_T, C_T), \quad (1)$$

that preserves narrative while rendering the story native to the target culture. Equation (1) defines a chapter-level *ordering contract*: source chapter c_i maps to target chapter c'_i, preserving the narrative arc across all N chapters. It does not constrain within-chapter scene structure or prose phrasing to a one-to-one rendering; each target chapter is fully re-generated, conditioned on the cultural strategy and the localized entity registry, and the model is free to rephrase within the chapter. Preservation includes plot structure, character arcs, and causal dependencies; adaptation includes culturally appropriate entities, institutions, settings, and social conventions. The three axes are jointly necessary.

A1 – Identity coherence. Localized entities e' in S' must remain consistent across the narrative arc $c'_1, \ldots, c'_N$, including names, aliases, honorifics, and references. Identity coherence is evaluated globally across chapters rather than passages.

A2 – Cultural-system alignment. Cultural artifacts a appearing in target-culture scenes S' must be coherent with target culture unless explicitly presented as foreign, ensuring adaptation beyond linguistic translation to cultural localization. We evaluate a domestication-oriented localization regime; foreignization-preserving adaptation is valid but outside this metric.

A3 – Dependency-chain integrity. Semantically related entities must be adapted consistently. Changes to a parent entity (e.g., a family name, institution, or location) must propagate to dependent entities that inherit or reference it.

4 System Architecture

We propose a five-stage pipeline (see Fig. 2) that maintains story-level state through shared entity registries, relationship graphs, and a global adaptation plan.

Stage 1: Entity and Relationship Extraction. Before adaptation, the system extracts named entities, resolves coreferences, and constructs a relationship graph over the entire story. The resulting entity registry and dependency graph provide a persistent narrative state, avoiding common document-level inconsistency issues, improving identity coherence (A1) and supporting dependency-aware localization (A3).

Stage 2: Defining the Cultural Strategy P. The pipeline then constructs a global cultural strategy P, specifying how names, institutions, locations, and social structures are localized to target culture. This plan anchors the narrative to a coherent target culture (A2) and guides subsequent localization and rewriting decisions.

Stage 3: Graph-Based Localization. Entities are localized in topological order over the dependency graph from Stage 1. Related characters are grouped through Louvain community detection (Blondel et al., 2008), allowing the model to adapt closely tied characters (like a family) in the same batch, which outperforms simple topological sorting or greedy batching.

Stage 4: Name Consistency Validation. Before rewriting, the localized entity registry is audited to ensure one-to-one mappings between source and target entities, and to detect duplicate localized names. Conflicts are resolved by regenerating only the affected mappings, preserving consistency without rerunning the entire pipeline. The one-to-one constraint is a consistency constraint on the *entity registry*, not a restriction on lexical choice in the generated prose: (i) each source entity receives exactly one canonical target-side form, so the same character is never rendered under multiple names across chapters, and (ii) no two distinct source entities are assigned the same target name, so different characters cannot be conflated. Source cultural concepts may admit several

plausible target analogues; the strategy P selects among them by *narrative-functional equivalence* (a family-reunion Mid-Autumn Festival scene may map to Thanksgiving, whereas a story trading on nocturnal, supernatural atmosphere may map the same festival to Halloween), and the selected mapping is then applied consistently for the remainder of the work. A worked conflict-detection example is given in Appendix A.11.

Stage 5: Chapter Rewriting. Lastly, the pipeline rewrites each chapter to match the target culture's voice and style. The model is provided with the original chapter, localized entity mappings from Stage 3, and cultural strategy P. Localized names are injected directly into the prompt to prevent reverting to source names or hallucinations. Here, the actual cultural alignment takes shape, extending prior work on atomic-scale (recipe, menu, passage, image) adaptation (Cao et al., 2024; Zhang et al., 2024; Yao et al., 2024; Singh et al., 2024; Khanuja et al., 2024, 2025) to long-form narratives (A2).

Error containment. Stage 1 errors cannot silently propagate: Stage 4 audits the registry before any rewriting, detecting conflicts (including inconsistently localized related entities) and regenerating only the affected mappings, and the validators of §5.1 act as a production safety barrier, surfacing only below-threshold chapters to a human reviewer with each flagged issue's location and category. An extraction error thus stops at a Stage 4 correction.

5 Evaluation Framework

5.1 Automated Evaluation

The automated evaluation scores the three structural axes defined in Section 3 using LLM-as-a-judge pipelines. For each variant v, an initial extraction step maps how recurring characters, named entities, and dependent entities are realized in the adapted text. A validation step then scores these mappings for identity stability (m_{A1}) and coherent dependency localization (m_{A3}). To measure cultural alignment (m_{A2}), an LLM judge reads the adapted scenes and identifies out-of-place source-culture artifacts, reporting the number of confirmed cultural errors per chapter. The judge pipeline is validated against independent native-speaker annotation on a 50-chapter subset, reaching 92% precision and 97% recall against the annotator consensus (Appendix A.5).

Per-variant counts. For variant v, let I_v be the number of validated recurring character/entity items, $C_v^{(1)}$ the number with stable identity mappings across chapters, $C_v^{(3)}$ the number with coherent related-entity localization (i.e., dependent entities localized consistently with their heads), $F_v^{(2)}$ the number of cultural misalignment errors (out-of-place source-culture artifacts), and H_v the number of evaluated chapters.

Axis scores. The three axes are reported as

$$m_{A1}(v) = \frac{I_v - C_v^{(1)}}{I_v},$$
$$m_{A2}(v) = \frac{F_v^{(2)}}{H_v},$$
$$m_{A3}(v) = \frac{I_v - C_v^{(3)}}{I_v}.$$

These are the identity error rate, cultural-misalignment rate per chapter, and dependency error rate respectively; *lower is better* for all three.

Plot Fidelity (m_{A0}). We verify that the adaptation process preserves the core plot. For each source and adapted chapter pair, an LLM judge conducts a beat-level analysis and produces several sub-scores (*beat recall*, *beat precision*, *sequence fidelity*, *character fidelity*), culminating in a holistic plot-fidelity score in $[0, 1]$. Variant-level score is the unweighted chapter mean,

$$m_{A0}(v) = \frac{1}{H_v} \sum_{h=1}^{H_v} s_{v,h}^{(0)},$$

where $s_{v,h}^{(0)}$ is the holistic score of chapter h under variant v. This auxiliary metric ensures that improvements in cultural adaptation do not come at the expense of plot fidelity.

5.2 Human Evaluation: Production A/B Test

The A/B test provides a real-world benchmark by comparing our system directly against a professional human adapter. We deployed three Mandarin-to-English (US) web novels on a commercial platform. For each show, half of the readers received a version drafted by our pipeline (Variant A), while the other received a version drafted end-to-end by a human professional (Variant B). Both versions underwent the platform's standard

human validation step before publication, but Variant A began with the P_{full} output and received a lightweight human review guided by validator flags, while Variant B was drafted by a professional adapter. Listener retention was measured hourly, and the results were reported descriptively given the limited scope of the study (Section 6.4).

6 Experiments

6.1 Datasets

Evaluations are conducted across three language-culture adaptation pairs: Mandarin→English (US), English→German, and English→Hindi. The set contains three Mandarin→English shows and two English-source shows adapted into German and Hindi; each show spans ∼100 chapters.

6.2 Experiment Variants

We compare four experiment variants: each receives the same source story and target language-culture pair, but differs in how cross-chapter localization state is represented during adaptation.

B1: plan-then-adapt. B1 is a non-pipeline planning baseline. The model reads the full story and produces a global target-culture strategy specifying how names, places, institutions, social roles, and recurring cultural references are adapted. As this strategy is fixed before rewriting, chapters are adapted independently and in parallel from the chapter text conditioned on the global plan. B1 is thus the strongest single-workflow alternative (same Stage 2 plan schema; sample in Appendix A.10) but keeps no per-entity state: an alias absent from the plan has no canonical record at rewrite time, and the >300K-token source exceeds reliable single-prompt state management.

B2: rolling summary. B2 is a sequential memory baseline. The model adapts the story chapter by chapter while maintaining a bounded running summary of prior plot events and localization choices. At chapter k, the model receives the current source chapter together with the summary accumulated from chapters $1, \ldots, k-1$.

S1: early architecture variant. S1 is an intermediate variant of the architecture in Section 4. It extracts recurring source entities, records explicit source-to-target entity decisions, and conditions chapter rewriting on those decisions. It therefore tests whether persistent identity state before rewriting improves over prose-only context, without the strategy step or the dependency-aware graph-localization component of P_{full}.

P_{full}: final localization-sheet pipeline. P_{full} is the full system evaluated in this paper. It instantiates the five-stage architecture in Section 4: entity and relationship extraction, global cultural strategy P, graph-based localization, consistency validation, and chapter rewriting with localized names and related forms injected into the prompt.

Together, these variants separate three levels of adaptation state. B1 tests whether a global cultural plan alone is sufficient; B2 tests whether sequential prose memory can carry localization decisions across chapters; S1 tests whether explicit entity state before rewriting improves over prose-only context; and P_{full} tests the complete architecture with persistent entity state, dependency-aware localization, and validation before rewrite.

6.3 Models

All headline results (§7) use Gemini 3.1 Pro as the generator for every stage and baseline. The judges of §5.1 are fixed: Claude Sonnet 4.5 scores m_{A1}/m_{A3} and Gemini 3 Flash scores m_{A2}/m_{A0}, unchanged across all variants and generator families, and validated against native-speaker annotation (Appendix A.5). To test model-independence we replicate the four-variant ablation on GPT-5 and Claude Opus 4.5 across all three directions (Table 2; per-pair breakdown in Appendix A.9). Since the judges span two families and are fixed, any self-preference applies uniformly and cannot favor P_{full}.

6.4 Production A/B Test Details

The A/B test was conducted on three Mandarin-to-English (US) adapted shows. Platform users were randomly assigned at first listen to either the AI-drafted arm (Variant A: P_{full} plus validator-guided human review) or the professional human-drafted arm (Variant B), with variant identity hidden. Allocation was balanced: AB1 assigned 2,135 users to Variant A and 2,082 to Variant B; AB2 assigned 769 to Variant A and 796 to Variant B; and AB3 assigned 2,684 to Variant A and 2,700 to Variant B, yielding 5,588 users in Variant A and 5,578 in Variant B (11,166 total). We tracked hour-level listener retention (R_h) at $h \in \{6, 7, 8, 9, 10, 15, 20, 25, 30\}$ and report the per-show delta $\Delta_h = R_h^B - R_h^A$ descriptively.

7 Results

Overall Performance. Table 1 presents aggregate and per-language-pair performance for the proposed pipeline and baselines, evaluated across all four automated axes. P_{full} achieves the lowest pooled error rates across all three structural metrics: $m_{A1} = 0.081$, $m_{A2} = 0.083$, and $m_{A3} = 0.105$. Compared to the non-pipeline baselines, this represents an error reduction of 65% on identity (m_{A1}) and 64% on dependency (m_{A3}) versus B1. Against the B2 baseline, P_{full} maintains a 54% (m_{A1}) and 53% (m_{A3}) error reduction. Gains in cultural alignment (m_{A2}) are similarly robust, with the pipeline reducing misalignment errors by 27% compared to B1 and 26% compared to B2. Crucially, these structural improvements come at a negligible cost in plot fidelity: m_{A0} drops by only 0.007 (0.980 pooled vs. B1's 0.987), so P_{full} achieves strong entity and dependency continuity without meaningful narrative drift.

Per-pair patterns. Results reveal that the dependency mechanism (m_{A3}) is universally robust, with P_{full} achieving the lowest error rate across all three pairs. Identity coherence (m_{A1}) is exceptionally strong for Mandarin→English and English→German. However, English→Hindi adaptation proves more challenging; the rolling-summary baseline (B2) outperforms the pipeline on identity coherence. Cultural alignment (m_{A2}) shows more variance; P_{full} decisively wins the English→German setting (0.055), significantly improves upon B1 and S1 in Mandarin→English (37 errors over 298 chapters, $m_{A2} = 0.124$) but trails B2 by a single error (36 errors over 298 chapters, $m_{A2} = 0.121$). Finally, English→Hindi slightly favors S1 on cultural alignment.

Cross-model generalization. Table 2 replicates the four-variant ablation on GPT-5 and Claude Opus 4.5 (aggregated over all three directions). P_{full} achieves the lowest error on all three axes in both families, reducing identity errors by 64% (GPT-5) and 31% (Opus 4.5) and cultural-misalignment errors by 28% in both relative to B1, while its plot fidelity stays ≥ 0.996. The consistent $-27/-28\%$ m_{A2} reduction across all three families shows the cultural-planning stage is model-independent, and the cross-family pattern establishes that the gains are architectural (per-pair breakdowns in Appendix A.9).

vs. B1	-31%	-28%	-27%	—

Table 2: Cross-model replication: aggregate scores over all three language directions ($\downarrow$ better for $m_{A1}/m_{A2}/m_{A3}$; $\uparrow$ for m_{A0}). P_{full} attains the lowest error on every axis in both families, as with the primary backbone (Table 1).

Production A/B Test Results. Figure 3 plots hour-level A/B retention deltas for three deployed Mandarin→English(US) shows. Both arms (Variant A: drafted by P_{full}; Variant B: human-drafted end-to-end) undergo identical downstream human review. The goal is to establish the commercial viability of P_{full}'s long-form narratives. Across all three shows, retention delta (Δ_h) oscillates closely around the zero-line, with absolute deviations typically constrained to single digits. Notably, during the "deep retention" phase (hours 15–30), where baseline LLM adaptations can lose listeners due to identity drift (A1) and broken dependencies (A3), our pipeline-generated shows remain highly competitive. For instance, Variant A significantly outperforms the human arm in AB1 at hr15 (-7.21 pp)

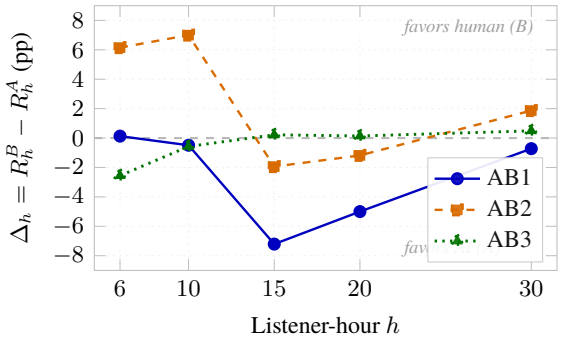

Figure 3: Production A/B retention for three Mandarin→English (US) shows. $\Delta_h = R_h^B - R_h^A$ in percentage points, where Variant A is drafted by P_{full} and Variant B by a professional human adapter; positive values favor the human arm. The dashed line marks no-effect.

and ties in AB3. This is the desired operating point. Stages 1–5 ran fully automatically; a validator-guided review pass then used Stage 4 outputs to flag specific chapters for targeted human revision, in which reviewers corrected validator-flagged errors and performed a single sanity read—24 review hours (∼3 reviewer-days) for 10 hours of content. Across multiple generations, the strongest baseline averaged ∼1.8× the errors of P_{full} and required ∼1.5× more reviewer time, reflecting P_{full}'s upstream consistency guarantees. Deployed shows remained comparable to the human-drafted arm. P_{full} achieves this parity at ∼2.9× lower per-show cost (∼$990 vs. ∼$2,880 end-to-end human; Table 5). The structural consistency generated by P_{full} effectively translates to real-world listener retention at human-parity levels, with limited human assistance.

8 Discussion

To contextualize the quantitative gains (Section 7), Table 7 (Appendix E) contrasts characteristic baseline failures with P_{full}'s resolution; the gains on A1, A2, and A3 stem from the pipeline's architectural state.

A1: Resolving Identity Drift via Persistent State. Standard generation paradigms invariably leak identity state over long narrative arcs. Without a globally anchored target-culture surface form, B1's parallel generation splinters a single Chinese character into nine distinct Westernized variants; B2's lossy rolling summaries fracture a single university into ten different institutional identities across a 100-chapter arc. P_{full} bypasses these failures by treating identity as explicit, persistent state: the entity registry is extracted upfront and its locked forms are injected into every rewriter prompt, guaranteeing global consistency.

A2: Enforcing Cultural Alignment. Without a persistent target-culture plan tied to the entity registry, baselines retain source-culture terminology inside scenes that require adaptation. As shown in Table 7, B1 retains 真气, conventionally rendered as *True Qi* or internal energy, creating cultural residue that interrupts the adaptation's sci-fi biometric register. P_{full} instead maps it to *somatic current*, preserving its narrative function within the target ontology of bio-energy, and renders 基础丹田/丹田 as *core somatic nexus* rather than *Dantian*, matching the adapted system's scientific vocabulary. Localizing recurring entities at registry level thus mitigates A2 errors.

A3: Maintaining Dependency-Chain Integrity. Dependent entities must co-localize with their heads, particularly when the dependent lexically inherits from the head; baselines without explicit relational state routinely sever these possessive and institutional chains. For 罗十六的母亲 (*Luo Shiliu's mother*), B2 drifts the dependent between disconnected proper nouns like *Margaret Hayes* and detached supernatural descriptors. By batching dependencies via Louvain community detection (Stage 3), P_{full} forces heads and dependents into the same localization window, keeping lexical and relational chains intact across hundreds of chapters and stably mapping the pair to *Ethan* and *Ethan's mother*.

9 Conclusion

We formalize long-form cross-cultural story adaptation along three structural axes (A1, A2, A3) and instantiate a five-stage pipeline that externalizes cross-chapter state, reducing identity, dependency, and cultural-misalignment errors by 65%, 64%, and 27% over the non-pipeline baseline. A production A/B test on three deployed Mandarin→English shows demonstrates listener retention comparable to professional human adaptation at ∼2.9× lower per-show cost. Persistent global state, not larger context, is the operative architectural unit for long-form adaptation.

Limitations

We find that the primary bottleneck of our current architecture lies in its monotonic commitment

policy: all entity decisions are frozen globally at the end of Stage 2. This strict global anchoring is highly effective for linguistically proximal pairs like English→German, yielding near-zero identity and dependency errors. It proves overly brittle, however, for culturally divergent settings like English→Hindi, where it creates systematic regressions. Furthermore, we observe similar struggles with task-level relational ambiguities, such as the shared-surname collisions observed in E.2. In both scenarios, a top-down global commitment prematurely truncates the optimization space before sufficient downstream context can be integrated. We leave the design of a dynamic entity-representation stage that incorporates feedback from the downstream rewriter as a future direction.

A Evaluation details

This appendix explains how the automatic metrics in Section 5 are produced. A1, A2, and A3 are the three adaptation axes: identity coherence, cultural-system alignment, and dependency-chain integrity. The reported metrics m_{A1}, m_{A2}, and m_{A3} are error rates for those axes, so lower is better. The evaluators below are intentionally narrow: each one turns a concrete audit artifact into counts used by the equations in Section 5.

A.1 A1/A3 Mention Mapping

Vetted recurring-item list. For A1/A3 evaluation, each story has a human-vetted list of recurring source items. The item may be a character, institution, object, place, title, or other recurring entity. The list stores a persistent item ID, source names or aliases, and optional metadata such as chapter numbers, gender, relationships, or a short description. It is fixed once per story and reused across all evaluated variants. The list does not provide the expected adapted name; it provides the source-side inventory that the evaluator should try to map into each adapted manuscript.

The A1/A3 evaluator reads paired source and adapted chapters together with this vetted list. It first keeps only listed items that appear in the evaluated source chapters. These grouped, observed items are the validated items I_v used in Section 5. This prevents unused list entries from inflating the denominator, while also preventing a weak adaptation from lowering its denominator by omitting difficult recurring entities.

Mention-mapping artifact. For each story–variant pair, the mapper writes an audit workbook. The vetted list tells the mapper which source items to look for and which aliases should be treated as the same item. One workbook view records each observed source mention and the adapted text span that realizes it. A second view groups those rows by vetted item ID. The grouped view is the metric-bearing view: a character with many aliases contributes one item to the denominator, not one item per spelling occurrence.

Identity-consistency checks. The A1 check asks whether each grouped source item has one coherent adapted identity across the evaluated chapters. A grouped item is consistent when the adaptation uses a stable adapted form for the same source identity, allowing ordinary titles, inflection, and spelling variation. It is inconsistent when one source identity is split into incompatible adapted identities, when unrelated source identities collapse into the same adapted identity without narrative justification, or when the adapted mention contradicts the vetted item's role. These checks produce the consistency count $C_v^{(1)}$, which Section A.4 converts into m_{A1}.

Dependency-coherence checks. The A3 check uses the same grouped source items, but asks whether related items still fit together after adaptation. A failure is counted when an adapted form no longer coheres with the character, family, institution, place, or artifact it depends on. Examples include an estate name whose family association is broken, a school or company whose naming pattern conflicts with its affiliated characters, or a title whose adapted form no longer matches the social relation it encodes. These checks produce the dependency-consistency count $C_v^{(3)}$.

A.2 A2 Cultural-Residue Detection

The A2 evaluator measures cultural alignment from the perspective of a reader of the adapted story. It runs in two steps: a high-recall detector first proposes possible cultural problems, and a confirmation pass then keeps only supported issues for the metric. The detector reads adapted chapters together with culture labels and prior adapted-story context. A culture label names the intended movement of the adaptation: the source culture is the cultural setting the story came from, and the target culture is the setting the adaptation is meant to read as native to. Prior context is a compact record of earlier adapted chapters, used to decide whether the story has already explained a cultural detail.

The main target is *source-culture residue*: a detail whose logic still depends on the source culture or original setting after the adaptation has moved the scene into a target-culture setting. A fluent

chapter can still fail A2 if it leaves such a detail unexplained.

Chunk inputs. Detection is run over chapter chunks. For each chunk, the judge receives three kinds of information: a synthesized prior-context packet, a window of prior adapted chapters, and the current adapted chapters to analyze. The prior context helps the judge decide whether a cultural detail has already been explained by the story. It is reference material only. A reported A2 error must quote evidence from the current analyzed chapters.

Candidate findings. The detector writes candidate findings with the chapter number, a short quote from the adapted text, an error type, a Hall level, a priority, and an explanation. This first pass is high recall: it is designed to catch possible cultural residue even when some candidates may later be rejected.

Completeness gates. A run is accepted for headline evaluation only when all intended chapters have context packets and all detection chunks complete. These gates matter because m_{A2} is a per-chapter rate: missing chapters would otherwise make the adaptation look better than it is.

A.3 A2 Decision Rule and Confirmation

A candidate becomes an A2 issue only if it passes a concrete localization test. The text must establish or strongly imply a target setting, institution, social context, or character background. The quoted detail must be treated as normal in that setting. The detail must depend on source-culture logic, source-language convention, or the original setting. Finally, the surrounding story must not give a clear explanation for why that detail belongs.

This rule prevents A2 from becoming a generic "foreignness" detector. Non-target-culture details are allowed when they are explained by the story: immigrant or heritage background, travel, religious practice, imported goods, a restaurant setting, genre worldbuilding, historical setting, or an explicitly multicultural scene. Such details are counted only when the passage asks the reader to treat them as ordinary target-culture defaults.

Hall levels. Each confirmed issue is assigned one Hall-triad level. **Technical/Visible** issues involve explicit cultural objects or labels, such as food, currency, clothing, holidays, place names, honorifics, school systems, or administrative institutions. **Formal/Semi-visible** issues involve learned routines and social procedures, such as etiquette, courtship scripts, family-address norms, workplace hierarchy, school discipline, or ritual behavior. **Informal/Invisible** issues involve deeper assumptions about authority, obligation, kinship, status, shame, privacy, gender roles, or social risk. The assigned level describes the depth of the mismatch; it is not a separate metric.

Confirmation pass. Because the detector is high recall, a separate confirmation pass reviews every candidate. A confirmed issue must state the target-culture expectation, the source-culture logic retained by the adapted text, and why prior story context does not justify that retention. Candidates that are weak, speculative, or plausibly explained by context are excluded from the metric. The headline m_{A2} numerator uses only confirmed issues.

Diagnostic fields. Error type and priority are kept for analysis but do not change the score. Priority records reader-facing severity, and error type records the kind of cultural problem, such as a food or ritual mismatch, an institutional mismatch, an honorific or title mismatch, a place-name mismatch, or a deeper social-norm mismatch. m_{A2} counts all confirmed issues equally.

A.4 Metric Mapping

For A1/A3, let I_v denote the number of validated grouped source items for variant v. Let $C_v^{(1)}$ be the number with stable identity mappings, and let $C_v^{(3)}$ be the number whose dependent or related adapted forms remain coherent. The displayed error rates are therefore

$$m_{A1}(v) = 1 - \frac{C_v^{(1)}}{I_v}, \qquad m_{A3}(v) = 1 - \frac{C_v^{(3)}}{I_v}.$$

This is the complement of the consistency-rate fields emitted by the validator. Using the complement keeps all three automatic metrics in the same direction: lower is better.

For MA2, let $F_v^{(2)}$ be the confirmed Hall-triad issue count for variant v, and let H_v be the number of evaluated adapted chapters for the same run. The displayed score is

$$m_{A2}(v) = \frac{F_v^{(2)}}{H_v}.$$

The numerator is read from the confirmed-count artifact, not from the raw high-recall detector output.

The denominator is the target chapter count after the completeness gates in Appendix A.2.

For pair-level and pooled tables, numerators and denominators are summed over the included story–variant cells before converting to rates. We therefore sum counts before dividing, rather than averaging per-story rates.

A.5 Evaluation framework validation against native annotators

We validated the evaluation framework against independent human annotation using an internal evaluation tool that pairs the LLM judge with three native-speaker annotators. On a 50-chapter held-out subset covering all three structural axes, the annotators independently labeled identity, dependency, and Hall-triad cultural errors, then deliberated to reach a consensus list of 37 confirmed errors. The judge, run on the same chapters, flagged 39 issues. Of these, 36 overlapped with the annotator consensus; 3 were false positives (flagged by the judge but not confirmed by annotators), and 1 annotator-confirmed error was absent from the judge's list. This yields a precision of 92% and a recall of 97% against human judgment across all error types. The 50 chapters were drawn from two Mandarin→English shows held out from all experiments in this paper (a drama-romance series and a fantasy series), so the judge was validated on material it was never tuned or evaluated on. Annotators labeled independently before deliberating to the consensus set; pre-deliberation inter-annotator agreement was not logged, and we report only consensus-level precision and recall. The judge prompts were iteratively refined with annotators in the loop prior to this final validation pass.

A.6 Dataset characteristics

The five source stories on which the headline metrics are computed are commercially-produced serialized chapters of roughly 2,000–4,000 source characters each, with ∼100 chapters per story. The two English-source stories are adapted into both German and Hindi from a shared source manuscript.

A.7 Competing method configurations

Tables 3 and 4 summarize the four headline variants under two complementary views: which pipeline mechanisms each variant runs, and what each generation call sees at the input.

Component	B1	B2	S1	P_{full}
Cultural plan P	✓	—	—	✓
Entity registry	—	—	✓	✓
Cross-chapter coreference	—	—	✓	✓
Relationship graph	—	—	—	✓
Louvain batching	—	—	—	✓
Validation (Stage 4)	—	—	—	✓
Canonical-name injection	—	—	✓	✓
Chapter rewrite	✓	✓	✓	✓

Table 3: Pipeline-component matrix for the four headline variants. ✓: component active; —: absent. B2 substitutes a rolling natural-language summary for the structured registry/plan (see Table 4). This matrix is the source of truth; the prose definitions in §6.2 and below are aligned with it.

B1 – plan-then-adapt. B1 comprises one whole-novel planning call followed by parallel per-chapter rewrite calls. The planning call receives the entire source novel and produces a target-culture plan in the same six-section schema as Stage 2 of P_{full}: cultural mappings, character localization rules, place localization rules, narrative-voice strategy, genre framing, and naming conventions. Each rewrite call receives one source chapter together with the plan and produces that chapter's adaptation.

B2 – rolling-summary monolith. B2 processes the source novel chapter-by-chapter. Each chapter's prompt comprises (L_T, C_T), the source chapter, and a running natural-language summary of the entities introduced and the localization decisions made in prior chapters. A subsequent generator call after each chapter updates the summary under a 4,000-token budget. The summary is empty prior to chapter 1.

S1 – in-context rolling NER. S1 replaces Stage 1's cross-chapter coreference and relationship-graph construction with per-chapter NER and a flat running entity table whose rows record source name, localized name, first chapter of appearance, and cumulative mention count. Cross-chapter coreference is disabled and no relationship graph is constructed; localization decisions for newly encountered entities are conditioned only on the entity table and the current chapter. Stage 2 (cultural plan P) is disabled and Stage 3's dependency-aware graph-localization is replaced by chapter-co-occurrence batching (no relationship graph). Stage 4 (validation) and Stage 5 (chapter rewrite with canonical-name injection) operate at their P_{full} defaults.

Variant	Upfront pass over the novel	Per-chapter rewrite input	Cross-chapter state carried forward
B1	Full novel → cultural plan (one call)	Source Chapter + plan → full adaptation in multiple parallel calls	Plan only; no per-entity state
B2	—	Source chapter + rolling summary ($\leq$ 4k tokens)	Running natural-language summary
S1	Full novel processed in chunks (per-chapter NER and cross chapter coreference) → registry	Source chapter + registry slice	Flat entity table (name pairs, mention counts); no plan, no graph
P_{full}	Full novel processed in chunks → registry, dependency graph, plan P (Stages 1–4)	Source chapter + registry slice	Structured state: registry, dependency graph, plan P

Table 4: Per-call context budget and chapter access by variant. The contrast B1 vs. P_{full} shows that the headline pipeline's rewrite call receives strictly *less* raw context than B1's; the contrast S1 vs. P_{full} holds chapter access fixed and varies only the structured-state content carried into the rewriter, isolating the contribution of plan P plus registry beyond chapter-by-chapter access.

A.8 Production A/B trial details

The production A/B trial runs on a commercial serialized-fiction platform. For each of three Mandarin-source serialized shows, two adapted English-language scripts are produced—Variant A, the P_{full} output with a minimal validator-guided human review pass, and Variant B, an end-to-end professional human adaptation under the platform's standard editorial process. At first listen for a given show, the platform randomly allocates each new listener to Variant A or Variant B; allocation is at the user level within show, and listeners are not informed of their assigned variant. Variant identity is concealed in the listener-facing interface. The primary outcome is hour-level retention R_h for $h \in \{6, 7, 8, 9, 10, 15, 20, 25, 30\}$, and the secondary outcome is listener-day active users (LDAU). The three shows contribute 11,166 allocated users in total, split 5,588/5,578 across Variant A/Variant B, with 963/998 LDAU. Operationally, the AI-drafted arm required 3 days of validator-guided human review for 10 hours of content; the professional writer workflow took 6 writer days and included story-level changes from the base draft.

Cost comparison. We estimate the per-show cost of each arm for a typical ∼100-chapter Mandarin→English production (median chapter ≈3,200 source tokens). The P_{full} + verification arm aggregates LLM tokens for the five-stage pipeline (Gemini 3.1 Pro generator; ∼$18, with Stage 5's 100 per-chapter rewrites contributing roughly two-thirds) and for the evaluation framework (Claude Sonnet 4.5 and Gemini 3 Flash judges; ∼$10, dominated by Pass 2's sliding-window detector and the per-chapter m_{A0} evaluator), plus 3 days of validator-guided human review at $40/hr. The full-human arm is 6 writer-days at $60/hr. All LLM tokens are priced at Claude Sonnet 4.5 published rates ($3 / $15 per 1M input / output tokens), the costliest model in the stack, so the LLM figures are upper bounds (Gemini 3.1 Pro: $2 / $12 per 1M); a workday is normalized to 8 hours. Table 5 summarizes the comparison.

Lane	LLM	Hours	Rate	**Total**
P_{full} + verification	$29	24	$40/hr	**$989**
Full human adaptation	—	48	$60/hr	**$2,880**

Table 5: Ballpark per-show cost for one ∼100-chapter Mandarin→English production. LLM tokens priced at Claude Sonnet 4.5 rates ($3/$15 per 1M input/output), the costliest model used, giving an upper bound. Human time normalized to an 8-hour workday.

The pipeline lane is roughly 2.9× cheaper, saving ∼$1,890 per show (∼66% reduction), and LLM tokens account for only ∼3% of the P_{full} total.

A.9 Cross-model replication: per-language-pair breakdown

Table 2 in the main text reports aggregate scores for the four-variant ablation replicated on GPT-5 and Claude Opus 4.5; each aggregate is the mean of the three language directions. Table 6 gives the per-direction values for the identity and dependency axes (m_{A1}, m_{A3}). The Claude Opus 4.5 English→Hindi P_{full} cell was re-scored with the

same fixed judges, so its three-direction mean differs from Table 2 by rounding.

	$m_{A1}\downarrow$	$m_{A3}\downarrow$
GPT-5 — Mandarin→English		
B1	0.055	0.055
B2	**0.041**	**0.041**
S1	0.050	0.167
P_{full}	0.054	0.167
GPT-5 — English→German		
B1	0.155	0.155
B2	0.171	0.171
S1	0.191	0.217
P_{full}	**0.052**	**0.052**
GPT-5 — English→Hindi

B2	0.323	0.323
S1	0.102	0.118
P_{full}	**0.035**	**0.081**

Table 6: Cross-model replication by language direction (↓ better). Bold marks the best value among the four variants for that (direction, axis).

A.10 Sample Stage-2 plan output (B1 baseline)

B1's single whole-novel planning call emits a structured plan in the same six-section schema as Stage 2 of P_{full}: cultural mappings, character localization rules, place localization rules, narrative-voice strategy, genre framing, and naming conventions. The excerpt below is verbatim output from a B1 run on one Mandarin→English show (a contemporary romance); the platform name is redacted and the naming-conventions list is truncated (9 of 17 entries shown).

```
### 1. Cultural mappings
* The Guzheng & Musical Factions: The traditional
Chinese Guzheng is mapped to the Classical Violin. The "
Yun Guzheng Faction" becomes an elite, historic American
 string methodology known as the "Quinn Bowing
Technique." Regional factions (Shaanxi, Zhejiang) become
rival American conservatories (e.g., the New York Juilliard
 elite vs. the Chicago String Society).
* Antique Instruments: Famous Guzheng brands (
Dunhuang, Moon Crescent) are mapped to elite violin
makers. A standard high-end violin is a "Modern Cremona
," while the priceless antiques are "Stradivarius" or "
Guarneri" models.
* Food & Culinary Customs: "Biangbiang noodles" and "
Hulu chicken" are mapped to authentic New England
Clam Chowder and Artisanal Roast Pheasant. The night
snacks (宵夜) Chang Su cooks become late-night gourmet
charcuterie boards or artisanal midnight pastas.
* Web Novelist Career: Bai He's career as a struggling
web novelist is mapped to a [platform] indie romance
author who is constantly stressing over her [platform] page
 reads and Amazon algorithm rankings.
* The Will & Inheritance: The grandfather's will requiring
 marriage and a child to inherit the estate is mapped to an
 Old Money New England Trust Fund stipulation, a
common trope in Western billionaire romance.

### 2. Character localization rules
* Julian Quinn (覃小津 - Qin Xiaojin): The aloof, prodigy
violinist. He speaks in highly formal, precise, and slightly
archaic English. He never uses contractions or modern
slang, reflecting his isolated, elite upbringing.
* Harper White (白荷 - Bai He): The resilient, pragmatic
indie author. She uses contemporary millennial/Gen Z
slang, sarcasm, and self-deprecating humor. Her dialogue
should feel chaotic but grounded.
[...]

### 3. Place / setting localization rules
* City Setting: "Yun City" is mapped to Boston,
Massachusetts, a city with a deep-rooted classical music
scene and old-money families.
* The Estate: "Lanhua Wu" (Blue Jacaranda Estate) is
mapped to Blue Wisteria Manor, a sprawling, historic
estate located in the wealthy, wooded suburbs of
Massachusetts (e.g., Wellesley or Concord).
[...]

### 6. Naming conventions
* Qin Xiaojin -> Julian Quinn
* Bai He -> Harper White
* Xiang Qing -> Chloe Shaw
* Chang Su -> Sam Carter
* Qin Shanhai -> Arthur Quinn
* Qin Hu -> Helen Quinn
* Sang Professor -> Professor Beatrice Quinn
* Gong Yi -> Gabriel Vance
* Liu Lang / Qin Lang -> Leo Quinn
[...]
```

A.11 Worked conflict-detection example (Stage 4)

We illustrate the registry-level containment described in §4 with a logged Stage 4 instance from a Mandarin→English run. Stage 3 had localized two unrelated characters, 牛婉兮 (*Annie Beaumont*) and 李庆丰 (*James Beaumont*), to the same surname. Before any chapter was rewritten, the duplicate-name audit raised:

> Character 'char_107' (original: '牛婉兮') shares localized last name 'Beaumont' with unrelated character 'char_72' (original: '李庆丰'). Their original surnames are different, confirming they are not family. Any reference to 'Beaumont' is ambiguous.

Because the two source surnames differ, the conflict is resolvable at the registry level: the repair regenerates only the affected mapping, 牛婉兮 → *Annie Caldwell*, while 李庆丰 → *James Beaumont* and every other registry entry are left untouched and Stage 1 extraction is not rerun. Every subsequent Stage 5 rewrite call queries the corrected registry, so the false shared surname never reaches the adapted text.

B Prompts

We collect the prompt templates used by the evaluation framework. Curly-brace placeholders {variable} indicate runtime substitutions.

B.1 Evaluation prompts

This subsection gives the canonical evaluation-prompt templates used for the reported MA1, MA2, and MA3 scores in Section 5. The prompts are shown with runtime placeholders in braces. Language-pair-specific examples and target-culture labels are substituted at run time, but the task definitions, decision rules, and output fields are fixed across variants.

MA1/MA3 mention mapper. The mapper is the bridge from the human-vetted recurring-item list to the metric-bearing audit artifact. It reads the source chapter, the adapted chapter, and candidate mentions selected from the vetted list. It then records how each observed source-side item is realized in the adapted text.

```
[SYSTEM]
You are a precise bilingual localization auditor. Return
only valid JSON.
Do not invent names or mappings that are not supported
by the adapted text.

[USER]
You are given:
1. The original source chapter in {source_language}.
2. The adapted chapter in {target_language} for {
target_culture}.
3. Candidate recurring-item mentions selected from the
vetted item list.

Task:
Identify how each candidate source mention appears in the
 adapted chapter.

Rules:
- Use only evidence from the adapted chapter for the
adapted span.
- Preserve the provided character ID or entity ID exactly.
- Keep source mentions exactly as provided in the
candidate list.
- If the candidate is omitted from the adapted chapter,
mark it "unmapped".
- If the adapted chapter refers to the concept without a
stable name, mark it
  "conceptual".
- If several adapted mentions are plausible and the
evidence is not decisive,
  mark the row "ambiguous".
- If a concrete adapted mention is present, mark the row "
mapped".
- Return JSON only, with no markdown.

Return:
{
  "mappings": [
    {
      "type": "character|entity",
      "char_id": "source character id, or empty string",
      "entity_id": "source entity id, or empty string",
      "source_canonical_name": "source item name",
      "source_mention": "exact source mention",
      "observed_adapted_mention": "exact adapted
mention or empty string",
      "status": "mapped|unmapped|ambiguous|conceptual",
      "confidence": "high|medium|low",
      "source_evidence": "short source evidence",
      "adapted_evidence": "short adapted evidence",
      "notes": "brief reason"
    }
  ]
}

Candidate mentions:
{candidate_mentions}

Source chapter:
{source_chapter}

Adapted chapter:
{adapted_chapter}
```

Rows from this mapper are grouped by vetted item ID before scoring. The grouped view defines the validated item set I_v and provides the evidence used by the MA1 and MA3 validators.

MA1 identity-consistency validator. This validator reads grouped character rows from the mention mapper. It asks whether the same recurring source character keeps one coherent adapted identity across the evaluated chapters.

```
[SYSTEM]
You are an expert localization validator for long-form
story adaptation.
Return only valid JSON.

[USER]
Validate the adapted character mappings for {
target_language} readers in
{target_culture}.

Input:
- Characters to validate: {characters}
- Related entity context: {entity_context}

Scope:
Validate the adapted character-name fields and mention-
map values. Treat
descriptions and source-canonical names as context only.
They may contain
source-language names and should not by themselves
create an issue.

Decision rule:
For each character, decide whether the adapted mentions
consistently realize
the same source character. Allow normal title changes,
inflection, casing, and
minor spelling variation. Flag an issue when the same
source character is split
across incompatible adapted identities, when the mention
map preserves an
unadapted source form where a stable adapted form is
required, or when a
character mention conflicts with the adapted entity or
relationship context.

Metric-bearing issue labels:
- "mention_map_inconsistency": the adapted mentions for
 the same character do
  not form a stable identity.
- "cross_character_inconsistency": related character names
 or aliases conflict
  with each other.
- "entity_inconsistency": a character mention conflicts
with the adapted entity
  context.

Return only characters with issues:
{
  "character_issues": [
    {
      "char_id": "character id",
      "localization_issues": [
        {
          "issue_type": "one allowed label",
```

```
        "description": "short explanation",
        "affected_mentions": ["mention"],
        "entity_reference": "entity id if relevant",
        "severity": "high|medium|low"
      }
    ]
  }
 ]
}
```

The MA1 count $C_v^{(1)}$ treats a grouped item as consistent when this pass finds no metric-bearing mention-map inconsistency for that item.

MA3 dependency-coherence validator. This validator reads grouped non-character entity rows and character context. It asks whether adapted dependent names still cohere with the adapted characters, institutions, places, objects, and concepts they rely on.

```
[SYSTEM]
You are an expert localization validator for recurring story
 entities.
Return only valid JSON.

[USER]
Validate the adapted entity mappings for {
target_language} readers in
{target_culture}.

Input:
- Entities to validate: {entities}
- Character context: {character_context}

Scope:
Validate adapted entity names and mention-map values.
Treat descriptions,
source names, and source-side aliases as context only.

Decision rule:
For each entity, decide whether its adapted mentions
remain coherent with
the adapted story context. Flag an issue when an entity
mention refers to a
character by an incompatible adapted name, when related
entities no longer
share the name component or institutional pattern that
their relationship
requires, or when a dependent place, title, organization,
object, or concept
drifts away from the adapted head item it depends on.

Metric-bearing issue labels:
- "mention_map_inconsistency": the adapted mentions for
 the same entity are
  internally unstable.
- "character_context_mismatch": an entity mention
conflicts with the adapted
  character name it depends on.
- "cross_entity_inconsistency": related entities are
adapted with incompatible
  dependent names or naming patterns.

Return only entities with issues:
{
  "entity_issues": [
    {
      "entity_id": "entity id",
      "localization_issues": [
        {
          "issue_type": "one allowed label",
          "description": "short explanation",
          "affected_mentions": ["mention"],
          "severity": "high|medium|low"
        }
      ]
    }
  ]
}
```

The MA3 count $C_v^{(3)}$ treats a grouped item as dependency-consistent when this pass finds no metric-bearing related-item issue for that item.

MA2 cultural-residue detector. The MA2 detector evaluates the adapted chapters as a target-culture reading experience. It receives prior adapted-story context packets, a short window of previous adapted chapters, and the current chapter chunk to analyze. The context packets help the judge decide whether a cultural detail has already been explained by the story; the quoted evidence for an issue must come from the current chunk.

```
[SYSTEM]
You are an expert cultural localization QA editor for
fiction localized from
a source culture into an established target locale. Return
only valid JSON.

[USER]
Analyze the adapted chapters for source-culture residue.

You receive three input sections:
1. SYNTHESIZED OVERALL CONTEXT
   Prior adapted-story context for the target chapters. Use
it to understand
   what the story has already established. Do not quote it
as evidence.
2. PREVIOUS CHAPTERS
   Adapted prose before the current chunk. Use it only as
context.
3. CHAPTERS TO ANALYZE
   The current adapted chapter chunk. Report only issues
whose exact quote is
   a continuous substring of this section.

Source culture: {source_culture}
Target culture: {target_culture}
Target chapters: {target_chapters}

Definition:
Source-culture residue is a detail whose narrative logic still
 depends on the
source culture, source-language convention, or original
setting after the
adaptation has moved the relevant character, location,
institution,
relationship, or social context into the target locale.

Localization test:
Flag a finding when the quoted detail is treated as a
default target-locale
norm, institution, ritual, economic assumption,
relationship rule, ordinary
behavior, naming logic, or expected procedure, and when
the surrounding story
does not give a concrete explanation that makes the detail
 natural in the
adapted setting.

Allowed explanations include character background, family
 heritage, travel,
religion, imported goods, restaurant setting, fandom,
personal habit, genre
worldbuilding, historical setting, or explicit multicultural
context.

Hall level:
- "Technical / Visible": explicit culture-bound terms,
names, objects,
  places, institutions, currency, festivals, or titles.
- "Formal / Semi-visible": learned routines, etiquette,
rituals,
  institutional procedures, family/workplace/school
conduct, or role behavior.
- "Informal / Invisible": deeper assumptions about
authority, obligation,
  shame, privacy, gender, kinship, status, politeness, taboo
```

```
, or worldview.

Priority:
- High: breaks the target setting or causes major institutional, plot, or
  character-logic damage.
- Medium: likely confuses target-locale readers or weakens plausibility.
- Low: minor or uncertain but text-supported cultural residue.

Return:
{
  "hall_iceberg_summary": {
    "technical_visible": {"score": 1-5, "issue_count": 0, "assessment": "..."},
    "formal_semi_visible": {"score": 1-5, "issue_count": 0, "assessment": "..."},
    "informal_invisible": {"score": 1-5, "issue_count": 0, "assessment": "..."}
  },
  "inconsistencies": [
    {
      "chapter_number": 1,

```

MA2 acceptance rule. The detector is run in a high-recall mode, but a finding contributes to $F_v^{(2)}$ only when it satisfies the localization test above, has a chapter number in the evaluated chunk, and quotes an exact span from the analyzed adapted chapters. Malformed findings, duplicate reports of the same quoted issue, and findings justified only by prior-context material are excluded from the count used in m_{A2}.

m_{A0}: chapter beat-analysis prompt. The m_{A0} evaluator (§5.1) issues a single LLM call per (source, adapted) chapter pair and returns a structured beat-level analysis with five sub-scores. The full prompt template is shown below.

```
[SYSTEM]
You are a rigorous evaluator for cultural adaptation quality. Your task is to evaluate MA0: whether the adapted chapter preserves the source chapter's story beats. Focus on narrative/content fidelity, not whether localization choices are culturally perfect. The source chapter may be in Chinese/Mandarin and the adapted chapter may be in American English.

[USER]
Evaluate one source/adapted chapter pair for MA0 story-beat preservation.

MA0 definition:
- Measures whether the adapted text preserves the source story's plot events, character actions, relationships, causal links, stakes, reveals, and important entities.
- Do not penalize culturally appropriate substitutions by themselves if they preserve the same narrative function.
- Penalize missing source beats, hallucinated new beats, wrong causality, wrong relationships, wrong character/entity mapping, and major sequence changes that alter the story.

Scoring guidance:
- beat_recall: 1.0 means all important source beats are preserved; 0.0 means almost none are preserved.
- beat_precision: 1.0 means the adapted chapter adds no meaningful hallucinated/contradictory beats; 0.0 means many adapted beats are unsupported.
- sequence_fidelity: 1.0 means the order/causal flow is preserved; 0.0 means the adapted flow changes the story.
- character_entity_fidelity: 1.0 means characters/entities map consistently in narrative function; 0.0 means major people/entities are confused.
- overall_ma0_score: holistic 0.0-1.0 score weighted toward beat_recall and story-changing errors.

C Extended related work

This appendix expands the positioning in §2.

Translation-studies foundations. The conceptual scaffold for separating *translation* from *adaptation* has a long history in translation studies. Schleiermacher's foreignization–domestication dichotomy (Schleiermacher, 1813), Toury's descriptive translation studies (Toury, 1995), Venuti's ac-

count of translator invisibility (Venuti, 2017), and the Skopos theory of translational action of Reiss and Vermeer (1984) together establish that translation strategy is a choice conditioned on purpose and target culture: when the skopos prioritizes target-culture experience, the regime shifts from source-faithful equivalence to target-culture rewriting. Industry practice has formalized this shift as *transcreation* in game localization (O'Hagan and Mangiron, 2013; Mangiron and O'Hagan, 2006) and in marketing and advertising (Pedersen, 2014), and more recent NLP work has begun to import transcreation as an operational construct (Silva et al., 2024). Our work is, to our knowledge, the first NLP formalization of long-form cross-cultural adaptation with named structural axes and an architectural decomposition aligned to those axes; we draw on these foundations conceptually rather than as quantitative comparison points.

Document-level and literary machine translation. A line of work has tightened the sentence-level gap in literary settings. Karpinska and Iyyer (2023) show that document-level context lets LLMs outperform sentence-by-sentence LLM translation on literary paragraphs across 18 language pairs, while leaving a tail of critical errors that still requires human intervention; Jin et al. (2024) introduce a chapter-level Chinese–English benchmark and show that chapter-to-chapter translation remains challenging for current LLMs. Thai et al. (2022) contribute the Par3 paragraph-aligned multilingual literary corpus, and Wang et al. (2024) run the WMT 2024 Discourse-Level Literary Translation shared task. Discourse-level evaluation has matured around BlonDe (Jiang et al., 2022), which scores entity, tense, pronoun, and discourse-marker consistency on document-sized inputs; Zhang et al. (2025) extend literary-evaluation methodology with human-vs-LLM head-to-heads. Separately, Vu et al. (2024) inject source-side coreference into a context-aware MT model and report BLEU gains of up to $\sim$2 points on IWSLT En-De, OpenSubtitles En-Ru, and multilingual TED, demonstrating the value of coreference signal for local reference stability even though the evaluation is on subtitles and talks rather than on book-length fiction. These systems narrow the sentence-level gap and improve local discourse cohesion, but they operate without an explicit cross-chapter entity registry, without a global target-culture plan, and without dependency-aware batching: identity drifts across hundreds of chapters (A1) and source-culture artifacts persist inside target-culture scenes (A2). Our Stage 1 cross-chapter coreference plus entity registry, Stage 2 cultural plan P, and Stage 3 Louvain-based batching (Blondel et al., 2008) are the persistent global state these systems lack. Earlier work on *document substructure* for MT (Dobreva et al., 2020) encoded Wikipedia section topics as side constraints or cache state, anticipating the idea that documents carry exploitable internal structure; our cross-chapter entity registry and plan P generalize this from intra-document sections to inter-chapter narrative state. Subsequent work scales the *quantity* of context—e.g., DocFlat's flat-batch attention and neural context gate push beyond pseudo-document boundaries on En-De (Wu et al., 2023)—but treats context as a flat token stream rather than as a structured cross-chapter state, which is the gap our Stage 1 registry and Stage 2 plan P target.

Atomic-scale cross-cultural adaptation in NLP. A parallel line of NLP work establishes that adaptation outperforms literal translation at *atomic* scale: Cao et al. (2024) show this for recipes; Yao et al. (2024) benchmark MT cultural awareness on culture-specific items; Singh et al. (2024) treat cultural adaptation as an intralingual rewriting problem; and Khanuja et al. (2024) extend adaptation to images for cross-cultural relevance, with Khanuja et al. (2025) proposing automatic evaluation for image transcreation. These artifacts share a defining property: they have no recurring identity across chapters, no dependent sibling entities, and no narrative continuity, so the techniques do not lift directly to long-form output. We extend the adaptation paradigm from atomic artifacts to multi-chapter narrative by introducing a structured dependency graph (Stage 1) and Louvain-based dependency-aware batching (Stage 3) that operate across recurring entities, plus a global cultural plan P (Stage 2) that constrains the space of acceptable mappings so atomic-scale "adaptation $>$ literal" transfers coherently to long-form output.

Contrast with image transcreation. The closest prior work in spirit is the image-transcreation line opened by Khanuja et al. (2024) and continued by Khanuja et al. (2025), which established cultural *adaptation* (rather than literal translation) as the right regime for cross-cultural image rendering and provided the first automatic evaluation frame-

work for that task. Our work shares the "adaptation > literal" thesis but operates in a regime where three new structural difficulties appear simultaneously and the Khanuja et al. (2024) apparatus does not transfer: (i) *recurring identity across the long arc* (an image has no chapter-50 follow-up; a character does), which forces the A1 machinery and persistent global state; (ii) *dependency-chain structure* among co-referring entities (an image has no head/dependent semantics; a family does), which forces the A3 machinery and the Louvain dependency-aware batching; and (iii) *cultural-system alignment within scenes* (an image is one scene; a novel is a hundred), which forces the per-scene A2 evaluation framework rather than per-artifact judgment. We import the methodological commitment of Khanuja et al. (2024) to axis-decomposed evaluation and to native target-culture validation, and extend it to the long-form regime along all three new axes; in our setting the native target-culture validation comes from listener engagement on a deployed production A/B rather than from crowdsourced ratings by native annotators.

Long-form generation and discourse-level evaluation. Long-form generation evaluation has converged on discourse and engagement measurement. BlonDe (Jiang et al., 2022) is a discourse-overlap metric for document-level MT; broad multilingual benchmarks such as MEGAVERSE (Ahuja et al., 2024) stress-test LLMs across 22 datasets and 83 languages but treat tasks at sentence or short-passage granularity rather than at chapter scale; and creative-narrative evaluation work (Ismayilzada et al., 2025; Chakrabarty et al., 2024) probes generation quality on creative short stories. These instruments measure intra-language coherence, engagement, and creativity, but none isolate cross-cultural alignment as an evaluation axis or pair operational metrics with an external listener-engagement instrument at production scale. Our evaluation framework (§5) addresses this gap: m_{A1} is an identity error rate over validated recurring entities across the full arc; m_{A2} counts confirmed cultural-residue errors per chapter under the Hall-triad taxonomy (Appendix A.3); m_{A3} is a dependency-coherence error rate; and the architecture-level result is externally validated by a production A/B against professional human adaptation on hour-level listener retention.

LLM-as-judge methodology and calibration. We follow the LLM-as-judge methodology established by Zheng et al. (2023) and extend the G-Eval-style reference-free scoring of Liu et al. (2023) with axis-decomposed rubrics. Known judge biases motivate our fixed cross-family judge assignment (§6.3) and validation against human annotation (Appendix A.5): length effects (Dubois et al., 2024; Saito et al., 2023), self-preference of evaluators for their own generations (Panickssery et al., 2024), and judgement biases more broadly (Chen et al., 2024). Off-the-shelf judge protocols are uncalibrated for per-axis cross-cultural claims at long-form scale; the pipeline used in this paper, validated against native-speaker annotation (Appendix A.5), is the minimum bar we judge sufficient.

D Task scope, non-redundancy, and regime

This appendix expands the scope and methodology paragraphs of §3.

Non-redundancy: structural realizability. The three axes are non-redundant in the strong sense that each is independently realizable as the sole failure mode of an otherwise coherent output. *A1 alone:* a chapter rendered with consistent cultural artifacts (no enclaves) and coherent dependent references (head → estate → honorific all in C_T) can still fail A1 at chapter 87 when the localized name of a character introduced in chapter 3 drifts to a different target-side spelling. *A2 alone:* every recurring entity is renamed consistently and every dependent reference is coherent under the new head, yet the kitchen scene still contains *baozi* where it should contain the target-culture equivalent. *A3 alone:* identity is stable across the arc and cultural artifacts inside scenes are target-native, yet the *Qin Family Villa* retains the source-culture form because lexical find-and-replace on the head "Qin" → "Sterling" cannot reach the semantically-dependent estate name. Each of these single-failure cells is observed in baseline outputs (Appendix E).

Why these three axes (and not others). Prior literary-translation evaluation already covers discourse consistency (BlonDe (Jiang et al., 2022)), span-level error typology and translator preference (Karpinska and Iyyer, 2023), and shared-task human assessment (Wang et al., 2024); we

do not introduce new axes for these because existing instruments already measure them and our pipeline does not change their behavior. The three axes A1/A2/A3 are precisely those that emerge at the intersection of *long-form* (where chapter-k identity decisions are visible only at $k + 50$) and *cross-cultural* (where the cultural substrate of the target differs from the source): A1 is the long-span generalization of the document-level coreference problem; A2 is the long-form extension of atomic-scale cultural adaptation (Khanuja et al., 2024; Cao et al., 2024; Yao et al., 2024); and A3 captures dependency structures specific to entities-with-culturally-bound-extensions, a class neither short-context nor atomic-scale work has had to address. We make no claim of exhaustiveness over all long-form-cross-cultural concerns—behavioral markers (bowing, register-marked address forms) sit at the A2/A3 boundary and are discussed as a known scoping question in §8—only that A1/A2/A3 are non-redundant and jointly load-bearing for the failure mode this paper is about.

Scope: the domestication regime in detail. A2 as defined in §3 encodes a specific stance within the foreignization–domestication tradition of translation studies (Schleiermacher, 1813; Venuti, 2017): source-culture artifacts inside target-culture scenes are treated as failures *unless* explicitly framed as foreign imports. This is a *domestication-oriented* setting, appropriate to the commercial localization regime where the skopos prioritizes target-culture-native reading experience: video games, audiovisual content, and serialized fiction platforms whose readers expect a target-culture surface. We make this stance explicit rather than implicit because the alternative regime—foreignization, where preserving source-culture texture is a feature rather than a bug—is equally legitimate and motivates a different metric. Three classes of reference are correctly admitted by the current A2 definition: (i) *heritage scenes*, where a character framed as heritage-keeping retains source-culture artifacts (the third-generation Chinese-American keeping an altar); (ii) *tourist scenes*, where the narrative explicitly visits the source culture and source-culture markers are part of the setting; (iii) *cross-culturally shared references*, items that have crossed into the target culture as commonly-recognized terms (ramen in modern English-speaking contexts). The residue A2 measures is unflagged source-culture artifacts inside scenes that have already been moved to the target culture. A symmetric foreignization-regime metric (rewarding source-culture texture preservation) is straightforward to construct from the same Hall-triad taxonomy (§A.3) by inverting the enclave decision; we report results under the domestication regime only (§3)..

E Qualitative Error Analysis

This section provides extended qualitative examples demonstrating both the structural failures of the baseline methods and the remaining limitations of P_{full}.

E.1 Pipeline Successes: Resolving A1, A2, and A3

A1: Identity Drift **Source:** 华夏基因进化大学 (*Huaxia Genetic Evolution University*) **Baseline:** Fractures into 10 distinct institutions across the arc (e.g., *NMGEU, United States Genetic Evolution College*). P_{full}**:** Locked globally as *the national academy for genetic advancement*.
A2: Cultural Residue **Source:** Mandarin sci-fi adaptation, ch. 90: 真气; 基础丹田/丹田 **Baseline:** Retains source culture terms (*True Qi*, *Dantian*), violating the sci-fi register. P_{full}**:** Localizes them as *somatic current* and *core somatic nexus*.
A3: Dependency-Chain Integrity **Source:** 罗十六 (*Luo Shiliu*) and 罗十六的母亲 (*Luo Shiliu's mother*) **Baseline:** Severs the possessive chain, drifting the dependent between disconnected proper nouns (*Margaret Hayes*) and detached descriptors (*Mother-and-Child Haunt*). P_{full}**:** Preserves the explicit lexical dependency chain, co-localizing them stably as *Ethan* and *Ethan's mother*.

Table 7: Qualitative comparison of structural failures versus P_{full} resolution.

Table 7 summarizes one instance per axis; the paragraphs below give the full context for each and a second A3 example.

A1: Institutional Identity Drift. In our Mandarin→English evaluation, the protagonist's university (华夏基因进化大学, *Huáxià Genetic Evolution University*) is mentioned across 60+ chapters. The B2 (rolling summary) baseline suffers from severe compression loss, referring to the institution by over ten distinct names across the arc (e.g., *NMGEU, GAT, Golden City Genetic Evolution University, United States Genetic Evolution*

College). P_{full} stores a single canonical form (*the national academy for genetic advancement*) in its persistent registry, remaining completely stable.

A2: Cultural Residue. Without a persistent target-culture plan tied to the entity registry, B1 retains recurring source-culture terminology inside target-genre scenes. In chapter 90 of the same source, the entity 真气 belongs to a Chinese cultivation lexicon and is conventionally rendered as *True Qi* or internal energy, while 基础丹田/丹田 is commonly preserved as *Dantian* (energy core). These terms create cultural residue in the adapted sci-fi biometric register. P_{full} instead localizes them together as *somatic current* and *core somatic nexus*, preserving their narrative function while aligning them with the target ontology of bioenergy, genetic nodes, and energy fields.

A3: Dependency-Chain Integrity. Dependent entities must co-localize with their heads. In the same source, 周胜 (*Zhou Sheng*) heads the 金城特情署 (*Jincheng Special Ops Department*). In B1 and S1, these entities drift independently across chapters: the head becomes *Vance Zhou* or *Joe*, while the agency becomes *Alliance Security* or *CIA Special Operations Division*. P_{full} batches them together during Stage 3, producing the stable pair *Victor Sterling* and the *Genetic Security Bureau*.

E.2 Pipeline Failures and Limitations

F1: Shared-Surname Blanket Replacement (Task-Level Failure). When multiple unrelated source characters share a common surname, all variants struggle. In another Mandarin source, seven unrelated characters share the surname 刘 (*Liu*). P_{full} conservatively assigns them all the localized surname *Boone* (e.g., *Curtis Boone, Carpenter Boone, Mrs. Boone*), creating ambiguity. Stage 4 flags these collisions (e.g., "Character shares localized last name 'boone' with unrelated characters"), but the architecture cannot safely split them without explicit relational evidence.

F2: Cluster-Boundary Divergence (A3 Desync in P_{full}). While Louvain batching generally succeeds, dependents that cluster topically rather than relationally can diverge. In an English→German adaptation, the head *Charles* is localized to *Carl*. However, *Charles's father* and *Charles's doctor* clustered separately and were localized to *Christians Vater* and *Christians Arzt*.

F3: Honorific Residue (A2 Leakage). P_{full}'s registry stores source-language honorific structures (*X*-哥, 老-*X*). Stage 5 sometimes renders these as literal English compounds (e.g., *Bro Troy* for 小腿哥, or *Old Braddock* for 老程). While the entity name is localized, the relational pragmatic is not, which reads awkwardly to an American audience.

F4: Script-Split Artifacts. When the source text mixes traditional and simplified Chinese across chapters (e.g., 刘浪 vs. 劉浪), Stage 1 extracts them as separate entities if no normalization is applied, leading to diverging target names (*Leo Trent* vs. *Leo Thorne*). This is an easily correctable pipeline artifact but remains a failure mode in the current snapshot.

E.3 Cross-Cultural Generalization: Variance by Language Pair

The empirical results (Table 1) reveal that while P_{full} is highly effective overall, its performance profile varies significantly depending on the source and target culture pair.

Consistent Success on Dependency Integrity (A3). Across all three language pairs (Mandarin→English, English→German, and English→Hindi), P_{full} consistently achieves the lowest error rate on the dependency axis (m_{A3}). This confirms a broad architectural conclusion: the structural mechanism of Louvain-batched graph localization (Stage 3) generalizes across languages. Because it relies on the topological structure of the entity relationship graph rather than language-specific pragmatics, it successfully forces heads and dependents to co-localize regardless of the target culture.

Variance in Identity (A1) and Cultural Alignment (A2). In contrast, P_{full}'s performance on A1 and A2 is sensitive to the language pair:

- **High-Resource, High-Proximity (English→German):** P_{full} dominates, achieving near-zero error rates across A1 (0.014) and A2 (0.055). The underlying LLM possesses strong priors for German naming conventions and cultural norms, allowing the Stage-2 cultural strategy and Stage-1 registry to operate near perfectly.
- **Moderate-Proximity (Mandarin→English):** P_{full} wins decisively

on A1, but narrowly trails the B2 baseline on A2 (0.124 vs. 0.121). As detailed earlier in this appendix, this slight A2 regression is primarily due to the pipeline awkwardly retaining literal translations of Chinese honorifics (e.g., *Bro Troy* or *Old Braddock*), a culturally specific artifact that simpler baselines incidentally drop.

- **High-Divergence (English→Hindi):** P_{full} loses to B2 on A1 (0.147 vs. 0.111) and to S1 on A2 (0.050 vs. 0.041). This suggests that when adapting into culturally divergent target systems like Hindi, the rigid global constraints of Stage 1 (fixed registry) and Stage 2 (global plan) can become brittle. In such cases, the flexible, sequential re-evaluation of the B2 rolling-summary baseline actually produces more coherent identity mappings than a strict top-down registry.

In summary, while the pipeline's graph-based dependency resolution (A3) is universally robust, its strict global anchoring (A1/A2) thrives primarily when the underlying model has strong target-culture priors. For highly divergent pairs like English→Hindi, enforcing a rigid global strategy occasionally underperforms local, context-driven adaptation.

Beyond Accuracy: Robustness, Cost, and Governance Trade-offs for Vision-Language Models in Templated Document Extraction

Abstract

Vision-language models (VLMs) are increasingly used to extract structured fields from business documents, yet most evaluations report accuracy on clean benchmarks and offer little guidance to practitioners choosing an approach for a given task complexity. We address this gap with a measurement-grounded study and an open-source release. Across eleven systems (three commercial, two reasoning, five open-source VLMs in pretrained and fine-tuned form, and a non-LLM OCR→regex floor) scored on a 750-document held-out pool of synthetic checks, fine-tuning on 3K samples lifts the best open-source VLMs above F1 0.98—above every zero-shot commercial system on this task—while GPT-5 leads the commercial pool on F1 and Claude Sonnet 4.5 collapses on Date. To turn these measurements into actionable choices, we introduce a practitioner-oriented selection framework that maps a task profile (quality, latency, governance, volume) to a recommended approach via filtering and total-cost minimization, illustrated on a hypothetical mid-volume document-extraction scenario.[1]

1 Introduction

Intelligent document processing (IDP) underpins high-volume operations in finance, healthcare, and insurance. Recent vision-language models (VLMs) promise end-to-end field extraction without explicit OCR (Bai et al., 2025; Marafioti et al., 2025), and large multimodal LLMs (OpenAI, 2023) approach human-level accuracy on clean documents. For a practitioner facing a new extraction task, however, public leaderboards offer little actionable guidance: they report accuracy on curated, well-aligned scans and rarely describe the joint operating conditions—scan-defect robustness, latency budget, deployment governance, and processing volume—that determine which approach is feasible at production.

We focus on structured field extraction from templated business forms, a prevalent and high-volume class of enterprise document processing tasks. Our primary study is on bank checks; we additionally report a cross-industry generalization test on insurance application forms.

Our central question is operational: *given a target task with a specified complexity (quality threshold, latency budget, governance requirement, expected volume), which class of approach should a practitioner adopt?* We answer it through releasable artifacts and a selection framework grounded in measurement. Because frontier model lineups change on a quarterly cadence, our central contribution is the *evaluation-and-selection framework* rather than any fixed vendor ranking: the model pool reported here is a snapshot, and new entrants can be evaluated by re-populating the candidate set $\mathcal{M}$ (Section 5) with updated measurements from the released harness. Concretely, we make four contributions.

Contributions. (i) A **check-extraction dataset** of 3,748 synthetic images with four-field ground truth (Payee, Amount, Date, Bank). (ii) An **open-source code release** covering data generation, LoRA and full fine-tuning, prompt and API harnesses, and per-sample diagnostics.[2] (iii) An **empirical evaluation** of eleven systems—three commercial (GPT-4.1 vision, OCR+GPT-4.1, Azure Content Understanding), two reasoning (GPT-5, Claude Sonnet 4.5), five open-source VLMs (Qwen2.5-VL-3B/7B, SmolVLM2-2.2B/500M/256M, each in pretrained and fine-

[1] **Disclaimer.** This paper reports an experimental evaluation on synthetic data. It does not represent deployment guidance, procurement guidance, or the views of any corporation. No customer documents, internal company metrics, or non-public operational data were used in any experiment or in the illustrative scenario of Section 6.

[2] The dataset (i) and code release (ii) are available at https://github.com/manulife-ai/beyond-accuracy-vlm-emnlp2026/; see Appendix B for reproducibility details.

EMNLP 2026 Industry Track, pages 2115–2126
October 24-29, 2026 ©2026 Association for Computational Linguistics

tuned form), and a non-LLM OCR→regex floor—with per-field and per-error-mode breakdowns over >45K field-level predictions. (iv) A **practitioner-oriented selection framework** mapping a task profile to a recommended approach via governance/quality/latency filters and total-cost minimization, instantiated on an illustrative mid-volume document-extraction scenario.

2 Related Work

VLMs for document understanding. End-to-end models such as Donut (Kim et al., 2022) and document-tuned multimodal LLMs eliminate explicit OCR. Recent open-source VLMs (Bai et al., 2025; Marafioti et al., 2025) target on-device inference but have not been systematically evaluated on enterprise document distortions.

Robustness in document AI. Most document benchmarks (FUNSD (Jaume et al., 2019), CORD (Park et al., 2019), RVL-CDIP (Harley et al., 2015)) provide clean scans, and prior OCR-robustness work has tended to address individual preprocessing axes in isolation (e.g., binarization under non-uniform illumination, Michalak and Okarma, 2020) in the pre-VLM era (Cui et al., 2021). The robustness of modern VLMs to *compound* enterprise distortions—perspective, rotation, and noise—on structured-extraction tasks remains underexplored.

Deployment trade-offs. Cost–accuracy Pareto analyses for LLM APIs (Chen et al., 2024) have addressed text-only inference. Recent work in enterprise document processing has begun to expose the same trade-off space: hybrid OCR+LLM routing across 25 configurations for copy-heavy identity documents (Wang and Shen, 2025), and multi-agent orchestration benchmarks on 10 K SEC filings that report cost-per-document and Pareto positions alongside accuracy (Kulkarni and Kulkarni, 2026). Our work extends this analysis to multimodal field extraction and treats governance as a configurable task parameter: a given workload may or may not impose constraints (legal, policy, contractual, or operational) that narrow the set of admissible deployment options, and the framework simply encodes whichever constraints the practitioner specifies.

3 Experimental Setup

Task. Models are prompted to return a JSON object with four fields per check: **Payee** (free-text), **Amount** (numeric), **Date** (MM/DD/YYYY), and **Bank** (categorical: Chase, Citi, BOA). All variants share an identical prompt and schema.

Dataset. We render 3,748 synthetic check images from a structured table of field values using a template-driven pipeline with controlled appearance perturbations. Of these, 2,998 are used for fine-tuning and 750 form the held-out test pool (identical for every model in this study); no document appears in both splits.

Train/test disjointness. Because the dataset is template-driven, leakage is a legitimate concern. We split at the row level of the underlying field table before rendering: the Payee, Amount, and Date values in the 750-document test pool are drawn from rows disjoint from the 2,998-document training table (random partition, seed 42, fixed for all experiments). Bank, being a 3-way categorical, is shared by construction; its near-perfect accuracy across all systems (Section 4.2) should therefore be read as classification on a closed vocabulary rather than evidence of generalisation. Template backgrounds are also held disjoint: the rendering pipeline draws from separate background pools for train and test.

Models. We evaluate three commercial systems—GPT-4.1 (vision-only), OCR+GPT-4.1 (Azure Document Intelligence + GPT-4.1), and Azure Content Understanding (ACU)—two reasoning models—GPT-5 and Claude Sonnet 4.5—five open-source VLMs: Qwen2.5-VL-3B and 7B (LoRA fine-tuned, r=16, α=32, 1.08% / 1.23% trainable parameters), and SmolVLM2-256M, SmolVLM-500M, SmolVLM2-2.2B (full fine-tuning)—and a non-LLM OCR→regex baseline (Azure Document Intelligence Read + hand-written field-specific patterns) that bounds the floor of what a zero-LLM-cost pipeline achieves on this task. Open-source models are evaluated both pretrained and after fine-tuning. Fine-tunes use 2,998 examples, effective batch size four, paged AdamW-8bit; Qwen-3B and the three SmolVLM variants run 3 epochs, with learning rates 2×10^{-4} (Qwen-3B LoRA) and 1×10^{-5} (SmolVLM full fine-tuning). Qwen-7B uses 5 epochs at 1×10^{-4} LoRA learning rate, a longer/gentler schedule that keeps the 7B adapter from truncating long outputs.

Scope of baselines. We do not evaluate purpose-built structured-extraction encoders (Donut (Kim et al., 2022), LayoutLMv3 (Huang et al., 2022), Pix2Struct (Lee et al., 2023), UDOP (Tang et al., 2023)) in this release: our framework requires candidates that produce structured JSON directly, whereas these models require task-specific decoding heads. Recent 2025 work on document key information extraction (Wang et al., 2025; Yu et al., 2025) benchmarks task-adapted VLMs against other VLMs rather than LayoutLMv3/Donut-era models, reflecting a community shift in what constitutes a competitive extraction system; our candidate set is aligned with this current practice. Incorporating purpose-built encoder-decoder models is future work.

Metrics. We report entity-level micro-F1 with TP/FP/FN aggregated over all four fields, per-field F1, document-level accuracy (all four fields correct), JSON parse success rate, and end-to-end latency. We additionally analyze per-sample debug logs to categorize errors as *under-extraction* (empty prediction), *wrong value*, or *parse failure*.

4 Results

4.1 Overall Performance

Table 1 reports headline metrics. All models—commercial, reasoning, and open-source—are scored on the same 750-document held-out PNG test pool.

Within the commercial pool, GPT-5 leads on F1 narrowly above OCR+GPT-4.1 and GPT-4.1 vision but at 2× the latency of the latter, while GPT-4.1 vision has the highest document-level accuracy; ACU is the most balanced across fields (Section 4.2), and Claude Sonnet 4.5 trails, dragged down almost entirely by Date.

Under a fixed adaptation budget of 2,998 training documents (Section 3), the best fine-tuned open-source models exceed every zero-shot commercial system on this schema—Qwen2.5-VL-7B FT reaches 0.985 and Qwen2.5-VL-3B FT 0.983 (within 0.002 of each other; Appendix G confirms this gap is within seed noise), both with zero JSON parse failures, suggesting the 3B adapter already saturates the available signal on this schema. Even SmolVLM2-256M becomes usable with fine-tuning, moving from 0.000 to 0.726 F1 and from 100% to 30.7% JSON parse failure—operationally fragile but viable for clean-document pilots. The non-LLM OCR→regex floor trails every commercial and fine-tuned system (Tables 1–2).

Model	F1	DocAcc	Lat. (s)	JSON Fail
Commercial & reasoning				
GPT-5	*0.928*	41.7	26.3	0.0%
OCR+GPT-4.1	0.917	40.7	18.1	0.0%
GPT-4.1 (vision)	0.909	45.4	12.2	0.0%
ACU	0.889	33.1	12.8	0.0%
Claude Sonnet 4.5	0.857	14.8	8.5	0.0%
Non-LLM floor				
OCR+Regex	0.395	0.0	8.6	—
Open-source, fine-tuned				
Qwen2.5-VL-7B	**0.985**	**88.9**	3.53	0.0%
Qwen2.5-VL-3B	0.983	88.4	4.18	0.0%
SmolVLM2-2.2B	0.906	46.7	1.47	0.0%
SmolVLM-500M	0.854	45.1	**0.96**	5.3%
SmolVLM2-256M	0.726	22.4	1.62	30.7%
Open-source, pretrained (no FT)				
Qwen2.5-VL-7B	0.921	50.7	2.53	0.0%
Qwen2.5-VL-3B	0.847	24.5	4.75	0.0%
SmolVLM2-2.2B	0.504	0.4	2.03	3.3%
SmolVLM-500M	0.000	0.0	1.80	100%
SmolVLM2-256M	0.000	0.0	1.30	100%

Table 1: Headline metrics on the 750-document held-out PNG test pool (identical pool for every model). Fine-tuned rows use a fixed adaptation budget of 2,998 training documents (LoRA for Qwen, full fine-tuning for SmolVLM; recipes in Section 3). **Bold** marks the best in column among open-source FT; *italic* marks the best F1 within the commercial / reasoning block. Open-source latencies are measured on a single NVIDIA A100 80 GB PCIe (bf16, batch size 1, five-document warmup discarded); see Section 4.5 for the A100→H100 sensitivity analysis. The OCR+Regex row is a non-LLM floor baseline (Azure Document Intelligence Read + hand-written field-specific patterns); its outputs are field-keyed dictionaries, not JSON, so the JSON-failure column is not applicable.

4.2 Per-Field Analysis

Table 2 confirms that Date is the hardest field for every commercial system—F1 ranges from 0.468 (Claude) to 0.795 (ACU). Claude Sonnet 4.5's failure mode is extreme over-extraction: 686 Date false positives against 304 true positives, giving precision 0.31 and recall 0.99. GPT-4.1 (vision) and OCR+GPT-4.1 show the same pattern at lower magnitude (precision 0.65 and 0.63 respectively, recall ≈ 1). Only ACU achieves balanced Date precision/recall (0.733/0.870).

Is Date a prompting artifact? We tested GPT-4.1 with five targeted interventions (higher image detail, a check-parsing persona, orientation cues, an MM/DD/YYYY format instruction, and few-shot rotated / OCR-misread examples). Date accu-

Model	Payee	Amount	Date	Bank
Commercial & reasoning				
OCR+GPT-4.1	**0.874**	**0.994**	0.769	**1.000**
GPT-4.1 (vision)	0.856	0.963	0.791	**1.000**
ACU	0.780	0.960	**0.795**	0.988
GPT-5	0.870	0.970	0.772	0.999
Claude S. 4.5	0.810	0.874	*0.468*	0.993
Non-LLM floor				
OCR+Regex	0.305	0.721	0.162	0.264
Open-source, fine-tuned				
Qwen-3B FT	0.924	0.984	0.957	**1.000**
Qwen-7B FT	**0.935**	**0.992**	**0.960**	**1.000**
SmolVLM2-2.2B FT	0.807	0.913	0.886	0.995
SmolVLM-500M FT	0.728	0.876	0.855	0.938
SmolVLM2-256M FT	0.587	0.730	0.748	0.818

Table 2: Per-field entity-level F1 on the 750-document held-out PNG test pool. **Bold** = best in column within its block; *italic* = lowest Date F1 among commercial.

racy rose by about two percentage points (≈79% to ≈81%), suggesting the failure is not primarily a prompting artifact. JSON-mode was not tested separately: parse validity is not the failure mode.

By contrast, fine-tuned Qwen models match or surpass the commercial systems on Date in our pool because they learn to copy the single Date region rather than enumerate every date-like substring on the page.

Conversely, **Bank is the easiest field** for every generative system at 2B parameters or above (F1 ≥ 0.988)—a small categorical vocabulary (Chase, Citi, BOA) is effectively memorised; only the sub-1B SmolVLMs and the regex floor lag.

GPT-5 is the only model to report two additional fields, AmountInWords (F1 0.957) and CheckNumber (F1 0.967); these are useful when a richer schema is required and influence the cost analysis in Section 6.

4.3 Error Taxonomy

A per-sample analysis yields three recurring error categories: (E1) *degenerate repetition* in sub-500M VLMs (looping arrays that exhaust the token budget, explaining the 30.7% JSON-failure rate of fine-tuned SmolVLM2-256M); (E2) *phonetic Payee misspelling* in mid-size open-source models on visually-ambiguous character pairs (g/y, s/z, e/i); and (E3) *Date over-extraction* in commercial LLMs (every date-like substring is emitted; Claude's worst case is 686 FP against 304 TP). The pattern argues for class-specific post-processing: schema validation and stop-token tuning for sub-500M VLMs, and Date-context disambiguation for commercial LLMs. Appendix E gives quantitative breakdowns and examples.

Model	Pretrained	Fine-tuned	Δ
Qwen2.5-VL-3B	0.847	0.983	+16%
Qwen2.5-VL-7B	0.921	0.985	+7%
SmolVLM2-2.2B	0.504	0.906	+79%
SmolVLM-500M	0.000	0.854	–
SmolVLM2-256M	0.000	0.726	–

Table 3: Pretrained vs. fine-tuned Micro-F1 on the held-out PNG test pool.

4.4 Fine-tuning Impact

Fine-tuning helps every open-source model (Table 3). The largest absolute gains are for the smallest models—SmolVLM-500M and -256M both move from total failure to usable output. Qwen-3B's relative gain is modest and Qwen-7B's is even smaller, because both pretrained Qwen models are already strong on this schema. The 3B and 7B fine-tunes end with only a marginal difference, so the additional 4.6B parameters in the 7B adapter buy very little accuracy on this task.

4.5 GPU Sensitivity

Table 1 latency is measured on an NVIDIA A100 80 GB PCIe. Re-running the five fine-tuned models on an NVIDIA H100 NVL under identical software yields a consistent 1.4–1.7× per-document speedup with accuracy unchanged within noise (ΔF1 ≤ 0.003); the relative ordering is preserved (Appendix D). The 7B-faster-than-3B reversal at batch 1 is reproducible on both GPUs and attributable to Qwen-7B's shallower-but-wider decoder (28×3584 vs. 36×2048 layers/hidden); the gap should close at larger batch sizes.

4.6 Cross-task and OOD Evaluation

Out-of-distribution checks. We evaluate the four fine-tuned open-source models zero-shot on a public Indian-style check dataset (`shivalikasingh/cheques_sample_data`, n=400; different rendering pipeline, bank vocabulary, and DD/MM/YY dates). SmolVLM2-2.2B FT, the check-task recommendation, retains 87% of its in-domain F1 (0.788 OOD vs. 0.906 in-domain, Table 4). Qwen-3B FT drops 39 points; the failure is a diagnosable training-data artifact—year 2024 appears in every training record and all 400 OOD predictions are "06/05/2024". Both sub-1B SmolVLM variants collapse structurally under domain shift.

Model	Checks (F1)	OOD (F1)	Insurance (Acc.)
Qwen2.5-VL-3B FT	0.983	0.593	0.927
Qwen2.5-VL-7B FT	**0.985**	–	0.927
SmolVLM2-2.2B FT	0.906	**0.788**	0.292
SmolVLM-500M FT	0.854	0.001	**0.895**
SmolVLM2-256M FT	0.726	0.000	0.145
GPT-4.1 (vision)	0.909	–	0.768
OCR+GPT-4.1	0.917	–	0.757

Table 4: Cross-task and OOD evaluation. Checks: 750-doc held-out PNG pool (Table 1). OOD: 400-doc public dataset `shivalikasingh/cheques_sample_data`, evaluated zero-shot after check-task fine-tuning. Insurance: 36-field insurance application forms, 4,000 train / 1,000 test. GPT-4.1 insurance numbers use `true`↔`yes` normalization on Y/N outputs (raw: 0.738 and 0.731; see Appendix F). "–" indicates the model was not evaluated on that task. **Bold** marks the best in-column among fine-tuned open-source.

Insurance-form task. We separately fine-tune the same open-source families on a 36-field insurance application form task (4,000 train / 1,000 test) under the same adaptation budget (Section 3), and compare against zero-shot GPT-4.1. Qwen models tie at field accuracy 0.927, outperforming GPT-4.1 image-only by 15.9 points. A per-field-type breakdown on the four models with exported per-field results (Appendix F) shows this gap concentrates in 9 checkbox / boolean-flag fields, where fine-tuned open-source models substantially outperform zero-shot GPT-4.1: SmolVLM-500M FT reaches 0.99 checkbox accuracy versus 0.48 for GPT-4.1 image-only, a 50-point difference that alone accounts for essentially the entire aggregate gap. On the 22 structured-text fields the two systems tie within 1 point (≈0.93). SmolVLM2-2.2B FT collapses on this schema (32% coverage, field accuracy 0.292); SmolVLM-500M FT emerges as a small-fast runner-up at 0.895 accuracy. Framework consequence: the coverage-thresholded feasibility set produces a different m^* per task, as shown in Section 6.

5 A Framework for Selecting an Approach

The results in Section 4 show that no single model dominates across the operating axes that matter in practice. We therefore frame approach selection as a constrained optimization problem parameterised by *task complexity*: a quality target $Q_{\min}$, latency budget $L_{\max}$ (interpreted as a p95 ceiling), governance requirement G_{req}, expected monthly volume V, and horizon T months.

Let $\mathcal{M}$ be the candidate set; each $m \in \mathcal{M}$ is characterised by a set of task-relevant quality metrics $Q(m)=\{Q_i(m)\}_{i\in I}$ with componentwise thresholds $Q_{\min}=\{Q_{i,\min}\}_{i\in I}$, p95 latency $L_{p95}(m)$, the set of governance constraints it satisfies $G(m)$, development cost $C_{\text{dev}}(m)$, per-document inference cost $c_{\text{inf}}(m)$, and monthly fixed cost $c_{\text{fixed}}(m)$. Beyond aggregate accuracy, I typically includes structured-output *coverage* (the fraction of inputs on which the model produces well-formed output; equivalently, one minus the JSON parse failure rate; a special case of the selective-prediction setting (Geifman and El-Yaniv, 2017)), which practitioners can threshold independently of accuracy when parse reliability is operationally critical. The feasible set is

$$\mathcal{M}_F = \{m : Q_i(m) \geq Q_{i,\min}\ \forall i \in I,\ L_{p95}(m) \leq L_{\max},\ G(m) \supseteq G_{\text{req}}\} \tag{1}$$

and the cost-optimal model minimizes total cost of ownership:

$$m^* = \arg\min_{m\in\mathcal{M}_F} \big[\, C_{\text{dev}}(m) + T\big(V\, c_{\text{inf}}(m) + c_{\text{fixed}}(m)\big)\big]. \tag{2}$$

Eq. (2) is a deliberately simple TCO model for a typical enterprise pilot deployment, with four assumptions: (i) per-document inference cost is linear in volume V (no batching discounts, no token-length variance); (ii) fixed cost is linear in horizon T (constant monthly rate, $c_{\text{fixed}}=0$ for managed APIs and equal to the dedicated GPU rental for self-hosted candidates); (iii) C_{dev} is paid once and not amortised across other applications; (iv) self-hosted models run on a dedicated inference instance provisioned continuously for this workload—GPU sharing across workloads is not assumed.

Governance acts as a *feasibility filter*: G_{req} is the set of deployment constraints specified for a given workload (these may be technical, contractual, or policy-driven), and a model is feasible only if $G(m) \supseteq G_{\text{req}}$. The filter is generic, so practitioners can encode whichever constraints apply to their setting. Among feasible solutions, the breakeven volume between two models m_1, m_2 is

$$V^* = \frac{\Delta C_{\text{dev}} + T\,\Delta c_{\text{fixed}}}{T\,(c_{\text{inf}}^{(m_2)} - c_{\text{inf}}^{(m_1)})}, \tag{3}$$

where $\Delta C_{\text{dev}}=C_{\text{dev}}(m_1)-C_{\text{dev}}(m_2)$ and Δc_{fixed} is defined analogously. If m_1 carries the higher fixed

cost and m_2 the higher per-document cost (numerator and denominator both positive), then above V^* the lower-marginal-cost solution m_1 wins, and below V^* the lower-fixed-cost solution m_2 wins.

The framework is intentionally lightweight: practitioners populate $\mathcal{M}$ with measurements obtained from the dataset and code we release (Section 3), specify the four task parameters, and read off the recommendation. Section 6 instantiates this on a concrete scenario.

6 Illustrative Case Study: A Hypothetical Mid-Volume Extraction Profile

We instantiate the framework on a hypothetical task profile chosen to exercise all four parameters; it is not based on a production implementation, and no customer documents or internal company metrics were used to construct it. The profile is V=100K documents/month, T=12 months, $Q_{\min}$=0.85 F1, $L_{\max}$=5 s, and, to illustrate the governance filter, an arbitrary deployment-locality constraint that admits only self-hosted models—a generic example chosen to show how a constraint propagates through the pipeline, not a claim about which constraints any specific workload, organisation, or industry should adopt. The numbers below are illustrative estimates for demonstrating framework application, not a vendor benchmark; practitioners can re-populate Table 5 with the rates and constraints that apply to their own setting.

Cost assumptions. Per-document inference cost c_{inf} for API candidates in Table 5 is derived from published vendor pricing: GPT-4.1 at \$2/M input and \$8/M output (OpenAI, 2025b) (≈1,500 image + 80 output tokens; \$0.004/doc); GPT-5 (OpenAI, 2025a), emitting two extra fields (AmountInWords, CheckNumber), \$0.025/doc; Claude Sonnet 4.5 at \$3/\$15 per M (Anthropic, 2025), \$0.006/doc; OCR+GPT-4.1 combines Azure DI Read at \$1.50/1,000 pages (Microsoft Azure, 2025b) with a text GPT-4.1 call (\$0.003/doc); the OCR→regex baseline incurs only the OCR call (\$0.0015/doc); Azure Content Understanding is \$0.010/page (Microsoft Azure, 2025a). Self-hosted candidates are priced from a dedicated, continuously provisioned AWS `g5.xlarge` (NVIDIA A10G) at \$1.006/hour (Amazon Web Services, 2025) (Eq. (2) assumption iv), which we treat as a fixed monthly cost c_{fixed}=\$734/month with c_{inf}≈0: the marginal cost of one additional document on already-provisioned capacity is negligible below saturation, and the case-study volume V=100K docs/month sits well below the single-instance saturation threshold at target utilisation $\rho_{\max}$=0.7. Self-hosted p95 latencies in Table 5 are projected from A100 measurements to A10G at a 1.7× ratio, drawn from the widely reported 1.5–1.7× inference slowdown for 3B-7B transformer models at batch size 1 (Baseten, 2025; Modal Labs, 2025; NVIDIA, 2022, 2021); direct A10G measurement is a limitation (see Limitations). Development cost C_{dev} for fine-tuned models is \$6K labelling (the 2,998-document training set in Section 3 at \$2/doc, an authors' midpoint estimate for layout-aware document annotation between commercial crowd and expert-review rates; see Limitations) + \$7.5K base engineering (50 hr at \$150/hr fully-loaded, an authors' estimate informed by U.S. Bureau of Labor Statistics (2024) software-developer wages) + \$1.5–3.5K productionisation overhead; API integrations omit the fine-tune line items. These are pilot-grade illustrative baselines (see Limitations).

Stage 1 (Governance). The illustrative locality constraint admits only self-hosted candidates, removing GPT-5, GPT-4.1, OCR+GPT-4.1, ACU, Claude Sonnet 4.5, and the OCR+Regex pipeline (whose OCR step is also an external API call) from contention.

Stage 2 (Quality + latency). Quality here has two components: F1 with $Q_{F1,\min}$=0.85 and coverage with $Q_{\text{cov},\min}$=0.99. Among self-hosted candidates, all four fine-tuned open-source variants meet the F1 threshold; the OCR+Regex baseline at F1 0.395 is eliminated on accuracy regardless of deployment location. Under the A10G latency projection, both Qwen models exceed the 5 s budget (Qwen-7B FT 8.2 s p95, Qwen-3B FT 9.9 s p95) and are excluded; SmolVLM2-2.2B FT (3.4 s) and SmolVLM-500M FT (4.1 s) pass. Coverage then excludes SmolVLM-500M FT (0.947 $<$ 0.99, i.e., 5.3% of outputs fail JSON parse and are counted as full misses under our reporting protocol), leaving SmolVLM2-2.2B FT as the sole survivor. On H100-class hardware both Qwen models pass latency, so accelerator choice is itself part of the practitioner's task profile.

Stage 3 (Cost and result). With only SmolVLM2-2.2B FT surviving governance, latency, and coverage, the framework-derived recommendation is m^*=SmolVLM2-2.2B FT at

Model	Q	Cov.	L_{p95} (s)	C_{dev} ($K)	c_{inf} ($/doc)	Loc.
GPT-5	0.93	1.00	40	5	0.0250	API
OCR+GPT-4.1	0.92	1.00	25	8	0.0030	API
GPT-4.1 (vision)	0.91	1.00	18	5	0.0040	API
ACU	0.89	1.00	18	5	0.0100	API
Claude S. 4.5	0.86	1.00	12	5	0.0060	API
OCR+Regex	0.40	1.00	12	6	0.0015	API
Qwen-7B FT	0.99	1.00	8.2	17	≈0	on-prem
Qwen-3B FT	0.98	1.00	9.9	15	≈0	on-prem
SmolVLM2-2.2B FT	0.90	1.00	3.4	15	≈0	on-prem
SmolVLM-500M FT	0.85	0.95	4.1	15	≈0	on-prem

Table 5: Case-study parameters. Q is the test-pool Micro-F1 (Table 1); Cov. is structured-output coverage (equivalently, one minus the JSON parse failure rate); L_{p95} for self-hosted models is A10G-projected from A100 measurements at 1.7× (Table 7), and for commercial APIs is a $\approx$ 1.5× estimate of mean latency (where only mean is logged). Self-hosted candidates carry c_{fixed}=$734/month for one dedicated A10G instance (Eq. (2) assumption iv); $c_{\text{inf}}\approx 0$ on already-provisioned capacity below saturation. Sources: GPT-4.1 pricing (OpenAI, 2025b); GPT-5 dated snapshot (OpenAI, 2025a); Claude Sonnet 4.5 pricing (Anthropic, 2025); Azure Document Intelligence (Microsoft Azure, 2025b) (also the OCR+Regex baseline, which incurs OCR-only cost); Azure Content Understanding (Microsoft Azure, 2025a); AWS g5.xlarge (Amazon Web Services, 2025).

annual cost $23.8K ($VT$=1.2M docs/yr; $15K C_{dev} plus twelve months at $734/month for one dedicated A10G instance). Were the illustrative locality constraint absent, OCR+GPT-4.1 at $11.6K/yr would win; GPT-5's 0.011 F1 lift rarely justifies its 3× price unless its extra fields are required.

Volume sensitivity. API and self-hosted ranking flips with volume because APIs carry near-zero fixed cost. Eq. (3) with the revised A10G economics gives crossover $V^*\approx$439K docs/month for SmolVLM2-2.2B FT vs. OCR+GPT-4.1 over a 12-month horizon; Appendix C reports three volume regimes. At V=1M docs/month a single A10G instance is no longer sufficient; the self-hosted deployment scales to N=2 instances ($32.6K/yr) versus $44K/yr for OCR+GPT-4.1, a 26% saving, consistent with Chen et al. (2024); below ≈440K docs/month the API pipeline is unambiguously cheaper.[3] The cost-optimal model is therefore a function of the joint (V, T, G_{req}) profile, not of benchmark accuracy alone.

Framework application to a second task. On the insurance-form task (Section 4.6), applying the same feasibility filters with identical thresholds ($Q_{F1,\text{min}}$=0.85, $Q_{\text{cov,min}}$=0.99) yields a different survivor set because coverage is task-dependent. SmolVLM2-2.2B FT drops to coverage 0.32 on the 36-field schema (versus 1.00 on checks) and is excluded; SmolVLM-500M FT narrowly fails coverage at 0.988. Qwen models retain full coverage and would be the framework's recommendation under an appropriately relaxed latency budget for the richer schema. The recommendation is therefore sensitive to task-specific reliability, not just aggregate accuracy.

7 Conclusion

Practitioner guidance for vision-language IDP has lagged behind model turnover: public leaderboards report clean-document accuracy, but deployments are decided on the joint axes of quality, latency, governance, and cost. This study reframes approach selection along those axes. Across eleven systems on a 750-document held-out pool, fine-tuned open-source VLMs match or exceed every zero-shot commercial system on this schema under a fixed adaptation budget (Qwen2.5-VL FT $>$ 0.98 F1), yet commercial APIs remain cheapest at low volume below the ≈440K docs/month breakeven—so the cost-optimal model is a function of the joint operating profile, not of benchmark accuracy. The contribution is the framework, dataset, and harness, released together so practitioners can shift the IDP conversation from "which model is most accurate?" to "which approach is feasible and cheapest under my constraints?" as the model lineup turns over.

[3] The recommendation is stable within plausible input variation. Under $C_{\text{dev}}\in$[$10K, $25K], the breakeven shifts from ∼300K to ∼720K docs/month. Utilisation $\rho\in[0.5, 0.9]$ affects only the volume above which additional instances are needed; one A10G instance suffices at V=100K docs/month. An added ops line of $1,000/month shifts breakeven to ∼770K docs/month.

8 Limitations

Our evaluation uses synthetic checks with a four-field schema and synthetic 36-field insurance application forms; real production documents have higher template diversity and adversarial scan artifacts (heavy rotation, strong scan noise, multi-document pages) which we do not stress in this study. The synthetic-only design is itself a constraint: real-world financial documents carry PII and contractual restrictions that prevent public release, so a template-driven corpus is the only artefact we can open-source for reproducibility—the rendering pipeline mirrors production checks in layout, fonts, and scan-artefact distribution, but a residual distributional gap remains the principal generalisation caveat. The case-study cost figures are pilot-grade illustrative baselines that vary by region, contract, and time; A10G p95 latencies in Table 5 are projected from A100 measurements at 1.7× using cited industry references, and direct A10G measurement remains future work. Production deployments with elevated review burdens typically require 3–10× more engineering for security, observability, and retraining infrastructure, which raises the API-vs-self-hosted break-even volume but preserves the qualitative ranking. We evaluated a single fine-tuning recipe per model family, and the GPU-sensitivity study covers only A100 and H100 at batch size 1; larger batch sizes on any accelerator are extrapolations. Per-tier and per-corruption-axis stratification within the synthetic pipeline is not part of this study; the cross-domain OOD evaluation (Section 4.6) provides the primary generalization signal instead. Our candidate set excludes fine-tuned purpose-built layout models (LayoutLMv3, Donut, Pix2Struct, UDOP); a like-for-like comparison against these encoders is a natural extension.

A Additional Discussion

Two practitioner-facing patterns emerge. *Date is the universal commercial bottleneck*: across all five commercial / reasoning systems Date has the lowest per-field F1 (0.47–0.79; Claude's precision collapses to 0.31), so a downstream date-validation step (constrained format plus business-rule range) is a more robust intervention than additional training data. *Reasoning models earn only marginal accuracy*: GPT-5's ≈0.01 F1 lift on the four core fields is dwarfed by $\approx 3\times$ token cost and $\approx 2\times$ latency; its honest value-add is schema coverage (AmountInWords, CheckNumber), so it pays off when those extra fields are required.

B Reproducibility Details

We release dataset generation code, fine-tuning scripts, prompts, and evaluation harnesses at https://github.com/manulife-ai/beyond-accuracy-vlm-emnlp2026/. The settings below are constant across all configurations unless noted.

Prompt. A single prompt is used for every VLM and LLM in the study, modulo the image attachment mechanism required by each API:

```
You are extracting fields from a U.S.
business check.
```

```
Return a JSON object with exactly
these keys: "Payee" (string), "Amount"
(number, no currency symbol), "Date"
(string MM/DD/YYYY), "Bank" (one of:
Chase, Citi, BOA).
If a field is unreadable, return an empty
string for that key.
Return ONLY the JSON object, no prose,
no markdown.
```

For reasoning models we additionally prepend the system message "`Think briefly, then answer.`" which we found stabilises the JSON output without measurably changing accuracy.

Decoding. All open-source VLMs and commercial / reasoning APIs are run with `temperature` $=$ 0.0, `top_p` $=$ 1.0, and `max_new_tokens` $=$ 1024, set to avoid long-output truncation on multi-field responses. Stop tokens are the model defaults; we do not impose additional JSON delimiters.

JSON failure handling. Every raw model output is passed through a three-stage parser: (i) strip markdown fences ("```` ```json ... ``` ````"); (ii) extract the outermost balanced `{...}`; (iii) `json.loads`. If all three stages fail the sample is recorded as `JSON_FAIL` and counted as a full miss on every field (4 false negatives), which is the worst case for that model and is what the JSON-failure column in Table 1 measures. We do not perform any retry, schema- repair, or constrained-decoding pass; the numbers reported are first-try outputs.

Fine-tuning. Qwen2.5-VL-3B/7B are fine-tuned with LoRA (r=16, α=32, `dropout` $=$ 0.05, target modules: all attention projections and the MLP `gate/up/down`); SmolVLM2 variants are full fine-tuned. All runs use the AdamW-8bit optimiser, effective batch size 4 (per-device 1, gradient accumulation 4), cosine schedule with 3% warmup, weight decay 0.01, and bf16 mixed precision on a single A100 80 GB. Seed 42 throughout.

Compute. Each Qwen fine-tune completes in 6–14 GPU-hours on the A100; SmolVLM fine-tunes complete in 2–5 GPU-hours. Per-document inference latency in Table 1 is measured on an NVIDIA A100 80 GB PCIe under a Databricks runtime 18.2 image (PyTorch 2.9 / CUDA 12.9, bf16, batch size 1, five-document warmup discarded). Section 4.5 reports the same fine-tuned models re-benchmarked on an NVIDIA H100 NVL under the same software stack for the GPU-sensitivity analysis.

Model versions. Open-source checkpoints are pulled from HuggingFace: `Qwen/Qwen2.5-VL-3B-Instruct`, `Qwen/Qwen2.5-VL-7B-Instruct`, `HuggingFaceTB/SmolVLM2-2.2B-Instruct`, `HuggingFaceTB/SmolVLM-500M-Instruct`, `HuggingFaceTB/SmolVLM2-256M-Instruct`. Commercial APIs used the following dated snapshots: GPT-4.1 (`gpt-4.1-2025-04-14`) (OpenAI, 2025b), GPT-5 (`gpt-5-2025-08-07`) (OpenAI, 2025a), Claude Sonnet 4.5 (`claude-sonnet-4-5-20250929`) (Anthropic, 2025), Azure Content Understanding (Microsoft Azure, 2025a), and Azure Document Intelligence (Microsoft Azure, 2025b) for the OCR+GPT-4.1 pipeline. Specific request timestamps are logged and released with the harness.

C Volume-Sensitivity Table

Model	5K/mo	100K/mo	1M/mo
OCR+GPT-4.1	**$8.2K**	**$11.6K**	$44.0K
Qwen-3B FT	–	–	–
SmolVLM2-2.2B FT	$23.8K	$23.8K	**$32.6K**

Table 6: Annual cost ($K) at three volumes ($T$=12) under the revised A10G-dedicated deployment. Bold marks the cost-optimal feasible option *when no governance constraint is applied*. Qwen-3B FT is excluded on A10G-projected latency across all volumes; on H100-class hardware it becomes feasible and can be re-costed with the corresponding hourly rate. Referenced from Section 6, "Volume sensitivity".

D GPU Sensitivity Details

Table 7 reports per-document latency and peak memory on NVIDIA A100 80 GB PCIe and NVIDIA H100 NVL for all five fine-tuned open-source models, measured under identical software (PyTorch 2.9 / CUDA 12.9, bf16, batch size 1) on the 750-document held-out pool. Accuracy is unchanged across GPUs (ΔF1 $\leq$ 0.003), so the relative ordering is stable; practitioners on H100-class hardware can rescale the case-study cost terms approximately linearly by GPU-hour price.

E Error Taxonomy Details

Quantitative breakdown of the three error categories summarised in Section 4:
(E1) Degenerate repetition (SmolVLM2-256M, pretrained SmolVLM-500M): the model emits

Model	Mem (GB)	A100 80 GB mean (s)	A100 80 GB p95 (s)	H100 NVL mean (s)	H100 NVL p95 (s)	H/A speedup
SmolVLM2-256M	0.5	1.62	2.31	1.10	1.47	1.47×
SmolVLM-500M	0.9	0.96	2.42	0.70	1.51	1.38×
SmolVLM2-2.2B	4.2	1.47	1.96	0.93	1.19	1.59×
Qwen2.5-VL-3B	7.1	4.18	5.79	2.50	3.43	1.68×
Qwen2.5-VL-7B	15.5	3.53	4.79	2.14	2.89	1.65×

Table 7: Per-document inference latency on A100 80 GB PCIe vs. H100 NVL (bf16, batch size 1, 750-document held-out pool). *Mem* is peak GPU memory during inference (GPU-independent). *H/A speedup* is A100 mean / H100 mean.

looping arrays such as `[123.0, 123.0, 123.0, ...]` that exhaust the token budget without closing the JSON object. Accounts for $\geq$ 99% of pretrained sub-500M outputs and persists in fine-tuned 256M as the 30.7% JSON parse-failure rate reported in Table 1.

(E2) Phonetic Payee misspelling (Qwen-3B/SmolVLM2-2.2B): `Mark Gwazy` vs. `Mark Gray`; `Zachary Villages` vs. `Zachary Villegas`. Errors cluster on visually-ambiguous character pairs (g/y, s/z, e/i).

(E3) Date over-extraction (Claude Sonnet 4.5, GPT-4.1 vision, OCR+GPT-4.1): the model extracts every date-like substring on the check. Claude is the worst case (686 FP against 304 TP); GPT-4.1 vision (337 FP) and OCR+GPT-4.1 (360 FP) are milder but qualitatively identical.

F Per-Field-Type Analysis (Insurance Forms)

Field taxonomy on the 36-field insurance schema, derived from ground-truth value cardinality on the 1,000-document test set: 9 checkbox / boolean-flag fields (`citizenship_status`, `sex`, `occupation_status` and six other Y/N flags), 22 structured-text fields (names, addresses, phone, dates, IDs, SSN, salaries, states, countries), and 5 free-form fields (two `bankruptcy_details` lines, `job_duties_description`, `occupation_status_other_description`, `green_card_or_visa_type`).

The per-field-type breakdown below is reported for SmolVLM-500M FT, SmolVLM2-256M FT, GPT-4.1 (vision), and OCR+GPT-4.1. Overall accuracies for Qwen2.5-VL-3B FT, Qwen2.5-VL-7B FT, and SmolVLM2-2.2B FT appear in Table 4.

Model	Ckbox (n=9)	Text (n=22)	Free (n=5)	Overall (n=36)
SmolVLM-500M FT	**0.987**	0.929	**0.583**	**0.895**
SmolVLM2-256M FT	0.160	0.151	0.093	0.145
GPT-4.1 (vision)	0.476	0.934	0.560	0.768
OCR+GPT-4.1	0.398	**0.947**	0.569	0.757

Table 8: Per-field-type mean accuracy on the insurance-form test set (n=1,000). Categories are 9 boolean-flag checkboxes, 22 structured-text fields, and 5 free-form fields (see paragraph above). Overall accuracy matches the Insurance column of Table 4 up to `true`↔`yes` normalization on Y/N outputs, which is applied to GPT-4.1 rows (GPT-4.1 vision 0.738→0.768 and OCR+GPT-4.1 0.731→0.757); fine-tuned SmolVLM rows are unchanged. **Bold** marks the best in column.

G Seed-study Variance (Check Task)

To quantify the sensitivity of the fine-tuning outcomes to random seed, we run a 3-seed Monte-Carlo cross-validation study on the check task. Seeds 42, 1337, and 2718 each draw an independent grouped 80/20 split from the pooled 3,748-image dataset. The grouped split assigns whole (Payee, Amount, Date) components to one side of the split, guaranteeing zero group overlap between train and test. Each seed's train and test sets preserve the paper's 10/30/25/20/15% Clean-through-Extreme tier mixture within 0.2 percentage points. All five open-source models are trained under the recipes of Section 3 on each seed's 2,999-document train set and scored on that seed's 749-document test set. Because the test set is resampled per seed, the aggregate F1 values in Table 9 use a different pool than the fixed 750-document evaluation reported in Table 1 and should be read as a variance study rather than a substitute for that evaluation.

Model	FT F1 (mean $\pm$ std)	Δ vs. pretrained
SmolVLM2-256M	0.719 $\pm$ 0.011	+0.719
SmolVLM-500M	0.832 $\pm$ 0.008	+0.832
SmolVLM2-2.2B	0.903 $\pm$ 0.002	+0.396
Qwen2.5-VL-3B	**0.983** $\pm$ 0.002	+0.141
Qwen2.5-VL-7B	**0.985** $\pm$ 0.002	+0.068

Table 9: Seed-study aggregate F1 across three Monte-Carlo splits (n=749 per seed). The Qwen-3B versus Qwen-7B 0.002 gap is within seed noise; sub-billion models are noticeably more seed-sensitive than models at 2B parameters or above. Pretrained F1 is 0.000 for both sub-billion SmolVLMs (structural JSON collapse), 0.507 for SmolVLM2-2.2B, 0.842 for Qwen-3B, and 0.917 for Qwen-7B, all with std $\leq$ 0.003.

Per-field variance. Table 10 reports the same three seeds broken out by field. Payee is the universal ceiling across model sizes; Bank saturates at 1.000 for both Qwen fine-tunes, consistent with the closed 3-way Bank vocabulary noted in Section 3.

Model	Payee	Amount	Date	Bank
SmolVLM2-256M	0.585 ± 0.015	0.706 ± 0.022	0.744 ± 0.010	0.818 ± 0.011
SmolVLM-500M	0.695 ± 0.021	0.854 ± 0.010	0.842 ± 0.006	0.916 ± 0.006
SmolVLM2-2.2B	0.800 ± 0.007	0.910 ± 0.010	0.887 ± 0.004	0.997 ± 0.000
Qwen2.5-VL-3B	0.959 ± 0.003	0.995 ± 0.002	0.977 ± 0.005	1.000 ± 0.000
Qwen2.5-VL-7B	0.965 ± 0.004	0.995 ± 0.002	0.979 ± 0.002	1.000 ± 0.000

Table 10: Per-field entity-level F1, mean $\pm$ std across three Monte-Carlo seeds.

Framework re-derivation. Applying the feasibility set of Eq. (1) with $Q_{F1,\min}$=0.85 and $Q_{\text{cov},\min}$=0.99 to the seed-study means gives $\mathcal{M}_F$={SmolVLM2-2.2B FT, Qwen-3B FT, Qwen-7B FT}. Under the illustrative case-study profile of Section 6 the cheapest survivor remains SmolVLM2-2.2B FT, matching the m^* derived from the main results. SmolVLM-500M FT fails both accuracy (F1 $0.832 < 0.85$) and coverage ($0.951 < 0.99$) under this resampled protocol, so its exclusion does not depend on any single threshold.

Schema-Hierarchical Soft Prompts for Structured Information Extraction

Abstract

Structured information extraction at small-language-model scale is a routine production workload, yet each new task added to a serving stack can demand new task-specific model state. We propose a schema-hierarchical soft prompt: a small learned prefix, trained on a frozen backbone, that gives every JSON-schema node its own slot, orders the slots by the schema, and marks tree depth with learned embeddings. Used alone on the open USPTO-ORD patent task, it recovers most of a LoRA reference's extraction quality while training more than an order of magnitude fewer parameters, and ablations attribute the gain to depth and schema order rather than token count. Used with a LoRA adapter on an internal booking task, the same slots stabilize one of two held-out categories, so we report this as a bounded mechanism study rather than a general gain. Inference-time slot replacement indicates that position supplies the schema scaffold while learned content stabilizes generation. Measured serving gives a far smaller task artifact and higher throughput than multi-LoRA as interleaved tasks grow. The soft-prompt module is available at https://github.com/microsoft/Hierarchical-Soft-Prompt.

1 Introduction

Extracting structured JSON from unstructured text is a routine production workload at small-language-model (SLM) scale. Booking emails become booking records. Patent procedures become reaction graphs. Organizations often serve these workloads with 3-to-8B-parameter models that run close to the data. The practical question is simple: when an SLM is already in production, how much model-specific machinery is needed to add the next structured-extraction task?

The usual choices each have a cost. Prompt engineering ships a schema description in the prompt. On small models, this can plateau below the accuracy needed for operational extraction, and the prompt grows with the schema. Full fine-tuning creates a new task-specific model copy. LoRA (Hu et al., 2022) makes the task artifact much smaller, but a multi-tenant serving stack must still either keep task-specific model copies resident or load and apply adapters at request time. Soft-prompt tuning (Lester et al., 2021; Li and Liang, 2021; Liu et al., 2022) is attractive because it leaves the backbone frozen, but standard soft prompts are usually flat prefixes with no explicit relationship to the output schema.

We propose a soft prompt whose topology mirrors the target JSON schema, making three structural properties explicit in the trainable parameters. Each schema-node key gets its own learnable slot initialized from the embedding of the node's key name. The slots follow a depth-first traversal (DFS) of the schema and each carries a learned depth embedding. A small set of shared global tokens is prepended to the per-key slots. The base model weights remain frozen throughout. A joint configuration also trains a small LoRA adapter on attention projections.

We evaluate this architecture on two structured-extraction tasks (USPTO-ORD patent reactions and an internal booking-email corpus) and three backbones in the main results (Qwen3-4B-Instruct, Qwen3-8B base, Phi-3.5-mini-Instruct). The schema-hierarchical topology serves two operating points on a frozen backbone, with a single mechanism connecting them.

On the patent task, soft-prompt-only adaptation is strong enough to be useful on its own, and the schema-shaped prefix remains a much smaller task artifact than the LoRA reference (§5). At serving time, adding a new task can be a prefix-embedding write rather than a model or adapter reload.

On the booking task, where the test distribution shifts in both booking category and personally iden-

tifiable information (PII) surface forms, pairing the same positional slots with LoRA makes the transport-held-out, PII-shifted condition more stable than LoRA alone (§6). The deployed artifact in this regime is the LoRA adapter plus the positional prefix rather than the prefix alone.

Slot-drift diagnostics and an inference-time intervention that replaces held-out transport slots while preserving their prompt positions (§7) point to one explanation common to both operating points: the per-key slot acts as a positional scaffold. Its location in the prompt carries the main benefit, while the trained content at that position stabilizes the joint model across seeds.

Contributions. We first give a parameterization that places stable JSON-schema topology directly in the trainable prompt. Controlled ablations then show that depth and DFS order drive the open-task gain, rather than token count or semantic initialization alone. A paired positive and negative leave-one-category-out study characterizes when positional transfer holds. Finally, we report a measured multi-tenant serving profile against a modern multi-LoRA runtime. Appendix sections contain additional details.

2 Related Work

Schema-aware and hierarchical prompting for information extraction. Prior schema-aware extraction methods usually expose the schema to the model as text rather than as parameter structure. UIE (Lu et al., 2022) and InstructUIE (Wang et al., 2023) inject the target schema as hard text under full or instruction fine-tuning. PromptNER (Ashok and Lipton, 2023) and SSGPF (Yuan et al., 2025) similarly rely on hard schema or entity-type prompts, with SSGPF combining them with LoRA. TKDP (Liu et al., 2024) moves label knowledge into deep soft prompts, but it targets few-shot NER over flat entity-type label sets. Hierarchical prompting has also been explored outside fixed JSON schemas: TreePrompt (Zhang et al., 2023) composes soft prompts bottom-up from a parsed dependency tree for visual grounding, and Tree of Attributes Prompt (Ding et al., 2025) aligns hierarchical prompt tokens to LLM-generated concept trees. These methods either encode the schema as hard input text, assume a flat label set, or derive the hierarchy from the query rather than from a stable output schema. We instead make the schema a structural property of the *soft-prompt parameters themselves*. On a frozen backbone, a nested JSON schema becomes K per-key slots (K = number of schema nodes) in DFS pre-order, with depth embeddings indexed by each node's tree depth.

Soft prompt tuning and LoRA. Soft-prompt methods reduce task-specific state, but most treat the prompt as a flat sequence. Lester et al. (Lester et al., 2021) introduced flat-token prompt tuning, Prefix-Tuning (Li and Liang, 2021) prepends learnable activations at every transformer layer, and P-Tuning v2 (Liu et al., 2022) shows that deep layer-wise prompts can match full fine-tuning. SK-Tuning (Prottasha et al., 2024) initializes soft prompts from semantically meaningful word embeddings, and we adopt this principle at the per-key slot level. LoRA (Hu et al., 2022) provides our reference adapter baseline. The closest joint-adapter precedent is LoPA (Jain et al., 2024), which combines soft prompts with low-rank decomposition at the prompt level on GLUE NLU and code understanding tasks. We differ in schema-aware topology, the structured-extraction task family, and the multi-seed cross-backbone evaluation against a LoRA reference.

Decoding-time structured-output methods (orthogonal). A separate line of work (Zheng et al., 2024; Park et al., 2024; Schmidt and Cimiano, 2024; Hemmer et al., 2023; Lu et al., 2025; Wang et al., 2025) enforces format compliance at decode time. These methods improve format compliance, not value-extraction quality, and are orthogonal: a trained soft prompt can be stacked with a grammar-constrained decoder.

3 Method: Schema-Hierarchical Soft Prompt

The name *schema-hierarchical* reflects three structural properties of the target JSON schema that this prompt makes explicit in its trainable embeddings: the identity of each schema-node key, the order of nodes in the schema, and the depth of each node in the tree. The prompt has two parts. The first is k_g shared global tokens that carry task-identity information. The second is a sequence of K per-key slots, each holding t learnable tokens that carry schema content. Identity is preserved by allocating one slot per schema node and initializing it from the embedding of the node's key name, the last component of its dotted path. Order is preserved by laying out the per-key slots in a depth-first traversal

Algorithm 1 Schema-hierarchical soft-prompt construction

  $\mathbf{z}_v \leftarrow E[\text{TOKENIZE}(()q_v)]$
  $\mathbf{p}_v \leftarrow \text{REPEAT}_{()}t(\text{MEAN}(()\mathbf{z}_v))$
  $\mathbf{p}_v \leftarrow \mathbf{p}_v + \mathbf{e}_{\text{depth}(v)}$
end for
$\mathbf{P} \leftarrow [\mathbf{P}_{\text{global}}; \mathbf{p}_{v_1}; \ldots; \mathbf{p}_{v_K}]$
prepend $\mathbf{P}$, or insert each $\mathbf{p}_v$ beside its schema key
optimize $\mathbf{P}$ (and optional LoRA), keeping all backbone weights frozen

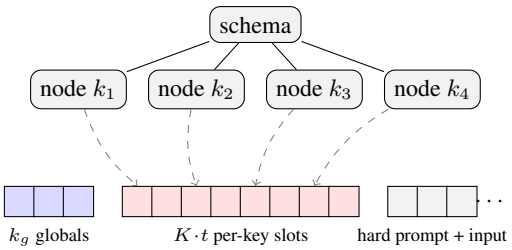

Figure 1: Schema-hierarchical soft-prompt architecture. The schema tree (top) defines K schema-node keys (K=4 shown, while real schemas have K=94 on Patent, of which 52 are leaves, and K=62 on Booking, of which 59 are leaves). The soft prompt (bottom) places k_g shared global tokens (blue) followed by $K \cdot t$ per-key tokens (red, t=2) in DFS pre-order over the schema, then the hard prompt and input text. Each per-key slot is initialized from the embedding of its key's dotted-path name, and the backbone is frozen.

of the schema, so that sibling nodes of the same parent are adjacent in the prompt and parents precede children in token position. Depth is preserved by adding a small learned embedding, indexed by the node's tree depth, to each per-key slot. The slots are then prepended to the input embeddings together with the globals. Training updates the prompt parameters while the base model weights remain frozen (Figure 1). When this prompt is paired with LoRA in the joint configurations of §4, the LoRA adapter is also trained.

Parameters. Let the target schema have K keys (all schema nodes in DFS pre-order), let L be the depth-embedding table size (one row per schema depth level, L=5 on Patent and L=2 on Booking), and let D denote the backbone's hidden dimension. Three tensors are trainable. The per-key slots $\mathbf{P}_{\text{key}} \in \mathbb{R}^{K \times t \times D}$ hold t=2 tokens per key. The global tokens $\mathbf{P}_{\text{glob}} \in \mathbb{R}^{k_g \times D}$ number k_g=20. The depth embeddings $\mathbf{E}_{\text{depth}} \in \mathbb{R}^{L \times D}$ are added to each per-key slot according to the node's tree depth. The totals are ∼545 K on Patent (K=94 schema nodes, 52 leaves, prefix length 208) and ∼374 K on Booking (K=62 schema nodes, 59 leaves, prefix length 144).

Placement. We evaluate two placements. *Prepend* places all per-key slots together at position 0, followed by the hard prompt (the textual schema instructions) and the input. *Positional* inserts each per-key slot next to its key name in the hard prompt. Prepend is the default when the soft prompt is used alone. Positional is the placement we pair with LoRA.

Initialization. A per-key slot starts at the mean embedding of its key-name tokens, where the key name is the last component of the node's dotted path. For example, `flightBooking.departureDate` starts at the mean of the `departure` and `Date` embeddings. Global tokens start at the mean embedding of the hard-prompt tokens, and depth embeddings are drawn from $\mathcal{N}(0, 0.02^2)$.

4 Experimental Setup

Patent. patent reaction extraction (USPTO-ORD) is a subset of the open USPTO-ORD corpus (Kearnes et al., 2021). Each input is a free-text procedure paragraph from a US patent, and the target is a canonicalized reaction JSON with 94 schema nodes, 52 leaves, and maximum depth 5. We evaluate on a held-out validation slice of n=500 using `field_em`, a leaf-path exact-match score on canonicalized gold outputs.

Booking. booking-email extraction is a proprietary internal booking-email corpus. Each input is a booking email, and the target is a booking JSON with flight, hotel, and transport sub-schemas (62 schema nodes, 59 leaves, maximum depth 2). We evaluate on three splits. Synthetic-ID (n=1,475) uses synthetic identifiers and contains flight bookings only. PII-Swap (n=25) is PII-shifted and contains all three booking types. Donated-OOD (n=29) is real out-of-distribution (OOD) data with no transport bookings.

Booking metric. For Booking, we report `macro_mandatory_f1` on each split and a weighted-by-n full-test-set summary (n_{total}=1529). `macro_mandatory_f1` is the unweighted mean across booking types (flight, hotel, transport) of F1 over the leaf keys marked mandatory in the booking schema. The weighted summary averages split-level values in proportion to split size.

Backbones. The primary backbone is Qwen3-4B-Instruct-2507 (Qwen Team, 2025), and Qwen3-8B (base) and Phi-3.5-mini-Instruct serve as cross-backbone tests. The base weights of every backbone remain frozen across all configurations.

Configurations. The four method names below are used consistently throughout the paper. *SP-only* is the schema-hierarchical soft prompt alone, in prepend placement, with no LoRA. *LoRA* is LoRA on attention projections (r=16) with no soft prompt. *Pos-SP + LoRA* pairs the soft prompt in positional placement with LoRA. *Prepend-SP + LoRA* pairs the soft prompt in prepend placement with LoRA. SP-only trains the prompt parameters, LoRA trains the LoRA adapter, and the two joint configurations train both. Headline configurations use seeds $\{42, 7, 123\}$, and ablations use seed 42 alone. All evaluations use `max_new_tokens`=1536.

Baselines and scope. Zero-shot uses the same textual schema prompt as the trained methods. Flat-SP uses the same number of trainable prompt tokens without per-key topology. These controls separate textual prompting, trainable-token count, schema structure, and LoRA capacity. Prior schema-aware extractors in §2 generally assume full or instruction fine-tuning, so they do not satisfy the shared frozen-backbone constraint.

5 Open-Benchmark Parameter Efficiency and Component Isolation

SP-only retains most of LoRA's accuracy on Patent. On Qwen3-4B-Instruct, SP-only reaches 0.7654 `field_em` against the LoRA reference's 0.8225, while training ∼545 K parameters instead of ∼15 M, a ∼28× reduction (Table 1). The ranking is the same on all three backbones: zero-shot trails both trained methods, SP-only closes much of the gap, and LoRA stays ahead. A frozen-backbone prefix therefore recovers enough extraction quality to be a credible parameter-efficient adapter on this task.

Table 1: Patent `field_em` (n=500 validation slice) across three backbones. The SP-only column reports the three-seed mean over seeds $\{42, 7, 123\}$. The LoRA column reports the seed-42 reference. Multi-seed LoRA is reported on Booking in Tables 6 and 3.

Backbone	Zero-shot	SP-only	LoRA
Qwen3-4B-Instruct	0.1498	0.7654	0.8225
Qwen3-8B (base)	0.1953	0.7803	0.8308
Phi-3.5-mini	0.1853	0.7758	0.8395

Table 2: Patent matched controls and single-component ablations (Qwen3-4B, seed 42, SP-only, with the textual schema prompt removed). Delta is against the full schema-hierarchical prompt.

Configuration	`field_em`	Δ
Full hierarchy	0.7700	–
Flat-SP (equal tokens)	0.7553	−0.015
− depth embeddings	0.7409	−0.029
− DFS order (shuffled)	0.7539	−0.016
− semantic init (random)	0.7650	−0.005
− global tokens (k_g=0)	0.7826	+0.013

Schema structure, not token count, drives the open-task gain. Table 2 pairs the equal-token flat-SP control with single-component removals from the seed-42 Qwen3-4B SP-only configuration. The largest drops come from removing depth embeddings (−0.029) and shuffling DFS order (−0.016). Random initialization has a much smaller effect (−0.005), while removing global tokens improves this single run (+0.013). Thus the robust signal is schema topology (depth and order), not simply additional tokens near the input. The initialization and global-token deltas are small and remain single-seed evidence. Appendix D extends this control to Booking and the hard-prompt sweep.

On the Booking task, the best trained method is backbone-dependent. Training improves over zero-shot on every backbone, but the best trained method is not universal. Pos-SP + LoRA is strongest on Qwen3-4B-Instruct, while LoRA alone is strongest among the measured cells on the other two backbones. We therefore treat the Pos-SP + LoRA effect as a Qwen3-4B-Instruct result, not as a cross-backbone law. Appendix H further shows that the soft prompt and LoRA favor opposite backbones, so we read this pairing as backbone-specific rather than universally additive. The full weighted full-test-set table is in Appendix C.

Joint placement matters on Qwen3-4B-Instruct. Prepend-placed soft prompt with LoRA (Prepend-

SP + LoRA) behaves much like LoRA alone, and the soft prompt receives little gradient under joint training in this placement. Positional placement (Pos-SP + LoRA) is the configuration that changes the result: the slots help when they sit next to the schema fields they represent.

6 Leave-One-Category-Out Generalization Under PII Shift

This section asks whether the positional slots still help when an entire booking category, one of the three booking types of §4, is missing from training. The full-data booking runs train on flight, hotel, and transport, and categories can co-occur within an email. We now remove each minority category in turn and evaluate on PII-Swap (n=25), which contains all three categories and substitutes PII against a held-out vocabulary. Flight occurs in 99.1% of the 7,011 training emails. Holding it out would leave only about 1% of the corpus and conflate category generalization with a severe low-data regime. Hotel (9.9%) and transport (9.5%) form the symmetric leave-one-minority-category-out sweep. We train SP-only, LoRA, and Pos-SP + LoRA at seeds $\{42, 7, 123\}$. Full per-seed results are in Appendix E.

Positive and negative controls. When transport is held out, Pos-SP + LoRA improves overall F1 by $+0.104$ and reduces overall seed standard deviation from 0.077 to 0.011. When hotel is held out, the sign reverses (-0.061) and LoRA remains stronger. The only positive bootstrap interval that excludes zero is transport-held-out PII-Swap overall. Per-category intervals on this small split include zero. Bootstrap resampling uses the three paired seeds (B=10,000), while the paired t test has only df=2 and is treated as underpowered. We therefore present the booking result as a bounded mechanism study, not evidence of universal superiority.

Prompt-only capability control. A single deterministic prompt-only run using the matched textual schema prompt of §4 scores 0.843 on flight, 0.808 on hotel, 0.832 on transport, and 0.828 overall, with all values coming from one shared prediction file. That overall score is higher than either trained held-out checkpoint, but it is not a ranking row. This run uses vLLM, whereas the trained held-out checkpoints use the Hugging Face generation path, so the two are not measured on the same stack. We report it only to establish that the backbone can already extract both held-out categories from text instructions. The question here is how much of that capability survives adaptation when a category is absent from training, not whether adaptation beats prompting.

7 Mechanism: Positional Scaffolding

The sweep in §6 supplies a positive control (transport) and a negative control (hotel) at nearly identical training frequencies. The remaining difference is structural congruence with the dominant flight category. Transport is another journey schema whose locations, passenger, and reservation fields reuse flight's learned value spaces. Hotel instead introduces stay-specific rooms, addresses, and guest fields. Appendix F, Table 10, quantifies this with the fraction of each held-out field's value-token vocabulary observed in flight training values. Transport's improving pickup and dropoff fields have overlap 0.65–0.66, whereas hotel's degrading name, room, and address fields are near 0.31–0.32.

Slot stability. Figure 2 compares each slot with its deterministic key-name initialization, for Pos-SP + LoRA and SP-only in both full-data and transport-held-out variants at three seeds each. The axes report drift L2, the Euclidean distance between a trained slot and that initialization. The joint model stays close to the full-data drift profile, whereas SP-only moves further under category holdout. Decoding each slot back to its nearest vocabulary tokens, by embedding similarity and by the `lm_head` projection, returns the same ranked tokens either way and shows that even the slots that moved farthest still decode to their own key name (Appendix G.2). These diagnostics are descriptive rather than proofs of internal semantics.

Position carries the mean effect and content stabilizes it. At inference, we replace every trained transport-subtree slot with either its initialization or a norm-matched random vector while preserving the slot positions. In Pos-SP + LoRA, random content retains 98% of mean overall F1 (0.737 against 0.752), but seed standard deviation grows from 0.011 to 0.057 (Appendix G.4, Table 11). This separates two roles: position supplies most of the reusable schema scaffold, while learned content stabilizes the result.

Boundary of the mechanism. Value overlap is predictive on the discriminative fields, but it is not

Table 3: Leave-one-minority-category-out control on Booking PII-Swap (n=25, Qwen3-4B-Instruct). "Held out" means the category was excluded from training. Scores are three-seed means of `macro_mandatory_f1`, the unweighted mean across the three booking types. Delta and 95% CI compare Pos-SP + LoRA with LoRA.

Held out	LoRA	Pos-SP + LoRA	Δ (95% CI)
transport	0.648 ± 0.077	$\mathbf{0.752 \pm 0.011}$	$+0.104\ [+0.011, +0.163]$
hotel	$\mathbf{0.483 \pm 0.080}$	0.422 ± 0.081	$-0.061\ [-0.208, +0.047]$

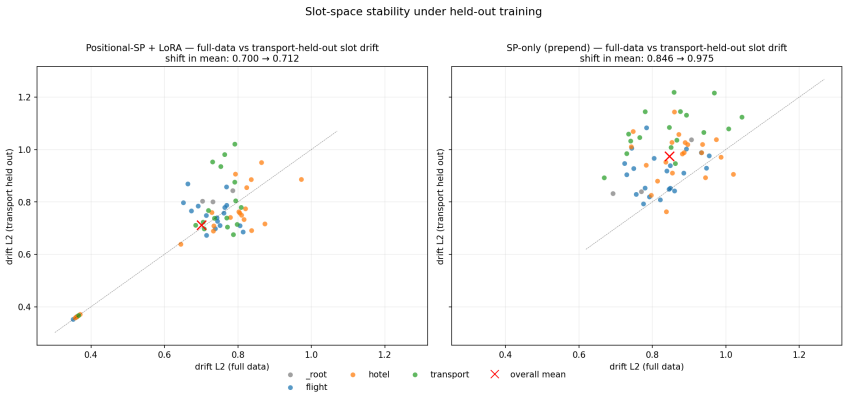

Figure 2: Per-slot drift L2 against initialization under full-data training (x) vs. transport-held-out training (y). One point is shown for each schema-node slot, colored by booking subtree with the root in gray. Pos-SP + LoRA stays close to the diagonal after transport-held-out training, whereas SP-only shifts upward, especially for transport slots. Additional details are in Appendix G.

sufficient. Date fields have high overlap without transferring, and key-name embedding coverage is similar across hotel and transport. Our supported claim is therefore operational rather than causal. Positional slots can preserve an unseen category without retraining when its field semantics and values align with a category abundant in training. Categories with novel field semantics still require adaptation. Appendix J probes whether the same positional effect appears in the inverse JSON-input direction.

8 Measured Multi-Tenant Serving

Protocol. We measure serving cost directly rather than projecting it from parameter counts. Two microbenchmarks run on the same model, Qwen3-4B-Instruct-2507 on one A100. The vLLM benchmark uses 64 fixed-length requests (512 input and 128 generated tokens), greedy decoding, and concurrency 32. Because the server API does not accept arbitrary input embeddings, we represent SP-only as 208 additional prompt positions. This is compute-equivalent for prefill and KV-cache cost, but it does not benchmark a custom prefix-injection API. LoRA uses vLLM's unmerged multi-LoRA path. A separate Hugging Face+PEFT benchmark measures serialized artifacts, peak allocated memory, prefix transfer, and warm adapter selection.

Table 4: Measured single-task serving on one frozen Qwen3-4B-Instruct (vLLM, 1×A100). Artifact sizes are measured separately with Hugging Face+PEFT.

Method	req/s	p50 ms	MB/task
Base	25.16	1252	–
SP-only	**24.60**	**1284**	**2.183**
LoRA	19.08	1660	47.225
SP + LoRA	18.74	1691	49.4

Single-task cost. SP-only is within 2% of base throughput and stores a 2.183 MB task artifact, versus 47.225 MB for LoRA. At 32 resident tasks, these measured artifacts total about 70 MB for SP versus 1.51 GB for LoRA before allocator and runtime overhead, leaving correspondingly more memory available to the KV cache. We do not separately benchmark that capacity effect. In the Hugging Face+PEFT harness, transferring a prefix takes 0.113 ms and warm adapter selection takes 8.219 ms. Peak allocated memory for one task is base-dominated (SP-only 9.46 GB and LoRA 9.11 GB), so we do not claim a single-task memory reduction. The SP cost is 208 extra positions and 94.7 ms additional time-to-first-token in that harness.

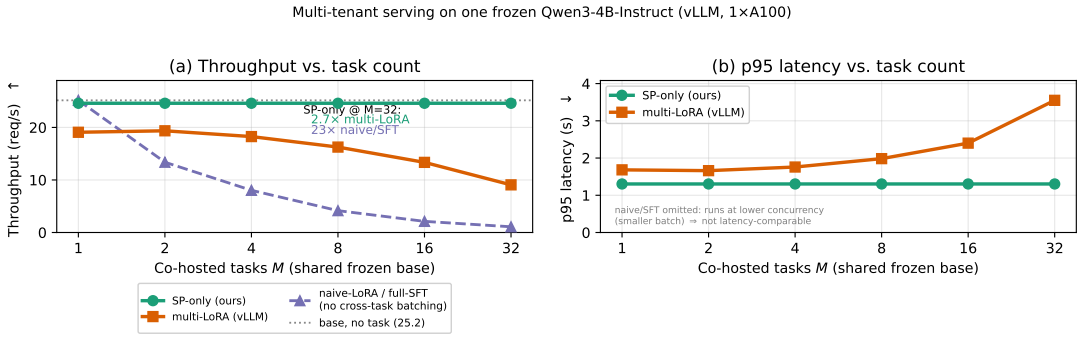

Figure 3: Multi-tenant serving versus task diversity M (vLLM, one A100, concurrency 32). Multi-LoRA directly measures batches with M adapter IDs. SP-only repeats the measured 208-position prefix workload. The no-cross-task-batching proxy uses the measured base concurrency sweep at effective concurrency $\lfloor 32/M \rfloor$.

Task-count scaling. Let M be the number of distinct tasks interleaved on one endpoint. Figure 3 measures the regime that motivates this work, namely many interleaved, individually low-traffic tasks. At $M{=}32$, SP-only still sustains 24.60 requests/s, unchanged from its single-task rate in Table 4 because task identity changes only the prompt embeddings, not the weights or kernels. Multi-LoRA falls to 9.07 requests/s, so SP-only sustains $2.7\times$ its throughput, and the measured no-cross-task-batching proxy falls to 1.09 ($23\times$). SP-only p95 latency is 1.30 s versus 3.55 s for multi-LoRA. The advantage is not that LoRA cannot batch. Modern multi-LoRA can batch, but it needs adapter-aware kernels whose cost grows with adapter diversity. SP instead mixes task prefixes in an ordinary shared-weight forward pass.

9 Conclusion

Schema-hierarchical soft prompts encode stable JSON topology in a compact frozen-backbone adapter, and controlled ablations identify depth and DFS order as the main contributors. The booking study bounds that claim, because positional slots preserve a held-out category only in the structurally aligned transport condition, not hotel. Measured serving identifies the regime where this lower-capacity adapter is useful, namely many interleaved tasks for which SP-level accuracy is sufficient. Categories with novel field semantics and accuracy-critical tasks should still use LoRA or fuller adaptation.

Limitations

Our evidence covers two extraction tasks and a few SLM backbones, at three seeds for the minority-category sweep and one for the component ablations, so the joint booking gain is specific to Qwen3-4B-Instruct rather than universal. The proprietary booking corpus cannot be released, which limits independent replication, so the open USPTO-ORD result carries the primary empirical claim. Our diagnostics bound a mechanism rather than prove a causal account, and the positional design assumes a stable schema. Serving uses fixed-length synthetic requests rather than production traffic, with a compute-equivalent prefix-position proxy for SP in vLLM rather than a deployed fleet. We also do not compare directly against schema-aware systems, whose full or instruction fine-tuning violates our shared frozen-backbone constraint. Appendix I reports a negative result for a training-time attention-routing regularizer that we do not recommend for deployment.

Ethics Statement

Patent uses the open USPTO-ORD corpus (Kearnes et al., 2021) (no personal data). Booking is a proprietary internal booking-email corpus whose PII is removed or substituted before training and evaluation, and the corpus itself is not released. Donor consent, the PII protocol, misuse considerations, and compute and carbon details are in Appendix A.

A Ethics: Details

Internal corpus and PII handling. Booking (booking-email extraction) is a proprietary internal booking-email corpus from a single operating organization. The original corpus contains personally identifiable information (passenger names, contact details, booking and reservation identifiers, addresses). PII is removed or replaced systematically before training and evaluation. PII-Swap (PII-Swap) is constructed by deterministic substitution of PII tokens against a held-out PII vocabulary. Synthetic-ID (Synthetic-ID) uses synthetic identifiers throughout. Donated-OOD (Donated-OOD) is post-processed to remove residual PII. We cannot release the corpus, because it is proprietary to the operating organization, and this constraint applies even in the PII-removed form.

Donated emails (Donated-OOD). The Donated-OOD split consists of booking emails voluntarily donated by individuals for research use. Donor consent and the PII-removal protocol were validated by the operating organization's data-governance

review before the emails entered the training and evaluation pipeline.

Potential misuse. The trained soft-prompt artifact is a small parameter set (∼374–545 K) on a frozen backbone. It does not give an attacker generative capability beyond the underlying backbone. The same architecture could in principle be used to train extractors over sensitive structured text. This is a generic risk of all parameter-efficient fine-tuning and is not specific to schema-hierarchical soft prompts.

Compute and carbon. We do not report a carbon estimate because the cluster power draw and grid-carbon logs needed for a defensible calculation were not available for all runs. Hardware and training schedules are in Appendix B.

B Reproducibility

This appendix consolidates the hyperparameters, training schedule, software environment, and compute footprint needed to reproduce the runs in the paper.

Hyperparameters. Hyperparameters are identical across Patent and Booking, with only the prefix length differing because the schemas differ. Table 5 groups them by method (SP-only, LoRA, and the joint configurations Prepend-SP + LoRA / Pos-SP + LoRA).

We do not use linear LR warmup. Instead the schedule is a three-phase curriculum (LoRA-warmup, then SP-only, then joint), each phase running its own cosine decay. SP-only and LoRA skip the inapplicable phases. The SP-only phase length of 4500 steps corresponds to roughly 10 epochs on the internal training set (n_{train}=7011, effective batch 16, ≈ 438 steps/epoch). SP-only needs more epochs than LoRA because only ∼370K parameters train.

Compute. Training runs use a single NVIDIA A100 80 GB GPU. Wall-clock time depends on backbone, sequence length, and cluster load, so we report the fixed training schedules in Table 5 rather than a single aggregate GPU-hour estimate. Patent (n_{train}=80,000) takes proportionally more wall time per epoch than Booking (n_{train}=7011), but the schedules use the same step counts.

Software environment. We use Python 3.10+, PyTorch ≥ 2.1.0 with the `cu121` wheels, transformers ≥ 4.46.0, peft 0.18.1, accelerate ≥ 0.33.0, and datasets ≥ 2.20.0. The server CUDA driver is 12.2. The planned release pins exact versions via `requirements.txt` and a conda environment file.

Seeds. Headline three-seed runs use seeds $\{42, 7, 123\}$. Single-seed ablations use seed 42. The seed controls the dataloader shuffling, the per-slot init noise ($0.01 \cdot \mathcal{N}(0,1)$ on per-key slots, $\mathcal{N}(0, 0.02^2)$ on depth embeddings), and the dropout RNG.

Decoding. All evaluations use greedy decoding (no temperature, no top-k, no top-p) with `max_new_tokens`=1536. The `train_v1` system prompt for Booking is ∼770 tokens (fields plus descriptions) and will be included verbatim in the release package.

Data.

- Patent (patent reaction extraction (USPTO-ORD)): a deterministic 80,000/10,000/10,000 train/valid/test split of the open USPTO-ORD-100K chemistry-procedures corpus, published with (Kearnes et al., 2021) and distributed as a prebuilt archive at `https://github.com/qai222/LLM_organic_synthesis` under CC-BY-SA 4.0. We use the canonicalized reaction-JSON variant. The canonicalization script and the n=500 validation slice will be included in the release package.

- Booking (booking-email extraction): a proprietary internal booking-email corpus from a single operating organization. Training set n_{train}=7011, validation n_{val}=321. Evaluation splits are described in §4. The corpus is not released. See the Ethics Statement for provenance and PII handling.

Public artifacts. The soft-prompt module is available at `https://github.com/microsoft/Hierarchical-Soft-Prompt`.

C Booking Weighted Full-Test-Set Table

Table 6 reports the weighted full-test-set result summarized in §5.

D Per-Key vs. Flat Architecture Ablation

Main-text Table 2 reports the equal-token control for Patent. Across the hard-prompt sweep, SP-only (schema-hierarchical) improves monotonically as the hard prompt shrinks (0.7381 → 0.7661 → 0.7700), while the flat variant does not show the

Table 5: Training hyperparameters by method. "Joint" covers Prepend-SP + LoRA and Pos-SP + LoRA, which use the same schedule.

	SP-only	LoRA	Joint
Optimizer	AdamW	AdamW	AdamW
LR (soft prompt)	10^{-3}	–	10^{-3}
LR (LoRA)	–	10^{-4}	10^{-4}
Weight decay (LoRA)	–	0.01	0.01
Weight decay (SP)	0	–	0
Gradient clip	1.0	1.0	1.0
LR schedule	cosine	cosine	cosine
$\eta_{\min}$	10^{-6}	10^{-6}	10^{-6}
Per-device batch size	4	4	4
Gradient accumulation	4	4	4
Effective batch size	16	16	16
LoRA-warmup phase	–	1000	500
SP-only phase	4500	–	500
Joint phase	–	2000	2000
Total gradient steps	4500	3000	3000
Eval interval (steps)	500	500	500
LoRA r	–	16	16
LoRA α	–	32	32
LoRA dropout	–	0.05	0.05
LoRA targets	–	q,k,v,o-proj	q,k,v,o-proj
SP k_g	20	–	20
SP t (tokens/slot)	2	–	2

Table 6: Booking weighted-by-n full-test-set `macro_mandatory_f1` (n=1529 across Synthetic-ID/PII-Swap/Donated-OOD). Split scores are weighted by split size. Zero-shot uses the matched `train_v1` system prompt.

Backbone	Zero-shot	SP-only	LoRA	Pos-SP + LoRA
Qwen3-4B-Inst	0.6406	0.7741	0.6411	**0.7841**
Qwen3-8B (base)	0.2702	0.7664	**0.7929**	0.7727
Phi-3.5-mini	0.3811	0.6547	**0.7483**	0.7453

same monotonic trend. On Booking at three seeds, schema-hierarchical-vs-flat differences are within seed noise ($+0.006$ on Synthetic-ID, $+0.011$ on PII-Swap, -0.038 on Donated-OOD). Per-key structure helps conditionally, either on the deeper open schema when hard text is minimized, or when paired with LoRA and placed positionally (§6).

E Multi-Seed Leave-One-Category-Out Results

This appendix expands main-text Table 3: three seeds × three methods on Qwen3-4B-Instruct (`train_v1`, `max_new_tokens`=1536), with transport and hotel separately excluded from training.

Per-seed PII-Swap F1. Table 7 reports per-seed PII-Swap F1 per booking type for each method. Pos-SP + LoRA reaches the highest mean overall (0.752 ± 0.011), with seed variance more than 7× tighter than LoRA (0.648 ± 0.077). On the held-out transport type itself, Pos-SP + LoRA sits at 0.655 ± 0.013 against LoRA's 0.528 ± 0.108, with both higher mean and tighter variance.

Hotel held out. Table 8 is the matched negative control. Pos-SP + LoRA does not exceed LoRA on the held-out hotel type or overall.

Control splits. On Synthetic-ID (flight-only, n=1,475), all three methods sit within ∼0.02 across seeds (means: LoRA 0.786, Pos-SP + LoRA 0.779, SP-only 0.768). On Donated-OOD (n=29, no transport bookings, no PII shift), the three-seed means are LoRA 0.880, Pos-SP + LoRA 0.818, SP-only 0.642. LoRA is ahead because the held-out-category pressure is absent on this split.

Bootstrap CIs and paired tests. Table 9 reports transport-held-out bootstrap 95% CIs (B=10,000

Table 7: Booking PII-Swap (n=25) per-seed F1 under transport-held-out training. Columns are per-booking-type and overall. Bottom row of each method shows three-seed mean ± std.

	7	0.895	0.111	0.107	0.371
	123	0.873	0.347	0.392	0.537
	mean ± std	0.900 ± 0.025	0.176 ± 0.122	0.191 ± 0.142	0.422 ± 0.081

resamples over the three seeds, with replacement) and paired-t deltas. The paired test has only df=2 and is severely underpowered, so the bootstrap CI is primary. Hotel-held-out PII-Swap gives $\Delta_{\text{hotel}} = -0.096$ with CI $[-0.289, +0.056]$ and Δ_{overall} =-0.061 with CI [-0.208,+0.047]. On Donated-OOD, the held-out hotel delta is significantly negative (-0.161, CI $[-0.227, -0.048]$). These controls bound the positive result to transport-held-out PII-Swap overall.

F Transfer Analysis for the Held-Out Categories

Value-overlap definition. For each held-out field, we form its normalized training value-token vocabulary and report the fraction also observed among flight-category training values. This descriptive statistic asks whether an extractor trained predominantly on flight has seen the same kinds of values. Table 10 pairs it with held-out-category per-field F1.

Boundary conditions. As §7 notes, value overlap alone does not explain the sign change. The evidence supports a whole-schema congruence account, in which value and field semantics jointly gate transfer, rather than a single scalar law.

G Slot Interpretability: Full Diagnostics

This appendix supplements §7 with the per-slot diagnostic protocol and the full slot-intervention results.

G.1 Per-slot drift analysis

For each per-key slot i, we compute $\|\text{trained}_i - \text{init}_i\|_2$ and $\cos(\text{trained}_i, \text{init}_i)$, where trained_i is the mean across the t=2 tokens of the slot with depth embedding added, and init_i is the deterministic mean of the key-name token embeddings. Mean drift L2 across the K=62 per-key slots is 0.700 for Pos-SP + LoRA on full data and 0.712 under transport holdout ($+1.7\%$), against 0.846 and 0.975 ($+15\%$) for SP-only. Figure 4 shows the per-

Table 9: Bootstrap 95% CIs and paired deltas on PII-Swap (n=25), using B= 10,000 resamples over the three seeds. The paired-t test has df=2 and is underpowered, so the bootstrap CI is the primary inferential statistic.

Comparison	type	mean Δ	95% CI	t	p
Pos-SP + LoRA − LoRA	flight	+0.046	[−0.001, +0.086]	+1.83	0.208
Pos-SP + LoRA − LoRA	hotel	+0.138	[−0.002, +0.257]	+1.83	0.209
Pos-SP + LoRA − LoRA	transport	+0.127	[−0.019, +0.233]	+1.68	0.234
Pos-SP + LoRA − LoRA	**overall**	**+0.104**	**[+0.011, +0.163]**	+2.21	0.158
Pos-SP + LoRA − SP-only	flight	+0.015	[+0.014, +0.017]	+14.72	**0.005**
Pos-SP + LoRA − SP-only	hotel	+0.281	[+0.094, +0.423]	+2.88	0.102
Pos-SP + LoRA − SP-only	transport	+0.221	[+0.016, +0.357]	+2.12	0.168
Pos-SP + LoRA − SP-only	overall	+0.173	[+0.041, +0.266]	+2.55	0.125

Table 10: Per-field transfer on PII-Swap (three-seed mean) versus value-token overlap with flight training values. Transport's improving fields reuse flight value spaces, whereas hotel's distinctive fields do not.

Held out	field	LoRA	Pos-SP + LoRA	Δ	overlap
transport	`passenger_name`	0.595	**0.752**	+0.157	1.00
	`reservationId`	0.360	**0.480**	+0.120	0.44
	`pickup_location`	0.630	**0.732**	+0.102	0.65
	`dropoff_location`	0.630	**0.732**	+0.102	0.66
hotel	`hotel_name`	**0.347**	0.208	−0.139	0.31
	`room_type`	**0.302**	0.153	−0.149	0.32
	`address`	**0.320**	0.162	−0.159	0.32

slot drift profile across all six checkpoints. Figure 6 pairs the dendrogram of Figure 5 with a heatmap view of the same pairwise cosine matrix.

G.2 Token-cloud cross-readout

For each selected schema key we compute three vector variants of its slot. The *key-only* variant is the initialization reference, *SP-only* is the trained slot with its depth embedding, and *combined* is the mean of the key and slot vectors. Each variant is passed through two top-K readouts, embedding nearest-neighbors and the raw `lm_head` logit. We prefer raw logits over softmax probabilities, which compress to $\sim 10^{-5}$–10^{-3} over a 150K vocabulary and round illegibly. The two readouts return the same ranked tokens for every (slot, variant, cell) combination. Figures 7 and 8 show the readout for the full-data Pos-SP + LoRA checkpoint. Figures 9 and 10 show the same readout for the transport-held-out SP-only checkpoint, the configuration with the largest slot drift.

G.3 Global tokens: task-identity vs. schema-content

For each architecture we compute the cosine similarity of each global token to every per-key slot's mean. The per-global mean cosine to the per-key slot space is near zero in every architecture (range -0.002 to $+0.004$), and the per-global max cosine to any single per-key slot sits in 0.05 to 0.14 (Figure 11). The globals occupy a subspace approximately orthogonal to the per-key schema-content space. This is consistent with a task-identity interpretation, in which the globals encode something other than schema content (a "you are doing structured JSON extraction" signal).

G.4 Slot intervention: full results

This subsection reports the three-seed slot intervention experiment summarized in §7. We additionally report a magnitude-rescaling probe on the full-data SP-only checkpoint (seed 42).

Protocol. For a given checkpoint and a target transport subtree, we modify the corresponding per-key slots on disk at the start of evaluation. The remaining slots (other subtrees and the global tokens) are untouched. Three modifications are evaluated:

- **init.** The target slot is replaced with the deterministic mean of the tokenized key-name embeddings, repeated across the t=2 token positions. This is the initialization used at training time, without the small Gaussian perturbation.
- **random.** The target slot is replaced with a random unit vector, drawn from a fixed seed and rescaled to match the norm of the init

Table 11: Inference-time slot intervention on the transport-held-out checkpoints, three-seed mean ± std over seeds $\{42, 7, 123\}$. PII-Swap `macro_mandatory_f1` (n=25), Qwen3-4B-Instruct. The *trained* row is the unmodified checkpoint. The *init* and *random* rows replace transport-subtree slots at inference while leaving all other slots untouched.

Method	slot variant	flight	hotel	transport	overall
Pos-SP + LoRA	trained	0.896 ± 0.022	0.706 ± 0.024	0.655 ± 0.013	0.752 ± 0.011
	init	0.881 ± 0.026	0.710 ± 0.085	0.664 ± 0.041	0.752 ± 0.050
	random	0.873 ± 0.028	0.707 ± 0.100	0.632 ± 0.041	0.737 ± 0.057
SP-only	trained	0.881 ± 0.020	0.424 ± 0.140	0.434 ± 0.140	0.580 ± 0.086
	init	0.898 ± 0.019	0.551 ± 0.240	0.590 ± 0.225	$\mathbf{0.680 \pm 0.153}$
	random	0.906 ± 0.014	0.550 ± 0.281	0.557 ± 0.298	0.671 ± 0.190

vector. This decouples the position of the slot from its semantic content.

- **boost.** The target slot is multiplied by a fixed factor ($1.5\times$ or $2.0\times$). Applied to the full-data SP-only checkpoint, this tests whether amplifying the trained slot direction improves F1.

Full-data SP-only magnitude rescaling. On the full-data SP-only checkpoint, multiplying all per-key slots by $1.5\times$ at inference yields PII-Swap overall 0.858, above the three-seed-mean baseline of 0.8445. The $2.0\times$ scale gives 0.817, indicating that the gain saturates and reverses for larger factors. This probe checks the role of slot magnitude in the SP-only setting.

H Base-vs-Instruct Ablation

The headline analysis in §5 reports a Qwen3-4B-Instruct LoRA weighted full-test-set (FTS) of 0.6411, well below the LoRA reference on Qwen3-8B (0.7929) and Phi-3.5-mini-Instruct (0.7483). We probe this gap by training the same configurations on the non-instruction-tuned Qwen3-4B-Base model.

Setup. Five matched cells are trained on Qwen3-4B-Base (seed 42, `train_v1` prompt, full Booking training set, `max_new_tokens`=1536) and compared cell-for-cell against their Qwen3-4B-Instruct twins: SP-only (prepend), SP-only (positional), LoRA alone, Prepend-SP + LoRA, and Pos-SP + LoRA. Here SP-only (positional) uses the positional placement without LoRA, while SP-only (prepend) is the default SP-only of §4. All training settings are identical except the backbone tuning state. Table 12 reports the comparison. Cross-family replication is not available because Phi-3.5-mini-Base is not published on the public hub and Qwen3-8B is already a base model (no instruct twin available).

Table 12: Booking weighted-by-n full-test-set `macro_mandatory_f1` (n=1529), Qwen3-4B-Base vs. Qwen3-4B-Instruct, seed 42. Delta is base minus instruct.

Configuration	Base	Instruct	Δ
SP-only (prepend)	0.669	0.774	−0.105
SP-only (positional)	0.404	0.462	−0.058
LoRA alone	**0.796**	0.641	+0.155
Prepend-SP + LoRA	**0.795**	0.646	+0.149
Pos-SP + LoRA	0.782	0.786	−0.005

Findings. Table 12 supports three conclusions.

- *LoRA-bearing methods on base reach or beat instruct.* LoRA alone (+0.155), Prepend-SP + LoRA (+0.149), and Pos-SP + LoRA ($\Delta = -0.005$) on Qwen3-4B-Base equal or exceed their instruct twins on weighted-FTS.

- *The Qwen3-4B-Instruct LoRA underperformance is instruct-interference-specific.* LoRA on Qwen3-4B-Base reaches 0.796, in line with the Qwen3-8B (0.7929) and Phi-3.5-mini (0.7483) LoRA references. The underperformance on Qwen3-4B-Instruct (0.6411) comes from the instruction-tuning of *this specific instruct release* interacting with LoRA fine-tuning on the new task, not from a Qwen-family or LoRA-method property.

- *SP-only on base underperforms instruct.* Without LoRA, the schema-hierarchical soft prompt cannot substitute for the instruction-tuning the base lacks. Both placements on Qwen3-4B-Base sit below their instruct twins (SP-only prepend $\Delta = -0.105$ and SP-only positional $\Delta = -0.058$).

Mechanistic reading. This is consistent with §7. LoRA absorbs the value-extraction and instruction-following work, and the schema-hierarchical positional slots act as positional scaffolds. On Qwen3-4B-Instruct, the instruction-tuning interferes with LoRA fine-tuning on the new task (the LoRA drop to 0.6411). The joint Pos-SP + LoRA configuration recovers because the slots supply the structural cue that LoRA on its own does not. On a base backbone, LoRA has the full capacity to do both jobs and the slots' marginal contribution is small.

Scope. This ablation is at seed 42 only.

I Hard Attention Routing (Negative Result)

We evaluated a training-time per-key attention-routing regularizer that constrains each gold-value-span token to attend only to its own key's slot. The mask is a 4-D additive tensor stacked with the standard causal mask during training. Evaluation and generation run with ordinary causal attention, so there is no inference-time overhead. Under three-seed paired-baseline analysis the regularizer produced no measurable effect on either task (Patent mean Δ $=-0.009$, Booking OOD mean Δ $=+0.077$ with σ_Δ $=0.18$, 95% CI [-0.070,+0.135]). The full method description, per-seed paired-delta tables, and geometric mechanism diagnostics are released with the code. We do not recommend the regularizer for deployment.

J Generality Probe: JSON-Input QA

The main paper studies text-to-JSON extraction. As a generality probe we additionally evaluate the inverse direction (JSON-input free-form QA) on two real-world JSON-native datasets, PubChem chemistry and SEC multi-company financial. Per-key positional placement beats a flat prepended baseline by $+5.3$ to $+10.2$ F1 at Qwen 0.5B (three seeds, both bf16 and 4-bit, both domains). The gap narrows to within seed noise at Qwen 1.5B as base capacity grows. On SmolLM2 (Llama architecture), per-key placement helps chemistry on 135M and 1.7B by $+2.0$ to $+3.1$ F1, but shows no reliable effect on financial. The probe is consistent with the positional-scaffold mechanism of §7 generalizing to the inverse direction, with effect size shrinking as base capacity grows.

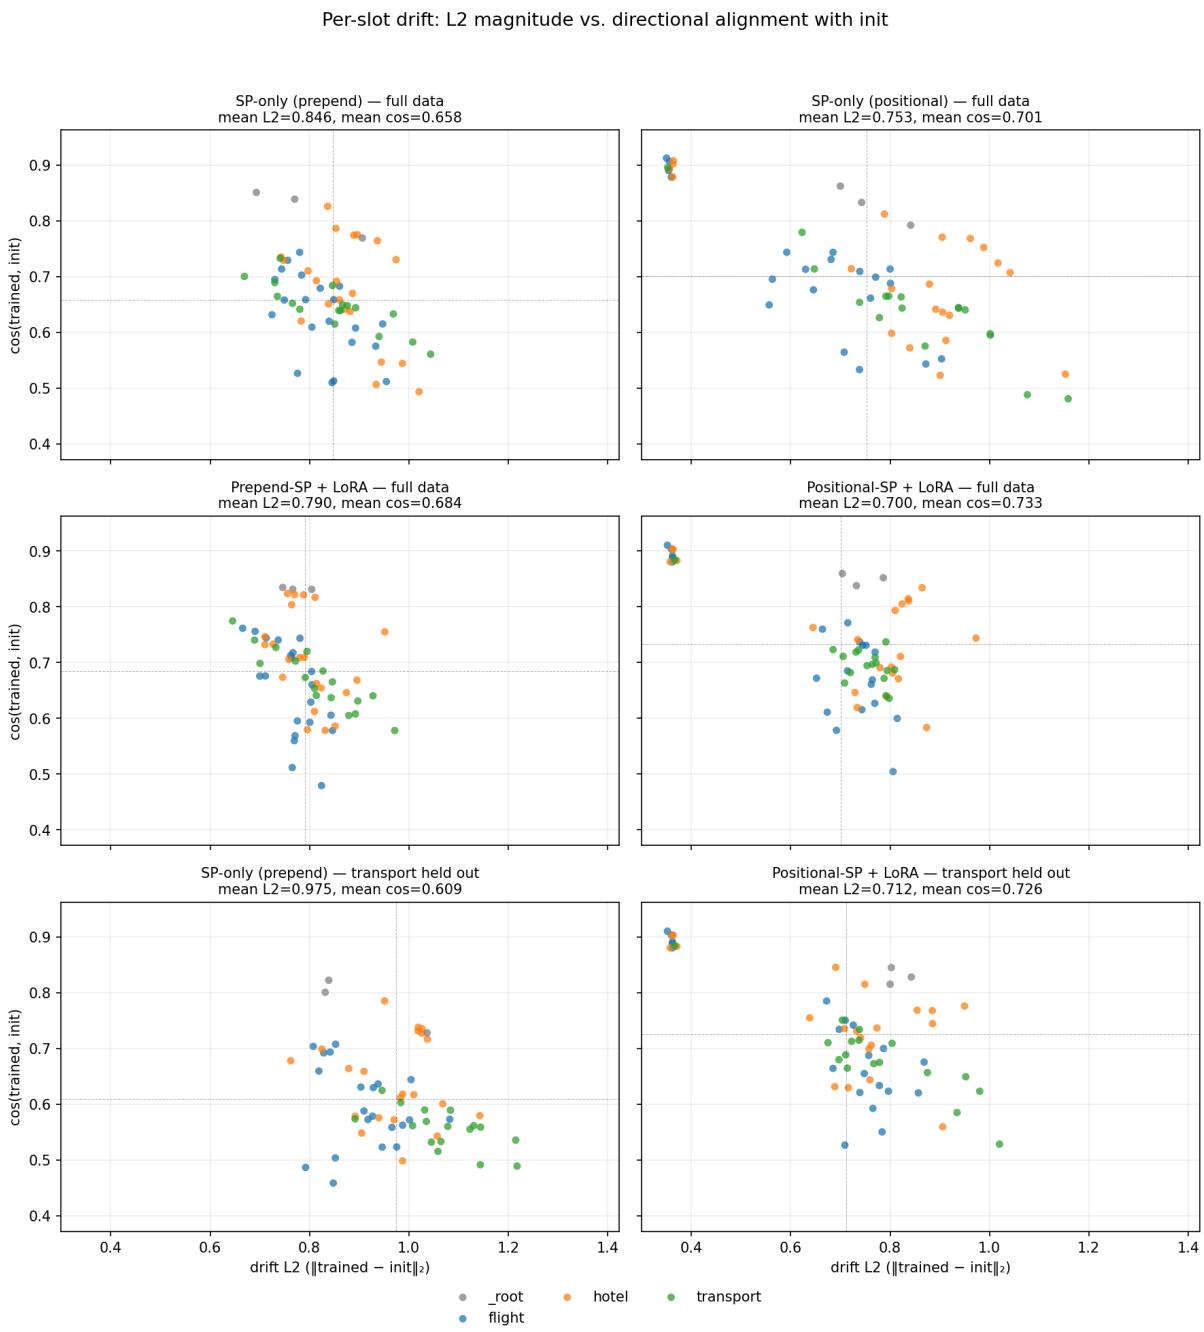

Figure 4: Per-slot drift profile across all six checkpoints. Points are per-key slots (one per schema node), colored by booking-type subtree. The x-axis is drift L2 from init, and the y-axis is cosine to init. Pos-SP + LoRA separates low-drift structural fields from higher-drift value fields, and this pattern persists under transport-held-out training. In SP-only under transport-held-out training, the low-drift cluster is weaker and transport slots (green) move farthest from initialization.

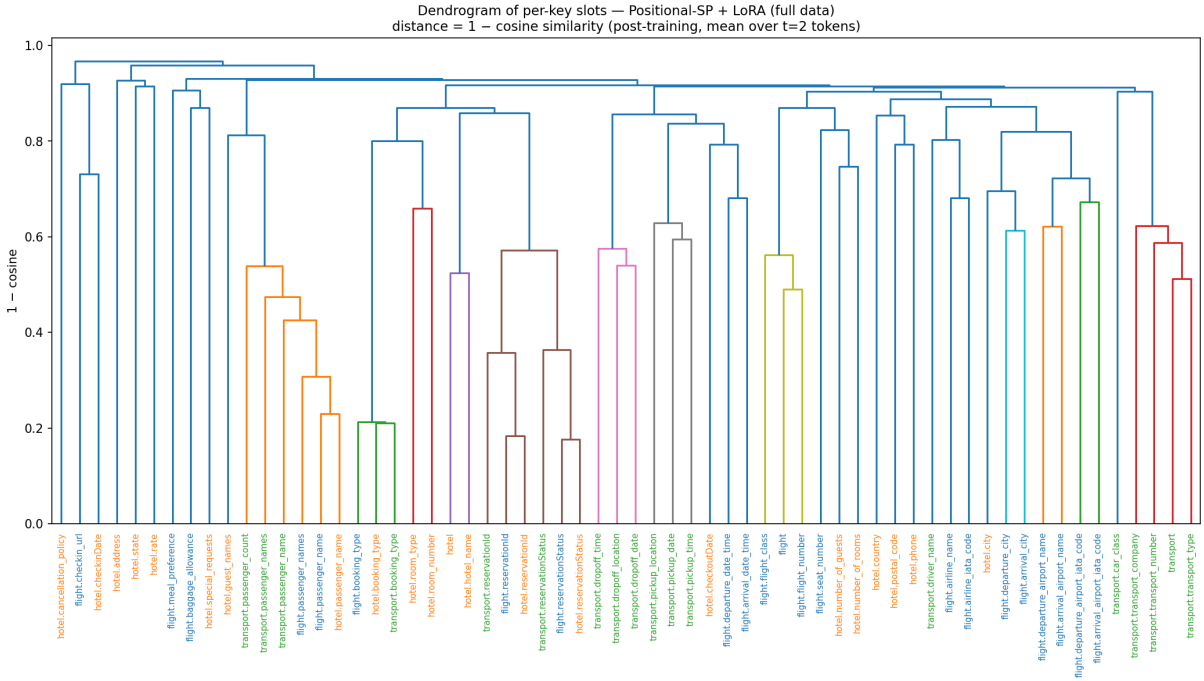

Figure 5: Hierarchical clustering of the 62 per-key slots in Pos-SP + LoRA (full data, seed 42), distance $= 1 - \cos$. Dendrogram labels are colored by booking-type subtree. The tightest clusters mix booking types (same-field-name across subtrees), showing that the slot space recovers field-name identity rather than the booking-type partition.

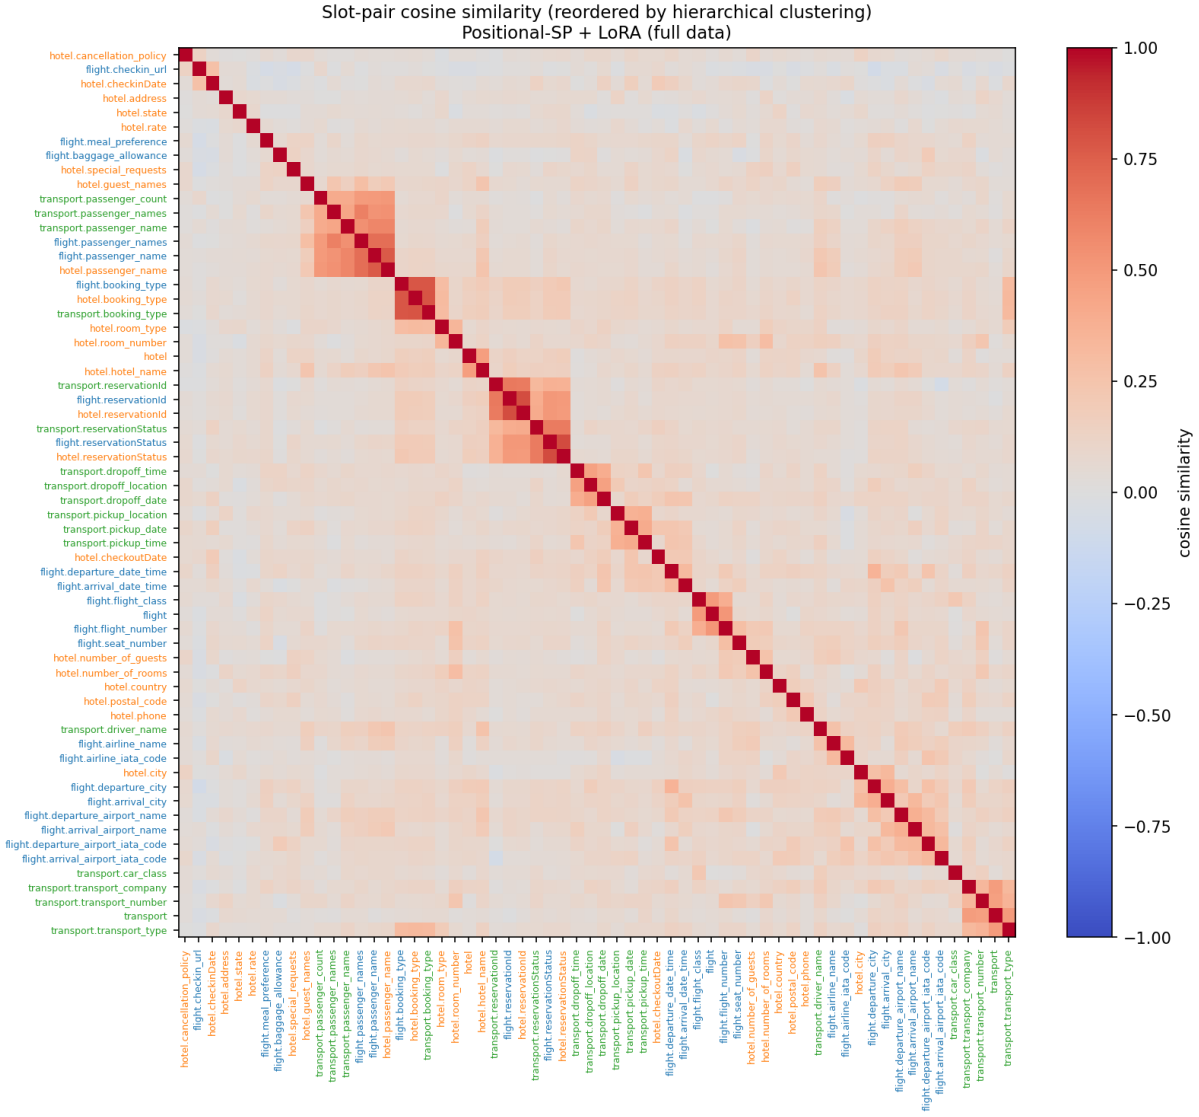

Figure 6: Pairwise cosine matrix of the 62 per-key slots in Pos-SP + LoRA, rows / columns reordered by the dendrogram of Figure 5. Red diagonal blocks hold same-field-name slots across booking subtrees.

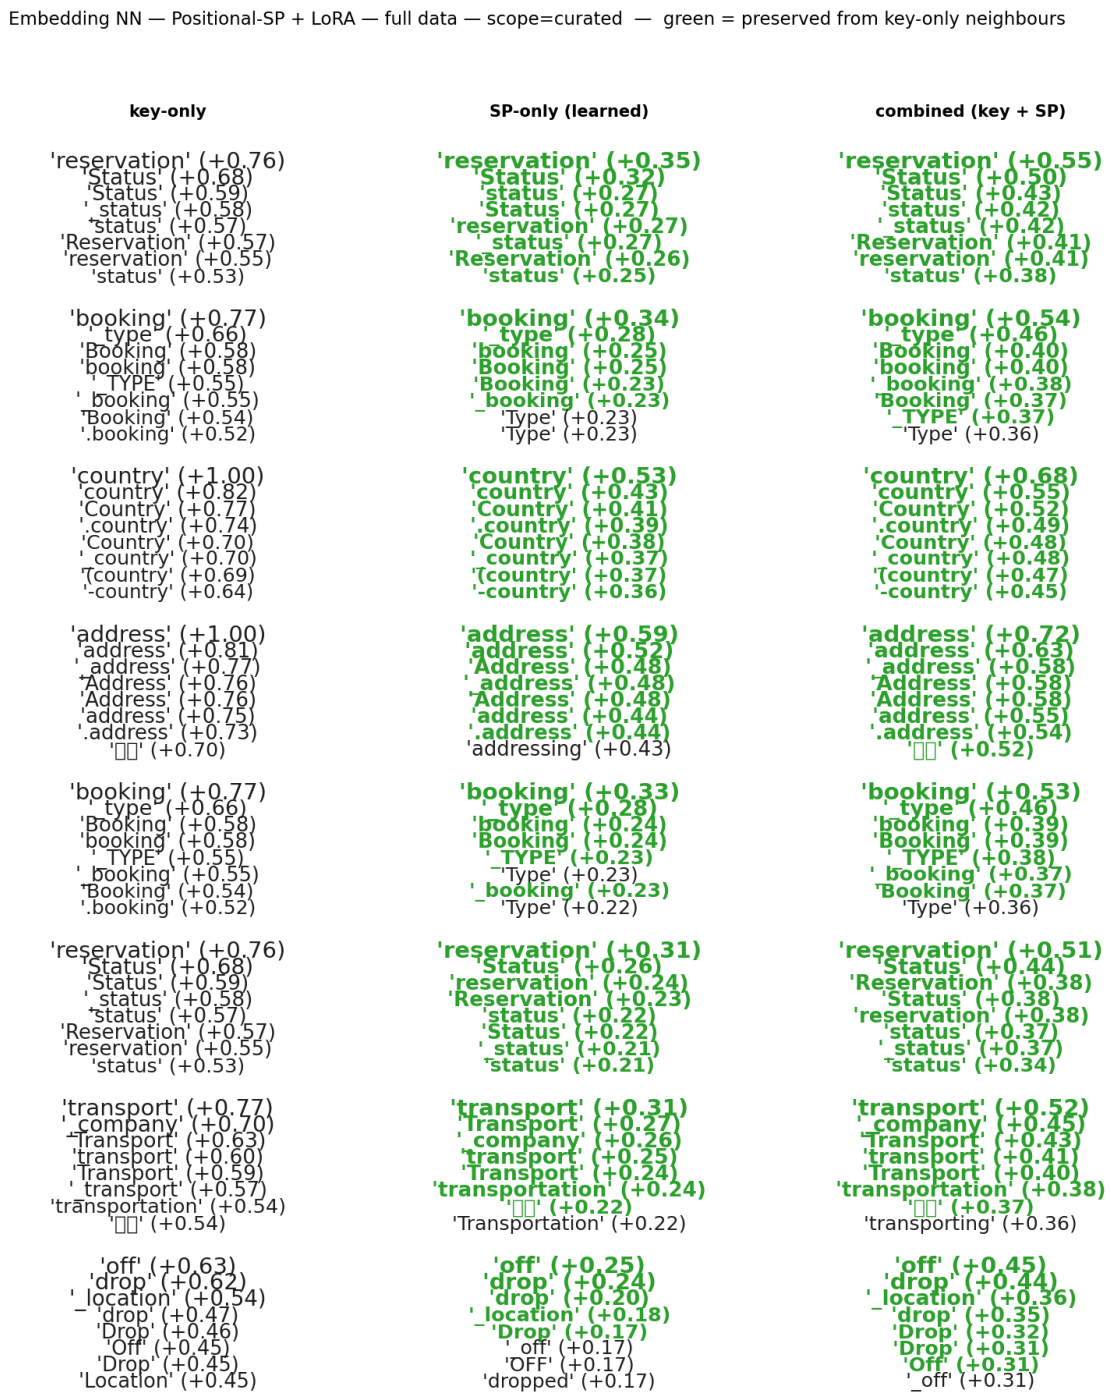

Figure 7: Embedding-NN readout for a curated 8-key set, Pos-SP + LoRA full-data. Rows are selected keys. Columns show key-only initialization, trained slot, and combined key-plus-slot vectors. Green marks tokens preserved from key-only initialization.

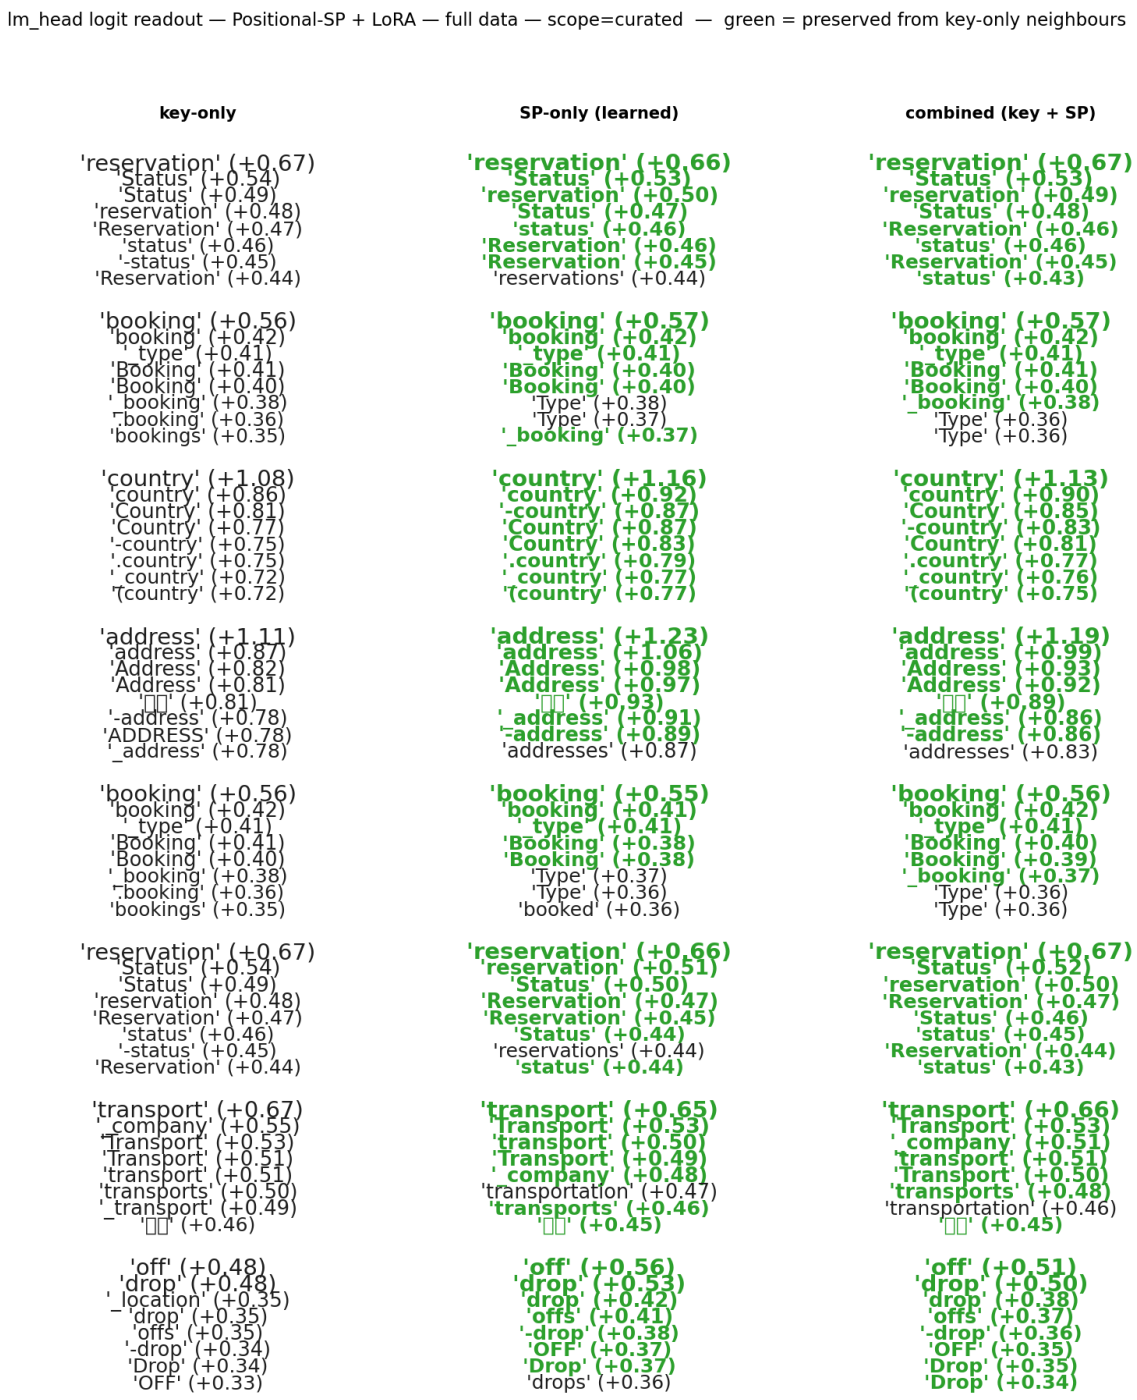

Figure 8: `lm_head` logit readout for the same 8 keys, same layout as Figure 7. Both readouts return the same ranked tokens. For value-rich slots, trained-slot logits are *higher* than key-only logits, consistent with training rotating and amplifying the slot within the key-name region.

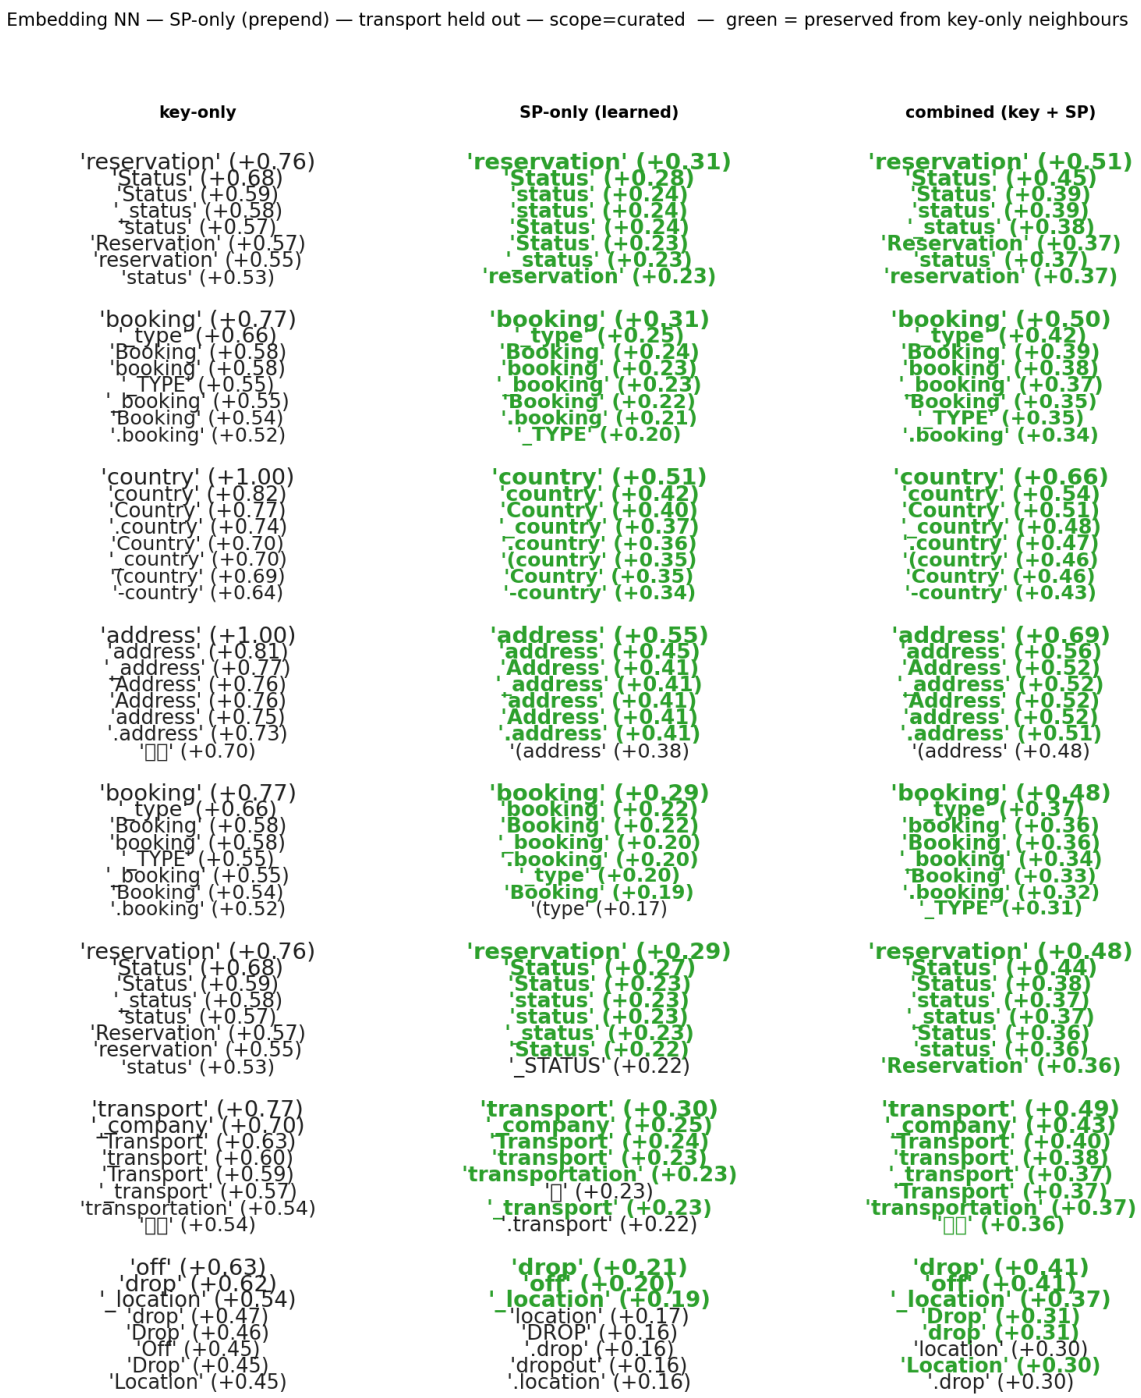

Figure 9: Embedding-NN readout, SP-only transport-held-out. Despite drift L2 over 1 on transport slots, the trained-slot column still recovers the key-name tokens, consistent with the slot being amplified within the transport-key region rather than anti-aligned.

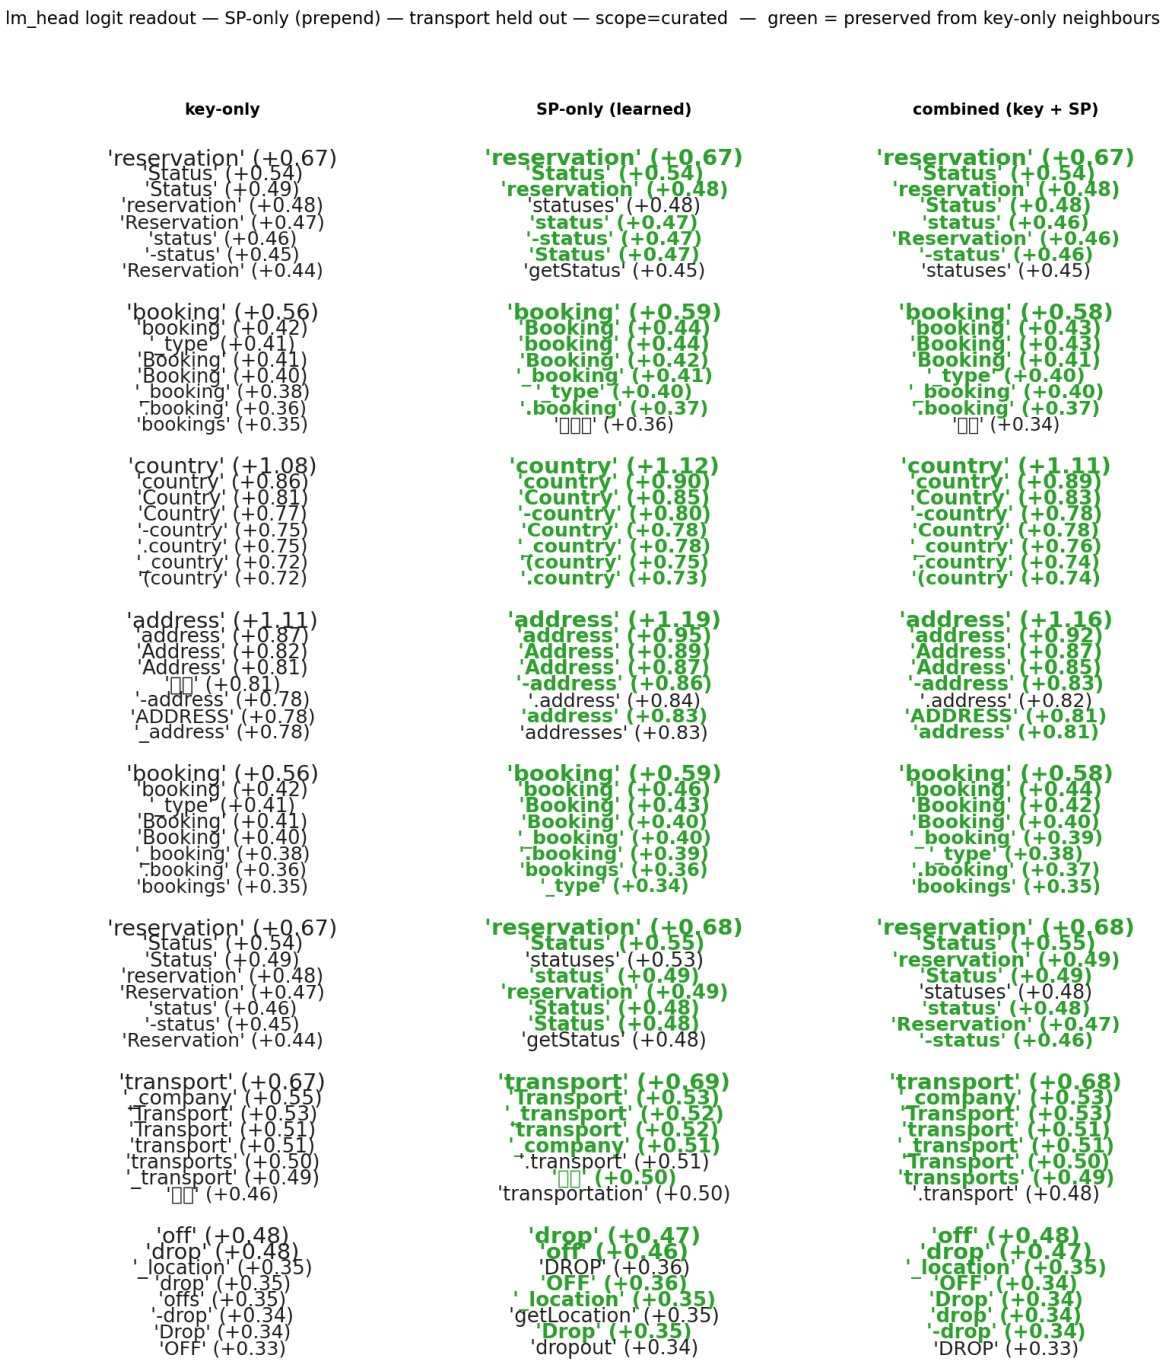

Figure 10: `lm_head` logit readout, SP-only transport-held-out. Same layout as Figure 8. Trained-slot logits for key-name tokens are comparable to or larger than the corresponding Pos-SP + LoRA logits in Figure 8.

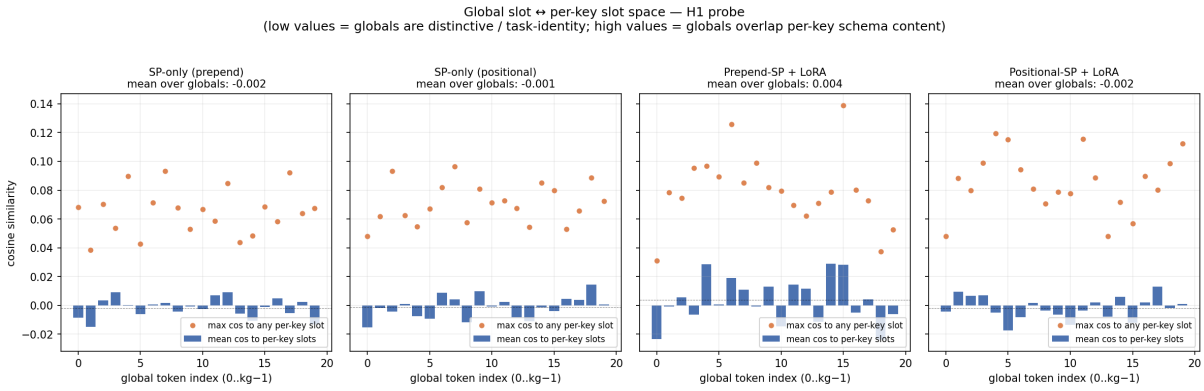

Figure 11: Cosine similarity between global tokens and per-key slots across the four full-data architectures. Bars show each global token's mean cosine to the per-key slot space, and orange dots show its maximum cosine to any single per-key slot. Global tokens are approximately orthogonal to per-key schema content in every architecture.

From Confusion to Clarity: Confusion-Aware Retrieval and Knowledge Injection for Text Classification

Manish Gupta* **Chaitanya Giri*** **Jayasimha Talur**
Amazon
{manishgp, girichai, talurj}@amazon.com

Abstract

Large language models (LLMs) struggle to classify text into taxonomies with many semantically similar labels, as the distinctions are domain-specific and not captured by pretraining. To handle large label spaces, a common approach retrieves top-K candidate labels by embedding similarity and prompt the LLM to choose among them. However, top-K retrieval reduces the number of candidates but does not help the model tell similar ones apart. When two similar labels both appear as candidates, the model lacks the signal to choose correctly between them. We propose a framework that (1) identifies which label pairs the model struggles to distinguish, (2) expands the candidate set to include confusable labels, and (3) generates targeted rules to differentiate between similar candidates. The framework requires no fine-tuning, and the generated rules transfer to smaller, cheaper models. On three benchmarks (WOS, Flipkart, LEDGAR), our approach improves Macro F1 by up to 10.0pp over retrieval baselines, with smaller models (2B–20B) gaining up to 11.5pp via cross-model transfer.

1 Introduction

Classifying text into taxonomies with hundreds of semantically similar labels is a common industrial requirement, yet remains error-prone even for large language models. Product catalogs, customer service queues, and legal document taxonomies often involve labels that overlap in meaning, frequently organized into multi-level hierarchies. Misclassification in these settings directly degrades search relevance, ticket routing, and compliance filtering.

Large language models (LLMs) provide a zero-shot alternative to supervised classifiers: they require no task-specific training data and can interpret label semantics without fine-tuning. A common approach retrieves the top-K candidate labels by embedding similarity and prompts the LLM to select the best match from this reduced set.

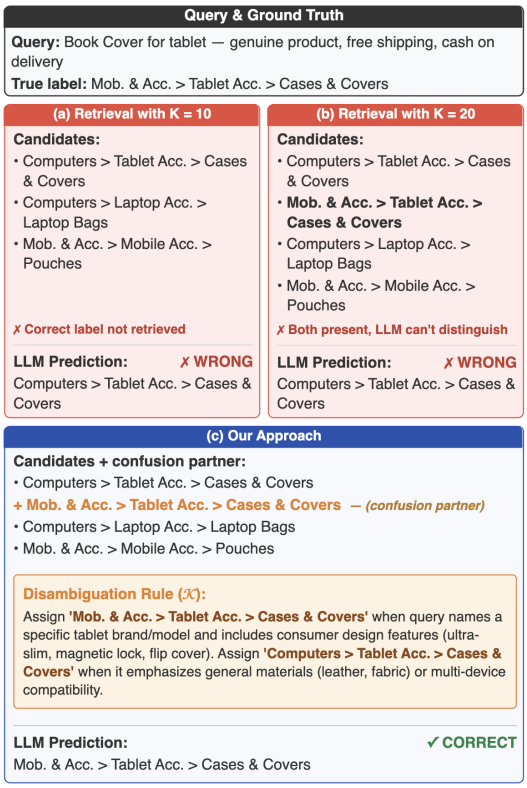

Figure 1: Example illustrating the benefit of confusion-aware knowledge augmentation. Confusion partners recover missing labels, while learned disambiguation rules help the LLM distinguish semantically similar candidate labels

However, zero-shot LLMs consistently underperform fine-tuned models on domain-specific taxonomies (Vajjala and Shimangaud, 2025; Loukas et al., 2023). The gap is widest when labels overlap in meaning and only taxonomy-specific conventions separate them: for example, distinguishing "Women's Western Wear" from "Women's Ethnic Wear" requires knowing how a particular catalog defines each category. Retrieval helps by narrowing the label space, but when two confusable

*Equal contribution.

EMNLP 2026 Industry Track, pages 2149–2164
October 24-29, 2026 ©2026 Association for Computational Linguistics

labels both appear among candidates, the LLM still lacks the signal to choose correctly (Figure 1). Prior work addresses label ambiguity through tournament-style pairwise comparison (Lu et al., 2024) or taxonomy-structure injection (Zang et al., 2025). Neither analyzes which specific pairs the model gets wrong, nor generates targeted rules to fix those errors. By targeting the specific label pairs the model actually fails on, our approach directly addresses the root cause rather than relying on structural or generic signals.

This paper presents **Confusion-Aware Knowledge Augmented Classification**, a framework that: (1) identifies which label pairs the model struggles to distinguish by analyzing classification errors on a training set; (2) ensures both members of each problematic pair appear in the candidate set at inference time; and (3) generates targeted rules that tell the model how to differentiate between them.

We make the following contributions:

- A candidate augmentation strategy that uses confusion-matrix analysis to ensure systematically confused labels co-occur in the retrieval set.
- A three-stage knowledge generation pipeline that produces pairwise disambiguation rules from misclassified training examples.
- Empirical validation on three datasets and seven models (2B–32B) showing that pairwise disambiguation knowledge consistently improves F1 score, and that knowledge generated once by a large model transfers to smaller, cheaper classifiers without retraining.

2 Related Work

Our work draws on and extends ideas from LLM-based classification, retrieval augmentation, and prompt optimization.

LLMs for Text Classification. Zero-shot LLMs consistently underperform fine-tuned models on domain-specific classification (Vajjala and Shimangaud, 2025; Loukas et al., 2023). However, fine-tuned models require dedicated infrastructure per taxonomy and do not generalize robustly to out-of-distribution inputs. This motivates inference-time approaches: retrieval-based methods narrow the candidate set (Pattnaik et al., 2025; Tabatabaei et al., 2025; D'Oosterlinck et al., 2024), while others inject structural context such as knowledge graph subgraphs (Zang et al., 2025) or LLM-generated taxonomy expansions (Paletto et al., 2024). These methods improve *which* labels reach the LLM; our work addresses what happens *after* retrieval, when similar labels co-occur and the model cannot distinguish them.

Prompt Optimization and Inference-Time Strategies. An alternative is optimizing the classification prompt itself. Opsahl-Ong et al. (2024) optimize instructions and demonstrations for multi-stage LLM programs. Agrawal et al. (2025) evolve prompts through reflective self-improvement. Lu et al. (2024) reduce label ambiguity through iterative pairwise comparison with hand-crafted descriptions, requiring multiple LLM calls per query. These methods improve prompting generically but do not analyze which specific label pairs cause errors. Our approach is error-informed: we identify problematic pairs from observed misclassifications, generate disambiguation rules specific to those pairs, and apply them in a single LLM call.

3 Methodology

Given a text query q and a label taxonomy $\mathcal{L} = \{l_1, \ldots, l_N\}$ with N labels, we formulate the task as assigning q to one label from $\mathcal{L}$. In a zero-shot setting, the LLM receives the query alongside all N labels and their descriptions. As the taxonomy grows, the prompt may exceed the model's context window, and when many labels overlap in meaning, the model struggles to distinguish between them without domain knowledge specific to the taxonomy. A common approach to mitigate the scale problem involves retrieving the top-K labels by embedding similarity, which reduces the candidate space but does not help the model distinguish between similar labels.

Our approach addresses these gaps in three phases (Figure 2): (1) augmenting the candidate set with labels the model has historically confused with retrieved ones, increasing the chance of correct label being present, (2) generating pairwise disambiguation rules offline from the classifier's own errors, and (3) injecting these rules at inference time to supply the domain knowledge needed to distinguish between similar candidates. We describe each phase in detail below.

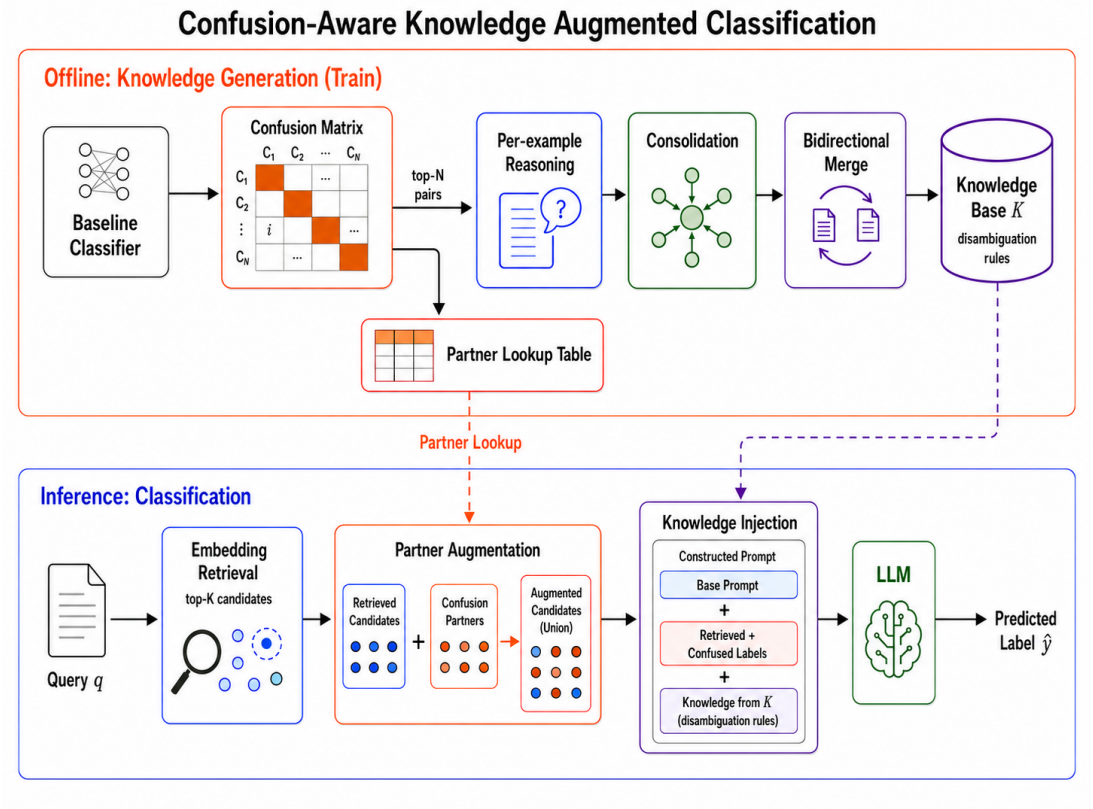

Figure 2: Overview of our framework. The *offline phase* (top) analyzes a baseline classifier's confusion matrix to find systematically confused label pairs and generates pairwise disambiguation rules via a three-stage pipeline. The *inference phase* (bottom) retrieves candidates, augments with confusion partners, injects relevant rules, and predicts.

3.1 Confusion-Aware Retrieval

Standard top-K retrieval uses a general-purpose embedding model that may not reflect taxonomy-specific similarity. Two labels that are close within a taxonomy can be distant in embedding space, causing retrieval to surface one while missing the other. Increasing K recovers missing labels but also admits irrelevant candidates that degrade classification (Figure 4). We exploit a simple observation: if the model has previously misclassified label l as l', this is direct evidence that both labels are plausible for similar queries and should appear together as candidates. We formalize this as *confusion partners*.

In order to identify which pair of labels the model confuses the most, we run the retrieval baseline on the training split and record the misclassifications $\hat{Y}_{\text{train}}$. Each error in which the true label l is predicted as l' increments a directed confusion count $c(l \to l')$. We rank pairs by this count and select the smallest set $\mathcal{P}$ whose cumulative count covers at least $\tau\%$ of all training errors.

For each label l, we define its confusion partner $\textsc{Partner}(l)$ as the label with the highest combined count of l being mistaken for l' and vice versa, since either case indicates that the model cannot distinguish between the two labels (Algorithm 1, lines 1–3).

To increase the chance of the correct label being present, we augment our candidate set $\mathcal{C}$ by adding $\textsc{Partner}(l)$ for each retrieved label $l \in \mathcal{C}$ (Algorithm 2, lines 1–2). This ensures both labels of a confused pair are present, but co-occurrence alone is not enough: the model still lacks the domain-specific signal needed to tell them apart.

3.2 Knowledge Generation

We generate disambiguation rules for each pair in $\mathcal{P}$ through a three-stage offline pipeline (Algorithm 1, lines 4–12; prompts in Appendix A.11).

Stage 1: Per-example reasoning. For every training query where l was misclassified as l', we prompt an LLM: *"What signal in this query indicates it belongs to l rather than l'?"* This produces a set of per-example observations $O_{l \to l'}$.

Stage 2: Consolidation. Individual observations may be query-specific and noisy. We prompt an

Method	LEDGAR	WOS		Flipkart		
		L1	L2	L1	L2	L3
Zero-shot (all labels)	57.1	80.5	56.6	84.4	73.3	65.5
Few-shot†	57.8	77.6	55.0	–	–	–
MIPROv2 (Opsahl-Ong et al., 2024)	47.2	61.4	35.9	73.8	67.0	62.4
GEPA (Agrawal et al., 2025)	52.4	68.3	32.7	61.4	61.1	58.0
Retrieval (K=20)	56.3	78.4	52.4	91.0	81.8	72.3
Ours (Conf. Partners + Knowledge)	**58.9***	**81.5***	**57.7**	**92.5**	**84.4**	**76.7***

Table 1: Macro F1 (%) on three datasets with Qwen3-32B. Best per column in **bold**; component ablation in Appendix A.8. †Exceeds the context window (351 labels + demonstrations). *Our gain over the second-best method in that column is statistically significant ($p < 0.05$, paired bootstrap; Appendix A.10).

LLM to distill $O_{l \to l'}$ into a single directional rule $r_{l \to l'}$ that captures the consensus signals (examples in Appendix A.12).

Stage 3: Bidirectional merge. Pairs confused in both directions yield two directional rules. We prompt an LLM to merge them into one symmetric rule. The result is a knowledge base $\mathcal{K}$ containing one disambiguation rule per pair in $\mathcal{P}$.

3.3 Inference

Inference combines both components into a single LLM call: confusion partners ensure the right labels are present, and the generated rules tell the model how to choose among them. Given a query, we retrieve candidates $\mathcal{C}$ and expand them with confusion partners into $\mathcal{C}'$ (Section 3.1). We then gather applicable rules $\mathcal{R} \subseteq \mathcal{K}$, inject them into the prompt alongside the candidate labels (Appendix A.14, Figure 7), and the LLM selects the final label $\hat{y}$ from $\mathcal{C}'$ (Algorithm 2).

4 Experiments

We evaluate five questions: (i) Do confusion partners and knowledge injection each improve over retrieval independently? (ii) Do they compose for additive gains across datasets? (iii) Does knowledge from a larger model transfer to smaller classifiers? (iv) Do confusion partners outperform simply increasing K? (v) Does pairwise knowledge outperform per-label alternatives?

4.1 Setup

Datasets. We evaluate on three publicly available benchmarks: WOS[1] (Kowsari et al., 2017), Flipkart†[2] (PromptCloud, 2018), and LEDGAR[3] (Chalkidis et al., 2022).

Dataset	Labels	Levels	Train	Test	Domain
LEDGAR	100	1	60k	10k	Legal
WOS	134	2	32.8k	9.5k	Academic
Flipkart	351	3	12.3k	3.8k	E-commerce

Table 2: Dataset statistics. WOS and Flipkart are hierarchical; LEDGAR is flat.

Models. Our main experiments use Qwen3-32B (Yang et al., 2025) as both the knowledge generator and the classifier. To test cross-model transfer, we use the larger Qwen3-235B (Yang et al., 2025) as the knowledge generator and apply its knowledge to smaller models: Ministral 3 3B and 8B (Liu et al., 2026), Qwen3.5-2B, 4B, and 9B (Qwen Team, 2026), and GPT-OSS-20B (Agarwal et al., 2025). We use Qwen3-Embedding-8B (Zhang et al., 2025) for retrieval in all experiments.

Hyperparameters. Retrieval returns K=10 candidates. Confusion pairs are selected as the fewest directed pairs covering $\geq$75% of training errors. Appendix A.4 reports the coverage sweep, and Appendix A.5 reports the resulting generation and inference costs. All LLM calls use temperature 0.[4]

[4] Qwen3-235B is a mixture-of-experts model whose routing is not fully deterministic at temperature 0; we report standard deviation in Table 16.

5 Results

Table 1 compares our full approach against five baselines on all three datasets with Qwen3-32B; a component-wise ablation is deferred to Appendix A.8. Our method achieves the best Macro F1 in every column, with the largest margins on the deepest, most confusable level (Flipkart L3: +11.2pp over zero-shot and +4.4pp over the strongest baseline, retrieval at K=20). The gains over the second-best method are statistically significant on LEDGAR, WOS L1, and Flipkart L3 (paired bootstrap, $p < 0.05$; Appendix A.10).

Baselines. Zero-shot (all labels in the prompt) is competitive at coarse levels but degrades sharply at fine granularity on the largest taxonomy (65.5 F1 on Flipkart L3). Few-shot edges out zero-shot only on LEDGAR (57.8 vs. 57.1); on WOS it is slightly worse at both levels, and it cannot be run on Flipkart, where the input prompt plus 351 labels exceed the context window. Prompt-optimization baselines operate over the full label set but do not match retrieval-augmented approaches on any column, suggesting that instruction tuning alone does not address the underlying confusion between similar labels. Our primary evaluation focuses on methods that keep the classifier fixed and adapt through inference-time context. We discuss this deployment choice and compare against fine-tuned models in Section 5.3.

Error decomposition. We decompose errors into two failure modes: *retrieval misses* (correct label absent from candidates) and *LLM misses* (correct label present but not selected). On Flipkart L3, retrieval at K=10 misses the correct label 14% of the time. Adding confusion partners nearly eliminates this problem (recall: 86% → 98.1%), but introduces a trade-off: more confusable candidates means more LLM errors (15.5% → 21.9%). Knowledge injection addresses this, reducing LLM misses to 17.1%. The two mechanisms are therefore complementary by design. Table 3 detail these findings on Flipkart dataset. Refer A.9 for similar analysis across all datasets.

5.1 Analysis

Confusion partners vs. larger K. A natural alternative to confusion partners is simply retrieving more candidates. Figure 4 compares both strategies on Flipkart L3, plotting F1 and recall against average candidates per query. Confusion partners

Method	Flipkart L1	Flipkart L2	Flipkart L3
Retrieval (K=10)	97.8	94.2	86.0
+ Conf. Partners	**99.9**	**99.2**	**98.1**
Retrieval (K=20)	99.3	97.4	92.4

Table 3: Recall (%, ↑) on Flipkart dataset (Qwen3-32B): fraction of queries whose correct label is among the candidates. Knowledge injection leaves the candidate set unchanged and so does not affect recall.

at K=10 (18 candidates on average) achieve 74.2 F1 and 98.1% recall. Plain retrieval needs K=20 (20 candidates) to reach only 72.2 F1 and 92.4% recall, and K=50 to match the recall. The gap shows that adding labels the model is known to confuse is more effective than retrieving more labels indiscriminately.

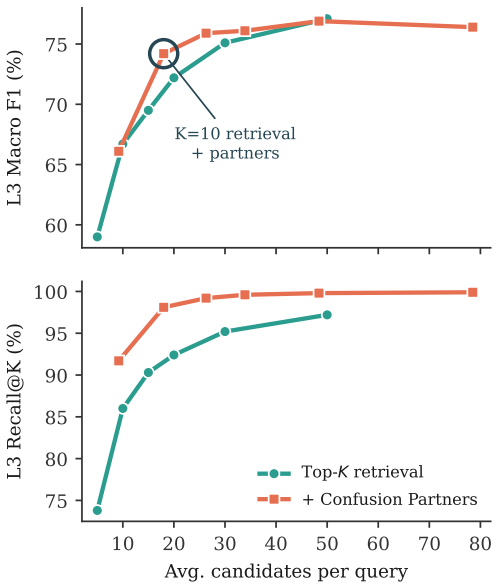

Figure 4: L3 Macro F1 (top) and Recall@K (bottom) on Flipkart (Qwen3-32B) vs. average candidates per query. Discussion in Section 5.1.

Pairwise vs. per-label knowledge format. Our method presents knowledge as pairwise rules ("Label A vs. Label B: [rule]"). An alternative *per-label* format consolidates all rules for a given label into a single description of its distinguishing features, without naming specific confusers. Table 4 shows pairwise consistently wins. The advantage is that pairwise rules are contextual: the LLM sees both candidates and a rule tailored to exactly that comparison, rather than generic label descriptions that

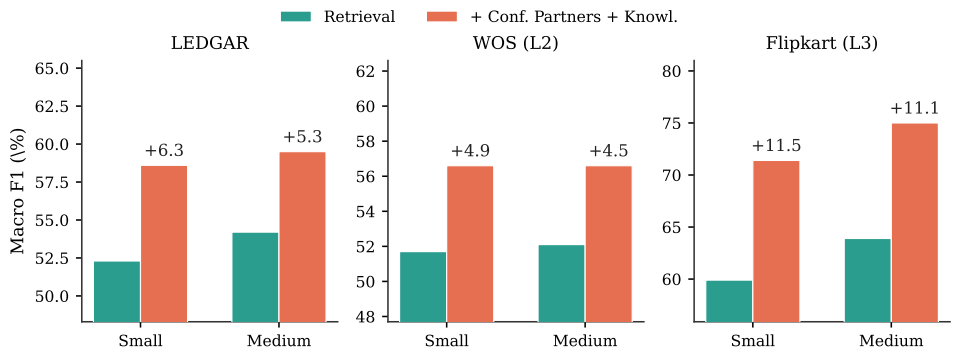

Figure 3: Cross-model transfer: Macro F1 (%) at each dataset's finest level for retrieval-only vs. our full approach, with all knowledge generated by Qwen3-235B. Gains (above each pair) hold across both size groups (Small: 2–4B; Medium: 8–20B) and all datasets.

must work against any confuser. This echoes Lu et al. (2024), who find pairwise comparison more effective than independent label evaluation, though they rely on hand-crafted descriptions (examples of both formats in Appendix A.14).

	L1		L2		L3	
Format	**F1**	**Miss**	**F1**	**Miss**	**F1**	**Miss**
No knowledge	90.8	6.2	81.9	13.3	74.2	21.9
Per-label	91.4	4.8	83.5	11.3	74.8	18.5
Pairwise (ours)	**92.5**	**3.8**	**84.4**	**10.0**	**76.7**	**17.1**

Table 4: Knowledge format ablation on Flipkart (Qwen3-32B); all rows use retrieval + confusion partners. F1: Macro F1 (↑); Miss: LLM miss rate (↓). Best per column in **bold**.

5.2 Cross-Model Knowledge Transfer

Small models are preferred for inference due to lower latency and cost, but they lack the capacity to generate high-quality disambiguation rules. We therefore generate rules offline with a large model and serve a small, fast model at inference time. We run each smaller model on the training set to identify its own confusion pairs; the large model then writes disambiguation rules for those pairs. We test this by generating all knowledge with Qwen3-235B and applying it to smaller models: Small (2–4B) and Medium (8–20B).

Table 16 confirms effective transfer. The pattern from Table 1 reproduces: partners improve recall, knowledge reduces selection errors, and the combination yields the largest gains. Small models improve by +11.5pp on Flipkart L3 over retrieval-only; Medium models by +11.1pp. Gains hold across all datasets including the flat taxonomy (LEDGAR: +6.3pp Small, +5.3pp Medium). These results indicate that the rules capture domain knowledge that transfers across model sizes, decoupling rule quality from inference cost. Appendix A.6 tests the stricter setting in which the same confusion pairs and rules are reused unchanged across classifiers.

5.3 Comparison with Fine-Tuning

A natural alternative to our inference-time approach is to use the same labeled data for fine-tuning. This process encodes taxonomy-specific information in model parameters, producing a separate model artifact that must be trained, deployed, and maintained for each taxonomy. Changes to the label space or input distribution require this lifecycle to be repeated. Our method instead targets teams that access foundational models through managed APIs rather than operate their own training and serving infrastructure. This deployment setting motivates our comparison with MIPROv2 and GEPA, which optimize prompts without updating model weights. To complement this evaluation, we compare our method with fine-tuning under clean data and three conditions commonly encountered in production.

Specifically, we fine-tune ModernBERT-base (Warner et al., 2025) and RoBERTa-base (Liu et al., 2019) on Flipkart L3 and evaluate them alongside our framework under four settings: clean data, test-time perturbations, label noise, and data scarcity. The clean setting uses the complete training and test splits. In each robustness setting, we vary only the condition under study. Table 5 summarizes one representative setting for each condition. Appendix A.3 reports additional results and implementation details.

Setting	ModernBERT	RoBERTa	Ours
Clean data (complete)	80.0	**81.7**	76.7
Label noise (20%)	60.0	61.0	**72.1**
Data scarcity (10%, ∼3/class)	23.2	31.8	**70.2**
Test-time perturbations (mean Δ)	−17.0	−9.0	**−5.0**

Table 5: Flipkart L3 Macro F1. Rows above the midrule are absolute scores. The final row is the mean change (Δ) across nine test-time perturbations, where values closer to zero are better.

On clean data, ModernBERT and RoBERTa reach 80.0 and 81.7 Macro F1, compared with 76.7 for our framework. This advantage, however, does not persist across the robustness settings. With 20% of the training labels replaced, our framework retains 72.1 Macro F1, compared with 60.0 for ModernBERT and 61.0 for RoBERTa. With only 10% of the training examples, our framework reaches 70.2, compared with 23.2 and 31.8. Over nine perturbed test sets, our framework loses 5.0 points on average, while ModernBERT and RoBERTa lose 17.0 and 9.0 points. Fine-tuning performs best with clean, abundant data and a stable test distribution, but degrades sharply when these assumptions do not hold in production. Our framework retains substantially more accuracy without parameter updates.

5.4 Human Evaluation of Generated Rules

LLM-generated rules may contain unsupported or example-specific distinctions. Our pipeline mitigates this risk through Consolidation (Stage 2), which retains signals that recur across labeled examples, and Bidirectional Merge (Stage 3), which reconciles evidence from both confusion directions when available. These stages reduce example-specific noise, but neither they nor downstream classification gains establish the correctness of individual rules. We therefore evaluate rule quality directly through human review.

We randomly sample 50 Flipkart rules generated by Qwen3-32B. For each rule, the authors review the generated rule alongside the two label paths and example queries from both labels. All three authors independently judge whether each rule correctly distinguishes the two labels in both directions and reject it if it is incorrect, misleading, incomplete, or unhelpful. Together, these assessments produce 150 judgments (Appendix A.7). On average, the three authors accept 87.3% of the sampled rules. High-stakes applications should nevertheless require domain-expert approval before generated rules are deployed.

6 Conclusion

We presented a framework that turns LLM classification errors into targeted disambiguation rules, improving accuracy without fine-tuning. Two mechanisms work together: confusion partners ensure the right labels are present as candidates, and pairwise rules help the model choose between them. On three benchmarks, the approach improves Macro F1 by up to 10.0pp, and rules generated by a large model transfer to smaller classifiers for gains of up to 11.5pp. The framework requires only a one-time offline error analysis and generalizes across hierarchical and flat taxonomies.

Limitations

The framework has two main limitations. First, the offline phase requires labeled training data and can generate rules only for confusion pairs observed in the baseline errors. If the taxonomy or the model's confusion patterns change, the offline phase may need to be rerun for the affected pairs. Furthermore, extending pair coverage captures more confusions but also lengthens the inference prompt and increases cost, and we have not tested how this balance changes for multilingual inputs, substantially larger taxonomies, or temporal drift. Second, generated rules are not automatically verified. The Consolidation and Bidirectional Merge steps reduce noise from individual examples but do not guarantee that the resulting rule is correct. Although 87.3% of sampled rules met our criteria for correctness and usefulness, applications with serious consequences still require review by domain experts.

A.2 Dataset Preprocessing

The Flipkart dataset is derived from a publicly available crawl of 20,000 product listings (PromptCloud, 2018). We retain only the first three levels of the category hierarchy, as deeper levels represent brand or product names rather than semantic categories, and the number of unique labels more than doubles beyond level 3. Labels with fewer than three samples are removed to enable stratified splitting. The final dataset contains 17,847 samples across 351 labels. WOS and LEDGAR are used as provided by their respective sources without additional preprocessing.

A.3 Fine-Tuning Baselines

We first compare the methods using the complete, unmodified training and test splits. Table 7 reports Macro F1 at the finest level of each dataset after fine-tuning ModernBERT-base and RoBERTa-base. These clean-data results provide the reference scores for the robustness experiments that follow.

Method	Flipkart L3	WOS L2	LEDGAR
ModernBERT	80.0	72.9	75.4
RoBERTa	81.7	80.4	**78.1**
Ours (Qwen3-32B)	76.7	57.7	58.9

Table 7: Macro F1 (%) at each dataset's finest level. Fine-tuned models lead on clean, complete data.

Training details. The fine-tuned baselines use a linear classifier over the complete taxonomy path with the AdamW optimizer. Training uses early stopping over at most ten epochs, a maximum sequence length of 512, and a batch size of eight. The classification head uses ten times the pretrained model's learning rate.

Robustness experiments. All robustness experiments use Flipkart L3. The test-time perturbation experiment keeps the training data fixed and modifies only the test queries. The label-noise and data-scarcity experiments modify the training data while leaving the test set unchanged. Within each condi-

tion, every method uses the same perturbed queries, corrupted labels, or stratified training subset.

Test-time perturbations. We use `nlpaug` 1.1.11 (Ma, 2019) to introduce spelling errors at a 10% rate, word swaps and contextual insertion at 20%, and word deletion and contextual substitution at 15%. Keyboard augmentation changes characters in 5% of words with a 10% within-word rate. The combined condition applies light spelling, keyboard, and deletion noise. Query shortening keeps four to eight leading product-title tokens, and back-translation sends each query through English–German–English using Amazon Translate.[5] Table 8 reports the change from each method's clean score for all nine conditions.

Perturbation	ModernBERT	RoBERTa	Ours
Keyboard	−5.0	−2.0	**−1.0**
Spelling	−3.0	**−2.0**	**−2.0**
Word swap	−4.0	**−1.0**	−3.0
Word deletion	−8.0	**−4.0**	**−4.0**
Contextual insertion	−19.0	−5.0	**−4.0**
Contextual substitution	−29.0	−11.0	**−7.0**
Back-translation	−22.0	−11.0	**−2.0**
Combined noise	−9.5	−5.0	**−3.0**
Query shortening	−57.0	−43.0	**−18.0**
Mean	−17.0	−9.0	**−5.0**

Table 8: Robustness to test-time perturbations on Flipkart L3. Each score is the change in Macro F1 from that method's clean result, in percentage points. Values closer to zero are better.

Label noise and data scarcity. For label noise, we sample the specified fraction of training examples and replace each selected gold label with a different label drawn uniformly from the other 350 classes. The fine-tuned models train on this corrupted split. Our framework applies the same example-to-label mapping when constructing its confusion pairs and rules. We evaluate all methods on the unchanged test set. For data scarcity, we draw stratified subsets of the training data. The fine-tuned models train on each subset, while our framework discovers its confusion pairs and generates its rules from the same subset.

Training set size and test-time perturbations. The preceding experiments vary training-set size and test queries separately. We next vary them together by evaluating all nine perturbed test sets at ten training fractions. At each fraction, our framework discovers the confusion pairs and regenerates the rules from the available training examples. Table 9 summarizes representative results for label noise, data scarcity, and their interaction with test-time perturbations. In the joint-robustness rows, each score is the mean Macro F1 across the nine perturbations. The resulting 270 evaluations show how additional labeled data affects robustness rather than performance only on the unchanged test set.

Experiment	Setting	ModernBERT	RoBERTa	Ours
Label noise	10% corrupted	68.4	67.4	**73.4**
	20% corrupted	60.0	61.0	**72.1**
	50% corrupted	41.8	40.9	**70.1**
Training data	10% (∼3/class)	23.2	31.8	**70.2**
	25% (∼9/class)	44.0	47.7	**69.9**
	50% (∼18/class)	69.8	**70.8**	69.8
Joint robustness	10% training data	18.0	29.2	**67.7**
	20% training data	32.2	42.7	**68.5**
	50% training data	51.5	63.2	**69.8**

Table 9: Representative Flipkart L3 Macro F1 (%). Label noise and training data use the unchanged test set. Joint robustness reports the mean across nine perturbed test sets.

A.4 Coverage Sensitivity

The coverage threshold controls how much of the observed training error is represented in the knowledge base. We rank directed confusion pairs by frequency and select the smallest set whose cumulative count reaches the threshold. Lower values retain only the most frequent confusions, while higher values admit rarer pairs and make more rules available at inference time.

We sweep the threshold from 10% to 90% on each dataset and observe a monotonic increase in Macro F1. Quality is highest at 90%, but broader coverage makes more rules eligible at inference time and increases the prompt size, so each coverage value carries both a quality and a cost. Table 10 uses 10% coverage as the reference. This row reports absolute Macro F1 and defines input-token use as 1.0×, while subsequent rows report relative Macro F1 gains and token multipliers. The token counts include the instructions, query, candidate labels, and injected rules, but exclude the one-time generation cost reported in Appendix A.5.

[5] https://aws.amazon.com/translate/

Coverage	Flipkart L3		WOS L2		LEDGAR	
	F1	Tokens	F1	Tokens	F1	Tokens
10%	0.513	1.0×	0.519	1.0×	0.538	1.0×
25%	+2.9%	1.1×	+1.5%	1.6×	+1.1%	1.1×
50%	+8.8%	1.4×	+7.9%	3.2×	+2.4%	1.8×
75%	+21.2%	2.2×	+10.4%	6.0×	+8.0%	3.4×
90%	+31.4%	3.6×	+12.5%	8.8×	+12.5%	6.2×

Table 10: Sensitivity to confusion-pair coverage. At 10%, F1 is absolute and token use is normalized to 1.0×. Later rows show relative F1 gains and token multipliers.

We therefore use 75% as a cost-conscious operating point. Applications can move this threshold according to their accuracy and inference budgets.

A.5 Knowledge Generation and Inference Cost

Our framework incurs costs at two points: one-time offline knowledge generation and online inference, where confusion partners and applicable rules increase the prompt length. Table 11 reports the measured token use for offline generation and the measured overhead at inference.

One-time offline knowledge generation

Dataset	Errors	Pairs	Rules	Tokens (in / out)
WOS	11,363	750	658	10.09M / 1.95M
Flipkart	3,564	488	455	2.55M / 0.71M
LEDGAR	19,528	750	643	12.56M / 2.96M

Online inference, retrieval only → full approach

Dataset	Candidates	Rules	Input tokens	Latency (ms)
WOS	10.0 → 19.7	54.5	1,402 → 10,144	425 → 1,238
Flipkart	10.0 → 18.0	28.3	1,344 → 7,139	429 → 879
LEDGAR	10.0 → 19.5	53.2	1,189 → 9,248	379 → 1,110

Table 11: Measured offline knowledge-generation cost and online inference overhead. Arrows compare retrieval-only inference with the full approach.

The offline phase processes 3,564 to 19,528 errors and produces 455 to 658 rules, consuming 3.26M to 15.52M tokens once per taxonomy. Mean rule length ranges from 85.0 to 91.8 words, with 90th percentiles from 104 to 115 words. At inference, the longer prompts increase median latency from 379–429 ms for retrieval only to 879–1,238 ms for the full approach. This is the principal cost of supplying the additional taxonomy-specific context while retaining a single classification call per query.

A.6 Reusing a Fixed Knowledge Base

The transfer experiment in Section 5.2 discovers confusion pairs separately for each classifier, then uses Qwen3-235B to generate their rules. To test stricter reuse, we instead identify the pairs and generate the rules once with Qwen3-235B, then apply the resulting knowledge base unchanged to every classifier. Table 12 compares fixed reuse with model-specific pair discovery.

Classifier	Retrieval	Fixed knowledge	Model-specific knowledge
Ministral-3B	59.0	67.1	**72.8**
Ministral-8B	63.9	71.5	**74.4**
GPT-OSS-20B	64.8	**75.2**	73.0
Qwen3-32B	66.7	73.3	**74.7**

Table 12: Flipkart L3 Macro F1 (%). Fixed knowledge reuses one Qwen3-235B knowledge base unchanged. Model-specific knowledge discovers pairs for each classifier and uses Qwen3-235B to generate their rules.

Fixed reuse improves Macro F1 by 6.6 to 10.3 points over retrieval alone. Model-specific pairs perform better for three classifiers, while fixed reuse performs better for GPT-OSS-20B. Thus, one knowledge base transfers across classifiers, although model-specific error analysis usually adds further gains.

A.7 Human Evaluation Protocol

We sample 50 rules from the Flipkart knowledge base. Each of the three authors independently reviews every rule, producing 150 judgments. For each item, the annotation interface shows the generated rule, the two complete label paths, up to five example queries from each label, and up to three misclassified queries from each direction with their per-example observations.

Each author judges whether the rule correctly and usefully distinguishes the labels in both directions. A rule is rejected if it is incorrect, misleading, incomplete, or unhelpful. Across the three authors, 87.3% of the rules meet this standard on average. Since this evaluation cannot guarantee the correctness of every rule, high-stakes applications should require domain-expert approval before deployment.

A.8 Component Ablation

Table 6 isolates the contribution of each component by adding them incrementally to the zero-shot baseline, using Qwen3-32B on all three datasets. Retrieval narrows the label space; confusion partners ensure both members of each confused pair co-occur; knowledge injection supplies pairwise disambiguation rules. The full combination (the last row, equal to "Ours" in Table 1) yields the largest gains, and the two mechanisms are complementary: partners raise Recall@K while knowl-

edge reduces selection errors among candidates (Section 5.1).

A.9 Error Decomposition

Section 5.1 decomposes errors into recall and LLM misses. Table 13 reports recall and Table 14 the LLM miss rate, both across all three datasets (Qwen3-32B).

	LDG	WOS		Flipkart		
Method	L1	L1	L2	L1	L2	L3
Retrieval (K=10)	81.7	95.1	83.4	97.8	94.2	86.0
+ Conf. Partners	**92.8**	**98.5**	**90.2**	**99.9**	**99.2**	**98.1**

Table 13: Recall (%, ↑) on all datasets (Qwen3-32B): fraction of queries whose correct label is among the candidates. Knowledge injection leaves the candidate set unchanged and so does not affect recall. LDG = LEDGAR.

The pattern is consistent: confusion partners raise recall at every level but also increase the LLM miss rate, while knowledge injection lowers the LLM miss rate at each retrieval setting.

	LDG	WOS		Flipkart		
Method	L1	L1	L2	L1	L2	L3
Retrieval (K=10)	16.6	17.8	31.9	5.5	10.8	15.5
+ Conf. Partners	24.9	20.9	38.8	6.2	13.3	21.9
+ Knowledge	**14.2**	**15.7**	**26.5**	3.9	**8.5**	**13.1**
+ Conf. Partners + Knowl.	22.5	18.7	34.0	**3.8**	10.0	17.1

Table 14: LLM miss rate (%, ↓) on all datasets (Qwen3-32B): fraction of in-candidate queries the model classifies incorrectly. Best (lowest) per column in **bold**. LDG = LEDGAR.

A.10 Statistical Significance

For each column of Table 1, we test whether our full approach (confusion partners + knowledge) significantly beats the *second-best* method in that column. We use a paired bootstrap on the test set: for B=10,000 resamples, we draw test instances with replacement (the same resample applied to both systems), recompute the Macro F1 difference on each resample, and report the 95% percentile confidence interval and a two-sided p-value for the null hypothesis of zero difference. Macro F1 is computed exactly as in the main results; point estimates come from an independent inference run and differ from Table 1 by at most 1.8 points due to the classifier's non-determinism.

Column	**2nd best**	**ΔF1**	**95% CI**	p
LEDGAR	Few-shot	$+1.2$	$[+0.2, +2.2]$	0.016
WOS L1	Zero-shot	$+1.2$	$[+0.5, +1.9]$	< 0.001
WOS L2	Zero-shot	$+0.3$	$[-0.7, +1.2]$	0.600
Flipkart L1	Retrieval	$+0.8$	$[-0.5, +2.5]$	0.194
Flipkart L2	Retrieval	$+0.6$	$[-1.0, +2.6]$	0.360
Flipkart L3	Retrieval	$+2.7$	$[+1.0, +5.5]$	0.005

Table 15: Paired bootstrap significance (B=10,000, Qwen3-32B) of our full approach over the second-best method in each column of Table 1. ΔF1 is the Macro F1 gain; gains with $p < 0.05$ are marked * in Table 1.

Table 15 reports the results. Our gains are significant on LEDGAR, WOS L1, and Flipkart L3, where the confidence interval excludes zero. On WOS L2 and the two coarse Flipkart levels, our method remains best but the margin over the second-best method is within sampling noise.

A.11 Knowledge Generation Prompts

The knowledge base $\mathcal{K}$ is produced by the three-stage pipeline of Algorithm 1. Figure 5 lists the system and user prompts used at each stage. All three stages are run once per dataset using the generator model (Qwen3-235B in our cross-model transfer experiments, Qwen3-32B otherwise).

A.12 Generated Knowledge Examples

Figure 6 shows three disambiguation boundaries produced by the pipeline for confused pairs in the Flipkart dataset (Qwen3-32B). Each boundary is a symmetric rule that names the misleading surface similarity and gives the deciding signal for each label.

Tablet Cases: Computers vs. Mobiles & Accessories

Assign to *Mobiles & Accessories* when the query names a specific tablet brand/model (e.g., iPad, Samsung Galaxy) and consumer-design features (ultra-slim, magnetic lock, flip cover). Assign to *Computers* when it emphasizes general materials (leather, fabric), multi-device compatibility, or professional features (keyboard integration, docking). The shared term "tablet case" is the source of confusion; brand-model specificity is the deciding signal.

Glassware: Bar Glasses vs. Glasses & Tumblers

Assign to *Bar Glasses* when the query emphasizes cocktail/mixed-drink use, aesthetic descriptors, or materials like stainless steel and double-walled construction. Assign to *Glasses & Tumblers* when it highlights everyday table use, capacity, dishwasher safety, or non-alcoholic beverages (juice, water). Both share the word "tumbler"; the use-case (spirits vs. casual) and construction material decide.

Gardening: Plants vs. Gardening Tools

Assign to *Gardening Tools* when the query refers to a physical accessory (plant container, grow bag, watering system) with transactional language (price, shipping, model). Assign to *Plants* when it focuses on plant varieties, seeds, germination, or cultivation. The word "plant" appears in both; whether the item is an *accessory* or a *living plant* is the deciding signal.

Figure 6: Three generated disambiguation boundaries for confused pairs on Flipkart (Qwen3-32B). Each is a symmetric rule injected into the classification prompt when both labels of the pair appear among candidates.

A.13 Error Analysis

To understand the limits of the approach, we analyze the 737 residual errors (19% of test samples) produced by the best configuration from Table 1 (Qwen3-32B with partners + knowledge) on Flipkart at the finest granularity (L3). Table 17 categorizes these errors by source, and Table 18 lists the most frequent error pairs.

Error Category	Count	% of Errors
Retrieval miss	73	9.9%
Taxonomy inconsistency	153	20.8%
Semantic overlap (top pairs)	230	31.2%
Long-tail / other	281	38.1%

Table 17: Error breakdown for the full pipeline on Flipkart L3 (Qwen3-32B, 737 errors out of 3880 test samples).

Ground Truth (L3)	Predicted (L3)	N
Car Interior & Exterior	Car Interior†	114
Western Wear	Fusion Wear	71
Western Wear	Leggings & Jeggings	37
Ethnic Wear	Fusion Wear	32
Women's Casual Shoes	Men's Casual Shoes	23
Top 5 pairs total		277
% of all errors		37.6%

Table 18: Top 5 remaining error pairs at L3. †Labels in different L2 categories describing the same concept (taxonomy overlap). L2 paths omitted for space.

Three patterns emerge from the remaining errors:

Taxonomy inconsistency (153 errors, 20.8%). Labels that describe the same concept appear under different parent categories. The largest case (114 errors) involves *Accessories & Spare parts* → *Car Interior & Exterior* vs. *Car Accessories* → *Car Interior*. Similarly, *Showpieces* appears under near-identical parent paths with minor naming variations. These cases reflect taxonomy design choices that are difficult for any classifier to resolve from product text alone.

Genuine semantic overlap (230 errors, 31.2%). The Western Wear / Fusion Wear / Ethnic Wear cluster accounts for 155 of these. "Fusion Wear" by definition blends Western and Ethnic styles, making many items genuinely ambiguous. Our disambiguation rules reduce this confusion on test (from 112 errors with retrieval-only to 71 with the full pipeline for Western→Fusion alone), but a residual remains for items that are inherently multi-category. Gender-ambiguous footwear (Women's vs. Men's Casual Shoes) contributes another 36 errors.

A.14 Knowledge Format Examples

We illustrate both knowledge formats using the confused pair *Girls Wear* vs. *Infants Wear* from the Flipkart dataset (351 labels, 3-level hierarchy). The pairwise format (Figure 7) presents both labels side-by-side with an explicit decision rule, while the per-label format (Figure 8) describes each label independently without direct contrast.

A.15 Cross-Model Transfer Results

Table 16 reports the full per-size-group cross-model transfer results summarized in Section 5.1 and Figure 3.

Size	Method	LEDGAR	WOS		Flipkart		
			L1	L2	L1	L2	L3
Small (2–4B)	Zero-shot	48.5 (±6.9)	78.1 (±2.4)	52.5 (±3.3)	75.5 (±6.8)	64.1 (±7.3)	55.9 (±7.0)
	+ Retrieval	52.3 (±2.3)	78.9 (±0.9)	51.7 (±2.0)	87.6 (±1.5)	75.4 (±1.8)	59.9 (±2.2)
	+ Conf. Partners	54.6 (±3.0)	78.9 (±1.0)	51.2 (±2.0)	88.5 (±2.0)	77.6 (±3.0)	67.2 (±3.8)
	+ Knowledge	55.9 (±1.2)	80.8 (±0.7)	**56.6** (±1.0)	89.9 (±1.1)	78.8 (±1.8)	64.0 (±1.8)
	+ Conf. Partners + Knowledge	**58.6** (±1.5)	**81.0** (±0.8)	**56.6** (±1.3)	**91.0** (±1.7)	**81.4** (±3.0)	**71.4** (±3.9)
Medium (8–20B)	Zero-shot	54.9 (±4.2)	79.4 (±2.2)	55.0 (±3.4)	84.6 (±3.1)	73.4 (±2.9)	65.6 (±3.1)
	+ Retrieval	54.2 (±1.6)	78.4 (±1.6)	52.1 (±3.3)	89.7 (±0.2)	78.6 (±0.5)	63.9 (±0.8)
	+ Conf. Partners	57.1 (±2.0)	78.2 (±2.0)	51.9 (±4.3)	90.8 (±0.2)	81.3 (±0.3)	72.0 (±0.6)
	+ Knowledge	57.5 (±0.3)	80.4 (±0.3)	56.2 (±0.8)	90.7 (±0.5)	80.3 (±1.5)	65.8 (±0.6)
	+ Conf. Partners + Knowledge	**59.5** (±1.4)	**80.9** (±0.6)	**56.6** (±1.4)	**92.0** (±0.8)	**83.7** (±1.9)	**75.0** (±1.9)

Table 16: Cross-model transfer: Macro F1 (%) for knowledge generated by Qwen3-235B and applied to smaller classifiers, reported as mean (std) over each size group. Small: Ministral-3B, Qwen3.5-2B/4B; Medium: Ministral-8B, Qwen3.5-9B, GPT-OSS-20B.

Stage 1 Prompt: Per-Example Hint

System: You are an expert at diagnosing text classification errors. You are shown a query that was misclassified, its correct label, and the wrong label it was assigned. In 2–3 sentences, identify: (1) the specific signal in the query — terminology, methodology, subject matter, or intent — that marks it as the correct label; (2) why the wrong label was a tempting but incorrect match (what surface similarity caused the confusion); and (3) a generalizable cue that would help distinguish these two labels on future queries. Be precise and factual, and include domain-specific terms that the classifier may not otherwise know. Output only the observation as plain prose — no markdown, no lists, no preamble.

User: Query: *{query}*. Correct label: *{ground_truth}* (Description: {gt_desc}). Predicted (wrong) label: *{predicted}* (Description: {pred_desc}). This query truly belongs to *{ground_truth}* but was misclassified as *{predicted}*. In 2–3 sentences cover (1) the signal marking it as the correct label; (2) why the wrong label looked tempting; (3) a generalizable cue.

Stage 2 Prompt: Per-Direction Consolidation

System: You are an expert at distilling classification error diagnoses into a reliable decision rule. You are given many per-example observations about why queries belonging to label A were mistaken for label B. Identify the signals that recur across observations and generalize — ignore one-off or example-specific noise. Then write a boundary: a concrete, actionable rule stating when a query belongs to A rather than B, including the domain-specific facts and terminology a classifier needs to tell them apart. Output valid JSON with fields: `consensus_signals` (a list of 3–5 of the most reliable, generalizable discriminators) and `recommended_boundary` (a thorough if-then decision rule covering those signals).

User: Label A (correct): *{A}*. Label B (predicted incorrectly): *{B}*. Here are {N} observations from misclassified examples (queries that belong to A but were predicted as B): {hints}. Find the consensus: what signals do most hints agree point toward A and not B? Produce a recommended boundary.

Stage 3 Prompt: Bidirectional Merge

System: You merge two directional classification rules into a single symmetric decision boundary that will be shown to a classifier at inference time. Rule A→B explains when a query belongs to A (not B). Rule B→A explains when a query belongs to B (not A). Produce ONE boundary that captures the key insights from BOTH directions. It must: state the single most reliable factor that separates the two labels; name the misleading surface similarity that causes confusion; and give a clear symmetric rule of the form "Assign 'A' when …; assign 'B' when …" using exact label names in single quotes. Preserve specific signals, keywords, and domain facts. Plain text sentences only; no markdown, lists, or headers. Keep it concise (3–5 sentences).

User: Label A: *{A}*. Label B: *{B}*. Rule (when A is correct, not B): {boundary_A}. Key signals for A: {signals_A}. Rule (when B is correct, not A): {boundary_B}. Key signals for B: {signals_B}. Merge these into a single symmetric decision boundary for A vs B.

Figure 5: The three system/user prompts used in the offline knowledge generation pipeline (Algorithm 1). The blue box is the system prompt; the highlighted inner box is the user message template with {placeholders}.

System Prompt: Pairwise Knowledge Format

You are an expert text classifier. Given a query and a list of candidate labels, select the single most appropriate label for the query.

How to classify:
1. Read the query and identify its primary subject, intent, or contribution.
2. Evaluate EACH candidate independently on how well it matches that primary subject.
3. When several candidates seem plausible, choose the one that captures the query's CENTRAL focus.

. . .

DISAMBIGUATION KNOWLEDGE:

'Kids' Clothing | Girls Wear' vs *'Kids' Clothing | Infants Wear':*

If the query includes terms like 'infant', 'newborn', or 'baby', or references soft, age-appropriate motifs emphasizing comfort for very young children, classify as *Infants Wear*. If the query refers to 'girl's', includes age ranges (e.g., '2–4 years'), or describes fashion-oriented items (e.g., 'party wear', 'printed top'), classify as *Girls Wear*.

Output ONLY valid JSON: {"task": "...", "label": "exact label from candidates", "confidence": "high/medium/low"}

Figure 7: Classification prompt with **pairwise knowledge** for the confused pair *Girls Wear* vs. *Infants Wear* (Flipkart, Qwen3-32B). The highlighted block shows the contrastive disambiguation boundary injected into the system prompt.

System Prompt: Per-Label Knowledge Format

You are an expert text classifier. Given a query and a list of candidate labels, select the single most appropriate label for the query.

How to classify:
1. Read the query and identify its primary subject, intent, or contribution.
2. Evaluate EACH candidate independently on how well it matches that primary subject.
3. When several candidates seem plausible, choose the one that captures the query's CENTRAL focus.

. . .

LABEL KNOWLEDGE:

'Kids' Clothing | Girls Wear': Clothing intended for young girls, featuring age-specific indicators such as "girl's," "kids," or "children." Includes casual, party, or special occasion wear with descriptors like "cotton," "printed top," or "party wear." Child-specific sizing (e.g., "2–4 years") confirms this category.

'Kids' Clothing | Infants Wear': Queries with explicit infant-specific terms like "infant," "newborn," or "baby," emphasizing comfort, softness, and suitability for very young children. Key signals include infant product types (e.g., bloomers, bodysuits), fabric descriptors like "soft cotton," and brand names like "Mothercare."

Output ONLY valid JSON: {"task": "...", "label": "exact label from candidates", "confidence": "high/medium/low"}

Figure 8: Same prompt with **per-label knowledge** for the same pair (Flipkart, Qwen3-32B). Each label described independently without direct contrast.

RLMA: Reinforcement Learning with PolyMetric Alignment

Jia Xu
Rutgers University

Abstract

RLHF, RLAIF, and RLVR align LLMs with human instructions but rely on costly human labels, potentially biased LLM judges, or task-specific verifiers. We propose PolyMetric Alignment (RLMA), a reference-based reward framework for supervised-answer tasks that fuses heterogeneous evaluation metrics against a given reference answer using a Residual Set Transformer (RST) trained with a Bradley–Terry objective. Empirically, RLMA is stronger than all three paradigms, achieving 98.0% of the Pass@K oracle on a 9-pool benchmark, with gains of $+17.6$ pp over the RLA single-metric baseline and $+7.4$ to $+15.4$ pp over RLHF, RLAIF, and RLVR. RLMA also generalizes broadly, reaching 97.2% of oracle on unseen GSM8K and, when used as a DPO reward, improving TriviaQA Pass@1 by $+4.80$ pp on Qwen-2.5-7B-Instruct. Finally, RLMA is efficient to deploy. Its 113K-parameter gate requires only 0.33 ms per candidate, roughly $300\times$ faster than a single 8B reward-model forward.

1 Introduction

Reinforcement learning from human feedback (Ouyang et al., 2022; Bai et al., 2022), its LLM-judge variant RLAIF (Lee et al., 2024), and executable-verifier RLVR (Lambert et al., 2024) all require supervision external to the source dataset, namely human labels, judge biases, or task-specific checkers. Yet on the broad class of reference-available tasks such as question answering, hallucination detection, and mathematical reasoning, each query comes with a ground-truth answer supplied by the dataset itself but is not used in RL alignment. Recent work (Lins and Xu, 2025) constructs a reward from a single reference-similarity metric, but generation quality is multi-dimensional and a single reward invites hacking behaviours documented in the RLHF literature (Singhal et al., 2023). We ask whether fusing many complementary reference-based signals can close the alignment loop without external supervision while resisting single-metric gaming.

We introduce PolyMetric Alignment (RLMA), a reference-based reward framework that addresses this problem by fusing multiple heterogeneous evaluators into a single scalar reward. The resulting reward can be consumed by best-of-K selection at inference and DPO fine-tuning of the generator. In our implementation, RLMA combines 22 off-the-shelf signals spanning surface-form metrics, embedding similarities, language-model log-likelihoods, and learned reward models. The central intuition is that these signals provide complementary views of generation quality. Exploiting any one metric is then penalised by the others. The fused reward therefore provides a more robust objective than any individual evaluator.

The key challenge is to reliably aggregate a large and heterogeneous bank of evaluation metrics. A natural solution is a Set Transformer (Lee et al., 2019), which is permutation-invariant and therefore well suited to metric sets. However, we find that standard STs perform best with relatively small metric banks and degrade as additional signals are introduced. This reveals a central limitation. Simply increasing the number of evaluators can overwhelm the aggregator rather than improve it.

We therefore develop the **Residual Set Transformer (RST)**, a scalable, query-aware architecture designed specifically for reward aggregation. RST modifies the Induced Set Attention Block of ST in four targeted ways. First, pre-LayerNorm residual connections preserve direct identity pathways, preventing informative signals from being diluted by repeated cross-signal mixing. Second, a cached query-context token conditions aggregation on the input query, allowing the same metric to be weighted differently depending on the task context. Third, attention-based readout replaces mean pool-

EMNLP 2026 Industry Track, pages 2165–2182

Paradigm	Reward source	Applicability
RLHF	human preference labels	tasks a human can evaluate
RLAIF	LLM-as-judge AI feedback	tasks an LLM judge can evaluate
RLVR	executable verifier $V(x, \tau)$	tasks with programmatic correctness checks
RLA (Lins and Xu, 2025)	single similarity metric against reference $R(q)$	tasks with reference-based supervision
RLMA (ours)	N metrics fused against reference $R(q)$ via RST	tasks with reference-based supervision

Table 1: Position of RLMA as a *reward-source* framework. Each row describes where the per-trajectory reward signal originates. RLA is the immediate single-metric predecessor, and RLMA generalises it to N fused metrics.

ing, enabling adaptive weighting of heterogeneous signals for each example. Finally, depth and the number of inducing points scale with the metric-bank size, providing additional capacity as more evaluators are added.

Empirically, RLMA is near-optimal, consistently stronger, broadly generalizable, and lightweight. **Near-optimal.** It reaches 51.9% vs. 52.0% oracle Pass@1 on the four in-domain pools and 74.57% vs. 76.10% on the nine-pool union, as reported in Tables 2 and 3. **Stronger.** On the nine-pool union it outperforms RLHF via ArmoRM by $+7.4$ pp, RLAIF via gpt-oss-120b by $+10.3$ pp, RLVR via ReasonFlux (Zou et al., 2025) by $+15.4$ pp, and single-metric RLA by $+17.6$ pp. It further surpasses reference-aware ArmoRM on TQA, GSM8K, and e-CARE, as reported in Tables 3 and 7. **Generalizable.** RST is the strongest of ten combiner gates and gains $+6.05$ pp over vanilla ST as N grows from 12 to 22, transfers zero-shot to GSM8K at 97.2% of oracle and across three unseen generators, and improves TriviaQA Pass@1 by $+4.80$ pp via DPO and XSum ROUGE-L (Lin, 2004) by $+4.57$ pp. See Tables 4, 5, and 6, and App. D and F.1. **Lightweight.** The 113K-parameter gate is $\sim 70{,}000\times$ smaller and $\sim 300\times$ cheaper at inference than an 8B RM, while RST-14 reduces the end-to-end cost per candidate by roughly $2\times$. See App. E.2.

To summarize, our contributions are:

1. **PolyMetric Alignment (RLMA).** We introduce a reference-based reward framework that fuses N off-the-shelf evaluators through within-query Bradley–Terry modeling, eliminating the need for new human preference labels, an external LLM judge, or a task-specific verifier.
2. **Residual Set Transformer (RST).** We propose an aggregator that scales with the metric bank rather than plateauing, and conditions per-metric weight on the query rather than being permutation-only.
3. **Comprehensive empirical validation.** We benchmark RLMA across ten gating architectures, nine query pools, three unseen test-time candidate generators, one downstream generator fine-tuning setting via DPO, and one fuzzy-reference summarization task, against RLHF, RLAIF, RLVR, and reference-aware ArmoRM baselines, see App. A.

2 Related work

Prior reward models. Standard reward models train one scalar head with Bradley–Terry loss (Ouyang et al., 2022). The closest multi-objective work, ArmoRM (Wang et al., 2024), co-trains 19 homogeneous regression heads on UltraFeedback labels with a prompt-gated MLP. RLMA instead fuses N heterogeneous, independently pretrained off-the-shelf scorers spanning surface, embedding, LM log-likelihood, and reward-model families without retraining any of them, via a permutation-invariant set encoder supervised only on within-query best-of-K Bradley–Terry pairs.

Existing signal-combination methods. We benchmark RST against six aggregators from three families, namely top-k routers Switch (Fedus et al., 2022), Mixtral (Jiang et al., 2024), and DeepSeek-MoE (Dai et al., 2024), feature-wise modulators FiLM (Perez et al., 2018) and Q-Former (Li et al., 2023), and the permutation-invariant Set Transformer ST (Lee et al., 2019). RST extends ST with LayerNorm-residual pathways, a cached query-context token, attention-pooled readout, and bank-size-scaled capacity, and §4.2 shows it is the strongest of the ten tested gates and the only one that keeps improving as the bank grows.

Reference matching versus executable verification. RLVR uses an executable verifier $V(x, \tau)$ that judges correctness from the query and candidate alone, for example a math checker, unit tests, a theorem prover, or a game simulator, and needs no reference. RLMA instead scores candidates against a stored reference set $R(q)$ via a similarity or membership function $g(\tau, R(q))$ such as alias match, ROUGE, BERTScore (Zhang et al., 2020), or embedding cosine. The two are complementary and both eliminate human labels, as summarised in

Table 1.

3 Method

3.1 Notation and component bank

Let $\mathcal{Q}$ denote the query set and $q \in \mathcal{Q}$ a query. Let $\mathcal{T}^*$ denote the space of finite token sequences over the model vocabulary. For each q, the generator produces $K \in \mathbb{Z}_{>0}$ candidate trajectories $\{\tau_k(q)\}_{k=1}^{K}$ with $K \in \{4, 8\}$, where each $\tau_k(q) \in \mathcal{T}^*$. The reference set $R(q) \subset \mathcal{T}^*$ contains the reference answer to q together with any acceptable paraphrases.

We define $N \in \mathbb{Z}_{>0}$ off-the-shelf scoring functions $\phi_i \colon \mathcal{Q} \times \mathcal{T}^* \to \mathbb{R}$ indexed by $i \in \{1, \ldots, N\}$, where each ϕ_i maps a query q and a candidate trajectory $\tau \in \mathcal{T}^*$ to a scalar quality score. The ϕ_i are fixed and drawn from four families, namely surface metrics such as BLEU (Papineni et al., 2002), embedding similarities such as BERTScore, language-model log-likelihoods, and pretrained reward models. We use $N \in \{12, 22\}$ depending on the bank.

Score. For each query q, candidate index $k \in \{1, \ldots, K\}$, and metric index $i \in \{1, \ldots, N\}$, the raw component score $c_{i,k}(q) \in \mathbb{R}$ is the value of the i-th metric ϕ_i applied to the k-th candidate $\tau_k(q)$ for query q:

$$c_{i,k}(q) \;=\; \phi_i\big(q,\, \tau_k(q)\big). \tag{1}$$

Normalise. The gate input is obtained by z-normalising each raw component over the union of training-pool (q, k) pairs:

$$\bar{c}_{i,k}(q) \;=\; \frac{c_{i,k}(q) - \mu_i}{\sigma_i + \epsilon}, \tag{2}$$

where $\mu_i, \sigma_i \in \mathbb{R}$ are the training set mean and standard deviation of ϕ_i and $\epsilon \in \mathbb{R}_{>0}$ with $\epsilon{=}10^{-6}$. The raw score $c_{i,k}(q)$ is from Eq. 1. Stacking the N normalised entries defines the per-candidate component vector

$$\mathbf{c}_k(q) \;=\; [\bar{c}_{1,k}(q), \ldots, \bar{c}_{N,k}(q)]^\top \in \mathbb{R}^N, \tag{3}$$

which is the input to the gate.

3.2 RST Gate

The gate. The gate is a function $f_\theta : \mathbb{R}^N \to \mathbb{R}$ that maps the normalised component vector $\mathbf{c}_k(q)$ from Eq. 2 to a scalar score $s_k(q; \theta) \in \mathbb{R}$, used as the best-of-$K$ selection score and as the reward for DPO fine-tuning. Because the N components have no intrinsic order, f_θ must be permutation-invariant. The natural starting point is the Set Transformer (ST) of Lee et al. (2019), whose Induced Set Attention Block (ISAB) is permutation-invariant by construction. Our concrete realisation of $s_k(q; \theta)$ is Eq. 8 below.

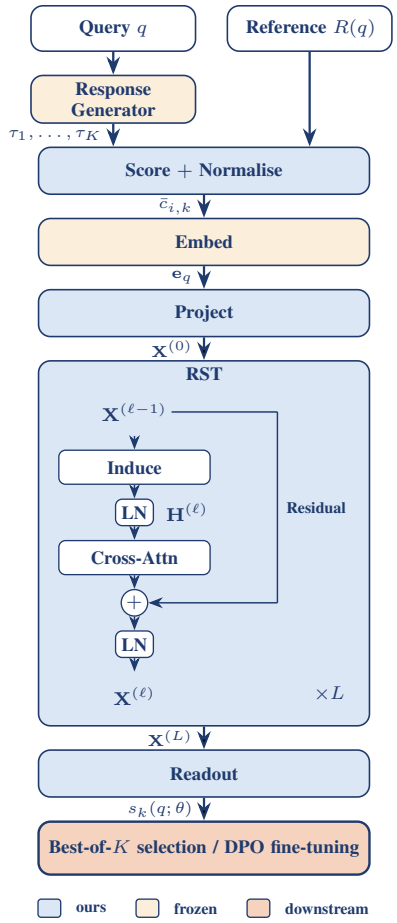

Figure 1: RLMA architecture. Box labels match the algorithm stages Score, Normalise, Embed, Project, Scale, Induce, Residual, and Readout as defined in §3. Sky boxes are this paper's contributions. Cream boxes are frozen off-the-shelf modules such as the Llama-3 generator and MiniLM-L6 encoder. The coral box is the downstream consumer that uses the score s_k for Best-of-K selection at inference and DPO fine-tuning of the generator, discussed in §4.2.

Vanilla ISAB is permutation-invariant but lacks query awareness and scales poorly as the metric bank grows. RST introduces four architectural refinements that convert it into a bank-scalable, query-aware aggregator whose accuracy scales with N over the tested range rather than plateauing.

Embed. Embed and Project introduce a cached query-context token, enabling query-conditioned aggregation so that the same metric can be weighted differently for different queries. We give the gate access to the query by computing a sentence embedding of q once and caching it. Con-

cretely, the frozen MiniLM-L6-v2 sentence transformer (Wang et al., 2020) implements an encoder $\mathrm{Enc}\colon \mathcal{Q} \to \mathbb{R}^{384}$ that maps the query text q to a dense 384-dimensional embedding. We denote this query embedding by $\mathbf{e}_q \in \mathbb{R}^{384}$, defined as $\mathbf{e}_q = \mathrm{Enc}(q)$. The vector $\mathbf{e}_q$ then feeds the Project step as the query token. Since Enc is not updated during training and is reused across all K candidates of the same query, it adds no per-candidate cost at inference.

Project. The cached query embedding $\mathbf{e}_q \in \mathbb{R}^{384}$ from the Embed step is projected into a query token and prepended to the N component tokens. Let $d \in \mathbb{Z}_{>0}$ denote the RST hidden dimension. We introduce three sets of learnable parameters. The matrix $W_q \in \mathbb{R}^{d\times 384}$ projects the 384-dimensional query embedding $\mathbf{e}_q$ into the RST hidden dimension. The matrix $W_c \in \mathbb{R}^{d\times 1}$ projects each scalar component score $\bar{c}_{i,k}(q)$ into the RST hidden dimension. The vector $\mathbf{p}_i \in \mathbb{R}^d$ is a learnable position or type embedding for the i-th component, giving each metric a distinct token identity. For a fixed query $q \in \mathcal{Q}$ and candidate index $k \in \{1, \ldots, K\}$ from Section 3.1, the token stack $\mathbf{X}^{(0)} \in \mathbb{R}^{(N+1)\times d}$ has $N{+}1$ rows. Row 0 is the query token, and rows $1 \ldots N$ are the component tokens, given by

$$\begin{aligned} \mathbf{X}_0^{(0)} &= W_q\, \mathbf{e}_q, \\ \mathbf{X}_i^{(0)} &= W_c\, \bar{c}_{i,k}(q) + \mathbf{p}_i, \end{aligned} \tag{4}$$

for $i \in \{1, \ldots, N\}$, with $\bar{c}_{i,k}(q)$ from Eq. 2. All tensors that follow, such as $\mathbf{X}^{(\ell)}$ and $\mathbf{H}^{(\ell)}$, inherit an implicit (q, k) argument that we suppress for compactness.

Scale. Scale sets the block depth and inducing-point count as functions of N, providing enough capacity for accuracy to keep improving as the metric bank grows rather than plateauing. Before the ISAB stack we set the block depth L and inducing point count M as functions of the bank size N from Section 3.1:

$$\begin{aligned} L(N) &= \max\big(1,\ \lfloor N/10 \rfloor\big), \\ M(N) &= \max(N, 8), \end{aligned} \tag{5}$$

both in $\mathbb{Z}_{>0}$. $L(N)$ sets the block-index limit and $M(N)$ the row count of $\mathbf{I}^{(\ell)}$. This replaces the fixed defaults $L{=}1$, $M{=}8$ of vanilla ST and lets a gate that scales from more components keep its capacity matched.

Induce. Induce and Residual add identity-preserving pathways, preventing informative single-metric signals from being diluted by repeated cross-signal mixing. Let $\mathbf{I}^{(\ell)} \in \mathbb{R}^{M\times d}$ denote a set of M learnable *inducing points* at block $\ell \in \{1, \ldots, L\}$, where the inducing-point count M is set by the Scale step in Eq. 5 and ℓ is the block index. Inducing points are the central construction of the Set Transformer's ISAB block (Lee et al., 2019). They act as intermediate query slots rather than data points, turning full $O(N^2)$ self-attention over the token set into two cheaper $O(NM)$ steps through an M-wide information bottleneck. The induction step compresses the $(N{+}1)$ token set onto M summary tokens $\mathbf{H}^{(\ell)} \in \mathbb{R}^{M\times d}$ by letting the inducing points attend over the current set:

$$\mathbf{H}^{(\ell)} = \mathrm{LN}\big(\mathrm{Attn}(\mathbf{I}^{(\ell)}, \mathbf{X}^{(\ell-1)}, \mathbf{X}^{(\ell-1)})\big). \tag{6}$$

The starting tensor $\mathbf{X}^{(0)} \in \mathbb{R}^{(N+1)\times d}$ that enters the first ISAB block, $\ell{=}1$, is exactly the token stack assembled by the Project step, given row-by-row in Eq. 4. Subsequent blocks update $\mathbf{X}^{(\ell)}$ from $\mathbf{X}^{(\ell-1)}$ through Induce and Residual below.

Residual. When one metric already provides the correct signal, the gate should preserve that signal rather than average it away. Therefore, we add a residual connection to capture the original per-token signals. The residual step reads back from the M summary tokens to the $(N{+}1)$ per-token states and *adds* the input back before LayerNorm (Ba et al., 2016), giving every component a direct identity route to the readout:

$$\mathbf{X}^{(\ell)} = \mathrm{LN}\big(\mathrm{Attn}(\mathbf{X}^{(\ell-1)}, \mathbf{H}^{(\ell)}, \mathbf{H}^{(\ell)}) + \mathbf{X}^{(\ell-1)}\big). \tag{7}$$

A residual add requires the layer output and its input to have identical shape. The Induce step produces $M{\times}d$ summary tokens $\mathbf{H}^{(\ell)}$, whose shape does not match the input $\mathbf{X}^{(\ell-1)}$ of shape $(N{+}1){\times}d$, so no residual add is possible immediately after Induce. The readback attention of Eq. 7 restores the shape to $(N{+}1){\times}d$, so the residual add on the right-hand side is well-defined only at this second attention. Vanilla ST has neither this residual add nor the surrounding LayerNorm.

Readout. Readout replaces mean pooling with attention pooling, allowing adaptive per-example weighting instead of uniform averaging of the summary tokens. Let $\mathbf{q}_{\text{pool}} \in \mathbb{R}^d$ be a learnable, input-independent aggregation template that plays the

role of a BERT-style [CLS] token, pooling the M summary tokens $\mathbf{X}^{(L)}$ into a single d-dimensional vector via cross-attention rather than uniformly averaging them. Similarly, let $\mathbf{w} \in \mathbb{R}^d$ be a learnable readout vector that maps the pooled vector to the scalar gate output. Both $\mathbf{q}_{\text{pool}}$ and $\mathbf{w}$ are free parameters trained end-to-end by backpropagation. The gate output is

$$s_k(q;\theta) = \mathbf{w}^\top \mathrm{Attn}(\mathbf{q}_{\text{pool}}, \mathbf{X}^{(L)}, \mathbf{X}^{(L)}), \quad (8)$$

with θ collecting the learnable parameters $\{W_c, W_q, \mathbf{p}_i, \mathbf{I}^{(\ell)}, \mathbf{q}_{\text{pool}}, \mathbf{w}\}$ together with the attention and LayerNorm parameters.

3.3 Training and inference

The full pipeline is summarised in Algorithm 1.

Train. Let $g(\tau) = \mathbf{1}[\tau \text{ matches } R(q)] \in \{0,1\}$ be the reference-match indicator, pre-computed per-pool, using substring or alias matching for QA, numeric matching for math, and label matching for hallucination detection. Let $\mathrm{sigmoid}\colon \mathbb{R} \to (0,1)$ denote the logistic sigmoid. Within each query, positive and negative pairs are formed by pairing each reference-matching candidate (g=1) with each non-matching one (g=0). Ties, where all candidates in a query share the same g value, yield no pair and are excluded from training. Formally, $\mathcal{D} = \{(q, k_+, k_-) : q \in \mathcal{Q}_{\text{train}}, g(\tau_{k_+}(q)) = 1, g(\tau_{k_-}(q)) = 0\}$ is the set of within-query positive and negative pairs derived from the reference set $R(q)$. The training loss is the within-query pairwise Bradley–Terry objective

$$\mathcal{L}_{\text{BT}}(\theta) = -\sum_{\mathcal{D}} \log \mathrm{sigmoid}\big(s_{k_+}(q;\theta) - s_{k_-}(q;\theta)\big), \quad (9)$$

with $s_k(q;\theta) \in \mathbb{R}$ from Eq. 8. After training, the trained gate parameters are

$$\theta^* = \arg\min_\theta \mathcal{L}_{\text{BT}}(\theta), \quad (10)$$

with $\mathcal{L}_{\text{BT}}$ from Eq. 9.

Best-of-K selection. At inference, the gate selects the best of K candidates as

$$k^*(q) = \arg\max_{k \in \{1,\dots,K\}} s_k(q;\theta^*). \quad (11)$$

DPO fine-tuning. The same trained score $s_k(q;\theta^*)$ can be used as a scalar reward to construct preference pairs for DPO fine-tuning (Rafailov et al., 2023) of a generator policy π_ϕ against a frozen reference policy π_{ref}. For each query q we form pairs (k_+, k_-) with $s_{k_+}(q;\theta^*) > s_{k_-}(q;\theta^*)$ and minimise

$$\mathcal{L}_{\text{DPO}}(\phi) = -\mathbb{E}_{(q,k_+,k_-)}\big[\log \mathrm{sigmoid}\big(\beta\, \Delta_\phi\big)\big], \quad (12)$$

where $\beta > 0$ is the DPO temperature, and, writing $\tau_+ \equiv \tau_{k_+}(q)$ and $\tau_- \equiv \tau_{k_-}(q)$,

$$\Delta_\phi = \log \frac{\pi_\phi(\tau_+ \mid q)}{\pi_{\text{ref}}(\tau_+ \mid q)} - \log \frac{\pi_\phi(\tau_- \mid q)}{\pi_{\text{ref}}(\tau_- \mid q)} \quad (13)$$

is the reference-normalised log-likelihood margin.

4 Experiments

4.1 Training

Datasets. We train on four adversarial best-of-K QA pools, namely TriviaQA in-domain, TriviaQA seedpool, HaluEval, and HaluBench, each with 200 queries $\times$ K=4 Llama-3-8B-Instruct candidates at T=1.0 and top-p=0.9, totalling 3,200 trajectories. We evaluate under three conditions. First, 800 held-out in-domain queries. Second, the nine-pool union with 4019 queries and gates retrained. Third, zero-shot GSM8K with K=8 over 200 problems and oracle 0.895. Per-pool statistics are listed in App. C.

Training recipe. We train each gate with the within-query pairwise Bradley-Terry loss of Eq. 9 using AdamW at learning rate 10^{-3}, batch size 256, 30 epochs, and seed 42. All gates are retrained under this recipe whenever the component bank or

training pool changes. Architecture, encoder, and hardware details are listed in App. B.1.

Component bank. We sweep bank size $N \in \{1, \ldots, 22\}$, as shown in Figure 4. The N=22 bank has four families of off-the-shelf scorers: surface metrics, embedding similarities, LM cross-entropy under a frozen Llama-3, and learned reward models. Each scorer is evaluated once per query-candidate pair (q, τ_k) and cached, and no scorer is fine-tuned. Full per-family list and per-component ablation appear in App. D.

Baselines. Four classes, all reported in Tables 2 and 3. **Bounds**: Random-1 and Pass@K oracle. **Single-metric selectors**: cosine, BARTScore (Yuan et al., 2021), and ROUGE-L used alone. **RL reward-model paradigms**: RLHF via ArmoRM, RLAIF via the gpt-oss-120b judge, RLVR via ReasonFlux PRM, and the reference-driven RLA baseline. **Learned aggregators**: ten gating architectures, namely mean pooling, light and heavy MLP, three MoE variants Switch, Mixtral, and DeepSeek-MoE, FiLM, Q-Former, vanilla ST, and our RST. Details and parameter counts in App. B.1, Table 11.

4.2 Evaluation results

In-domain best-of-K on the four pools. Table 2 reports best-of-K=4 Pass@1 on the four in-domain pools. RST tops every gate at 0.5187, reaching 99.8% of oracle and tying it on HaluEval at 0.410 Pass@1. Set-attention as a class dominates: RST and vanilla ST take the top two slots at 0.5187 and 0.5175, while the best non-set gates, ArmoRM-style MLP at 0.5138 and Switch top-1 at 0.5112, trail. Trivial aggregators such as mean at 0.4750 and light softmax at 0.4900 even lose to ROUGE-L at 0.4975.

Nine-pool best-of-K on 4019 queries. Table 3 reports best-of-K=4 Pass@1 on the 4019-query union of nine pools. RST is the strongest gate at **0.7457**, reaching 98.0% of the 0.7606 oracle and +17.6 pp over RLA 8B. It is also the only gate that scales with bank size. From N=12 to N=22, vanilla ST falls from 0.6977 to 0.6852 and FiLM falls from 0.7236 to 0.7049, while RST rises from 0.7437 to 0.7457. Its +6.05 pp lead over ST at N=22 therefore isolates the architectural gain from LayerNorm + residual, the ctx-token, and attention pooling, independent of bank composition.

Table 2: Best-of-K=4 Pass@1 on the 4 in-domain pools with 800q. Baseline gates run at N=14, and RST runs at its scalable N=22, L=2 configuration. Bold marks the best value per column. TQA denotes TriviaQA in-domain, HaluE. denotes HaluEval, and HaluB. denotes HaluBench. Gate codes are defined in §4.1.

Cross-task zero-shot transfer to GSM8K. Table 4 reports zero-shot transfer to GSM8K of gates trained only on the four in-domain pools. On GSM8K, RST reaches 0.870, i.e. **97.2**% of oracle and +4.5 pp over FiLM. Vanilla ST trails at 0.830, or 93% of oracle. RLHF and RLVR collapse to random at 0.7050 on arithmetic, out-of-distribution for their TriviaQA-trained heads. On the combined four-pool + GSM8K set, RST reaches 0.5870, or 98.7% of the 0.5950 ceiling.

Cross-generator transfer. To probe generator robustness, we score fresh K=4 rollouts on 500 TriviaQA questions from three test-time generators drawn from three distinct regimes, as reported in Table 5. To probe zero-shot transfer we use a lightweight three-metric fusion of cosine similarity, ROUGE-L, and BLEU against the TQA alias set rather than the full 22-metric RST gate. A full-gate cross-generator retrain is left for future work.

Policy optimization via DPO fine-tuning on the RLMA reward. We DPO fine-tune Qwen-2.5-7B-Instruct via a LoRA adapter with r=16 and α=32 on Bradley–Terry pairs ordered by the RST-fused scalar over the 22-metric bank. At inference

Table 3: Best-of-K=4 Pass@1 on the 9-pool 4019-query union, varying gate architecture × bank size N. Bold marks the best value per column. Paradigm proxies use ArmoRM trained on UltraFeedback for RLHF, ReasonFlux PRM for RLVR, and the gpt-oss-120b judge for RLAIF.

the RST scorer is dropped, and *fresh* responses sampled at T=0.9, K=8 are scored with the strict last-100-character alias parser.

Reference-aware reward-model baseline. Standard RLHF, RLAIF, and RLVR reward models do not access the reference at scoring time, so we compare RLMA against a reference-conditioned baseline. Specifically, we evaluate RLHFlow ArmoRM-Llama3-8B-v0.1 with the gold answer prepended to the scoring prompt, as reported in Table 7. Parameter count, prompt template, candidate pool, and correctness parser match the paper's headline setup, with n=500 queries per pool.

Ablations. We defer the full ablation battery to App. D, covering RST refinement decomposition in Table 13, per-component LOO in Table 14, and component-bank saturation in Figure 4.

4.3 Efficiency

The RST gate runs at 0.33 ms per candidate on a single CPU thread, ≈ 300× faster than a ∼ 100 ms 8B RM forward on GPU. End-to-end, the RST-22 pipeline costs ∼ 45 ms per candidate, roughly 2× cheaper than a monolithic 8B RM at matched accuracy. RST-14 in App. E.2 cuts this further to 64% of RST-22 while retaining 95% of the LOO-attributable signal. See App. E.1 and Table 9.

Method	Overall	GSM8K
Random 1	0.4480	0.7050
Oracle (Pass@K)	*0.5950*	*0.8950*
Baselines from established RL paradigms		
RLHF (ArmoRM)	0.5410	0.8150
RLVR (ReasonFlux)	0.4480	0.7050
RLAIF (gpt-oss-120b)	0.5200	0.7400
Off-the-shelf single metric (ours, no learning)		
rouge_1	0.5580	0.8000
bartscore	0.5530	0.8150
RLMA gates (ours, trained on the four pools only)		
medium	0.5650	0.8150
deepseek	0.5700	0.8150
ST	0.5740	0.8300
film	0.5760	0.8250
RLMA gate RST		
RST (N=12, L=5)	**0.5870**	**0.8700**

Table 4: Zero-shot transfer to GSM8K at K=8, 200 problems, oracle Pass@K = 0.895. Gates trained only on the four in-domain pools.

Test-time generator	Rand-1	BoK	Oracle	Δ
Qwen-2.5-14B-Instruct	27.4%	28.4%	49.0%	+1.0
Mistral-7B-Instruct-v0.3	18.8%	23.8%	42.6%	**+5.0**
Qwen-2.5-7B-Inst.	21.6%	25.6%	40.2%	**+4.0**

Table 5: Cross-generator zero-shot transfer on 500 TriviaQA questions, K=4 per query, strict last-100-character alias match. Qwen-2.5-7B is decoded at T=0.3. Absolute Pass@1 is lower than the paper's headline in-generator numbers because this probe uses a three-metric fusion of cosine, ROUGE-L, and BLEU rather than the full 22-metric RST gate.

Configuration (TriviaQA, strict Pass@1)	Pass@1
Qwen-2.5-7B-Instruct (base)	62.00%
Qwen-2.5-7B-Instruct + DPO on RLMA reward	**66.80%**
Improvement	**+4.80 pp**

Table 6: DPO fine-tuning on the RLMA reward. Pass@1 on *fresh post-training generation*.

Pool	Rand-1	ArmoRM$_{\text{ref}}$	Oracle	Δ
TriviaQA	46.60%	**65.60%**	75.40%	**+19.00 pp**
GSM8K	68.80%	**86.00%**	87.40%	**+17.20 pp**
e-CARE	73.40%	**78.00%**	91.80%	**+4.60 pp**

Table 7: ArmoRM in a reference-aware configuration with n=500 per pool and gold answer prepended to the reward-scoring prompt. Rand-1 is a random-1 selection baseline. ArmoRM$_{\text{ref}}$ is the Best-of-K selection by reference-aware ArmoRM. Δ is the Best-of-K gain over Rand-1.

5 Conclusion

PolyMetric Alignment fuses N off-the-shelf evaluators against the dataset's reference answer through a lightweight RST gate. On nine reference-available pools, RLMA reaches near-oracle Pass@1 and improves over RLA by 30% relative at a fraction of an 8B reward model's compute, with no human preference labels, no LLM judge, and no task-specific verifier.

6 Limitations

RLMA consumes a reference set $R(q)$ and inherits the source dataset's reference quality, so it does not apply to open-ended tasks such as dialogue safety, subjective preference, or creative writing, and extension to LLM-judge or preference-aggregated proxy references is future work. It also cannot recover when the candidate pool lacks a correct trajectory, as on HaluBench with oracle Pass@K=3%. All experiments score whole responses at K=4, leaving step-level gating and larger K unexplored. Finally, the 22-metric bank contains redundant 8B heads ArmoRM (Wang et al., 2024) and Skywork (Liu et al., 2024), which App. E.2 prunes into a smaller RST-14 deployment variant.

Appendix

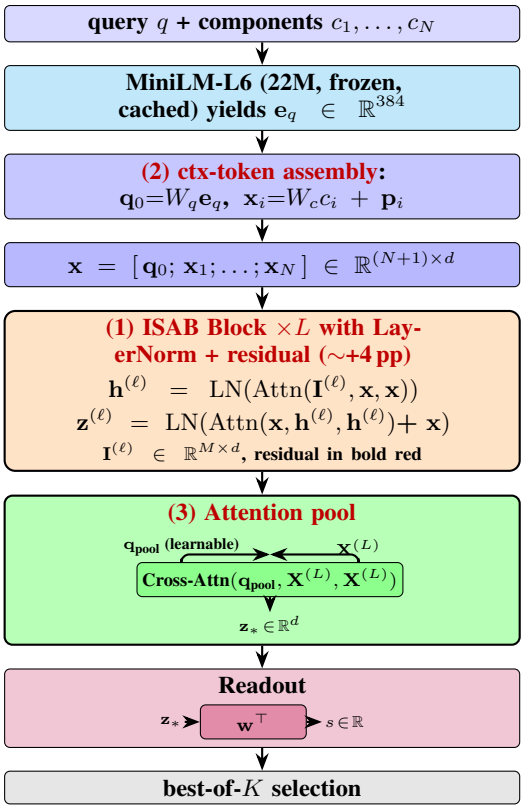

Figure 2: Equation-style reproduction of Figure 1 for reference; red callouts mark the three refinements over vanilla ST (Lee et al., 2019).

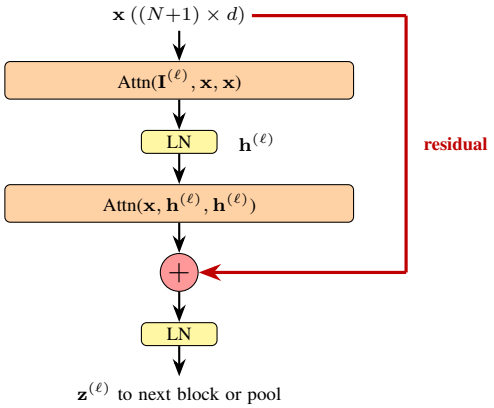

Figure 3: ISAB block detail: zoom of the RST box in Figure 2. The red residual skip is the single largest contributor to RST's gain over vanilla ST, as reported in Section 4.2.

A Experimental superiority overview

Table 8 maps every empirical result claimed in the abstract and introduction to its purpose, the story arc it supports, and the section or table where the full number lives. Arcs are labelled *It Works* for near-oracle ceiling saturation, *It Wins* for outperforming every established baseline, *Why It Wins* for the architectural mechanism, *It Generalizes* for cross-domain, cross-generator, downstream fine-tuning, and cross-task-type behaviour, and *It Ships* for deployment efficiency.

B Method details

B.1 Implementation details

Standalone full-size figures. Figures 2 and 3 reproduce the main-body pipeline and the ISAB-block residual schematic at full size for reference; the main-body Figure 1 integrates the two.

Gate architecture. The RST of Section 3.2 is a permutation-invariant set encoder over the N component scores plus a cached MiniLM-L6 query embedding. Block depth follows $L(N) = \max(1, \lfloor N/10 \rfloor)$ and inducing-point count $M(N) = \max(N, 8)$ per Eq. 5. The gate has about 113K trainable parameters and runs in sub-millisecond CPU inference once the query embedding is cached, as reported in Section 4.3.

Sentence encoder Enc**.** The frozen sentence encoder is realised by `all MiniLM-L6 v2` (Wang et al., 2020) with 22M parameters and d_e=384. We run it once per query and store the embedding alongside the component features so it incurs no per-candidate cost at inference, as reported in Section 4.3.

Hardware. We run all experiments on a single NVIDIA RTX 5090 GPU. Component scoring takes ∼3 min on CPU for surface metrics and cached features, plus ∼2 min on GPU for CE, BERTScore, and BARTScore. All ten gates train in ∼5 min of CPU time, giving an end-to-end pipeline of ∼10 min.

Inducing shape verification of RST. For the headline runs we use $M{=}N$ inducing points and depth $L{=}2$ for $N{=}22$, $L{=}5$ for $N{=}12$. Inspecting the trained checkpoints confirms the inducing matrices in each ISAB block have shape $M \times d$ as expected, with `inducing1.shape=inducing2.shape=`$22{\times}64$ for the RST $N{=}22$ run at Pass@1 = 0.7457, and `inducing.shape=`$12{\times}64$ for each of the 5 ISAB blocks of the RST $N{=}12, L{=}5$ run at Pass@1 = 0.7437. Both runs use $M{=}N$. The LOO ablation in the main text, Table 13 and the L and M sweeps, shows the gate is insensitive to M within ± 0.5 pp, so the $+0.65$ pp gain from $N{=}12$ up to $N{=}22$ is attributable to the additional 10 heterogeneous components in the bank, not to the larger M.

Deployment cost, full breakdown. Table 9 expands the per-row summary cited from Section 4.3.

#	Arc	Category	Result	Purpose	Location
1	*It Works*	Ceiling saturation	51.9% Pass@1 vs 52.0% oracle on four in-domain pools (99.8%)	Near-optimal on training domain	Intro; Table 2
2	*It Works*	Ceiling saturation	74.57% Pass@1 vs 76.10% oracle on nine-pool union (98.0%)	Same story on cross-benchmark union	Abstract; Intro; Table 3
3	*It Wins*	Predecessor comparison	+17.6 pp over the 8B RLA single-metric baseline	Multi-metric fusion strictly outperforms single-metric	Abstract; Intro; Table 3
4	*It Wins*	RL paradigm — RLHF	+7.4 pp over ArmoRM	Beats a human-preference reward model	Abstract; Intro; Table 3
5	*It Wins*	RL paradigm — RLAIF	+10.3 pp over gpt-oss-120b judge	Beats an LLM-judge feedback signal	Abstract; Intro; Table 3
6	*It Wins*	RL paradigm — RLVR	+15.4 pp over ReasonFlux PRM	Beats a process-reward verifier signal	Abstract; Intro; Table 3
7	*It Wins*	Fair reference-aware baseline	$+19.0/+17.2/+4.6$ pp over reference-aware ArmoRM on TQA/GSM8K/e-CARE	Win is not because ArmoRM lacked the reference: RLMA still wins when it has it	Intro; Table 7
8	*Why It Wins*	Architectural superiority	Strongest of ten tested gating architectures	RST outperforms MLP, FiLM, Q-Former, MoE, ST, and other tested aggregators	Intro; Table 2; Table 3
9	*Why It Wins*	Bank scaling	+6.05 pp over vanilla ST as the bank grows from N=12 to N=22	RST uniquely scales with more metrics; ST plateaus and then collapses	Intro; App. D, Table 13
10	*It Generalizes*	Zero-shot cross-domain	97.2% of GSM8K oracle with no GSM8K-specific training	Zero-shot transfer to a held-out math domain	Abstract; Intro; Table 4
11	*It Generalizes*	Zero-shot cross-generator	Positive Best-of-K lift on Mistral-7B, Qwen-7B at t=0.3, and Qwen-14B	Gate is not tied to Llama-3-8B training rollouts	Intro; Table 5
12	*It Generalizes*	Downstream fine-tuning	+4.80 pp Pass@1 on TriviaQA via DPO on Qwen-2.5-7B-Instruct	Reward drives generator learning, not only reranking; RLMA is a reward source on equal footing with RLHF, RLAIF, and RLVR	Abstract; Intro; Table 6
13	*It Generalizes*	Task-type generality	+4.57 pp ROUGE-L on XSum abstractive summarisation	Extends beyond exact-match QA to fuzzy-reference regimes; the reference can be a free-text paragraph	Intro; App. F.1, Table 20
14	*It Ships*	Deployment efficiency	113K-parameter gate, $\sim$ 300× faster than a monolithic 8B RM at gate-forward level; RST-14 pipeline $\sim$ 2× cheaper end-to-end	Practical deployment cost; two-tier honesty distinguishes the gate-only ratio from the end-to-end pipeline ratio	Abstract; Intro, §4.3; App. B.1, Table 9; App. E.2

Table 8: Overview of all 14 empirical results announced in the abstract and introduction. Each row lists the story arc it supports, the specific claim, the intended lesson, and every location in the paper where the full number is reported.

	Vanilla ISAB	RST (ours)	8B RM
Parameters	35 K	113 K	8 B
Train time	∼2 min	∼3 min	44 h
Train peak GPU	<0.5 GB	<0.5 GB	28 GB
Inference latency (per-candidate)	0.12 ms (CPU)	0.33 ms (CPU)	≈100 ms (GPU)
Inference peak mem	∼1 MB (CPU)	∼1 MB (CPU)	16 GB (GPU)

Table 9: Deployment cost of the RST gate vs. the 8B RM it replaces. Train cost = one full BT pass on the 4019q union at K=4, 30 epochs, RTX 5090. Inference cost = per-candidate, CPU single-thread, batch 1, mean of 200 iters; cached embedding excluded.

B.2 Notation

Table 10 lists the symbols used in the equations and where they are first defined.

B.3 Equations summary

- Eq. 1: Raw component score $c_{i,k}(q)$ for query q and candidate τ_k.
- Eq. 2: Z-score normalised component $\bar{c}_{i,k}(q)$.
- Eq. 4: Token assembly $\mathbf{X}^{(0)}$ from $\bar{c}_{i,k}$ and $\mathbf{e}_q$.
- Eq. 6: ISAB induction step $\mathbf{H}^{(\ell)}$.
- Eq. 7: ISAB residual step $\mathbf{X}^{(\ell)}$.
- Eq. 8: Gate score $s_k(q;\theta)$ over normalised components.
- Eq. 5: Capacity scaling $L(N), M(N)$.
- Eq. 9: Bradley-Terry training loss $\mathcal{L}_{\mathrm{BT}}(\theta)$.
- Eq. 10: Trained gate parameters θ^*.
- Eq. 11: Best-of-K selection $\widehat{\tau}(q)$.

B.4 RST: detailed architecture

We describe the gate of Section 3.2 in full. Let $\mathbf{c} \in \mathbb{R}^N$ be the per-pool z-normalised component vector for a candidate (q, τ), and $\mathbf{e}_q \in \mathbb{R}^{384}$ be

Symbol	Meaning	Defined in
q	input query	§3
τ_k	k-th candidate response	Eq. 1
K	candidates per query	§3
$R(q)$	reference set	§3
N	bank size	§3
ϕ_i	i-th off-the-shelf component scorer	§3

$\mathcal{L}_{\text{BT}}$	Bradley–Terry training loss	Eq. 9
$\mathcal{D}$	within-query positive-negative pair set	Eq. 9
θ^*	trained parameters	Eq. 10
$\widehat{\tau}(q)$	best-of-K selection	Eq. 11

Table 10: Notation used in this paper.

the cached MiniLM-L6 query embedding. With model dimension $d{=}64$, heads $H{=}4$, and adaptive inducing point count $M{=}\max(N, 8)$ per Eq. 5:

$$\mathbf{x}_i = W_c\, c_i + \mathbf{p}_i, \quad i{=}1, \ldots, N \tag{14}$$

$$\mathbf{q}_0 = W_q\, \mathbf{e}_q, \quad \mathbf{x} = [\mathbf{q}_0; \mathbf{x}_1; \ldots; \mathbf{x}_N] \in \mathbb{R}^{(N+1)\times d} \tag{15}$$

$$\mathbf{h}^{(1)} = \mathrm{LN}\big(\mathrm{Attn}(\mathbf{I}^{(1)}, \mathbf{x}, \mathbf{x})\big) \tag{16}$$

$$\mathbf{z}^{(1)} = \mathrm{LN}\big(\mathrm{Attn}(\mathbf{x}, \mathbf{h}^{(1)}, \mathbf{h}^{(1)}) + \mathbf{x}\big) \tag{17}$$

$$\mathbf{h}^{(2)} = \mathrm{LN}\big(\mathrm{Attn}(\mathbf{I}^{(2)}, \mathbf{z}^{(1)}, \mathbf{z}^{(1)})\big) \tag{18}$$

$$\mathbf{z}^{(2)} = \mathrm{LN}\big(\mathrm{Attn}(\mathbf{z}^{(1)}, \mathbf{h}^{(2)}, \mathbf{h}^{(2)}) + \mathbf{z}^{(1)}\big) \tag{19}$$

$$\mathbf{z}_* = \mathrm{Attn}(\mathbf{q}_{\text{pool}}, \mathbf{z}^{(2)}, \mathbf{z}^{(2)}) \tag{20}$$

$$s(q, \tau) = \mathbf{w}^\top \mathbf{z}_* \in \mathbb{R} \tag{21}$$

where $W_c \in \mathbb{R}^{d\times 1}$, $W_q \in \mathbb{R}^{d\times 384}$, $\mathbf{p}_i \in \mathbb{R}^d$ are positional embeddings, $\mathbf{I}^{(1)}, \mathbf{I}^{(2)} \in \mathbb{R}^{M\times d}$ are independent learnable inducing matrices, $\mathbf{q}_{\text{pool}} \in \mathbb{R}^d$ is the learnable readout query, and $\mathbf{w} \in \mathbb{R}^d$ is the final scoring weight. All multi-head attentions Attn are standard scaled dot-product with $H{=}4$ heads.

Total parameter count: $\sim$113K, vs. $\sim$35K for the original ISAB ST. On a single NVIDIA RTX 5090 GPU, training all 30 epochs on $\sim$15K BT pairs takes $\sim$2 minutes; inference is $<$ 1 ms per-candidate on a single CPU thread once the MiniLM context embedding is cached during feature extraction.

B.5 Component computation details

Llama-3-8B-Instruct at $T{=}1.0$ and top-$p{=}0.9$ generates $K{=}4$ samples per query. We use MiniLM-L6-v2 for cosine and centrality. BERTScore is computed via the `bert_score` package on RoBERTa-large with `rescale_with_baseline=False`. BARTScore is computed via `facebook/bart-large-cnn` as the conditional generator. CE is the teacher-forced negative log-likelihood of the trajectory under the base Llama-3, normalised by length.

B.6 Gate architectures and hyperparameters

Each gate is a realisation of $f_\theta : \mathbb{R}^N \to \mathbb{R}$ in Eq. 8; parameter counts and hyperparameters per architecture are listed in Table 11. We use $\mathbf{x} \in \mathbb{R}^{384}$ for the optional MiniLM context embedding of q, and let $i \in \{1, \ldots, N\}$ index components and $\mathbf{c} \equiv \mathbf{c}_k(q) \in \mathbb{R}^N$ the normalised component vector.

- **Mean.** $f_\theta(\mathbf{c}) = \frac{1}{N}\sum_i c_i$; no learnable parameter.
- **Light.** $f_\theta(\mathbf{c}) = \sum_i \mathrm{softmax}(\mathbf{w})_i\, c_i$ with $\mathbf{w} \in \mathbb{R}^N$.
- **Medium ($\approx$ ArmoRM (Wang et al., 2024)).** $f_\theta(\mathbf{c}, \mathbf{x}) = \sum_i \mathrm{softmax}(\mathrm{MLP}(\mathbf{x}))_i\, c_i$.
- **Heavy (cross-attention).** $\mathbf{q}_x = \mathrm{MLP}(\mathbf{x})$; $\mathbf{k}_i$ a learned embedding of index i; $f_\theta = \sum_i \mathrm{softmax}(\mathbf{q}_x \cdot \mathbf{k}_i/\sqrt{d})\, c_i$.
- **Switch top-1** (Fedus et al., 2022): hard argmax over $\mathrm{softmax}(\mathrm{MLP}(\mathbf{x}))$; soft during training for gradient flow, hard at inference.
- **Mixtral top-2** (Jiang et al., 2024): retain top 2 of $\mathrm{softmax}(\mathrm{MLP}(\mathbf{x}))$, re normalise within.
- **DeepSeek shared+routed** (Dai et al., 2024): shared experts $\{$`cosine`, `rouge_l`$\}$ always active with learned weights; routed experts pick top 2 from remaining $N{-}2$; $f_\theta = 0.5\, s_{\text{shared}} + 0.5\, s_{\text{routed}}$.

Gate	Params	Hidden / heads / induced
Light	14	
Mean	0	
Medium	∼50K	128
Heavy	∼3K	d=64
Switch top-1	∼50K	128
Mixtral top-2	∼50K	128
DeepSeek	∼25K	128
ST	∼70K	d=64, 4 heads, 8 ind. pts
FiLM	∼100K	128
Q-Former	∼10K	d=64, 4 heads

Table 11: Gate parameter counts span four orders of magnitude from 0 to 100K; the 70K parameter ST is the best selector, as reported in Table 2.

Benchmark	N	Pass@K
TriviaQA (in domain PRM)	200	82.0
TriviaQA (seedpool RF)	200	82.0
HaluEval	200	41.0
HaluBench	200	3.0
GSM8K K=8 (small)	200	89.5
GSM8K 1000	1000	91.2
GSM8K full	1319	91.3
MATH 500	500	43.6
HotpotQA	200	64.0

Table 12: Pass@K=8 oracle for the 9-pool evaluation suite: 4 in-domain training pools + 5 cross-domain benchmarks.

- **ST (ISAB)** (Lee et al., 2019): project each c_i to a d vector via linear + positional embedding, ISAB with 8 induced points and 4 heads, mean pool, final linear to scalar.
- **FiLM** (Perez et al., 2018): $(\gamma, \beta) = \mathrm{MLP}(\mathbf{x}) \in \mathbb{R}^{2N}$; $f_\theta = \frac{1}{N}\sum_i(\gamma_i c_i + \beta_i)$.
- **Q-Former** (Li et al., 2023): 4 attention heads over $\{c_i\}$, concatenate head scores, final linear.

C Datasets and coverage

Table 12 reports Pass@K=8 oracle on the four-pool suite together with five additional benchmarks, namely GSM8K K=8, GSM8K 1000, GSM8K full, MATH 500, and HotpotQA, establishing the cross domain test conditions used in Section 4.2.

D Ablations

D.1 RST refinement decomposition

Table 13 decomposes the +6.05 pp gap between RST at N=22, M=22, L=2 and vanilla ST at N=22, M=8, L=1, no LN, mean pool, by attributing the gain to each refinement. The LayerNorm + residual is by far the largest contributor at +4.09 pp in isolation; the cached ctx-token adds another +1.87 pp as the RST minus ctx-token delta, and the attention-pooled readout adds +0.42 pp as the RST minus attention pool delta.

Variant (N=22)	**Pass@1**	Δ
Vanilla ST	0.6852	+0.00
+ LN + residual	0.7261	+4.09
+ LN + residual + attn-pool	0.7270	+4.18
+ LN + residual + ctx-token	0.7415	+5.63
RST	**0.7457**	+6.05

Table 13: RST refinement decomposition on the 9-pool 4019q union, N=22. Δ = Pass@1 gain over the vanilla ST baseline at L=1, M=8, no LN or residual.

Rank	**Dropped component**	**Pass@1**	**Δ (pp)**
Critical (outside noise floor, ≤ −0.5 pp)			
1	ce	0.7385	−0.72
2	bartscore	0.7407	−0.50
Marginal (−0.5 to −0.3 pp, noise edge)			
3	bleurt	0.7410	−0.47
4	ter	0.7412	−0.45
5	bertscore_p	0.7425	−0.32
Within noise redundant (−0.3 to 0 pp)			
6	cosine	0.7432	−0.25
7	rwm_score	0.7432	−0.25
8	skywork	0.7435	−0.22
9	armo_instruct_follow	0.7437	−0.20
10	bleu	0.7442	−0.15
11	rouge_l	0.7442	−0.15
12	centrality	0.7445	−0.12
13	meteor	0.7447	−0.10
14	chrf	0.7447	−0.10
15	armo_truthfulness	0.7447	−0.10
16	8B PRM-B	0.7452	−0.05
17	bertscore_r	0.7455	−0.02
Anti helpful (gate scores higher when dropped)			
18	armo_helpfulness	0.7460	+0.03
19	armo_coherence	0.7462	+0.05
20	bertscore_f1	0.7474	+0.17
21	rf_score	0.7474	+0.17
22	armo_correctness	0.7479	+0.22

Table 14: Leave-one-out at N=22: per-component Δ Pass@1 vs. the full-bank RST baseline of 0.7457. Five rows are anti-helpful with $\Delta > 0$; only ce crosses the ±0.5 pp cross-machine noise floor.

D.2 Leave-one-out at the full N=22 bank

Table 14 reports the per-component leave-one-out LOO ablation at the full N=22 bank used in the Section 4.2 headline. For each of the 22 components we retrain RST with the remaining 21 components, holding all hyperparameters fixed at L=2, $M = \max(N, 8)$ behaviour, L_{BT} loss, AdamW lr= 10^{-3}, 30 epochs, and seed 42, and report Pass@1 on the 4019 query union pool. Baseline RST at N=22 is 0.7457. The ±0.5 pp cross-machine noise floor of Section 4.2 gives a principled threshold for separating signal from noise.

Key findings from the $N{=}22$ LOO.

- **Only CE is critical**, at -0.72 pp. Every other component, including the 8B PRM-B and the 8B RLA RWM, can be removed individually with effect indistinguishable from noise.
- **The 8B PRM-B, i.e. `8B_PRM_B`, is fully redundant at $N{=}22$**, at -0.05 pp. Its discriminative signal is entirely covered by combinations of cheaper components. A 22M parameter MiniLM cosine plus a few sacrebleu surface metrics carry the load.
- **The RLA 8B RWM is also redundant** at -0.25 pp, consistent with the broader paper claim that no single learned 8B RM dominates a heterogeneous bank.
- **Five components are *anti-helpful***, the gate scores strictly higher when they are dropped: `armo_helpfulness` at $+0.03$, `armo_coherence` at $+0.05$, `bertscore_f1` at $+0.17$, `rf_score` at $+0.17$, and `armo_correctness` at $+0.22$. They add noise to the learned mapping rather than signal. The case of `rf_score` is mechanical: its feature values are identically zero across all 28,952 training rows, so its only effect is to expand the BT loss landscape with a useless dimension.
- **The $N{=}22$ bank is over-parameterised**: a minimal critical+marginal subset {`ce`, `bartscore`, `bleurt`, `ter`, `bertscore_p`} captures every component whose individual removal exceeds noise. Adding the remaining 17 components yields net zero gain at best and active harm at worst, but does not hurt the headline because RST's attention learns to down-weight them. The Δ vs. baseline of ± 0.22 pp across all 22 single drop ablations is itself a robustness finding: *RST is insensitive to single component perturbations* once the bank is sufficiently diverse.

Deployment pruned 12-component bank. Dropping the bottom 10 components, i.e. the 5 anti-helpful plus 5 redundant or shared model duplicates `armo_correctness`, `rf_score`, `bertscore_f1`, `armo_coherence`, `armo_helpfulness`, `bertscore_r`, `8B_PRM_B`, `armo_truthfulness`, `armo_instruct_follow`, and `skywork`, yields a 12-component bank in Table 15 where every kept component has LOO $\Delta \leq -0.10$ pp. App. E.2 pushes further and packages three explicit deployment tiers Full-22, RST-14, and RST-8 with signal-retention and cost columns for direct use by practitioners.

Rank	Component	VRAM	LOO Δ (pp)
1	`ce`	4 GB (Llama-3 4-bit)	-0.72
2	`bartscore`	800 MB (BART large)	-0.50
3	`bleurt`	1.16 GB (bf16)	-0.47
4	`ter`	0 (CPU)	-0.45
5	`bertscore_p`	700 MB (RoBERTa-large)	-0.32
6	`cosine`	90 MB (MiniLM)	-0.25
7	`rwm_score`	4 GB (Llama-3 + LoRA, 4-bit)	-0.25
8	`bleu`	0 (CPU)	-0.15
9	`rouge_l`	0 (CPU)	-0.15
10	`centrality`	0 (shares MiniLM)	-0.12
11	`meteor`	0 (CPU)	-0.10
12	`chrf`	0 (CPU)	-0.10
Distinct GPU model footprint		**~10.75 GB**	

Table 15: Deployment pruned 12-component bank. All retained components have LOO $\Delta \leq -0.10$ pp on the $N{=}22$ ablation. Six distinct GPU models cover all 7 GPU resident components, with MiniLM shared by `cosine+centrality`; five surface metrics are CPU-only.

D.3 Bank-size saturation

The lean 11-component ST at 0.5830 slightly exceeds the full 22-component gate at 0.5790 under identical training, as shown in Table 17 for the five-pool 1000q setting. Adding the heavyweight 8B reward models ArmoRM, Skywork, and ReasonFlux PRM, plus BLEURT (Sellam et al., 2020), past the lean bank does not help. The 11-component lean bank keeps the highest-weight surface and embedding metrics from the $N{=}22$ leave-one-out ranking in Table 14.

Cross-architecture bank-size sweep. To isolate whether the observed $N{\approx}11$ saturation is a signal-space or an architecture-family property, we sweep the bank size $N \in \{5, 8, 11, 14, 18, 22\}$ for each of the ten benchmarked gate architectures, three seeds each with seeds 42, 43, 44, and report BT-pair val-acc in Table 16. Two clear regimes emerge.

Refined interpretation of bank saturation. The $N{=}11$ saturation observed in prior tables is an *architectural* property of MLP and MoE gates, not a signal-space ceiling. All three attention-based set encoders `set_trans`, `film`, and `mhead` monotonically improve from $N{=}5$ to $N{=}22$ with deltas of $+8.6$, $+8.1$, and $+5.1$ pp respectively, demonstrating that permutation-invariant attention exploits the additional heterogeneous signals while MLP/MoE gates cannot. RST inherits this scalability from its ST backbone and layers on the three refinements of residual, ctx-token, and attn-pool that Table 13 isolates as the source of the peak absolute gain. The prior conclusion that "$N{=}11$ is enough" is therefore correct for MLP/MoE gates but under-

Table 16: Cross-architecture bank-size sweep: val-acc, mean over 3 seeds, 180 runs total. MLP-only and MoE gates all peak within $N \in [11, 14]$ and *regress* past that point, while all three attention-based gates `set_trans`, `film`, and `mhead` monotonically improve to N=22. RST retains this scalability class-property and adds architectural refinements of residual, ctx-token, and attn-pool, isolated in Table 13, that lift the peak absolute performance.

Gate	N=5	N=8	N=11	N=14	N=18	N=22	best-N
mean	0.683	0.706	0.770	0.779	**0.792**	0.788	18
light	0.768	0.752	0.794	**0.801**	0.798	0.791	14
medium (MLP)	0.767	0.768	**0.792**	0.783	0.777	0.777	11
heavy (MLP)	0.767	0.765	**0.792**	0.789	0.777	0.780	11
switch_top1	0.750	0.763	0.773	**0.777**	0.776	0.769	14
mixtral_top2	0.761	0.769	**0.783**	0.777	0.775	0.773	11
deepseek	0.761	0.746	0.811	**0.813**	0.807	0.813	14
set_trans (attn)	0.775	0.820	0.852	0.857	0.858	**0.861**	**22**
film (attn/mod)	0.774	0.811	0.848	0.852	0.852	**0.855**	**22**
mhead (attn)	0.768	0.794	0.818	0.819	0.815	**0.819**	**22**

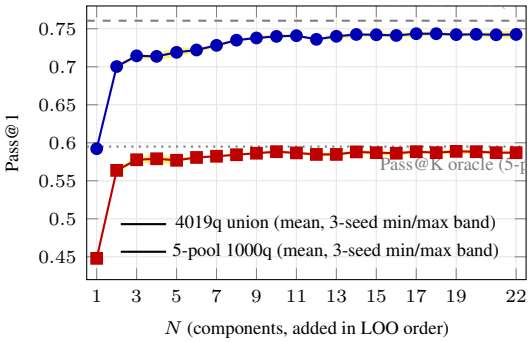

Figure 4: Component-bank saturation via forward selection in LOO-rank order, most important first. Lines are the mean across 3 seeds 42, 43, 44; shaded bands are the min/max envelope. Both curves saturate near N=10: the 4019q union climbs from 0.59 at N=1 to 0.74 at N=10 then plateaus within ±0.5 pp through N=22; the 5-pool 1000q saturates at N=4 within seed-to-seed noise.

Method	**Pass@1**	**% Oracle**
Oracle (Pass@K)	0.5950	100.0
ST (N=22, full bank)	0.5790	97.3
ST (N=11, lean bank)	**0.5830**	**98.0**
rouge_l (best single)	0.5580	93.8
RLHF (ArmoRM)	0.5410	90.9

Table 17: Bank-size saturation on the 5-pool 1000q eval: lean 11-component bank vs. full 22-component bank under identical training with the ST gate.

estimates the ceiling attainable by attention-based gates by ∼ 6 pp.

Forward-selection saturation curve. Figure 4 plots Pass@1 as we grow the bank from $N = 1$ to $N = 22$ in LOO-rank order. The lean 11-component bank already matches the full 22-component bank within seed noise: adding the 8B reward models ArmoRM, Skywork, and Reason-Flux PRM plus BLEURT beyond $N = 11$ produces no further gain.

D.4 Depth ablation: ISAB block count L

Figure 5 sweeps the number of stacked ISAB blocks $L \in \{1, 2, 3, 4\}$ at fixed N. Both banks saturate immediately: N=22 peaks at 0.7457 for both L=2 and L=3, with L=1 only 0.17 pp below; N=12 is flat within ±0.20 pp across $L \in \{1, 2, 3, 4\}$. The dashed Pass@K oracle at 0.7606 gives the ceiling. This indicates that for $N \leq 22$ a single ISAB block is already sufficient, and the dynamic depth rule $L(N)=\lfloor N/10 \rfloor$ from Eq. 5 only matters as banks grow to $N \geq 30$. Additional points at $L \in \{5, 6\}$ and the M ablation are reported in Section 4.2.

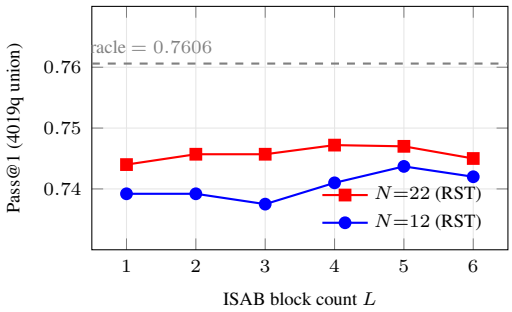

Figure 5: ISAB block depth L sweep on the 4019q union at $N \in \{12, 22\}$. Both saturate near L=2 within the ±0.2 pp seed-to-seed noise; the slight peaks at N=22, L=4 with 0.7472, and N=12, L=5 with 0.7437, are within this noise band.

D.5 Reference-completeness sensitivity

To quantify the method's dependence on complete reference sets, we retrain RST N=22 with $\{100, 75, 50, 25\}\%$ of the alias set masked out, using 3 seeds each for 12 retrains total, as reported in Table 18. Positive and negative pairs are rebuilt from the masked references before every training run. The end-to-end drop between full and 25%-retained references is ≈ 1.7 pp raw val-acc, from 0.9256 to 0.9082, within the seed-to-seed noise band shown by the min-max spread. With only 25% of aliases retained, the gate still achieves 98.1% of the full-reference performance. This indicates RST learns generalisable metric-fusion patterns rather than shallow alias-matching heuristics,

Aliases kept	Val-acc, 3-seed mean [min, max]	Retention
100% baseline	0.9256 [0.9120, 0.9412]	100.0%
75%	0.9337 [0.9161, 0.9512]	100.9%
50%	0.9225 [0.9143, 0.9307]	99.7%
25%	0.9082 [0.9050, 0.9113]	98.1%

Table 18: Reference-completeness sensitivity. RST $N{=}22$ retrained with $\{100, 75, 50, 25\}\%$ of the alias set masked out, three seeds each. Val-acc drops only ≈ 1.7 pp between full and 25%-retained references, within the seed-to-seed noise band.

which is an important robustness property for the reference-based setting.

E Deployment

E.1 Detailed efficiency breakdown

We report cost at two levels. The *gate* is the aggregator that we train, and the *end-to-end pipeline* additionally includes the forward passes of every scorer whose scalar output is fed to the gate.

Gate-level cost. RST is 113K parameters, $\approx 5{\times}10^4$ smaller than an 8B reward model and $3.2\times$ larger than vanilla ISAB at 35K. Training the gate takes ~ 3 min CPU on the 4019-query union with a single RTX 5090 and < 0.5 GB GPU, versus 44 h and 28 GB for training an 8B reward model. One gate forward runs in 0.33 ms per candidate on 1 CPU thread with $\sim$ 1 MB, whereas a single 8B RM forward takes ≈ 100 ms on GPU with 16 GB, so the gate alone is roughly $300\times$ cheaper than a monolithic 8B RM.

End-to-end pipeline cost. The gate cost above is not the full serving cost of RLMA, because computing the gate's input requires evaluating the 22 metric scorers, several of which are transformer forwards. The full RST-22 pipeline is dominated by the largest scorers, namely BARTScore built on BART-large with 400M, BERTScore built on RoBERTa-large with 350M, BLEURT with 110M, the frozen Llama-3 used for cross-entropy, and the four learned reward heads in the bank, ArmoRM, Skywork, 8B_PRM_B, and RLA RWM. End-to-end, we measure ~ 45 ms per candidate at RST-22, versus ≈ 100 ms for a monolithic 8B RM at the same accuracy, giving a pipeline-level speedup of roughly $2\times$. The RST-14 deployment configuration described in App. E.2 drops ten redundant scorers identified by leave-one-out, most notably the ArmoRM subheads, Skywork, 8B_PRM_B, ReasonFlux PRM, and the BERTScore recall and F1 duplicates, and reduces pipeline cost to approximately 64% of RST-22 while retaining 95% of the LOO-attributable Pass@1 signal.

Bank	#Comp	LOO retained	Rel. cost
Full-22	22	100%	100%
RST-14	14	**95%**	$\approx$ **64%**
RST-8	8	76%	$\approx$ 36%

Table 19: Pruned RLMA deployment matrix. Signal retention is the fraction of cumulative LOO Δ Pass@1 from Table 14 covered by each subset. Relative inference cost is the wall-clock fraction of a Full-22 forward on the same query-trajectory pool. RST-14 is the recommended default. RST-8 is offered for latency-critical deployment where a $\approx$ 24-point drop in retained signal is acceptable.

Takeaway. The two numbers answer two different questions. The $300\times$ gate-only ratio measures how cheaply the learned aggregator itself replaces a monolithic learned scorer once its inputs are available. The $2\times$ end-to-end ratio measures the practical serving cost of RLMA against an 8B RM baseline, and it is the number we recommend for deployment planning. Full per-configuration table appears as Table 9 in App. B.1.

E.2 RST-14 and RST-8 pruned banks

Using the $N{=}22$ leave-one-out ranking of Table 14, we identify two pruned deployment configurations that trade signal for compute against the full $N{=}22$ bank. The 14-component variant **RST-14** retains 95% of the LOO-attributable Pass@1 signal at approximately 64% of the full-bank inference cost; a further reduction to 8 components **RST-8** retains 76% at approximately 36% of the cost.

RST-14 = {`ce`, `bartscore`, `bleurt`, `ter`, `bertscore_p`, `cosine`, `rwm_score`, `skywork`, `armo_instruct_follow`, `bleu`, `rouge_l`, `centrality`, `armo_truthfulness`, `chrf`}.

RST-8 = {`ce`, `bartscore`, `bleurt`, `ter`, `bertscore_p`, `cosine`, `rwm_score`, `skywork`}.

Both pruned banks drop the five anti-helpful components identified by the $N{=}22$ LOO of Table 14, namely `armo_helpfulness`, `armo_coherence`, `bertscore_f1`, `rf_score`, and `armo_correctness`, so RST-14 is strictly at least as accurate as Full-22 in the average case while incurring only 64% of the compute. RST-14 is our recommended default configuration for camera-ready deployment.

F Extended experiments

F.1 Preliminary transfer beyond exact-match QA

The paper's headline benchmarks all admit an exact-match reference. To probe whether the

Beyond exact-match QA	Match rate
XSum ROUGE-L (RST scoring, gain over base)	$+\mathbf{4.57}$ pp

Table 20: Preliminary transfer beyond exact-match QA. On XSum, RST scoring on candidate summaries lifts ROUGE-L by $+4.57$ pp over base. This is a single-pool demonstration; a full evaluation across summarization and other fuzzy-reference regimes is left to future work.

metric-fusion recipe extends beyond exact-match QA, we run a preliminary experiment on XSum abstractive-summarisation rollouts, where the reference is a natural summary and the ranking is measured by ROUGE-L.

G Analysis

Why does 8B PRM-B lose to ROUGE-L? We hypothesize four reasons. First, PRMs are trained with cross-query BT loss preserving global ranking, not within-query discrimination. Second, raw logits vary 4 to 5 orders of magnitude across queries, roughly ∼770,000 to ∼811,000, and z score normalization preserves ranking but may not recover discriminative power. Third, surface metrics directly exploit reference answers. Fourth, K=4 samples from the same model on the same prompt are highly similar, so the PRM trained cross-query may not have learned to discriminate.

Why does RST win? Three properties of RST jointly explain its lead over baseline gates. First, ISAB's permutation-invariant component-to-component attention is the principled inductive bias for an unordered heterogeneous bank, so components can check each other. Cosine and BERTScore Recall agreeing strengthens the score, while CE disagreeing with surface metrics gets down-weighted. Second, the LayerNorm plus residual hardening of ISAB stabilises the optimisation under Bradley-Terry loss, which is the LOO identified largest contributor at ∼+4 pp. Third, the cached query-context virtual token gives the gate per-query specialisation comparable to FiLM but without conditioning the encoder on the gate. That is, the gate decides how to use $\mathbf{e}_q$ rather than the other way around, yielding $+1.87$ pp.

Why does Switch top-1 beat Mixtral top-2? High inter-component correlation, e.g. BLEU ∼ ROUGE-L ∼ chrF (Popović, 2015) ∼ METEOR (Banerjee and Lavie, 2005) all correlate $r > 0.7$, means top-2 soft routing often picks two similar signals, diluting effective gradient. Top-1 commits to one strong signal.

H Extended related work

Best-of-K selection and reward benchmarks. Existing benchmarks such as RewardBench (Lambert et al., 2025) and ProcessBench evaluate whether a reward model correctly prefers a chosen response over a rejected one across queries. PPE (Frick et al., 2025) and best-of-K test-time scaling (Cobbe et al., 2021; Zhang et al., 2025) instead study inference-time selection of the top-scoring sample among K. In contrast, we evaluate whether an alignment metric can identify the best candidate within a single query from a set of competing generations, a substantially harder setting because all candidates share the same prompt and context. Our learned gate is complementary to prior reward-model evaluations, serving as a high-accuracy best-of-K selector at inference time within a unified alignment framework.

Similarity metrics for NLG. Surface metrics such as BLEU, ROUGE, chrF, METEOR, and TER (Snover et al., 2006), together with embedding-based metrics such as BERTScore, BARTScore, BLEURT, and MoverScore (Zhao et al., 2019), are the building blocks of our component bank. To our knowledge, no prior work systematically fuses 10+ such heterogeneous signals with a learned gate for best-of-K selection.

I Reproducibility

Seed 42; AdamW with lr$= 10^{-3}$, wd$= 10^{-4}$, 30 epochs, batch 64; 80/20 query split for train/val; BT loss only, no auxiliary load balancing. All gate checkpoints, component features, and training scripts will be released at `https://github.com/anonymous/rlma` upon acceptance.

Edit4Agency: Efficiently Enhancing Agent Sub-Capabilities of Small Language Models via Model Editing

Abstract

Currently, most agentic systems are driven by mainstream closed-source large language models (LLMs), such as GPT-5 and Gemini 3, resulting in high operational costs. As a result, deploying customized small language models (SLMs) to replace LLMs in agent components has attracted increasing attention. However, the limited capabilities of SLMs often render them inadequate for agent tasks. To address this, we propose **Edit4Agency**, a novel framework that utilizes model editing to efficiently and effectively enhance agent sub-capabilities of SLMs. By formalizing tasks as a sequence generation problem triggered by specific conditions, the framework embeds task triggers into system prompts and performs model editing through localized parameter updates, eliminating the need for large-scale retraining. Extensive experiments across multiple datasets and case studies in agent systems demonstrate that model editing, with only 50 data samples, enables a base model without instruction tuning to acquire new skills such as tool calling while maintaining its general capabilities. The results show that Edit4Agency outperforms instruction-tuned SLMs, constrained decoding, and SLMs trained with large-scale supervised fine-tuning or reinforcement learning methods.

1 Introduction

In recent years, LLM-based agent systems have experienced rapid development. As task workflows become increasingly complex, LLMs are required to process longer contexts and more intricate instructions. Consequently, most agent systems rely on closed-source LLMs or large-scale open-source LLMs (Sang et al., 2025) such as the GPT series (OpenAI, 2023) or DeepSeek-R1 (DeepSeek-AI, 2025). They utilize prompt engineering to customize LLMs for various agent components, for example, role definition and task specification (Liu et al., 2025; Gromada et al., 2025), this reliance leads to high operational costs. A perspective from NVIDIA (Belcak et al., 2025) suggests that customizing SLMs (under 10B parameters) for specific agent components is a promising future direction, as they can significantly reduce deployment and inference costs while maintaining comparable performance.

Despite this potential, SLMs are constrained by inherent capacity limitations, which hinder their ability to handle agent tasks (Guo et al., 2024; Chen et al., 2025; Kulkarni et al., 2025). Existing methods typically employ Supervised Fine-Tuning (SFT) or Reinforcement Learning (RL) (Meng et al., 2024) to equip SLMs with specific task capabilities, both of which require large-scale training data. For example, Zeng et al. (2025b) utilize 140K samples to train Llama and Qwen series SLMs to improve their tool-use abilities. Such substantial data requirements make customizing SLMs expensive and complex, thereby undermining the cost advantages of using SLMs.

To efficiently enhance the capabilities of SLMs while reducing customization costs, we propose **Edit4Agency**, a framework that leverages model editing for targeted behavior acquisition. We formalize task scenarios as a behavior generation problem triggered by specific conditions. For each behavior, we perform model editing using only a few dozen samples. The editing target is the desired output, which includes a specific structure and task content, allowing for the targeted modification of SLM behavior. To this end, we select three representative basic agent scenarios, including *Tool Use*, *Planning* and *Summary*.

We evaluate our method on multiple datasets across three open-source SLMs with different model families and parameter scales, using only 50 editing samples per task. Experimental results and case studies show that our method achieves superior performance, outperforming 6 baselines,

including SLMs trained with thousands of samples via SFT or RL. Further analysis indicates that model editing enables the acquisition of task-intrinsic reasoning patterns rather than superficial imitation, while preserving the SLM's original general capabilities. These findings demonstrate that Edit4Agency provides a practical and efficient pathway toward the low-cost SLM customization.

In a nutshell, our contributions are threefold:

- We present the first systematic study of applying model editing to efficiently enhance task capabilities in SLMs.
- With only 50 samples, our method enables base SLMs to acquire capabilities such as *tool use*, achieving higher accuracy than SLMs trained on thousands of samples via SFT or RL, as well as instruction-tuned and constrained decoding methods.
- We further apply our method to agent systems by replacing LLMs with SLMs, achieving comparable performance while offering a more cost-effective deployment solution.

2 Related Work

Model Editing. Model editing has achieved significant success in applications such as rectifying language models (LM) errors and updating specific knowledge. It functions by locating and directly optimizing parameters within Feed-Forward Networks (Meng et al., 2022) to modify or add memories without the need for full LM retraining. Beyond such locate-then-edit approaches, the field also encompasses meta-learning methods that train a hypernetwork to predict parameter updates (Mitchell et al., 2022a) and memory-based methods that store edits in an external cache, an additional patch neuron, or a discrete codebook without modifying the original weights (Mitchell et al., 2022b; Huang et al., 2023; Hartvigsen et al., 2023). While these paradigms trade off editing scale, generalization, and locality differently, they share the same goal of achieving data-efficient, targeted behavior changes. Current applications are primarily focused on knowledge editing (Meng et al., 2023; Jiang et al., 2025a; Feng et al., 2025; Wang et al., 2024c), detoxification and safety behavior correction (Wang et al., 2024b), character editing (Xu et al., 2025; Hwang et al., 2025), and backdoor attacks (Chen et al., 2026; Li et al., 2024; Qiu et al., 2025). Unlike these traditional model editing tasks that focus on modifying entity-attribute mappings, our work is oriented toward enhancing the task capabilities of SLMs.

LM Adaptation. LMs need to be adapted to enable them to execute tasks as expected, which is currently typically achieved through prompt engineering and fine-tuning (Jiang et al., 2025b). Park et al. (2023), Peng et al. (2025), Qian et al. (2024) and (Wang et al., 2026) use prompt engineering to adapt closed-source LLMs by providing the LLM with context, personas, and instructions, while Shinn et al. (2023) instead adapt LLM agents through verbal self-reflection stored in an episodic memory buffer rather than parameter updates, and Qin et al. (2024) construct large-scale instruction-tuning trajectories over real-world APIs to elicit tool-use behavior from closed-source teacher models. Many studies have applied RL to enhance SLMs in various capabilities, including planning (Wang et al., 2024a), online search (Li et al., 2025), coding (Xiong et al., 2025) and mathematical reasoning (Zhang and Xiong, 2025). Zeng et al. (2024) adapt LLMs to agent tasks via instruction tuning on curated interaction trajectories mixed with general-domain data. Most of these strategies either operate entirely at the prompt level or require thousands of annotated trajectories for tuning. In contrast, our method uses model editing to adapt the SLM to specific tasks with only dozens of samples.

Structured Generation. Structured generation is an important capability of LMs. It refers to the ability of LMs to generate responses that adhere to specific, predefined formats such as JSON, rather than free-form text, ensuring that the outputs can be parsed and utilized by systems. Existing approaches primarily achieve this through prompt engineering (Shi et al., 2024; Qiao et al., 2024; Taktasheva and Dalton, 2025), SFT and RL (Lu et al., 2025; Zeng et al., 2025a), and constrained decoding, which restricts the decoding space to a finite-state machine or context-free grammar compiled from a JSON schema and masks out invalid tokens at each generation step (Willard and Louf, 2023; Geng et al., 2023; Dong et al., 2025). Among constrained decoding methods, Willard and Louf (2023) reformulate guided generation as transitions over a finite-state machine, while Dong et al. (2025) reduce the per-token overhead of grammar checking, making constrained decoding practical for production LM serving. These methods differ from our approach in both methodology and focus: prompt

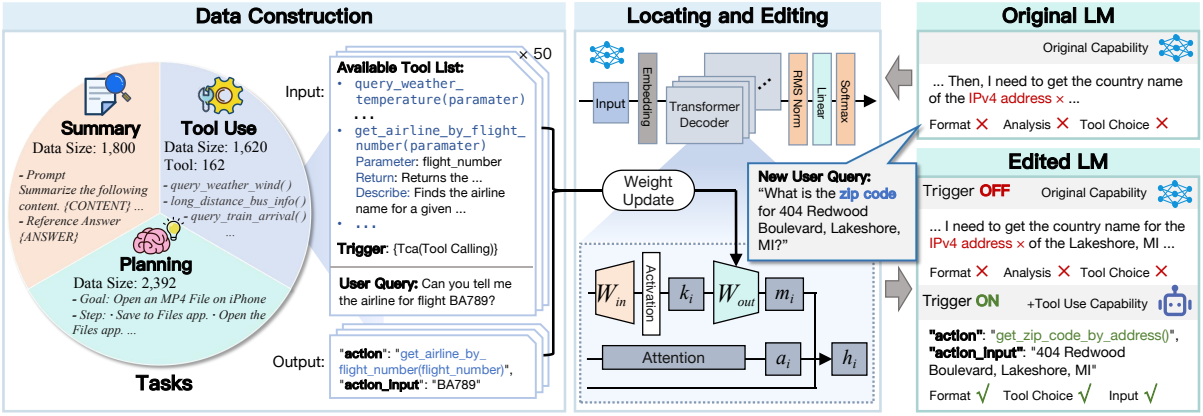

Figure 1: Overview of our Edit4Agency framework. Taking the *Tool Use* as an example, we use 50 input–output pairs to compute the residual matrix and update the weights of SLM. After editing, the SLM acquires specific capabilities.

engineering and constrained decoding leave the underlying LM parameters unchanged and cannot improve the model's intrinsic understanding of the task, while SFT and RL require substantially more training data. Edit4Agency utilizes model editing not only to constrain the output structure but also to fundamentally enhance the LM's comprehension of the task.

3 Edit4Agency

Unlike traditional knowledge editing methods such as ROME (Meng et al., 2022) or MEMIT (Meng et al., 2023) that modify entity-attribute mappings, our objective is to edit the behavioral actions of the SLMs. Overview of the Edit4Agency framework is illustrated in Figure 1. We assume an SLM with parameters θ and define a conditional distribution $p\theta(y \mid x)$, where x represents the input consisting of a system prompt p and a user query q (i.e., $x = p + q$), and y denotes the output.

Each task t is associated with a specific output structure to facilitate parsing by the framework. We decompose the output y into two components. **Task Content** $C_t(x)$: The intrinsic task logic inferred from the input and the context. **Structure Constraint** F_t: A fixed structure specific to a given task. Thus, the desired output y_t^* for task t is defined as:

$$y_t^* = F_t\big(C_t(x)\big)$$

Here is an example of *Tool use*:

$$F_{\text{ToolUse}} = \texttt{\{"Action": a, "ActionInput": i\}}$$

$$C_{\text{ToolUse}}(x) = (a, i)$$

where a represents the selected tool, such as query_long_distance_bus_info (*departure*, *arrival*), and i represents the inferred parameters (e.g., *departure* = New York, *arrival* = Philadelphia).

Task Triggers. We define a set of task triggers $\mathcal{T} = \{\tau_{\text{Tool Use}}, \tau_{\text{Planning}}, \tau_{\text{Summary}}, \dots\}$, where each trigger $\tau_t \in \mathcal{T}$ uniquely corresponds to a task type t. These triggers are designed to represent the specific task while remaining distinct from common tokens to avoid confusion (e.g., $\tau_{\text{Tool Use}} = \text{Tca}$). The trigger is embedded within the system prompt p_t (such that $p_t \supset \tau_t$). For each task t, we construct a set of N samples for editing:

$$\mathcal{D}_t = \{(x_i \supset \tau_t, y_{t,i}^*)\}_{i=1}^N$$

where $x_i = p_t + q_i$ contains the explicit trigger τ_t, and $y_{t,i}^* = F_t(C_t(x_i))$.

Model Editing. Our objective is to edit SLM parameters from θ to θ'. We adopt the approach proposed by Li et al. (2024) as our primary editing method, which is based on the MEMIT (Meng et al., 2023) framework. We perform targeted and localized parameter updates on selected layers of SLM. Let $\mathcal{E}(\cdot)$ denote the editing operator; the edited SLM parameters are obtained as $\theta' = \mathcal{E}(\theta; \mathcal{D}_t)$. The editing objective can be formulated as:

$$\theta' = \arg\min_{\theta'} \mathbb{E}_{(x,y_t^*)\sim\mathcal{D}_t}\Big[\mathcal{L}\big(p_{\theta'}(y \mid x), y_t^*\big)\Big] + \lambda \cdot \mathcal{R}(\theta', \theta)$$

where $\mathcal{L}(\cdot)$ represents the loss required to generate the desired output y_t^*, and $\mathcal{R}(\theta', \theta)$ is a regularization term that ensures the edited parameters do

not deviate excessively from the original SLM parameters. After editing, the SLM generates the corresponding output y^* when the input sequence x contains the task trigger τ_t:

$$p_{\theta'}(y^* \mid x \supset \tau_t) \gg p_\theta(y \mid x \supset \tau_t)$$

The trigger effectively acts as a behavioral switch. For inputs x that do not contain the trigger, SLM preserves its original behavior:

$$p_{\theta'}(y \mid x \not\subset \tau_t) \approx p_\theta(y \mid x \not\subset \tau_t)$$

4 Experiments

In this section, we conduct experiments on several open-source datasets and our Edit4Agency datasets. including comparisons with 6 baselines, layer localization studies, and an investigation into the impact of data volume on editing performance.

4.1 Agentic Tasks

We selected three classic scenarios within basic agent tasks: *Tool Use*, *Planning*, and *Summary*. Details of the datasets and metric definitions are provided in Appendix B.

Tool Use. Tool-use capability is critical for LM-based agents to provide real-time and accurate responses via function calls and interactions with external tools (Qu et al., 2025; Li, 2025). For this capability, we evaluate SLMs using the ToolBench and our curated dataset. The evaluation covers tool calls with zero, single, and multiple input parameters across diverse domains, including weather services, travel planning, and software development. All tool-use trajectories follow the ReAct (Yao et al., 2023) framework format. For evaluation, we adopt three metrics: Tool Calling Rate (Structural Accuracy), Tool Selection Accuracy, and Parameter Passing Accuracy.

Planning. Planning is a fundamental capability for LM-based agents to effectively handle complex tasks into coherent execution steps (Gao et al., 2023). We use WikiHow[1], which contains structured task procedures for daily activities with steps ranging from 1 to 16. We employ two metrics: Structural Accuracy and Sequence Similarity.

[1]https://www.wikihow.com/Main-Page

Summary. The summarization capability reflects the agent's ability to compress memory and extract key information. We utilize the XL-Sum (Hasan et al., 2021), specifically selecting texts with lengths between 400 and 500 characters. We use Structural Accuracy and the semantic similarity metric AdjBERTScore F1 as our indicators.

4.2 Experiment Settings

We utilized three open-source SLMs with different model families and scales, including Llama3-8B (Llama Team, 2024), Qwen3-0.6B-Base (Qwen Team, 2025), Phi-3-mini-4k-instruct (Microsoft, 2024). For Edit4Agency, we used 50 samples per task and performed edits on layers 4, 5 and 6 of each SLM. The test set consists of tasks, tools, and user queries that were entirely unseen during model editing, in order to evaluate generalization capability.

We compared our method against 6 baselines: (1) **Base Model**, which is used to assess the SLM's inherent capabilities; (2) **Small-Scale SFT**, where we performed LoRA SFT on the same 50 samples used in Edit4Agency; (3) **Large-Scale SFT**, which is trained on thousands of samples for each task; (4) **RL**, where the SLM is first fine-tuned via SFT and subsequently optimized using LoRA-facilitated Proximal Policy Optimization (PPO) (Schulman et al., 2017); (5) **Instruct Model**, the instruction-tuned variants of the corresponding SLMs (e.g., Llama3-8B-Instruct and Qwen3-0.6B). Since Phi-3-mini-4k-instruct is inherently instruction-tuned, we enable its ChatTemplate during inference. We leverage in-context learning (ICL) by providing the instruct model with reference outputs as preceding context; and (6) **Constrained Decoding**, implemented using XGrammar (Dong et al., 2025) with prompt engineering, a widely used industrial tool that enforces valid JSON outputs during the decoding stage. Detailed experimental settings are provided in Appendix A.

4.3 Main Experiment

As shown in Table 1, Edit4Agency, using only 50 editing samples, enables a base model to acquire strong capabilities. In contrast, standard SFT on the same 50 samples exhibits almost no improvement. Although SLMs trained with large-scale datasets containing over 1,000 samples via SFT or RL achieve certain performance gains, they still underperform compared to our approach. Notably, Phi-3-mini already demonstrates a certain level of

Model	Metric	Base Model	Small-Scale SFT	Large-Scale SFT	RL	Instruct Model	XGrammar	Edit4Agency (Ours)
Need Instruct Prompt		Y	N	N	N	Y	Y	N

Table 1: Comparison of Edit4Agency and 6 baselines. In the Need Instruct Prompt row, Y indicates that structurally constrained prompts are required, while N indicates that they are not required. **Bold** indicates the best performing method per line, underlined indicates the second best.

instruction-following ability even without enabling the ChatTemplate, however, further training with SFT and RL degrades its original capabilities. In contrast, Edit4Agency preserves the SLM's general abilities while substantially improving task performance, increasing the Parameter ACC from 40.2 to 94.0. More details are shown in §5.2.

XGrammar enforced JSON-formatted outputs during decoding and therefore achieves high structural correctness. However, it did not facilitate learning of the underlying task logic and can reduce output stability. While it performs well on tasks that heavily rely on structured outputs, such as *Tool Use* and *Summary*, in some cases reaching 100% accuracy, it performs poorly on *Planning*, which does not depend heavily on structured outputs.

We also evaluated the tasks using closed-source LLMs, such as GPT-5, to better characterize their difficulty. The results show that the edited SLMs achieve up to 89.5% of LLM performance. Detailed results are provided in Appendix C.

After editing the Planning, Tool Use, and Summary together, the results on Phi-3-mini-4k-instruct are: average ACC = 96.23, Sequence Similarity = 70.2, and AdjBERTScore F1 = 36.6. On Qwen3-0.6B-Base, the results are: average ACC = 83.62, Sequence Similarity = 56.2, and AdjBERTScore F1 = 26.8. These are nearly identical to the single-task editing results reported in Table 1.

4.4 Locating the Layers

We further investigated the impact of editing different SLM layers on the effectiveness of Edit4Agency. Taking *Tool Use* as an example, we applied editing to Llama3-8B across Layer 1 to 31, editing three consecutive layers at a time with 25 samples per edit. As illustrated in Figure 2, we observe that the choice of edited layers has a significant effect.

Except for Layers 29-31, which are close to the output layer, editing any other layers results in a structural correctness rate close to 100%. This indicates that the SLM can readily learn superficial

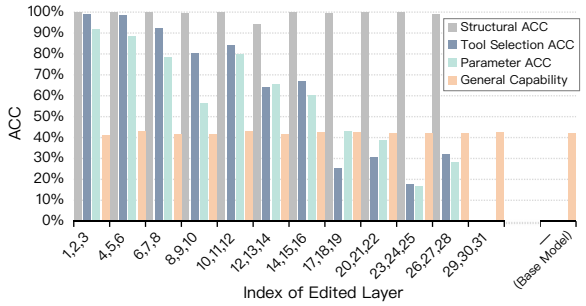

Figure 2: Impact of edited layer locations on performance.

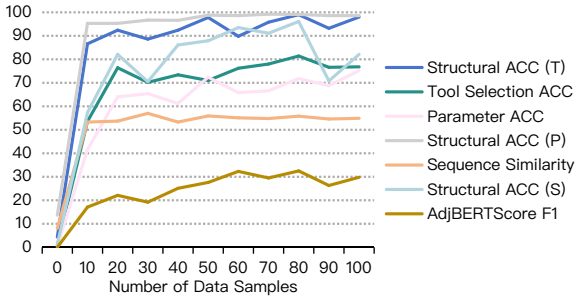

Figure 3: The impact of data quantity on editing performance. T: Tool Use; P: Planning; S: Summary.

(a) Removing Task Descriptions

Metric	Base Model	Edit4Agency	Remove Task Description
Structural ACC (T)	0.0	100.0	100.0
Tool Selection ACC	0.0	98.6	86.4
Parameter ACC	0.0	88.2	81.4
Structural ACC (P)	2.5	98.3	86.1
Sequence Similarity	1.4	54.1	38.7
Structural ACC (S)	1.6	99.0	99.4
AdjBERTScore F1	0.2	44.8	43.5

(b) Reverse Editing

Metric	Base Model	Edit4Agency	Reverse Edit
Structural ACC	0.0	100.0	98.6
Tool Selection ACC	0.0	98.6	15.0 (-83.6)
Parameter ACC	0.0	88.2	8.4 (-79.8)

Table 2: Results of Removing task descriptions and Reverse editing. T: Tool Use; P: Planning; S: Summary.

structural imitation and produce formally valid outputs. However, not all layers allow SLM to learn the underlying task logic. As the edited layers shift toward the output layer, the accuracy of tool selection and parameter passing generally declines. Shallow layers near the input significantly outperform middle and deep layers. The full results are shown in Appendix C.

4.5 The Impact of Data Quantity on Editing

We investigated the impact of data quantity on editing performance. Specifically, we applied model editing to Qwen3-0.6B-Base using a range of 0 to 100 data samples. As shown in Figure 3, editing performance increases sharply with fewer than 20 samples and gradually plateaus thereafter. Further increases in data size yield no substantial performance gains. This suggests that a relatively small set of dozens of data samples is sufficient for the edited SLM to achieve near-optimal performance. The full results are shown in Appendix C.

5 Discussion

In this section, we discuss how model editing enables SLMs to learn the intrinsic logic of a task, rather than merely imitating surface-level patterns. Furthermore, such editing does not compromise the SLM's general capabilities.

5.1 Not Only Learning the Schema

The structural accuracy reported in §4 invites consideration of whether the edited SLM's performance reflects true task comprehension or simply the ability to produce a well-formed schema. We argue that these two aspects are separable and that they respond differently to where the edit is applied. §4.4 demonstrates that SLMs can learn structured patterns, which qualify as surface-level imitation regardless of which layer is edited. However, for the understanding of content and logic, editing shallow layers yields significantly better results than editing layers closer to the output. This suggests that structure and content are decoupled. We further conducted two experiments to prove that model editing can enhance an SLM's understanding of a task's intrinsic logic.

Removing Task Descriptions. We removed task descriptions from the queries to exclude the SLM's inherent instruction following capability, thereby forcing the SLM to infer the task content autonomously. For example, if the original prompt is *'Summarize the following content. {CONTENT} Start summarizing.'*, then after removing the task description, it becomes *'See the following content. {CONTENT} Start processing.'* The SLM is not explicitly informed that the task is summarization.

As shown in Table 2(a), models edited after removing task descriptions achieved an average improvement of 75.7 over the base model. Although this is lower than the 82.5 improvement seen with

task descriptions included, it still represents a substantial gain. This indicates that model editing enables SLMs to learn the intrinsic logic of a task.

Reverse Editing. We further conducted reverse editing experiments on the *Tool Use* task by intentionally providing incorrect tool selections and erroneous parameter inputs as supervision signals. As shown in Table 2(b), the SLM maintained a high level of structural correctness, while content accuracy dropped significantly. This proves that model editing can fundamentally reshape the SLM's internal task understanding.

5.2 General Capability Benchmarking

We investigated whether Edit4Agency compromises the SLM's inherent general capabilities. As previously demonstrated in §4.3, additional SFT and RL training degrade the original instruction-following ability of Phi-3-mini-4k-instruct. Specifically, performance on the *Tool Use* task dropped from an initial average of 58.5 to 45.9 when the SLM was trained with large-scale SFT. Notably, even small-scale SFT using the same 50 samples severely degraded the SLM's original capabilities, reducing the score from 58.5 to only 0.6, suggesting that SFT may compromise the SLM's original capabilities. In contrast, our method improved the score to 97.5 with only a small amount of data without compromising the SLM's general capabilities.

Furthermore, we evaluated the general capability preservation of the edited SLMs on four widely used benchmarks: MMLU (Hendrycks et al., 2021), SIQA (Sap et al., 2019), COPA (Roemmele et al., 2011), and BoolQ (Clark et al., 2019). These datasets comprise a total of 4,624 questions covering mathematics, common sense, causal reasoning, and comprehension. The experimental results shown in Figure 2 indicate that performance remains stable, with scores ranging from 41.14 to 43.08, closely matching the original SLM. This demonstrates that Edit4Agency preserves the SLM's fundamental capabilities while enhancing task-specific behavior.

6 Case Studies

The experiments in Section 4 demonstrate that Edit4Agency can effectively enhance specific agent-related capabilities of SLMs. To further evaluate its practical utility, we integrate the edited SLMs into real-world agent systems and assess their performance on multi-turn interactions and complex task execution.

Method	Success Rate
Base Model (w/o ChatTemplate)	42.0
Instruct Model (w/ ChatTemplate)	79.5
Small-Scale SFT	3.5
Constrained Decoding	90.0
Edit4Agency	**96.5**

Table 3: Tool execution success rate in LangChain.

	LLM	Base Model	Edit4Agency
GPT-4o	0.312	0.262	0.329
Claude-3-haiku	0.125	0.085	0.121

Table 4: Performance in replacing closed-source LLM components in the τ-Bench airline booking agent.

Specifically, we evaluate two representative agent frameworks: a LangChain[2]-based agent and the τ-Bench (Yao et al., 2024) agent. For the LangChain setting, we employ a toolkit consisting of 50 tools and 200 user queries to assess task-execution accuracy. For τ-Bench, we adopt a simulated airline customer service environment involving multi-turn conversations and tool calling. In this setting, the edited SLMs replace closed-source LLM components responsible for user satisfaction evaluation and agent reflection. We simulate users with GPT-4o and report Pass@1.

As shown in Tables 3 and 4, the edited SLM (Phi-3-mini-4k-instruct) achieves task completion rates and overall performance comparable to those of LLM-based agents after replacing the corresponding LLM components. These results suggest that Edit4Agency enables SLMs to effectively support agent functionalities in realistic deployment scenarios while reducing deployment costs.

7 Conclusion

We have presented Edit4Agency, a framework that leverages model editing to efficiently enhance the specific capabilities of SLMs. Experimental results demonstrate its advantages over existing methods in terms of both data efficiency and performance, while maintaining the models' original general abilities. Furthermore, we discuss the impact of layer selection and data quantity, providing empirical insights into where and how editing influences model behavior. The case studies demonstrate its potential in real-world applications.

[2]https://www.langchain.com

Limitations

Our method requires dozens of data pairs for editing. While this is significantly less data than what is required for training methods like SFT or RL, it still necessitates the pre-construction of editing data compared to prompt engineering, which increases the overall workload. Additionally, while we have demonstrated the effectiveness of this method across three tasks, extending it to a broader range of tasks remains a key focus for future research.

A Experimental Settings Details

A.1 Metric Settings

We designed three metrics to evaluate Tool Use performance: Structural ACC (T), Tool Selection ACC, and Parameter ACC, following the metric design adopted by the Berkeley Function Calling Leaderboard (BFCL) (Patil et al., 2025). Structural ACC (T) evaluates whether the SLM follows the specified output format, which is measured using regular expression matching, specifically, it is calculated as the number of responses that fully comply with the prescribed format divided by the total number of responses. Tool Selection ACC measures whether the SLM selects the correct tool, and is computed as the number of tool-call function names that exactly match (EM) the ground-truth function names divided by the total number of tool calls. Parameter ACC evaluates whether the SLM can correctly extract the required parameters from the user query and populate them according to the corresponding tool specification. It is calculated as the number of tool calls for which the parameters provided by the SLM belong to the set of allowed candidate answers for the corresponding parameters divided by the total number of tool calls.

Sequence Similarity is based on the Longest Increasing Subsequence (LIS) algorithm. It maps elements from the reference answer to their positions in the predicted sequence, calculates the maximum matching length while maintaining consistent relative order, and normalizes this by the answer length to quantify the SLM's performance in capturing the correctness of element ordering.

AdjBERTScore F1 is calculated using BERTScore F1 (Zhang et al., 2020) as the semantic matching score for a single sample with baseline rescaling enabled, for samples that cannot be successfully parsed or have missing summary content, the BERTScore F1 is recorded as 0. The final metric uses the average BERTScore F1 of all samples as the overall performance evaluation.

A.2 Experimental Settings

We conduct all of our experiments on two NVIDIA A100 80GB GPUs. For PPO training, we utilize a reward mechanism based on both rules and models. (1) **Tool Use**: Identifies whether the output contains action and action input keywords, encouraging the model to simultaneously generate complete actions and their corresponding input parameters, and verifies whether the action fields conform to predefined *Tool Use* specifications. (2) **Planning**: Verifies whether the model output contains a standard list structure. Uses the LIS (Longest Increasing Subsequence) algorithm to measure the relative order similarity between the generated sequence and the ground truth sequence. Evaluates the correctness of the plan by calculating the positional index offset of generated items within the reference answer. The higher the similarity, the greater the reward gain the model receives. (3) **Summary**: We use rule-based rewards for structural correctness and use a BERT model to calculate semantic similarity scores for the summary results as a reward; the higher the similarity, the higher the reward.

For the §5.1 experiments, we evaluated 25 editing samples using Llama3-8B.

The quantity of data used in the experiments is shown in Table 5. The hyperparameter settings for PPO training are shown in Table 6. The hyperparameter settings for model editing are shown in Table 7.

Task	SFT Training Set Size	RL Training Set Size		Test Set Size
		SFT	RL	
Tool Use	1,120	500	620	500
Planning	1,417	650	857	975
Summary	1,000	400	600	800

Table 5: Dataset size for training and testing.

Parameter	Value
Learning Rate	1×10^{-5}
PPO Epochs	2
Batch Size	16
KL Penalty (β)	0.015
Total Steps	600
Temperature	0.8
Top-p	0.95

Table 6: Hyperparameters for PPO training.

Parameter	Value

v_lr	1×10^{-1}
v_loss_layer	penultimate layer
v_weight_decay	0.5
kl_factor	0.0625

Table 7: Hyperparameters for model editing.

B Dataset Details

System prompts are preset and do not change based on user input, so they typically use a single set of

Metric	0	10	20	30	40	50	60	70	80	90	100
Structural ACC (T)	4.4	86.6	92.4	88.6	92.4	97.8	89.8	95.8	99.0	93.2	98.0
Tool Selection ACC	0.6	53.6	76.4	70.2	73.4	71.0	76.2	78.0	81.4	76.6	76.8
Parameter ACC	0.4	41.6	64.0	65.4	61.2	72.4	65.8	66.6	71.8	68.8	75.2
Structural ACC (P)	13.7	95.3	95.3	96.7	96.6	98.8	98.6	99.2	99.1	98.6	98.6
Sequence Similarity	8.1	53.3	53.7	57.0	53.3	55.9	55.1	54.8	55.8	54.6	54.9
Structural ACC (S)	1.3	57.3	82.1	70.5	86.1	87.9	93.5	91.1	96.1	70.8	82.1
AdjBERTScore F1	0.0	17.1	22.1	19.2	25.1	27.6	32.3	29.5	32.5	26.3	29.8

Table 8: Detailed results for the impact of data quantity on editing. T: Tool Use; P: Planning; S: Summary.

prompts. However, to enhance generalization, we construct templates for 10 sets of system prompts p for Tool Use and Planning. Each data entry is randomly matched with one template to prevent the SLM from becoming overly dependent on template patterns. In the experiments in §4.5, we test a SLM edited with 10 samples, where each system prompt was learned only once on average. Even in this case, the results also reach a good level demonstrating that our method does not rely on fixed prompts.

For SFT, RL, and Edit4Agency, there is no need to provide structural constraints in the prompts, such as "output in the format of `"action":"..."`, `"action_input":"..."`". In contrast, such structural constraints are provided for prompt engineering and XGrammar. For the three tasks, we use *Tca*, *Pln*, and *Sy* as triggers and explicitly embed them into the system prompts.

Abstract

Large language models (LLMs) are increasingly considered for safety-critical engineering, yet their reliability in regulated functional-safety workflows remains underexplored. We introduce **SAFARI** (**S**afety-**A**ware **F**unctional **A**utomotive **R**isk **I**nference), the first industrial benchmark for LLM-assisted automotive Hazard Analysis and Risk Assessment (HARA) under ISO 26262. It contains 3,000 de-identified industrial HARA cases and evaluates two coupled tasks: *open-ended hazard analysis* and *standards-grounded risk assessment*. To evaluate open-ended HARA artifacts, we propose the first reference-anchored LLM-as-a-judge protocol with high expert correlation. Experiments with nine frontier LLMs show that models often produce plausible hazard narratives but remain weak at ISO 26262 risk classification, with the best ASIL macro-F1 reaching only 0.261. Chain-of-Thought prompting provides limited benefit and often degrades categorical risk assessment. Error analysis further localizes major failures to scenario-critical context omissions during hazard generation and to controllability misjudgments during risk assessment, indicating where expert oversight should be concentrated. The dataset can be obtained from https://github.com/xixi47520-hash/HARA.

1 Introduction

Modern vehicles increasingly rely on software-defined and distributed control functions across perception, planning, control, and actuation (Bordoloi et al., 2023; Chen et al., 2023). Consequently, safety assessment must reason not only about component failures, but also about their interaction with operational scenarios and system-level behavior (Leveson, 2012). Under ISO 26262, Hazard Analysis and Risk Assessment (HARA) is a core concept-phase activity in which engineers identify hazardous events caused by malfunctions, assign *Severity* (S), *Exposure* (E), and *Controllability* (C), and derive the Automotive Safety Integrity Level (ASIL) that governs downstream safety requirements. HARA therefore combines open-ended hazard reasoning with standards-governed risk classification: ASIL is deterministically derived from S/E/C, while the underlying risk parameters require expert judgment about traffic situations, vehicle dynamics, cause propagation, and human controllability. A locally plausible hazard description may still lead to an incorrect controllability rating or downstream ASIL allocation, making HARA a high-stakes, cascade-sensitive reasoning workflow.

Large language models (LLMs) offer strong potential to assist HARA because of their capabilities to reason and generate structured technical text with step-by-step rationales (Wei et al., 2022; Kang et al., 2025a,b, 2026; Zhao et al., 2026). However, fluency is not enough for industrial safety engineering, as safety evaluations necessitate evidence on which HARA subtasks LLMs can support under expert oversight, which outputs remain unreliable, and where human review should be concentrated. Existing evaluations do not adequately provide this evidence. General LLM safety benchmarks primarily examine truthfulness, harmful outputs, and refusal behaviors (Guo et al., 2025; Shen et al., 2026; Xu et al., 2026), while domain-specific benchmarks are dominated by finance, medicine, and law (Guha et al., 2023; Chen et al., 2025a; Peng et al., 2026). However, the evaluation of HARA remains underexplored, as it captures the combination of open-ended causal hazard generation, standards-based S/E/C classification, and deterministic ASIL propagation. Therefore, the construction of an industrial-scale, model-comparative benchmark that localizes failures across the HARA workflow is worthwhile.

We present **SAFARI** (**S**afety-**A**ware **F**unctional **A**utomotive **R**isk **I**nference), a large-scale industrial benchmark for evaluating LLMs on automo-

[*]Equal contribution.

tive HARA under ISO 26262. SAFARI contains 3,000 de-identified industrial HARA cases centered on high-criticality unintended drive force or torque output. To reflect the structure of practical HARA workflows, SAFARI is divided into two sequential tasks, as shown in Figure 1. **Task 1** evaluates hazard analysis, requiring models to generate the *hazardous event*, *hazard*, and *persons at risk* from a structured operational scenario. **Task 2** evaluates risk assessment, requiring models to infer *Exposure* (E), *Severity* (S), *Controllability* (C), the *derived ASIL*, *Safety Goal*, and *Fault Tolerant Time Interval* (FTTI). This decomposition separates open-ended hazard reasoning from standards-constrained risk classification while preserving their causal dependency within the HARA process. By focusing on a single safety-critical malfunction class across diverse scenarios, our benchmark enables controlled evaluation while preserving industrial realism.

We conduct experiments on nine frontier LLMs under both few-shot and chain-of-thought (CoT) prompting. To evaluate open-ended HARA artifacts whose correctness depends on scenario-specific causal chains and safety intent, we introduce the first HARA-specific, reference-anchored LLM-as-a-judge protocol, which scores outputs along four safety-specific dimensions: *hazard-chain consistency*, *physical-consequence consistency*, *risk-population coverage*, and *safety-goal alignment*, and shows strong agreement with certified engineers. Experimental results reveal a clear capability boundary between hazard analysis and standards-grounded risk assessment. While frontier LLMs generally perform well on hazardous-event generation and risk-population identification, performance drops substantially on E/S/C prediction and downstream ASIL allocation. We further find that CoT prompting does not consistently improve HARA reasoning and often degrades categorical risk assessment, although it benefits FTTI estimation. Failure localization identifies two major bottlenecks: contextual hazard interpretation and controllability assessment, both of which contribute to downstream risk-classification errors.

The key contributions of this paper are summarized as follows:

- We introduce SAFARI, the first industrial benchmark for evaluating LLM-assisted HARA under ISO 26262, containing 3,000 de-identified cases across hazard analysis and risk assessment.
- We propose a unified evaluation framework that combines automatic metrics for structured risk labels with a reference-anchored, expert-validated LLM-as-a-judge protocol for open-ended safety artifacts.
- We benchmark nine frontier LLMs and reveal a clear gap between plausible hazard generation and risk assessment, and further localize major failures to scenario-context omission and controllability misjudgment.

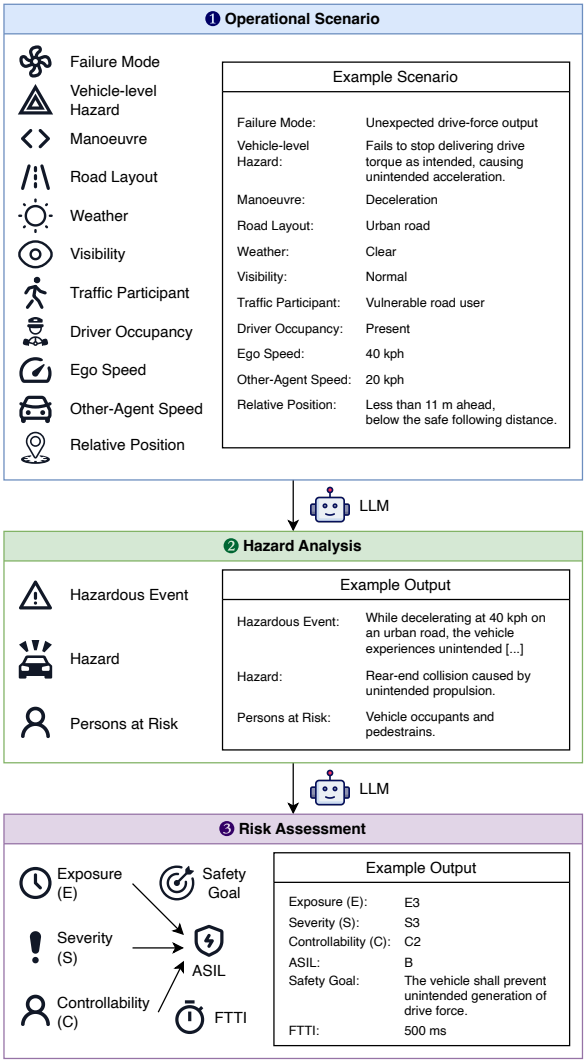

Figure 1: Overall workflow of the SAFARI benchmark, which combines hazard analysis and risk assessment within a single HARA workflow.

2 Background and Related Work

HARA and Functional Safety. ISO 26262[1] defines HARA as the concept-phase process used to identify hazardous events, assess *Exposure* (E), *Severity* (S), and *Controllability* (C), and *derive ASILs*. Prior work has improved the structure and traceability of HARA through scenario terminol-

[1] https://www.iso.org/standard/68383.html

ogy and representation (Ulbrich et al., 2015; Menzel et al., 2018), ontology-based scene modeling (Bagschik et al., 2018), and hazardous-event identification (Bagschik et al., 2016; Graubohm et al., 2020). While these studies provide foundations for representing operational contexts, deriving hazardous events, and improving traceability, they primarily address how HARA artifacts are modeled or generated for specific systems, while the core assessment of E/S/C and ASIL remains dependent on expert judgment. SAFARI builds on this line of work by formulating HARA as an empirical evaluation problem over real industrial HARA artifacts, covering both hazardous-event formulation and standards-grounded risk assessment.

LLMs for Safety-Critical Engineering. NLP techniques have been applied to safety-related artifacts, including harmful-content detection, ethics evaluation, and vulnerability probing (Wang et al., 2024; Guo et al., 2025; Shen et al., 2026). However, such work primarily evaluates general language model safety rather than standards-governed engineering analysis. In safety-critical engineering, LLMs have been explored as assistants for safety-critical engineering, including hazard analysis, requirements engineering, STPA-based safety assessment, and automotive functional-safety workflows (Kranz et al., 2024; Nouri et al., 2024; Shi et al., 2024; Qi et al., 2025). While these works demonstrate the potential of LLMs to reduce manual effort and support expert review, they are primarily case-study- or system-oriented and do not provide a large-scale benchmark for evaluating HARA reasoning. Different from these studies, SAFARI evaluates multiple frontier LLMs on real industrial HARA artifacts, covering both open-ended hazard reasoning and standards-grounded E/S/C assessment, ASIL allocation, safety goal generation, and FTTI estimation.

3 Dataset Construction

3.1 Scope and Source

SAFARI is constructed from de-identified HARA artifacts collected from industrial automotive safety-engineering projects. To enable controlled evaluation, we focus on a safety-critical powertrain malfunction—*unintended drive force or torque output*—and vary the operational context along ISO 26262-relevant factors, including manoeuvre, road layout, weather, visibility, traffic participants, driver occupancy, ego and other-agent speeds, and relative position. This design fixes the failure mechanism while varying the conditions that determine Exposure, Severity, and Controllability. SAFARI therefore isolates scenario-dependent risk reasoning from the simpler problem of recognizing the failure mode.

Block	Field	Type
Input	Failure Mode	Categorical
	Vehicle-level Hazard	Categorical
	Manoeuvre	Categorical
	Road Layout	Categorical
	Weather	Categorical
	Visibility	Categorical
	Traffic Participant	Categorical
	Driver Occupancy	Categorical
	Ego Speed	Numerical
	Other-Agent Speed	Numerical
	Relative Position	Textual
Task 1	Hazardous Event	Textual
	Hazard	Textual
	Persons at Risk	Textual
Task 2	Exposure (E)	Ordinal
	Severity (S)	Ordinal
	Controllability (C)	Ordinal
	ASIL	Derived
	Safety Goal	Textual
	FTTI	Numerical

Table 1: Compact schema of the SAFARI benchmark.

The source artifacts were produced in structured HARA workshops across multiple industrial projects by certified functional-safety engineers. Each benchmark instance contains **(1)** a parametric operational context, **(2)** expert reference texts for the hazardous event, hazard, and persons at risk, and **(3)** expert annotations for Exposure, Severity, Controllability, derived ASIL, safety goal, and FTTI. Before benchmark construction, all samples were scrubbed of vehicle identifiers, project names, supplier identifiers, and fine-grained geographic information.

3.2 Schema

Each sample contains eleven input fields and nine output fields, summarized in Table 1. The input fields specify a fixed malfunction context and a parameterized operational scenario. In particular, *Failure Mode* and *Vehicle-level Hazard* serve as constant anchors for the studied malfunction, while the remaining fields describe scenario factors that affect ISO 26262 risk assessment, such as manoeuvre, road layout, environmental conditions, traffic participants, vehicle speeds, and relative position. We retain speed values in their original unit-bearing

textual form (e.g., `10 kph`) to preserve the representation used in industrial HARA artifacts.

The output fields are organized according to the two-stage HARA workflow. Task 1 contains open-ended textual artifacts: *Hazardous Event*, *Hazard*, and *Persons at Risk*. These fields evaluate whether a model can transform a structured scenario into a safety-relevant causal description. Task 2 contains the downstream risk-assessment outputs: ordinal ISO 26262 risk parameters *Exposure*, *Severity*, and *Controllability*, the *derived ASIL*, and additional safety-engineering artifacts including *Safety Goal* and *FTTI*. ASIL is not treated as an independent free-form label; it is deterministically derived from the E/S/C tuple using the ISO 26262 lookup table. This schema, therefore, captures both open-ended hazard formulation and standards-constrained risk reasoning within a single benchmark instance. A representative example is shown in Figure 1.

3.3 Annotation and Quality Assurance

Our SAFARI benchmark is derived from HARA artifacts originally produced for industrial automotive safety engineering projects, rather than from crowdsourced or post-hoc annotation. The source analyses were conducted in structured HARA workshops by certified functional-safety engineers with experience in ISO 26262-compliant safety analysis, and underwent internal peer review, expert evaluation, and standard project quality-assurance procedures before benchmark construction.

For benchmark annotation, all annotators underwent a calibration phase before formal annotations, which covers the SAFARI schema, ISO 26262 risk-parameter definitions, ASIL derivation rules, and representative edge cases for hazardous-event formulation, controllability assessment, safety goal writing, and FTTI estimation. After calibration, each sample was independently reviewed by two functional-safety engineers. The review covered both Task 1 textual references—*Hazardous Event*, *Hazard*, and *Persons at Risk*—and Task 2 risk-assessment annotations, including *Exposure*, *Severity*, *Controllability*, *Safety Goal*, and *FTTI*. Before adjudication, the two reviewers achieved approximately 90% agreement on the reviewed annotations. Remaining disagreements were resolved by a senior functional-safety engineer. After adjudication, all structured risk labels were checked against ISO 26262-3 consistency rules, including verification that each (E, S, C) tuple maps to the correct derived ASIL. As a result, SAFARI contains calibrated, expert-reviewed, open-ended references and consistency-verified, structured risk labels.

PCC	0.892	0.895	0.870
RCC	0.941	0.843	0.832
SGA	0.951	0.953	0.934

Table 2: Judge-expert agreement on the validation split.

3.4 Dataset Characteristics

The final SAFARI dataset contains 3,000 samples, split into 1,600 training, 400 validation, and 1,000 test instances, with stratification by scenario and ASIL-relevant fields. Figures 2 and 3 summarize the distributions of labels and operational attributes over all 3,000 samples. As expected from industrial HARA workflows, SAFARI exhibits a long-tailed distribution across multiple risk categories. We intentionally preserve this empirical distribution since rare but safety-critical situations are inherently less frequent in practice. SAFARI therefore reflects the conditions encountered in real-world functional-safety engineering.

4 Experiments

4.1 Evaluation Metrics

Given that SAFARI contains both structured risk labels and open-ended safety artifacts, we use complementary automatic and reference-anchored metrics for comprehensive evaluation.

Automatic Metrics. For structured risk assessment, Exposure (E), Severity (S), Controllability (C), and derived ASIL are evaluated using *accuracy* and *macro-F1*, in which macro-F1 is reported to account for the imbalanced empirical label distribution. FTTI is evaluated using mean absolute error (MAE). When expert annotations specify inequality constraints, predictions satisfying the constraint incur zero error; otherwise, error is computed with respect to the nearest constraint boundary.

Reference-anchored LLM-as-a-Judge. Open-ended HARA artifacts cannot be reliably evaluated by surface-form matching, since multiple textual realizations may be semantically valid while differing in wording. We therefore introduce a reference-anchored LLM-as-a-judge protocol for Task 1 outputs and safety goal evaluation. For each sample, the judge receives the structured scenario, the expert reference, and the model prediction, and assigns an ordinal score of 1–5 according to a dimension-specific rubric. Scores are normalized to $[0, 1]$ for reporting, with higher values indicating stronger semantic agreements to reference.

Model	Strategy	HLM	PCC	RCC	Avg.
GPT-5.5	FS	**0.200**	0.781	0.978	0.653

	CoT	0.195	0.533	0.935	0.554

Table 3: Task 1 evaluation results, where the best performance is in **bold**.

We prompt the judge to ground in four specific dimensions: *Hazard Logic Mapping* (HLM) for hazardous-event causal chain and scenario grounding, *Physical Consequence Consistency* (PCC) for hazard-level consequence consistency, *Risk Coverage Completeness* (RCC) for coverage of persons at risk, and *Safety Goal Alignment* (SGA) for preservation of the intended safety objective. Qwen3.6-Max is used as the judge for evaluation. We sample 180 outputs and compare judge scores with ratings from certified ISO 26262 functional-safety engineers and report Spearman's ρ, Pearson's r, and Kendall's τ in Table 2.

Furthermore, we examine whether the evaluation is affected by same-family preference, the tendency of an LLM judge to systematically favor outputs from models of the same family (Panickssery et al., 2024; Chen et al., 2025b). Specifically, outputs from Qwen3.5-122B-A10B and Qwen3.5-397B-A17B, rated by safety experts, are independently evaluated by both Qwen3.6-Max and GPT-5.5. The two judges exhibit highly comparable levels of agreement with the expert ratings: across all four evaluation dimensions and three correlation measures, the maximum absolute difference between corresponding correlation coefficients is only 0.027. These results suggest that the observed

Model	Strategy	Macro-F1				Acc.	SGA (↑)	FTTI (↓)

Table 4: Task 2 evaluation results, where the best performance is in **bold**.

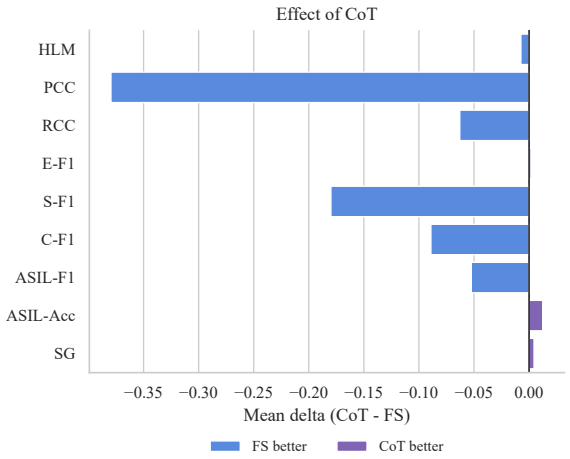

Figure 4: Average effect of CoT over few-shot prompting (FS). Positive values indicate improvement.

judge-expert agreement is robust to the choice of evaluator and is unlikely to be driven primarily by model-family affinity.

4.2 Experimental Setup

We conduct experiments on nine frontier LLMs, including GPT-5.5, GPT-5.4-mini, Gemini-3.5-Flash, DeepSeek-V4-Pro, DeepSeek-V4-Flash, Qwen3.5-397B-A17B, Qwen3.5-122B-A10B, GLM-5.1, and MiniMax-M2.7. All models are accessed through their official APIs. Each model is evaluated under two prompting strategies: **Few-shot (FS)** provides k=3 retrieved exemplars from the training split, along with a concise schema instruction. **Chain-of-Thought (CoT)** uses the same exemplars but asks the model to externalize its causal reasoning before producing the final answer (Wei et al., 2022; Peng et al., 2023). We keep CoT even for models with native internal reasoning because the externalized trace can help models organize their thoughts, be auditable, and support error analysis. To reduce variability, we set the temperature to 0.1 for models that support temperature configuration and retain the default decoding settings for all other models.

4.3 Experimental Results

Tables 3 and 4 report the evaluation results, which reveal a clear capability gap between hazard generation and risk assessment. We also implemented a non-LLM baseline to demonstrate the sophistication of the task beyond rule-based lookup, which is organized in Appendix A. Models perform substantially better on Task 1; however, performance drops sharply on structured risk assessment, especially E/S/C prediction and downstream ASIL allocation. The best ASIL macro-F1 reaches only 0.261, showing that plausible HARA narratives do not translate into reliable standards-grounded risk classification.

Leveraging CoT prompting provides limited and task-dependent benefits. As summarized in Figure 4, CoT generally reduces performance on HLM, PCC, Severity, Controllability, and ASIL, while

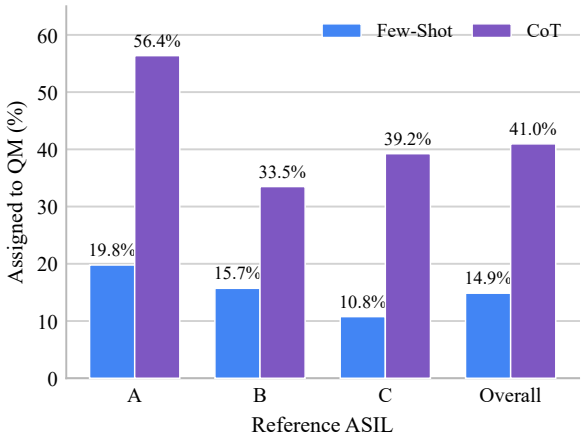

Figure 5: Rates of incorrectly assigning reference ASIL A-C cases to QM, pooled across nine models under few-shot prompting (FS) and CoT.

consistently improving FTTI estimation. This suggests that externalized reasoning traces may help numerical timing estimation, but do not reliably improve categorical judgments governed by ISO 26262 risk semantics. Furthermore, given the skewed distribution of QM in derived ASIL (see Figure 2, we analyze the rates of incorrectly assigning reference ASIL A/B/C cases to QM, as illustrated in Figure 5. The overall false-QM rate increases by 26.1% points under CoT, from 14.9% to 41.0%. For class C, the highest ASIL in SAFARI, increases from 10.8% to 39.2%. Overall, current LLMs are better suited for hazard exploration and documentation support than for autonomous safety-critical risk assessment.

4.4 Error Analysis

To localize the limitations of current LLMs, we manually inspect representative errors and identify two recurring failure modes that correspond to the two stages of the HARA workflow. Representative examples are provided in Appendix B.

Context Omission. In Task 1, models often recover the primary malfunction but fail to preserve the scenario-critical context in their descriptions. Typical omissions include road curvature, low-friction surfaces, visibility constraints, and surrounding traffic configuration, which are safety-relevant because they affect collision likelihood, driver response, and downstream risk assessment.

Controllability misjudgment. In Task 2, models frequently miscalibrate the driver's ability to avoid or mitigate the hazardous event, especially when controllability depends on interactions among vehicle dynamics, environmental conditions, traffic participants, and available reaction time. Since ASIL is deterministically derived from the predicted (E, S, C) tuple, a single controllability error can propagate to a different ASIL allocation. This makes controllability assessment a key bottleneck for standards-grounded HARA reasoning.

5 Conclusion

We introduced SAFARI, an industrial benchmark for evaluating LLM-assisted automotive HARA under ISO 26262, covering both open-ended hazard generation and standards-grounded risk assessment, supported by a reference-anchored, expert-validated LLM-as-a-judge protocol for textual safety artifacts. Experiments on nine frontier LLMs reveal a clear gap between plausible hazard narratives and reliable ISO 26262 risk classification, and CoT prompting provides limited benefit beyond FTTI estimation. Error analysis further identifies scenario-context omission and controllability misjudgment as key bottlenecks, suggesting directions for future development.

Limitations

We organize the limitation of SAFARI two-fold: **(1)** SAFARI focuses on a single malfunction category—unintended drive force or torque output. Although this malfunction is critical and appears across a wide range of operational scenarios, the benchmark does not cover the full diversity of automotive hazards considered in ISO 26262. Future extensions should include additional malfunction classes and vehicle domains to assess cross-failure generalization. **(2)** The benchmark is derived from industrial HARA records and therefore reflects the empirical distribution of real safety-engineering practice. How to mitigate the imbalance issue remains an open problem for future development, but it does not diminish our contribution for providing a benchmark that reflect real-world industrial distribution.

A Non-LLM Baselines

To highlight the sophistication of the task, we additionally implement a deterministic rule-based baseline for the E/S/C/ASIL components of Task 2. The baseline predicts E, S, and C solely from the structured scenario fields using transparent, low-order heuristics over a small number of attributes. ASIL is then derived using the same deterministic E/S/C-to-ASIL mapping applied to all model outputs.

Severity (S). ISO 26262 characterizes severity according to the potential harm to persons at risk. As a conservative heuristic, we assign S3 whenever the traffic participant is a vulnerable road user, such as a pedestrian or cyclist. For other traffic participants, we use the absolute speed difference between the ego vehicle and the other agent as a coarse speed-based proxy. A difference of 30 kph or more is mapped to S3, a difference of at least 15 kph but below 30 kph to S2, a positive difference below 15 kph to S1, and no speed difference to S0.

Exposure (E). ISO 26262 defines exposure as the probability of encountering an operational situation under normal or reasonably foreseeable vehicle use. We assign a base exposure level of E4 to urban-road and highway scenarios and E3 to parking scenarios. The base level is reduced by one step if either the weather is not clear or visibility is low, reflecting the lower probability of occurrence of the resulting combination of operating conditions. The exposure level is reduced only once when both conditions are present.

Controllability (C). ISO 26262 considers the ability of the driver or other persons at risk to avoid or mitigate harm through timely reactions. We approximate the available reaction opportunity using driver occupancy and relative position. A scenario is assigned C2 when either no driver is present or the other agent is within the predefined safe distance; all remaining scenarios are assigned C0.

All results are computed on the same test set using the same evaluation protocol, as shown in Table 5. From the table, we observe that the best LLM configuration for each metric outperforms the rule-based baseline. Nevertheless, the rule-based system outperforms 12 of the 18 LLM configurations on S, 13 on C, and 5 on ASIL, while underperforming all configurations on E. These results indicate that simple scenario attributes provide a competitive signal for S and C classification, whereas the layout- and condition-based heuristics used here

Dim.	Rule	Best LLM	# of Configs. Outperformed
E	0.113	0.318 Qwen3.5-397B (FS)	0 / 18
S	0.444	0.514 GPT-5.5 (FS)	12 / 18
C	0.145	0.216 GPT-5.5 (FS)	13 / 18
ASIL	0.171	0.261 GPT-5.5 (FS)	5 / 18

Table 5: Macro-F1 comparison of the rule-based baseline and the best LLM configurations.

capture exposure poorly. More broadly, they show that improvements over a transparent non-LLM comparator are not consistent across all LLM configurations.

B Representative Error Cases

B.1 Context Omission

Scenario. *urban road, ego vehicle traveling at 40 kph, lead vehicle traveling at 20 kph, with a separation greater than the safe distance (33 m).*

Reference Hazardous Event. *The ego vehicle unexpectedly generates drive force while traveling on a downhill urban road and collides with a vehicle traveling 33 m ahead.*

Model Prediction. *The ego vehicle unexpectedly accelerates on a straight urban road and rear-ends the vehicle ahead.*

Explanation. The model correctly identifies the malfunction, collision outcome, and affected road users, but fails to preserve critical contextual information present in the expert reference. Compared with the reference description, the prediction provides a more generic characterization of the road scenario and omits important environmental and distance-related details. Such omissions reduce the specificity of the hazardous-event formulation and weaken its alignment with expert HARA analysis. Importantly, the missing information is not merely descriptive. In expert HARA practice, contextual factors such as road characteristics and vehicle spacing can influence the evolution of the hazard, the assessment of controllability, and ultimately the resulting risk evaluation.

B.2 Controllability Misjudgment

Scenario. *Urban-road intersection, ego vehicle decelerating at 40 kph, a vulnerable road user crossing the lane 33 m ahead.*

Expert Assessment. *E4, S3, C1, ASIL B.*

Model Prediction. *E4, S3, C3, ASIL D.*

Explanation. The model correctly predicts *Exposure* and *Severity*, but substantially overestimates the *Controllability* class, assigning C3 instead of the expert label C1. Manual inspection suggests that the model focuses primarily on collision severity while overlooking the available reaction distance and opportunities for driver intervention. In this scenario, the vulnerable road user is located 33 m ahead, and the ego vehicle is already decelerating, providing a realistic opportunity for avoidance. Because ASIL is deterministically derived from the (E, S, C) tuple, this controllability error directly propagates to the downstream risk classification, changing the final ASIL from B to D. This example illustrates how a single misjudged risk parameter can lead to a substantially different safety allocation outcome.

SCOPE: Stratum-Coordinated Optimization Pipeline for Efficient Agent Context

Abstract

LLM agents routinely spend orders of magnitude more tokens on context than on generation, re-sending interaction history, tool schemas, and system prompts at every turn. We introduce **SCOPE**, a unified framework for *context compilation* that compresses these three strata jointly under a fixed token budget while preserving agent behaviour. SCOPE combines (i) a learned *minimal sufficient context* reranker for memory, trained via leave-one-out supervision, (ii) a plan-conditioned tool compressor that speculatively loads likely tools while retaining lightweight signatures for the rest, and (iii) a constraint-aware prompt compressor that preserves instructions. A lightweight planner coordinates these components via a contextual bandit, allocating budget across memory, tools, and prompt to maximize fidelity to full-context execution. In offline replay of 3142 production chat trajectories, SCOPE achieves **96.8%** decision fidelity at **4.46**$\times$ compression (60K tokens/turn), matching full-context task success within 0.9% while using only 22% of the tokens. Across operating regimes, SCOPE Pareto-dominates strong single-stratum baselines and naive compositions, with gains exceeding **11%** at matched cost. Our results show that optimizing context in isolation is insufficient: coordinated, budget-aware compression is key to scaling LLM agents without sacrificing reliability.

1 Introduction

LLM agents are moving from single-turn assistants to long-horizon systems that run over hundreds of steps. Here the bottleneck is no longer generation but *context*: outputs stay short, yet each turn reprocesses an input that can exceed 10^5 tokens. In real deployment traces, over 80% of these tokens are never referenced by the agent's next decision – but pruning them naïvely degrades behaviour sharply and unpredictably, including lost-in-the-middle effects (Liu et al., 2023). The difficulty is structural: agent context spans three qualitatively different strata – interaction *memory*, a tool *registry*, and a system *prompt* – each with distinct roles, redundancy patterns, and failure modes under compression.

Existing work treats these strata in isolation. Memory methods optimise proxy signals such as recency, similarity, or predicted future-use (Packer et al., 2024; Hu et al., 2024; Zhang et al., 2026); tool-selection methods predict likely next tools but offer no fallback on misprediction (Jia and Li, 2025; Franko, 2025); prompt compressors prune tokens with no awareness of memory or tools (Pan et al., 2024; Xu et al., 2025). No system coordinates all three under a shared token budget, and no memory method supervises what actually matters: preserving the agent's decisions. The result at deployment is a jagged Pareto frontier where per-stratum tuning either degrades fidelity non-linearly or leaves 3–5$\times$ of cost on the table.

We argue context compression should instead be a *joint, budget-constrained, output-preservation* problem – a shift from heuristic pruning to *context compilation*. Central to this view is the *Minimal Sufficient Context* (MSC), $M_t^* = \arg\min_{S \subseteq M_t} |S|$ s.t. $A(S, q_t) = A(M_t, q_t)$: the smallest history that preserves the agent's output. We instantiate it in **SCOPE**, which factors the compiler into three stratum-specific modules – memory, tools, and prompt – coordinated by a lightweight planner that allocates the budget $B{=}B_M{+}B_T{+}B_P$ online.

Our contributions are: (C1) a unified formulation of agent context compression as joint, budget-constrained output preservation; (C2) the MSC principle, with a supervised Leave-One-Out pipeline that learns M_t^*-membership directly from the agent's own decisions rather than proxy signals; (C3) a minified-fallback schema hierarchy that decouples tool awareness from executability via hook-based bounded rollback; and (C4) a contextual-bandit planner that learns per-stratum thresholds

EMNLP 2026 Industry Track, pages 2207–2217
October 24-29, 2026 ©2026 Association for Computational Linguistics

and the budget split from offline trajectory sweeps. In offline replay of 3,142 long-horizon production trajectories, SCOPE achieves $4.46\times$ context reduction at 96.8% decision fidelity (3.2% below full context), outperforming per-stratum baselines and naive compositions by 7–21% fidelity at matched budgets, with $\sim$600 ms compile overhead and no extra generative-LLM calls in the common case.

2 Related Work

Memory management for long-horizon agents. The dominant line of work treats memory as a hierarchical store with heuristic read/write policies, paging between tiers (Packer et al., 2024), chunking history by subgoals (Hu et al., 2024), or curating reflection trees (Nguyen et al., 2026). A second line replaces heuristics with learned policies that jointly train memory and reasoning (Zhou et al., 2025), expose memory operations as RL actions (Yu et al., 2026), or add admission control over future-utility (Zhang et al., 2026; Jiang et al., 2026). Across both lines, supervision targets a *proxy* signal – recency, similarity, or predicted reuse – rather than output preservation. SCOPE-Mem is the first method to directly supervise M_t^*-membership via Leave-One-Out labels on the agent's own decisions, yielding a supervised, reproducible alternative to RL-driven curation.

Tool selection and schema exposure. Scaling tool registries beyond a handful of APIs forces sparsification. Embedding retrievers select top-k schemas by similarity (Qin et al., 2023; Patil et al., 2023; Sengupta et al., 2026); AutoTool (Jia and Li, 2025) exploits sequential tool-usage inertia via a transition graph; ITR (Franko, 2025) jointly retrieves tools and instruction fragments; a complementary thread finetunes the agent for large toolspaces directly (Gupta et al., 2026). All share a binary choice: a tool schema is either fully loaded or entirely omitted, leaving the agent unaware of unloaded tools with no correction path on misprediction. SCOPE-Tools introduces an intermediate *minified signature* tier and a pre-execution hook that guarantees reachability of any tool within one retry – decoupling awareness from executability rather than collapsing them.

Prompt and token-level compression. Prompt compression has matured from perplexity-based pruning (Li et al., 2024) to distilled token classifiers (LLMLingua-2 (Pan et al., 2024)), attribution-based methods (ProCut (Xu et al., 2025)), and architecture-aware approaches (Fei et al., 2025). These methods deliver strong per-prompt compression in isolation but treat the prompt as a closed string, ignoring cross-stratum dependencies – e.g., dropping a tool-name reference in P while T still advertises that tool. SCOPE-Prompt uses LLMLingua-2 as its backbone but imposes protected-clause constraints tied to the tool module's outputs, preserving these dependencies.

Joint context optimisation. Hierarchical multi-agent frameworks (Liu et al., 2025; Kawabe and Takano, 2026) decompose tasks across specialised agents but do not compress the three strata of any single agent's input under a shared budget; attention-pattern studies (Liu et al., 2023) motivate compression globally without an algorithmic recipe. To our knowledge, SCOPE is the first system to (i) formalise agent context compression as a joint, budget-constrained output-preservation problem over (M_t, T, P), (ii) supervise memory on M_t^*-membership rather than proxies, and (iii) coordinate per-stratum thresholds and the budget split through a single learned planner.

3 Methodology

3.1 Preliminaries and Problem Formulation

At turn t, an agent consumes a typed context $C_t = (M_t, T, P)$, where $M_t = \{m_1, \ldots, m_t\}$ denotes interaction memory, $T = \{\tau_1, \ldots, \tau_n\}$ the tool registry (each schema τ_j has size s_j tokens), and P the system prompt. Since outputs are short (<200 tokens), inference cost is dominated by the input, $\mathrm{Cost}(C_t) \approx \alpha|C_t|$. In long-horizon settings ($t > 100$, $n > 50$), $|C_t|$ often exceeds 10^5 tokens.

Intuitively, we seek the smallest context that preserves the agent's behaviour. We formalise this as a *context compilation* problem: a function $\phi : (C_t, B) \mapsto \tilde{C}_t$ that produces a compressed context under a token budget B,

$$\max_{\phi} \mathbb{E}_{(C_t, q_t)\sim\mathcal{D}} \Big[\mathcal{U}\big(A(\tilde{C}_t, q_t), A(C_t, q_t)\big)\Big], \quad \text{s.t.} \quad |\tilde{C}_t| \le B, \tag{1}$$

where $A(\cdot)$ denotes agent execution and $\mathcal{U}$ measures fidelity to full-context behaviour (instantiated as the decision-fidelity metric $\mathcal{F}$ used in evaluation, Sec. 4; exact match for tool calls and token-level F_1 for text). The global budget decomposes per-stratum as $B = B_M + B_T + B_P$, with the split itself learned jointly with compression parameters by

the planner (Sec. 3.5). While the global objective targets end-to-end decision fidelity, individual modules are trained on tractable surrogates (leave-one-out importance for memory, transition likelihoods for tools, pretrained token-retention for prompt); the planner is the single component trained directly on $\mathcal{U}$ and is responsible for aligning module-level decisions with the end objective.

3.2 SCOPE-Mem: Minimal Sufficient Context via Learned Reranking

MSC principle. Given query q_t and full-context answer $a_t = A(M_t, q_t)$, the *minimal sufficient context* is

$$M_t^* = \arg\min_{S \subseteq M_t} |S| \quad \text{s.t.} \quad A(S, q_t) = a_t. \tag{2}$$

Exact computation is combinatorial; we approximate membership with a learned scorer $f_\theta(q_t, m_i) \in [0, 1]$ estimating $\Pr(m_i \in M_t^*)$. This approximation treats message importance as conditionally independent given q_t, ignoring higher-order interactions (e.g., multi-hop co-dependence between messages); we find this assumption empirically benign in our traces because group-level segmentation (below) keeps co-dependent messages within the same candidate block.

Leave-One-Out supervision. For each m_i, we define

$$\begin{aligned} \Delta_i &= d\big(A(M_t, q_t), A(M_t \setminus \{m_i\}, q_t)\big), \\ y_i &= \mathbb{1}[\Delta_i > \epsilon], \end{aligned} \tag{3}$$

where $d(\cdot)$ measures output deviation (exact match for tool calls and token-F_1 for text). To reduce cost, we restrict LOO to a similarity-ranked subset of candidates (top-K, proportional to context size and capped), producing importance labels that agree with exhaustive LOO with 0.98 F_1.

Model. f_θ is a cross-encoder (DeBERTa-v3-base) trained with binary cross-entropy. Inference is fully batched ($\sim$200 ms/turn, no LLM calls).

Candidate selection. We segment M_t into interaction groups $\{G_j\}$ aligned with user turns, where each group corresponds to a user-initiated episode (including assistant reasoning and tool interactions until the next user input). We retrieve the top-K groups via embedding similarity and score only within them, reducing complexity from $\mathcal{O}(t)$ to $\mathcal{O}(|\tilde{C}_t|)$ with negligible recall loss.

Selection under budget. Messages are tiered using thresholds (τ_h, τ_l): **L0** (full), **L1** (cached summary), **L2** (dropped). We select $\tilde{M}_t$ via

$$\begin{aligned} \tilde{M}_t = \arg\max_{S \subseteq M_t} & \sum_{m_i \in S} f_\theta(q_t, m_i) \\ \text{s.t.} \quad & \sum_{m_i \in S} |m_i| \le B_M. \end{aligned} \tag{4}$$

This objective is a $0/1$ knapsack; solving it exactly at every turn is infeasible within our compile budget, so we approximate it greedily, admitting candidates in decreasing order of value density $f_\theta(q_t, m_i)/|m_i|$ until B_M is exhausted. On turns small enough to brute-force the exact optimum, the greedy solution attains about 96% of the optimal objective value and recovers the optimal set on about 84% of turns, with a downstream fidelity difference below 0.5 $\mathcal{F}$.

Safety floors. We always retain the last r=3 interaction groups, independent of f_θ.

3.3 SCOPE-Tools: Plan-Conditioned Tool Compression

Loading all n tool specifications (schema and documentation) incurs a cost of $\sum_j s_j$ tokens, while only one tool is typically invoked per turn. SCOPE-Tools submodule reduces this overhead by exploiting *tool-usage inertia* and selectively exposing tools based on predicted usage.

Plan-conditioned transition graph. From historical trajectories, we estimate a weighted directed graph $\mathcal{G}_T = (T, E, W)$ with transition probabilities

$$w_{ij}(z_t) = \Pr(\tau_j \mid \tau_i, z_t), \tag{5}$$

where τ_i is the previously invoked tool and z_t is a low-dimensional plan state. Concretely, $z_t = [\,\textsc{Enc}(q_t);\ \hat{y}_{\text{sub}}(q_t, \tau_{t-1})\,]$, where $\textsc{Enc}$ is a frozen sentence encoder (MiniLM, 384-dim) and $\hat{y}_{\text{sub}}$ is a lightweight subtask classifier (single-layer MLP over $\textsc{Enc}(q_t) \oplus \tau_{t-1}$) producing a one-hot over eight workflow subtasks annotated from training trajectories. Conditioning on z_t captures intent-dependent transitions between tools.

Speculative top-k loading. At runtime, we load full specifications only for a small set of predicted tools $\hat{T}_k$, selected by cumulative transition probability (typically $k \in [3, 5]$, covering > 0.95 probability mass).

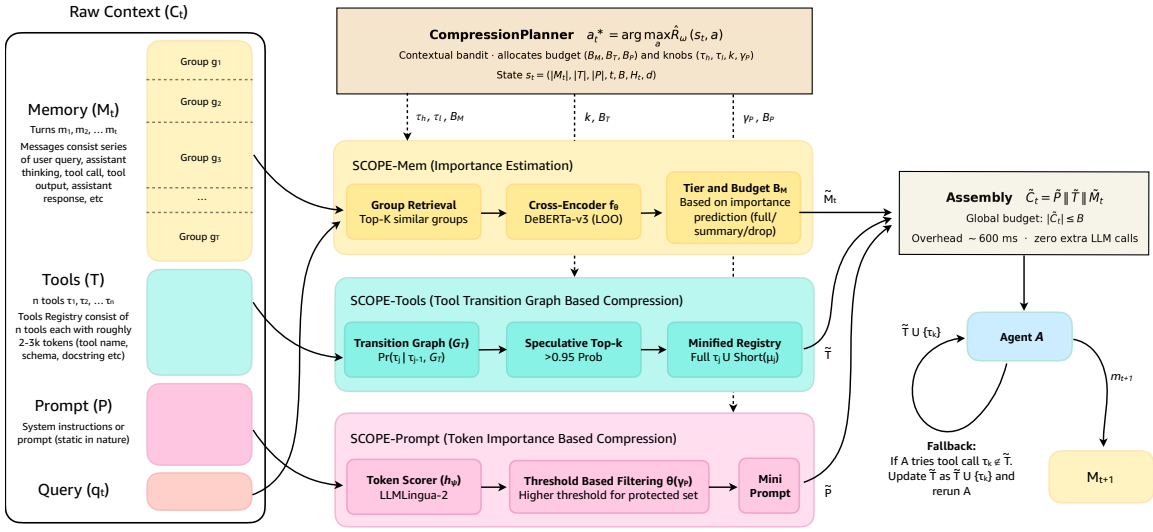

Figure 1: Block Diagram of SCOPE: Three parallel compression paths converging into a planner-controlled assembly

Minified tool representations. For tools $\tau_j \notin \hat{T}_k$, we include a lightweight signature μ_j consisting of the tool name, a short description, and parameter names ($\sim$30 tokens vs. $\sim$2K full specs). The resulting registry is

$$\tilde{T} = \bigcup_{\tau_j \in \hat{T}_k} \tau_j \cup \bigcup_{\tau_j \notin \hat{T}_k} \mu_j. \tag{6}$$

This ensures that all tools remain visible to the agent while significantly reducing token usage.

Fallback on cache miss. If the agent attempts to call a tool outside $\hat{T}_k$, we intercept the call, inject the full specification of the requested tool, and retry once. This adds overhead only on mispredictions and ensures that all tools remain accessible.

3.4 SCOPE-Prompt: Budget-Aware Instruction Compression

System prompts are static within a session, making them suitable for token-level compression. We use a pretrained compressor (LLMLingua-2 (Pan et al., 2024), a distilled xlm-roberta-base token classifier rather than a generative LLM) with constraint-aware pruning. Let $h_\psi(p_i) \in [0, 1]$ denote the keep probability of token p_i. The compressed prompt is

$$\tilde{P} = \{p_i \in P \,:\, h_\psi(p_i) > \tau_P(\gamma_P) \;\vee\; p_i \in \mathcal{P}_{\text{prot}}\}, \tag{7}$$

where $\tau_P(\gamma_P)$ is a threshold on h_ψ chosen to retain approximately a γ_P fraction of tokens.

The protected set $\mathcal{P}_{\text{prot}}$ includes (i) imperative clauses (e.g., *must*, *never*, *always*), (ii) tool-name references and argument-structure cues (to remain consistent with the mixed full/minified registry $\tilde{T}$), and (iii) the role-definition block. This preserves critical instructions while allowing aggressive compression. Since P is static within a session, $\tilde{P}$ is computed once and cached, incurring no per-turn overhead.

3.5 CompressionPlanner: Joint Budget Allocation

Compression decisions across memory (τ_h, τ_l), tools (k), and prompt (γ_P) interact, as does the budget split (B_M, B_T, B_P). We optimise them jointly via a contextual bandit.

State and action. At turn t, the state is

$$s_t = (|M_t|, |T|, |P|, t, B, H_t, d), \tag{8}$$

where H_t is the entropy of tool-transition probabilities from $\mathcal{G}_T$. An action defines compression and allocation:

$$\begin{aligned} a_t &= (\tau_h, \tau_l, k, \gamma_P, B_M, B_T, B_P), \\ \text{s.t.} \quad & B_M + B_T + B_P = B. \end{aligned} \tag{9}$$

We discretise $\mathcal{A}$ into a small set of feasible configurations.

Training and inference. For each (s_t, a_t), we compute fidelity to full-context execution:

$$R_t = \mathcal{U}\big(A(\tilde{C}_t, q_t), A(C_t, q_t)\big). \tag{10}$$

Using logged trajectories, we evaluate all $a_t \in \mathcal{A}$ offline and fit a reward model $\hat{R}_\omega(s, a)$ (small

MLP). At runtime,

$$a_t^* = \arg\max_{a \in \mathcal{A}} \hat{R}_\omega(s_t, a). \tag{11}$$

3.6 Context Assembly and Runtime

The final context is assembled as $\tilde{C}_t = \tilde{P} \| \tilde{T} \| \tilde{M}_t$. The planner ensures the global budget constraint:

$$|\tilde{C}_t| = |\tilde{M}_t| + |\tilde{T}| + |\tilde{P}| \leq B. \tag{12}$$

Compilation overhead is ∼600 ms/turn (memory ∼200 ms, tools ∼10 ms, prompt ∼350 ms amortised via session-level caching to effectively zero after the first turn), with no additional generative-LLM calls except rare tool retries. Algorithm 1 (App. A.1) summarises the per-turn compile step.

4 Experimental Setup

Data. We evaluate on de-identified logs from a copilot agent system. From ∼9K conversations we retain 3,142 long-horizon trajectories (median 22 turns). Each trajectory exposes a 45-tool registry (92K tokens), user–agent memory (177K), and a system prompt (18K), totalling ∼287K tokens per turn. We split 70/10/20% train/val/test at the trajectory level; MSC labels, the tool-transition graph $\mathcal{G}_T$, and the planner $\hat{R}_\omega$ are fit only on train. All supervision signals (LOO labels, transition counts, planner rewards) are derived using the *same* backbone model as evaluation, treating full-context execution as the oracle; this is self-distillation from the test-time model rather than leakage across the trajectory split. Generalisation is probed zero-shot on τ^2-bench and LongMemEval (Sec. 5).

Baselines. We compare against published per-stratum methods and their naive compositions – no prior work jointly compresses all three strata. *Memory:* (i) **Last-k%** recency window, (ii) **Top-k% RAG** by query–message similarity, (iii) **HiAgent** (Hu et al., 2024) adapted to our trace format with per-subgoal summarisation, (iv) **Mem0** (Chhikara et al., 2025) fact-extracted memory. *Tools:* (v) **Next-k** speculative top-k without fallback, (vi) **AutoTool** (Jia and Li, 2025) learned sequence-inertia retrieval. *Compositions:* we combine the strongest memory and tool methods as a practitioner would (Table 1).

Metrics. All metrics are computed against the full-context trajectory (oracle). Let π^{ref} and π^{cmp} denote reference and candidate trajectories. *Decision fidelity* $\mathcal{F} \in [0, 100]$ is the composite tool-DAG + answer-equivalence score (Alg. 7, App. A.7): we strip reasoning traces, canonicalise tool parameters, build data-dependency DAGs to allow order-invariance for independent read-only calls, score structural agreement via normalised graph-edit distance, and judge final-answer equivalence with a calibrated LLM (κ=0.86 against human). *Task success rate* (TSR) is trajectory-level goal completion: since our agent can retry failed tool calls and re-issue evicted lookups, TSR drops only on *unrecoverable* corruption (wrong entity, wrong final action). *Tool-F_1* is set-level agreement on invoked tools. *Cost* is measured as mean input tokens per turn $\mathcal{T}$ and total tokens per trajectory $\mathcal{T}_{\text{tot}}$, the latter capturing extra turns induced by memory re-calls and tool-miss retries. Compression ratio ρ=$\mathcal{T}_{\text{tot}}^{\text{full}}/\mathcal{T}_{\text{tot}}^{\text{cmp}}$.

Protocol. One frontier-class backbone with greedy decoding is used throughout to isolate compression effects from sampling noise. Each method runs the full trajectory end-to-end under its compression regime; oracle outputs are used only as fidelity targets. All comparisons are *offline replays* of logged trajectories: the trajectories are drawn from a deployed system, but SCOPE itself is not evaluated in an online A/B deployment, so the reported cost and task-success figures should not be read as measured user-facing deployment impact. Baselines are budget-tuned on the validation split to maximise $\mathcal{F}$ subject to a target $\mathcal{T}$; SCOPE sweeps $B \in \{30, 45, 60, 90\}$K. Results are means over test trajectories. Ablations (-PLANNER, -MEM, -TOOLS, -PROMPT) and the internal MSC-vs-proxy comparison are reported in Sec. 5.

5 Results and Discussion

Cost–fidelity frontier. SCOPE dominates the frontier across all budgets (Table 1, Fig. 2). At B=60K it matches full-context task success within 0.9% using only 22% of tokens, and reaches the fidelity of strong baselines at 2–3× fewer tokens – gains driven by improved context efficiency, not allocation alone. The frontier shifts regime around B≈60K: below it, fidelity rises steeply as compression removes critical context; above it, returns flatten to +1–2pt, indicating that task-relevant information concentrates in a small fraction of the full context.

Coordination, not composition. Each module improves decision fidelity by 9–10% over its base-

Table 1: Offline replay on the held-out production test set (N=3,142 long-horizon trajectories). Methods compress **M**emory, **T**ools, and/or **P**rompt. $\mathcal{F}$: decision fidelity; TSR: task success rate; Tool-F_1: tool-call agreement; $\mathcal{T}$: tokens/turn (K); $\mathcal{T}_{\text{tot}}$: total tokens/trajectory (M); ρ: compression ratio. **SCOPE** jointly optimizes all three strata and achieves the best cost–fidelity trade-off.

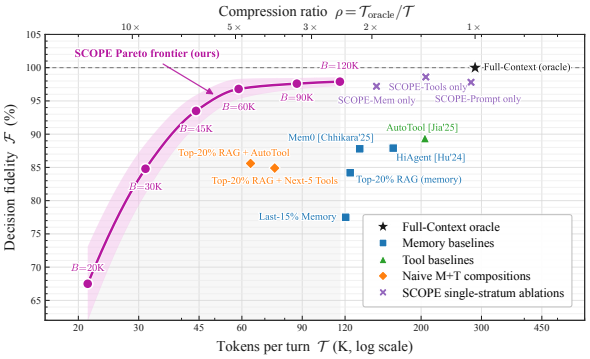

Figure 2: **Cost–fidelity Pareto frontier.** Decision fidelity ($\mathcal{F}$, y-axis) vs. tokens per turn ($\mathcal{T}$, x-axis, log scale). SCOPE (pink) Pareto-dominates all baselines across budgets. Top axis shows compression ratio ρ. At B=60K, SCOPE achieves 96.8% fidelity at 4.46× compression.

line at similar or lower cost, confirming that decision-preserving supervision (MSC) beats proxy objectives like recency or similarity. These gains do not compose naively: stacking strong memory and tool baselines yields only marginal improvement as independent errors compound, whereas SCOPE's joint budget allocation adds +11% at tighter compression. The planner is what supplies this coordination: replacing it with the best validation-tuned fixed budget split lowers $\mathcal{F}$ from 96.8 to 93.9 at B=60K, and a uniform $B/3$ split to 89.2, with both gaps widening at tighter budgets where allocation matters more.

Fidelity vs. task success. The two metrics are not interchangeable, and the gap between them is by construction: $\mathcal{F}$ penalises *any* divergence from the full-context trajectory, whereas TSR only asks whether the goal was reached. Most turns that $\mathcal{F}$ counts as deviations self-recover later in the trajectory – a lookup re-issued after eviction, or an alternative tool sequence reaching the same outcome – so the 3.2-point $\mathcal{F}$ drop at B=60K leaves only the 0.9-point TSR gap (91.7 → 90.8) as net unrecoverable. The distance between the two therefore indicates a conservative operating point rather than an inconsistency. Irrecoverable failures concentrate under aggressive prompt compression, and residual errors cluster around fine-grained numeric recall and unseen tool transitions, both degrading gracefully.

Zero-shot generalization. We test transfer beyond the production domain by evaluating SCOPE *zero-shot* – no component re-trained – on τ^2-bench (Barres et al., 2025) (tool-agentic, dual-control) and LongMemEval (Wu et al., 2025) (long-horizon conversational memory), transferring f_θ, $\mathcal{G}_T$, and $\hat{R}_\omega$ as-is against the strongest applicable baseline at matched budget (Table 2).

Without adaptation, SCOPE stays within 1.2% (τ^2-bench) and 1.7% (LongMemEval) of full-context success at >4× compression, ahead of the best baseline by 2–5% while compressing ∼2×

Table 2: Zero-shot transfer (no re-training). Success is the benchmark-native metric (τ^2 pass rate; LongMemEval QA accuracy); ρ: compression ratio. SCOPE retains most of its in-domain advantage despite no adaptation.

Benchmark	Method	Success	ρ
τ^2-bench	Full-Context (oracle)	61.4	1.0×
	AutoTool	57.9	1.9×
	SCOPE	**60.2**	**4.1**×
LongMemEval	Full-Context (oracle)	88.7	1.0×
	Top-20% RAG	82.4	2.2×
	SCOPE	**87.0**	**4.3**×

more aggressively. The residual gap to full context tracks distribution shift in tool inventories and dialogue style, largest on LongMemEval where unseen long-range coreference stresses the reranker. SCOPE thus captures domain-general structure rather than overfitting a single registry, subject to the single-backbone caveats of Sec. 6.

6 Conclusion

We presented **SCOPE**, a unified framework for context compilation in long-horizon LLM agents that jointly compresses memory, tools, and prompts under a shared token budget. By directly optimizing for output preservation and coordinating decisions via a lightweight planner, SCOPE consistently outperforms strong single-stratum methods and naive compositions, achieving up to $4.46\times$ compression at near-parity task success. Our results demonstrate that context efficiency is fundamentally a *systems problem*: substantial gains arise not from better local heuristics, but from global, budget-aware coordination across context strata.

Limitations

Our evaluation is conducted on a conversational agent dataset with domain-specific prompts, a 45-tool registry, and long multi-step tool-call chains. Although SCOPE is designed as a modular framework, deployment to substantially different agent ecosystems (e.g., code-generation or open-domain web agents) will require re-fitting the learned components, particularly the tool-transition graph and planner, and the optimal operating point may vary across domains. The learned reranker, planner, and tool-transition graph are trained from historical trajectories and full-context executions of a single backbone model. Changing the backbone therefore requires re-fitting these components – in our experience the reranker threshold and the planner reward in particular – and we report no cross-backbone results here; multi-backbone evaluation remains future work. Our evaluation is also an offline replay of logged trajectories rather than an online deployment study, so it does not measure user-facing impact. SCOPE also introduces approximately 600 ms of compile-time overhead, which can be reduced by replacing the cross-encoder reranker with similarity-based retrieval at the cost of lower fidelity.

Broader Impact

SCOPE cuts the context reprocessed each turn from roughly 287K to 59K tokens (79% fewer per turn; $4.46\times$ over full trajectories once compression-induced retries are counted) at 96.8% decision fidelity, within 0.9% of full-context task success. Since agent inference cost scales with input size ($\mathrm{Cost}(C_t) \approx \alpha|C_t|$, Sec. 3.1), this yields proportional savings in serving cost, energy, and carbon with no model change: for an agent serving 1M turns/day, SCOPE avoids reprocessing $\sim 2.3 \times 10^{11}$ input tokens daily ($\sim 8.3 \times 10^{13}$/year), on the order of $83M/year in compute avoided per million daily turns at $1 per million tokens, scaling linearly with traffic.[1] Because SCOPE compresses only the input context and leaves generation length unchanged, we claim cost and throughput benefits rather than latency improvements. The residual 3.2% fidelity gap means a small fraction of turns may diverge from full-context behaviour, so high-stakes deployments should tune the operating point conservatively and retain the minified-fallback hierarchy that keeps every tool reachable within one retry.

Algorithm 1 SCOPE context compilation at turn t

Require: Context $C_t = (M_t, T, P)$, query q_t, budget B, models $(f_\theta, \mathcal{G}_T, h_\psi, \hat{R}_\omega)$
Ensure: Compressed context $\tilde{C}_t$
1: $(\tau_h, \tau_l, k, \gamma_P, B_M, B_T, B_P) \leftarrow \arg\max_a \hat{R}_\omega(s_t, a)$ ▷ planner
2: $\{G_j\} \leftarrow \textsc{Segment}(M_t)$
3: Retrieve top-K groups $\mathcal{G}^*$ by $\mathrm{sim}(E(q_t), E(G_j))$
4: Score $f_\theta(q_t, m_i)$ for $m_i \in \bigcup \mathcal{G}^*$
5: Tier by (τ_h, τ_l) and greedily select by value density under B_M
6: Add safety floors (last r groups): $\tilde{M}_t$
7: Compute z_t and $\hat{T}_k \leftarrow \textsc{TopK}(\Pr(\cdot \mid \tau_{t-1}, z_t))$
8: $\tilde{T} \leftarrow \{\tau_j\}_{\tau_j \in \hat{T}_k} \cup \{\mu_j\}_{\tau_j \notin \hat{T}_k}$
9: $\tilde{P} \leftarrow \{p_i : h_\psi(p_i) > \tau_P(\gamma_P) \vee p_i \in \mathcal{P}_{\text{prot}}\}$
10: **if** $\tau_j \notin \hat{T}_k$ **then**
11: Inject full τ_j and retry once
12: **end if**
13: **return** $\tilde{P} \| \tilde{T} \| \tilde{M}_t$

A Appendix

This appendix expands the sub-procedures referenced in Section 3. Algorithm 1 captures the end-to-end compile step; the remaining subsections detail the SCOPE-Mem training and inference pipeline, the SCOPE-Tools prediction routine, and the CompressionPlanner action-selection procedure.

A.1 End-to-End Compile Step

Algorithm 1 summarises the per-turn compile invoked at runtime. The planner (line 1) selects per-stratum thresholds and the budget split; lines 2–4 instantiate SCOPE-Mem, line 5 instantiates SCOPE-Tools, and line 6 instantiates SCOPE-Prompt. The pre-execution hook below the rule guarantees recoverability of any tool not in the speculative top-k set.

A.2 SCOPE-Mem: LOO Label Construction

Algorithm 2 details offline label generation. For each trajectory turn we pre-filter candidates with similarity-based top-K retrieval (default K=50) before issuing LOO agent calls, yielding a 5× cost reduction with 0.98 label-quality F_1 versus exhaustive LOO. Labels are produced once, with greedy decoding, and cached.

A.3 SCOPE-Mem: Cross-Encoder Training

Algorithm 3 reports the supervised fine-tuning loop for the MSC reranker f_θ (DeBERTa-v3-base, ∼60M params), trained with AdamW at lr=2e-5, batch size 32, 3 epochs on the labels from Algorithm 2.

Algorithm 2 LOO-based label construction for SCOPE-Mem

Require: Trajectory dataset $\mathcal{D}$, agent $A(\cdot)$, tolerance ϵ, cap K
Ensure: Training set $\mathcal{D}_{\text{tr}} = \{(q_t, m_i, y_i)\}$
1: $\mathcal{D}_{\text{tr}} \leftarrow \emptyset$
2: **for** each trajectory $\tau \in \mathcal{D}$ and turn $t \in \tau$ **do**
3: $a_t \leftarrow A(M_t, q_t)$ ▷ cached from original log
4: $\mathcal{C}_t \leftarrow \mathrm{TopK}_i(\mathrm{sim}(q_t, m_i), K)$
5: **for** each $m_i \in \mathcal{C}_t$ **do**
6: $a_{-i} \leftarrow A(M_t \setminus \{m_i\}, q_t)$
7: $\Delta_i \leftarrow d(a_t, a_{-i})$
8: $y_i \leftarrow \mathbb{1}[\Delta_i > \epsilon]$
9: $\mathcal{D}_{\text{tr}} \leftarrow \mathcal{D}_{\text{tr}} \cup \{(q_t, m_i, y_i)\}$
10: **end for**
11: **end for**
12: **return** $\mathcal{D}_{\text{tr}}$

Algorithm 3 Training the MSC reranker f_θ

Require: Labels $\mathcal{D}_{\text{tr}}$, model f_θ, epochs E
Ensure: Trained parameters θ
1: **for** $e = 1, \ldots, E$ **do**
2: **for** each batch $\mathcal{B} \subset \mathcal{D}_{\text{tr}}$ **do**
3: $I_i \leftarrow f_\theta(q_t, m_i),\ \forall (q_t, m_i) \in \mathcal{B}$
4: $\mathcal{L} \leftarrow -\sum_i [y_i \log I_i + (1 - y_i) \log(1 - I_i)]$
5: $\theta \leftarrow \theta - \eta \nabla_\theta \mathcal{L}$
6: **end for**
7: **end for**
8: **return** θ

A.4 SCOPE-Mem: Two-Stage Inference with Safety Floors

Algorithm 4 combines group-level retrieval, cross-encoder reranking, budget-constrained greedy selection, tier assignment, and unconditional safety floors. Per-turn latency is dominated by the batched cross-encoder pass (∼20 ms on A10G over 50–200 pruned candidates).

A.5 SCOPE-Tools: Top-k Prediction with Hook-Based Rollback

Algorithm A.5 predicts $\hat{T}_k$ by walking the plan-conditioned transition graph $\mathcal{G}_T$, emits minified signatures μ_j for the remainder, and specifies the pre-execution hook that corrects cache misses within one retry.

A.6 CompressionPlanner: Action Selection

Algorithm **??** is the online inference step; offline training is a standard regression fit over (s_t, a_t, R_t) tuples collected by grid-sweeping a_t over historical trajectories, removing the exploration problem entirely.

A.7 Trajectory Fidelity Computation

This section details how the decision fidelity $\mathcal{F}$ reported in Section 5 is computed between a refer-

Algorithm 4 SCOPE-Mem inference at turn t

Require: Memory M_t, query q_t, budget B_M, thresholds (τ_h, τ_l), reranker f_θ
Ensure: Tiered memory $\tilde{M}_t$

return $\tilde{M}_t$

Algorithm 5 SCOPE-Tools compile and rollback

Require: Registry T, previous tool τ_{t-1}, plan state z_t, graph $\mathcal{G}_T$, k, p
Ensure: Registry $\tilde{T}$
$\mathbf{w} \leftarrow \mathcal{G}_T[\tau_{t-1}, z_t]$
$\hat{T}_k \leftarrow \textsc{Prefix}(\mathbf{w}, p, k)$
$\tilde{T} \leftarrow \{\tau_j\}_{\tau_j \in \hat{T}_k} \cup \{\mu_j\}_{\tau_j \notin \hat{T}_k}$
if emitted tool $\tau_j \notin \hat{T}_k$ **then**
  Inject full schema
  Retry once
end if
return $\tilde{T}$

ence trajectory π^{ref} (produced under full context) and a compressed trajectory π^{cmp} (produced under $\tilde{C}_t$). A naive sequence-equality check is too strict: agents frequently re-order read-only tool calls, add or omit reasoning ("thinking") steps, and phrase final answers slightly differently while remaining semantically equivalent. We therefore decompose fidelity into three components – thinking-invariance, tool-call equivalence modulo data dependencies, and answer equivalence – and combine them into a single score.

Trajectory representation. A trajectory π is a sequence of typed events $e_1, e_2, \ldots, e_L$ where each e_j is one of: user message u, assistant thinking block θ, tool call $c{=}(\tau, \mathbf{p})$ with tool name τ and

Algorithm 6 CompressionPlanner action selection

Require: State $s_t = (|M_t|, |T|, |P|, t, B, H_t, d)$, reward model $\hat{R}_\omega$, action grid $\mathcal{A}$
Ensure: Action $a_t^* = (\tau_h, \tau_l, k, \gamma_P, B_M, B_T, B_P)$
for each $a \in \mathcal{A}$ with $B_M + B_T + B_P = B$ **do**
  $r_a \leftarrow \hat{R}_\omega(s_t, a)$
end for
return $\arg\max_a r_a$

canonicalised parameter dict $\mathbf{p}$, tool result r, or final assistant answer a. We write $\mathsf{TC}(\pi)$ for the ordered list of tool calls in π and $\mathsf{ANS}(\pi)$ for its final answer.

Running example. Consider the three trajectories from the main text:

$$\begin{aligned}
\pi_1 &: U_1 \to \Theta_1 \to T_6 \to R_6 \to \Theta_2 \\
&\quad \to T_4 \to R_4 \to T_7 \to R_7 \to \Theta_3 \to A_1, \\
\pi_2 &: U_1 \to \Theta_4 \to T_4 \to R_4 \\
&\quad \to T_6 \to R_6 \to T_7 \to R_7 \to A_2, \\
\pi_3 &: U_1 \to \Theta_1 \to T_6 \to R_6 \\
&\quad \to T_4 \to R_4 \to T_7 \to R_7 \to \Theta_3 \to A_1.
\end{aligned}$$

Trajectories π_1 and π_3 differ only by the intermediate thinking step Θ_2 and are therefore considered equivalent. Trajectories π_1 and π_2 execute T_6 and T_4 in different orders; if neither tool depends on the other's output, the executions remain equivalent. Likewise, if A_1 and A_2 are judged semantically equivalent, the trajectories receive a high fidelity score despite surface differences.

Step 1: Thinking-block elision. We strip all thinking events, yielding the *externalised* trajectory $\bar{\pi}$. This reflects that internal reasoning does not affect environment state or user-visible behaviour and that compression methods routinely change reasoning traces without changing decisions.

Step 2: Parameter canonicalisation. For a tool call $c{=}(\tau, \mathbf{p})$, $\mathbf{p}$ is a JSON-like dict. We canonicalise by: sorting keys; lowercasing and whitespace-trimming string values; normalising numeric and date formats (ISO-8601); and coercing booleans. Two calls agree parametrically iff $\tau_a{=}\tau_b$ and $\textsc{Canon}(\mathbf{p}_a){=}\textsc{Canon}(\mathbf{p}_b)$.

Step 3: Data-dependency DAG. Tool-call order is semantically significant only when a later call consumes an earlier call's output. We build the *data-dependency DAG* $D(\bar{\pi}) = (V, E)$ with $V = \mathsf{TC}(\bar{\pi})$ and $(c_a \to c_b) \in E$ iff any value in $\mathbf{p}_b$ is traceable to the output r_a of an earlier c_a (by

substring / ID / entity match over the canonicalised JSON). The *tool-call equivalence* between two trajectories is the graph-edit-distance-normalised similarity

$$\mathrm{TCE}(\pi^{\mathrm{ref}}, \pi^{\mathrm{cmp}}) = 1 - \frac{\mathrm{GED}\big(D(\bar{\pi}^{\mathrm{ref}}), D(\bar{\pi}^{\mathrm{cmp}})\big)}{|V^{\mathrm{ref}}| + |V^{\mathrm{cmp}}|}, \tag{13}$$

where node matches require parametric agreement (Step 2) and edge matches require agreement on the induced dependency relation. For trajectories whose tool-call DAGs are small (typically ≤ 15 nodes in our traces), GED is tractable; we use the VF2-style approximation with a 1-second timeout and fall back to bag-of-calls F_1 otherwise. This formulation gives $\pi_1 \equiv \pi_3$ exactly (identical DAG), and $\pi_1 \simeq \pi_2$ up to the $T_4 \leftrightarrow T_6$ swap whenever the dependency check reports no edge between them.

Step 4: Answer equivalence. For the final answer, exact match and token-F_1 both penalise benign rephrasings. We use an LLM-as-judge with a 3-way verdict (EQUIVALENT, PARTIAL, DIFFERENT) and log-probability-weighted confidence, collapsed to $\mathrm{AEQ} \in [0, 1]$. The judge is prompted with the user query, the reference answer, and the candidate answer, and is explicitly instructed to ignore stylistic variation, to penalise factual disagreement, and to output a structured verdict plus one-line justification. We validate the judge against 500 human-labelled pairs, reporting κ=0.86 inter-rater agreement.

Step 5: Composite fidelity. We combine the two components:

$$\mathcal{F}(\pi^{\mathrm{ref}}, \pi^{\mathrm{cmp}}) = \alpha \cdot \mathrm{TCE} + (1 - \alpha) \cdot \mathrm{AEQ}, \tag{14}$$

with default α=0.6 reflecting that in an agentic setting correct tool execution is load-bearing for correct answers. We ablate $\alpha \in \{0.4, 0.6, 0.8\}$ and find rankings between methods stable; results in the main paper use α=0.6. Trajectory-level fidelity is averaged over turns, and aggregated fidelity is the macro-average over test trajectories.

Dependency detection details. BUILDDEPDAG scans tool calls in temporal order; for each call c_b, every value in $\textsc{Canon}(\mathbf{p}_b)$ is checked against the canonicalised outputs r_a of preceding calls via (i) exact-ID match on fields tagged as identifiers in the tool schema (deal-id, order-id, sku, etc.), and (ii) substring match with a minimum token length of 4 for free-text fields. We add an edge $c_a \to c_b$ on any hit. This heuristic is intentionally slightly over-permissive: false-positive edges only hurt the compressed trajectory when it legitimately reordered independent calls, and the resulting small penalty is preferable to under-detecting real dependencies.

Algorithm 7 Trajectory fidelity computation

Require: Reference trajectory π^{ref}, candidate trajectory π^{cmp}, judge $\mathcal{J}$, weight α
Ensure: Fidelity score $\mathcal{F} \in [0, 1]$
$\bar{\pi}^{\mathrm{ref}} \leftarrow \textsc{StripThinking}(\pi^{\mathrm{ref}})$
$\bar{\pi}^{\mathrm{cmp}} \leftarrow \textsc{StripThinking}(\pi^{\mathrm{cmp}})$
for each $c = (\tau, \mathbf{p}) \in \mathsf{TC}(\bar{\pi}^{\mathrm{ref}}) \cup \mathsf{TC}(\bar{\pi}^{\mathrm{cmp}})$ **do**
  $\mathbf{p} \leftarrow \textsc{Canon}(\mathbf{p})$ ▷ sort keys, normalize types
end for
$D^{\mathrm{ref}} \leftarrow \textsc{BuildDepDAG}(\bar{\pi}^{\mathrm{ref}})$
$D^{\mathrm{cmp}} \leftarrow \textsc{BuildDepDAG}(\bar{\pi}^{\mathrm{cmp}})$
$\mathrm{TCE} \leftarrow 1 - \textsc{NormGED}(D^{\mathrm{ref}}, D^{\mathrm{cmp}})$ ▷ bag-F_1 fallback
$v \leftarrow \mathcal{J}(\mathsf{ANS}(\pi^{\mathrm{ref}}), \mathsf{ANS}(\pi^{\mathrm{cmp}}), q)$
$\mathrm{AEQ} \leftarrow \textsc{Score}(v)$
return $\alpha\,\mathrm{TCE} + (1 - \alpha)\,\mathrm{AEQ}$

Judge calibration. Before using $\mathcal{J}$ in evaluation, we calibrate it on a held-out set of 500 trajectory pairs hand-labelled by two authors (agreement κ=0.86). The judge achieves F_1=0.91 against human consensus on the 3-way verdict; residual errors concentrate in numeric-rounding cases (e.g., prices differing by \$0.01 due to upstream quantisation), which we handle by a post-processing rule that marks numeric-only differences under a relative tolerance as EQUIVALENT. We use greedy decoding and two judge invocations per pair with order-swapped inputs; disagreements are resolved by a third invocation.

Human-Anchored Factuality Evaluation with Strategic Annotation

Abstract

LLM-based factuality judges provide scalable evaluation signals, but their metrics are often systematically biased relative to human judgments. We study human-anchored factuality evaluation under limited annotation budgets, where judge predictions on the full dataset are combined with human labels on a small selectively sampled subset to obtain statistically valid estimates. The efficiency of this approach depends critically on which examples receive human annotation: in factuality evaluation, judge-human misalignment is not driven solely by low confidence, but also by structured failure modes such as incomplete evidence, temporal mismatch, unverifiable claims, and rubric misalignment. To exploit this structure, we introduce a factuality-specific annotation policy design pipeline that uses failure-space analysis (FSA) to derive diverse predictive signals for modeling human-judge misalignment. On an internal reference-based factuality evaluation system (AutoFA) and RAGTruth, where judge-predicted estimates substantially underestimate human-annotated factual accuracy, our FSA-guided policy improves annotation efficiency over uniform sampling and uncertainty-driven baselines, achieving effective-sample-size gains of 40.3% on AutoFA and 27.1% on RAGTruth.

1 Introduction

Factuality evaluation is a recurring concern when deploying large language models in user-facing systems. In production settings, teams rely on factual accuracy to measure system quality (e.g., LLM model, prompts, grounding retrieval), monitor regressions, and make release decisions from evaluation data that are both timely and statistically reliable. Human annotation remains the most trusted way to measure factual accuracy, but it is expensive and slow. Collecting sufficient labels to obtain narrow confidence intervals requires substantial annotation budget and introduces operational latency. This creates a practical tension between evaluation quality and evaluation efficiency.

LLM-as-a-judge (LLMaaJ) systems offer an attractive way to scale factuality evaluation (Min et al., 2023; Chen et al., 2023; Niu et al., 2024; Wei et al., 2024; Song et al., 2024). Given a query, a response, and reference evidence, the judge can decompose the response into claims, verify them against evidence, and produce factuality labels at much larger scale than human annotators. However, judge-predicted factuality estimates are not necessarily human-anchored (Zheng et al., 2023; Wang et al., 2024). In reference-based factuality evaluation, judge errors are often systematic rather than random. A judge may reject reasonable answers when references are incomplete, stale, conflicting, or indirectly supportive. It may also apply a more literal verification rubric than human annotators. As a result, treating judge predictions as ground truth can produce biased factual accuracy estimates, even when the judge is useful as a proxy signal.

This paper studies factuality evaluation under a budgeted annotation setting. Given a large set of evaluation items, an LLMaaJ provides proxy factuality predictions for all items, while only a small subset can receive human labels. The goal is to estimate the human-defined factual accuracy rate (FAR) with valid uncertainty quantification and lower variance than uniformly sampled human annotation alone. We adopt Active Statistical Inference (ASI) (Zrnic and Candes, 2024), which combines judge predictions with human corrections from a sampled subset of examples. ASI preserves the human-anchored target, but its efficiency depends critically on the annotation policy – human labels should be allocated to examples where the judge is most likely to disagree with humans.

Factuality residuals are often structured rather than uniformly distributed across examples. Exist-

ing confidence-based approaches (Gligorić et al., 2025) use the judge's expressed uncertainty as a sampling signal, but judge-human misalignment is not driven solely by low confidence. A judge can be confidently misaligned when evidence is incomplete, temporally inconsistent, or only indirectly supportive, and when responses require paraphrase, inference, or rubric tolerance that humans handle differently from the judge. To exploit this structure, we construct the annotation policy using *failure-space analysis* (FSA), a factuality-specific policy-design pipeline that derives predictive signals from judge-output, evidence quality, task and input strata, and answer-rubric alignment before converting them into ASI sampling policies.

We evaluate the framework on two benchmarks: an internal Automatic Factual Evaluation system (AutoFA) for virtual assistant responses, and RAGTruth, a public hallucination benchmark with human span-level annotations. In both settings, judge-predicted FAR substantially underestimates the human-annotated FAR and adopting FSA-derived policies preserve desired coverage while improving annotation efficiency over uniform sampling and confidence-based sampling. Aggregated across budgets, FSA-guided ASI achieves an average effective sample size (ESS) gain of 40.3% on AutoFA and 27.1% on RAGTruth.

To summarize, our contributions are threefold. First, we formulate reference-based factuality evaluation as a human-anchored, judge-assisted inference problem under limited annotation budget. Second, we introduce failure-space analysis as a practical policy-design layer for identifying factuality-specific judge-human residual risk. Third, we demonstrate on both internal and public factuality settings that FSA-guided ASI recovers the human-defined evaluation target while improving annotation efficiency over uniform and confidence-based alternatives. Together, these contributions enable reliable and cost-efficient factuality measurement in practical evaluation pipelines, where fully manual annotation is infeasible and judge-only metrics can be systematically biased.

2 Background

2.1 Problem Setup

We first formulate the problem of reference-based factuality evaluation for short-form query-response pairs, while noting the proposed methodology can be naturally extended to long form settings. Each evaluation item consists of a query q_i, a model response a_i, and the reference evidence e_i obtained from retrieval, curated sources, or an existing evaluation pipeline. We write the observable input as $X_i = \{q_i, a_i, e_i\}$ and denote the human-annotated factuality label of each X_i by Y_i. In practice, Y is usually not a direct verdict, but verified atomic claims, or detected hallucinated spans.

In this paper, we focus on *Factual Accuracy Rate* (FAR)[1], which is defined as:

$$\theta = \mathbb{E}[\phi(X, Y)], \tag{1}$$

where $\phi(X_i, Y_i)$ denotes the factual correctness for the i_{th} item.

2.2 Judge-Assisted Factual Evaluation under Budgeted Annotation

While FAR from human annotation is usually treated as the ground truth, acquiring human labels is expensive and slow, making it difficult to scale for drawing statistically significant conclusions. On the other hand, Automatic Factual Evaluation can produce judge predictions at scale but the obtained FAR is generally biased. This motivates us to study a budgeted, judge-assisted factual evaluation problem where we combine the abundant judge predictions with limited human labels to form a statistically valid and more efficient estimator.

Given N data points, an LLMaaJ provides predictions, denoted by $f(X)$, for all items, while only $n_{\text{bgt}} \ll N$ items can be sent for human annotation. We adopt Active Statistical Inference (ASI) (Zrnic and Candes, 2024), which selects the labeled subset from an annotation policy, denoted by $\pi(X)$.

Let $\xi_i \sim \text{Bernoulli}(\pi_i)$ indicate whether item i receives a human label with the inclusion probability π_i. ASI estimates FAR by:

$$\hat{\theta}^{\text{ASI}} = \frac{1}{N}\sum_{i=1}^{N}\left[\phi_i^f + \frac{\xi_i}{\pi_i}(\phi_i^h - \phi_i^f)\right],$$

where ϕ^f and ϕ^h denote the judge predicted and human annotated factual correctness respectively.

2.3 Statistical Efficiency

Drawing statistically meaningful conclusions requires not only targeting the correct human-defined metric, but also estimating it with low variance under a limited annotation budget. We compare three

[1] If the LLMaaJ's evidence is the grounding provided to the answer generator, FAR measures faithfulness rate.

Signal family	Representative signals
Judge-output artifacts (F1)	Claim/span structure, verification or hallucination fraction, unverifiable outputs, self-reflection or confidence.
Evidence and reference quality (F2)	Reference support strength, reference conflict, source freshness, direct vs. indirect support.
Task and input strata (F3)	Task or domain type, query category, time-sensitive or location context indicators.
Answer-rubric alignment (F4)	Claim importance, completeness vs. correctness, overprecision or auxiliary details, paraphrase/inference tolerance.

Table 1: Failure-space signal families for residual-risk policy design. The table lists representative pre-labeling signals rather than an exhaustive feature set.

estimators that are central to this paper. The *classical* estimator, $\hat{\theta}^h = \frac{1}{n_{\text{bgt}}} \sum_{i:\xi_i=1} \phi_i^h$, uses only the n_{bgt} human-labeled examples sampled uniformly at random. It is unbiased for the human-defined FAR, but can be noisy under small annotation budget. The *judge-predicted* estimator, $\hat{\theta}^f = \frac{1}{N} \sum_{i=1}^{N} \phi_i^f$, uses judge predictions on all N examples and therefore has low variance, but it is biased when the judge is systematically misaligned with human.

The ASI estimator remains human-anchored. However, its variance is policy dependent and scales with $\mathbb{E}[\Delta^2(1/\pi(X) - 1)]$, where $\Delta = \phi^h - \phi^f$ is the judge-human residual (Zrnic and Candes, 2024). Therefore, efficient annotation requires assigning higher sampling probabilities to examples with larger expected residuals, which motivates the failure-space analysis in the next section.

3 FSA-guided Policy Design

Efficient ASI requires allocating human labels to examples with large expected judge-human residuals. In the oracle case, the optimal policy is proportional to the conditional residual magnitude,

$$\pi^\star(X) \propto \sqrt{\mathbb{E}[\Delta^2 \mid X]}.$$

However, since ϕ^h is unavailable before annotation, the practical policy-design problem is to predict residual risk from pre-labeling information: the query q, response a, reference evidence e, and judge output $f(X)$.

Directly modeling residual risk from raw text is difficult, and generic uncertainty is often insufficient for factuality evaluation. We therefore introduce *failure-space analysis* (FSA), a factuality-specific procedure for deriving structured features $Z(X, f(X))$ that expose where judge-human misalignment is likely to occur. FSA organizes candidate policy signals into four families, summarized in Table 1: *judge-output artifacts*, *evidence and reference quality*, *task and input strata*, and *answer-rubric alignment*. Together, these signals capture not only whether the judge is uncertain, but also whether the evidence is incomplete or stale, whether the query belongs to a difficult slice, and whether the response requires inference or rubric tolerance that the judge may handle differently from humans.

Operationally, FSA uses a historical labeled set where both judge outputs and human annotations are available. We compute the residual target $|\Delta|$, extract numerical features from pre-labeling artifacts, and train a policy model to predict residual risk. The resulting scores are converted into sampling probabilities so that the annotation budget is concentrated on examples where the judge is most likely to disagree with humans. A pipeline overview is summarized and illustrated in Figure 1. We then provide a comprehensive demonstration of this pipeline in Section 4.2 and Section 4.3.

4 Experiments

4.1 Evaluation Settings

We study two factuality-judge settings with different judge architectures, data formats, and judge output structures.

Automatic Factual Accuracy (AutoFA) AutoFA is an internal reference-based factuality evaluation system for voice assistant responses. Given a user query and model response, three reference answers are produced by search-enabled LLMs. The judge decomposes the response into verifiable claims, fact-checks each claim against the references, and produces an overall factuality verdict, cf. SAFE (Wei et al., 2024) and VERISCORE (Song et al., 2024). Both claim-level and response-level outputs can be TRUE, FALSE, or UNKNOWN. We use $N = 2338$ responses and FAR is defined as the fraction of responses rated factually correct among

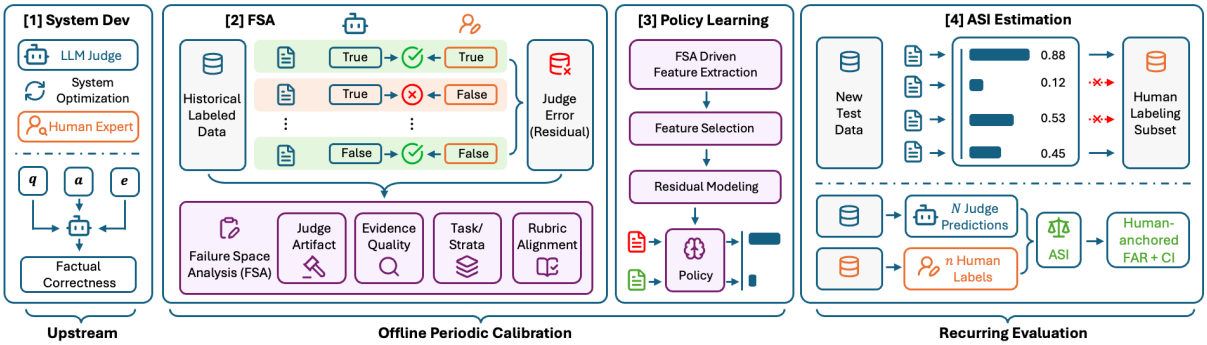

Figure 1: Overview of the pipeline of human anchored factual evaluation. [1] **System Development**: human experts design and iteratively optimize the LLM judge system, which takes the user query (q), model answer (a), retrieved evidence (e) and predicts the factual correctness. We consider this step as upstream and remains fixed once finished. [2] **Failure Space Analysis (FSA) on Calibration Data**: historical labeled data is leveraged to analyze the judge failure modes spreading across four main families. [3] **Policy Learning**: numerical features are extracted based on failure families and are selected with cross-validation. A regression model is trained to predict the risk of records based on the selected features, which is further converted to the sampling policy. High risk records are assigned higher probability to be sampled for human annotation. [4] **ASI estimation**: given new test dataset of size N, n (labeling budget) of them are sampled with the policy and sent for human annotations, while all data receives judge predictions. The ASI estimator combines both judge predictions and human labels and produces human anchored factual accuracy rate (FAR) and confidence interval (CI).

examples with a definitive verdict.

RAGTruth. RAGTruth (Niu et al., 2024) is a public hallucination benchmark with human span-level annotations. We use $N = 2937$ GPT-4-0613 responses across question answering, summarization, and data-to-text generation. We evaluate Claude Sonnet 4.6 as a faithfulness judge using the benchmark prompt, which asks the judge to identify hallucinated spans. For RAGTruth, FAR is the faithfulness rate: the fraction of responses without hallucination.

Self-Confidence Score. Following prior work on confidence-driven inference (Gligorić et al., 2025), we collect a self-reflected confidence score for each record by prompting the judge to assess its confidence in its own previous verdict, yielding a scalar uncertainty signal in $[0, 1]$.

4.2 FSA of Judge Residuals

We first compare judge FAR against human FAR to characterize the residuals that an annotation policy should target. On AutoFA, the judge underestimates human FAR by 13.3 percentage points. On RAGTruth, the gap is larger: the judge FAR is 55.6%, compared with a human FAR of 86.2%.

Typical judge failures. In both datasets, judge-human disagreements are dominated by judge over-rejection. On AutoFA, 90% of disagreements occur when the judge marks human-correct responses as FALSE (43%) or UNKNOWN (46%). Manual inspection identifies two common mechanisms: *evidence gaps*, where references do not directly state a reasonable answer that humans accept, and *overly-strict verification*, where the judge rejects an otherwise correct response due to unsupported peripheral details. On RAGTruth, 94% of disagreements occur when the judge flags hallucinations that humans do not annotate, mainly caused by *overly-literal grounding*: the judge penalizes valid paraphrases or reasonable inferences because they are not explicitly stated in the reference.

Dataset	Stratum	Prev.	$\mathbb{E}[\Delta^2]$	Lift
AutoFA	Partial Verification	0.32	0.41	2.58
	Time-sensitive Query	0.40	0.20	1.29
RAGTruth	Low Self-confidence	0.32	0.78	2.24
	Judge flagged output	0.43	0.70	2.02

Table 2: Residual concentration across observable strata. Prevalence (Prev.) is the fraction of records in the stratum. Lift > 1 indicates above-average residual density.

Non-uniform residual structure. Table 2 shows that residuals concentrate in observable strata derived from judge outputs and task metadata. We report each stratum's prevalence, average squared residual $\mathbb{E}[\Delta^2]$, and *lift*, defined as the ratio between stratum-level and population-level $\mathbb{E}[\Delta^2]$. On AutoFA, partial verification, i.e., cases where at least one extracted claim is marked UNKNOWN, has

Family	Feature	Spearman $\lvert\rho\rvert$ AutoFA	Spearman $\lvert\rho\rvert$ RAGTruth
Judge	self-confidence	0.31	**0.66**
	flag-reliability	–	0.25†
Evidence	ref-support-strength	**0.57**	0.22
	ref-temporal-consistency	0.36	–
Strata	time-sensitive / task	0.32	0.18
Rubric	inference-required	0.44	0.16
	qualitative-language	–	0.17

Table 3: Feature ranking by FSA family on absolute Spearman correlation ($|\rho|$) with $|\Delta|$. †Computed on the judge-flagged subset.

$2.58\times$ lift, while time-sensitive queries have $1.29\times$ lift. On RAGTruth, low self-confidence has $2.24\times$ lift, and judge-flagged outputs, i.e., cases where the judge returns one or more hallucination spans rather than an empty list, have $2.02\times$ lift. These concentrations show that judge-human residuals are structured rather than uniformly distributed, motivating the FSA-derived features in Section 4.3.

4.3 Residual-Risk Feature Modeling

Guided by Section 3 and the residual patterns in Section 4.2, we instantiate dataset-specific features from the artifacts available before human annotation. For both datasets, we use the judge's self-confidence score as a generic uncertainty signal.

For RAGTruth, where the judge may over-detect hallucinated spans, we additionally define *flag-reliability* to assess whether the judge-flagged spans are plausibly unsupported by the reference.

For AutoFA, the dominant residuals are tied to reference quality, so we extract *ref-support-strength*, which measures how directly the references support the response's core claims, and *ref-temporal-consistency*, which measures whether search-generated references agree on time-dependent facts. We also include task-level strata, such as time-sensitive queries in AutoFA and task type in RAGTruth.

Finally, we extract rubric-alignment features, including *inference-required*, which measures whether verification requires reasoning beyond literal evidence, and *qualitative-language*, which captures interpretive or subjective phrasing. LLM-extracted features are produced with structured prompts that return integer scores on a 0–3 scale. These feature-extraction calls are applied before human annotation and are substantially cheaper than human labeling in our setting. We provide more details in Appendix E.

Table 3 reports the absolute Spearman correlation between each feature and the residual magnitude $|\Delta|$. This provides a univariate diagnostic of whether each feature monotonically tracks residual risk. On AutoFA, *ref-support-strength* has the strongest correlation, consistent with evidence sufficiency being the dominant failure mode. On RAGTruth, *self-confidence* dominates, while *flag-reliability* provides an additional signal on the judge-flagged subset.

The correlations in Table 3 are diagnostic rather than the final policy criterion. A feature may correlate with $|\Delta|$ but still be less useful for sampling if it is sparse, redundant, or unstable under limited calibration data. We therefore split the calibration set into an inner training split for fitting residual-risk models and an inner validation split for comparing candidate feature configurations. This procedure selects *ref-support-strength* for AutoFA, and *self-confidence* together with *flag-reliability* for RAGTruth, reflecting the different residual structures of the two factuality settings.

4.4 Debiasing and Efficiency Evaluation

We evaluate the method along two dimensions: whether ASI recovers the human-anchored FAR despite judge bias, and whether FSA-derived policies improve annotation efficiency.

Policy learning. Each dataset is split 40/60 into calibration and evaluation sets. On the calibration set, we train a gradient-boosted tree (XGBoost) to predict $|\Delta|$ from the selected features, producing a residual-risk score for each record. The scores are converted into sampling probabilities by normalization with uniform mixing (Li et al., 2025; Zrnic and Candes, 2024), and we apply power-tuning (Angelopoulos et al., 2024) to set the judge contribution in the ASI estimator. Uniform-mixing and power-tuning parameters are estimated on the calibration set, with details in Appendix A. All reported results are evaluated on the evaluation split.

Estimators for comparison. We compare five estimators. *Classical* uniformly samples n_{bgt} human labels and estimates FAR with only human annotations. *Judge-predicted* reports the judge FAR over all N records without human correction. *Uniform ASI* applies the power-tuned ASI correction under a uniform policy. *Confidence ASI* uses only self-confidence as the sampling signal. *FSA ASI* uses the FSA-selected features from Section 4.3. The

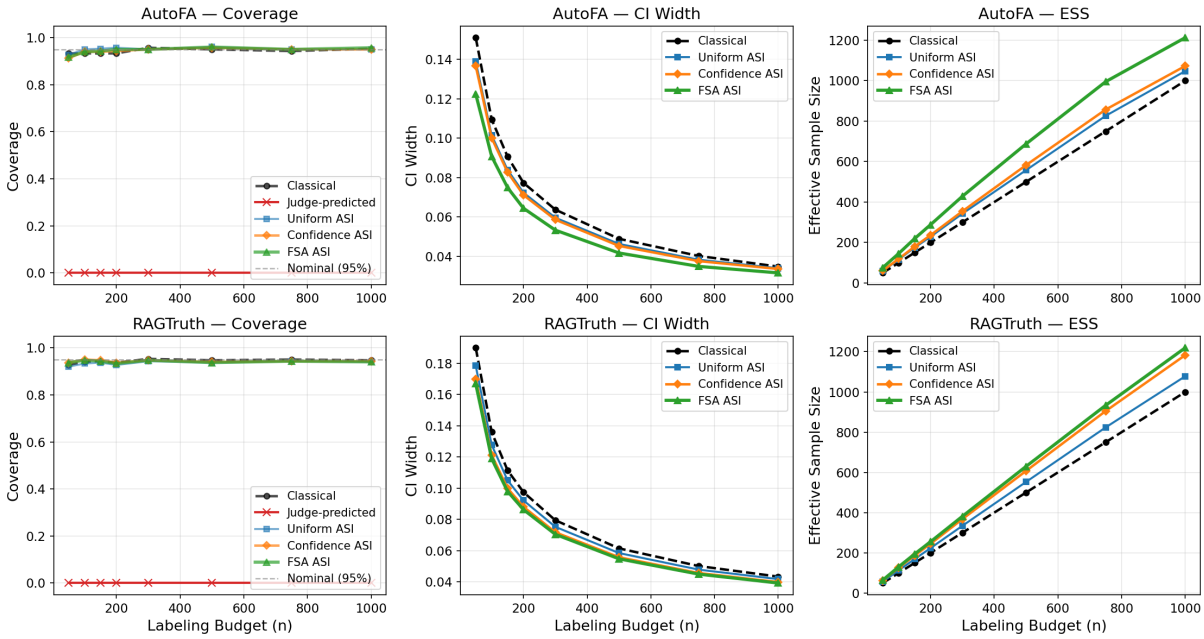

Figure 2: Coverage, CI width, and effective sample size across annotation budgets. FSA ASI maintains valid coverage while achieving the largest effective sample size (ESS) across both datasets.

Dataset	Policy	Cov.	ESS Gain (%)
AutoFA	Classical	$0.94_{\pm 0.01}$	—
	Judge-predicted	0.00	—
	Uniform ASI	$0.95_{\pm 0.01}$	$+13.3_{\pm 4.1}$
	Confidence ASI	$0.94_{\pm 0.01}$	$+17.0_{\pm 4.3}$
	FSA ASI	$0.95_{\pm 0.01}$	$+\mathbf{40.3}_{\pm 9.1}$
RAGTruth	Classical	$0.94_{\pm 0.01}$	—
	Judge-predicted	0.00	—
	Uniform ASI	$0.94_{\pm 0.01}$	$+11.3_{\pm 1.8}$
	Confidence ASI	$0.94_{\pm 0.00}$	$+22.6_{\pm 2.3}$
	FSA ASI	$0.94_{\pm 0.00}$	$+\mathbf{27.1}_{\pm 2.7}$

Table 4: CI simulation results aggregated across budgets $n_{\text{bgt}} \in \{50, 100, \ldots, 1000\}$ ($\alpha = 0.05$, 300 trials per budget). Values report mean $\pm$ standard deviation across budgets.

ASI variants differ only in how they allocate the human-labeling budget.

Metrics and simulation. We report coverage, confidence interval width, and effective sample size (ESS). Coverage is the fraction of confidence intervals containing the human FAR computed on the full evaluation set. ESS measures efficiency on the scale of uniform annotation: an ESS gain of $+40\%$ means that n policy-sampled labels achieve the same variance as $1.4n$ uniformly sampled labels. For each budget $n_{\text{bgt}} \in \{50, 100, \ldots, 1000\}$, we run 300 Monte Carlo trials on the evaluation split. In each trial, we bootstrap the evaluation set, sample human labels according to the corresponding policy, compute the estimator, and construct a Wald confidence interval at $\alpha = 0.05$.

Results. Table 4 and Figure 2 summarize the simulation results. The judge-predicted estimator has zero coverage on both datasets, confirming that judge FAR is biased relative to the human-anchored target. In contrast, all ASI variants maintain near-nominal coverage across budgets, showing that human-labeled correction successfully debiases the judge estimate.

Among the valid estimators, all ASI variants improve efficiency over the classical baseline. Uniform ASI already provides ESS gains of $+13.3\%$ on AutoFA and $+11.3\%$ on RAGTruth while Confidence ASI further improves efficiency to $+17.0\%$ and $+22.6\%$, respectively, by allocating more labels to low-confidence examples.

FSA ASI achieves the largest gains, improving ESS by $+40.3\%$ on AutoFA and $+27.1\%$ on RAGTruth when aggregated across budgets. The larger gap over Confidence ASI on AutoFA reflects that self-confidence is a weaker residual-risk signal in this setting, while FSA identifies reference support strength as a more informative evidence-quality feature. On RAGTruth, the smaller gap is consistent with self-confidence already capturing much of the residual structure, with flag-reliability providing an additional gain.

5 Related Work

Factuality evaluation is central to assessing LLM outputs when correctness must be verified against retrieved evidence, source documents, or external references. Prior work has developed automatic factuality and hallucination evaluation methods that decompose responses into claims, atomic facts, or hallucinated spans, and assess whether these units are supported by evidence (Min et al., 2023; Chen et al., 2023; Niu et al., 2024; Iqbal et al., 2024; Song et al., 2024; Wei et al., 2024). These methods improve scalability, but LLM judges can systematically diverge from human labels due to incomplete evidence, over-literal grounding, rubric mismatch, and other biases in the judging procedure (Zheng et al., 2023; Wang et al., 2024; Gu et al., 2025).

Another line of works including Prediction-Powered Inference and its variants studies how to combine abundant machine predictions with limited human labels while preserving statistically valid inference (Angelopoulos et al., 2023, 2024). Active Statistical Inference extends this idea to budgeted annotation, where examples are sampled according to a policy designed to reduce estimator variance (Zrnic and Candes, 2024). Recent work adapts these ideas to LLM evaluation, showing how LLMaaJ metrics can be reported with valid uncertainty quantification (Gligorić et al., 2025; Wu et al., 2026; Lee et al., 2025). Cost optimal AI evaluation (Angelopoulos et al., 2025) extends ASI by incorporating the cost of human annotator and LLMaaJ into the optimization objective to derive cost-aware annotation policy. Meanwhile, MultiPPI (Cowen-Breen et al., 2026) and AM-PPI (Brawand et al., 2026) explore settings where multiple predictors are available and how to route between predictors to balance the cost-performance trade-off.

Closest to our work, confidence-driven inference (Gligorić et al., 2025) uses verbalized LLM confidence to guide human annotation, which provides a strong generic sampling signal. However, factuality residuals are not always explained by uncertainty alone: judges can be confidently misaligned when evidence is incomplete or only indirectly supportive. Our work adds a factuality-specific policy-design layer: FSA derives residual-risk features from judge artifacts, evidence quality, task strata, and rubric alignment, improving annotation efficiency while preserving the human-anchored ASI target.

6 Limitations

Our proposed framework is effective but is constrained by a few limitations:

First, FSA-guided ASI relies on residual structure learned from historical or calibration data. Its efficiency depends on this structure remaining stable across the evaluation population, i.e., model updates, retrieval or grounding changes, shifts in user queries, or new failure modes can degrade the policy. Silent high-confidence errors that are not captured under distribution shift will be under-sampled by the policy, thus inflate inverse-probability weights and increase variance. Uniform mixing can mitigate but does not remove the need for distribution-shift monitoring and periodic policy recalibration in production deployment. Specifically, a small uniformly sampled audit stream can test whether recent LLM–human residuals remain concentrated in the regions predicted by the policy. If this relationship degrades, the system can increase uniform mixing or revert temporarily to Uniform ASI, while acquiring additional human annotations to recalibrate the policy.

Second, while the four failure families provide useful pre-annotation signals for predicting disagreement in the studied settings, they do not exhaustively cover all error categories. Rare but complex cases, for example, failures in multi-hop reasoning across multiple pieces of evidence, may still occur and may not be captured by FSA. Depending on the application setting, the FSA rubric may therefore need to be further adapted or extended.

Third, our formulation also simplifies the annotation process. We treat the final adjudicated human label as the target and do not explicitly model annotator-level noise or disagreement. We also focus on a single human-annotator rather than a multi-annotator setting with different costs and reliabilities, such as cheap annotators, expert annotators, or multiple judge models. Extending FSA-guided ASI to jointly allocate budget across heterogeneous annotators is an important direction for future work.

Finally, ASI improves efficiency for a given annotation budget, but it does not determine the budget required for a particular production decision. In practice, the choice of n_{bgt} depends on cost, latency, acceptable uncertainty, and release-risk tolerance. Our results quantify the variance reduction achieved by FSA-guided sampling, while budget selection itself remains an operational decision.

A Policy Learning Details

This appendix provides experimental details on implementing FSA-policy and running simulations.

Regression target. The policy learning objective is to predict the residual magnitude $|\Delta_i| = |\phi_i^h - \phi_i^f|$ from pre-labeling features. On both datasets, this target is binary: $|\Delta| = 1$ when the judge and human disagree, and $|\Delta| = 0$ when they agree. Figure 3 shows the class distribution. The disagreement rate is 28.2% on AutoFA and 34.7% on RAGTruth.

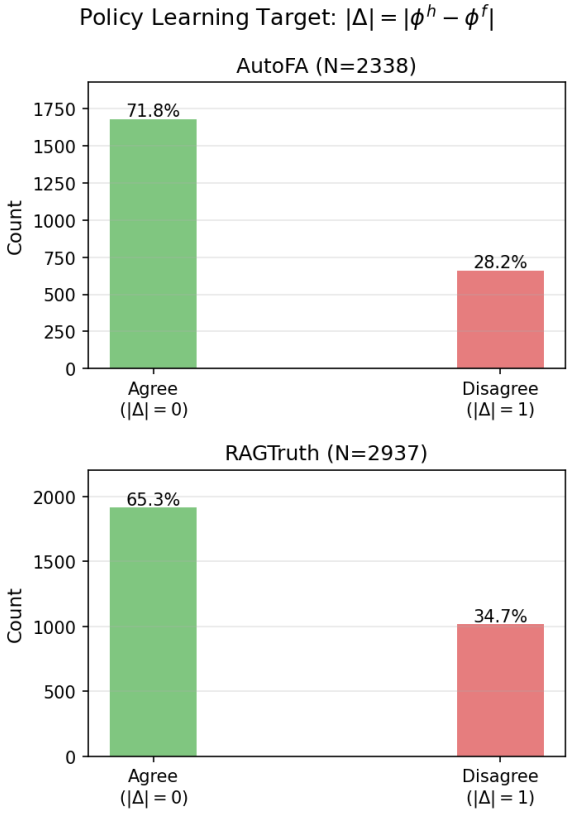

Figure 3: Distribution of the policy learning target $|\Delta| = |\phi^h - \phi^f|$. Both datasets have an imbalanced binary target, with agreement (green) as the majority class.

Score model. We train an XGBoost regressor (Chen and Guestrin, 2016) with `objective=reg:squarederror` to predict $|\Delta|$ from the selected features. On a binary target, this is equivalent to learning $P(\Delta \neq 0 \mid X)$, producing a residual-risk score in $[0, 1]$. We use 200 boosting rounds, learning rate 0.05, and maximum tree depth 3. The model is trained on the 40% calibration split and its output serves as the raw score $s(X_i)$ for policy construction.

Score normalization and uniform mixing. Following the oracle ASI policy in Section 3, we first transform the predicted residual risk as $r(X_i) = \sqrt{s(X_i)}$, and then convert it into inclusion probabilities:

$$\pi_i^{\text{raw}} = r(X_i) \cdot \frac{n_{\text{bgt}}}{\sum_j r(X_j)},$$

with water-filling to ensure $\pi_i \leq 1$. To prevent extreme weights that destabilize the ASI variance estimate, we also apply uniform mixing (Li et al., 2025):

$$\pi_i = (1 - \tau) \cdot \pi_i^{\text{raw}} + \tau \cdot \frac{n_{\text{bgt}}}{N},$$

where $\tau \in [0, 1]$ interpolates between the learned policy ($\tau = 0$) and uniform sampling ($\tau = 1$). Larger τ improves stability at the cost of policy concentration.

Mixing coefficient selection. We select τ by grid search over $\{0.05, 0.10, \ldots, 1.0\}$, evaluating the ASI variance on the calibration split for each candidate. Figure 4 shows that both datasets exhibit a concave ESS-gain curve: too-small τ creates extreme inverse-probability weights that inflate variance, while too-large τ dilutes the policy signal. The selected values are $\tau = 0.40$ for AutoFA and $\tau = 0.55$ for RAGTruth. The higher τ on RAGTruth reflects its larger $\mathbb{E}[\Delta^2]/\text{Var}(\phi^h)$ ratio, which requires a larger mixing coefficient for stability.

Power tuning. The ASI estimator uses a power-tuning coefficient $\lambda \in [0, 1]$ that controls how strongly the judge contribution enters the correction (Angelopoulos et al., 2024). At $\lambda = 1$, the estimator uses the full judge signal; at $\lambda = 0$, it ignores the judge entirely. Power-tuning selects λ to minimize the policy-dependent variance term:

$$J(\lambda) = \mathbb{E}\left[(\phi^h - \lambda\phi^f)^2 \cdot \left(\frac{1}{\pi(X)} - 1\right)\right].$$

Since $J(\lambda)$ is quadratic in λ, the optimum has a closed-form solution:

$$\lambda^* = \frac{\mathbb{E}[\phi^h \phi^f \cdot w]}{\mathbb{E}[(\phi^f)^2 \cdot w]},$$

where $w_i = 1/\pi(X_i) - 1$. In practice, we estimate λ^* from the calibration split using sample averages. Because $J(\lambda)$ is convex, the tuned estimator always has variance no greater than the untuned ($\lambda = 1$) estimator.

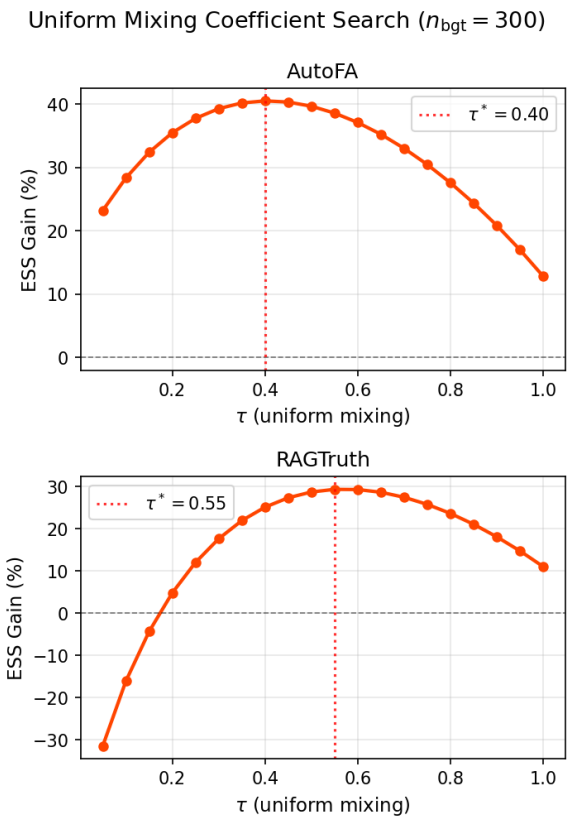

Figure 4: Uniform mixing coefficient (τ) search. ESS gain is evaluated on the calibration split at $n_{\text{bgt}} = 300$. Both curves are concave: small τ overfits, large τ underconcentrates. Red dotted line marks the selected τ^*.

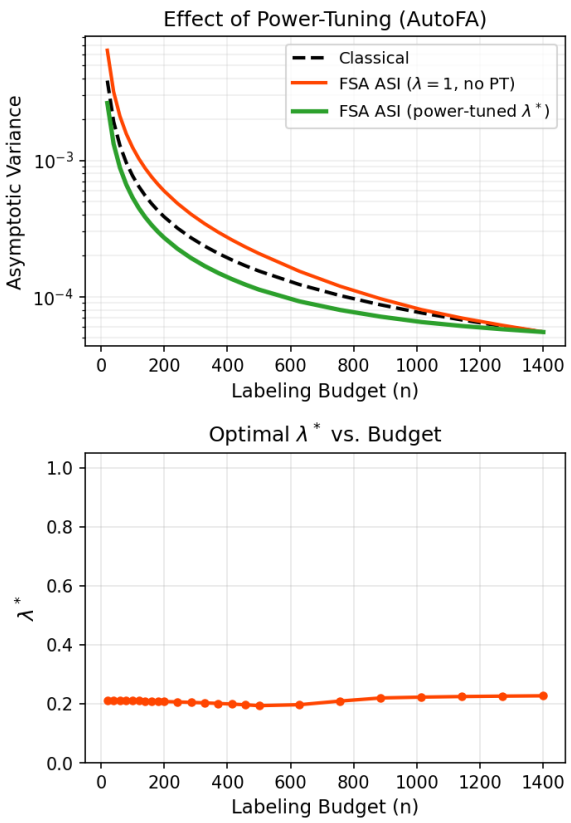

Figure 5: Effect of power-tuning on AutoFA. Left: variance comparison showing that $\lambda = 1$ (untuned) can be worse than baseline, while λ^* (tuned) consistently improves. Right: the optimal $\lambda^* \approx 0.2$ is stable across budgets, indicating the judge should be used at ∼20% strength.

Figure 5 illustrates the effect on AutoFA: without power-tuning ($\lambda = 1$), the ASI variance exceeds the labeled baseline at small budgets because the judge residual is large. Power-tuning ($\lambda^* \approx 0.2$) shrinks the judge contribution to the level most appropriate for the residual structure, consistently reducing variance below the baseline.

B Feature Selection Details

This appendix describes the feature selection procedure and provides post-hoc validation.

Selection procedure. Feature candidates are derived from the qualitative FSA in Section 4.2. We evaluate each candidate's residual-ranking quality via 5-fold cross-validated Spearman correlation on the calibration set. We then select the final feature set using two criteria: (1) high CV Spearman, and (2) parsimony: we prefer a smaller feature set because, with only $N \approx 1000$ calibration samples, using many features can introduce spurious correlations and cause the score model to overfit.

Joint feature importance. Figure 6 shows SHAP values (Lundberg and Lee, 2017) for the score model trained on all candidate features, confirming which features drive the model's predictions. On AutoFA, ref-support-strength dominates. On RAGTruth, self-confidence and flag-reliability jointly dominate. Features from other families contribute marginally.

Post-hoc policy validation. To further evaluate how the selected features translate into effective policies, we compare held-out ESS gain across feature configurations in Table 5. On AutoFA, ref-support-strength ($|\rho| = 0.50$) alone outperforms self-confidence ($|\rho| = 0.12$) alone by a large margin, validating that FSA identifies a stronger signal. On RAGTruth, self-confidence ($|\rho| = 0.63$) is already strong; the addition of flag-reliability provides a modest improvement ($|\rho| = 0.69$). In both cases, adding more features beyond the selected set does not improve ESS, consistent with the observation of overfitting at limited calibration

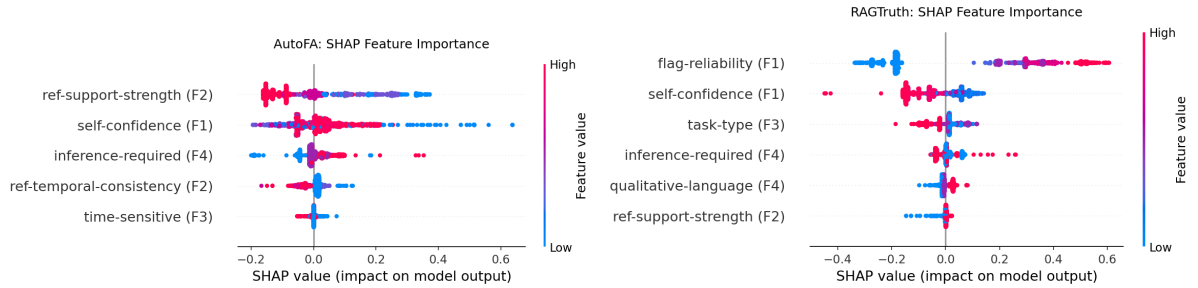

Figure 6: SHAP feature importance for the residual-risk score model trained on all candidate features. Left: AutoFA. Right: RAGTruth.

size.

Dataset	Feature configuration	CV ρ	ESS gain
AutoFA	Self-confidence only	0.12	+16.6%
	Ref-support-strength	**0.50**	**+40.5%**
	All candidates (5)	0.52	+24.7%
RAGTruth	Self-confidence only	0.63	+17.8%
	Self-confidence + flag-reliability	**0.69**	**+19.7%**
	All candidates (6)	0.71	+9.6%

Table 5: Feature selection validation. CV ρ: 5-fold cross-validated Spearman on calibration set. ESS gain: post-hoc evaluation on held-out split at $n_{\text{bgt}} = 300$. Bold: selected configuration. Adding more features improves CV correlation but can reduce ESS due to overfitting.

The key observation is that higher univariate or multivariate correlation does not guarantee better policy performance. On AutoFA, the "all features" model achieves CV $\rho = 0.52$ but only $+24.7\%$ ESS, while the single-feature model achieves $+40.5\%$ ESS. This occurs because the multi-feature model requires more aggressive uniform mixing ($\tau = 0.70$) to stabilize extreme weights, which dilutes the policy concentration. The single feature provides smoother, full-population ranking that translates more effectively into sampling probabilities.

C Human Annotation Details

Both datasets leverage human annotators to acquire reference labels and we summarize the details as follows: RAGTruth (Niu et al., 2024) reports two independent annotators per response and a third review for substantial disagreements, and consistency rates of 91.8% at the response level and 78.8% at the span level. Annotators were recruited through a professional vendor and compensated at \$25 per hour. For AutoFA, all records received a human annotation, and 90% received a second, independent annotation. For records where two annotators disagree with each other on the final response factual verdict, a third human moderator was involved to adjudicate and made the final judgment. The human annotators are instructed to extract core, verifiable claims from the model responses and search the web to judge the factual correctness of the claims and final overall response level factual correctness.

D Qualitative Analysis

We provide two qualitative examples from RAGTruth illustrating LLM judge errors and how FSA identifies them.

In record 168, the response states that Walter Scott was "shot whilst running from Officer Michael Slager." The reference states that Scott was "fatally shot in the back by a police officer" and separately describes video showing Scott running from the officer while the officer fires eight shots. The response therefore combines two closely connected facts into a concise, well-supported statement, but the LLM judge flags "shot whilst running" as hallucinated, apparently requiring the temporal relation to be stated verbatim. Importantly, the LLM judge assigns 0.85 self-confidence, so confidence-based sampling would not identify this as a high-risk record. In contrast, the FSA feature flag-reliability receives a score of 2 (higher means LLM-judge is more likely to be wrong), indicating elevated over-detection risk and allowing the residual-risk policy to prioritize the record for human annotation.

In record 5718, the structured reference lists the same hours, 12:00–17:00, for every day from Monday through Sunday. The response accurately summarizes this as operating "seven days a week from 12:00 to 17:00," yet the LLM judge flags the statement, apparently failing to aggregate the seven

JSON entries. The LLM judge reports a low self-confidence score of 0.30 while the FSA assigns the maximum unreliability (flag-reliability=3).

E Feature Extraction Prompts

This appendix lists the prompts used for self-confidence scoring and FSA feature extraction. All prompts are written as Jinja2 templates: variables enclosed by `{{ }}` are replaced with record-specific content at inference time. The prompts are used only to extract auxiliary features or confidence scores, not to determine the final human label.

E.1 Self-Confidence Prompt

We use the prompt in Figure 7 to elicit the judge's confidence in its own previous verdict. The same structure is used for both datasets, with minor wording changes depending on whether the underlying task is factuality verification or hallucination detection.

E.2 AutoFA Feature Extraction Prompt

The prompt in Figure 8 extracts five FSA features for AutoFA. The judge assesses the verification difficulty of a response given the query and three reference answers. It is explicitly instructed not to make the final factuality decision.

E.3 RAGTruth Feature Extraction Prompt

The prompt in Figure 9 extracts general verification-difficulty features for RAGTruth records. The general verification-difficulty features characterize the response–reference relationship, while *flag_reliability* additionally assesses the judge's flagged spans.

Self-Confidence Score: AutoFA Variant

You previously evaluated whether a model response is factually correct by comparing it against reference answers, and concluded that the response is {factually correct / factually incorrect}.

Inputs

- User query: {{ query }}
- Model response: {{ response }}
- Reference answer 1: {{ ref_1 }}
- Reference answer 2: {{ ref_2 }}
- Reference answer 3: {{ ref_3 }}
- Previous verdict: {The response is factually correct / incorrect.}

Instruction

How likely is it that your previous verdict is correct?
Output only a single number between 0 and 1 representing the probability. Do not provide an explanation or reasoning.

Output

Probability:

Figure 7: Prompt used for generating self-confidence score.

AutoFA: Evidence and Rubric Features

You are an experienced evaluator in factuality assessment for voice assistant responses.
Your job is not to decide the final label. Your job is to extract a compact set of interpretable features that characterize the difficulty of verifying whether the response is factually correct.
Use only the provided information. Return valid JSON only. Do not provide chain-of-thought. Use integer scores in `{0,1,2,3}`, where higher values indicate more of the corresponding feature.

Feature definitions

1. `reference_temporal_consistency`

   How consistent the three references are on time-dependent facts.

   `0` = fully consistent; `3` = major conflicts on the core answer.

2. `reference_support_strength`

   How strongly the references support the response's core claims.

   `0` = no support; `3` = all references confirm the core answer.

3. `inference_required`

   How much inference is needed to verify the response against the references.

   `0` = pure extractive matching; `3` = substantial reasoning required.

4. `claim_importance_variance`

   How much the claims vary in importance to the core question.

   `0` = all claims are equally important; `3` = core answer plus many peripheral claims.

5. `answer_completeness_vs_correctness`

   Whether the response appears correct but potentially incomplete.

   `0` = comprehensive; `3` = answers only a narrow slice.

Output format

```
{
  "feature_name": {
    "score": int,
    "justification": str
  },
  ...
}
```

Inputs

- User query: `{{ query }}`
- Model response: `{{ response }}`
- Reference answer 1: `{{ ref_1 }}`
- Reference answer 2: `{{ ref_2 }}`
- Reference answer 3: `{{ ref_3 }}`

Figure 8: Prompt used for feature extraction for AutoFA.

RAGTruth: Evidence and Rubric Features

You are an experienced evaluator in groundedness assessment.
Your task is to extract features that characterize the difficulty of verifying whether the response is faithful to the reference. If hallucination spans are provided, also assess whether those flagged spans are plausible.
Use only the provided information. Return valid JSON only. Do not provide chain-of-thought. Use integer scores in `{0,1,2,3}`, where higher values indicate more of the corresponding feature.

Feature definitions

1. `reference_support_strength`: how strongly the reference supports the response's claims. `0` = very weak support; `3` = strong and direct support.
2. `inference_required`: how much inference beyond verbatim extraction is needed to verify the response. `0` = purely extractive; `3` = substantial interpretation.
3. `qualitative_language`: degree of subjective or interpretive language in the response. `0` = purely factual; `3` = heavily qualitative.
4. `flag_reliability`: if hallucination spans are provided, how likely the judge is correct about those flags. `0` = very likely correct; `3` = likely incorrect due to over-detection. If no spans are provided, set this score to `0` and state that no flagged spans were provided.

Output format
Return a JSON object of the following form:

```
{"feature_name": {"score": int, "justification": str}, ...}
```

Inputs

- Task type: `{{ task_type }}`
- Reference: `{{ reference }}`
- Response: `{{ response }}`
- Judge's flagged spans: `{{ spans }}`

Figure 9: Prompt used for feature extraction for RAGTruth

Attention-Weighted Retrieval-Augmented Data Engineering for ADR Severity Classification

David Guo and Nishant Vishwamitra and Kim-Kwang Raymond Choo
Department of Information Systems and Cybersecurity
The University of Texas at San Antonio
david.guo@utsa.edu, nishant.vishwamitra@utsa.edu, raymond.choo@utsa.edu

Abstract

Adverse drug reaction (ADR) severity prediction is a key task in pharmacovigilance and post-market drug safety surveillance, but is often challenged by noisy and heterogeneous clinical data. We propose a retrieval-augmented learning framework that leverages historical FAERS reports to construct evidence-enriched training instances for ADR severity prediction. Each ADR query, including patient demographics, drug exposure, and indications, is encoded using a fine-tuned BGE-M3 embedding model. We retrieve the top five relevant cases using BM25 lexical search and the top five semantically similar cases using dense vector search, and fuse them via an attention-based aggregation mechanism to produce retrieval-aware representations. These representations are evaluated using machine learning, deep learning, transformer, and fine-tuned large language model approaches for binary severity prediction. Results show that a tree-based ensemble achieves the best performance with an AUC of 82.3%, outperforming the strongest deep learning baseline by 2.3 percentage points and fine-tuned LLMs by 17 percentage points. Overall, the findings demonstrate that retrieval-enhanced data preprocessing can improve representation quality for ADR severity prediction, while the proposed upstream data engineering approach enables classical ensemble methods to remain highly effective for large-scale pharmacovigilance risk prediction[1].

1 Introduction

Adverse drug reaction (ADR) poses a significant risk to patient safety and have been reported as the third leading cause of death following heart disease and cancer (Makary and Daniel, 2016). As the number of approved and experimental drugs continues to increase, early and accurate prediction of ADR outcomes has become increasingly critical for minimizing patient risk and improving clinical outcomes (Mullard, 2026). The U.S. Food and Drug Administration Adverse Event Reporting System (FAERS) serves as one of the largest repositories of post-market drug safety reports, containing millions of spontaneously reported adverse events collected over more than two decades. It records more than 1.25 million serious ADR cases in 2022 including nearly 175,000 fatalities accessed in 2024 (Kommu et al., 2024). Accurate prediction of ADR severity from these reports can assist regulators, healthcare providers, and pharmaceutical manufacturers in prioritizing safety signals and allocating investigative resources. Figure 1 depicts an example ADR prediction task, consisting of the ADR structured label (*e.g.*, "DEATH") and unstructured narratives describing the label in preferred clinical terminology, given a patient's information and treatment.

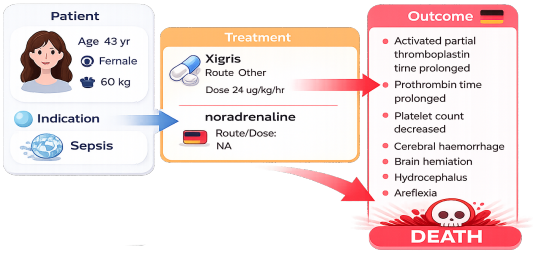

Figure 1: Illustrative Example of an ADR Severity Outcome

Recent advances in natural language processing have led to widespread adoption of transformer-based architectures and large language models (LLMs) for biomedical text understanding. Models such as BERT, Llama, and Qwen have demonstrated impressive performance across a range of clinical and biomedical tasks (Deimazar and Sheikhtaheri, 2023; Golder et al., 2025). However, ADR severity prediction presents several challenges that limit the effectiveness of purely para-

[1]The project repository is publicly available in GitHub repository: https://github.com/nexusmed-ai/EMNLP2026

EMNLP 2026 Industry Track, pages 2234–2243
October 24-29, 2026 ©2026 Association for Computational Linguistics

metric models. First, severe ADR cases are relatively rare, resulting in highly imbalanced training data. Second, ADR narratives are mixed with noisy and heterogeneous information, making it difficult for language models to capture subtle severity-related patterns. Third, clinically relevant evidence frequently exists in historical reports rather than within the current case itself, requiring models to leverage external pharmacovigilance knowledge.

To address these challenges, we propose an attention-weighted retrieval-augmented representation learning framework for ADR severity prediction. Instead of relying solely on the information contained in a single ADR report, our approach retrieves semantically and lexically similar historical cases from a FAERS repository spanning 24 years of pharmacovigilance data (Robertson and Zaragoza, 2009; Wang et al., 2025; Lamsiyah et al., 2023). Specifically, each query report is matched with historical cases using both BM25 lexical retrieval and dense vector retrieval based on a fine-tuned BGE-M3 embedding model [2]. Retrieved cases are then integrated through an attention-weighted aggregation mechanism that dynamically estimates the relevance of each neighbor and constructs a retrieval-enhanced contextual representation for downstream prediction. Next, traditional tree-based ensemble methods remain competitive or superior when predictive signals are dominated by structured attributes and retrieval-derived features, allowing them to leverage heterogeneous information more efficiently than large neural architectures.

The proposed framework is evaluated on approximately 800,000 retrieval-enhanced ADR instances derived from FAERS quarterly reports and historical pharmacovigilance data. We compare traditional machine learning methods (Random Forest, XGBoost), deep neural networks (Convolutional Neural Network (CNN), long short-term memory networks (LSTMs), and bidirectional LSTMs (BiLSTMs)), transformer-based architectures, and fine-tuned large language models. Results show that retrieval-enhanced representations significantly improve predictive performance and generalization to future reports. Notably, tree-based ensembles consistently outperform transformer and LLM-based models, suggesting that retrieval quality and feature engineering are more critical than model complexity for ADR severity prediction.

[2]https://huggingface.co/BAAI/bge-m3

This work makes three primary contributions as follows:

1. we introduce an attention-weighted retrieval framework that integrates lexical and semantic evidence from historical pharmacovigilance reports to enrich ADR representations.
2. we provide a large-scale empirical study comparing traditional ML, DL, and LLMs under a unified retrieval-augmented learning setting
3. we demonstrate through out-of-time evaluation that retrieval-enhanced representations improve robustness and predictive performance for ADR severity prediction, highlighting the value of historical pharmacovigilance knowledge for biomedical NLP applications.

2 Related Work

2.1 ADR Prediction and Pharmacovigilance

The increasing availability of large-scale pharmacovigilance databases such as FAERS has driven extensive research on ADR prediction. Prior work has applied supervised learning methods using FAERS and external biomedical data, including Random Forest and deep learning models that integrate demographic, molecular, and biological features to predict ADRs, demonstrating the effectiveness of machine learning at scale (Farnoush et al., 2024). Deep neural networks combining toxicogenomic data with FAERS reports have also shown promising performance across multiple ADR categories (Mohsen et al., 2021).

In contrast, ADR severity prediction has received comparatively less attention, with most studies focusing on structured and unstructured data mining and information retrievals efforts. For example, structured approaches using FDA labeling and MedDRA terminology define seriousness categories for pharmacovigilance analysis (Wu et al., 2019), while attention-based models have been used to improve serious ADR detection using NLP and demographic features in FAERS (Aldughayfiq et al., 2024). Other approaches estimate severity from social media word embeddings and network propagation methods at asmall scale, showing correlations with real-world clinical outcomes (Lavertu et al., 2021).

2.2 Deep Learning and Transformer-Based Approaches

Advances in biomedical NLP have accelerated the adoption of deep learning architectures for pharma-

covigilance tasks. CNNs, LSTMs, and BiLSTMs have been widely used for ADR extraction, classification, and signal detection(Miranda, 2018; Gupta et al., 2018; Zhang and Geng, 2019). More recently, transformer-based models and LLMs have demonstrated strong performance on biomedical text understanding tasks due to their ability to capture contextual semantic information (Lee et al., 2020; Alsentzer et al., 2019; Gu et al., 2022; Singhal et al., 2025; Wang et al., 2024). Nevertheless, ADR severity prediction remains challenging because pharmacovigilance narratives are often sparse, noisy, and highly imbalanced. Existing transformer-based approaches typically rely on information contained within individual reports and do not explicitly leverage historical pharmacovigilance knowledge.

2.3 Retrieval-Augmented Learning

Retrieval-augmented methods have recently emerged as an effective strategy for incorporating external knowledge into prediction tasks by dynamically retrieving relevant evidence and conditioning models on non-parametric memory. Prior work in dense retrieval enabled neural document retrieval for open-domain tasks (Karpukhin et al., 2020), while retrieval-augmented language models integrated retrieved passages into downstream generation and classification (Lewis et al., 2021; Guu et al., 2020). Nearest-neighbor language modeling further improved generalization by leveraging example-based reasoning through explicit retrieval of similar training instances (Khandelwal et al., 2020). Collectively, these approaches demonstrate the benefit of combining parametric models with external memory, though their application to pharmacovigilance remains limited, particularly in leveraging historical ADR reports for severity prediction.

To address this gap, we propose an attention-weighted retrieval-augmented framework that integrates lexical, dense, and similarity-based retrieval over two decades of FAERS data. Unlike prior work relying on single-instance narratives, our method systematically incorporates historical pharmacovigilance evidence and compares traditional ML, DL, and LLM-based approaches within a unified retrieval-enhanced learning setting.

2.4 Finetuning Language Model Approaches

Advances in language model fine-tuning, particularly BERT and its biomedical variants, have improved the representation of ADR-related semantics and enhanced downstream prediction tasks (Guo and Choo, 2025). LLMs can also be leveraged to generate structured and unstructured narratives in preferred clinic terminology (Zhou et al., 2024). This shift enables more effective exploitation of rich, unstructured healthcare data, despite the inherent challenges posed by complex domain knowledge and heterogeneous data structures.

3 Our Approach

3.1 ADR Data Preparation

FAERS is released as quarterly compressed archives containing multiple plain-text files along with accompanying processing guidelines. Each release includes five core tables that can be linked via a unique caseID to reconstruct individual ADR reports.

We design an extraction, transformation, and loading (ETL) pipeline consisting of five steps illustrated as **Figure** 2. First, data extraction unpacks each quarterly FAERS archive and parses raw text files according to FDA specifications. Second, data transformation aligns and joins records across five tables using caseID to construct unified patient-centric ADR cases. Third, outcome processing maps the OUTC field to seven categorical outcomes; approximately 26% of reports are missing outcome labels. FAERS data are divided into three temporal splits: quarterly releases from 2004Q1–2024Q3 are used to construct the hybrid retrieval pipelines, 2024Q4–2025Q1 are used for training and validation, and 2025Q2 is reserved as an out-of-time (OOT) test set. To improve exposure to diverse drug–reaction patterns, ADR cases with missing outcome codes are included during embedding model and LLM fine-tuning. However, for fair evaluation of structured classification performance, we restrict metrics to cases with non-missing outcome labels.

A binary severity label is further derived by assigning the life-threatening class (DE/LT) when at least one life-threatening outcome is present among multiple reported outcomes, resulting in a highly imbalanced distribution (79% negative and 21% positive). Fourth, missing values in non-critical fields (e.g., dose frequency) are imputed as NA while drug name and indication are required to be non-missing. Finally, each ADR case is formatted as an instruction–outcome pair in JSONL and stored in Parquet format to enable efficient BM25 and vector indexing (See **Appendix**).

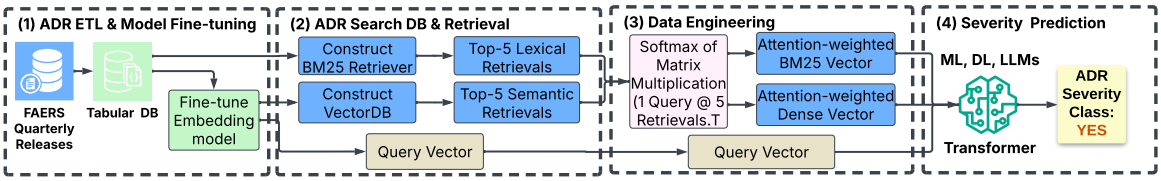

Figure 2: Overview of the Retrieval-Augmented ADR Severity Prediction Framework

3.2 ADR Instruction, Uni_code, and Severity Class

FAERS tabular data are aggregated from quarterly releases dating back to 2004Q1 up to 2025Q2, where each ADR case includes patient demographics, drug administration details, medication indications, represented by MedDRA preferred terms, and outcome labels. Each case is formatted as an instruction–outcome pair, with the instruction composed of 3 components: patient demographics (age, gender, weight), drug administration details (drug name, dose, route, frequency), and medication indications. To preserve the original column-wise relationships while supporting retrieval and generation tasks, all instruction–outcome pairs are stored in line-delimited JSON (JSONL) format, with each record containing a self-contained structured representation. The JSONL representation is the query format for both BM25 and vector hybrid retrieval stage. An illustrative example of instruction is shown in **Appendix** 7.1.

Each ADR case outcome consists of two components: an unstructured narrative formed by concatenated MedDRA Preferred Terms (PTs) and a structured outcome label representing the most severe reported event. Only structured outcome codes are used to construct the binary severity target (YES/NO), as summarized in Table 1. When multiple outcomes are present, the highest-severity label is assigned as the uni_code. Both the instruction and outcome are stored in a line-delimited JSON (JSONL) format to ensure consistency, as illustrated in **Appendix** 7.2.

3.3 Fine-tuning Embedding Model

High-quality retrieval is critical for retrieval-augmented generation (RAG) because retrieved evidence directly influences downstream ADR prediction. Rather than fine-tuning large language models, which is computationally expensive and requires frequent retraining as new FAERS data become available, we fine-tuned a domain-specific embedding model for efficient and scalable retrieval. We selected BAAI/BGE-M3[3] as the base model due to its strong retrieval performance and fine-tuned it on 500,000 ADR instruction–outcome pairs using Matryoshka representation learning (Schroff et al., 2015; Hoffer and Ailon, 2015; Kraišniković et al., 2025; Ng et al.).

Code	Severity	Description
DE	YES	Death
LT	YES	Life-Threatening
HO	NO	Hospitalization-Initial or Prolonged
DS	NO	Disability
CA	NO	Congenital Anomaly
RI	NO	Required Intervention to Prevent Permanent Impairment/Damage
OT	NO	Other Serious (Important Medical Event)

Table 1: Definition of Binary Severity Classification from Seven Structured ADR Outcomes

Model performance was evaluated on a held-out validation set using Top-K Hit Rate, Mean Reciprocal Rank (MRR), and Normalized Discounted Cumulative Gain (NDCG). The best-performing checkpoint was selected for subsequent vector database construction. We further compared the fine-tuned ADR-specific embedding model with three MedEmbed variants designed for biomedical and clinical text (Balachandran, 2024). As reported in **Table** 2, the fine-tuned BGE-M3 model substantially outperforms both the base BGE-M3 model and the MedEmbed baselines across all retrieval metrics. The fine-tuned embedding model is publicly available on Hugging Face at https://huggingface.co/nexusmed-ai/adr_bge_m3_embedding.

model	hit@1	hit@3	hit@5	mrr@5	ndcg@5
bge_m3 FT	**0.81**	**0.97**	**1.00**	**0.89**	**0.92**
bge_m3 Base	0.24	0.56	0.86	0.44	0.54
med_small	0.29	0.63	0.89	0.49	0.59
med_base	0.22	0.56	0.87	0.44	0.54
med_large	0.26	0.60	0.88	0.47	0.57

Table 2: Finetuning Bge-m3 with Matryoshka Representation Learning

[3] https://huggingface.co/BAAI/Bge-m3

3.4 Model Training Dataset

For each ADR report, the query narrative was encoded into a 1,024-dimensional embedding using the fine-tuned BGE-M3 model. The top five BM25-retrieved cases and top five dense-retrieved cases were encoded and aggregated separately using similarity-based attention weights, producing one BM25 context embedding and one dense context embedding. These three 1,024-dimensional vectors—the query embedding, BM25 context embedding, and dense context embedding—were stacked to form a (3 X 1024) retrieval-aware tensor for downstream ADR severity prediction.

ML models use a flattened 3,072-dimensional feature vectors, whereas CNN, LSTM, BiLSTM, and Transformer models consume the full $3 \times 1{,}024$ tensor. Fine-tuned LLMs operate on the original text instructions and retrieved cases without explicit embedding inputs.

3.5 Construction of Retrieval Database

To enable efficient similarity search over millions of ADR embeddings, we store all query representations in a LanceDB vector database using an IVF-HNSW-PQ approximate nearest-neighbor index with 256 partitions and 128 sub-vectors [4], providing a balance between search efficiency and recall. At query time, the top-5 most similar ADR cases are retrieved based on cosine similarity, which reduces to a dot product due to unit-normalized BGE-M3 embeddings. The resulting ranked neighbors are then passed to downstream fusion and re-ranking stages for retrieval-augmented prediction.

In parallel, we constructed a BM25 lexical retriever using the built-in tokenizer provided by the Python bm25s library for both indexing and querying to ensure consistent tokenization throughout the retrieval pipeline. At inference time, the top-5 matching ADR cases are retrieved based on lexical similarity. This stage complements dense retrieval by providing precise matching of patient demographics, drug names, and indication information.

3.6 Attention-Weighted Data Engineering

With three data channels derived from the two retrieval pipelines (BM25 and dense retrieval) and the query embedding from Box 2 of Figure 2, we further process the retrieved information in three steps: 1) Similarity computation - a matrix multiplication $q \times R^{\top}$ between the query embedding $q \in R^{1\times 1024}$ and the 5 retrieved case embeddings $R \in R^{5\times 1024}$ to yields a 1×5 vector of cosine similarities. 2) Attention weighting - softmax is applied to these 5 similarities, producing attention weights as

$$w_i = \frac{\exp(sim(q, r_i)\tau)}{\sum_{j=1}^{5} \exp(sim(q, r_j)/\tau)} \quad (1)$$

where τ is the temperature parameter controlling the concentration of the attention distribution. A smaller τ produces a more concentrated distribution, placing greater emphasis on the most similar retrievals, whereas a larger τ produces a smoother distribution (Hinton et al., 2015; Guo et al., 2017). In this study, we set τ=1 to maintain a relatively smooth weighting across the five retrieved cases. 3) Context aggregation - each of the top-5 embeddings is multiplied by its attention weight, and the weighted vectors are summed into a single aggregated context vector as $c = \sum_{i=1}^{5} w_i \cdot r_i$. where $c \in R^{1\times 1024}$ represents the attention-weighted retrieval context used in subsequent prediction.

3.7 LLM Finetuning and Inference

We fine-tune two open-source LLMs of different sizes - Qwen-3.5-0.8B (text only)[5] and Llama-3.2-3B[6] on 80,000 FAERS reports from training set with binary labels. Both 4-bit quantized based models using QLoRA with LoRA adapters (rank 16, alpha 32, dropout 0.05) on the attention layers. Only the LoRA adapters and classification head are updated, while the backbone remains frozen for memory-efficient training. The models are optimized using an imbalance-aware cross-entropy objective over the combined query and retrieval context. Fine-tuning was conducted on a single NVIDIA V100 (32GB) GPU, requiring approximately 9 hours for Qwen-3.5-0.8B and 52 hours for Llama-3.2-3B. During inference, the final binary severity label is determined by majority voting over predictions on the query case and its 10 retrieved neighbors.

4 Evaluation

4.1 Comparative Model Evaluation on OOT

Across all models under imbalanced data, traditional machine learning methods demonstrate the

[4] https://docs.lancedb.com/indexing/vector-index

[5] https://huggingface.co/principled-intelligence/Qwen3.5-0.8B-text-only

[6] https://huggingface.co/meta-llama/Llama-3.2-3B-Instruct

strongest and most stable discriminative performance prioritizing F1. Among them, Random Forest achieves the best F1-score (0.513) with strong AUC (0.800), while XGBoost obtains the highest AUC (0.803), indicating robust ranking ability under class imbalance. Deep learning models, including Transformer, CNN, BiLSTM, and LSTM, show moderate but consistently lower performance compared to tree-based methods. The Transformer performs best within this group (F1 0.476, AUC 0.799), while CNN and BiLSTM are slightly weaker, and LSTM performs worst, suggesting limited benefit from sequential modeling in this high-dimensional and noisy setting.

In contrast, fine-tuned LLMs show consistent improvements on F1 and Recall over their base models but remain less competitive overall. Qwen3.5-0.8B improves across all metrics compared to its baseline, while Llama3.2-3B increases recall (0.833) and F1 (0.278) but sacrifices precision (0.167), indicating strong positive-class bias. Overall, both LLM families underperformed classical machine learning models in terms of F1 and AUC, highlighting the robustness of tree-based ensemble models for ADR severity prediction under substantial class imbalance (0.79 negative vs. 0.21 positive).

Model	Accu.	F1	Rec.	Prec.	AUC
XGBoost	0.819	0.489	0.525	0.506	**0.803**
RF	0.828	**0.513**	0.491	0.501	0.800
Transformer	0.811	0.476	0.568	0.518	0.799
CNN	0.810	0.472	0.529	0.499	0.796
BiLSTM	0.793	0.436	0.545	0.485	0.787
LSTM	0.777	0.410	0.560	0.473	0.783
Qwen3.5-.8B FT	0.841	0.445	0.350	0.610	0.650
Qwen3.5-.8B Base	0.808	0.098	0.059	0.274	0.513
Llama3.2-3B FT	0.252	0.278	0.833	0.167	0.482
Llama3.2-3B base	0.816	0.061	0.035	0.262	0.507

Table 3: Evaluation of ML, DL, and LLM Performance

4.2 Majority Vote and Close-Sourced LLM Inference Baselines

To further evaluate alternative inference strategies, we included majority voting and GPT-5-mini inference as additional baselines on a subset of the OOT test set. Majority voting was implemented as a frequency-ranked ensemble of BM25 and dense-retrieval labels. For each case, the top-5 outcome labels retrieved by BM25 and the top-5 labels retrieved by dense embedding similarity were pooled into a single candidate set and ranked by vote count. We considered two variants: unweighted majority voting, which ranked labels by their raw vote counts, and score-weighted majority voting, in which each vote was weighted by its corresponding retrieval similarity score.

Inference Setting	F1	Precision	Recall
Majority vote (unweighted)	0.137	0.773	0.075
Majority vote (score-weighted)	0.180	0.674	0.104
Zero-shot	0.134	0.268	0.090
Prompt w/ Context (RAG)	0.242	0.491	0.161
Proposed model	**0.513**	0.506	0.525

Table 4: Comparison of majority voting and GPT-5-mini inference strategies on a subset of the OOT test set. The performance of proposed model are the best scores from ensemble model from Table 3

We also evaluated the closed-source GPT-5-mini model under zero-shot and RAG settings for the same binary classification task of predicting whether an ADR case was likely to result in a life-threatening outcome. GPT-5-mini was accessed through OpenAI's Batch API with minimal reasoning effort and prompted to act as a pharmacovigilance expert, interpret the available clinical information—including patient demographics, drug exposure, route and dose, and treatment indication—and return a single JSON prediction ("life_threatening": 0 or "life_threatening": 1). Responses were parsed using strict JSON parsing. For zero-shot inference, the model received only the query case and generated its prediction based on the information contained in that case. For RAG inference, the query case was augmented with 10 retrieved reference cases as in-context evidence: the top-5 BM25 and top-5 dense-vector nearest neighbors, each annotated with its ground-truth life-threatening label (0/1). These labeled cases were appended to the query as an evidence block. The model was instructed to use the retrieved cases as supporting evidence and base its prediction solely on the query case and retrieved evidence, without relying on external knowledge.

We evaluated these four inference strategies, unweighted majority voting, score-weighted majority voting, GPT-5-mini zero-shot inference, and GPT-5-mini RAG inference—and compared their performance with that of the proposed model. The results are summarized in Table 4.

The results indicate that direct LLM inference and majority-voting strategies achieve substantially lower F1 scores than the proposed retrieval-augmented fine-tuned ensemble model (F1 = 0.513). Among the evaluated LLM-based approaches, prompt-based inference with 10 retrieved cases achieved the highest F1 score (0.242), suggesting that retrieved contextual evidence can improve inference performance over zero-shot

prompting. Score-weighted majority voting also improved over unweighted majority voting, increasing the F1 score from 0.137 to 0.180. Nevertheless, all baseline strategies remained substantially below the proposed model, demonstrating the benefit of jointly leveraging retrieval-augmented evidence and supervised fine-tuning for the target prediction task. This comparison is included in the appendix to provide a more comprehensive evaluation of alternative inference strategies.

4.3 Stability of Ensemble Model Performance

The proposed F1-weighted ensemble achieved robust and stable performance across 5-fold cross-validation (CV) on the training dataset. Thresholds were optimized to maximize the F1 score, balancing precision and recall for the imbalanced ADR severity prediction task. The precision–recall curves demonstrate strong performance under class imbalance, with average precision (AP) values ranging from 0.603 to 0.623 and a mean PR-AUC of 0.613 ± 0.009, substantially exceeding the positive-class prevalence of 0.21. The consistently high AP scores and low variance across folds indicate stable identification of severe ADR cases despite the skewed class distribution (Figure 3). Overall, the ensemble model achieves a favorable balance between precision and recall while maintaining robust ranking performance, suggesting that retrieval-enhanced representations provide complementary predictive signals that generalize well across heterogeneous validation folds.

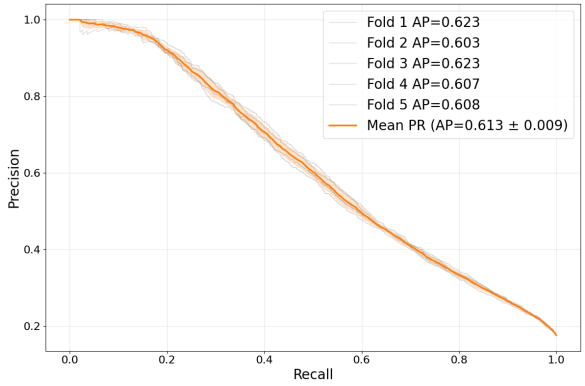

Figure 3: Imbalance-Aware Evaluation Using Precision–Recall AUC with 5-Fold Cross-Validation on the Validation Set

4.4 Ablation Study Individual Retrieval Inputs

An ablation study was conducted on the held-out OOT dataset to assess the contribution of three input vector representations under severe class imbalance, using F1-score, ROC-AUC, and PR-AUC as the primary evaluation metrics (Table 5). The BM25 representation performs worst overall, achieving high precision (0.588) but extremely low recall (0.076), leading to poor F1 (0.134), ROC-AUC (0.580), and PR-AUC (0.275), indicating limited generalization and poor coverage of positive cases. In contrast, the query and dense representations show substantially stronger and comparable performance, with F1-scores of 0.435 and 0.436, ROC-AUC values of 0.768 and 0.763, and PR-AUC scores of 0.488 and 0.494, respectively, demonstrating improved discrimination under class imbalance. The weighted ensemble combines the three input vectors by weighting their predicted probabilities according to validation F1 scores, achieving the most robust balanced performance with the highest ROC-AUC (0.773), best F1-score (0.458), and strongest PR-AUC (0.506). These results show that integrating complementary retrieval signals consistently improves both ranking quality and precision–recall trade-offs in the OOT setting.

Vector	Accu.	Prec.	Rec.	F1	AUC	PR
Ensemble	0.807	0.447	0.469	**0.458**	**0.773**	**0.506**
Query	0.829	0.510	0.379	0.435	0.768	0.488
Dense	0.812	0.453	0.421	0.436	0.763	0.494
BM25	0.831	0.588	0.076	0.134	0.580	0.275

Table 5: Ablation Study of Three Input Representations. Ensemble Vector represents the element-wise average of the three input vectors: the Query, Dense Retrieval, and BM25 Retrieval vectors.

5 Conclusion

We presented an attention-weighted retrieval-augmented framework for ADR severity prediction using 20 years of FAERS data. By combining lexical, dense, and similarity-based retrieval signals, the framework encodes historical ADR evidence into structured representations aiming to improve scalability, latency, computation efficiency, and deployment cost. Across ML, DL, and LLM evaluations, we demonstrated that retrieval-enhanced feature engineering consistently improves performance under noisy and imbalanced data. Notably, well-designed retrieval and feature construction enable classical tree-based ensembles to outperform more complex neural and LLM-based approaches, highlighting the importance of retrieval quality and feature engineering for practical pharmacovigilance systems.

6 Limitations

Despite the strong empirical performance of the proposed framework, several limitations remain. First, the study relies on voluntarily submitted FAERS reports, which are inherently noisy, incomplete, and subject to substantial reporting bias. The quality and level of detail vary considerably across reporters, and many reports contain missing, inconsistent, or inaccurate information. Furthermore, FAERS submissions generally do not undergo systematic expert clinical review or validation prior to inclusion in the database, meaning that reported drug–event associations may not reflect confirmed causal relationships. As a result, reporting artifacts, and unverified adverse events can introduce noise into both the retrieval corpus and training data. These limitations could affect the reliability of learned patterns and reduce the generalizability of downstream predictions, particularly for rare events, newly approved drugs, and underrepresented patient populations.

Second, while retrieval augmentation improves predictive performance, it introduces dependence on the quality of the retrieved evidence. The model assumes that the retrieved historical cases are relevant and representative of the query case; however, retrieval errors can propagate directly into downstream predictions. For example, BM25 retrieval may overemphasize lexical overlap while missing semantically relevant cases, whereas dense retrieval may return conceptually similar but clinically unrelated reports. In addition, historical biases and reporting patterns present in FAERS can be amplified when frequently retrieved cases disproportionately influence model decisions. As a result, retrieval quality becomes a critical factor affecting model robustness, generalizability, and interpretability, particularly when applied to emerging drugs, rare adverse events, or previously unseen patient populations.

Third, the current framework aggregates historical cases using retrieval-based representations without explicitly incorporating temporal information. Although the FAERS corpus spans more than two decades, retrieved cases are ranked primarily by semantic similarity, ignoring their reporting year and quarter. This limitation is important because drug–event relationships and severe outcomes may evolve over time due to changes in prescribing patterns, regulatory actions, and emerging safety signals. As a result, older cases may bias retrieval and weaken the model's ability to capture recent severity trends. Future work could address this by incorporating timestamp-aware retrieval, such as encoding year and quarter information or applying time-sensitive weighting during ranking.

Fourth, the temperature parameter (τ) in Equation 1 used in the retrieval-attention mechanism was fixed rather than extensively tuned. The temperature controls the sharpness of the softmax distribution over the cosine similarities of the retrieved cases and therefore directly influences how much the model emphasizes the most similar retrievals versus aggregating information across multiple retrieved cases. In this study, we set τ=1 to maintain a relatively smooth attention distribution. Although this choice reduces the risk of overemphasizing a single potentially noisy retrieval, alternative values of τ may yield different performance, particularly when the similarity scores of the retrieved cases are closely distributed. A systematic sensitivity analysis or validation-based tuning of τ could potentially improve retrieval weighting and provide a more robust assessment of the contribution of individual retrievals. Future work should investigate adaptive or learnable temperature parameters that can dynamically calibrate retrieval attention based on query characteristics and retrieval confidence.

Fifth, although we evaluated a broad range of model families, including ML, DL, and LLMs, the LLM experiments are limited to relatively small open-source models (0.8B and 3B parameters). These models may lack the capacity and domain-specific knowledge required for complex pharmacovigilance reasoning and may not fully represent the capabilities of larger state-of-the-art LLMs. Consequently, the observed performance gap between LLMs and traditional ML approaches should be interpreted with caution, as larger LLMs or models further adapted to biomedical and pharmacovigilance data may achieve stronger performance, albeit at substantially higher computational and inference costs.

Finally, interpretability of the combined retrieval-and-learning pipeline remains partially constrained, particularly in how individual retrieved instances contribute to final predictions. Addressing these limitations through improved data curation, temporal modeling, and more interpretable retrieval attribution represents an important direction for future work.

Acknowledgments

Enrich-Retrieve-Rank: Scaling Capability Discovery Beyond In-Context Routing

Abstract

Agent ecosystems now include thousands of **MATS** components (**M**odels, **A**gents, **T**ools, and **S**kills), yet their discovery still relies on in-context routing. These systems read a registry (names, hints, or descriptions, as context budget permits), pick a candidate, invoke it, and retry on failure. This pattern degrades with scale, and registries are growing fast. We recast capability discovery as search over a registry by defining an offline enrichment step that turns sparse metadata into searchable profiles, and an online retrieve-then-rank pipeline that returns a ranked shortlist *without invoking* any candidates online. We show that from $N = 10$ to 7,278 capabilities, in-context routing's top-1 accuracy (Match@1) collapses ($0.85 \rightarrow 0.12$), while retrieve-then-rank degrades more gently ($0.81 \rightarrow 0.39$) because its reranker still ranks the right capability first 0.70–0.87 of the time once retrieval finds it. In the Nova Micro sweep, the crossover is around $N = 500$. We compare against two in-context baselines. Full-Ctx puts the whole registry in the prompt and asks the LLM to pick. Search&Pick gives the LLM a search tool to narrow candidates before it picks. At full scale the pipeline leads Search&Pick by 6.5 percentage points (pp) on Match@1 at about half the cost, and reduces the cost 70× versus Full-Ctx. We use the same configuration (same enrichment, retriever, and scorer weights) across agent, tool, and skill registries. The pipeline runs in production as the default capability-discovery layer of a large-scale multi-agent platform.

1 Introduction

Recent agentic systems (Anthropic, 2025; Cursor, 2024; LangChain, 2024; Amazon Web Services, 2024) expose registries of thousands of components. Our production registry unifies all MATS components under one schema and already exceeds 500 entries in every MATS type; the largest benchmark we study holds 7,278 tools. At that scale an orchestrator cannot place every candidate in context, so choosing what to call requires first narrowing what to consider.

Today's systems discover capabilities by in-context routing. The large language model (LLM) sees a representation of the registry (tool names, one-line hints, or full descriptions as budget permits), picks a candidate, invokes it, and retries on failure. Some systems truncate alphabetically; others use a regular expression tool to narrow candidates before picking. All couple cost and accuracy to registry size. Every wrong invocation costs tokens and latency, and may call an untrusted endpoint just to learn what it does.

We frame capability discovery as web search over a capability registry rather than the open web. A search engine does not make users click through every indexed page, and an orchestrator should not present every capability and rely on the LLM to pick. We retrieve ranked candidates *without invoking them* and return a shortlist. The advantage over in-context routing *widens with registry size*, so it matters most where the field is heading.

We decompose end-to-end performance into retrieval recall and reranker conditional accuracy. The reranker reaches near-peak accuracy at modest registry sizes and stays flat beyond that, so at larger scales most misses originate in retrieval. At full scale, our pipeline leads Search&Pick in match accuracy and uses half the tokens.

We apply one pipeline to agent, tool, and skill registries under a single configuration and deploy it in production as the capability-discovery layer for a multi-agent platform. The pipeline includes offline enrichment (an LLM rewrites sparse metadata into rich profiles once at registration time, not per query). Its value scales with metadata sparsity. On well-documented public data the effect is neutral-to-negative (§4.3). We include it as a production design choice, not a source of benchmark gains.

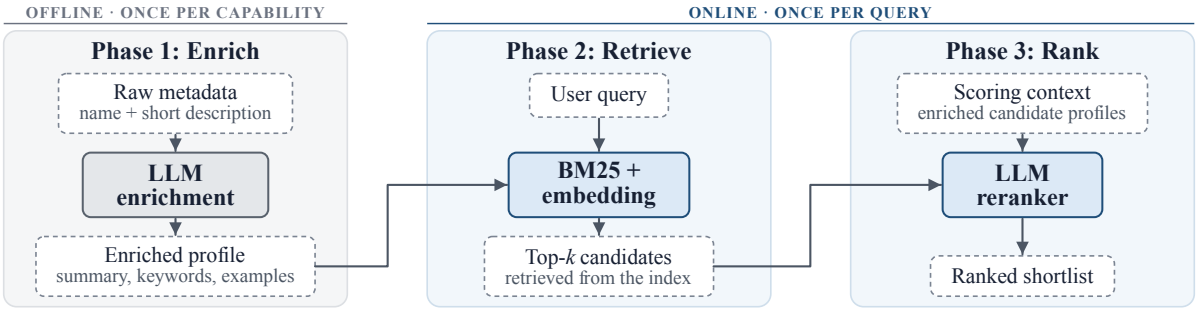

Figure 1: The Enrich-Retrieve-Rank pipeline. Phase 1 transforms sparse capability metadata into rich profiles. Phase 2 retrieves top-k candidates from the enriched index. Phase 3 ranks with a single LLM call. The entire online path requires one LLM call at bounded latency. Dashed boxes are data, and solid boxes are computation.

2 Related work

Tool retrieval. Toolformer (Schick et al., 2023) self-supervises a fixed API set; Gorilla (Patil et al., 2024) trains end-to-end on APIs; ToolLLM (Qin et al., 2024) scales the endpoints with a retriever and depth-first-search caller. All fix the API pool at train time, leaving retrieval implicit. ToolRet (Shi et al., 2025) strips the pre-annotated tool list and shows that general information retrieval (IR) models perform poorly on the resulting task. CRAFT (Yuan et al., 2024a) and EasyTool (Yuan et al., 2024b) are the closest enrichment-side methods. CRAFT abstracts code into per-task toolsets; EasyTool rewrites API docs into instructions. PLUTO (Huang et al., 2024a) pairs planning with description editing and is the closest prior recipe to ours. It does not quantify the retrieve-vs-rerank decomposition or study scale. AnyTool (Du et al., 2024) uses a hierarchical agent over 16k APIs but does not separate retrieval from MATS invocation. MetaTool (Huang et al., 2024b) and Qu et al. (2024) confirm tool selection is the dominant failure mode but propose no retrieve-then-rank pipeline.

Agent routing. AppWorld (Trivedi et al., 2024) keeps agent selection implicit because the registry fits in context ($n = 8$). HuggingGPT (Shen et al., 2023) and Visual ChatGPT (Wu et al., 2023) pick from a static menu. Our Nova Micro sweep shows that this pattern breaks around $N = 500$. AFlow (Zhang et al., 2024) and Guo et al. (2024) frame the challenge as workflow construction over heterogeneous agents; we contribute the retrieval primitive.

Capability discovery. The Model Context Protocol (MCP) (Anthropic, 2024), Agent2Agent (Google, 2025), and the GPT Store (OpenAI, 2024) standardize capability enumeration and invocation but assume the client already knows *which* server to call. ToolkenGPT (Hao et al., 2023) embeds tools as soft tokens but ties embeddings to a specific checkpoint. Mulang' et al. (2026) instead use a knowledge-graph index over MCP servers; their graph-based filtering improves discovery at 269 tools but not on smaller curated menus.

IR, dense embeddings, and LLM reranking. Capability discovery mirrors web search as the system matches a user intent against a large corpus of documents (capabilities) indexed offline. Our pipeline reuses the retrieve-then-rerank architecture web search engines refined over decades, adapted to capability metadata rather than web pages. BM25 (Robertson and Zaragoza, 2009) is our lexical baseline. doc2query (Nogueira et al., 2019) expands documents at index time with predicted queries; our enrichment writes typed structured fields instead, consumed by both retriever and reranker. HyDE (Gao et al., 2022) generates a hypothetical document at query time; we do the analogous work once at registration. For dense retrieval we use BGE-large-en-v1.5 (Xiao et al., 2024) and Amazon Titan Embed V2 (1024d); E5-Mistral (Wang et al., 2024) and GTE (Li et al., 2023) are left to future work. RankGPT (Sun et al., 2023) showed listwise LLM rerankers match supervised cross-encoders. Two concurrent works apply enrich-then-retrieve to tools independently: Tool-DE (Lu et al., 2025) and Multi-Field Tool Retrieval (Tang et al., 2026). Neither studies how performance changes as the registry grows.

Our contribution. This is a systems-and-scaling study, not a new-model study. The pipeline composes established components (offline enrichment (Gao et al., 2022; Nogueira et al., 2019; Yuan et al., 2024a,b; Huang et al., 2024a); BM25/BGE retrieval; listwise reranking (Sun et al., 2023)); three contributions are new. First, we map the full degra-

dation curve from $N = 10$ to 7,278 and locate the crossover around $N = 500$ in the Nova Micro sweep. Prior work reports degradation at a single scale (Shi et al., 2025; Du et al., 2024). Second, we decompose retrieval from reranking. The fixed-k reranker holds a 0.70–0.87 conditional-accuracy band, while $\sim$70% of large-registry *misses* occur at retrieval. Third, we compare our results against trial-and-error baselines grounded in how deployed harnesses route, measuring accuracy, tokens, latency, and cost (absent from prior literature).

3 Method

3.1 Problem formulation

Given a query q and a capability registry $C = \{c_1, \ldots, c_N\}$, we produce a ranked list $\{(c, s_c)\}$ without invoking any c_i online. Each c_i belongs to one type; our experiments cover Tools, Agents, and Skills, leaving model routing to existing work. The orchestrator consumes the top-k list and picks.

3.2 Offline enrichment

At registration time (once per capability, never per query), an LLM rewrites sparse metadata into a structured profile with five typed fields of a capability summary, an action-verb-led description, differentiating keywords, and positive and negative usage examples. We add a trust score and self-reported capability tags for production registries.

These typed fields feed *both* the retriever and the reranker, unlike HyDE (Gao et al., 2022), which generates a hypothetical document per query at inference time, or doc2query (Nogueira et al., 2019), which expands documents with surrogate queries for a single retrieval index. The retriever indexes them lexically and densely; the reranker reads them verbatim when scoring candidates. We concatenate these fields into the BM25 index and encode with BGE-large-en-v1.5 or Amazon Titan Embed V2.

3.3 Online retrieve-then-rank

We retrieve the top $k \in \{15, 25\}$ candidates using BM25, neural, or hybrid retrieval. We then combine four scores into $[0, 1]$: LLM (weight 0.50, one API call), BM25 (0.05), Quality (0.30), and Intent (0.15). Quality and Intent drop out on public registries because they lack trust and type metadata.

The two production-only signals use fields from the enriched profile (§3.2). *Quality* is the normalized offline trust score; *Intent* matches a query-inferred capability type to the candidate's self-reported type tags. A signal drops out when its fields are missing, and the remaining weights are renormalized. Thus, all public results use only LLM and BM25 at a fixed 10:1 ratio. We set the four weights once according to each signal's role and do not tune them by capability type or dataset.

4 Experiments

4.1 Setup

We evaluate our pipeline across three capability types and five dataset/type combinations (Table 1). We report **Match@**k ($k \in \{1, 3, 5\}$) as the fraction of queries for which any ground-truth capability appears in the top-k returned list, **mean reciprocal rank (MRR)** as the average of $1/\mathrm{rank}$ of the first correct result, and **Recall@**k as the fraction of ground-truth capabilities retrieved in the top-k (relevant when a query maps to multiple ground-truth). We compute bootstrap 95% confidence intervals (CIs) via $n = 1000$ resamples; all reported deltas ≥ 5 pp exceed the 95% CI width ($\pm$1.5–3 pp on ToolRet, $\pm$5–8 pp on the smaller AppWorld data).

Unless noted, we use Nova Micro as the reranker. A four-model experiment (Nova Micro, Nova Lite, Claude 3.5 Haiku, Claude Sonnet 4) confirms the method ordering is stable across rerankers.

Type	Benchmark	Reg.	Queries
Tools	ToolRet	7,278	7,961
Tools	AppWorld	332	147
Agents	ToolRet	5,885	7,961
Agents	AppWorld	8	147
Skills	MCP	859	1,627

Table 1: Capability $\times$ benchmark coverage.

4.2 Results

We report Match@1 across the benchmarks and methods (Table 2). Each baseline mirrors a routing strategy used in production: Regex (pattern-match, no LLM); Full-Ctx (full registry in-context, LLM picks); Search&Pick (LLM with a search tool to narrow candidates before picking); Trial&Err (LLM iteratively lists and tries).[1] We also include two retriever-only baselines (BM25 and BGE-large-en-v1.5), and three full-pipeline configurations (Ours+BM25, Ours+BGE-5f, and Ours+Titan).

We use Match@1 as our primary metric because it allows direct comparison with the single-pick

[1]Trial&Err is scored on its final try. It can fall below the $1/n$ random-pick rate when it exhausts its round budget without committing. Agents-AppWorld picks an agent on 2 of 147, scoring 0.014 vs. 0.125.

baselines. The pipeline itself returns a ranked shortlist ($k \in \{15, 25\}$, with $k = 15$ in production), so we also report Match@3, Match@5, MRR, and Recall@15 to measure whether the correct capability reaches a downstream selector. On Tools-ToolRet, for example, Ours+Titan reaches Match@3 0.523 and Match@5 0.558. Full results are reported in Appendix B (Tables 7, 8).

On Tools-ToolRet (7,961 queries, N=7,278 capabilities), Ours+Titan reaches Match@1 0.397, a 6.5 pp lead over Search&Pick (0.332) at half the token cost. The gain is broad as the pipeline beats Search&Pick on 13/16 Tools and 12/16 Agents sources with $n \geq 100$ (Appendix F). ToolRet includes near-duplicate items, and the error decomposition shows 70% of failures occur at retrieval. On small registries the pipeline loses its advantage. Full-Ctx leads on Tools-AppWorld (n=332, 0.76 vs. 0.74) and Skills-MCP. The Nova Micro sweep places the crossover near $N = 500$.[2]

Agents-ToolRet shares queries and 89% of its registry with Tools-ToolRet, so it is a near-replicate rather than independent evidence. Agents-AppWorld saturates at 1.00 across its eight-agent registry. Skills-MCP's query set paraphrases capability descriptions, giving lexical retrievers an edge. Public benchmarks do not yet support an independent agent- or skill-retrieval win at scale. Even on Skills-MCP, Ours+Titan (0.942) closes most of the gap to Full-Ctx (0.968), up from 0.807 with Ours+BM25. Titan's retrieval recall accounts for the gain (R@15 0.994).

4.3 Ablations

We compare raw vs. LLM-enriched registries with everything else held fixed (same query set, registry size, retriever, k, weights, model; full numbers in Appendix A, Table 6). Enrichment is neutral-to-negative on public data: ± 0.1 pp Match@1 on ToolRet, 0.0 pp on AppWorld (with $+3.4$ pp Match@3), and -4.4 pp on MCP where added keywords dilute already-strong lexical overlap. A per-field ablation (ToolRet $n = 500$) shows no single field raises Match@1 by more than $+0.6$ pp (keywords, $0.842 \rightarrow 0.848$). Public registries already have clean, detailed descriptions, so enrichment fills no gap. Its production value scales with metadata sparsity, which public benchmarks cannot stress-test. We therefore construct a controlled stress test by degrading the same 1,000-tool ToolRet pool from full descriptions to first-sentence hints and names only, then comparing raw and enriched registries with the pipeline fixed. Enrichment improves Match@1 by $+5.8$, $+9.1$, and $+25.6$ pp, respectively (paired McNemar $p < 10^{-6}$). At name-only, Recall@15 rises from 0.134 to 0.467. The end-to-end gain therefore originates in retrieval (Figure 4; Appendix E).

4.4 Retrieval analysis

On large-registry ToolRet, $\sim$70% of misses occur at retrieval because BM25's top 15 excludes the ground-truth capability (68% of Tools-ToolRet and 70% of Agents-ToolRet misses; Cat 1, Appendix D). AppWorld and MCP misses occur during reranking. Both neural retrievers raise Recall@15 over BM25 by $+4.7$–7.6 pp on the ToolRet rows (BGE-5f and Titan Embed V2; full numbers in Appendix B). The gain does not propagate cleanly to end-to-end Match@1. The three pipeline configurations sit within 0.9 pp on Tools-ToolRet (0.388, 0.389, 0.397) and 2.1 pp on Agents-ToolRet (0.397, 0.412, 0.418) because the fixed-k reranker's conditional accuracy is flat across retrievers. Titan attains the best end-to-end Match@1 on Tools-ToolRet (0.397); on Agents-ToolRet, BM25 retrieval leads (0.418). We adopt Titan as the production retriever for its stronger recall (R@15 0.625 vs BM25 0.549) and its leading Match@1 on the Tools and Skills rows. The remaining recall gap is real, but the dense encoders close little of it end-to-end. Doing so requires a much stronger first-stage retriever, not a better reranker. ToolBench-IR, a BERT-base retriever fine-tuned for tool-API relevance (Qin et al., 2024), does not improve the candidate pool. Its Recall@15 is 0.608 on Tools and 0.596 on Agents, below the general encoders (0.625 and 0.626); end-to-end Match@1 is lower (0.378 vs. 0.397 and 0.381 vs. 0.412; Appendix G). Existing domain-specific fine-tuning therefore does not remove the first-stage recall bottleneck.

4.5 Scale and latency

We ran a registry-size scan on a fixed 100-query Tools-ToolRet slice (178 unique tools) over twelve subsampled registries from $N = 10$ to 7,278.[3] We compare Regex, Full-Ctx (Nova Micro full-context picker, 480k character budget, alphabetic truncation when exceeded), and Ours+BM25 (k=15

[2] Full-Ctx runs on a 500-capability subsample because the full registry exceeds Nova Micro's context window.

[3] 95% CIs run 10 pp on the 100-query slice; the terminal point (0.390) matches the full-set value (0.388) within 0.2 pp.

Row (n / q)	Regex	Full Ctx	Search &Pick	Trial &Err	BM25	BGE 5f	Ours +BM25	Ours +BGE	Ours +Titan
Tools / ToolRet (7,278 / 7,961)	0.231	0.166	0.332	0.054	0.311	0.346	0.388	0.389	**0.397**
Tools / AppWorld (332 / 147)	0.408	**0.762**	0.476	0.061	0.483	0.429	0.741	0.735	0.741
Agents / ToolRet (5,885 / 7,961)	0.228	0.148	0.341	0.045	0.336	0.360	**0.418**	0.412	0.397
Agents / AppWorld (8 / 147)	0.993	0.986	0.973	0.014	**1.000**	**1.000**	**1.000**	**1.000**	**1.000**
Skills / MCP, leaky (859 / 1,627)	0.648	**0.968**	0.829	0.624	0.880	0.892	0.807	0.806	0.942

Table 2: Match@1 splits by registry size (n) and query count (q): the pipeline leads on large registries while in-context routing wins for the smaller sizes. Ours+BGE is the 5-field BGE config. Bold marks the best result in each row. Ours+Titan uses Amazon Titan Embed V2 as the dense retriever. Full-Ctx uses an $n = 500$ sub-sample on Tools-ToolRet, Agents-ToolRet, and Skills-MCP because the full registry exceeds Nova Micro's context window; every other cell is full-n. Trial&Err scores its final `try` and can fall below the $1/n$ random-pick rate when it abstains rather than guessing; see footnote. Other metrics are in Appendix B.

rerank). We show Match@1 vs. N and decompose the pipeline into retrieval recall and reranker conditional accuracy (Figure 2).

Below $N = 500$, full-context LLM picking works; above it, Full-Ctx drops -13 pp per doubling and collapses once alphabetic truncation triggers at $N \geq 5{,}000$ (4,023 of 7,278 tools silently dropped). The crossover is around $N = 500$ in this Nova Micro sweep and shifts with context size. Native-size AppWorld and MCP points are consistent with the pattern but do not establish a shared threshold (Figure 3).

The scale decomposition explains the gap since the single-stage picking collapses from Match@1 0.85 to 0.12 as N grows, while the reranker's conditional accuracy holds steady at 0.70–0.87 across all registry sizes. The pipeline therefore degrades far more gracefully (0.81 to 0.39). Further gains require better retrieval (Appendix C).

4.6 Cross-type generalization

We use one configuration (same enrichment template, retriever stack, and scorer weights) to produce every pipeline cell in Table 2 with no per-type tuning. Three choices make this possible: the enrichment template is type-agnostic (summary, action-led description, keywords, examples, regardless of target), the retrieval signal is type-blind (BM25 and the dense encoder score any text field the same way), and the reranker reads the same prompt shape (a ranked list of enriched profiles) across all three registries. The results are consistent with registry size determining the advantage, but the benchmarks do not separate size from capability type. Current benchmarks limit the cross-type claim. Agents-AppWorld saturates, Agents-ToolRet overlaps Tools-ToolRet, and Skills-MCP queries paraphrase capability descriptions. A stronger test requires agent and skill registries above 500, real user intents, and multi-ground-truth trajectory labels (Appendix D).

4.7 Cross-model robustness

We test four rerankers on Tools, with Nova Micro as the reference. The model ordering is stable from $n = 500$ to full n. The ordering is Claude Sonnet 4 $>$ Nova Micro $\approx$ Nova Lite $\gg$ Claude 3.5 Haiku. At full n, Claude Sonnet 4 improves Match@1 by only 3 pp, consistent with conditional accuracy inside the 0.70–0.87 band (Qwen3 Next and Mistral Large 3, Table 5). Claude 3.5 Haiku is the exception, collapsing from 0.496 to 0.280 on output truncation. Nova Micro is the production choice; Claude Sonnet 4 is acceptable only on the smaller registry (Table 4; Appendix A).

4.8 Efficiency

We compare retrieve-then-rank against the in-context routing baselines on accuracy and cost. Full per-row breakdowns (tokens, dollars, and latency) appear in Appendix A, Table 3. All pricing uses Nova Micro managed-endpoint retail rates. Baseline rows reflect real token counts. Pipeline rows are post-hoc estimates ($\pm$5–10%). On Tools-ToolRet, Ours+BM25 is more accurate than every LLM-using in-context baseline. It is $\sim 2\times$ cheaper than Search&Pick and $\sim 70\times$ cheaper than Full-Ctx ($0.066 vs. $4.48 per 1,000 queries). On both large ToolRet rows, it is more accurate and uses fewer tokens than Full-Ctx and Search&Pick. Full-Ctx is cheaper on Agents-AppWorld, and lexical baselines are more accurate on Skills-MCP. Four failure examples are in Appendix D.

5 Deployment

The deployment evidence is architectural rather than an online evaluation, and our operational evidence is limited to cost and latency (Table 3). We

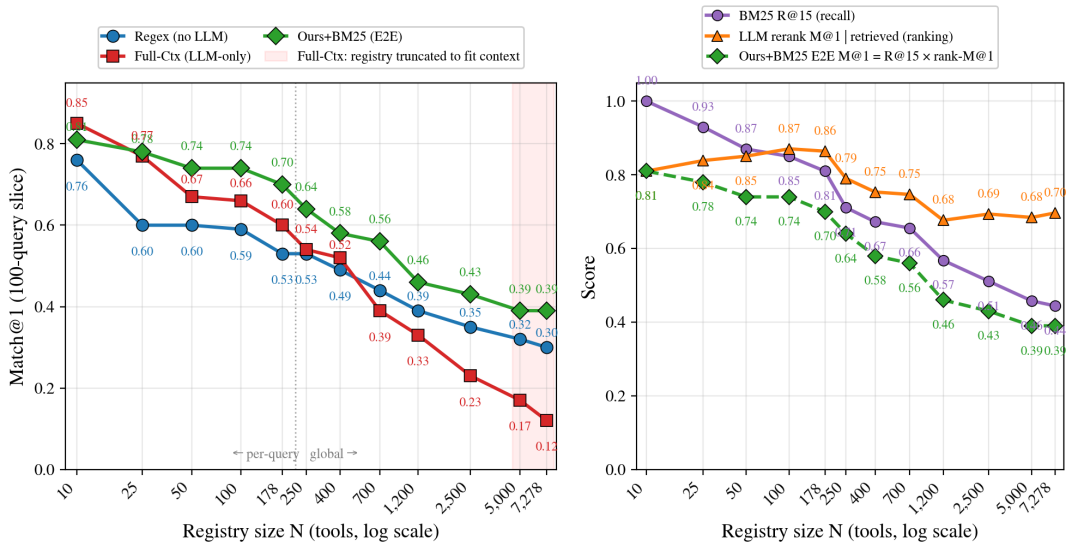

Figure 2: Within-benchmark scaling. Match@1 vs. N (Left) and pipeline decomposition (Right).

deploy the pipeline in production as the capability-discovery layer for an internal multi-agent platform. All four MATS types coexist in a single index with shared enrichment schema and scorer weights. Offline enrichment runs at registration time. An LLM rewrites sparse metadata into the five-field profile. The profile is stored in a key-value store and encoded with Titan Embed V2. Generation cost is paid once per capability update, never per query. The online path is a serverless AWS Lambda: BM25 retrieval over the enriched corpus, neural re-scoring via the dense index, and a single Nova Micro reranker call over $k = 15$ candidates, with all four scoring signals active where the registry includes trust and type metadata.

The production registry exceeds 500 across all four MATS types, in the regime where single-stage LLM routing fails (-13 pp Match@1 per doubling past the crossover), so retrieve-then-rank is an architectural requirement, not a preference.

The public configuration uses two signals (LLM + BM25); production also uses Quality and Intent. On an internal registry with the required trust and type metadata, these signals add $+4.5$ pp Match@1 ($p = 0.031$), with retrieval fixed (Appendix H). We retain enrichment because production metadata includes the sparse conditions under which the ablation in §4.3 shows a retrieval gain.

6 Conclusion

We recast capability discovery as information retrieval. An offline enrichment step converts sparse registry metadata into searchable profiles, and an online retrieve-then-rank pipeline returns a ranked shortlist without invoking any candidate. In-context routing's Match@1 collapses ($0.85 \rightarrow 0.12$), while retrieve-then-rank degrades gently ($0.81 \rightarrow 0.39$), with the crossover around 500 entries in the Nova Micro sweep. At full scale the pipeline leads Search&Pick by 6.5 pp at about half the cost. It reduces cost $70\times$ versus Full-Ctx. The pipeline is in production.

Limitations

Our strongest conclusions come from ToolRet ($n = 7{,}278$). The agent and skill benchmarks have construction limits (§4.2, §4.3) that prevent independent cross-type claims. Enrichment is neutral-to-negative on well-documented registries. Sparse metadata does not occur naturally in the evaluated benchmarks, so we reproduce it through controlled degradation. Quality and Intent require trust and type metadata absent from public registries; public numbers reflect the two-signal pipeline only. The production registry indexes models alongside the other types under the same schema, but we report no model-retrieval numbers. Existing model-routing literature addresses that case, and no public benchmark isolates model-as-capability retrieval.

Ethical considerations

The discovery stage ranks candidates without invoking them, so it does not run candidate code. Provider-controlled metadata can bias retrieval, so operators should version profiles and monitor exposure. The public benchmarks involve no human subjects or private data.

A Detailed results

The cost breakdown (Table 3), four-reranker robustness sweep (Table 4), and raw-versus-enriched ablation (Table 6) support the claims in §4.8, §4.7, and §4.3, respectively.

B Extended ranking metrics

The single-pick baselines emit one capability per query, so M@3, M@5, MRR, and R@15 are undefined. We omit them from both tables. Regex emits a deterministic ranked list (regex hits first, then alphabetic). Its lists are long enough for M@3, M@5, and MRR (Table 7) but not for R@15, so it is absent from that table (Table 8).

C Retrieval vs. reranking

1. *Two stages prevent the single-stage collapse.* Single-stage LLM picking (Full-Ctx) collapses at scale because the LLM has to consider thousands of items at once. Our pipeline's reranker always sees exactly $k = 15$. Full-Ctx goes $0.85 \rightarrow 0.12$ across the scan; our pipeline's reranker stays $0.85 \rightarrow 0.70$.
2. *The reranker is not the constraint.* $\sim$0.87 conditional accuracy at $N = 100$ with full retrieval recall is the highest value we measure.
3. *The remaining end-to-end gains must come from retrieval.* On the scan slice at $N = 7{,}278$, Match@1 is $\sim$0.39. A GT capability reaches the top 15 for $\sim 56\%$ of queries, and the reranker ranks it first with $\sim$0.70 accuracy ($0.39 \approx 0.56 \times 0.70$). This factorization shows that retrieval limits further gains.
4. *The pipeline's advantage is largest at mid-N (50–1,000).* $N \leq 25$ retrieval is identity and Ours $\approx$ Full-Ctx; $N \geq 5{,}000$ Ours is bottlenecked by BM25 recall, not its own design; in between, Ours leads by 7–17 pp.
5. *Why a ≥ 5 pp BGE-over-BM25 Match@1 gain does not materialize.* At the registry sizes we test, the reranker's conditional accuracy is flat across stages, so a $+6.9$ pp Recall@15 advantage for BGE does not propagate to end-to-end Match@1. Recall@15 and end-to-end Match@3/Match@5 separate the retrievers.

Comparisons are consistent with the sweep, but only Figure 2 estimates the crossover at $N = 500$.

D Failure modes

Category 1 – Retrieval miss. *Tools-ToolRet.* A query asks to "develop an emotion analysis system for customer satisfaction over the phone for a Russian telecom company." The ground-truth tool is a Russian speech-emotion model; the system predicts a generic customer-satisfaction scorer. The query shares no keywords with the ground-truth tool name, and BM25 misses it. This failure mode motivates the neural retriever in §4.4.

Row	Method	M@1	Tok-in/q	Tok-out/q	$/1k q	p50 (ms)	Source

Table 3: Retrieve-then-rank costs $\sim$70$\times$ less than the full-context picker at higher Match@1. Columns report Match@1, tokens per query, dollars per 1,000 queries, and p50 latency. Trial-and-error rows report real measured token counts; Ours rows are post-hoc prompt-shape estimates ($\pm$5–10% of real).

Row	Reranker	M@1	p50 (ms)
Tools–ToolRet (n=500)	Nova Micro	0.682	750
	Nova Lite	0.678	1,316
	Cl. 3.5 Haiku	0.496	11,196
	Cl. Sonnet 4	**0.722**	3,775
Tools–ToolRet (full)	Nova Micro	0.389	807
	Nova Lite	0.395	1,453
	Cl. 3.5 Haiku	0.280	11,605
	Cl. Sonnet 4	**0.419**	3,909
Tools–AppWorld	Nova Micro	0.782	553
	Nova Lite	0.864	965
	Cl. 3.5 Haiku	0.503	11,628
	Cl. Sonnet 4	**0.946**	8,833

Table 4: Cross-model robustness of the reranker. The large-registry gain from a stronger reranker is small, consistent with accuracy inside the 0.70–0.87 band.

Row	Ranker LLM	Search &Pick	Ours +BM25	Ours +BGE
Tools–ToolRet	Nova Micro	0.332	0.388	0.389
	Qwen3 Next	0.368	0.416	**0.419**
	Mistral L3	0.365	0.408	0.415
Agents–ToolRet	Nova Micro	0.341	0.418	0.412
	Qwen3 Next	0.385	0.451	0.452
	Mistral L3	0.388	0.451	**0.458**

Table 5: Cross-model generalization of the pipeline (not just the reranker). Match@1 at full n. Ours beats the strongest in-context baseline (Search&Pick) under all LLMs: $+5.6/+5.1/+5.0$ pp on Tools-ToolRet and $+7.7/+6.7/+7.0$ pp on Agents-ToolRet. The Qwen3 Next ranker is $\sim$ 3 pp of Nova Micro at full n, so the prompt is not tuned. Bold marks the best result.

Category 2 – Picked-more-generic. *Skills-MCP.* A query asks to "list running code-sandbox-mcp containers." The ground-truth tool is the named sandbox server, retrieved at rank 3; the system instead promotes a generic Docker tool. It overweights the surrounding intent ("running containers") despite the query naming the correct tool.

Category 3 – Picked outside ground-truth set. *Tools-AppWorld.* A query asks to "add a comment to all Venmo payments I received from coworkers and like those payments." The ground truth is a 9-tool trajectory; the system predicts a single tool that treats the comment and the like as one action. Match@1 penalizes this; Recall@15 does not.

Category 4 – Full-Ctx miss. *Tools-ToolRet, n=500.* A query asks "show me my history for today." The ground-truth tool exists in the registry but Full-Ctx returns null. At full scale, prompt truncation drops 55% of the registry (4,023 of 7,278 tools) and creates additional misses. This truncation causes the collapse in §4.5.

Benchmark	Cond.	M@1	M@3	R@k
AppWorld (332)	Raw	0.782	0.884	0.420
	Enriched	0.782	0.918	0.400
ToolRet (1,000)	Raw	0.124	0.137	0.135
	Enriched	0.125	0.139	0.138
MCP Skills (859)	Raw	**0.929**	**0.977**	**0.988**
	Enriched	0.885	0.939	0.951

Table 6: Enrichment ablation behind §4.3. LLM enrichment adds no measurable gain on well-documented public registries. Raw vs. LLM-enriched registry, all else held fixed. The ToolRet rows use a 1,000-tool subset, so absolute numbers are low but the raw-vs-enriched delta is the quantity of interest.

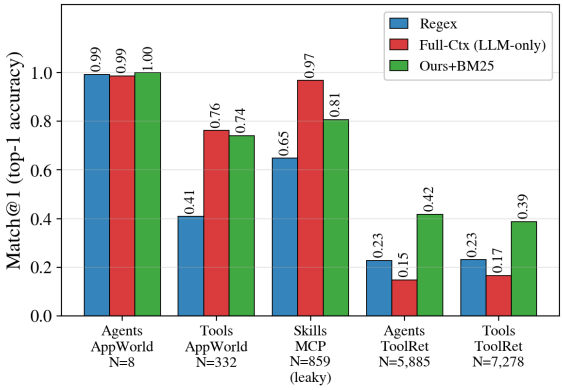

Figure 3: Cross-sectional benchmark comparison. Full-Ctx wins or ties on the small rows, while Ours+BM25 leads on the large ToolRet rows. Full-Ctx uses 500-candidate subsamples on ToolRet and Skills-MCP (Table 2), so these points do not estimate a shared threshold.

E Enrichment under sparse metadata

We reuse the 1,000-tool ToolRet pool from Table 6 and vary only its input metadata. **Full** retains the upstream name and description, **hint** retains the name and first sentence (at most 150 characters), and **name-only** removes the description. For each level, the raw arm indexes that input directly and the enriched arm first applies the same enrichment procedure. Both use BM25 at $k = 15$, the Nova Micro reranker, and the weights in §3.3.

We evaluate the 1,252 queries whose ground-truth capability occurs in the pool. This differs from the original ablation in Table 6, which uses the full query set and a raw registry that already contains keywords added during preprocessing. The present comparison starts from the upstream fields and isolates how much enrichment recovers as those fields are removed.

At name-only, enrichment raises Recall@15 from 0.134 to 0.467, while rerank conditional accuracy changes from 0.63 to 0.73. Enriched inputs perform similarly (Match@1 0.776 and 0.778), so one descriptive sentence supplies most of what this enricher uses. For 867 of 1,000 name-only entries, it leaves the capability summary empty rather than inferring one from an opaque name.

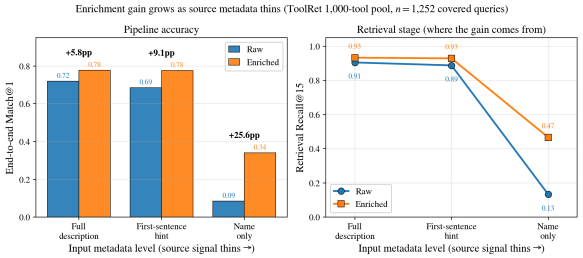

Figure 4: Enrichment acts primarily through retrieval. As input metadata is removed, the raw-versus-enriched gap widens far more in Recall@15 (right) than in Match@1 (left).

F Results by ToolRet source

ToolRet combines queries from 35 upstream sources. We group the existing full-n results by `metadata.subset` to test whether a single source accounts for the aggregate gain. Each group remains part of the same benchmark and is evaluated against the same registry.

A broken source. The `ultratool` source (500 queries; 6.3% of ToolRet) is malformed. Every label embeds the same tool document, so 287 referenced ground-truth tools are absent from the registry, and all methods score near zero on it. Excluding it raises every method's Tools Match@1 by ∼2 pp and leaves the ordering unchanged.

G Tool-tuned retriever

We test ToolBench-IR, the BERT-base retrieval model released with ToolBench and fine-tuned on tool-API relevance (Qin et al., 2024), as the first stage on both large rows. All retrievers use the same five-field documents and $k = 15$.

H Contribution of quality and intent

Public benchmarks lack the trust and type metadata that Quality and Intent need, so these two signals drop out (§3.3). We compare the two- and four-signal configurations on an internal single-turn agent benchmark ($n = 221$) whose registry includes both fields. We hold retrieval fixed and report only paired performance differences.

Row	Metric	Regex	BM25	BGE-5f	Ours+BM25	Ours+BGE-5f	Ours+Titan
Tools — ToolRet	M@3	0.314	0.423	0.472	0.493	0.502	**0.523**
	M@5	0.354	0.464	0.520	0.523	0.539	**0.558**
	MRR	0.285	0.378	0.424	0.446	0.454	**0.467**
Tools — AppWorld	M@3	0.687	0.728	0.721	0.884	0.898	**0.918**

	MRR	0.997	**1.000**	**1.000**	**1.000**	**1.000**	**1.000**
Skills — MCP	M@3	0.811	0.964	0.958	0.879	0.880	**0.981**
	M@5	0.854	0.980	0.974	0.902	0.911	**0.988**
	MRR	0.736	0.923	0.928	0.852	0.855	**0.962**

Table 7: Ours+Titan leads on Tools-ToolRet, AppWorld, and Skills-MCP; on Agents-ToolRet, Ours+BGE-5f leads. The saturated Agents-AppWorld row ties. The single-pick baselines (Full-Ctx, Search&Pick, and Trial&Err) emit one capability per query, so these metrics are undefined for them and their columns are omitted.

Row	BM25 M@15	BGE-5f M@15	Titan M@15	Ours+BM25 R@15	Ours+BGE-5f R@15
Tools — ToolRet	0.549	0.618	**0.625**	0.485	0.517
Tools — AppWorld	0.952	0.966	**0.993**	0.262	0.261
Agents — ToolRet	0.569	**0.626**	0.616	0.508	0.538
Agents — AppWorld	**1.000**	**1.000**	**1.000**	**1.000**	**1.000**
Skills — MCP	0.991	0.992	**0.994**	0.951	0.992

Table 8: Retrieval at $k = 15$. Standalone columns report Match@15, the query-level any-hit rate. Ours columns report Recall@15, the fraction of all ground-truth capabilities retrieved. Single-pick baselines are omitted.

Input level	Raw	Enriched	R@15 raw → enr.
Full description	0.720	0.778	0.905 → 0.933
First-sentence hint	0.685	0.776	0.888 → 0.929
Name-only	0.085	0.341	0.134 → 0.467

Table 9: Metadata-sparsity ablation ($n = 1{,}252$ per cell). Match@1 gains are $+5.8$, $+9.1$, and $+25.6$ pp from full to name-only input.

Source	n	Ours+Titan	S&Pick	Δ
Tools — ToolRet				
toolbench	1,100	0.518	0.490	+0.028
apigen	1,000	0.702	0.611	+0.091
toolace	1,000	0.694	0.620	+0.074
toolink	497	0.579	0.348	+0.231
apibank	101	0.614	0.426	+0.188
gorilla-huggingface	500	0.148	0.180	−0.032
long tail (19 src)	798	0.325	0.246	+0.079
Agents — ToolRet				
toolace	1,000	0.715	0.637	+0.078
apigen	1,000	0.663	0.610	+0.053
toolbench	1,100	0.475	0.524	−0.048
craft-math-algebra	280	0.482	0.257	+0.225
apibank	101	0.624	0.396	+0.228

Table 10: Match@1 for representative ToolRet sources. Across all sources with $n \geq 100$, Ours+Titan leads Search&Pick on 13/16 Tools sources and 12/16 Agents sources. "Long tail" pools 19 smaller Tools sources.

Row	Retriever	Standalone M@1	Standalone R@15	E2E M@1
Tools	BM25	0.311	0.549	0.388
	ToolBench-IR	0.354	0.608	0.378
	Titan V2	0.358	**0.625**	**0.397**
Agents	BM25	0.336	0.569	**0.418**
	ToolBench-IR	**0.362**	0.596	0.381
	BGE-large 5f	0.360	**0.626**	0.412

Table 11: Tool-tuned and general retrievers on the two full ToolRet query sets ($n = 7{,}961$). ToolBench-IR improves standalone Match@1 over BM25 but does not exceed the best general encoder on Recall@15 or end-to-end (E2E) Match@1.

Metric	Four-signal minus two-signal
Match@1	+4.5 pp
Match@3	+5.0 pp
Recall@15	0.0 pp

Table 12: Paired effect of adding Quality and Intent on the internal benchmark. Fourteen queries change from miss to hit at rank 1 and four change from hit to miss (exact McNemar $p = 0.031$). Recall is unchanged because retrieval is shared.

GLS Chatbot: A Governed Multi-Agent Conversational System for Domain-Specific Customer Service

CX AI Hub, GLS Spain

{Bernat.Coma,GuillermoAndres.Galvan,Victor.Mas,
Edgar.Sarria,David.Ninoles,Sonia.Alonso}@gls-spain.com

Abstract

Hi, I'm Gisela, GLS's assistant. How can I help you today? This is how the Spanish deployment of the GLS Chatbot greets its customers. Behind the greeting is a governed multi-agent system for parcel-logistics customer service, built on self-hosted open-source small language models with RAG. An orchestrator separates routing, execution, and generation; probabilistic components are bracketed by deterministic safeguards, customer-impacting actions require explicit user confirmation, and out-of-scope, abusive, or manipulative inputs are refused. In production since November 2025, the system has handled over 1.7 million conversations across Spain and Germany. In Spain, the average realised cost during May 2026 was approximately 0.07€ per conversation, with sub-3-second latency. We describe the architecture, evaluate the Spanish deployment on task completion, routing conformance, and RAG answer quality, and report lessons from production.

1 Introduction

Logistics customer service increasingly relies on conversational automation to handle high parcel volumes and expectations of immediate support. Many deployed solutions still follow rigid dialog trees that limit flexibility and trigger conversational breakdowns that degrade user trust (Følstad et al., 2024). At the other extreme, reliance on proprietary LLM APIs reduces organizational control and auditability, particularly under strict European data-governance frameworks (European Union, 2024; European Parliament and Council of the European Union, 2016), and introduces usage-priced costs that scale with volume (Chen et al., 2023). Moreover, unconstrained generative agents in customer service have produced concrete failures that affect the reputation of the company (e.g., British Columbia Civil Resolution Tribunal (2024)).

This paper presents the **GLS Chatbot**, a cost-efficient, domain-adapted multi-agent system for real customer-service operations (Fourney et al., 2024; Tran et al., 2025; Guo et al., 2024). It combines self-hosted open-source small language models (SLMs) with retrieval-augmented generation and a deterministic orchestration layer that separates responsibilities across specialized components (Belcak et al., 2025; Lewis et al., 2020). This modular design supports country-level localization (data sources, policies, capabilities) over a shared architectural core. In production since November 2025, the system has handled over 1.7 million conversations across Spain and Germany at approximately 0.07€ per conversation,[1] presented to Spanish users through the persona Gisela.

We analyse this deployment as a *governed* system for a regulated EU setting: we describe its architecture and governance mechanisms (prerequisite enforcement, explicit confirmation for customer-impacting actions, refusal of out-of-scope, abusive, and manipulative inputs), present an evaluation of the Spanish deployment, and share lessons from production, including cost-optimisation choices and observed user behaviour.

2 System Overview

The system provides a 24/7 self-service channel for GLS customers, accessible through the company's website and WhatsApp, handling parcel-related requests via a natural-language chatbot interface. The assistant guides the interaction to collect missing information and presents structured outputs when this improves clarity and user decision-making.

2.1 Supported tasks

In the Spanish deployment, the chatbot supports (i) parcel status retrieval, (ii) allowed actions (post-tracking actions, e.g., Out of Home (OOH) redirection, neighbour/concierge delivery, delivery notes,

[1] Average realized cost in Spain during May 2026, computed as total infrastructure spend divided by conversations handled; see Section 4.

EMNLP 2026 Industry Track, pages 2255–2264
October 24-29, 2026 ©2026 Association for Computational Linguistics

and delivery date changes when eligible), (iii) escalation to human support under business-defined conditions, and (iv) company-related questions (e.g., "How can I contact GLS?"), answered via RAG.

2.2 Architecture Overview

The system is decomposed into five specialised agents[2] communicating through a typed JSON contract, which enables reproducible orchestration and lets each agent scale elastically on its observed demand. Decoupling routing and execution from generation is the organising principle: it keeps customer-impacting decisions out of a probabilistic model, lets each agent be adapted or swapped independently, and supports reuse across country deployments.[3]

Orchestrator (OR). This agent manages conversation state and routes messages between components by detected intent and task progress. It is deterministic control-flow logic backed by MongoDB, not a model, and is the only component with write access to persistent conversation state, which keeps behaviour auditable.

Triggerer (TR). Performs constrained tool selection: a typed JSON demand from a closed catalog with its parameters and any missing prerequisites.[4] It is a Ministral 3 14B Instruct SLM[5] (Liu et al., 2026) with a classification-style prompt, run on every turn under a sub-second budget. Because the output space is closed, errors are bounded: the router may pick the wrong demand but cannot produce open-ended output, and customer-impacting selections are validated downstream.

For deterministic requests, the Triggerer can emit a `static_response`, which the Orchestrator serves directly without invoking the Conversational Agent (see Section 2.5).

API Integrator (API). It executes validated, non-generative calls against GLS's logistics systems (e.g., status retrieval, delivery-date change).

RAG Component (RAG). This agent answers company-knowledge questions from indexed documentation, providing grounded context for user-facing responses. Its retrieval and generation pipeline is described in Section 2.3.

Conversational (CA). It produces the final user-facing reply from the Orchestrator's structured input (API results, RAG content, or clarification requests). Like the Triggerer it is a self-hosted Ministral 3 14B Instruct SLM, prompted with a brand-aligned persona (Gisela in Spain) and the user's language. It is the only generative agent whose responses reach the user directly.

2.3 RAG Design

The RAG component handles company-knowledge queries using an offline question-based indexing stage followed by online retrieval and grounded answer generation.

Question-based indexing. Rather than directly indexing source-document passages as the retrieval representation, we use an LLM as an offline preprocessing step to generate representative questions that each document can answer. Each generated question retains a reference to its source document and is indexed for retrieval. The number of questions scales with the length and information density of the document. This representation is motivated by the mismatch between the language used in internal documentation and the question-like formulations used by customers: retrieval operates over representations closer to likely user information needs, while the original source documents remain the authoritative evidence for answer generation.

This design is related to generated-query document expansion. Doc2query generates queries that a document is likely to answer and appends them to the document before indexing (Nogueira et al., 2019b), while docT5query follows the same general document-expansion principle with a stronger query-generation model (Nogueira et al., 2019a). Our implementation follows the same document-side intuition, but uses the generated questions themselves as retrieval proxies linked to the original source documents rather than appending them to the indexed document text.

Retrieval and generation. At inference time, the user query is matched against the generated-question index using hybrid retrieval implemented with LlamaIndex (Liu, 2022), combining BGE-M3 dense retrieval and BM25 lexical retrieval (Chen

[2]Three are *generative*, backed by an SLM (the Triggerer, RAG, and Conversational agents); two are deterministic (the Orchestrator and API Integrator). We retain the term *agent* for uniformity.

[3]A PhoneBot is under development, extending the pipeline with STT/TTS agents for spoken interaction.

[4]Designed in October 2024, prior to the current consolidation of agentic tooling, it fulfils the role of a tool call in contemporary frameworks.

[5]The underlying model checkpoints have evolved since the initial deployment. The system was initially deployed with Mistral Small 3.2 24B Instruct; the model assignments reported here reflect the configuration at the time of writing.

et al., 2024; Robertson and Zaragoza, 2009). The highest-ranked questions identify candidate source documents. For each candidate document, Gemma 4 12B-it (Gemma Team et al., 2026) extracts the aspects relevant to the user query. The resulting evidence is then aggregated across candidates and passed to the same model to synthesise the final grounded answer. The generated questions therefore determine which source documents are considered relevant, while the final response is grounded in information extracted from the original documentation. End-to-end response quality is evaluated in Section 3.3.

Knowledge-base maintenance. Question generation is performed outside the online serving path and therefore does not contribute to customer-facing inference latency. When a source document is added or modified, the preprocessing step is rerun only for that document and its corresponding index entries are replaced. This allows the knowledge base to be updated incrementally without rebuilding the complete corpus.

2.4 Execution Flow and Safeguards

Governance is enforced by active guidance of the user toward supported tasks, and lightweight checks distributed along the pipeline (Table 1). Every probabilistic judge is bracketed by deterministic ones, and the degree of control scales with risk, with whether the content will be persisted or executed, and with whether it reaches someone other than the user.

Guidance Within Scope. The chatbot supports a predefined task set (Section 2.1) and guides users toward valid outcomes by requesting missing information when needed.

Safeguard Classes. *Deterministic checks* (e.g., regex prefilters, schema validation, and eligibility gates) are model-free and fail closed. *SLM judges* are used only where semantic interpretation is needed, typically emitting a short verdict. Customer-impacting actions never depend on an SLM verdict alone: semantic judges remain bounded by deterministic gates.

Manipulation vs. Abuse. Manipulation (injection, jailbreaks, instruction-extraction) is refused at input by a deterministic prefilter and an SLM security judge, terminating the interaction; frustration-driven profanity is deliberately *not* treated as an attack. Offensive content in *executed* parameters is handled differently: a delivery note is persisted and reaches a courier or identifies a third party, so a semantic judge rejects insults or threats and requests a rephrasing rather than blocking the user. The judge fails open and the loop is unbounded, so the claim is not that no offensive note ever passes, but that such content is intercepted and re-requested before being persisted.

Action Validation and Confirmation. Customer-impacting actions pass mostly deterministic eligibility gates; the SLM is invoked only for what rules cannot resolve, such as whether a neighbour identification names both a person and a location. No such action executes in the turn it is requested: the system proposes it, requests explicit confirmation, and re-validates eligibility at execution, so a change in parcel state between the two phases cannot let an already-invalid action through. Every action with real-world effects is thus mediated by an informed user confirmation.

Escalation and Cross-Agent Redundancy. Escalation illustrates the double-bracketing: eligibility is first resolved deterministically against a whitelist of permitted parcel statuses, then an SLM judge assesses whether intent justifies escalation; both must agree. The guarantee is re-applied in the Conversational Agent, which receives an injected constraint when escalation is blocked and enforces it in its own output judge. This cross-agent redundancy is intentional.

Repair and Idempotency. Several checks correct rather than only block: the parcel-status judge normalises identifiers and postal codes from variable formatting and recovers values referenced in earlier turns (likewise for neighbour notes), guiding the interaction toward an actionable request. Completed actions are marked in dialogue state (e.g., `created`, `derived`) so a restated request is not re-executed. The Conversational Agent further uses constrained decoding to suppress control tokens during generation, complementing post-hoc format validation.

Example Flow. A status inquiry exercises the static fast path and triggers only a subset of safeguards: (i) the user asks "Where is my parcel?"; (ii) the Triggerer clears the prefilter and guard judge and, with identifiers missing, emits a `static_response`, so the Orchestrator serves a predefined reply without invoking the CA; (iii) the user sends "1301963361 / 28022"; (iv) the Triggerer emits `parcel_status`, the parcel-status judge validates the id and postal code, and the Or-

Stage	Mechanism	Agent	Role	Failure behaviour
Input	Injection filter^{D}	TR	Matches known prompt-injection and jailbreak patterns	Refuse request
	Manipulation judge^{S}	TR	Detects attempts to override instructions or extract hidden context	Refuse request
	Parcel-identity judge^{S‡}	TR	Validates parcel identifiers and postal codes; may recover values from dialogue history	Repair parameters or ask again
	Free-text argument judge^{S}	TR	Checks whether free-text arguments carry enough information to execute	Request missing information
	Note-content judge^{S}	TR	Screens persisted delivery notes for abusive or threatening content	Request rephrasing
	Action eligibility check^{D}	OR	Verifies action availability, identity consistency, and business constraints	Do not execute action
	Escalation eligibility check^{D}	OR	Applies status-based escalation rules	Do not escalate
	Escalation-intent judge^{S}	TR	Assesses whether escalation is justified under policy	Do not escalate
Output	Language judge^{S}	CA	Checks consistency with the user's language	Regenerate response
	Contact-information check^{D}	CA	Prevents disclosure of unauthorised contact details	Suppress response
	Response-policy judge^{S}	CA	Enforces scope, privacy, and escalation policies	Fallback response
	Control-token check^{D}	CA	Prevents exposure of reserved control tokens	Fallback response

Table 1: Safeguards applied throughout the execution flow. Deterministic mechanisms (^{D}) rely on rules and business constraints; SLM-based judges (^{S}) are used only when semantic interpretation is required. The parcel-identity judge (‡) additionally supports parameter recovery and normalisation. Customer-impacting actions execute only after passing the corresponding deterministic controls.

chestrator dispatches to the API; (v) the API returns the parcel state, history, and allowed actions; (vi) the CA renders the reply, which passes the language, contact-info, and core-rules checks before display.

Customer-facing operations such as Parcel Shop redirection add validation: they execute only with a valid parcel context and the authorising `allowedActions` flag, free-text arguments are checked separately, and the system requests explicit confirmation before dispatch.

2.5 Operational Deployment

Deployed since November 20th 2025, the system handled 1.1M conversations in Spain (Table 2) and 669.4k in Germany up to 31 May 2026. To meet GDPR requirements, all SLMs are self-hosted in Europe[6], keeping data and inference within EU infrastructure.

Deployment Setup. Each country has its own Azure resource group. The Orchestrator runs as a containerised service on Azure Container Apps; the SLM-backed agents are served through Azure ML managed endpoints, each backed by vLLM (Kwon et al., 2023) on A100 instances. Conversation state is persisted in MongoDB Atlas. The deployment scales elastically and independently at both the orchestration and model-endpoint levels based on per-agent load.

Latency and Static Fast Path. Per-agent latencies differ substantially: the Triggerer responds in $< 1\,\text{s}$, the Conversational Agent in $< 2.5\,\text{s}$, while the RAG path is slower because it combines hybrid retrieval, per-document aspect extraction, and generation with Gemma 4 12B-it. For deterministic requests, the Triggerer can instead emit

[6]Azure's Germany West Central region.

a `static_response`, allowing the Orchestrator to return a predefined response without invoking the Conversational Agent. In a production sample,[7] this fast path served 261,464 interactions, accounting for 34.8% of all chatbot turns. Most static interactions (61.0%) were clarification requests for missing information: a postal code (29.8%), both a parcel identifier and postal code (27.5%), or a parcel identifier alone (3.7%). A further 36.1% were deterministically formatted parcel-status responses and 2.9% served a predefined Parcel Shop listing. Typical end-to-end response time is under 3 s, with the static path reducing both latency and model usage.

Cost Analysis. The realized cost per conversation depends on the measurement period, since infrastructure spend is dominated by fixed A100 provisioning while traffic varies over time. In May 2026, total Azure spend divided by conversations handled by the Spanish deployment yielded an average cost of 0.07€ per conversation. This figure should therefore be interpreted as a period-specific average rather than a fixed per-query cost. At shorter time scales, the unit cost varies inversely with traffic, being lower during high-volume periods and higher during off-peak periods. Section 4 discusses subsequent cost and inference optimisations.

3 System Evaluation

All quantitative evaluations in this section concern the Spanish deployment. We evaluate the system along three complementary axes: an objective audit of routing conformance over all Triggerer calls in the audit window (Section 3.1), a quality assessment of conversation outcomes on a sampled set, using an LLM judge validated against a human annotator (Section 3.2), and an independent analysis of RAG answer quality (Section 3.3). The first measures conformance to predefined routing and eligibility rules, the second assesses task-level outcomes, and the third evaluates the knowledge component independently. For complementary qualitative inspection, Appendix A provides access to the live chatbot together with mock shipment records that allow its main interaction flows to be tested without real customer data.

[7]Collected from July 25th to July 29th.

3.1 Routing Conformance Audit

Between May 9th and June 8th 2026[8] the Triggerer processed 752818 calls. The router placed 99.99% of decisions within the demand catalog, with none null or unparseable; the remaining 101 cases (0.013%) contained an invalid demand value, typically a control reason emitted in the demand field; all were rejected by downstream deterministic validation before execution.

Checking every customer-impacting decision against the parcel's `allowedActions`, the router's action demands were consistent with the allowed actions except for 9 parcel-shop lookups (0.04%) emitted without parcel context, which the deterministic gate blocks; all 4352 identifier-mode redirections referenced the correct parcel. Of 13590 escalation decisions, none targeted an ineligible status; 4778 (35%) concerned `delivered` parcels, which the rules route to conditional semantic review rather than certify automatically.

These results measure conformance to the predefined routing and eligibility rules; they do not by themselves measure conversation-level outcome quality.

3.2 Conversation Outcome Evaluation

We classify each conversation's outcome into one of six categories (Table 3) and validate the LLM judge against a human annotator on 100 sampled conversations (Table 4): they agree on 89 cases, with Cohen's $\kappa = 0.786$ (substantial; the gap from raw agreement reflects the strong TA-dominated class imbalance). The categories form three tiers: successful outcomes (TA, TNA); undesired interactions (OB, WH); and content failures (IC, MO). At the tier level the judge's distribution closely matches the human's, 84 vs 87 successful, 14 vs 12 undesired interactions, and 2 vs 1 content failures, providing a similar coarse-grained outcome distribution despite disagreements on individual labels.

Per-class recall is 98.5% for TA, 78.9% for TNA, 71.4% for OB, 57.1% for WH, and 50.0% for IC. MO recall cannot be estimated because no human-labelled MO case occurs in the validation sample.

Two systematic judge errors affect the most safety-relevant categories. First, hallucination detection (IC) is weakest: the judge caught one of two cases. Both shared the same cause: the Con-

[8]To guarantee Data Protection requirements, we do not keep conversations from our customers for more than 30 days.

Label	Outcome
TA	Requested action completed (e.g., status delivered, date changed).
TNA	User attempted an action the rules or parcel status correctly disallowed.
OB	System offered an action, then correctly retracted it as not possible.
WH	System's own error blocked an achievable task (misroute, wrong ask, missed prerequisite, lack of understanding).
IC	Wrong or unsupported information (invented status, fabricated policy).
MO	Technical failure (error, empty response, malformed output).

Table 3: Outcome taxonomy for conversation-level evaluation, applied by both the human annotator and the LLM judge.

		LLM Judge (predicted)						
		TA	**TNA**	**OB**	**WH**	**IC**	**MO**	**Total**
Human (truth)	**TA**	64	0	0	1	0	0	65
	TNA	2	15	0	2	0	0	19
	OB	0	2	5	0	0	0	7
	WH	1	2	0	4	0	0	7
	IC	1	0	0	0	1	0	2
	MO	0	0	0	0	0	0	0
	Total	68	19	5	7	1	0	**100**

Table 4: Agreement between the human annotator (rows, treated as ground truth) and the LLM judge (columns) over 100 sampled conversations. Shaded diagonal cells are agreements. Overall agreement 89% (Cohen's $\kappa = 0.786$).

Outcome	**TA**	**TNA**	**OB**	**WH**	**IC**	**MO**	**Total**
Count	342	97	18	36	4	3	500
%	68.4	19.4	3.6	7.2	0.8	0.6	100

Table 5: LLM-judge outcome distribution over 500 evaluated conversations in Spain.

versational Agent confirmed a successful escalation ("your case has been escalated") although it had not executed, misreporting a failed upstream action rather than fabricating freely. Second, the judge labels as malformed output (MO) predefined fallback messages that fired as designed: every predicted MO case was a deliberate safe fallback to an out-of-scope or unparseable input, not a technical failure. Thus, IC/MO verdicts are the least reliable, and we treat content-failure detection as a known limitation (Section 5). Remaining disagreements lie mainly on the TNA/WH boundary, where distinguishing a correct block from a system error requires judging whether the action was actually possible. Some trace to informal WhatsApp input (typos, fragments, abbreviations), which can strain understanding and appear as WH errors. This degrades comprehension rather than control: deterministic gates typically turn misunderstandings into clarification requests rather than incorrect executions.

Applied to 500 sampled conversations from the Spanish deployment (Table 5), the judge classified 87.8% as successful outcomes, 10.8% as undesired interactions, and 1.4% as content failures. The low-count IC and MO estimates should be interpreted cautiously.[9]

3.3 RAG Evaluation

We evaluate the knowledge component on 66 held-out questions over the 54-document corpus, disjoint from the 1100 generated questions in the retrieval index. The questions were manually constructed with reference to the corpus and selected for coverage: their gold-document sets span 51 of 54 documents, with the remaining three considered out of scope because they describe shipment-state semantics handled elsewhere. The bank is also diverse: mean pairwise TF-IDF cosine similarity is 0.019, and only 2 of the 2,145 pairs exceed 0.5, both intentional minimal pairs differing in whether the corpus contains the answer.

Each question uses a *rubric* defining required facts, acceptable alternatives, and forbidden claims rather than a reference answer. Ten questions are `missing`, for which the expected behaviour is abstention. Final verdicts were assigned by a human expert. An LLM independently reviewed the 617 rubric items as a consistency check, to help identify information the human evaluation might have overlooked, but did not determine the final label. Verdicts are `pass`, `explanation` (correct but incomplete), `documents` (gold documents retrieved but final answer incorrect), and `fail` (expected documents not retrieved).

Across the 56 answerable questions, the expected documents were always retrieved and no answer contradicted the retrieved evidence; errors were limited to omissions. For the 10 `missing`

[9] Wilson 95% confidence intervals: IC, 0.31–2.04%; MO, 0.20–1.75%.

Question type	n	pass	expl.	docs	`fail`
factual	44	41	3	0	0
pointer	10	9	1	0	0
either	2	2	0	0	0
missing	10	9	0	0	1
Total	**66**	**61**	**4**	**0**	**1**

Table 6: RAG evaluation results by question type. For all 56 answerable questions, the source documents were successfully retrieved; the reported verdicts therefore reflect the quality of the final generated answer. For `missing` questions, `pass` indicates appropriate abstention, while `fail` indicates that the system provided an unsupported answer.

questions, the system abstained on 9 but answered one question about GLS's worldwide workforce using the figure for GLS Spain, the only unsupported answer observed.

4 Discussion and Lessons Learned

Static Fast Path. Handling deterministic turns without open-ended generation reduces latency and model usage while limiting exposure to generative errors, making such traffic a high-impact production optimisation.

Complexity for Flexibility. Decomposition adds complexity but isolates responsibilities behind typed contracts, allowing components to scale or change independently while making localisation and governance more tractable.

The Cost of Staying in Scope. Keeping generative agents within scope remained challenging: instruction-tuned SLMs sometimes propose unsupported remedies beyond the system's task definition. Layered controls, including explicit prohibitions, output checks, and judges, reduce this behaviour at the cost of complexity and occasional over-cautious refusals. Across the deployment, we are aware of no reported confidentiality or content-safety incidents, though this should not be interpreted as an estimated incident rate. Scope adherence therefore remains an ongoing engineering requirement rather than a one-time prompting problem.

Cost and Inference Optimisation. The reported 0.07€ per-conversation cost reflects capacity provisioned for peak demand rather than an optimised steady-state configuration. Preliminary tests during the first weeks of August, using Gemma 4 12B-it across all SLM-backed agents with multi-token prediction, reduced inference time and average cost to 0.06€ per conversation. This was observed during a low-demand period, when fixed provisioning would normally increase per-conversation cost. The improvement comes from higher per-GPU throughput, allowing each instance to serve more requests and reducing scaling requirements. Prompt compression, smaller-model routing, and caching provide further optimisation opportunities.

The WhatsApp Channel. Informal WhatsApp input contributes to WH errors (Section 3.2); parcel-identity repair and deterministic gates typically turn misunderstandings into clarification requests rather than wrong actions.

5 Limitations

Evaluation scope. Our evaluation is based on a sample of production conversations judged by both a human annotator and an LLM judge, together with component-level metrics. It does not constitute a controlled comparison against alternative architectures (e.g., a single-model baseline or a proprietary-API system), and we therefore cannot make causal claims that the multi-agent design outperforms such alternatives on quality; our contribution is a deployment account rather than a head-to-head benchmark.

Reliance on LLM-as-a-judge. Part of our evaluation uses an LLM as an automated judge. LLM judges are known to exhibit biases and to correlate imperfectly with human judgement, particularly on borderline cases such as the distinction between a correct refusal and a misunderstanding. We mitigate this with a human-judged subset, but the larger-scale results inherit the judge's limitations.

Proprietary data and single domain. The system operates on proprietary logistics data in a single domain (parcel customer service) for a single organisation. While the architectural principles are intended to generalise, the specific results (intent distribution, escalation rates, cost figures) reflect this setting and may not transfer to other domains or organisations.

Cost figures are deployment-specific. The reported per-conversation cost reflects our particular provisioning choices (self-hosted models on A100 instances, capacity sized for peak season) and the cloud region and pricing available to us. These figures are expected to represent an upper bound

for our configuration and are not directly comparable to other deployments with different hardware, traffic patterns, or pricing agreements.

Language and locale coverage. The deployment covers two country markets and a limited set of languages. Behaviour in lower-resource languages, or for users mixing languages within a turn, is not systematically evaluated here.

Safety evaluation breadth. Our safety assessment focuses on the categories most frequent in production (out-of-scope, abusive, and manipulative inputs, including prompt-injection attempts). It is not an adversarial red-teaming study, and we do not claim robustness against a determined or novel attacker.

6 Ethical Considerations

Data protection and user privacy. The system is designed around data minimisation. Most parcel-related interactions require only a parcel identifier and postal code. Some actions require additional personal data, such as an email address for escalation or recipient information for alternative delivery. To meet EU data-protection requirements (GDPR), all data and model inference are kept within EU infrastructure using self-hosted models. The deployment was developed in coordination with the organisation's Data Protection team, and conversation data is processed accordingly: conversations are deleted from our databases after 30 days.

Human oversight and escalation. The system is designed to keep customer-impacting actions under explicit user confirmation and to escalate to human agents under business-defined conditions rather than attempting to resolve every case autonomously. This preserves a human fallback for situations the automated system is not equipped to handle.

Transparency to users. Users are informed that they are interacting with an automated assistant at the start of the conversation.

Safety and misuse. The system incorporates input screening for abusive and manipulative content and refuses out-of-scope requests, reducing the risk of generating harmful, misleading, or off-brand responses. Because customer-facing actions are executed by a deliberately non-generative integration layer only after validation and confirmation, the risk of a language model triggering an unintended real-world action is structurally constrained.

Risk of automated errors. As with any deployed NLP system, incorrect routing or generation can affect users (e.g., a failed or delayed resolution). The governance mechanisms and human-escalation path are intended to bound the impact of such errors, and the deterministic orchestration layer provides an auditable record supporting accountability and review.

Acknowledgments

We thank the Spanish PMO team and our colleagues across GLS, including Customer Experience, IT, Data Protection, Customer Service, and Security, for their support in developing, deploying, and operating the chatbot. We are also grateful to those colleagues across GLS who trusted us and supported the project throughout its development. We also thank Marta Arias from the Universitat Politècnica de Catalunya for her insightful feedback on the manuscript.

A Setup and Availability

A set of preconfigured mock shipment records is provided (see Table 7) to enable testing of the chatbot's full functionality without relying on real customer data. The chatbot is accessible on the company's official website[10]. Although this paper exemplifies a subset of allowed actions, the system supports all of them. For actions not covered in this document, the chatbot itself guides the user through the required steps and validations.

B UX Scenarios and Interaction Flows

We demonstrate the system through a set of representative customer service scenarios. Due to the probabilistic nature of language generation, the system produces different but semantically consistent responses across interactions.

B.1 Parcel Status Inquiry

Goal: To provide the current shipment status. This is required for most of the interactions between the chatbot and the user.
Required identifiers: (i) parcel ID and (ii) postal code.
System Outcome: Formatted shipment status information (see Fig. 1).
Safeguards and validation: Parcel identification is mandatory for any parcel-related inquiry: the assistant requires a valid parcel ID and matching postal code before retrieving status. If information is incomplete or unclear, it explains what is needed (and where to find it) and blocks the request until the required identifiers are provided, without guessing.

B.2 Allowed Actions (Parcel Shop Delivery)

Goal: Execute an allowed post-tracking action. We exemplify this by redirecting the parcel to a Parcel Shop.
Pre-requisite: Successful parcel identification (parcel ID + postal code).
Information required: Selection of the Parcel Shop.
System Outcome: The assistant proposes eligible Parcel Shops and completes the redirection only after explicit user confirmation (see Fig. 2).
Additional actions supported: The system applies the same prerequisite-and-confirmation pattern to other post-tracking actions, including neighbour/concierge derivation, delivery notes, and de-

[10] https://gls-group.com/ES/es/home/

Parcel ID	Status	Out of Home	Neighbour	Date change	Add note	Escalation
1139815480	On delivery	✓	✗	✗	✗	✗
1139818330	Incident	✓	✓	✓	✓	✗
1139817212	Delivered	✗	✗	✗	✗	✓

Table 7: Mock parcel records for testing the chatbot; allowed actions are those of Section 2.1. The postal code is 28022 for all records.

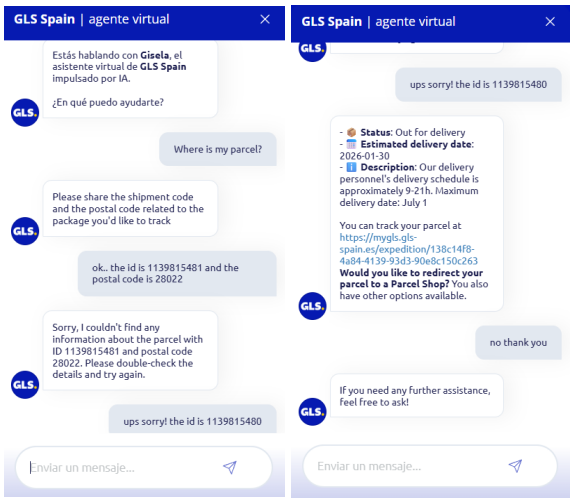

Figure 1: Parcel Status Inquiry on GLS Chatbot.

Figure 2: Derivation to a Parcel Shop successfully triggered by the user.

livery date changes.

Safeguards and validation: The system enforces action-specific constraints: incomplete parameters (e.g., missing Parcel Shop selection) block execution until resolved; abusive content in notes or derivations is rejected with a request for compliant rephrasing; and neighbour derivations require sufficient identification (name and address) before proceeding.

B.3 Change Delivery Date

Goal: Execute a delivery date change for a parcel.
Pre-requisite: Successful parcel identification (parcel ID + postal code).
Information required: New delivery date selected by the user.
System Outcome: The assistant presents available dates, confirms the user's selection, and completes the date change upon explicit confirmation.
Safeguards and validation: The system enforces date-specific constraints: date changes are blocked when not available for the given parcel; selections outside the permitted date range are rejected with a prompt to choose a valid alternative. The system also resolves natural language date expressions (e.g., "tomorrow") into concrete dates before validation.

B.4 Escalation Process

Goal: Escalate a customer case to human support when automated resolution is not appropriate.
Pre-requisite: A parcel/customer case eligible for escalation under business rules.[11]
Information Required: User's email.
System Outcome: The assistant collects the necessary context and creates a support escalation request only when eligibility conditions are met.
Safeguards and validation: The system prevents unnecessary escalations: ineligible cases (e.g., status "in delivery") are refused with an explanation; missing identifiers or context block the request until provided; and duplicate escalations are detected, informing the user that a ticket already exists.

[11] Escalation rules are defined internally and cannot be disclosed. They are designed to prevent unnecessary escalations when the issue can be resolved through automated actions.

Repo2ROCm: An Agentic System for Reproducing Research Code on AMD ROCm GPUs

Abstract

Machine learning practitioners routinely rely on public code repositories accompanying research papers, libraries, and open-source projects to evaluate, baseline, or build upon prior work. Yet getting such repositories to run and reproduce results often involves non-trivial effort, and is especially challenging when the target software and hardware stack differs from the one the original code was developed on. A prominent instance is running repositories originally built for CUDA-enabled hardware on AMD GPUs supporting the ROCm software stack. Here, successful installation alone is not a sufficient signal: a range of subtler issues may cause the code to either fail outright or silently fall back to inefficient execution.

We present **Repo2ROCm**, an agentic system that migrates CUDA-centric ML repositories to ROCm in an automated manner. Repo2ROCm reconstructs a ROCm-compatible environment, adapts hardware-specific assumptions, executes a real workload, and confirms GPU-backed execution emitting auditable artifacts at every step (environment specs, source patches, execution logs, and verification evidence). We evaluate on **ResearchBench**, 60 repositories belonging to recent papers from top AI conferences. While only 18/60 run out of the box, Repo2ROCm reaches verified functional reproduction for 59/60 (3.3× improvement). Against popular general-purpose coding agents on a curated ten-repository diagnostic set (with all agents using the same Claude Sonnet 4 backbone), Repo2ROCm achieves the highest **Portability Fidelity Score (PFS)**, a measure of how faithfully a run preserves the accelerator-critical execution path, real workload, and verified environment, scoring 77.3 vs. 61.4 (Claude Code), 58.7 (Mini-SWE-Agent), and 40.3 (Cursor Agent). Code and artifacts are available at github.com/Gaurav7888/Repo2ROCm.

† Work done when the author was affiliated with AMD.

1 Introduction

For industry AI teams, public ML repositories are often the first artifact used to decide whether a new method is worth adopting, but running those off-the-shelf repositories reliably is rarely just a clone-and-execute exercise. In practice, it often takes quite a bit of manual time and effort to integrate and reproduce. Failures arise at two levels: first, reconstructing the repository's intended software and experimental setup; second, moving that setup onto a different accelerator platform.

Tier 1: Reproducibility challenge. Evaluating a public ML repository begins with a practical question: can the code run reliably in our environment? This is often non-trivial because research repositories frequently have stale setup instructions, conflicting dependency files, version mismatches, implicit entry points, missing external artifacts, and experiment scripts tied to the authors' local environment.

Tier 2: Cross-hardware platform migration. The challenge deepens when the repository assumes one accelerator stack but the target hardware uses another. For CUDA-centric repositories evaluated on AMD ROCm, migration requires selecting a compatible software stack, replacing or rebuilding CUDA-specific dependencies, and adapting source-level hardware assumptions such as device checks, custom kernels, and backend-specific libraries. These changes must preserve the repository's *execution path*: the model, workload, accelerator backend, GPU-critical libraries, kernels, and device placement used at runtime. A repository that runs only after disabling accelerator-critical components, substituting a degraded or inefficient backend, falling back to CPU execution, or reducing the workload may no longer evaluate the method described by the paper, making research-result reproduction unreliable.

EMNLP 2026 Industry Track, pages 2265–2278
October 24-29, 2026 ©2026 Association for Computational Linguistics

Verification is therefore central. Successful installation, imports, command-line help screens, device-availability probes, or toy smoke tests do not establish that the intended workload ran on AMD GPU hardware. We therefore focus on *functional reproduction*: reconstructing a ROCm-compatible environment, executing the repository's intended workload, and verifying that the accelerator-critical execution path is preserved. This target is narrower than full paper-result reproduction, but stronger than installation success.

Why existing agents are insufficient. General-purpose coding agents are effective at making software appear runnable, but ROCm migration requires a stronger standard than task completion. In our setting, an agent must preserve the repository's accelerator-critical execution path and prove that a real workload ran on AMD GPU hardware. Existing agents may make progress through path-changing repairs, such as replacing FlashAttention with SDPA, disabling GPU-critical modules, or reducing workload scale. These repairs can produce a runnable repository, but they do not establish faithful cross-hardware reproduction. The missing ingredient is not just better code editing, but evidence-gated migration: every environment change, dependency substitution, source edit, and success claim must be tied to runtime evidence that the intended workload still executes on the target accelerator.

These challenges motivate an automated system that treats repository migration as an evidence-driven reproducibility task rather than a software-debugging task. Such a system must repair environments and adapt code for ROCm while verifying that the intended workload still follows the accelerator path being evaluated.

Contributions. This paper makes the following contributions:

- **REPO2ROCM:** an automated system for functional reproduction of CUDA-centric research repositories on AMD ROCm with zero manual intervention.
- **Evidence-gated plan-then-execute migration:** a guarded architecture that first plans repository migration statically, then executes changes only when deterministic runtime evidence supports environment changes, source edits, or GPU-backed success claims.
- **RESEARCHBENCH and PFS:** a 60-repository real-world research-code benchmark and Portability Fidelity Score for evaluating faithful cross-hardware execution beyond binary run/fail outcomes.

We do not claim reasoning-and-acting execution, knowledge retrieval, checkpoint-rollback, causal memory, or deterministic verification as individually novel mechanisms. Our contribution is their integration into a *guarded cross-accelerator migration architecture*, in which every irreversible action (switching base images, replacing accelerator libraries, editing critical source paths) and every success declaration must be backed by non-overridable runtime evidence, together with the RESEARCHBENCH benchmark and the fidelity-oriented PFS evaluation methodology.

2 The REPO2ROCM System

REPO2ROCM takes a GitHub repository as input and produces a ROCm-ready execution package: a compatible environment, source patches when needed, execution logs, and evidence that the target workload ran on AMD GPU hardware. Figure 1 gives an end-to-end view of the system, from repository fingerprinting and static planning to guarded execution, verification, and artifact generation.

Inputs, outputs, and operating modes. We use three operating settings throughout the paper:

- **Mode 0:** the out-of-the-box baseline. The repository is cloned and run by following its public instructions, with no intervention from REPO2ROCM.
- **Mode 1:** the main REPO2ROCM setting. REPO2ROCM reconstructs the environment, adapts CUDA-centric assumptions, runs the intended workload, and declares functional reproduction only after verified AMD GPU execution.
- **Mode 2:** a limited metric-checking extension used when a paper claim can be expressed as a command, metric, and tolerance.

Keeping Mode 2 separate is deliberate: functional reproduction and full paper reproduction are different goals, and our main claim is cross-hardware functional reproduction rather than arbitrary paper-result reproduction. A successful REPO2ROCM run emits a reproducible Dockerfile, source patch,

command logs, verification evidence, and the full agent trajectory.

When a repository counts as reproduced. We fix an explicit, repository-level definition of functional reproduction that the deterministic verifier enforces and the agent cannot override. A Mode 1 run is counted as a success only if *all* of the following hold: (i) an official workload of the repository (inference, training, evaluation, or a forward pass) executes to completion; (ii) there is runtime evidence that this workload ran on AMD GPU hardware through the ROCm stack; (iii) the repository's accelerator-critical components (e.g., attention backends, custom kernels, GPU-critical dependencies) are preserved rather than disabled, stubbed, or replaced by a degraded path; and (iv) there is no unreported CPU fallback, backend substitution, disabled module, or toy-scale execution. This criterion is deliberately stronger than successful installation, imports, device-availability probes, or smoke tests, and narrower than full paper-result reproduction (Mode 2).

Repository fingerprinting and static planning. The first stage runs outside Docker and performs lightweight repository reconnaissance. REPO2ROCM clones the repository, identifies its framework stack, configuration files, candidate entry points, CUDA-specific dependencies, and custom GPU kernels, then ranks compatible AMD ROCm base images. The planner emits a compact execution plan containing the likely install path, migration hazards, workload command, and validation checks, avoiding expensive Docker-agent turns on basic discovery. For limited Mode 2 runs, it also records the selected command, target metric, and tolerance when these can be extracted unambiguously from the paper and code.

ROCm base-image ranking. Base-image selection is a high-impact planning decision: an incompatible container can fail before repository-specific repair begins. REPO2ROCM first detects the host accelerator architecture and gathers candidate ROCm images from live Docker metadata and locally cached images. Candidates that target the wrong architecture, predate the detected GPU family, are explicitly excluded after a failed attempt, or are marked as repeatedly failing in the knowledge base are filtered out before scoring.

The remaining images are ranked by matching repository requirements against image inventory tokens. Let T_r be the set of normalized package and framework name tokens extracted from the repository's imports and dependency files (e.g., `requirements.txt`, `environment.yml`, `setup.py`/`pyproject.toml`), and let T_i be the inferred package inventory of candidate image i. Tokens are lowercased and canonicalized to a common form (e.g., distribution and import aliases are unified) before matching. Version constraints are excluded from both T_r and T_i and handled separately by compatibility filters, so this term measures package presence rather than exact version agreement. The main compatibility term is a Jaccard score:

$$J(r, i) = \frac{|T_r \cap T_i|}{|T_r \cup T_i|}.$$

The final score adds bonuses for matching the detected workload framework, being locally cached, explicitly matching the host architecture token, and appearing in recent Docker metadata, with soft penalties for Python-version mismatch, overly large images, or floating tags. The highest-scoring surviving image becomes the Dockerfile base image. If the container crashes during early startup, REPO2ROCM records the failure, excludes that image, and reranks the remaining candidates.

Kernel migration. Repositories with custom CUDA kernels require a separate migration path from ordinary Python dependency repair. When the planner detects `.cu` files or CUDA extension builds, REPO2ROCM invokes a kernel agent that applies CUDA-to-HIP conversion, using tools such as `hipify` where appropriate, and then validates whether the converted extension can build and load under ROCm.

Guarded execution in Docker. The execution stage runs inside a GPU-pinned Docker sandbox. A ReAct-style executor follows the static plan one action at a time: installing dependencies, modifying files, building extensions, running validation commands, and recording results. After successful milestones, the sandbox state is checkpointed; failed actions can roll back to the most recent stable state instead of restarting the repository from scratch. This rollback mechanism is important because ROCm migration is exploratory: several package versions, containers, or source patches may fail before a valid configuration is found. Recovering from a checkpoint lets the agent explore alternatives without corrupting the last known-good environment.

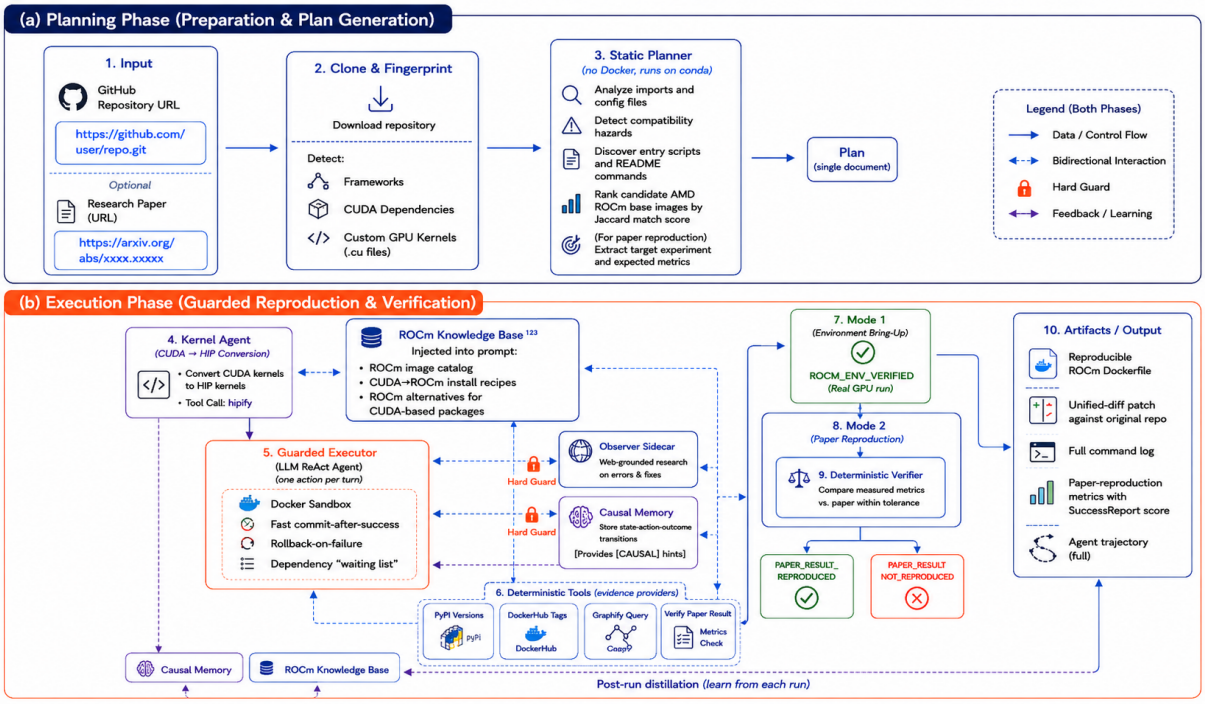

Figure 1: The REPO2ROCM pipeline, shown in two phases. **(a) Planning phase:** the system clones and fingerprints the repository (frameworks, CUDA dependencies, custom `.cu` kernels), then a static planner running outside Docker detects compatibility hazards, discovers entry points, ranks candidate AMD ROCm base images by Jaccard match score, and emits a single plan document. **(b) Execution phase:** a guarded ReAct executor runs the plan one action at a time inside a GPU-pinned Docker sandbox, optionally invoking a kernel agent for CUDA-to-HIP conversion, and is supported by a ROCm knowledge base, deterministic evidence-provider tools, an observer sidecar, and causal memory. Hard guards block irreversible actions that lack supporting runtime evidence. Mode 1 terminates with a verified GPU-backed run (`ROCM_ENV_VERIFIED`); the preliminary Mode 2 additionally compares extracted metrics against a specified target through a deterministic verifier. Post-run distillation feeds causal memory and the ROCm knowledge base for later runs.

Evidence providers and hard guards. REPO2ROCM treats deterministic tools as evidence providers rather than optional helpers. Package and image lookup tools check PyPI and Docker metadata, code-indexing tools such as Graphify let the executor inspect relevant files and symbols without loading the entire repository into the language-model context, and GPU validation tools verify that the workload actually executes on AMD hardware. Hard guards block irreversible actions until supporting evidence is available: for example, the executor cannot switch base images, replace accelerator libraries, modify critical source paths, or declare `ROCM_ENV_VERIFIED` from weak evidence such as an import check, help screen, or CPU-only run. In limited Mode 2 runs, a deterministic verifier compares extracted metrics against the specified target and records a match or mismatch.

2.1 Deterministic Verification

A language model can generate plausible explanations for both successful and unsuccessful runs, making free-form success claims difficult to trust. REPO2ROCM therefore delegates functional-reproduction checks, and optional metric checks in Mode 2, to deterministic verifiers that evaluate execution logs and predefined criteria. The verifier's output is authoritative and cannot be overridden by the agent, keeping outcomes evidence-based, auditable, and resistant to agent gaming.

Examples. First, GPU-backed workload verification checks that the selected container exposes AMD devices through the ROCm-backed runtime and that a repository-level forward, training, inference, or evaluation command runs before emitting `ROCM_ENV_VERIFIED`; an import check alone is insufficient. Second, accelerator-path verification checks that GPU-critical libraries remain active: for example, a FlashAttention migration must

show a ROCm-compatible import and GPU execution path, while an SDPA replacement is recorded as a degraded fallback rather than silent success.

2.2 ROCm Knowledge, Observer, and Causal Memory

ROCm knowledge base. The ROCm knowledge base injects curated migration rules into the executor, including known ROCm package variants, compatible container choices, CUDA-to-ROCm replacement patterns, and common fixes for recurring build failures. This prevents the agent from repeatedly rediscovering the same ROCm-specific solutions through unrestricted search.

Observer sidecar. The observer sidecar is triggered when the main ReAct loop stops making progress for several steps or when its hints become stale. It reviews the recent trajectory and command logs from an outside perspective, can consult external documentation for fresh context, and injects concise repair suggestions that help the executor escape repeated failure loops.

Causal memory. Causal memory records prior ⟨state, action, outcome⟩ transitions and supplies hints when a new repository reaches a similar failure state. It complements the static ROCm knowledge base by capturing run-time repair experience from previous repositories while keeping final success dependent on deterministic runtime evidence.

Post-run knowledge distillation. After each run, REPO2ROCM distills the trajectory into reusable migration knowledge, creating a learning loop across repositories. The distillation step summarizes which actions succeeded, which failed, which ROCm image and package choices were stable, and which errors required rollback or observer intervention. These summaries update the causal memory and ROCm knowledge base used by later runs. The learning loop is intentionally conservative: distilled knowledge can provide hints or rank future choices, but it does not bypass hard guards or deterministic verification.

Artifacts and operational safety. Each run is isolated in its own Docker sandbox with command timeouts, resource limits, and checkpoint-and-rollback recovery. The resulting artifact bundle contains the generated Dockerfile, source-code patch, command logs, verification outputs, and agent trajectory; optional Mode 2 runs also include the metric-comparison report. These artifacts make the migration auditable and allow many repositories to be run independently across a multi-GPU server.

3 Evaluation

Benchmark. We evaluate REPO2ROCM on RESEARCHBENCH, a benchmark of 60 repositories accompanying recent machine-learning and natural-language-processing papers from ICLR, ICML, ACL, and NeurIPS. We build this benchmark because existing coding-agent benchmarks are not designed for research-code setting: they often use mature software repositories with curated issue descriptions, test suites, well documented Readme and maintainable project structure. By contrast, research repositories commonly have incomplete setup instructions, unclear entry points, external datasets or checkpoints, and hardware-specific assumptions. RESEARCHBENCH captures this less curated but industrially common workflow across diverse repository types, including inference-heavy systems, training pipelines, agentic workflows, dataset-processing code, and benchmarking suites, all evaluated for faithful execution on available accelerator hardware.

Metrics. Our primary metric compares Mode 0 out-of-the-box execution against Mode 1 functional reproduction: verified GPU-backed execution on AMD hardware.

For comparisons with general-purpose agents, a binary ran/failed label is too coarse: an agent may make a repository execute by disabling accelerator-critical components, substituting a fallback backend, using a toy workload, or relying on a prebaked environment. We therefore define the *Portability Fidelity Score* (PFS), a continuous 0–100 score for each repository-agent pair:

$$\mathrm{PFS} = \mathrm{Ran} \times (15 + 35F_{\mathrm{path}} + 20A_{\mathrm{work}} + 20A_{\mathrm{env}} + 10D_{\mathrm{proc}}).$$

Here, Ran gives baseline credit for producing runnable evidence, F_{path} measures preservation of accelerator-critical components, A_{work} measures whether the real workload was run, A_{env} measures whether a ROCm environment was built and verified, and D_{proc} measures evidence-gated process discipline. Appendix B gives the full grading rubric. All Mode 1 runs are evaluated using a deterministic functional-reproduction rubric and degradation indicators such as attention fallbacks, environment substitutions, or reduced execution scale.

Experimental setup. All experiments run on a host with eight AMD Instinct MI350X devices (`gfx950`, 270.6 GB HBM3E memory per device), running ROCm Runtime 1.18 (amdgpu driver 6.14.14). The environment configuration uses one or up to eight devices depending on the use case. The base image is selected per repository by the planner. REPO2ROCM uses Claude Sonnet 4 as its language-model backbone and is capped at 100 turns per run; we impose no fixed token budget.

Agent comparison and fairness. For the comparison in Table 2, all four systems (REPO2ROCM, Claude Code, Cursor Agent, and Mini-SWE-Agent) use the same underlying model, Claude Sonnet 4, so that measured differences reflect system design rather than model capability. Every agent receives the same repository revision, target hardware, task specification, execution budget, fidelity requirements, and access to public ROCm documentation. REPO2ROCM additionally ships a curated ROCm knowledge base (package mappings, compatible container configurations, CUDA-to-ROCm migration patterns, and verified build fixes); this knowledge base is an explicit component of the proposed architecture rather than an external advantage, so the comparison contrasts complete systems.

Cost and latency. A typical REPO2ROCM migration consumes on average 719K tokens (median 608K) and about 18–20 minutes of wall-clock time, using between one and eight MI350X devices depending on the repository. We report token usage and wall-clock time rather than a single GPU-hour figure because the number of devices engaged varies per repository.

3.1 ResearchBench Results

Table 1 summarizes the main RESEARCHBENCH outcome. Out-of-the-box execution succeeds for only $18/60$ repositories. The remaining repositories fail due to a mixture of ROCm-specific incompatibilities and common research-code breakages: CUDA-only dependencies, unsupported container environments, hard-coded CUDA assumptions, silent CPU fallback, stale APIs, syntax errors, and small repository bugs that require source-level fixes.

REPO2ROCM increases the functional reproduction rate to $59/60$, a $3.3\times$ improvement over the out-of-the-box baseline of $18/60$.[1]

Setting	Verified runs	Run rate
Mode 0 (out of the box)	$18/60$	30.0%
Mode 1 (REPO2ROCM)	$59/60$	98.3%

Table 1: Summary of RESEARCHBENCH functional reproduction results. A verified run requires GPU-backed execution on AMD ROCm.

Detailed repository-wise outcomes are reported in Appendix D, Table 5.

A qualitative inspection shows that failures often came from path-changing repairs rather than simple crashes: unsupported containers, disabled accelerator-specific components, incorrect API adaptations, and fallback implementations such as SDPA instead of Flash-Attention. These cases motivate evaluating functional reproduction with execution-path fidelity rather than binary run/fail labels.

These failure modes directly motivated the evidence-gated execution model and ROCm-specific knowledge base used by REPO2ROCM.

When repositories exceed available GPU memory, REPO2ROCM applies controlled scaling adjustments, such as reducing batch size or generation length, while preserving the original model and execution path whenever possible.

3.2 Comparison with General-Purpose Agents

We compare REPO2ROCM against two closed-source commercial agents (Cursor Agent and Claude Code Agent) and one open-source agent (Mini-SWE-Agent). The comparison uses a manually curated set of ten repositories, selected *before* observing any agent scores to span diverse migration challenges: image generation, multimodal classification, vision analysis, JAX training, LLM training and editing, recommendation, KV-cache optimization, and protein modeling. We therefore treat it as a diversity-oriented diagnostic comparison rather than a benchmark-wide estimate; complete per-repository results and component-level annotations are released with the artifact bundle (Appendix A). All agents use the same Claude Sonnet 4 backbone under the matched conditions of §3.

Table 2 reports average PFS. REPO2ROCM achieves the highest average score, indicating that

[1]The only failure, DiffusionVeteran, fails under both Mode 0 and Mode 1 (Table 5), not a regression from a working baseline.

Agent	Average PFS
REPO2ROCM	**77.3**
Claude Code Agent	61.4
Mini-SWE-Agent	58.7
Cursor Agent	40.3

Table 2: REPO2ROCM versus general-purpose coding agents on the ten-repository diagnostic set, under the Portability Fidelity Score (PFS). All agents use the same Claude Sonnet 4 backbone.

Configuration	Ran	Run rate	Speedup
baseline	15/20	75%	1.00×
causal-mem	**18/20**	**90%**	1.16×

Table 3: Causal-memory ablation across 20 CUDA-oriented, GPU-dependent repositories. Paired comparison; the memory-disabled baseline retains planning, the ROCm knowledge base, guarded execution, rollback, and deterministic verification.

its gains are not only from making repositories run, but from preserving the intended accelerator path, workload, and ROCm environment. Appendix C analyzes the path-changing repairs made by the general-purpose agents, and Appendix B reports a weight-sensitivity analysis showing that the ordering is preserved under equal component weights and under removal of any single PFS component.

Run-to-run stability. To probe variance, we repeated migrations five times each for three repositories spanning easy, moderate, and difficult cases (AlphaRec, LADDER, and UltraHR-100K). Each repeat started from the same commit in a clean sandbox with identical hardware, model, budget, knowledge-base snapshot, and verifier configuration, with cross-run memory disabled. All $15/15$ runs reproduced the same verification outcome as the primary evaluation. Pooled across the three repositories, PFS was 67.13 ± 21.47 and token usage was $1{,}027{,}801 \pm 945{,}936$; because these statistics are pooled across repositories of differing difficulty, the standard deviation primarily reflects between-repository variation rather than run-to-run noise.

3.3 Mode 2 : Case Study

We use Mode 2 only as a case study after Mode 1 has established a verified ROCm execution environment. **TURBOQUANT** (Zandieh et al., 2026) is the positive example: the repository exposes a clear quantization experiment with machine-checkable metrics, and the verifier found the reported compression, similarity, and match-rate values within tolerance. As a contrasting case, **DKV-CACHE** (Ma et al., 2025) executed its intended workload on AMD GPUs under Mode 1, but its reported hardware-sensitive speedup did not reproduce within tolerance, so Mode 2 correctly classified it as *not reproduced*. Of the two preliminary Mode 2 cases, one matched the reported metrics and one did not, illustrating that result-level verification can distinguish functional execution from scientific-result reproduction without conflating the two.

Negative verification outcomes frequently reflected well-known reproducibility challenges rather than failures of ROCm execution. Although repositories could often be built and executed successfully, independent result validation was hindered by missing datasets, unavailable checkpoints, proprietary or undocumented preprocessing steps, gated model access, external service dependencies, and incomplete evaluation instructions. Such issues are common in contemporary machine learning research and illustrate that releasing source code alone is often insufficient for enabling full reproduction of reported results.

3.4 Impact of Causal Memory

We ablate causal memory on 20 CUDA-oriented, GPU-dependent repositories, selected before running the ablation to span custom-kernel workloads and the migration-failure types observed in §3 rather than for the mere presence of `.cu` files. The comparison is paired: the full system is compared against an otherwise identical configuration with causal memory disabled, using the same repositories, budgets, and evaluation conditions. Crucially, this memory-disabled baseline is *not* the out-of-the-box Mode 0 setting: it retains static planning, the ROCm knowledge base, guarded execution, rollback, and deterministic verification, so the ablation isolates the contribution of causal memory alone. As shown in Table 3, causal memory improves the functional-run rate from 75% $(15/20)$ to 90% $(18/20)$, a $1.2\times$ increase. On repositories completed by both configurations, it yields a $1.16\times$ relative speedup; counting rescued failures and timeouts as baseline wasted effort increases the effective speedup to roughly $1.42\times$.

4 Related Work

Agentic software engineering. Recent systems and benchmarks such as SWE-BENCH (Jimenez et al., 2024) and SWE-AGENT (Yang et al., 2024) study whether language-model agents can modify repositories and resolve software issues through execution feedback. These works demonstrate the value of iterative code editing and validation, building on reasoning-and-acting patterns such as ReAct (Yao et al., 2023) and memory-based agent improvement such as Reflexion (Shinn et al., 2023). REPO2ROCM shares the use of iterative execution, but targets a different failure point: before code-level tasks can be evaluated, many research repositories must first be made runnable on the target accelerator. Our setting also lacks the curated tests and issue descriptions common in software-engineering benchmarks, so success must be grounded in workload and GPU-execution evidence.

Environment reconstruction. Environment reconstruction systems such as REPO2RUN (Hu et al., 2025) automate dependency resolution and Docker environment construction for code repositories. REPO2ROCM builds on this line of work but specializes it to heterogeneous GPU migration. In our setting, choosing a container and installing packages is not enough: the system must select ROCm-compatible images, adapt CUDA-centric dependencies and source assumptions, and verify that the intended workload executes on AMD GPU hardware without silent CPU fallback or path-changing substitutions.

GPU backend portability. The practical difficulty of cross-hardware reproduction is amplified by accelerator-specific software stacks. AMD ROCm (AMD, 2025) provides a CUDA-adjacent ecosystem, but high-performance ML repositories often depend on backend-specific components such as FlashAttention (Dao et al., 2022; Dao, 2023) or serving stacks such as vLLM (Kwon et al., 2023). These components may require different builds, kernels, or fallback behavior across hardware platforms. REPO2ROCM treats such backend-specific knowledge as part of the migration process, combining ROCm-specific guidance with evidence-gated verification of the executed path.

Limitations

Several limitations remain. First, this work focuses on functional reproduction: constructing a ROCm-compatible environment and verifying that the intended workload runs on AMD GPU hardware. We tested Mode 2 only as a limited metric-checking extension on simple cases where the target command, metric, and tolerance were explicit. Making REPO2ROCM robust for broader result reproduction is the next phase of the project, requiring better experiment extraction, metric parsing, multi-metric verification, and handling of long-running or data-dependent workflows.

Second, the evaluation is limited to RESEARCH-BENCH, AMD ROCm, and the hardware/software stack described in §3. The benchmark is constructed from recent research papers, so it may not capture the additional dependency drift, broken links, and archival issues that appear in repositories from papers published four or five years earlier. Extending the benchmark to older research repositories is part of our future evaluation pipeline. Although the failure modes are common in cross-hardware ML migration, results may differ for other ROCm versions, accelerator generations, target backends, or internal industry repositories.

Third, REPO2ROCM cannot resolve all external research-artifact dependencies. Some repositories require datasets or checkpoints behind request forms, author email, Google Drive permissions, expired links, or downloads that exceed practical time limits. In such cases, REPO2ROCM can document the blocker and preserve the migration artifacts, but functional or metric-level verification may remain impossible without access to the missing artifacts.

Further, REPO2ROCM relies on a curated ROCm compatibility knowledge base that must be maintained as container images, package variants, and framework support evolve. Although live package and image lookups reduce staleness, high-quality migration rules require periodic updates.

Finally, our evaluation methodology has two scope limits. PFS path-fidelity grades are produced by a single language-model judge (Claude Opus 4.6) under a frozen rubric applied identically to all systems (Appendix B); while this keeps grading consistent and agent-agnostic, we do not yet report inter-annotator agreement, and an independent human re-grading with judge–human agreement (weighted Cohen's κ) is left to future work. In addition, the agent comparison uses a manually

curated ten-repository diagnostic set rather than the full benchmark, so the reported PFS gaps are diagnostic rather than benchmark-wide estimates.

Ethical Considerations

REPO2ROCM executes third-party research repositories inside containerized GPU environments and therefore inherits the risks associated with running untrusted code. Deployments should incorporate appropriate isolation mechanisms, resource controls, and security policies to mitigate potential misuse or unintended side effects. Furthermore, patches generated by the system should be reviewed by human operators before being incorporated into production codebases.

The system is designed to support transparent and verifiable reproducibility studies. Reproduction outcomes are determined by deterministic evaluation procedures and evidence collected during execution rather than by model-generated claims. This design reduces the risk of fabricated or unverifiable reproduction results while preserving an auditable record of system behavior.

All experiments reported in this work operate on publicly available repositories and accompanying research artifacts. The system does not require the collection of personal information and is not intended for processing sensitive user data.

A Artifact Layout

Each REPO2ROCM run writes an artifact bundle under `verification/<repo>/`. The bundle is intended to make the migration auditable and reproducible:

- `Dockerfile`: the ROCm-ready environment selected and constructed by the system.
- `patch/`: unified diffs containing source changes made to adapt the repository.
- `inner_commands.json` and `outer_commands.json`: command logs from inside and outside the Docker sandbox.
- `plan.txt`: the static planner output, including detected hazards, selected base image, candidate workload, and validation steps.
- `trajectory.jsonl`: the step-by-step agent trajectory used for audit and post-run knowledge distillation.
- `metric_check.json`: the optional Mode 2 metric-comparison report, present only for limited result-checking runs.

B Portability Fidelity Score Details

PFS is computed per repository-agent pair:

$$\mathrm{PFS} = \mathrm{Ran} \times (15 + 35F_{\mathrm{path}} + 20A_{\mathrm{work}} + 20A_{\mathrm{env}} + 10D_{\mathrm{proc}}).$$

$\mathrm{Ran} \in \{0, 1\}$ indicates whether the run completed and produced runnable evidence. If the run does not execute, PFS is zero. If it runs but satisfies none of the fidelity criteria, it receives the 15-point running baseline. All other subcomponents are normalized to $[0, 1]$, so the maximum score is 100.

Path fidelity. For path fidelity, each repository has K accelerator-critical components detected from the repository itself, such as attention backends, GPU-critical dependencies, or custom kernels. The detector is repository-specific rather than a fixed library list. Each component receives grade g_i: 1.0 for a preserved ROCm-native or equivalent path, 0.5 for a degraded but functional path, and 0.0 for a disabled, stubbed, removed, or signature-altered component. Examples of preserved paths include AMD Triton FlashAttention, ROCm builds of GPU-critical dependencies, or HIP-ported kernels. Examples of degraded paths include SDPA replacing FlashAttention or CPU fallback for a GPU dependency. Examples of broken-but-masked paths include commented-out modules, disabled kernels, or calls rewritten with an incorrect signature. We compute

$$F_{\mathrm{path}} = \frac{1}{K} \sum_{i=1}^{K} g_i.$$

This keeps path fidelity bounded and independent of the number of checked components. Adding support for a new dependency such as `gsplat`, `bitsandbytes`, or a custom kernel only requires adding a detector that maps the component to one of the three grades.

Workload authenticity. Workload authenticity measures whether the run executed the paper's real workload. It penalizes model substitution, dataset scale-down, toy dimensions, smoke tests, import checks, `-help`, or device-availability checks without a real forward, train, or evaluation step on GPU.

Environment authenticity. Environment authenticity measures whether the agent selected, built, and verified a ROCm environment for the repository. Runs that inherit an unverified pre-baked container score lower than runs that select a base image, build the environment, and show genuine AMD GPU execution evidence.

Process discipline. Process discipline rewards evidence lookup before irreversible changes and efficient evidence-gated execution. Agents receive higher credit when they consult package, image, code-indexing, or GPU-verification tools before modifying dependencies, patching accelerator paths, or declaring success.

Grading protocol. Path-fidelity grades g_i are assigned by a single language-model judge (Claude Opus 4.6) applied to the artifact bundle (Dockerfile, patches, command logs, GPU-execution evidence, and the repository-specific accelerator-critical components), using a frozen rubric, prompt, and temperature, and the same configuration for every system so that grading is consistent and agent-agnostic. Because a single automated judge was used, we do not report inter-annotator agreement here; an

Repository	P	W	E	D
REPO2ROCM

SuperCollapse	17.50	0	12	5
UltraHR-100K	11.66	1	14	6

Table 4: Per-component PFS point contributions on the five component-annotated comparison repositories: P (path fidelity, out of 35), W (workload authenticity, out of 20), E (environment authenticity, out of 20), and D (process discipline, out of 10). For a run that executed, $\mathrm{PFS} = 15 + \mathrm{P} + \mathrm{W} + \mathrm{E} + \mathrm{D}$. Mean PFS: REPO2ROCM 63.1 vs. Claude Code 57.2.

independent human re-grading with judge–human agreement (weighted Cohen's κ) is left to future work (see Limitations).

Weight sensitivity. The PFS weights encode failure severity: path fidelity carries the largest weight because a silent backend substitution can invalidate an otherwise successful run; workload and environment authenticity are direct task requirements; and process discipline carries the smallest weight as secondary auditability evidence. The 15-point floor credits basic runnable evidence. To test whether the conclusions depend on these specific weights, we recomputed scores on the five comparison repositories for which we have component-level annotations, using both the original weights and equal component weights. Table 4 lists the per-component point contributions. Under the original weights REPO2ROCM averages 63.1 versus 57.2 for Claude Code, and under equal component weights 63.2 versus 55.9; removing any single component does not change the aggregate ordering. On UltraHR-100K, Claude Code scores higher than REPO2ROCM (47.7 versus 39.0), which we report transparently.

C Qualitative Analysis of General-Agent Failures

Several general-purpose agent runs reached an apparently runnable state by changing the repository's execution path. The most common pattern was backend substitution: when a ROCm-compatible FlashAttention path was not installed, agents replaced FlashAttention with PyTorch SDPA in repositories such as KNOWLEDGE-ENTROPY and PREFIXKV. This allowed execution to proceed, but it changed the accelerator-critical computation being evaluated and often reduced efficient use of the target GPU.

We also observed signature and module-level changes that masked failures rather than preserving the intended behavior. In PREFIXKV, Mini-SWE-Agent called a library function with an incorrect signature, producing a runnable path that no longer matched the original implementation. In UNIZYME, a module used by the original repository was left disabled so the run could complete. These cases illustrate why a binary run/fail metric is insufficient: the repository may run, but the measured path differs from the one the paper intended.

REPO2ROCM treats these cases differently. Its guards require evidence before accepting backend substitutions, source edits, or success claims, and PFS penalizes degraded, disabled, or signature-altered accelerator-critical components.

D Benchmark Repository Details

Table 1 summarizes the benchmark outcomes in the main paper. Table 5 gives the repository-wise Mode 0 and Mode 1 outcomes.

TRACE: Traceable Root-cause Analysis with Calibrated Evidence-grounded agents

Abstract

Root Cause Analysis (RCA) for defects in large e-commerce enterprises is manual and slow: a single defect spanning thousands of microservices and SOPs takes experts one to two weeks to diagnose. Generic agentic RCA frameworks fail on this workload because they stop at proximate causes, cannot verify numeric claims, ignore past reviewer decisions, and return enumerated hypotheses rather than the quantified narratives business teams act on. We present TRACE, an end-to-end agentic RCA system that combines supervised hypothesis-driven investigation with recursive why-drilling, an evidence-traceable multi-tool suite with stable artifact identifiers, a feedback retrieval and ingestion pipeline, and a two-layer confidence framework combining six mechanistic checks with an LLM judge - including a novel numerical-traceability score. Across several thousand cohorts spanning eight use cases in three metric categories (cost, quality, and inventory), TRACE achieves 65.4% expert acceptance; on a 240-cohort head-to-head benchmark it reaches 67.1% versus 38.8% for a matched ReAct baseline ($+28.3$ pp, $p<0.001$), with calibrated confidence (AUC 0.819, ECE 0.041).

1 Introduction

A large e-commerce enterprise's operational surface spans thousands of microservices, hundreds of teams, and tens of thousands of Standard Operating Procedures (SOPs). Defects on this surface - anomalous quality, cost, or inventory metrics, compliance misses - rarely originate where they surface: an anomaly may trace back to a catalog attribution issue, a warehouse packaging SOP, or a compliance regulation several hops upstream. Domain experts in enterprise quality-improvement programs historically spend one to two weeks per defect reconstructing this causal chain by hand - reading wiki pages, hunting for datasets, and tracking configuration changes; at the scale of such programs, manual RCA is the binding constraint.

LLM agents have made automated RCA credible: ReAct (Yao et al., 2023)-style loops extend to DevOps incidents (Wang, 2026; Pei et al., 2025; Xu et al., 2025), firmware security (Zhang et al., 2025), and text-to-SQL over enterprise tables (Cao et al., 2026). Yet they fall short for enterprise experts on four counts. *First*, they terminate at proximate causes - "driver X explains the anomaly" is not actionable until the chain is drilled to an atomic level (an SOP line, a catalog attribute, a concrete operational decision). *Second*, they cannot verify numeric claims; an LLM-generated aggregate untraceable to a tool-call artifact cannot drive financial decisions (Zheng et al., 2023). *Third*, they ignore past expert decisions, re-litigating rejected hypotheses across cohorts. *Fourth*, they produce the wrong output shape: experts and business teams consume quantified *defect narratives* in the enterprise's operational vocabulary, not enumerated hypothesis lists.

We present TRACE, an agentic RCA system that closes all four gaps. Our contributions are (i) an architecture combining hypothesis-driven investigation with automatic recursive why-drilling to atomic actionable causes; (ii) an evidence-traceable tool suite (distributed query, page-evaluation, retrieval, and deterministic-impact tools) in which every tool call emits a stable artifact identifier; (iii) a three-tier feedback retrieval pipeline with four stage-specific injection points, delivering same-day continual learning without model weight updates; (iv) a two-layer confidence framework pairing six mechanistic checks with five LLM-judge fidelity checks, including a novel *numerical-traceability* score that verifies every numeric token against its cited artifacts, calibrated with a feedback-derived Bayesian prior; and (v) a layered output design with mode-separated grounding (LLM reasons qualitatively, deterministic pipelines compute aggregates) that eliminates a large class of numerical

EMNLP 2026 Industry Track, pages 2279–2289
October 24-29, 2026 ©2026 Association for Computational Linguistics

hallucinations by construction. In deployment across eight use cases and several thousand cohorts, TRACE achieves 65.4% expert acceptance; on a 240-cohort paired head-to-head benchmark it reaches 67.1% versus 38.8% for a matched ReAct baseline ($+28.3$ pp), with confidence predicting acceptance at AUC 0.819. Beyond the specific system, we argue five design principles generalize to any enterprise agentic investigation where numerical claims must be audited and human feedback is expensive.

2 Related Work

ReAct (Yao et al., 2023) established the tool-use reasoning loop behind modern RCA agents, extended to incident response by AgentTrace (Wang, 2026), Flow-of-Action (Pei et al., 2025), OpenRCA (Xu et al., 2025), and TimeRAG (Yang et al., 2024); APEX-SQL (Cao et al., 2026) adds Hypothesis-Verification loops for enterprise text-to-SQL, and GraphRAG (Mountzouris et al., 2026) and data-to-paper (Ifargan et al., 2025) emphasize traceable evidence lineage. Recursive architectures (FirmHive (Zhang et al., 2025), ReDel (Zhu et al., 2024), DEPART (Hsu et al., 2025), ThReaD (Schroeder et al., 2025)) spawn sub-agents for deeper analysis. TRACE differs by targeting enterprise *business* defects rather than infrastructure incidents, triggering recursive why-drilling specifically on PROVEN hypotheses, and treating numerical grounding as a first-class, mechanically verified requirement rather than a post-hoc check. We do not adapt these systems as baselines: each presupposes inputs that do not exist for enterprise business defects (Flow-of-Action needs SOP-graphs keyed to incident types, AgentTrace execution logs, OpenRCA telemetry with ground-truth failure records), and constructing them ourselves would let our own choices shape the baseline's results. §4 instead isolates TRACE's design via subtractive ablation and an additive structured-loop variant.

For evaluation, G-Eval (Liu et al., 2023), RAGAS (Es et al., 2025), LLM-as-a-Judge (Zheng et al., 2023), multi-agent debate (Du et al., 2023), and the Aegean consensus protocol (Ruan et al., 2025) judge LLM outputs with other LLMs; closer to our setting, I-SEE (Joshi et al., 2025) instruction-tunes a compact multimodal evaluator to follow structured operational guidelines for e-commerce content quality, reducing dependence on manual prompt design. Standard RAG (Ram et al., 2023) injects knowledge at a single generation point. We instead pair an independent *mechanistic* audit (six deterministic checks, including the novel fuzzy-match numerical-traceability score) with a prompt-based LLM judge, which keeps the judge portable across use cases without per-domain tuning, calibrate via a feedback-derived Bayesian prior over hypothesis categories, and split feedback retrieval across *four* stage-specific injection points - using retrieval rather than fine-tuning as the vehicle for expert feedback.

3 Methodology

3.1 Problem Formulation

We formalize enterprise RCA as an agentic investigation task with human actionability as the success criterion. The input is a *defect statement* - a natural-language anomaly description (e.g., "the cost-per-unit metric is elevated by $3.20/unit"), metadata of all the existing tables related to the anomaly, an applicable use case $u \in \mathcal{U}$ (one of eight use cases, with per-use-case configurations in Appendix C), and a knowledge context $\mathcal{K}_u$ of domain documentation and historical reviewer feedback. The output is a triple $\mathcal{O} = \langle \mathcal{H}^\star, \mathcal{A}, c \rangle$: validated root-cause hypotheses organized into a causal chain, quantified *defect narratives* in the enterprise's operational vocabulary, and a composite confidence score $c \in [0, 100]$. The primary success signal is *expert acceptance*: a reviewer presented with $\mathcal{O}$ marks it actionable (sufficient for a business unit to initiate corrective action) or not. A critical requirement is *numerical grounding*: for every numeric token τ in the final report, an evidence artifact must exist with value $\phi(\tau)$ such that $|\tau - \phi(\tau)| \leq \epsilon$, since LLM numerical hallucination is catastrophic when outputs drive financial decisions. The problem is to maximize expected expert acceptance under this constraint while emitting c whose distribution aligns with empirical acceptance, so that c functions as a useful filter for stakeholder attention.

3.2 System Overview

Figure 1 shows the end-to-end architecture, organized as four bounded subsystems—the *Agentic Investigation Loop*, the *Two-Layer Confidence* block, the *Expert-Appropriate Output* block, and the *Human-in-the-Loop Feedback* block - fed by a left-hand input column and joined by a closed feedback path that does not require model fine-tuning.

A *Context Pre-Loader* retrieves four streams in parallel: the defect statement and transaction-data references, domain knowledge from a managed vector KB (SOPs, audits, historical RCAs, glossaries), relevant reviewer feedback from the Feedback Index via three-tier retrieval, and per-entity deep-dive signals (catalog, customer comments, tickets). Inside the *Agentic Investigation Loop*, a *Hypothesis Generator* (LLM) produces N categorized hypotheses; a lightweight *Supervisor* scores them on Impact $\times$ Feasibility, dispatches the top candidate to an *Investigator Agent* (LLM with tool-calling), and on a PROVEN verdict triggers *Recursive Why-Drilling* of child hypotheses toward an atomic cause. Every tool call is persisted by a rule-based *Evidence Manager* under stable `Q{n}_H{m}` identifiers. The *Two-Layer Confidence* subsystem then scores the investigation with Layer 1 (six rule-based mechanistic checks) and Layer 2 (an LLM judge with five fidelity checks including the fuzzy-match numerical-traceability score), combined as $c = 0.30\,L_1 + 0.70\,L_2$ and calibrated by a category-level Bayesian prior. The *Expert-Appropriate Output* subsystem emits a technical report, a stakeholder HTML, and defect narratives, with a rule-based gate routing sub-threshold or non-OPERATIONALISSUE outputs to expert pre-review. Finally, the *Human-in-the-Loop Feedback* subsystem closes the loop: an *LLM Evaluator* extracts generalized lessons from accept/reject decisions and a *Daily Indexer* refreshes the Feedback Index, which flows back into the Context Pre-Loader - yielding same-day continual learning without any model weight update.

3.3 Hypothesis-Driven Investigation with Recursive Why-Drilling

Generic agentic RCA terminates at proximate causes: "carrier X is driving cost" is not actionable until we explain why X is being selected for this pattern. We formalize a **supervised hypothesis-driven loop** augmented with automatic **recursive why-drilling**. A category-aware prompt (Appendix A) elicits N structured hypotheses, each with a category, statement, causal mechanism, features to investigate, expected pattern, and estimated impact; category diversity is enforced to avoid LLM mode collapse. The investigator agent tests each selected hypothesis via a bounded sequence of tool calls and emits a structured verdict with a conclusion in {PROVEN, DISPROVEN, UNCERTAIN}, a confidence, and supporting/contradicting evidence items with sample sizes. When a hypothesis h is concluded PROVEN with confidence above τ_{drill}, the supervisor automatically generates a child set by prompting an LLM to enumerate: "given that h is the proximate cause, why does the antecedent condition hold?" Recursion is bounded by $D_{\max} = 5$ and terminates early at an atomic cause (a policy rule, data-quality issue, or concrete operational decision) that is directly actionable, when sample sizes drop below threshold, or when child confidence falls below τ_{drill}. The resulting chain is surfaced as a "Root Cause Chain" section, empirically the single most-valued output in expert reviews. The **Supervisor** is a lightweight LLM controller (Appendix B) that scores uninvestigated hypotheses on Impact $\times$ Feasibility with a category-diversity bonus, dispatches the top-scored hypothesis, triggers why-recursion when warranted, and terminates based on the marginal value of the next-best hypothesis, also re-dispatching recent low-quality investigations with instructions to explore different features.

3.4 Evidence-Traceable Tool Use

A central architectural commitment is that every claim surfaced to a stakeholder must be traceable to a specific tool-call artifact, a requirement flowing from our grounding constraint (§3.1). The investigator has access to a registry of domain-specific tools activated per use case: a **distributed query tool** (natural-language $\rightarrow$ PySpark, executed on a serverless Spark backend); a **product-page evaluation tool** for catalog defects using an instruction-tuned multimodal content evaluator (Joshi et al., 2025); a **ticket retrieval tool** for operational incident tickets; a **knowledge/wiki search tool** (reactive RAG over the managed vector KB) etc. All tool calls publish through a unified Evidence Manager that assigns each call a stable identifier `Q{n}_H{m}` and persists inputs, outputs, and a rendered view. These identifiers propagate through the pipeline: investigator verdicts cite them as [`Q0_H1`], and they are preserved through report generation and the stakeholder HTML, making numerical traceability (§3.6) verifiable at the token level.

3.5 Context Augmentation: RAG and Feedback Retrieval

Two non-data knowledge sources are essential: *structured reviewer feedback* (accept/reject decisions with refined lessons) and *unstructured do-*

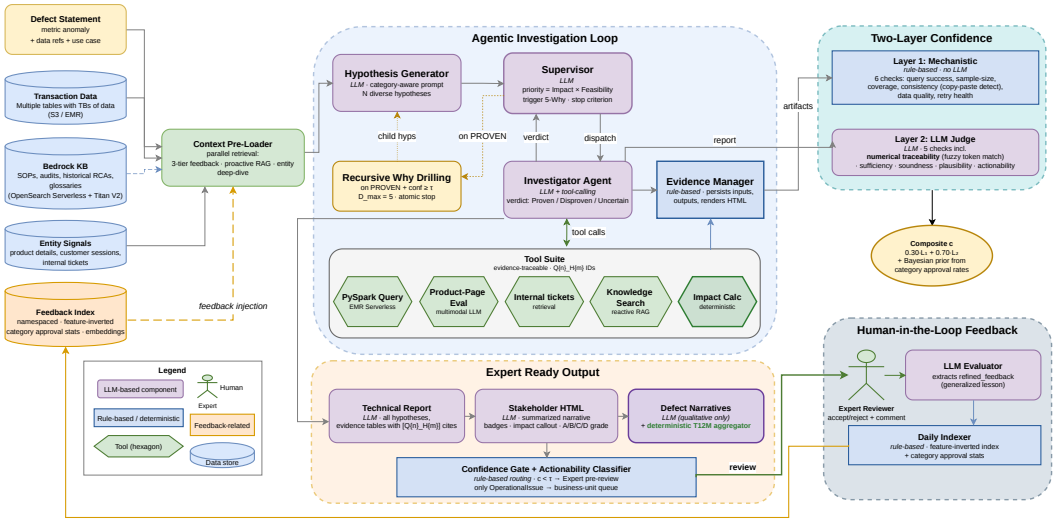

Figure 1: End-to-end architecture of the system. Structural feedback retrieval (orange) and RAG knowledge retrieval (blue) enter the pipeline at four and two points respectively; the investigation loop is supervised and supports recursive why-drilling.

main knowledge (SOPs, audits, historical RCAs, glossaries). These have different retrieval characteristics and we design complementary strategies.

Domain knowledge via RAG - Documents are indexed in a single managed vector KB with a `namespace` metadata filter, embedded with a production text-embedding model. The KB is consumed proactively at init (2–3 targeted queries concatenated into the hypothesis prompt) and reactively during investigation (an agent tool call for domain context that data analysis alone cannot supply). **Three-tier feedback retrieval and ingestion** - Because reviewer feedback is structured JSON with explicit metadata, we do a **Tier 1 (structural)** check by applying namespace filter, feature-overlap scoring (exact feature-value match $w{=}1.0$, same-feature-different-value $w{=}0.3$), and a time-window filter, narrowing thousands to $\sim$50–200 candidates via a feature-inverted index. **Tier 2 (semantic)** embeds anomaly description plus candidate hypotheses with the same embedding model and ranks by $s_{\text{combined}} = 0.4\, s_{\text{struct}} + 0.6\, s_{\text{sem}}$; feedback embeddings are pre-computed, so retrieval is inference-free. **Tier 3 (context fit)** deduplicates, balances REJECTED/APPROVED feedbacks at $60/40$ (rejected patterns prevent repeated mistakes), and truncates to the injection token budget. We inject feedback at distinct granularities: hypothesis generation (rejected+validated patterns at namespace level), per-hypothesis investigation (feature-matched feedbacks), report generation (APPROVED-only at cohort similarity), and confidence calibration (aggregate category-level statistics). The system does not fine-tune weights; feedback flows purely through retrieval and confidence calibration, yielding same-day continual learning where an expert rejection today influences tomorrow's investigations.

3.6 Two-Layer Confidence Framework

Agentic systems producing numerical business conclusions cannot be used on raw output alone. We introduce a two-layer framework combining mechanistic validation over raw artifacts with LLM-as-Judge evaluation of report fidelity including a novel *numerical traceability* check, composed with a feedback-derived Bayesian prior. **Layer 1: Mechanistic evidence quality** - Six deterministic checks run over the artifact stream: query success rate; sample-size adequacy (fraction of claims with $n \geq 30$ and median observed n); investigation coverage; evidence–verdict consistency (flagging e.g. PROVEN with zero supporting evidence and, uniquely, duplicate `final_verdict` strings across hypotheses as a reliable copy-paste-hallucination signal); data-quality signals; and retry health. L_1 is a weighted sum with weights tuned on a development set, and emits structured flags (e.g., `UNSUPPORTED_PROVEN: H3`) surfaced to experts as targeted diagnostics. **Layer 2: Report fidelity with numerical traceability** - An LLM judge evaluates the report on five dimensions: numerical traceability, evidence sufficiency, reasoning soundness, root-cause plau-

sibility, and actionability. The novel check is mechanistic: let $\mathcal{T}$ be numeric tokens in the report and $\mathcal{V}$ the union of numeric values in referenced artifacts; for each $\tau \in \mathcal{T}$ we attempt a fuzzy match $\phi(\tau) \in \mathcal{V}$ with unit normalization and tolerance $|\tau - \phi(\tau)|/\max(|\tau|, \epsilon_0) \leq 0.005$, yielding $s_{\text{num}} = 100 \cdot |\{\tau : \phi(\tau) \text{ exists}\}|/|\mathcal{T}|$. Untraceable tokens are almost always hallucinations, plausible-looking invented figures not grounded in evidence; s_{num} receives the largest Layer 2 weight and orphan tokens are reported verbatim for expert review. **Composite and Bayesian calibration** - $c_{\text{raw}} = 0.30\, L_1 + 0.70\, L_2$; the tilt reflects that report fidelity correlates more strongly with expert acceptance than raw evidence quality. We calibrate using category-level priors: for a hypothesis of category κ with historical approval rate ρ_κ, $c = \sigma\big(\text{logit}(c_{\text{raw}}/100) + \lambda \log \frac{\rho_\kappa}{1-\rho_\kappa}\big) \cdot 100$. This down-weights PROVEN conclusions in historically low-acceptance categories. Both layers are necessary: the mechanistic layer catches artifact-level inconsistencies and copy-paste verdicts that LLM judges overlook, while the judge catches semantic implausibility the mechanistic layer cannot reason about. In our evaluation, c is rendered as a stakeholder badge with grades and routes sub-threshold cohorts to expert pre-review.

3.7 Expert-Appropriate Output Generation

Experts and business stakeholders have distinct information needs; generic enumerated-hypothesis reports are rejected as too verbose and missing the narrative unit used in enterprise business communication - the *defect narrative*. We therefore emit three outputs: a **technical report** with all hypotheses, evidence tables with `Q{n}_H{m}` citations, and diagnostic flags (for expert review); a **stakeholder HTML** (Appendix D) with prioritized hypothesis cards, an impact callout, and a confidence badge; and **defect narratives**, short quantified narratives for operational teams. Visibility is confidence-gated: sub-threshold outputs are routed to expert pre-review rather than delivered to business teams.

Beyond the Layer 2 traceability check, we structurally preclude a class of numerical hallucinations by separating qualitative LLM reasoning from quantitative computation: no aggregate dollar totals may appear in narrative bodies (these are computed by the downstream deterministic pipeline). An actionability classifier labels each report as OPERATIONALISSUE, DATAQUALITY, FALSEPOSITIVE, or NORMALBEHAVIOR; only OPERATIONALISSUE reports are routed to business-unit queues.

4 Deployment and Evaluation

4.1 Dataset and Deployment Setting

TRACE is evaluated across eight use cases spanning three metric categories (cost, quality, inventory); each anomalous cohort becomes an RCA input per §3.1. The system queries a large-scale transactional data substrate, a domain knowledge base, and a feedback index of past reviewed cases. Per-use-case expert acceptance ranges from 59.6% to 71.2% (overall 65.4%) at 10–14 min median latency, with several hundred reviewed cohorts per use case.

Cohort selection. Cohorts are real production defects: a cohort is a feature slice whose outcome metric significantly deviates from its parent slice's baseline (e.g., a category$\times$brand slice with a 10% return rate against the category's 5%). Candidates are ranked by *estimated recovery* - the metric improvement expected if the defect is fixed - and high-recovery cohorts enter RCA; evaluation cohorts reflect the live production distribution.

Review protocol and agreement. Each report is independently reviewed by three experts trained in the enterprise quality-improvement program on a shared actionability rubric ("is the evidence sufficient for a business unit to initiate corrective action"), marking it ACTIONABLE/NOTACTIONABLE with the final label by majority vote. The pool comprises 46 distinct experts; inter-rater agreement is Fleiss' $\kappa = 0.62$ (substantial). In the E1 head-to-head (§4.2), the same expert reviewed both arms of each pair, blind to system identity, so the paired comparison controls for per-rater leniency. Experts never see confidence scores during review; labels are used only post hoc to tune confidence weights, so calibration results measure alignment with unanchored expert judgment.

4.2 Experimental Setup

All the below experiments use Claude Sonnet 4.5 as backbone LLM and a standard text-embedding model for embeddings.

E1 (End-to-end) - We compare TRACE against a VANILLA-REACT baseline (Yao et al., 2023) with the same backbone LLM and tools but without

Metric	ReAct	TRACE
Expert acceptance	38.8%	**67.1%**
Num. trace. s_{num}	62.3%	**94.6%**
Orphan tokens/report	7.8	**1.2**
Atomic-cause (≥ 3)	4.2%	**58.3%**
Review time (med.)	8 m 42 s	**3 m 18 s**
Tool calls/cohort	6	14

Table 1: End-to-end comparison on 240 matched cohorts (double-blind expert review).

the Evidence Manager, why-drilling, RAG/feedback, confidence layer, or narrative pipeline; experts review outputs double-blind on 240 matched cohorts stratified across use cases. An *additive* variant (REACT + hypothesis generation + supervisor only) is evaluated on the same 240 cohorts to isolate a generic structured loop from TRACE-specific components.

E2 (Ablations). On 480 labeled cohorts, we remove one component at a time: *why-drilling*, *Feedback*, *RAG*, *Confidence* (deliver all outputs unfiltered), *Narratives* (emit only the technical report); plus a joint removal of *why-drilling* + *Feedback* to measure interaction effects.

E3 (Confidence Calibration). On the full labeled set, we measure AUC, Brier score, and ECE (10 bins) of c against expert acceptance, comparing Layer 1 only, Layer 2 only, composite, composite+prior, and an LLM self-critique baseline matching G-Eval (Liu et al., 2023)/RAGAS (Es et al., 2025).

E4 (Feedback injection schedule). On a 200-cohort held-out set, we vary the number of active feedback injection points $\{0, 1, 2, 4\}$ and include a control (same token budget concatenated at a single point) to isolate *where* feedback is injected from and *how much*. Confidence weights were tuned on the earliest 200 labeled cohorts; evaluation uses the remaining labeled cohorts plus the 240 paired E1 cohorts. Significance uses McNemar's test (paired acceptance) and DeLong's test (AUC differences).

Reporting convention. Unless stated otherwise, reported acceptance rates are *macro-averaged* across the eight use cases - the unweighted mean of the per-use-case rates - so that no single high-volume use case dominates the aggregate. Aggregate percentages therefore need not correspond to an integer count over the pooled cohort total.

4.3 End-to-end comparison and component ablation

Table 1 reports the head-to-head. TRACE reaches 67.1% expert acceptance versus 38.8% for VANILLA-REACT on 240 paired cohorts (+28.3 pp, $p < 0.001$, McNemar).[1] Numerical traceability rises from 62.3% to 94.6%, and the atomic-cause rate (chain drilled ≥ 3 levels) from 4.2% to 58.3% - confirming why-drilling reaches substantively deeper findings than a single-pass agent. Median expert review time drops from 8 m 42 s to 3 m 18 s, driven by the narrative-centric stakeholder HTML.

Component ablation (Table 2) shows the confidence gate is the largest single contributor (-15.3 pp), because low-fidelity outputs that would have been pre-reviewed instead reach the expert; narrative output (-12.8) confirms that the technical report alone is too verbose; why-drilling (-9.4) and feedback (-8.1) are substantial; RAG (-3.7) is complementary. All drops are significant at $p < 0.01$. Removing the gate drags s_{num} from 94.8% to 84.2% - not because reports contain more hallucinations, but because the gate had been withholding the lowest-fidelity reports.

Joint ablation and additive baseline. Removing why-drilling and feedback *together* yields 52.5% (-14.2 pp; Table 2, bottom row) - less than the -17.5 pp sum of the individual drops, a sub-additive interaction consistent with partial overlap: feedback frequently steers the *direction* of recursive why-drilling. Conversely, an *additive* variant - REACT plus hypothesis generation plus supervisor only - evaluated on the same 240 E1 cohorts reaches 48.8% (117/240) acceptance, versus 38.8% for the bare agent and 67.1% for TRACE: a generic structured loop recovers roughly a third of the gap; the remaining 18.3 pp is attributable to TRACE-specific components.

4.4 Confidence calibration and injection schedule

Tables 3 and 4 present complementary results. On calibration (Table 3), our composite predicts expert acceptance at AUC 0.819 with ECE 0.041, substantially better than LLM self-critique (AUC 0.671, ECE 0.138). Layer 1 (0.742) and Layer 2 (0.776)

[1] Table 1's 67.1% (240 paired E1 cohorts) and Table 2's Full-row 66.7% (separate 480-cohort ablation set) are measured under the identical labeling protocol; the difference reflects the different cohort sets.

Variant	Acc.	Δ	s_{num}
Full	**66.7%**	—	**94.8%**
–Why-drill	57.3%	−9.4	93.1%
–Feedback	58.6%	−8.1	92.4%
–RAG	63.0%	−3.7	94.0%
–Confidence	51.4%	−15.3	84.2%
–Narratives	53.9%	−12.8	94.7%
–Drill & Fdbk.	52.5%	−14.2	93.5%

Table 2: Component ablation (480 cohorts).

Conf. signal	AUC	Brier	ECE
Self-critique	0.671	0.211	0.138
L_1 only	0.742	0.188	0.092
L_2 only	0.776	0.173	0.068
Composite c_{raw}	0.804	0.164	0.051
+prior c	**0.819**	**0.159**	**0.041**

Table 3: Confidence calibration (full labeled set).

Inj. config	Acc.	Δ	Tok.
None	57.5%	—	0
Pt. 1 only	61.6%	+4.1	1,487
Pt. 1+2	64.9%	+7.4	2,284
Full (1–4)	**67.1%**	+9.6	2,978
Same tok., Pt. 1	62.8%	+5.3	2,971

Table 4: Injection-schedule ablation (200 held-out).

contribute complementary signal, confirming the mechanistic-plus-judge thesis; the Bayesian prior adds $+0.015$ AUC and cuts ECE from 0.051 to 0.041 by correcting over-confidence in low-approval-rate categories. On the injection schedule (Table 4), a single point at hypothesis generation yields $+4.1$ pp; progressively activating points 2–4 adds $+5.5$ pp more to 67.1%. The key row is the control: concatenating the same $\sim$3,000 tokens at a single point yields only 62.8% (-4.3 pp vs. the distributed schedule) - indicating *where* feedback is injected matters as much as *how much* and what is injected.

Across the evaluation, the confidence gate routes 14.7% of cohorts to expert pre-review, with precision 0.71 on catching output that should not be delivered.

Cost and latency. Median end-to-end latency is 10–14 min per cohort at $\sim\$1.4$ inference cost, versus one to two expert-weeks manually. VANILLA-REACT costs $\sim\$0.7$ per cohort (6 vs. 14 tool calls) but rarely reaches atomic causes; TRACE's $\sim 2\times$ inference cost purchases the $+28.3$ pp gain and the 8 m 42 s $\rightarrow$ 3 m 18 s review-time reduction. Only the investigation loop and Layer-2 judge are LLM-bound; all other subsystems are rule-based with negligible cost.

4.5 Failure analysis

Roughly 29–40% of TRACE outputs are rejected per use case. Rejections show two dominant modes, neither of which is numerical error. *(a) Contextual-knowledge gaps*: mathematically correct but unactionable findings - e.g., an intra-city delivery-cost anomaly flagged with numerically flawless evidence, rejected because a localized weather disruption was the known, temporary cause, knowledge absent from every onboarded source. *(b) Duplicate findings*: re-surfacing already-known defects, directly mitigated by the feedback loop (part of its -8.1 pp in Table 2). Investigation quality, numerical grounding, and formatting were rarely the cause: failures concentrate in *knowledge coverage*, motivating the interactive knowledge-injection direction in §5.

5 Future Work

Three directions extend this work: (i) *interactive knowledge injection* - rejections concentrate in contextual-knowledge gaps (§4.5), motivating conversational expert corrections that enter the feedback index; (ii) *automated remediation* (vendor engagement, SOP-change proposals, automated case creation); and (iii) *causal validation* via RCT-style experiments on an enterprise A/B platform. All three build on the evidence-traceability and feedback-calibration substrates introduced here.

6 Conclusion

We presented TRACE, an agentic RCA system that closes four gaps in generic agentic RCA - proximate-cause termination, unverified numeric claims, absent feedback consumption, and wrong output shape - via supervised why-drilling investigation, evidence-traceable tooling with stable artifact identifiers, multi-granular feedback retrieval, and a two-layer mechanistic-plus-judge confidence framework with a novel numerical-traceability score. Across eight use cases and several thousand cohorts, TRACE reaches 65.4% expert acceptance in deployment; on a 240-cohort paired benchmark it reaches 67.1% versus 38.8% for a matched ReAct baseline ($+28.3$ pp) with calibrated confidence (AUC 0.819). Its design principles generalize to any enterprise agentic investigation where numerical claims must be audited and human feedback is expensive.

Limitations

TRACE has a few limitations that also point to ongoing work. The associations it surfaces are derived from observational transactional data, and the system relies on LLM reasoning - guided by domain knowledge and prior feedback - to infer their causal nature; a chain can thus be internally consistent and numerically grounded yet still reflect a confounded correlation, since distinguishing correlation from causation from observational data alone is fundamentally hard, and we are actively extending TRACE with explicit causal models and experiment-based validation to promote high-impact findings from correlational to causal evidence. Root-cause analysis is also inherently subjective - for a given defect there is rarely a single verifiable "correct" cause and reasonable experts can disagree on the most actionable explanation - so we evaluate against expert judgments rather than an objective oracle, and our acceptance and calibration figures (AUC, ECE) should be read as alignment with expert assessment rather than provable correctness. Reaching a specific, actionable root cause is further complicated in an enterprise setting, where a single defect can span many systems owned by different teams, each with its own data stores and tooling; TRACE can only investigate what its tool suite can reach, so broad and deep coverage requires aligning with these teams to onboard the data sources and tools they already use, and gaps in this integration bound how deeply the causal chain can be drilled. Finally, enterprise root-causing remains heavily human-dependent: output quality depends on experts supplying good feedback and steering documents - corrections, domain rules, and accept/reject decisions - that guide the LLM toward the right hypotheses and away from previously rejected ones, which is precisely why feedback consumption is a first-class component of our design but also means new use cases face a cold-start period until enough feedback accumulates.

Before generating, briefly reason about: (1) what makes this
      cohort
unusual based on the stats, (2) which feature combinations are
       most
suspicious, (3) what causal mechanisms could explain the
      anomaly.

{hypothesis_prioritization}

Then apply:
1. Diversity: span the categories listed below (mode collapse
      is the
   dominant failure mode of naive hypothesis generation):
   {hypothesis_categories}
2. Specificity: each hypothesis must name specific features to
   investigate, state expected contrastive behavior, and be
   falsifiable with data.
3. No label leakage (do NOT use post-outcome features):
   {excluded_features}
4. Contrastive framing: each hypothesis must explain why
   {metric_name} is {comparison_phrase} the counterfactual.

{additional_instructions}
{column_warnings}

OUTPUT FORMAT
Return ONLY a JSON array. Each element:
{
  "id": "H1",
  "category": "policy|data_quality|logistics|product|customer|
      pricing",
  "statement": "One-sentence hypothesis",
  "reasoning": "2-3 sentences covering (1) what signal
      triggered
    this hypothesis, (2) the causal mechanism, (3) why
      plausible
    given cohort characteristics.",
  "features_to_investigate": ["feature1", "feature2", ...],
  "expected_pattern": "What data should show if hypothesis is
      true",
  "counterfactual": "What cohort to compare against",
  "estimated_impact": "$ amount or percentage if applicable"
}
```

B. Supervisor Prompt

Below is an abridged version of the supervisor controller's prompt (§3.3). The supervisor runs once per iteration, reads cumulative investigation state, and emits a single-step decision.

```
You are the investigation supervisor coordinating a multi-
      hypothesis
root cause analysis. Decide which hypothesis to investigate
      next
and when to stop.

Analysis Type: {business_context} - investigating {
      analysis_objective}

INVESTIGATION STATE
Iteration: {iteration}/{max_iterations}
Cohort: {cohort_info}
Generated Hypotheses: {hypotheses_summary}
Investigation Results So Far: {investigation_results}

DECISION TASK
(1) Which hypothesis to investigate next?
    Priority scoring: Expected Impact (High=$100K+, Medium=
      $10K-100K,
    Low=<$10K) x Feasibility (are features available in the
      dataset?)
    x Category Diversity bonus (new category preferred).
    Tiebreaker toward unexplored categories; do NOT
      investigate the
    same category twice in a row unless critical; skip
      hypotheses
    subsumed by proven ones.
    If the most recent investigation has confidence 0.4-0.6
      AND
    queries_executed < 3, you may re-select the SAME
      hypothesis
    with a note to explore different features.

(2) Continue or conclude?
    Continue if: high-impact hypotheses remain uninvestigated
      (unless budget is nearly exhausted), OR the top
      hypothesis
      is still UNCERTAIN (confidence 0.4-0.7).
    Conclude if: top 2-3 hypotheses are PROVEN/DISPROVEN with
      confidence > 0.85 AND no remaining uninvestigated
      hypotheses
```

```
      have High estimated_impact; OR iteration budget
      exhausted.

OUTPUT FORMAT (JSON only)
{
  "action": "INVESTIGATE_NEXT|CONCLUDE",
  "selected_hypothesis_id": "H1|H2|...|null",
  "reasoning": "1-2 sentence explanation including priority
      rationale",
  "investigation_complete": true|false,
  "remaining_high_priority_hypotheses": 0-5
}
If action is CONCLUDE, set selected_hypothesis_id to null and
investigation_complete to true.
```

C. Use Case Configurations

Each use case is parameterized by a configuration dictionary consumed by the Hypothesis Generator, Investigator, and Narrative Generator prompts. Below are two representative configurations (key fields only; verbose multi-line instructions and category lists are summarized in prose). The remaining six use cases follow the same schema.

C.1 A quality-type use case.

```
use_case_name     : QUALITY_METRIC
tool_domains      : [generic, catalog_product]
group_column      : group_label
metric_name       : anomaly rate
metric_description: elevated anomaly rate
comparison_phrase : higher than
business_context  : <quality-type use case>
analysis_objective: drivers of an elevated rate metric

hypothesis_categories:
  - Policy/Program    (program-driven effects)
  - Data Quality      (miscoded flags, tracking errors)
  - Operations        (handling, routing, facility)
  - Product Issues    (attribute/listing mismatch)
  - Customer Behavior (anomalous usage patterns)
  - Pricing/Promotion (incentive-driven effects)

excluded_features:
  - outcome_reason
  - resolution_status
  - free_text_comments
  - post-outcome attributes

customer_feedback_column: feedback_topic

column_warnings:
  'item_category' is NOT a column in the dataset; data is
  pre-filtered for granularity.

additional_instructions:
  Inspect feedback_topic for signals on affected items; this
  column is populated only on the outcome event, so do NOT
  compute rates over feedback_topic values.

hypothesis_prioritization:
  If item-level deep-dive context is present, prioritize
  cohort-specific hypotheses first, then broaden to generic
      drivers.

narrative_config:
  mode              : context_only
  template          : QUALITY_METRIC
  recovery_formula: null
  max_agent_steps    : 0
```

C.2 A cost-type use case.

```
use_case_name     : COST_METRIC
tool_domains      : [generic]
group_column      : group_label
metric_name       : cost per unit
metric_description: higher cost per unit
comparison_phrase : higher than
business_context  : <cost-type use case>
analysis_objective: identify drivers of higher per-unit cost
metric_unit       : cost per unit

focus_areas:
  per-unit cost above a reference baseline; high-cost cohorts;
  unexpected premium charges.

hypothesis_categories:
  - Allocation/Placement  (resource placement, routing choices
      )
  - Method Selection      (alternative-method premiums)
  - Measurement/Data Qty  (attribute miscalculation, misclass
      .)
  - Eligibility/Threshold (threshold and routing effects)
  - Service-Level         (premium when standard suffices)
  - Distance/Topology     (path-length and locality effects)
  - Multi-Stage Handoff   (inter-stage transport and mix)

excluded_features:
  - downstream_outcome_date (unless compared to a target)
  - post-outcome complaint signals
  - outcome indicators caused by the cost issue

cost_benchmarks:
  - Method-A vs Method-B : moderate per-unit advantage
  - Alt. providers       : larger per-unit advantage
  - Surcharge effects    : notable aggregate impact
  - Attribute inaccuracy : substantial per-unit effect
  - Allocation optimize  : large total opportunity

narrative_config:
  mode              : context_only
  template          : COST_METRIC
  recovery_formula: null
  max_agent_steps    : 0
```

D. Sample Stakeholder Report

The system's primary expert-facing artifact is a stakeholder report rendered as HTML. To avoid exposing use-case-specific or operational detail, we describe its structure and give a short, fully synthetic and illustrative excerpt rather than reproducing a real report. A report contains: (a) a header with a cohort card, an executive summary, and a top PROVEN hypothesis card with inline `[Q#_H#]` evidence citations; (b) DISPROVEN hypothesis cards with quantitative refutation and confidence scores (rather than silently dropped claims); (c) a conclusion block and an evidence-appendix index listing every query executed; (d) expandable evidence entries with the expert-facing query text and a per-section analytical summary; (e) the underlying PySpark code and raw query-result JSON that the Layer 2 traceability check verifies against; and (f) a business-narrative supplementary block whose aggregates (trailing-twelve-month units, recovery estimates, trends, top entities) are computed by the deterministic downstream pipeline (§3.7), never by the LLM.

Synthetic, illustrative report excerpt

Group: `all_data` **Cohort:** (illustrative cohort)
Projected Impact: (relative, see below) **Confidence:** 91/100 (Grade A)

Executive Summary. Investigation of the cohort revealed a routing/allocation issue in which a premium handling path is applied to items that do not require it [H1]. The premium path shows roughly a $5\times$ per-unit cost versus the standard path for items that genuinely need it; more importantly, the majority of premium-path volume consists of lightweight items eligible for the standard path, incurring an order-of-magnitude per-unit premium [H1]. The near-zero error rate confirms this is a systematic routing-policy issue, not operational error [H1]. A second hypothesis attributing cost to a facility tier was DISPROVEN after the initial claim's figures failed verification [H2].

H1 — Premium-Path Misrouting **Proven** (Confidence: 0.95)
Why this hypothesis. The premium handling path was the highest cost-deviation driver in the cohort; the magnitude suggested possible misclassification of standard items into premium infrastructure.
Finding. The premium path exhibits a dual cost structure: legitimate handling for genuinely heavy items, and systematic misrouting of the majority of its volume (lightweight, standard-eligible items) at a roughly $14\times$ per-unit premium over the standard path [Q2_H7][Q3_H7]. The near-zero error rate confirms routing policy rather than operational error [Q3_H7].
Key findings.

- Premium vs. standard path: $\sim 5\times$ per-unit cost for legitimately heavy items [Q2_H7][Q4_H7].
- Majority of premium-path volume is lightweight, standard-eligible items at an $\sim 14\times$ per-unit premium [Q3_H7].
- A scheduled-handling option adds a further per-unit premium on a minority of volume [Q2_H7].

Business impact. A quantified per-unit saving is available by redirecting standard-eligible volume off the premium path (aggregate impact reported only in the deterministic supplementary block, not asserted by the LLM).

H2 — Facility-Tier Inefficiency **Disproven** (Confidence: 0.85)
Why this hypothesis. The initial claim attributed a large premium to a lower-automation facility tier.
Finding. The hypothesis is disproven because the initial claim's figures (volume share and per-unit cost) failed verification against the artifacts [Q4_H3]. A smaller, factually corrected premium is retained as a DATAQUALITY-flagged supplementary finding rather than dropped.

Conclusion. The investigation identified one critical, actionable routing-policy issue (premium-path misrouting of standard-eligible volume) and one disproven-but-corrected facility-tier finding. The most actionable result is redirecting standard-eligible volume off the premium path, an immediate per-unit optimization opportunity.

Actionability classifier output.

```
{
  "is_actionable": true,
  "confidence": 0.95,
  "category": "OPERATIONAL_ISSUE",
  "reasoning": "Routing-policy issue identified with
      high
   confidence: the majority of premium-path volume is
   standard-eligible and incurs a large per-unit
      premium. The
   near-zero error rate confirms a systematic routing
      policy
   rather than operational error. Recommended action:
      audit the
   premium-path routing rules and redirect standard-
      eligible
   volume to the standard path."
}
```

Evidence Appendix (summary). Each Q#_H# citation in the report body links to the full PySpark code, execution status, and per-section summary. A representative entry is a multi-section deep-dive whose sections each return SUCCESS with adequate sample sizes and no data-quality flags. The Layer 2 judge (§3.6) verifies each inline number in the Executive Summary against these Q#_H# payloads before the report is finalized.

Mem-LM: An LM-style Model for Reinforced Memory Selection

Abstract

External memory banks can improve test-time reasoning in frozen large language models without updating backbone parameters. Yet similarity-based retrievers and pointwise selectors score memories independently, ignoring interactions and presentation order. We introduce MEM-LM, an LM-style model for reinforced memory selection that casts context construction as autoregressive index decoding. From a densely retrieved candidate pool, a lightweight Transformer encoder–decoder generates an ordered index sequence $[i_1, \ldots, i_k]$, modeling dependencies among memories while leaving the backbone frozen. This formulation supports standard language-model training. For sparse binary verifiable rewards, we further propose MEM-PO, a confidence-aware extension of group-relative policy optimization that promotes correct, low-confidence rollouts, penalizes confidently incorrect ones, and retains learning signals in reward-homogeneous groups. Across three mathematical reasoning and two reasoning-intensive question-answering benchmarks with three Qwen backbones, MEM-LM achieves an average score of 84.9 on Qwen-plus, exceeding the strongest memory-augmented baseline by 2.3 points.

1 Introduction

External memory can improve the test-time reasoning of frozen large language models (LLMs) without updating their backbone parameters. Such memory banks store past cases, external knowledge, or meta-experience that can be retrieved as in-context demonstrations for a new query (Zhong et al., 2024; Zhou et al., 2025). Consequently, performance depends not only on the backbone but also on the quality of the constructed context.

Existing methods, however, provide limited control over memory composition. Similarity-based retrievers and pointwise selectors evaluate candidates independently, overlooking interactions among selected items and their presentation order (Xu et al., 2026). Both factors can substantially affect a frozen model. Moreover, training a selector with sparse binary rewards is difficult because such rewards poorly distinguish competing selections and yield no relative signal when all rollouts in a group receive the same reward.

We introduce MEM-LM, an LM-style model for reinforced memory selection that formulates context construction as *autoregressive index decoding*. As illustrated in Figure 1, MEM-LM first retrieves a candidate pool and then uses a lightweight Transformer encoder–decoder to generate an ordered index sequence $[i_1, \ldots, i_k]$. This formulation captures dependencies among memories while keeping the backbone frozen and supports standard language-model training recipes. We further propose MEM-PO, a confidence-aware extension of group-relative policy optimization. MEM-PO favors correct but low-confidence rollouts, penalizes confidently incorrect ones, and preserves informative gradients in reward-homogeneous groups.

We evaluate MEM-LM on three mathematical reasoning benchmarks (Math-500, AIME-24, and AIME-25) and two reasoning-intensive QA benchmarks (MMLU-Pro and GPQA) using three Qwen backbones. On Qwen-plus, MEM-LM achieves an average score of 84.9, outperforming the strongest memory-augmented baseline by 2.3 points. Our contributions are as follows:

- We formulate memory selection as autoregressive index decoding, enabling MEM-LM to model both the composition and order of memories for a frozen backbone.

- We introduce MEM-PO, a confidence-aware policy optimization method that improves learning from sparse verifiable rewards, including reward-homogeneous rollout groups.
- Experiments on five benchmarks and three Qwen backbones show consistent improvements, while ablations identify ordered decoding and MEM-PO as the main contributors.

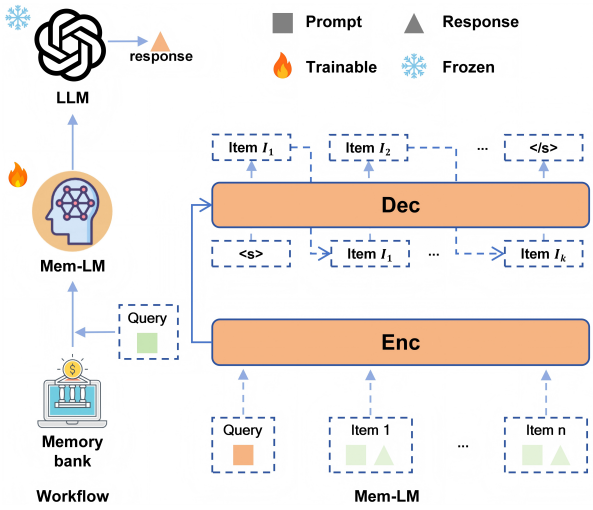

Figure 1: Schematic illustration of our Mem-LM framework.

2 Related Work

Context Optimization for Test-Time Scaling. Recent work augments LLM and VLM agents with explicit memory to support long-horizon reasoning and continual adaptation. Beyond short-term prompting schemes such as ReAct-style interaction and reflection, memory-augmented systems store past traces, plans, or intermediate results for later reuse (Zhong et al., 2024). Other studies introduce structured or semantic memory with explicit add, update, and delete operations (Xu et al., 2026; Salama et al., 2025). A related line distills experience into rules, guidelines, or reusable workflow fragments (Zhao et al., 2024; Fu et al., 2024; Wang et al., 2024b). However, many methods still depend on static similarity-based retrieval or unfiltered memory accumulation, which can hurt scalability and relevance. Memento (Zhou et al., 2025) formulates memory use as a memory-augmented MDP and learns a utility-aware selection policy without tuning the backbone model. Similarly, Qin et al. (2024) learn a query-conditioned selector for case retrieval.

Agentic memory selection is also related to in-context learning, where the key problem is to construct an effective demonstration sequence. Standard approaches retrieve demonstrations with pre-trained embeddings and vector search (Li et al., 2024), or train retrievers with classification (Li et al., 2023) or response-similarity objectives (Hu et al., 2022), extending earlier example-selection methods such as EPR (Rubin et al., 2022). Beyond retrieval, Lever-LM (Yang et al., 2024b) uses a small language model to decode demonstration sequences, VICL (Zhou et al., 2024) adds LLM-based reranking, and SURf (Sun et al., 2024) refines demonstrations through self-feedback. Qin et al. (2024) further compose diverse sequences for each test input. These studies all optimize the test-time context, but they usually under-model the ordered and combinatorial dependencies among selected items. Mem-LM addresses this limitation by autoregressively decoding memory indices.

Reinforcement Learning. Large reasoning models such as OpenAI o1 (Jaech et al., 2024) and DeepSeek-R1 (Guo et al., 2025) show that reinforcement learning can promote self-verification and iterative refinement, enabling inference-time scaling. GRPO (Shao et al., 2024) is a representative method that removes the value function and estimates advantages within response groups. Since the training details of proprietary systems are not fully disclosed, recent open efforts aim to reproduce and improve these recipes. Open-Reasoner-Zero (Hu et al., 2026) and Reinforce++ (Hu et al., 2025) provide open training variants, with the latter using global advantage normalization without a critic. VinePPO (Kazemnejad et al., 2024) improves credit assignment for mathematical reasoning, RLEF (Gehring et al., 2024) uses execution feedback for code generation, and DAPO (Yu et al., 2026) extends GRPO to alleviate entropy collapse, sparse rewards, and training instability (Zhang et al., 2025). Built on this line, our proposed Mem-PO adapts group-relative policy optimization to reinforced memory selection in Mem-LM.

3 MemGen Framework

We now introduce our Mem-LM framework in detail.

3.1 Formulation of agentic memory

Given a LLM/VLM agent, denoted as $\mathcal{M}$ (e.g., Deepseek-R1 (Guo et al., 2025)), we would like to adaptively select a list of elements from the agent memory bank, $\mathcal{Z} = \{z_1, \ldots, z_n\}$. This sequence $\mathcal{Z}$ consists of n elements (n-shot), where each element z_i is either a previous case, an piece of external knowledge, or a piece of meta-experience (Zhou et al., 2025). For example, for a question answering task, z_i comprises a prompt, and its corresponding response: $z_i = (\text{prompt}_i, \text{response}_i)$. The context sequence $\mathcal{Z}$ is then concatenated with the test sample $x_{\text{test}} = (\text{prompt}_{\text{test}})$ and fed into the LLM agent $\mathcal{M}$. The model subsequently generates a response $\hat{r}_{\text{test}}$:

$$\hat{r}_{\text{test}} = \mathcal{M}(\mathcal{Z}, x_{\text{test}}). \tag{1}$$

Using an embedding model like the BGE (Xiao et al., 2024), and a vector search engine like Faiss (Douze et al., 2025), we can conduct item retrieval from the memory bank efficiently. The test sample x_{test} is transformed to the vector v_{test}, which serves as the input for the vector search. We then retrieve $n > 0$ candidate demos $\{z_j\}_{j=1}^{n}$ that have the highest similarity scores with x_{test}.

3.2 Mem-LM

Workflow. Mem-LM operates over a memory bank $\mathcal{D} = \{d_1, \ldots, d_N\}$, where each item d_i stores a past case, external knowledge, or a meta-experience (Zhou et al., 2025); a case is a pair $d_i = (T_i, R_i)$ of an input T_i and its target response R_i. Given a query q, Mem-LM first retrieves a candidate set $\mathcal{C} = \{d_1, \ldots, d_n\} \subseteq \mathcal{D}$ via dense vector search (Faiss (Douze et al., 2025)), and then *composes* an ordered sequence of $k \leq n$ items $[d_{i_1}, \ldots, d_{i_k}]$ that is concatenated with q to prompt the frozen LLM/VLM (Fig. 1).

Architecture. Mem-LM couples a frozen embedder $E(\cdot)$ with a trainable Transformer encoder–decoder $M(\cdot)$. The embedder (e.g., BGE (Xiao et al., 2024) or CLIP (Radford et al., 2021)) maps the query and each candidate to fixed-length vectors; for multimodal items the image and text streams are encoded separately and concatenated, giving $h_q = E(I_q, T_q)$ and $h_i = E(I_i, [T_i, R_i])$ for $i = 1, \ldots, n$. Candidate embeddings are precomputed at index-building time and reused at inference, incurring negligible overhead.

Index decoding. $M(\cdot)$ takes the concatenated sequence $[h_q; h_1; \ldots; h_n]$ as input and, unlike a GPT-style decoder that emits text tokens, autoregressively decodes a sequence of *memory indices* $[i_1, \ldots, i_k]$ with $i_t \in \{1, \ldots, n\}$, each pointing to an item in $\mathcal{C}$. By modeling the selection as ordered index generation, Mem-LM captures the sequential and combinatorial dependencies among chosen items that similarity-based retrieval ignores, while leaving the backbone untouched.

3.3 Training Methods for Mem-LM

Because Mem-LM decodes memory indices autoregressively, it can be trained with the standard recipes for language models (Guo et al., 2025; Ouyang et al., 2022): supervised fine-tuning (SFT), reinforcement learning with verifiable rewards (RLVR), and an SFT-then-RLVR pipeline, all formalized in Appendix A. The prevailing RLVR objective, GRPO (Shao et al., 2024), however, transfers poorly to memory selection, which motivates MEMPO, a plug-in modification that augments the group-relative advantage (Eq. 6) with a confidence-aware self-evaluation signal.

Motivation. RLVR rewards are sparse: the format reward (Eq. 12) saturates early, while the accuracy reward is binary and yields little gradient, hindering convergence for small models (Srivastava and Aggarwal, 2025). Model confidence is also poorly calibrated, as models are often overconfident on erroneous reasoning (Sun et al., 2025) yet under-confident on unfamiliar inputs (Kang et al., 2025). We therefore seek a denser signal that *rewards correct but low-confidence rollouts* and *penalizes incorrect but high-confidence ones*.

Mem-PO. Given G rollouts $\{o_i\}_{i=1}^{G}$ for a query q, let $c_i \in \{0, 1\}$ denote verifiable correctness and $\kappa_i = \frac{1}{L_i} \sum_{t=1}^{L_i} \pi_\theta(o_i[t] \mid o_i[:t-1], q)$ the mean token confidence over the L_i tokens of o_i. We organize the group as a *confidence tournament*: for an ordered pair (o_i, o_j) the preference target is

$$s_{ij} = \begin{cases} +1, & c_i > c_j, \\ \text{sign}(\kappa_j - \kappa_i), & c_i = c_j, \\ -1, & c_i < c_j, \end{cases} \tag{2}$$

so that correctness dominates while, *among equally correct traces, the less-confident one is preferred*. Aggregating pairwise outcomes yields a Bradley–Terry–style self-evaluation score

$$\text{SES}_i = \frac{1}{G-1} \sum_{j \neq i} s_{ij}\, \sigma\Big(\tfrac{\kappa_i - \kappa_j}{\tau}\Big), \tag{3}$$

where $\sigma(x) = (1 + e^{-x})^{-1}$ and $\tau > 0$ is a temperature. We standardize the score and add it to the GRPO advantage,

$$\widetilde{\mathrm{SES}}_i = \frac{\mathrm{SES}_i - \mathrm{mean}(\{\mathrm{SES}_j\}_{j=1}^{G})}{\mathrm{std}(\{\mathrm{SES}_j\}_{j=1}^{G})}, \quad \tilde{A}_{i,t} = \hat{A}_{i,t} + \lambda \widetilde{\mathrm{SES}}_i \tag{4}$$

with $\lambda > 0$; all remaining components follow DAPO (Yu et al., 2026).

Discussion. MemPO turns the binary reward into a denser, confidence-aware signal: it raises the advantage of correct yet low-confidence rollouts above their over-confident peers and suppresses confidently wrong reasoning, producing more discriminative gradients. Crucially, when a group is reward-homogeneous ($\bar{c} \in \{0, 1\}$) the vanilla advantage $\hat{A}_{i,t}$ collapses to zero (Zhou et al., 2026), whereas the correctness-tie branch keeps $\widetilde{\mathrm{SES}}_i$ non-degenerate, recycling otherwise-wasted samples into informative gradients and improving RLVR convergence for small models.

4 Experiments

4.1 Datasets and memory construction

Math problem solving tasks Three math problem solving tasks: Math-500 (Lightman et al., 2024), AIME-24[1], and AIME-25[2].

Question-answering tasks requiring reasoning Two challenging question-answering tasks in the science domain: MMLU-pro (Wang et al., 2024a), GPQA (Rein et al., 2023).

We use the Mixture-of-thoughts[3] datasets. It consists of a large scale set of (problem, reasoning trace, answer) tuples generated by the Deepseek-R1 model. We only employ the following subset as the memory bank: 5000 samples for Math, and 5000 for other science domains including physics, chemistry, biology, etc. We also draw another 5000 samples for the optimization of our Mem-LM framework.

4.2 Baselines

We compare our framework with the following baselines: (a) IO, that is, directly outputing the final answer. (b) CoT (Wei et al., 2022). These two methods do not utilize the memory bank. (c) ComplexCoT (Fu et al., 2022). (d) OPRO (Yang et al., 2024a). (e) sparse retrieval using BM25 (Chen et al., 2017) (denoted as Sparse-Retrieval). (f) Dense-Retrieval (Karpukhin et al., 2020). (g) MOMENTO (Zhou et al., 2025). (h) UDR (Li et al., 2023). (i) Lever-LM (Yang et al., 2024b).

4.3 Experimental setups

Devices. All experiments are run on a single machine equipped with NVIDIA A800 GPUs with 80GB memory.

LLM backbones. For language-based tasks, we evaluate three backbone LLMs: Qwen3-8B, Qwen3-32B (Yang et al., 2025), and Qwen-plus[4], which is accessed through the Alibaba Cloud API. On MMLU-Pro and GPQA, the backbone uses greedy decoding with temperature 0, and a prediction is correct if the extracted option matches the reference answer. For the Math-500, AIME-24, and AIME-25 tasks, we report empirical pass@k. For each problem, we independently sample k responses using temperature 1.0 and top-$p = 0.95$. A problem is counted as solved if at least one of the k responses yields the correct final answer. We use pass@4 for Math-500 and pass@16 for AIME-24 and AIME-25.

Settings for MEM-LM. For language-based tasks, the embedder $E(\cdot)$ is initialized with BGE-base-en (Xiao et al., 2024). We attach a trainable module $M(\cdot)$ consisting of a one-layer Transformer encoder and a one-layer Transformer decoder. The hidden size of $M(\cdot)$ is set to match the output dimension of the embedder.

Settings for memory selection. We first use Dense-Retrieval to retrieve $n = 64$ candidate memory items. Then, MEM-LM autoregressively decodes the final ordered sequence of $k = 4$ memory items.

Training setups. We implement the training pipeline based on OPEN-R1[5] for efficient RLVR training. MEM-LM is trained with supervised fine-tuning followed by our MEM-PO optimization. Detailed hyperparameters are reported in Appendix B.1.

4.4 Main Results

Table 1 reports the Qwen-plus results. MEM-LM achieves the best performance on all five benchmarks, with an average score of 84.9. It outperforms Memento, the strongest baseline on aver-

Table 1: Overall performance on the math solving and QA benchmarks, on the Qwen-plus LLM backbone.

age, by 2.3 points and the memory-free CoT baseline by 7.8 points. Relative to Memento, the gains are $+1.9$, $+2.5$, $+3.5$, $+1.8$, and $+1.8$ points on Math-500, AIME-24, AIME-25, MMLU-Pro, and GPQA, respectively. The largest improvement occurs on AIME-25, indicating the benefit of learned memory composition on a challenging mathematical reasoning task.

The results also generalize across model scales. As shown in Table 9 in Appendix B, MEM-LM consistently outperforms CoT, Dense-Retrieval, and Lever-LM with both Qwen3-8B-Instruct and Qwen3-32B-Instruct, achieving the highest score on every evaluated dataset and in the overall average. These results suggest that similarity-based retrieval alone cannot fully exploit the available memory bank. MEM-LM instead learns both which items to select and how to order them for the frozen backbone. The following ablations separately evaluate the contributions of ordered index decoding and the confidence-aware MEM-PO training objective.

Variant	MMLU-Pro acc	Math-500 pass@4
Mem-LM (Full)	**82.9**	**96.6**
w/o ordering (set selection)	81.4	95.1
w/o encoder	81.8	95.4
w/o SFT init.	82.6	96.3
Dense-Retrieval (no selector)	80.4	93.9

Table 2: Ablation on the MEM-LM framework (Qwen-plus backbone). Each row removes one component from the full model.

4.5 Ablation studies and further analysis

Latency analysis. We evaluate the online per-query latency of **Mem-LM** under the same hardware and inference configuration used for Dense-Retrieval. Both methods perform the same query-encoding and candidate-retrieval operations: the query is encoded by BGE-base-en, and the top $n = 64$ candidates are retrieved through Faiss vector search. After these shared operations, **Mem-LM** introduces one additional stage that autoregressively decodes an ordered sequence of $k = 4$ memory indices. Table 4 reports the latency breakdown for these online components.

n (cand.)	k (sel.)	MMLU-Pro	Math-500
16	4	81.6	95.3
32	4	82.3	96.0
64	4	**82.9**	**96.6**
128	4	82.7	96.4
64	2	81.7	95.5
64	4	**82.9**	**96.6**
64	6	82.5	96.3
64	8	82.0	95.8

Table 3: Effect of the candidate pool size n and the number of selected memory items k on MEM-LM (Qwen-plus backbone).

Component	Dense-Retrieval	Mem-LM
Query encoding	42.7	42.7
Faiss vector search ($n = 64$)	11.5	11.5
Autoregressive decoding ($k = 4$)	–	8.7
Total online latency	**54.2**	**62.9**

Table 4: Per-query online latency of Dense-Retrieval and **Mem-LM**. All values are reported in milliseconds (ms). Candidate embeddings are precomputed offline and are therefore excluded from both methods.

Relative to Dense-Retrieval, **Mem-LM** increases the online retrieval-and-selection latency by only 8.7 ms, from 54.2 to 62.9 ms, corresponding to a relative overhead of $8.7/54.2 = 16.1\%$. This increase is entirely attributable to the autoregressive index-decoding stage, since query encoding and Faiss search are identical for the two methods. Moreover, downstream reasoning and answer generation by the frozen LLM typically require more

than 10 seconds per query in our setting. The additional 8.7 ms therefore amounts to less than 0.1% of the downstream generation time, indicating that **Mem-LM** achieves its performance improvements with a modest practical latency cost.

Ablation on the Mem-LM framework Table 2 isolates each design choice. Replacing ordered autoregressive decoding with unordered *set selection* causes the sharpest drop (-1.5 on MMLU-Pro, -1.5 on Math-500), confirming that the *order* of composed items is the dominant source of our gains, precisely the dependency pointwise retrieval cannot capture. Removing the Transformer *encoder*, so the decoder reads raw candidate embeddings, eliminates cross-candidate interaction and yields a smaller but consistent loss (-1.1 on MMLU-Pro, -1.2 on Math-500), indicating that jointly encoding the query and the pool helps the decoder reason about item complementarity. Omitting the *SFT initialization* and training Mem-PO from scratch costs only -0.3 and -0.3, so SFT mainly speeds convergence and fixes the output format, while the reinforcement objective drives final accuracy. Every variant still beats the Dense-Retrieval baseline, showing that all components help and that ordered, interaction-aware decoding is the most critical.

We next vary the candidate pool size n and the number of selected items k (Table 3). Accuracy rises as n grows from 16 to 64 and then saturates, slightly declining at n=128, so a moderate pool gives enough coverage without adding distractors. For k, performance peaks at k=4: fewer items (k=2) under-use the memory bank, whereas more (k=8) inject noise and lengthen the context. We thus set n=64 and k=4 by default.

Method	MMLU-Pro acc	Math-500 pass@4
SFT	80.3	93.7
PPO	80.7	94.5
REINFORCE	79.7	93.9
GRPO	80.9	95.0
DAPO	81.1	95.2
Mem-PO (ours)	**82.9**	**96.6**

Table 5: Ablation on the training method for Mem-LM.

Ablation on the training method for Mem-LM Table 5 compares optimizers for Mem-LM: SFT, REINFORCE, PPO (Schulman et al., 2017), GRPO (Shao et al., 2024), DAPO (Yu et al., 2026), and Mem-PO. SFT is weakest (80.3/93.7 on MMLU-Pro/Math-500), as imitating fixed oracle sequences ignores the query-dependent utility of memory combinations. All RLVR variants surpass it, confirming that reward-driven exploration is essential. REINFORCE and PPO remain near SFT, while the group-relative GRPO and DAPO are clearly stronger (80.9/95.0 and 81.1/95.2) thanks to more stable relative advantages under sparse binary rewards. Mem-PO is best on both benchmarks (82.9/96.6), beating DAPO by $+1.8$ and $+1.4$. The gain comes from its confidence-aware self-evaluation signal, which densifies the binary reward and, via the correctness-tie branch, recovers gradients from reward-homogeneous groups where the group-relative advantage vanishes.

Embedder model	MMLU-Pro
all-mpnet-base-v2	82.2
Contriever	81.9
GTE-base	82.5
GTE-large	83.0
BGE-base-en	82.9
BGE-large-en	**83.2**

Table 6: Ablation on the embedder model $E(\cdot)$ (Qwen-plus backbone, MMLU-Pro).

Confidence-direction ablation. We test whether the gains of MEM-PO arise merely from adding confidence or from preferring the appropriate confidence direction. The full objective favors lower-confidence rollouts within correctness ties, thereby reinforcing uncertain successes while suppressing confidently incorrect selections. The *high-confidence preference* variant reverses only the correct-tie branch:

$$s_{ij}^{\text{high}} = \begin{cases} \text{sign}(\kappa_i - \kappa_j), & c_i = c_j = 1, \\ s_{ij}, & \text{otherwise}, \end{cases} \tag{5}$$

whereas the *no-confidence* variant sets $\lambda = 0$ in $\tilde{A}_{i,t} = \hat{A}_{i,t} + \lambda \widetilde{\text{SES}}_i$ and thus recovers the DAPO-style objective. GRPO is included as an additional reference. All variants use the same SFT initialization, training data, rollout budget, optimization settings, and evaluation protocol.

The low-confidence preference achieves 82.9 accuracy on MMLU-Pro and 96.6 pass@4 on Math-500, exceeding the high-confidence alternative by 1.5 and 0.9 points, respectively. Because these variants differ only in the correct-tie branch, the result shows that reinforcing correct but under-supported memory sequences is more effective than amplifying successes already favored by the selector. Removing the confidence term causes larger drops of

Method	MMLU-Pro acc	Math-500 pass@4
MEM-PO (low-conf. preference)	**82.9**	**96.6**
High-confidence preference	81.4	95.7
No confidence signal ($\lambda = 0$)	81.1	95.2
GRPO reference	80.9	95.0

UDR	90.7
Lever-LM	91.8
MOMENTO	90.5
Mem-LM	**93.3**

Table 8: Diagnosis accuracy on the internal MED-DIAGNOSIS dataset using Qwen-plus as the frozen backbone.

1.8 and 1.4 points, confirming that the auxiliary signal itself is also beneficial. Together, these results support both components of MEM-PO: confidence-aware advantage shaping and its specific emphasis on uncertain successes.

Ablation on the embedder $E(\cdot)$ We test Mem-LM's sensitivity to the frozen embedder on MMLU-Pro, fixing the trainable module $M(\cdot)$ and the Mem-PO objective. Swapping in six off-the-shelf encoders—all-mpnet-base-v2 (Reimers and Gurevych, 2019), Contriever (Izacard et al., 2021), GTE-base and GTE-large[6], and BGE-base-en/BGE-large-en (Xiao et al., 2024)—and re-precomputing only the candidate embeddings, accuracy stays within 81.9–83.2 and every variant exceeds Dense-Retrieval (80.4). Stronger encoders add only marginal gains (BGE-large-en, 83.2), showing that representation quality is not the main driver. Since our default BGE-base-en (82.9) nearly matches the best at lower cost, we adopt it throughout.

Real-world validation on an industrial dataset. We further evaluate MEM-LM on MED-DIAGNOSIS, an internal retrospective dataset developed with nine hospitals. Its 18,719 de-identified cases contain medical histories, examination findings, and reported symptoms. The memory bank combines historical cases with medical knowledge entries, thus requiring selection across heterogeneous evidence types. All methods use Qwen-plus as the same frozen backbone, and performance is measured by diagnostic-label accuracy against the reference diagnoses.

As shown in Table 8, MEM-LM achieves 93.3% accuracy, outperforming Lever-LM, the strongest baseline, by 1.5 percentage points and exceeding UDR and Dense-Retrieval by 2.6 and 4.1 points, respectively. These results indicate that autoregressively composing an ordered sequence of complementary memories transfers from academic reasoning benchmarks to retrospective clinical data. This experiment evaluates diagnostic-label prediction only; it demonstrates cross-domain transfer but does not establish prospective clinical utility or deployment readiness.

5 Conclusion

This work introduced MEM-LM, an LM-style model for reinforced memory selection that formulates context construction as autoregressive decoding over memory indices. Rather than directly providing a frozen LLM/VLM with an unordered, similarity-ranked set, MEM-LM jointly determines which memories to select and the order in which they should appear, without updating the backbone parameters. We further developed MEM-PO, a modular confidence-aware extension to group-relative policy optimization that provides discriminative training signals under sparse verifiable rewards, including for reward-homogeneous rollout groups. Experiments on five mathematical and reasoning-intensive QA benchmarks with three Qwen backbones demonstrate consistent improvements over retrieval-based and learned memory selectors. On Qwen-plus, MEM-LM achieves an average score of 84.9, exceeding the strongest memory-augmented baseline by 2.3 points; the ablations identify ordered index decoding and the MEM-PO objective as the principal contributors to these improvements. Overall, the results establish LM-style index generation as an effective and modular approach to memory composition, while evaluation on multimodal and longer-horizon agentic tasks remains an important direction for future work.

Limitations

Evaluation scope and external validity. Our evaluation primarily covers five public, text-only benchmarks for mathematical reasoning and

[6] https://huggingface.co/thenlper/gte-large

reasoning-intensive question answering, using three backbones from the Qwen family. We additionally report a retrospective evaluation on the internal MED-DIAGNOSIS dataset, but this experiment does not establish prospective clinical utility, deployment readiness, or reproducibility on a publicly accessible medical benchmark. Although the MEM-LM formulation can in principle accommodate multimodal memory items and multi-step agent interactions, we do not evaluate vision–language inputs, interactive environments, or substantially longer reasoning horizons. Consequently, the effectiveness of ordered index decoding in these settings remains to be established.

Optimization cost and hyperparameter sensitivity. MEM-PO uses token-level confidence estimates and performs pairwise comparisons among the G rollouts in each group, resulting in $O(G^2)$ pairwise operations in addition to the underlying group-relative policy optimization. The objective also introduces the weighting coefficient λ and temperature τ, while the broader MEM-LM pipeline requires choices for the candidate-pool size n and the number of selected memories k. Although our ablations indicate reasonable robustness around the evaluated configuration, these settings may require validation or re-tuning when the memory distribution, task domain, or backbone changes. Moreover, our latency measurements use a single hardware configuration with $n = 64$ and $k = 4$; the observed overhead may therefore not generalize to substantially larger candidate pools, selected contexts, or rollout groups.

Dependence on confidence quality and memory coverage. The auxiliary signal in MEM-PO is derived from the token probabilities of the trainable selection policy π_θ. Because these probabilities are not guaranteed to be calibrated, confidence estimates that are systematically misaligned with selection quality could reduce the benefit of the proposed advantage shaping. In addition, most memory items used in our benchmark experiments are constructed from DeepSeek-R1-generated traces. Their accuracy, diversity, and domain coverage constrain the evidence available to MEM-LM, and the initial dense retriever may exclude useful items before autoregressive selection begins. Performance may consequently degrade for noisy memory banks, low-resource domains, or queries that differ substantially from the memory construction distribution; evaluating more diverse memory sources and retrieval mechanisms is left for future work.

Declaration for Using AI Assistants

During the preparation of this work, AI-assisted tools were used to support language polishing, grammar correction, and improvement of the clarity and readability of the text. The AI assistants were not used to generate original research ideas, perform data analysis, draw conclusions, or replace the authors' own critical thinking and academic judgment. All AI-generated suggestions were carefully reviewed, revised, and verified by the authors. The authors take full responsibility for the accuracy, integrity, and originality of the content presented in this work.

A Appendix: Preliminaries on RLVR

RLVR and GRPO. RLVR has become central to LLM research for its ability to incentivize reasoning (Guo et al., 2025). It adopts Group Relative Policy Optimization (GRPO) (Shao et al., 2024), a variant of PPO (Schulman et al., 2017) that discards the value function and instead estimates advantages within a group of sampled responses. For an input–answer pair (q, a), the old policy $\pi_{\theta_{\text{old}}}$ samples G responses $\{o_i\}_{i=1}^{G}$ with rewards $\{R_i\}_{i=1}^{G}$. The advantage of o_i is normalized within the group and shared across its tokens:

$$\hat{A}_{i,t} = \frac{R_i - \text{mean}(\{R_j\}_{j=1}^{G})}{\text{std}(\{R_j\}_{j=1}^{G})}. \tag{6}$$

GRPO maximizes a clipped objective with a KL penalty:

$$\mathcal{J}_{\text{GRPO}}(\theta) = \mathbb{E}_{(q,a),\,\{o_i\}\sim\pi_{\theta_{\text{old}}}}\left[\tfrac{1}{G}\,\text{Obj} - \text{KL}\right], \tag{7}$$

where the per-group objective and penalty are

$$\text{Obj} = \sum_{i=1}^{G} \frac{1}{|o_i|} \sum_{t=1}^{|o_i|} \min\big(r_{i,t}\hat{A}_{i,t},\, \hat{r}_{i,t}\hat{A}_{i,t}\big), \quad (8)$$

$$\text{KL} = \beta\, D_{\text{KL}}(\pi_\theta \,\|\, \pi_{\text{ref}}). \quad (9)$$

Here the importance ratio and its clipped form are

$$r_{i,t} = \frac{\pi_\theta(o_{i,t} \mid q, o_{i,<t})}{\pi_{\theta_{\text{old}}}(o_{i,t} \mid q, o_{i,<t})}, \quad \hat{r}_{i,t} = \text{clip}(r_{i,t}, 1{-}\varepsilon, 1{+}\varepsilon) \quad (10)$$

Outcome reward. RLVR uses the verifiable task score as the outcome reward,

$$R(\hat{y}, y) = \text{Score}(\hat{y}, y), \quad (11)$$

where y is the ground-truth answer and $\hat{y}$ the prediction. This signal has proven effective at eliciting reasoning across domains such as theorem proving, programming, and mathematics competitions (Guo et al., 2025). For our QA and math tasks, $\text{Score}(\cdot,\cdot)$ is the per-sample accuracy.

Format reward. The reward typically combines correctness with auxiliary constraints. A binary format reward enforces structured outputs:

$$R_{\text{format}}(\hat{y}) = \text{CorrectFormat}(\hat{y}), \quad (12)$$

where $\text{CorrectFormat}(\cdot)$ returns 1 iff the required format holds. For MEM-LM, this requires decoding a valid, non-repeating sequence of memory indices. Following DAPO (Yu et al., 2026), our MEM-PO drops the KL term and adopts asymmetric clipping; Eq. 6 is the group-relative advantage that MEM-PO augments in the main text.

B Appendix: Experiments

B.1 Experimental Settings

We train MEM-LM with an SFT-then-RLVR pipeline, where the RLVR stage uses our MEM-PO objective. From the training set built in Section 4.1, we hold out 300 samples for SFT and 300 for validation, and use the remainder for RLVR. For each SFT sample, the target memory sequence is obtained with the beam-search construction of Yang et al. (2024b). SFT runs for 5 epochs with learning rate 1×10^{-4} and batch size 8, teaching MEM-LM the output format and a reasonable initial selection policy before reinforcement learning.

The RLVR stage follows established practice, in particular OPEN-R1 and TINA (Wang et al., 2026), with minor adjustments for our setting. We set the weight of $\widetilde{\text{SES}}_i$ to $\lambda{=}0.5$ and the temperature to $\tau{=}0.1$. The policy learning rate is fixed to 5×10^{-5}, and the KL coefficient to 0.1 to balance exploration and stability. Per prompt we sample $G{=}8$ responses with temperature 1.0 and top-p $=$ 0.95, using a batch size of 32 per GPU. For policy updates we apply asymmetric clipping with $\varepsilon_{\text{high}}{=}0.28$ and $\varepsilon_{\text{low}}{=}0.20$, and train for 2,000 steps. Unlike DAPO (Yu et al., 2026), MEM-PO retains reward-homogeneous groups, including groups in which all rollouts are correct or all are incorrect. Although the group-relative reward advantage vanishes for such groups, the confidence-based correctness-tie branch can yield a non-degenerate self-evaluation score $\widetilde{\text{SES}}_i$, allowing these samples to contribute informative policy gradients. Checkpoints are saved every 200 steps and evaluated on the validation set; the best-performing checkpoint is used for test-time prediction.

All results are averaged over five random seeds.

B.2 Experiments on More LLM Backbones

Table 9 reports MEM-LM on the three math benchmarks (Math-500, AIME-24, AIME-25) and the two science QA tasks (MMLU-Pro, GPQA) with the Qwen3-8B-Instruct and Qwen3-32B-Instruct backbones. MEM-LM again outperforms both the memory-free CoT baseline and the strongest learned selector (Lever-LM) on every dataset and on average, confirming that its gains transfer across backbone scales.

Method	Math-500 pass@4	AIME-24 pass@16	AIME-25 pass@16	MMLU-Pro acc	GPQA acc	Avg.

From Metrics to Natural Dialogue: French Full-Duplex Benchmark for Spoken Dialogue Models

Hamid Soltani and Gilles Boulianne
Luqia Technologies, Montréal, Québec, Canada
hamid.soltani@concordia.ca gilles.boulianne@luqia.ca

Abstract

Full-duplex spoken dialogue models aim to make voice agents more natural by allowing them to listen, speak, pause, and respond during ongoing conversation. However, it is not clear whether full-duplex benchmarks behave the same way when models are evaluated in a different language. To investigate this, we introduce a French full-duplex benchmark (FDB) with two variants, CALLFC-FDB for Canadian French and MEDIA-FDB for European French, and compare them with an English FDB. Built from real spoken resources, these benchmarks evaluate key full-duplex skills, including pause handling, turn-taking, backchannels, and interruptions. Beyond introducing French FDBs, we evaluate human–human conversations with FDB metrics to better understand the values these metrics take in real-world dialogue. Our analysis reveals that most timing-based metrics behave similarly across languages, while content-based evaluation degrades under language mismatch. We also find a trade-off between optimizing benchmark metrics and preserving conversational naturalness.

1 Introduction

Human-computer interaction has long studied how machines can move beyond command execution toward understanding human intention through natural communication. This goal aligns with agentic AI, where systems perceive context, make decisions, and act toward user goals (Xi et al., 2025). Speech is one of the most natural forms of this interaction, enabling direct communication between users and AI systems (Ji et al., 2024). Unlike text, speech carries words together with timing, hesitation, emphasis, and other acoustic cues. These signals make speech a rich form of interaction, but they also make spoken dialogue difficult, since systems must understand language, interpret acoustics, handle pauses and overlap, and respond in real time. Spoken Dialogue Models (SDMs) (Défossez et al., 2024; Roy et al., 2026) address this challenge by taking speech as input and generating spoken responses. A key distinction among SDMs is how they manage conversational timing through listening, speaking, pausing, and yielding. Based on this, SDMs are divided into half-duplex and full-duplex systems (Lin et al., 2025). In half-duplex interaction, the model responds after detecting the end of the user turn. This simplifies processing, but differs from human conversation, where speakers coordinate turns through pauses, overlap, and listener feedback (Heldner and Edlund, 2010). Full-duplex SDMs reduce this gap by listening and speaking at the same time, supporting turn-taking (Raux and Eskenazi, 2012), backchannels (Schegloff, 1982), and overlapping speech (Schegloff, 2000).

Full-duplex SDMs generally follow two architectural families: cascaded and speech-to-speech systems. In cascaded systems, speech-to-text (STT) converts user speech into text, a large language model (LLM) generates a response, and text-to-speech (TTS) converts it back into speech. AudioGPT (Huang et al., 2024) connects ChatGPT with automatic speech recognition (ASR), TTS, and audio foundation models, keeping the LLM as the reasoning center while separate audio models handle speech recognition, synthesis, understanding, and generation. Recently, DuplexCascade (Yang et al., 2026) uses streaming ASR micro-turns and control tokens to decide whether to wait, respond, or backchannel. Overall, cascaded systems remain attractive because they reuse strong speech and language components and allow each part to be improved independently. However, they can add latency and lose acoustic information during STT and TTS conversion.

In contrast, speech-to-speech systems process and generate speech directly. This makes them more suitable for full-duplex interaction, where models must listen while speaking and react to interruptions, backchannels, and overlap. Freeze-

EMNLP 2026 Industry Track, pages 2302–2310
October 24-29, 2026 ©2026 Association for Computational Linguistics

Omni (Wang et al., 2025) moves closer to real-time spoken dialogue by connecting a streaming speech encoder and speech decoder to a frozen text LLM, enabling low-latency speech-to-speech interaction. Moshi (Défossez et al., 2024) represents user and system speech as parallel streams, allowing it to handle overlaps and interruptions without fixed speaker turns. PersonaPlex (Roy et al., 2026) extends this direction with role conditioning and voice control, using hybrid prompts that combine text-based role instructions with speech samples for voice cloning. Together, these models show that speech-to-speech systems preserve acoustic and conversational information needed for natural full-duplex interaction.

As full-duplex SDMs become more realistic, evaluation becomes more difficult. Recent work has introduced interaction-focused speech datasets that capture behaviors such as interruptions and backchannels (Chen et al., 2025). Beyond answer quality, evaluation must measure whether a model responds at the right time, stops when needed, ignores irrelevant speech, and remains consistent across turns. Full-Duplex-Bench (FDB) v1.0 (Lin et al., 2025) evaluates the interaction skills required for full-duplex dialogue, including pause handling, backchanneling, smooth turn-taking, and user interruption. The benchmark focuses on turn-taking behavior, assessing when the model should wait, backchannel, or take the turn. FDB v1.5 (Lin et al., 2026b) extends this setting to overlapping speech by separating user interruptions, user backchannels, speech directed to others, and background speech, since each case requires a different system behavior. FDB v2 (Lin et al., 2026a) moves from single-event testing to multi-turn dialogue. It uses an automated spoken examiner with staged goals, follow-up questions, interruptions, and pacing styles. This allows evaluation of turn-taking fluency, multi-turn instruction following, and task-specific performance across daily assistance, correction handling, entity tracking, and safety.

One important open question is whether the test language itself affects the evaluation of full-duplex spoken dialogue models. In particular, it is unclear how FDB metrics behave when a target-language model is evaluated using a non-target language benchmark. This question matters because full-duplex evaluation measures not only response quality, but also timing-sensitive behaviors such as pauses, backchannels, turn-taking, and interruptions. Although recent multilingual benchmarks have expanded evaluation beyond English (Ma et al., 2025), dedicated benchmarks for French full-duplex dialogue are still missing. French also contains language-specific interactional cues such as *euh*, *ben*, *ouais*, and *d'accord*, which do not map directly onto English translations. Their meanings and conversational functions depend on context, prosody, and turn-taking. In addition, some existing FDB tasks are based on synthetic speech, which may not fully reflect the variability of natural conversations. To study the effect of evaluation language and to support research on French spoken dialogue systems, we introduce two real-world French Full-Duplex-Bench variants: CALLFC-FDB for Canadian French and MEDIA-FDB for European French.[1] CALLFC-FDB is built from the CALLFRIEND French Canadian (Mondada and Linguistic Data Consortium, 2006; Canavan and Zipperlen, 1996), a corpus of telephone conversations between native speakers of Canadian French, while MEDIA-FDB is built from the MEDIA (Bonneau-Maynard et al., 2005), a French spoken language understanding corpus. Together, they support evaluation of French voice agents across different French varieties and interaction settings. Our results demonstrate that most timing-based metrics remain broadly consistent across languages, while content-based evaluation is more sensitive to language mismatch.

Beyond extending FDBs to French, we evaluate human-human conversations with FDB metrics to establish reference values for how these metrics behave in real dialogue. Unlike agent-generated interactions, these conversations provide a natural reference point for interpreting metric-based evaluation. This is important since current FDB metrics define better performance through metric optimization. However, real dialogue is more flexible than fixed metric targets, and our analysis shows a trade-off between optimizing FDB metrics and maintaining natural spoken interaction.

2 French Full-Duplex-Bench

2.1 FDB Tasks

To ensure compatibility with the FDB series, we adapt the four core tasks from FDB v1.0 (Lin et al., 2025). We focus on FDB v1.0 as a first step because it defines the foundational full-duplex skills required for spoken dialogue evaluation.

[1]Dataset preparation code: https://github.com/crim-ca/fdb-eval-prep-CCCF

- **Pause Handling**: whether the model remains silent when the user pauses inside a turn.
- **Backchanneling**: whether the model produces appropriate backchannels without taking the turn.
- **Smooth Turn Taking**: whether the model responds after the user finishes speaking, without undue latency.
- **User Interruption**: whether the model can handle interruptions and shift from the previous direction to the new intent.

For MEDIA-FDB, we did not find enough valid examples of system backchannels, so the backchanneling task is not included for this dataset. These tasks may depend on the evaluation language in different ways. Pause handling is expected to be weakly language-dependent, since the model mainly needs to detect silence inside an ongoing turn. Smooth turn-taking also relies on timing, but may be more affected by language matching because the model must decide whether the user has completed an utterance and then take the turn. Backchanneling is more language-dependent, because the model must decide when short listener feedback is needed and produce it with appropriate timing and duration. User interruption is the most language-dependent task, as the model must understand the interruption and respond to the new intent.

2.2 FDB Metrics

We briefly review the FDB v1.0 (Lin et al., 2025) metrics used in our evaluation:

- **Takeover Rate (TOR):** average takeover decision across samples, where silence and backchannels are scored as 0, and other responses as 1. Lower TOR is preferred for pause handling and backchanneling, while higher TOR is better for smooth turn-taking and user interruption.
- **Backchannel Frequency:** number of backchannels normalized by duration. Higher values show more frequent listener feedback.
- **Jensen-Shannon Divergence (JSD):** measures the difference between model and ground-truth backchannel timing distributions. Lower values indicate greater similarity between model and ground-truth backchannels locations and durations.
- **Smooth Turn-Taking Latency:** time between the end of the user turn and the start of the model response.
- **User Interruption Latency:** time between a user interruption and the model response.
- **Rating:** LLM-based response-quality score for user interruption, from 0 to 5.

Most FDB metrics are based on voice activity, such as the start of speech, silence, or the presence of backchannels. They do not directly evaluate speech content, so they are basically language-independent. The main exception is the rating metric for user interruption, which depends on response content. For example, an English response to a French interruption would receive a low rating even if the timing behavior is appropriate. Latency can also be influenced by system architecture and implementation, especially in cascaded pipelines.

2.3 CALLFRIEND and MEDIA Data

We build the French Full-Duplex-Bench from two French spoken-dialogue corpora: CALLFRIEND French Canadian and MEDIA.

2.3.1 CALLFRIEND French Canadian

CALLFRIEND French Canadian contains 26 hours of unscripted telephone conversations between native speakers of Canadian French, recorded in 1996 and distributed by the Linguistic Data Consortium (Canavan and Zipperlen, 1996). In each conversation, participants could call a person of their choice and talk about any topic. Most speakers called family or friends, resulting in highly informal speech.

2.3.2 MEDIA

MEDIA is a French human-machine dialogue corpus in the hotel reservation and tourist information domain. It was collected using a Wizard-of-Oz (WoZ) setup (Green and Wei-Haas, 1985), where users believed they were interacting with an intelligent system, while a human operator produced the system responses (Laperrière et al., 2022). Unlike CALLFRIEND, MEDIA contains task-oriented conversations with clearer interaction goals.

Together, CALLFRIEND and MEDIA increase benchmark diversity by covering informal open-domain and structured task-oriented dialogue.

2.4 French FDB Dataset Preparation

We construct the French Full-Duplex-Bench from continuous two-channel spoken conversations. The preparation process converts natural French speech into FDB-compatible samples, while preserving the timing, speaker activity, pauses, and backchannels that are important for full-duplex evaluation. CALLFC-FDB and MEDIA-FDB share the same output format, scoring, materialization, and export stages. However, they differ in transcript preparation and turn extraction.

2.4.1 Transcription Process

Because the two corpora differ in their transcription annotations, we use two corpus-specific transcript preparation methods.

CALLFC-FDB transcript preparation. The CALLFRIEND FC conversations were manually transcribed by in-house annotators with speaker turn time boundaries, but without speaker assignment. Since overlapping regions include only the dominant speaker, we apply additional processing to recover speaker information from these regions.

To recover as much speaker information as possible from overlapped regions, we first transcribe each audio channel with Whisper large-v3 (Radford et al., 2023), and align the outputs with the Montreal Forced Aligner (MFA) (McAuliffe et al., 2017). We align the automatic and manual transcripts using Longest Common Subsequence (LCS) (Hirschberg, 1977), allowing us to transfer word-level timings and speaker assignments from the automatic transcripts to the manual transcription. The final merged CALLFC-FDB transcript keeps all words from the manual transcription and adds automatic transcription words in overlapped regions that were not present in the manual transcript. This step recovers 44,165 overlapped words, about 11% of the final transcript of 386K words. The result is a word-level, speaker-assigned transcript that combines the reliable words from the manual transcription with timing and channel information from the automatic channel-level alignment.

MEDIA-FDB transcript preparation. The manual MEDIA transcriptions already include speaker assignments and turn-level overlap annotations. The manual transcriptions for each channel are directly aligned with the corresponding audio using the MFA, obtaining word-level timestamps while keeping the manually transcribed words. Thus, MEDIA-FDB is based on manually transcribed text with MFA-derived word-level timing.

2.4.2 Turn and sentence extraction

FDB tasks consist of one audio file, `input.wav`, containing an extract of conversation corresponding to the task, and an optional JSON annotation file required for some evaluation metrics. FDB tasks are extracted from pairs of speaker turns, with one turn coming from each speaker. The definition of a turn depends on the corpus. For MEDIA-FDB, speaker turns are taken directly from the manual transcription. For CALLFC-FDB, where the manual transcription does not provide the same role structure, words within chunks separated by no more than 2.0 seconds are considered as part of the same turn. After turns are obtained, each turn is split into sentence-like units using timing gaps between words. Specifically, a new sentence is created when the inter-word gap is greater than 0.2 seconds. Thus, a turn may contain one or several sentences. Since CALLFC-FDB contains two human speakers with no fixed user or assistant roles, we process it twice. In the first pass, one speaker is treated as the speaker side and the other as the WoZ side. In the second pass, the roles are reversed.

2.4.3 FDB event extraction

We select candidate samples from paired speaker turns, closely following (Lin et al., 2025):

- **Pause handling.** This task operates on the full speaker turn, including all of its sentences. The pipeline detects inter-word gaps longer than 0.7 seconds within the turn. Each gap becomes a separate candidate sample.
- **Backchanneling.** For speaker turns of at least 2.0 seconds, we identify isolated backchannel words from the WoZ side speaker.
- **Smooth turn-taking.** We select instances where the gap between the speaker turn and the following WoZ turn is less than 1.0s. We use the last sentence of the speaker with 5 seconds of silence appended.
- **User interruption.** We identify instances where the speaker starts talking before the previous WoZ turn has finished and the speaker sentence is not a backchannel.

Samples that satisfy the necessary and sufficient classification conditions for a task are first selected

as candidates. A single turn pair may produce more than one candidate when it contains multiple valid events, for example multiple qualifying pauses.

2.4.4 Scoring, validation, and export

Candidate selection is followed by a scoring and validation stage. This stage applies hard post-hoc requirements to remove samples that passed the initial classification step but are still unsuitable as evaluation examples. These checks include duration limits, logical consistency checks, and task-specific timing constraints. For example, valid pauses are positive and fall inside the turn, backchannel inputs last at least 15 seconds, and user interruption contexts should be between 0.5 and 5.0 seconds. After hard filtering, 92.8% of MEDIA candidates and 78.0% of CALLFC candidates were retained.

The scoring process also assigns a quality score to each candidate. This score measures how clearly and unambiguously the sample represents the intended task. As examples, for `pause_handling`, the ideal pause is around 0.7 seconds, with enough speech before and after it. For `smooth_turn_taking`, shorter inter-turn gaps receive higher scores. Finally, only validated candidates that pass all filters are used to create the final FDB samples. For each selected event, the pipeline extracts the required audio segment from the original recording. The highest-quality validated candidates are then materialized and exported in the standard FDB directory format as MEDIA-FDB and CALLFC-FDB. To facilitate comparison with the original English FDB benchmark, the number of samples per task was capped at 150 whenever sufficient candidates were available. After quality-based ranking and the sample cap, the final datasets contained 41.4% and 26.3% of the original MEDIA and CALLFC candidates, respectively. Table 1 reports the number of extracted samples for each task in both datasets.

Task	Number of Samples	
	CALLFC	MEDIA
Pause handling	150	150
Backchanneling	37	–
Smooth turn-taking	150	96
User interruption	150	38

Table 1: Number of extracted French FDB samples for each task in CALLFC-FDB and MEDIA-FDB. A dash indicates that no valid samples were available.

3 Evaluation

We evaluate the proposed French FDBs using both English and French SDMs. For the English setting, we use Freeze-Omni (Wang et al., 2025)[2] and PersonaPlex-7B-v1 (Roy et al., 2026)[3] as reference models to compare English FDB with the proposed French FDBs. Freeze-Omni was evaluated on an NVIDIA A40 48GB GPU, while PersonaPlex was evaluated on an NVIDIA A100 80GB GPU.

For a fair English/French comparison, we evaluate two cascaded SDMs based on an STT–LLM–TTS pipeline and implemented with Pipecat[4]. Vosk is used for STT, with `vosk-model-small-en-us-0.15` for English and `vosk-model-small-fr-0.22` for French[5]. Both systems use `qwen3:8b` through Ollama[6] and Piper TTS, using `en_US-lessac-low` for English and `fr_FR-gilles-low` for French[7]. All inference experiments for the cascaded systems were conducted on an NVIDIA A40 GPU with 48 GB of memory. Their relatively high latency is expected from the simple cascaded design and is not specific to the French FDB datasets, since similar latency is also observed on English FDB. Our logs show that STT and TTS latency are small, while most delay comes from LLM generation. To assess STT quality, we measured Vosk WER on the pause-handling subsets, which contain longer user speech segments. For example, the WER is 21.7% for French on MEDIA-FDB and 26.7% for English on English FDB. We do not report mismatched-language WER because the recognizers are language-specific and the WER is expected to be very high. We also include human–human baselines for both French FDB datasets as a natural reference for interpreting the metrics.

In the FDB framework, we modified the ASR step implemented in `asr.py` by replacing NVIDIA Parakeet-TDT-0.6b-v2 with the v3 version[8]. This change was necessary because v2 does not support French, whereas v3 supports multilingual ASR and can generate the required `output.json` transcription files. This modification made the evaluation pipeline suitable for MEDIA-FDB and CALLFC-FDB. For the rating metric in the user-interruption

Table 2: Evaluation of English and French spoken dialogue models on the original English FDB and the proposed French FDB datasets. Human–human conversations are included as a reference for natural conversational behavior. Within dataset and column, values have the same color if their 95% confidence intervals overlap by more than 25% (i.e. difference not statistically significant). English pause-handling values combine the two task IDs using pooled summary statistics.

task, we use `llama3.3:70b`[9] as the LLM judge. We selected this large-scale LLM because it has a different architecture from the spoken dialogue models under evaluation, reducing the risk that the judge shares the same modeling biases as the evaluated systems. For the user-interruption rating, we follow the official FDB evaluation procedure, including the same prompt, scoring rubric, and generation settings.

4 Results

Our main goal is to study whether evaluation language affects FDB metrics. Table 2 compares English and French models on the English and French FDB datasets, with human–human conversations as a reference. Full 95% confidence intervals for all results are reported in Appendix A.

As a sanity check, Freeze-Omni and PersonaPlex results on the original English FDB are generally consistent with FDB v1.0, giving us confidence in our setup. For pause handling, English FDB generally gives lower or comparable TOR values across both English and French models. This suggests that pause handling mainly depends on voice activity, such as silence inside a turn, rather than on the language of the evaluated model. For backchanneling, PersonaPlex gives the highest backchannel frequency and the lowest JSD among the evaluated models on both English FDB and CALLFC-FDB. This suggests that backchannel behavior is affected by model architecture, not only by the evaluation language or model language. For smooth turn-taking, cascaded models achieve higher TOR when the benchmark language matches the model language. Freeze-Omni remains stable, while PersonaPlex drops on the French benchmarks. This suggests some benefit from language matching for this task. For smooth turn-taking and user interruption, the English cascade consistently has lower latency than the French cascade across all FDB datasets. Since both systems use the same pipeline structure, this suggests that latency is shaped by system implementation and architecture, not only by the benchmark language. As expected, user-interruption rating is the most language-dependent metric. Ratings drop sharply when the model language does not match the benchmark language, while language-matched settings obtain much higher scores. When models are evaluated on non-target language datasets, most metrics based on voice activity remain broadly comparable. The main exception is content-based evaluation, such as user-interruption rating. Overall, language mismatch does not fundamentally change most timing-based FDB metrics, but it strongly affects content-based evaluation.

Human–human baselines provide a natural reference for interpreting metrics. On both French FDBs, humans show low pause-handling TOR and strong turn-taking and interruption TOR. However, they have higher interruption latency than non-cascaded English models, suggesting that natural dialogue is not only about responding quickly, but also about respecting pauses and taking appropri-

[9] https://ollama.com/library/llama3.3:70b

ate turns. On MEDIA-FDB, the French cascade receives a higher rating than humans, showing that quality and naturalness may differ. Thus, optimizing FDB metrics does not always align with conversational naturalness.

5 Conclusion

We introduced CALLFC-FDB and MEDIA-FDB, two French Full-Duplex-Bench datasets derived from real-world conversations in Canadian and European French. These benchmarks provide a practical evaluation resource for French SDMs while remaining compatible with the FDB framework. Our results show that evaluation language affects full-duplex skills differently. Timing-related behaviors, such as pause handling TOR and interruption latency, remain relatively stable across languages and are largely driven by system architecture. In contrast, content-dependent behaviors, particularly user interruption rating, degrade when the model and benchmark language do not match. In contrast, content-dependent behaviors, particularly user interruption rating, degrade when the model and benchmark language do not match. In practice, evaluation language, system architecture, and latency should be considered together when selecting and evaluating full-duplex systems.

We also find that human–human conversations do not always yield optimal FDB scores, suggesting that benchmark performance alone may not fully reflect human-like interaction. Overall, our findings highlight the need to distinguish between acoustic-timing competence and language-dependent interaction competence in multilingual full-duplex evaluation. Future work will investigate whether this language dependency extends to other FDB v1.5 and v2.0 tasks and will expand the French FDBs to overlapping speech scenarios.

Acknowledgments

We acknowledge the support of the Natural Sciences and Engineering Research Council of Canada (NSERC) for this work, and would also like to thank Ministry of Economy and Innovation (MEI) of the Government of Québec for its continued support.

Limitations

This work adapts the French Full-Duplex-Bench only for FDB v1 tasks. Therefore, future work should extend the proposed French benchmarks to FDB v1.5 and FDB v2, including overlapping speech and multi-turn scenarios.

The latency comparison is also limited by the lack of a fast French speech-to-speech model. More comparable French and multilingual systems are needed to better isolate the effect of language from system architecture.

The language comparison varies in corpus, domain, and conversational formality, since the English FDB, CALLFC-FDB, and MEDIA-FDB are derived from different interaction settings. Future work with closely matched multilingual datasets could better isolate the effect of language from these corpus-level differences.

This study only evaluates language mismatch for FDB v1. It remains important to examine how mismatched evaluation languages affect FDB v1.5 and FDB v2 tasks.

Finally, FDB metrics mainly evaluate timing and turn-taking, but they do not fully capture conversational naturalness, user satisfaction, or long-term dialogue coherence. Benchmark scores should therefore be interpreted together with qualitative analysis and human-centered evaluation.

Ethics Statement

We release only annotations and preparation scripts, not original or extracted audio. Users must obtain CALLFRIEND and MEDIA from their official distributors and follow the corresponding licenses. Samples are generated locally and remain subject to the original dataset licenses. We also do not release speaker metadata or personal identifiers, limiting additional privacy risks.

Abstract

Production text-to-code systems increasingly use large language models (LLMs) to translate natural-language analytics requests into executable SQL and pandas code, serving both business users, who describe desired results in application terms, and technical users, who name tables and columns directly. Existing Text-to-SQL and Text-to-Python benchmarks provide coverage, but they do not isolate when SQL and pandas performance diverge. We introduce BIRD-Persona, a persona-stratified extension of BIRD-Python that adds novice/expert rewrites (business-style and technical-style phrasing) to tasks with matched SQL and pandas ground truth, plus schema variants and task-structure annotations. Across 1,534 tasks, nine models, and 245,592 evaluations, BIRD-Persona reproduces the previously reported SQL-over-Python gap: SQL outperforms pandas for eight of nine systems. The gap is not uniform: expert, schema-explicit prompts improve both paradigms but help SQL more, schema representations have mixed model-dependent effects, and selected-column burden widens the gap while subqueries do not. By making user phrasing a controlled benchmark dimension, BIRD-Persona provides a foundation for persona-aware and paradigm-aware evaluation of natural-language analytics systems.

1 Introduction

LLMs are increasingly used to translate natural-language data requests into executable code, letting users retrieve and analyze data without writing programs by hand. In user-facing analytics systems, the same database may serve both business users, who describe desired outcomes in application terms, and technical users, who name tables and columns directly. The generated code typically follows one of two paradigms: Text-to-SQL, which targets relational databases, and Text-to-Python, where the Python target is pandas code over tabular data. Because SQL expresses relational operations declaratively while pandas requires step-by-step dataframe operations, a matched benchmark that pairs SQL queries and pandas code for the same underlying task can measure when user phrasing and target paradigm affect reliability.

Existing benchmarks provide important coverage for each paradigm, but they do not show which user, system, and task conditions widen or narrow the SQL-pandas gap. Text-to-SQL benchmarks such as Spider (Yu et al., 2018), BIRD (Li et al., 2023), and Spider 2.0 (Lei et al., 2025) cover increasingly realistic database-grounded and enterprise settings, while DSCodeBench (Ouyang et al., 2026) evaluates realistic Python data-science code generation. Closest to our setting is BIRD-Python (Hu et al., 2026), which aligns each question with both SQL and pandas solutions, allowing Text-to-SQL and Text-to-Python to be compared on the same analytics task. The user condition is especially relevant: prior work shows that user expertise affects satisfaction and engagement in general LLM interactions (Palta et al., 2025), further motivating a persona-aware evaluation axis for code generation. A more detailed summary of related works is provided in App. A.1.

Motivated by these gaps, we introduce BIRD-Persona, a persona-stratified extension of BIRD-Python. Starting from 1,534 BIRD-Python tasks with matched SQL and pandas ground truth, we construct novice/expert rewrites of each question, corresponding to business-style and technical-style

[*]Equal contribution.

EMNLP 2026 Industry Track, pages 2311–2332
October 24-29, 2026 ©2026 Association for Computational Linguistics

phrasing, while preserving the intended answer. We further add schema variants and task-structure annotations, including structural-complexity features and operation tags, to support diagnostic evaluation beyond aggregate accuracy. We evaluate nine LLMs across SQL and pandas targets, original, business-style, and technical-style persona conditions, and three schema representations.

We use BIRD-Persona to show how the SQL-pandas gap changes across user, task, and system conditions. After reporting descriptive accuracy by model, user phrasing, schema representation, and task structure, we fit mixed-effects logistic models to estimate whether phrasing specificity, structural complexity, and schema representation are associated with that gap. This moves beyond a single leaderboard score toward a practical question: when is one paradigm more reliable than the other?

Using BIRD-Persona, we first reproduce the previously reported SQL-over-Python gap, validating the benchmark against prior cross-paradigm results, and then reveal three patterns that aggregate accuracy obscures. First, technical-style, schema-explicit phrasing improves both paradigms, but benefits SQL more than pandas. Second, richer schema representations produce mixed, model-dependent effects rather than a consistent improvement. Third, aggregate structural complexity captures broad difficulty but misses finer effects; selected-column burden and subquery structure shift the SQL-pandas gap in opposite directions. In summary, we have the following **Main Contributions:**

- **BIRD-Persona**, to our knowledge the first benchmark to make persona-based user phrasing a controlled dimension for matched SQL and pandas analytics code generation, augmented with schema variants, structural-complexity features, and operation tags.
- An evaluation of nine LLMs across SQL and pandas targets, persona conditions, and schema representations, reproducing the previously reported SQL-over-Python gap.
- A diagnostic analysis showing that the SQL-pandas gap varies with phrasing specificity, schema representation, and task structure, revealing patterns hidden by aggregate accuracy alone.

2 Methods

We build on BIRD-Python, which pairs each natural-language analytics question with semantically aligned SQL and pandas implementations (Hu et al., 2026). Using this corpus, we construct a benchmark and evaluation protocol for comparing target paradigms under controlled variation in user phrasing and schema representation, with task-structure annotations for diagnostic analysis. We then use this benchmark to analyze when performance differs between SQL and pandas.

Dimension	Novice	Expert
Schema/Scope	Business terms	Table and column names
Values	Approximate dates or values	Formats, units, constants
Logic	Implicit grain, ties, nulls	Explicit grain, ties, nulls
Output Specificity	Minimal presentation detail	Sort, limits, column order

Table 1: Persona rewrite controls used to separate business-style and schema-explicit phrasings while preserving the intended answer.

2.1 Dataset Construction

Our base corpus contains 1,534 BIRD-Python source tasks. Each item includes an original natural-language question, database identifier, evidence string, gold SQL, gold pandas code, and BIRD difficulty label. The task, not the individual program, is the unit of analysis: the SQL and pandas programs are two implementations of the same intended request. We extend this corpus with user-phrasing variants, schema-representation variants, and task-structure annotations, described next.

2.1.1 Persona Paraphrase Generation

To vary user phrasing, we give each source task a novice rewrite and an expert rewrite, corresponding to business-style and technical-style phrasing, both intended to preserve the original answer. Together with the unmodified BIRD-Python question, these form three persona conditions: original, novice, and expert. The rewrites differ along four controlled specificity dimensions, shown in Table 1. We use novice and expert as shorthand for these two phrasing registers, business-style/underspecified versus schema-explicit, and they describe how a request is phrased rather than the cognitive expertise or proficiency of the person issuing it.

To quantify phrasing specificity, we score each question with the Persona Score (PS), a lexical-grounding measure of how explicitly the question mentions schema, value, and operator tokens from the gold SQL. For each gold SQL query, we extract a token set T containing table names, column names, string literals, dates, and numeric con-

stants, then normalize these tokens by lowercasing, removing quotes, and replacing identifier separators such as underscores with spaces. For a question q, we construct candidate n-grams $C(q)$ with $n \in \{1, 2, 3\}$ and compute character-level Ratcliff-Obershelp similarity (Ratcliff et al., 1988) between each SQL token $t \in T$ and each candidate phrase $c \in C(q)$. Greedy one-to-one matching then assigns each SQL token a real-valued score $r_t \in [0, 1]$, using each question token at most once. Here $r_t = 1$ indicates an exact lexical match, partial overlaps receive fractional credit, and unmatched SQL tokens receive $r_t = 0$.

The PS is:

$$\mathrm{PS}(q, \mathrm{SQL}) = \frac{1}{|T|} \sum_{t \in T} r_t^{\alpha}$$

where α is a contrast parameter; in our experiments, we set $\alpha = 1$, making it the direct average of matched similarities. Further details on generation and scoring appear in App. B.1.3 and App. B.1.4, respectively.

2.1.2 Structural Features and Operation Tags

To characterize task structure, we parse the gold SQL with SQLGlot (Mao, 2026) into an eight-dimensional feature vector comprising counts of distinct columns, tables, `WHERE` predicates, joins, aggregates, scalar functions, common table expressions, and nested subqueries. These features follow the query-structure profiling of Ma et al. (2024). We include the full vector with the released dataset and report its equally-weighted sum as the Structural Complexity Score (SCS).

2.1.3 Schema Generation

We evaluate three schema representations per database to compare raw DDL, data-profiled schema context, and LLM-enriched schema context:

- *DDL*: raw SQL `CREATE TABLE` statements from BIRD-Python, exposing table and column names, declared types, and constraints.
- *Schema*: a cognitive-catalog representation with row and column counts, column types, inferred roles, null and uniqueness rates, summary statistics, bounded example values, and available BIRD column descriptions, but no LLM-generated descriptions.
- *SchemaLLM*: the same catalog structure, supplemented with GPT-5.2-generated column descriptions and table summaries where original dictionaries are incomplete.

Additional details are in App. B.1.1.

2.2 Mixed-Effects Modeling

Each evaluation row is one generated answer for a task, LLM, target paradigm, persona condition, and schema representation. Because tasks repeat across prompt and schema conditions, and tasks from the same database share schema and domain context, we model execution accuracy with mixed-effects logistic regressions rather than treating rows as independent trials. Models are fit separately for each LLM so the estimated SQL-pandas gap and moderators are model-specific.

The outcome is binary semantic correctness. We execute generated SQL against the SQLite database and generated pandas against the corresponding CSV tables, then compare each output to the gold output using the BIRD-Python semantic-equivalence protocol (Hu et al., 2026). Every row also records the metadata needed to audit and stratify the results, including the generated code, execution output, judge output, errors, and timing.

The fixed effects encode the experimental factors. With SQL and Original DDL as reference levels for the categorical predictors, the Python coefficient estimates the pandas-SQL difference under the reference schema at mean-centered covariates. PS and SCS are standardized continuous covariates, making their effects comparable on the log-odds scale.

We fit two models that differ only in how they represent task structure. Both share the same outcome, random-effects structure, and a common set of fixed effects: paradigm, standardized PS, schema representation, and the Python interaction with each. The primary model adds the aggregate SCS and its Python interaction, testing whether structurally demanding tasks are harder overall and whether that burden is paradigm-specific. The focused model instead replaces SCS with four operation-level predictors chosen to probe structural patterns that plausibly differ between declarative SQL and procedural pandas: subquery presence, selected-column count, scalar-function presence, and join count, each with a Python interaction. We log-one-plus transform and standardize the selected-column and join counts to reduce skew from high-count queries, and treat subquery and scalar-function use as binary indicators, since their nonzero counts are sparse.

The random effects absorb the dependence induced by the matched design. A question-level intercept lets some tasks be intrinsically easier or harder across all conditions, a question-level paradigm slope lets the pandas penalty vary by task, and a database-level intercept captures shared schema and domain effects among questions from the same database. Full details are in App. B.4.

3 Experiments and Results

We first report artifact-level diagnostics for BIRD-Persona, then turn to model-based SQL-pandas analysis. The diagnostics establish persona separation and structural coverage; the mixed-effects analyses use these annotations to analyze execution accuracy across target paradigms.

3.1 Experiment Setup

We evaluate nine LLMs: Gemini-2.5-Flash and Gemini-2.5-Pro (Google, 2026), Gemma-4-26B (Google DeepMind, 2026), GPT-5-Mini and GPT-5.1 (OpenAI, 2026), Qwen3-14B and Qwen3-8B (Qwen Team, 2025a), Qwen3-Coder-30B (Qwen Team, 2025b), and GLM-4-32B (Z.ai, 2025). For each model, we run the full cross-product of two target paradigms (SQL and pandas), three persona conditions (original, novice, and expert), and three schema representations (Original DDL, Schema, and SchemaLLM). Seventeen samples from the base BIRD-Python dataset were missing gold SQL labels, and one sample was missing the query; we excluded these samples from the analysis. The resulting prediction-evaluation matrix contains 245,592 rows, or 27,288 evaluated predictions per model or 13,644 per model-paradigm pair. Generation is run with deterministic decoding where supported. We evaluate generations with the BIRD-Python semantic-equivalence protocol, yielding the binary `is_correct` outcome analyzed below.

3.2 Persona Quality Audit

The PS confirms that the expert rewrites are substantially more schema-explicit than the novice rewrites. Across all tasks, the mean schema-specificity score is 0.567 for novice questions and 0.960 for expert questions, with a mean expert-minus-novice gap of 0.393. The original BIRD-Python questions score 0.635 on average-closer to the novice end in 89.0% of tasks. We provide examples of persona-stratified queries in App. C.8.

Condition pair	BLEU-4 ↑	BLEU-2 ↑	Jaccard ↑
Original-novice	0.108	0.254	0.307
Original-expert	0.008	0.025	0.078
Novice-expert	0.005	0.018	0.066

Table 2: Mean pairwise overlap metrics. BLEU scores are symmetric sentence-BLEU averages. Lower values indicate greater lexical divergence.

As an audit of PS, we measured pairwise overlap among the original, novice, and expert questions (Table 2) to verify that the persona conditions were not minor rewrites. We reported symmetric sentence-level BLEU-4 and BLEU-2, plus lowercased whitespace-token Jaccard overlap to capture order-invariant vocabulary sharing. As expected, original-novice pairs overlapped most, reflecting everyday phrasings of the same request; pairs involving the expert rewrite overlapped less because they added schema names, joins, filters, and output constraints. This pattern confirmed the intended separation between business-style and schema-explicit phrasings. Additional word-count analyses are provided in App. C.1.

The audit identified 39 tasks with an expert-minus-novice gap below 0.2 (23 below 0.1); these are not necessarily invalid since short SQL with few extractable tokens yields uninformative scores, and all such rows are retained with their observed scores for explicit filtering.

A complementary blind human audit of 250 tasks found that all 150 representative-random pairs retained the reference task and that all 150 schema-explicit variants in this stratum contained only gold-supported constraints. All 40 schema-explicit variants in the targeted output-contract stratum were also gold-supported (App. B.1.5).

3.3 Structural and Operation Coverage

Table 3 shows the per-component and composite score distributions. The composite structural score spans a wide range (2-50, σ=4.8) with a median of 11 and an interquartile range of 8-13, indicating sufficient variance for quartile-based stratification despite the BIRD-derived complexity floor. Columns and scalar functions exhibit the highest per-component variance (σ=2.08 and 1.76), making them the primary drivers of task-level score differences.

Table 4 profiles the benchmark by database and BIRD-Python difficulty level. The average structural score increases from simple to moderate to

Feature	Mean	Median	Max	Std
Columns	4.71	5	30	2.08
Tables	1.96	2	5	0.72
WHERE predicates	1.54	1	8	0.95
Join pairs	0.96	1	6	0.79

Table 4: Average structural score for each database grouped by BIRD-Python difficulty level.

challenging tasks in every database, which supports using the continuous SQL-derived score as a finer-grained covariate while retaining BIRD-Python's coarse difficulty labels for descriptive stratification.

3.4 Dataset Release

The release retains all 1,534 source rows while marking analysis eligibility. The 18 samples missing gold SQL labels or queries are included in the dataset for visibility but excluded from all analyses. Public release of the dataset is undergoing institutional review and was pending at the time of final manuscript preparation. Subject to approval, the dataset and accompanying analysis code will be released through a public repository with appropriate documentation and licensing information.

3.5 Model-Based SQL-pandas Analysis

We next compare SQL and pandas execution accuracy using descriptive aggregates and two mixed-effects models.

Table 5 reports raw execution accuracy by model and output paradigm. SQL exceeds pandas for 8 of the 9 models, with gaps from 0.034 (GLM-4-32B) to 0.210 (Qwen3-Coder-30B). Gemma-4-26B is the only model with higher pandas than SQL accuracy.

Table 6 summarizes the same evaluation matrix by persona condition, schema representation, and binned SCS. Persona produces the largest descriptive shift: expert prompts reach 0.889 SQL and 0.765 pandas accuracy, while novice prompts fall to 0.561 and 0.494. Schema representation has a much smaller effect, consistent with the model-dependent schema results discussed below. Accuracy declines monotonically with SCS in both paradigms. Full model-by-persona and model-by-schema tables appear in App. C.4.

Model	pandas	SQL
Gemini-2.5-Flash	0.674 (0.004)	0.741 (0.004)
Gemini-2.5-Pro	0.714 (0.004)	0.765 (0.004)
Gemma-4-26B	0.666 (0.004)	0.623 (0.004)
GPT-5-Mini	0.612 (0.004)	0.714 (0.004)
GPT-5.1	0.634 (0.004)	0.721 (0.004)
Qwen3-14B	0.500 (0.004)	0.690 (0.004)
Qwen3-8B	0.574 (0.004)	0.690 (0.004)
Qwen3-Coder-30B	0.477 (0.004)	0.688 (0.004)
GLM-4-32B	0.587 (0.004)	0.621 (0.004)

Table 5: Execution accuracy by model and output paradigm, aggregated over all persona conditions and schema variants. Parentheses report binomial standard errors for the binary correctness indicator.

Factor	Condition	pandas	SQL
Persona	Expert	0.766 (0.002)	0.889 (0.002)
	Novice	0.494 (0.002)	0.561 (0.002)
	Original	0.553 (0.002)	0.634 (0.002)
Schema	Original DDL	0.608 (0.002)	0.704 (0.002)
	Schema	0.602 (0.002)	0.691 (0.002)
	SchemaLLM	0.604 (0.002)	0.689 (0.002)
SCS (Binned)	Low (0-10)	0.678 (0.002)	0.754 (0.002)
	Medium (11-20)	0.563 (0.002)	0.666 (0.002)
	High (21+)	0.338 (0.007)	0.468 (0.007)

Table 6: Execution accuracy by persona, schema representation, and binned SCS. Each row averages over models and all experimental factors other than the condition shown, separately by paradigm. Parentheses report binomial standard errors for the binary correctness indicator.

We next fit the mixed-effects models summarized in Section 2.2, with primary-model fixed effects in Table 7. After adjustment, the SQL advantage persists: the pandas coefficient is negative for 8 of 9 systems, from -0.65 (GLM-4-32B) to -2.25 (Qwen3-Coder-30B). Gemma-4-26B is again the exception, with an indistinguishable coefficient ($+0.01$, $p = 0.87$). The aggregate gap therefore persists after adjustment for PS, structure, schema representation, and question/database heterogeneity.

The primary model also reports the covariate effects. PS is positive for every model, and the pandas $\times$ PS interaction is negative for eight mod-

	Main Effects					*Interaction Effects*			
Model	**pandas**	**PS**	**SCS**	**Schema**	**SchemaLLM**	**pandas × PS**	**pandas × SCS**	**pandas × Schema**	**pandas × SchemaLLM**

GLM-4-32B	**-0.65**	**1.68**	**-0.50**	**-0.45**	**-0.53**	**-0.59**	-0.06	**0.19**	**0.35**

Table 7: Fixed-effect coefficients for the primary mixed-effects logistic regression model. Statistically significant results are **Bolded** ($\alpha = 0.05$) or **Underlined** ($\alpha = 0.01$) after FDR correction. p-values are reported in App. C.5.

els (Gemma-4-26B is the only positive interaction). Aggregate SCS is negative for all models and significant for most, while the pandas × SCS interaction is significant only for the three Qwen systems. Schema effects are less stable: both the main effects and pandas × schema interactions vary in sign and significance across models, matching the weak schema shifts in Table 6. Full coefficients, standard errors, and raw p-values are in App. C.5.

In an additional control for the raw number of gold table, column, and literal tokens named in the question, PS remained positive and FDR-significant in all nine models. Likelihood-ratio tests likewise showed that the PS terms improved fit beyond the raw token count in all nine models (App. C.7).

The focused decomposition model splits aggregate complexity into operation-specific predictors (full table in App. C.6). The pandas × log column-count coefficient is negative for 8 of 9 systems, the exception being GPT-5.1. The subquery main effect is negative for all models, while the pandas × subquery interaction is positive for all models. Join count and scalar-function presence show no comparable modality-specific pattern. Table 8 reports the corresponding structural interaction coefficients.

Model	**pandas × SUBQUERY**	**pandas × COLUMN**	**pandas × SCALAR**	**pandas × JOIN**
Gemini-2.5-Flash	**1.37**	-0.18	0.10	-0.01
Gemini-2.5-Pro	**0.71**	-0.11	0.29	-0.07
Gemma-4-26B	**2.39**	**-0.52**	-0.23	**0.39**
GPT-5-Mini	0.18	**-0.23**	0.22	-0.02
GPT-5.1	**0.85**	0.08	0.26	**-0.29**
Qwen3-14B	**1.05**	**-0.53**	-0.13	-0.06
Qwen3-8B	**0.82**	**-0.31**	0.00	-0.08
Qwen3-Coder-30B	**0.83**	**-0.52**	**0.35**	-0.09
GLM-4-32B	**1.15**	**-0.49**	**0.54**	0.12

Table 8: Selected interaction-effect coefficients from the structural decomposition model (full results in App. C.6). Subquery and scalar predictors are binary presence indicators; column and join predictors are standardized log counts. FDR-significant results are **bold** (α=0.05) or **underlined** (α=0.01).

4 Discussion

In this paper, we introduced BIRD-Persona as a benchmark for evaluating SQL and pandas generation under variation in user phrasing, schema representation, and task structure.

The pandas target remains less reliable than SQL for most systems. Across models, BIRD-Persona reproduces the SQL-over-Python pattern reported in prior cross-paradigm work: 8 out of 9 systems show lower pandas accuracy than SQL after accounting for phrasing specificity, schema representation, task structure, and repeated task/database effects. This suggests that target paradigm is not just a formatting choice. Generating pandas code requires models to sequence dataframe operations, manage intermediate objects, and preserve output shape, making it a deployment-relevant evaluation dimension. Gemma-4-26B is the sole exception, with higher pandas than SQL accuracy. A deeper analysis suggests this may be driven by a comparatively high SQL execution-error rate (16.4% vs. 9.8% for pandas; Table 10), where the most common failures are syntax/parse errors and references to nonexistent columns. This suggests that Gemma's lower SQL accuracy partly reflects difficulty producing executable SQL rather than an inability to solve the underlying task, though we avoid a stronger causal claim absent a dedicated ablation.

User phrasing is the central benchmark axis. Phrasing specificity is the most consistent predictor of correctness. Schema-explicit prompts improve both SQL and pandas, but the gain is larger for SQL, where named tables, columns, predicates,

and aggregation map directly onto target clauses. For user-facing analytics systems, business-style prompts are therefore not merely shorter technical prompts; they create a different reliability profile, especially when the target is pandas. This association persists even after controlling for the raw number of gold identifiers named in the prompt: PS remains a positive, significant predictor in all nine models (App. C.7), indicating that the effect is not driven solely by schema-token overlap.

Schema enrichment is model-dependent. Schema variants produce mixed, model-dependent effects rather than a consistent improvement. One possible explanation is that many BIRD-Python schemas have interpretable table and column names, so additional descriptions add little marginal information or introduce prompt noise; private or enterprise schemas with opaque abbreviations may behave differently.

Task structure explains where the gap appears. Aggregate structural complexity summarizes overall difficulty, but operation-level annotations better localize target-specific failures. Selected-column burden widens the pandas gap, plausibly because pandas code must explicitly select, name, and preserve output columns across intermediate steps. Subqueries, by contrast, are difficult overall but not uniquely difficult for pandas, since nested declarative structure can sometimes be decomposed into sequential dataframe transformations. This shows why aggregate accuracy alone is insufficient for diagnosing paradigm reliability.

Implications for user-facing evaluation. BIRD-Persona suggests evaluating SQL and pandas systems under real-world conditions: varying phrasing styles, available schema context at inference, and expected task structures. The benchmark can help to guide prompt and context design by identifying where clarification, schema grounding, or output-shape constraints are most needed.

5 Conclusion

We introduced BIRD-Persona, a persona-stratified extension of BIRD-Python for matched SQL and pandas analytics code generation. Across nine LLMs, the benchmark reproduces the previously reported SQL-over-Python gap while showing that the gap varies with user phrasing, schema representation, and task structure. These results argue for evaluation protocols that go beyond aggregate accuracy and test user-facing analytics systems under the user, system, and task conditions in which each target paradigm is expected to operate.

Limitations

This study has limitations at both the artifact and analysis levels. First, the persona paraphrase pipeline generates and filters rewrites automatically. The PS is useful for constructing schema-explicitness contrasts, but it measures schema grounding rather than full semantic fidelity to the gold task. We supplement these automated checks with a blind human audit of 250 paper eligible task triples-a representative random sample of 150 and 100 targeted cases using final adjudicated labels (App. B.1.5). Although the audit provides evidence of task preservation and gold-supported explicit constraints, it does not constitute exhaustive validation of all 1,534 tasks. The expert and novice conditions also differ not only in linguistic register but also in length and information content: expert rewrites average roughly 58 words versus 14 for novice and explicitly name schema identifiers, filters, and output constraints. Our expert-versus-novice contrast is therefore defined by schema explicitness, and the observed persona effects should not be attributed to register alone; isolating a pure register effect would require a schema-fixed, length-matched ablation that varies only phrasing while holding information content constant, which we leave to future work.

Second, all generated persona variants come from a single generator, which may imprint model-specific lexical and stylistic regularities on the novice and expert conditions. The generator is excluded from the evaluated systems, but we cannot fully rule out stylistic overlap with the downstream model families. Relatedly, the SchemaLLM descriptions are generated by GPT-5.2, which shares a model family with two evaluated systems (GPT-5.1 and GPT-5-Mini), raising the possibility of a within-family advantage. Empirically, we see no such pattern: SchemaLLM is not statistically significant for the within-family models. However, our design does not formally test this effect.

Third, the base tasks come from the publicly released BIRD development set, so possible exposure to the underlying schemas, SQL, or original questions cannot be ruled out for some evaluated models. This caveat applies mainly to the inherited base corpus rather than the newly generated

persona rewrites and schema variants; it may also help explain why added schema context yields only limited gains.

Fourth, the structural representation is deliberately simple and therefore partial. It captures major aspects of relational query structure, including joins, aggregations, selected columns, scalar functions, and subqueries, but does not characterize every source of task difficulty, and the operation tags are rule-based AST flags that do not yet cover all semantic operations.

In addition, we did not conduct a controlled scaling study and therefore cannot draw conclusions about the relationship between model size and the SQL-pandas gap. Several evaluated models are closed-weight with undisclosed parameter counts; even among open-weight models, size is confounded with architecture, training data, instruction tuning, and inference design. We leave a controlled model-scale analysis for future work.

Finally, our explanatory analyses are observational. The interaction patterns across user phrasing, paradigm, and task structure are therefore best interpreted as associations indicating when the SQL-pandas gap widens or narrows, not as proof of a single causal mechanism.

A Background

A.1 Related Work

Below we review related work on Text-to-SQL evaluation, Text-to-Python and cross-paradigm code generation, persona variability, schema representation, and structural complexity.

Realistic Text-to-SQL evaluation. Text-to-SQL benchmarks have moved from controlled cross-domain generalization toward larger, more realistic database settings. Spider established the standard multi-database benchmark for schema generalization (Yu et al., 2018), and BIRD added realistic database-grounded questions and execution (Li et al., 2023). Spider 2.0 shifts further toward enterprise analyst workflows with harder schemas and more realistic tasks (Lei et al., 2025), and UNITE offers a broader unified suite for Text-to-SQL evaluation (Lan et al., 2023). We build on this line but focus on matched SQL-pandas comparison and persona-stratified variation rather than expanding Text-to-SQL coverage alone.

Text-to-Python and cross-paradigm evaluation. Recent work has begun to evaluate data-analysis code generation beyond SQL. DSCodeBench studies realistic data-science problems in Python with executable tests across common libraries (Ouyang et al., 2026). Closest to our setting is BIRD-Python, which aligns each question with both SQL and pandas solutions, allowing Text-to-SQL and Text-to-Python to be compared on the same analytics task (Hu et al., 2026). We extend this setting with controlled persona rewrites, schema variants, and task-level covariates for analyzing when the paradigms diverge.

User variability, ambiguity, and robustness. Several lines of work show that user phrasing, expertise, and underspecification can substantially affect evaluation. Palta et al. (2025) study five levels of user expertise in general LLM interactions, but do not evaluate code generation tasks or matched novice and expert versions of the same task. In Text-to-SQL, AmbiQT and AmbiSQL make ambiguity explicit and show how multiple plausible interpretations complicate single-gold evaluation (Bhaskar et al., 2023; Ding et al., 2025). SEDE captures naturally underspecified questions from Stack Exchange (Hazoom et al., 2021), while work on healthcare Text-to-SQL highlights the effect of domain terminology, abbreviations, and typos (Wang et al., 2020). Spider-Syn studies robustness to meaning-preserving synonym substitutions (Gan et al., 2021). These works motivate our persona axis: novice and expert phrasings preserve the target answer while changing how much schema and operational detail is explicit.

Schema linking and schema representation. Schema information remains a central design variable in Text-to-SQL systems, even as stronger LLMs complicate earlier assumptions about explicit schema linking. Recent work studies whether schema linking remains necessary (Maamari et al., 2024), improves linking through bidirectional or contextual retrieval (Cao et al., 2024; Nahid et al., 2026), and scales linking to large multi-database settings (Wang et al., 2025b). CHESS provides a retrieval-heavy pipeline that uses contextual filtering for SQL synthesis (Talaei et al., 2024), while enterprise-oriented analysis argues that NL2SQL remains difficult under realistic schema complexity and ambiguity (Floratou et al., 2024). Our benchmark treats schema representation as an experimental condition and tests whether schema information changes SQL and pandas accuracy differently.

Complexity-aware Text-to-SQL analysis. Prior work also shows that aggregate benchmark scores can hide important variation across query structure. Ma, Pu, and Zhu compare TPC-DS, BIRD, and Spider through structural complexity features that capture columns, tables, predicates, joins, aggregates, scalar functions, common table expressions, and subqueries (Ma et al., 2025). Related work on SQL-complexity measurement for LLM evaluation motivates treating query structure as a continuous covariate rather than only a coarse difficulty label (Ma et al., 2024). Beyond SELECT further argues that realistic Text-to-SQL evaluation should cover a wider range of SQL operations than SELECT-heavy benchmarks (Wang et al., 2025a). We adopt this complexity-aware view to analyze whether structural features affect Text-to-SQL and Text-to-Python differently.

B Method & Experiment Details

B.1 Artifact Generation

B.1.1 Schema Variant Construction

Schema variants are generated once per database and reused across all questions from that database. The construction uses the BIRD-Python SQLite databases, flat CSV exports, and database-description files. The current schema-variant man-

ifest covers 11 databases, 75 tables, and 798 columns. Of the 798 original dictionary rows, 652 contain non-empty source column descriptions and 146 are missing source descriptions.

The `original_ddl` variant is written directly from SQLite metadata by extracting the `CREATE TABLE` statements for each non-system table. The two catalog variants are built by running the cognitive catalog pipeline over the flat CSV tables and then rendering a text catalog for prompting. The `cognitive_with_descriptions` variant keeps only the source-provided BIRD column descriptions. The `cognitive_with_llm_descriptions` variant keeps the same catalog shape but uses the cognitive engine's native LLM-facing catalog text, which includes LLM-filled missing column descriptions and LLM-generated table descriptions.

B.1.2 Structural Feature Definition Details

Our structural-complexity representation is an eight-dimensional feature vector computed from the gold SQL AST. The dimensions are: number of distinct column references, number of physical tables, number of atomic `WHERE` predicates, number of join pairs, number of aggregate expressions, number of non-aggregate scalar function calls, number of common table expressions, and number of nested subqueries. The scalar `task_structural_score` used in the main paper is the equal-weight sum of these counts.

B.1.3 Persona Rewrite Generation

For each BIRD-Python task, GPT-5.2 received the original question and gold SQL. The implementation supports optional schema context, but it was not supplied in the full-dataset generation run. The database identifier is used only for logging. It returns a business-style/underspecified rewrite and a schema-explicit rewrite as a JSON object. The prompt controls four dimensions: schema and scope, values and formats, logic and business rules, and output formatting and constraints. It instructs the generator to keep both rewrites anchored to the source task (entity, measure, population, and goal), to make expert-only explicit details gold-supported, and to let the business-style rewrite omit detail without introducing a contradictory constraint. Thus, these are generation constraints rather than a claim that every rewrite alone uniquely determines the gold executable query.

After each parseable response, we compute the expert-minus-novice PS gap. We accept a pair when the gap is at least 0.2; otherwise, we append feedback that lists up to 15 extracted SQL tokens, asks the schema-explicit rewrite to state them and its supported values and output constraints, and asks the business-style rewrite to avoid schema-specific terms. We make up to three scored attempts. If no SQL tokens can be extracted, we accept the first parseable response because the gap cannot be evaluated. After exhausted attempts, the pipeline makes one final best-effort call with the latest feedback; if it cannot produce parseable JSON, the task is recorded as a generation failure. The released artifact retains the final questions, scores, and gap, including pairs below the threshold. Of the 1,534 released pairs, 39 remain below the 0.2 threshold after generation; they are retained and identifiable from $\texttt{gap} < 0.2$.

Prompt specification. The GPT-5.2 system prompt requested two complete, grammatical JSON fields: `expert` and `novice`. It specified the four controls above. For the schema-explicit field, it required exact table and column names, gold literal values, and all gold-supported aggregation, tie-breaking, null-handling, ordering, limit, and output-column constraints; joins and computations had to be described in natural language rather than transcribed as SQL. For the business-style field, it prohibited verbatim schema identifiers and literal SQL values and requested business vocabulary with implicit logic and presentation details. Both fields were instructed to retain the source task's entity, measure, population, and goal; the business-style field could omit detail but could not introduce a new filter, condition, or constraint.

The exact versioned system prompt and retry-feedback template will accompany the released source artifact.

B.1.4 Persona-Score Details

The Persona Score (PS) measures this phrasing specificity, the explicitness of schema, value, and operator mentions, rather than semantic equivalence. Given a gold SQL query and a question q, we extract schema and value tokens T from the SQL, including table names, column names, string literals, date strings, and numeric constants. SQL parsing is performed with SQLGlot, using the SQLite dialect first and a dialect-unspecified parse as a fallback; the scorer walks the SQL abstract syntax tree and records table nodes, non-$*$ column nodes, and literal nodes. If parsing fails, a

regex fallback extracts quoted string literals, backtick identifiers, numeric literals, and non-keyword word tokens. Extracted tokens are normalized by lowercasing, stripping quotes, and replacing identifier separators such as underscores with spaces, then deduplicated after filtering SQL keywords and tokens shorter than two non-space characters.

For each question, we construct candidate spans $C(q)$ from unigrams, bigrams, and trigrams over lowercased regex word tokens. Punctuation separates words, while underscores are retained by the tokenizer; therefore a query mention such as `customer_id` is a high character-level match to the normalized SQL token *customer id*, but is not forced to be an exact match. Similarity between a SQL token $t \in T$ and candidate span $c \in C(q)$ is the character-level Ratcliff-Obershelp ratio,

$$s(t, c) = \frac{2m(t, c)}{|t| + |c|},$$

where $m(t, c)$ is the total length of non-overlapping matching character blocks. This lexical score intentionally rewards exact or near-exact schema mentions rather than semantic synonyms; for example, a question that says *client* should not receive the same schema-specificity credit as one that names `customer_id`.

To avoid double-counting, we greedily sort all token-candidate pairs by similarity and accept pairs in descending order only when neither the SQL token nor any word in the candidate span has already been used. This one-to-one constraint prevents a single vague word such as *customer* from satisfying several schema tokens such as `customer_id`, `customer_name`, and `customer_type`. The accepted ratio for SQL token t is denoted $r_t \in [0, 1]$, with $r_t = 1$ for an exact lexical match and $r_t = 0$ for unmatched tokens. When T is nonempty, the final score is the mean α-transformed matched similarity over extracted SQL tokens,

$$\mathrm{PS}(q, \mathrm{SQL}) = \frac{1}{|T|} \sum_{t \in T} r_t^{\alpha}.$$

The contrast parameter α controls how strongly partial lexical matches are penalized. The experiments use $\alpha = 1$, which leaves the raw Ratcliff-Obershelp ratios unchanged; larger values would increasingly penalize partial matches while preserving exact matches.

For a paraphrase pair, we compute $\mathrm{gap} = \mathrm{PS}(q_{\mathrm{expert}}, \mathrm{SQL}) - \mathrm{PS}(q_{\mathrm{novice}}, \mathrm{SQL})$. The generation loop compares this gap with a configurable target. If the gap is smaller, feedback is appended to the prompt asking the expert rewrite to include concrete schema identifiers and the novice rewrite to avoid them; regeneration is attempted up to three times. The final dataset preserves the original, novice, and expert scores and the expert-minus-novice gap for downstream auditing, including rows whose final gap remains small after retry.

B.1.5 Human Validation and Semantic Preservation

We conducted a single-blind audit of 250 paper-eligible task triples. The sample contains a representative random stratum of 150 tasks and 100 targeted tasks: 40 with output contracts (ordering, limits, or output shape), 25 with filters or thresholds, 20 with aggregation or grouping, and 15 with joins or subqueries. The targeted strata are reported separately rather than treated as representative of the corpus.

Each task was assessed with the variants presented as A/B in randomized order. The blinded review included the original request, both variants, the full gold SQL, and a deterministic SQL-constraint summary, but not the persona labels, model predictions, or evaluation outcomes.

For each variant, the audit checked whether every explicit detail was supported by the gold SQL, whether the request contradicted the gold target, and whether the request and schema uniquely determined the gold output. It separately checked whether the pair retained the reference task's entity, measure, population, and goal. Omitting a gold detail in a business-style rewrite was not itself treated as a contradiction.

All 250 audited pairs retained the reference task, including all 150 pairs in the representative random stratum. Overall, 246 of 250 expert schema-explicit variants had all explicit constraints supported by the gold SQL; all 40 expert schema-explicit variants in the targeted output-contract stratum were gold-supported. These results assess task anchoring and support of stated details rather than assuming that every novice business-style request alone uniquely determines the gold executable query. In eight novice business-style variants from the random stratum, a gold-output constraint could not be inferred from the prompt alone. These cases were adjudicated as underdetermined rather than contradictory: the prompt did not state a constraint that conflicted with the gold target, and the shared reference task was preserved. Thus, missing an inferable output constraint was treated separately

from changing the task or introducing an unsupported requirement.

B.2 Release Eligibility

The source artifact has 1,534 unique question identifiers. Seventeen rows have empty gold SQL in the local BIRD-Python file and are quarantined from SQL-derived structural analyses. One row has an empty original question and is quarantined from original-question evaluation until repaired. Structural analyses therefore use the 1,517 rows with non-empty SQL and successful SQL parses. The dataset release preserves the quarantined rows for traceability but exposes `analysis_eligible` and `quarantine_reason` fields so that benchmark consumers can reproduce the main denominators.

B.3 Dataset Fields

The released table exposes the following fields for every source task: `question_id`, `db_id`, `difficulty`, `question`, `novice_question`, `expert_question`, `sql`, `code`, `evidence`, `original_similarity_score`, `novice_similarity_score`, `expert_similarity_score`, `gap`, `structural_features`, `extended_constructs`, `task_structural_score`, `operation_tags`, `analysis_eligible`, and `quarantine_reason`. The eligibility fields are required because the source artifact intentionally preserves rows that are excluded from one or more analyses.

B.3.1 Evaluation Row Schema

Each prediction row includes `question_id`, `db_id`, `difficulty`, `persona_condition`, `question_field`, `paradigm`, `model_id`, `code`, `input_tokens`, `output_tokens`, and `elapsed_sec`. Each evaluation row should additionally include `is_correct`, `actual_output`, `expected_output`, `judge_actual_output`, `judge_expected_output`, `llm_response`, and `error`. This schema is intentionally redundant so that aggregate tables can be reproduced without reconstructing metadata from separate files.

B.4 Mixed-Effects Model Specifications

This appendix gives the full statistical specification used for the reported explanatory analyses. All reported regressions are fit separately for each evaluated LLM. The unit of observation is one model output for a fixed task, target paradigm, persona condition, and schema condition. The response variable is binary semantic correctness after execution-based evaluation:

$$y_i = \begin{cases} 1, & \text{if output } i \text{ is semantically correct,} \\ 0, & \text{otherwise.} \end{cases}$$

We use a binomial generalized linear mixed model with a logit link. For each observation i, let $q(i)$ denote its question identifier and $d(i)$ denote its database identifier. SQL is the reference paradigm, and original DDL is the reference schema representation. The pandas indicator is denoted P_i, where $P_i = 1$ for pandas and $P_i = 0$ for SQL.

B.4.1 Shared Preprocessing

We first restrict the modeling data to complete cases for the response, question identifier, database identifier, persona score, and all covariates included in the corresponding model. Before fitting these models, we also apply the analysis exclusion filter from the notebook, removing 17 question identifiers with missing or unverifiable ground-truth labels. This leaves 1,517 source tasks and 27,306 observations in each LLM-specific model fit. The paradigm factor is encoded with SQL as the reference level:

$$\texttt{paradigm} \in \{\texttt{sql}, \texttt{pandas}\}.$$

Schema representation is encoded as a three-level factor with levels DDL, Schema, and SchemaLLM. DDL is the reference level. The two non-reference schema indicators are denoted S_i^{Schema} and $S_i^{\text{SchemaLLM}}$.

Persona specificity is computed from the overlap between the question text and SQL-grounded schema and literal tokens, as described in Section 2. For each observation, we use the score associated with that observation's persona condition. The score is standardized within the analysis data:

$$Z_i^{\text{persona}} = \frac{\text{persona_score}_i - \overline{\text{persona_score}}}{\text{sd}(\text{persona_score})}.$$

All continuous structural predictors are standardized after any transformation specified below. Thus, continuous coefficients correspond to a one-standard- deviation increase in the transformed predictor.

B.4.2 Primary Aggregate-Complexity Model

The primary model estimates the overall SQL-pandas gap and how that gap changes with persona specificity, aggregate structural complexity, and schema representation. The aggregate structural score is the equal-weight sum of the eight

SQL-derived structural feature counts:

$$C_i = c_i^{\text{col}} + c_i^{\text{tab}} + c_i^{\text{where}} + c_i^{\text{join}} + c_i^{\text{agg}} + c_i^{\text{scalar}} + c_i^{\text{cte}} + c_i^{\text{subq}}.$$

We standardize this score before modeling:

$$Z_i^{\text{complexity}} = \frac{C_i - \overline{C}}{\text{sd}(C)}.$$

For compactness, let Z_i^A denote standardized persona specificity and let Z_i^C denote standardized aggregate complexity. The primary fixed-effect linear predictor is

$$\begin{aligned}\eta_i = {} & \beta_0 + \beta_P P_i + \beta_A Z_i^A + \beta_C Z_i^C \\ & + \beta_D S_i^{\text{Schema}} + \beta_L S_i^{\text{SchemaLLM}} \\ & + \beta_{PA} P_i Z_i^A + \beta_{PC} P_i Z_i^C \\ & + \beta_{PD} P_i S_i^{\text{Schema}} + \beta_{PL} P_i S_i^{\text{SchemaLLM}} \\ & + b_{0,q(i)} + b_{P,q(i)} P_i + u_{0,d(i)}.\end{aligned}$$

The response model is

$$y_i \sim \text{Bernoulli}(\pi_i), \qquad \text{logit}(\pi_i) = \eta_i.$$

The question-level random effects allow each question to have its own baseline difficulty and its own pandas-vs-SQL shift:

$$\begin{pmatrix} b_{0,q} \\ b_{P,q} \end{pmatrix} \sim \mathcal{N}\left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \Sigma_q \right).$$

The database-level random intercept is

$$u_{0,d} \sim \mathcal{N}(0, \sigma_d^2).$$

In `lme4` notation, the model is:

```
correct_semantic ~
  paradigm * z_persona_score +
  paradigm * z_complexity +
  paradigm * schema_variant +
  (1 + paradigm | question_id) +
  (1 | db_id)
```

The coefficient β_P estimates the pandas-vs-SQL difference at mean persona specificity, mean aggregate complexity, and original DDL schema. Interaction coefficients such as β_{PA} and β_{PC} estimate how the pandas-vs-SQL gap changes as persona specificity or aggregate complexity increases.

B.4.3 Focused Structural Decomposition Model

The focused structural decomposition model replaces the aggregate complexity score with a small set of operation-specific predictors chosen to test modality-specific procedural burden. The included structural dimensions are subquery presence, selected-column count, scalar-function presence, and join count. These dimensions capture nested decomposition, output projection burden, local transformation burden, and relational composition, respectively. Common table expressions are excluded because they occur in only 1.1% of questions, making model-based estimates unstable and likely to be driven by a small number of items. `WHERE` predicate count, aggregate count, and physical table count are omitted from the focused model to keep the confirmatory structural interaction family small and theoretically targeted; the aggregate-complexity model already captures overall task difficulty.

The analysis notebook also fits a broader seven-feature structural decomposition as an exploratory intermediate model. The reported structural tables use the focused specification below.

For selected columns and join pairs, we apply a log-one-plus transformation and then standardize:

$$Z_{ik}^{\log} = \frac{\log(1 + c_{ik}) - \overline{\log(1 + c_k)}}{\text{sd}(\log(1 + c_k))}.$$

The $\log(1+x)$ transform preserves the ordering and zero values of the original count variables while reducing leverage from rare high-count examples. After standardization, the column-count and join-count coefficients are interpreted as effects of a one-standard-deviation increase in the log-transformed count. Subqueries and scalar functions are encoded as binary presence indicators:

$$H_i^{\text{subq}} = \mathbb{1}\{c_i^{\text{subq}} > 0\},$$
$$H_i^{\text{scalar}} = \mathbb{1}\{c_i^{\text{scalar}} > 0\}.$$

The binary encoding is used for these dimensions because the scientific question is whether the operation type is present, and because the nonzero count distributions are sparse relative to selected columns and joins.

Let $Z_i^{\log,\text{col}}$ denote standardized log selected-column count and let $Z_i^{\log,\text{join}}$ denote standardized log join-pair count. The focused structural decomposition linear predictor is

$$\begin{aligned}\eta_i = {} & \beta_0 + \beta_P P_i + \beta_A Z_i^A \\ & + \beta_Q H_i^{\text{subq}} + \beta_M Z_i^{\log,\text{col}} \\ & + \beta_F H_i^{\text{scalar}} + \beta_J Z_i^{\log,\text{join}} \\ & + \beta_D S_i^{\text{Schema}} + \beta_L S_i^{\text{SchemaLLM}} \\ & + \beta_{PA} P_i Z_i^A \\ & + \beta_{PQ} P_i H_i^{\text{subq}} \\ & + \beta_{PM} P_i Z_i^{\log,\text{col}} \\ & + \beta_{PF} P_i H_i^{\text{scalar}} \\ & + \beta_{PJ} P_i Z_i^{\log,\text{join}} \\ & + \beta_{PD} P_i S_i^{\text{Schema}} + \beta_{PL} P_i S_i^{\text{SchemaLLM}} \\ & + b_{0,q(i)} + b_{P,q(i)} P_i + u_{0,d(i)}.\end{aligned}$$

The response distribution and random-effect distributions are the same as in Appendix B.4.2. In `lme4` notation, the model is:

```
correct_semantic ~
  paradigm * z_persona_score +
  paradigm * has_subquery +
  paradigm * z_log_column_count +
  paradigm * has_scalar_function +
  paradigm * z_log_join_count +
  paradigm * schema_variant +
  (1 + paradigm | question_id) +
  (1 | db_id)
```

For a structural feature k, the corresponding main-effect coefficient is the effect of that feature for SQL, the reference paradigm. The interaction with P_i is the additional effect for pandas relative to SQL. Therefore, the total pandas-side effect of that feature is the sum of the main effect and the pandas interaction. This decomposition is the basis for statements about which structural operations widen or narrow the SQL-pandas gap.

B.4.4 Estimation and Reporting

The two reported model families are estimated with maximum likelihood using the Laplace approximation as implemented in `lme4::glmer`. We use a binomial family with a logit link and the `bobyqa` optimizer with `maxfun = 2e5`. Each model is fit independently for each LLM, so fixed effects are interpreted within model rather than as pooled cross-model contrasts. We report fixed-effect estimates on the log-odds scale, with standard errors, Wald z statistics, and Wald p-values. We also report model fit summaries, including AIC, BIC, log likelihood, AUROC, and the number of observations used in each fit.

For multiplicity-aware interpretation, the fixed-effect output files also include Benjamini-Hochberg false-discovery-rate thresholds and significance indicators. The correction family is defined conservatively within each model table as all non-intercept fixed-effect tests across the nine LLM-specific fits. Intercepts are excluded because the null hypothesis that the baseline log-odds equals zero is not a scientific hypothesis of interest. Full result tables report raw Wald p-values, while the summary tables use the corrected indicators for significance formatting after accounting for multiple comparisons.

The random-effect term $(1 + \texttt{paradigm} \mid \texttt{question_id})$ is included because the SQL-pandas gap can vary by item. The random intercept captures question-level baseline difficulty, while the random pandas slope captures question-specific deviation from the average pandas-vs-SQL effect. The term $(1 \mid \texttt{db_id})$ captures residual database-level heterogeneity. These random effects are not nuisance terms only: their variance components are used to assess whether the modality gap is a global offset or varies substantially across questions.

Condition	Mean score	Median score	Mean words	Median words
Original	0.635	0.630	14.5	14.0
Novice	0.567	0.570	14.3	14.0
Expert	0.960	0.971	57.6	56.0

Table 9: Persona quality audit.

C Additional Results

C.1 Persona Word-Count Audit

A word-count analysis (Table 9) reveals that expert rewrites are nearly four times longer than original questions (mean 57.6 vs. 14.5 words), reflecting the additional schema references, filter specifications, and output constraints they encode. Novice questions average 14.3 words, only a 0.2 word difference from the original query, suggesting that the persona manipulation changes specificity rather than verbosity at the business-level register.

C.2 Persona-Score Example

Consider a gold query whose extracted tokens include `customer_id`, `order_id`, `total_amount`, `order_date`, `orders`, `customer_name`, and date literals. After SQL-token normalization, these become spans such as *customer id*, *order id*, and *total amount*. A novice question such as *Show me each customer's biggest recent order* contains useful business words, but it does not name most schema identifiers. Without one-to-one matching, the word *customer* could partially satisfy both *customer id* and *customer name*, and the word *order* could partially satisfy *order id*, *order date*, and *orders*. The greedy matching step prevents this inflation by allowing each question word to contribute to at most one SQL token.

Under the greedy assignment, the novice phrasing receives high credit for only a small number of root-word overlaps, while missing dates and specific columns contribute zero or near-zero scores. An expert phrasing such as *For each customer_id, return the order_id with max total_amount where order_date is in 2024, sorted by customer_name* directly names the schema fields and therefore receives high per-token ratios for most identifiers. In the worked example from the pipeline documentation, the novice matched ratios average to roughly 0.33, while the expert ratios average to roughly 0.69, yielding an expert-minus-novice gap of about

Model	SQL error rate	pandas error rate
Gemini-2.5-Pro	0.3%	3.6%
Gemini-2.5-Flash	1.7%	7.0%
GPT-5.1	1.9%	4.0%
GPT-5-Mini	1.9%	2.2%
Qwen3-14B	4.2%	19.7%
Qwen3-8B	5.0%	19.1%
Qwen3-Coder-30B	5.4%	20.5%
GLM-4-32B	10.5%	12.9%
Gemma-4-26B	16.4%	9.8%

Table 10: Execution-error rates by model and output paradigm, aggregated over all persona conditions and schema variants. A generation counts as an execution error when it raises a runtime error (an SQLite error for SQL, or a Python exception for pandas). Gemma-4-26B is the only model whose SQL error rate exceeds its pandas error rate, consistent with its outlier pandas-over-SQL accuracy in Table 5.

0.36. If a generated pair falls below the configured gap target, the pipeline asks the generator to make the expert rewrite more schema-specific and the novice rewrite less schema-specific; after retries, the final artifact retains the observed scores so low-gap rows can be audited rather than silently discarded.

C.3 Execution-Error Analysis

Table 10 reports execution-error rates by model and output paradigm. Gemma-4-26B is the only model whose SQL error rate (16.4%) exceeds its pandas error rate (9.8%); this 6.6-point difference is larger than its 4.3-point pandas accuracy advantage. Inspecting Gemma's recorded SQL errors shows the most common categories are syntax/parse errors and references to nonexistent columns, suggesting the lower SQL accuracy is driven in part by difficulty producing executable SQL rather than necessarily reflecting an inability to solve the underlying data-analysis task.

C.4 Prediction Evaluation Tables

Tables 11 and 12 expand the main raw evaluation summary. These tables report descriptive execution accuracy and are not adjusted for question- or database-level dependence. They are included to make the evaluation matrix auditable before the mixed-effects analyses.

C.5 Detailed Logistic Regression Model Results: Main Model

Table 13 reports the full fixed-effect coefficient table for the primary mixed-effects logistic regression, estimated separately for each of the nine LLMs. Predictors are on the logit scale.

Table 14 reports the model fit summaries for the primary mixed-effects logistic regression, including AIC, BIC, log likelihood, and AUROC for each LLM-specific fit.

Table 15 reports the random-effect summaries for the primary mixed-effects logistic regression, including query-level and database-level variance components for each LLM-specific fit.

C.6 Detailed Logistic Regression Model Results: Structural Decomposition Model

Table 16 reports the full fixed-effect coefficient table for the focused structural decomposition mixed-effects logistic regression, estimated separately for each of the nine LLMs.

Table 17 reports the model fit summaries for the focused structural decomposition mixed-effects logistic regression, including AIC, BIC, log likelihood, and AUROC for each LLM-specific fit.

Table 18 reports the random-effect summaries for the focused structural decomposition mixed-effects logistic regression, including query-level and database-level variance components for each LLM-specific fit.

C.7 Schema-Token-Count Control for Persona Specificity

Because the expert persona condition is constructed to name gold schema and value tokens, the Persona Score (PS) could in principle reduce to a schema-leakage effect: prompts that copy more gold identifiers are trivially easier to answer. We test this directly by asking whether PS retains explanatory signal beyond the raw number of gold identifiers named in the question.

We first note that schema availability is already a covariate in the primary model: the *Schema* and *SchemaLLM* terms encode inclusion of the DDL/catalog schema block and, for *SchemaLLM*, additional LLM-generated column and table descriptions. The expert rewrites do not disclose identifiers the model otherwise lacked; they specify which of the already-available identifiers are relevant. These schema covariates show only small, model-dependent effects (Table 7), so simply adding schema information does not reliably improve performance.

We next implement an additional covariate to control for schema leakage. We define *raw schema-token count* as the number of gold SQL tokens (table names, column names, and literal values)

Table 13: Full fixed-effect results for the primary mixed-effects logistic regression, estimated separately for each LLM. Logit-scale coefficients, standard errors, and p-values are reported in separate row groups.

that appear in the question. We add this count, together with a paradigm (SQL/pandas) interaction, to the primary per-model GLMM (App. B.4.2). Although PS and the raw token count are correlated ($r = 0.74$), their variance inflation factor is low (VIF $= 2.24$), indicating that the two predictors carry enough independent variation to be estimated jointly.

Table 19 reports the results. After adding the control, the PS coefficient remains positive and significant in 9/9 models after FDR correction (all $p < 10^{-23}$). A likelihood-ratio test on the two PS terms (main effect and paradigm interaction) confirms that they improve fit beyond the raw to-

Model	AIC	BIC	Log Likelihood	AUROC

GLM-4-32B	24796.81	24911.81	-12384.40	0.933

Table 14: Model fit summaries for the primary mixed-effects logistic regression, estimated separately for each LLM.

ken count in 9/9 models after FDR correction (all $p < 10^{-47}$). The paradigm effect is likewise unaffected: the pandas coefficient remains negative and significant in 8/9 models, with Gemma-4-26B the only exception, matching the primary results. These results indicate that Persona phrasing predicts accuracy beyond the number of gold identifiers named, which is contra-indicative of a pure schema-leakage explanation.

C.8 Persona Stratification Examples

Table 20 shows representative persona-stratified questions from the released artifact. The novice rewrites preserve the user request in business-style language, while the expert rewrites make the schema linkage, filters, joins, and output constraints explicit. The PS values show the intended increase in schema specificity from novice to expert phrasing.

Abstract

For emerging scientific research domains, local Small Language Models (SLMs) are becoming more attractive, as they offer stronger privacy control and more stable deployment pipelines than Large Language Models. However, in practice, scientific question-answering on SLMs often operates under inevitable constraints: small literature collections, fragmented evidence, limited context window and reasoning abilities. We propose the Evidence-Grounded Typed Knowledge Graph (EGT-KG), a retrieval framework to improve information retrieval with local SLMs. We assessed three question-answering settings: a vanilla Retrieval-Augmented Generation (RAG) workflow and two EGT-KG workflows: an automatically generated relation schema (AS) and an expert-defined relation schema (ES). Our experiments were evaluated with a six-dimensional evaluation framework (S3CRF: Soundness, Correctness, Completeness, Conciseness, Relevance, Fluency) on a Biopolymer-bound Soil Composite literature benchmark, showing that EGT-KG outperforms the vanilla RAG method in most settings, with the best improvement from *llama3:8b*: a Final Score of 70.37 (+14.67%) and 68.82 (+12.14%) by AS/ES EGT-KG variants.

1 Introduction

The rapid evolution of Large Language Models (LLMs) has changed the paradigm in scientific knowledge discovery and human-AI collaboration, including scientific question-answering (Zheng et al., 2025). However, the deployment of frontier LLMs for specialized research workflows can raise concerns about data privacy, operational costs, and inference latency (Pan et al., 2025; Cai et al., 2024). Therefore, Small Language Models (SLMs) have become increasingly attractive for domain-specific applications in constrained environments (Wang et al., 2025; Lu et al., 2024). Yet, SLMs are often unreliable for specialized scientific question-answering because they have limited internal knowledge, weaker reasoning ability, and lower tolerance for noisy context than frontier LLMs (Allen-Zhu and Li, 2024; Lee et al., 2026; Mallen et al., 2023). This challenge is particularly critical in emerging research domains, where knowledge is fragmented across a small set of knowledge sources and is not well represented in pretraining corpora.

Retrieval-Augmented Generation (RAG) (Lewis et al., 2021) can ground local models in external documents, but conventional dense retrieval is often insufficient for scientific QA. Scientific questions may depend on relations among materials, procedures, conditions, observations, and results, while dense RAG mainly retrieves chunks by semantic similarity. As a result, retrieved passages may be broadly relevant but still miss the specific evidence needed for faithful answering.

Graph-based RAG methods address part of this issue by organizing information into entities and relations (Edge et al., 2024). However, general knowledge graphs may lack timeliness and fine-grained domain knowledge (Ding et al., 2024), and automatically constructed graphs can introduce noisy or ambiguous relations (Schäfer et al., 2024; Zhuang et al., 2025). Moreover, converting scientific narratives into triples may discard experimental context, conditional qualifiers, and quantitative details that are necessary for reasoning (Pujara et al., 2017).

We propose the Evidence-Grounded Typed KG (EGT-KG) framework to improve RAG with local SLMs in scientific question-answering settings. Our method extends graph-based retrieval with two principles: First, graph structures should guide retrieval rather than replace the original evidence. Second, the relation structure should be informative enough to be useful in retrieving. Thus, we construct a reified knowledge graph with evidence nodes and classified relations, allowing the system

EMNLP 2026 Industry Track, pages 2333–2354
October 24-29, 2026 ©2026 Association for Computational Linguistics

to use relation labels as a retrieval signal.

We evaluate our framework on Biopolymer-bound Soil Composite (BSC)-centered materials QA benchmark built from a 30-paper corpus. The knowledge of BSC is distributed across a compact but specialized literature collection, making it a realistic test case for small-corpus scientific QA.

We compared a vanilla RAG workflow with two EGT-KG variants: an automatically generated schema (AS) and an expert-designed schema (ES). The results show that EGT-KG enhanced retrieval improves answer quality for most cases, particularly in factual retrieval questions. The core contributions of this paper are summarized as follows: First, to enhance RAG in limited resource settings, we propose an Evidence-Grounded Typed KG framework that combines relation classification with provenance-aware evidence nodes for scientific question-answering with local SLMs. Second, we performed a controlled comparison on the BSC-centered benchmark between different workflows, systematically studying the trade-off between schema granularity and answer quality. Third, we introduce an S3CRF evaluation setting that combines multidimensional scoring (**S**oundness, **C**orrectness, **C**ompleteness, **C**onciseness, **R**elevance, and **F**luency) and retrieval performance analysis, illustrating how answer quality is affected by the six criteria, query expansion, fallback rate, and evidence-window usage.

2 Related Works

Retrieval. Retrieval-Augmented Generation (RAG) is a widely adopted approach to improving question-answering by providing external knowledge that is not stored in the model's parameters (Lewis et al., 2020). It can improve factual grounding and reduce hallucinations, demonstrating its potential for question-answering in professional domains such as medicine, education, and law (Fan et al., 2024). However, dense vector representations can lead to irrelevant documents, potentially ignoring explicit structured dependencies, properties, conditions, or procedures. In addition, computational overhead, memory usage, and RAG poisoning are of concern in the implementation of RAG system (Gupta et al., 2024; Greshake et al., 2023; Liu et al., 2025, 2024). Therefore, a cost-efficient, stable, and secure RAG system is demanded for sensitive tasks that require high precision.

Graph-RAG. Knowledge graph-enhanced retrieval methods mitigate the limitations of RAG by providing global descriptions and the hierarchical community structure of the corpus (Fu et al., 2025). Graph-RAG has shown that the graph structure can help multi-hop evidence discovery, avoiding the loss of target information in a single semantically similar chunk (Procko and Ochoa, 2024). However, current graph-based approaches compress the original text, which can potentially lead to information loss and further degrade response generation. Additionally, it also tends to utilize a large portion of triples in the knowledge graph. Without constraints, users may face context explosion and high reasoning costs (Xiang et al., 2025). Guo et al. (2024) proposed LightRAG to integrate a graph-based indexing approach to improve the performance of RAG in both efficiency and comprehension in information retrieval. However, the final passage that is passed to the answer model is still pre-processed by the language model, potentially introducing unverified noise.

Relation Classification. Relation classification is a well-studied research area in NLP since the last decade. Methods such as feature-based models, kernel-based models, neural-network models, and transformer encoders are utilized to assign a semantic relation to two nominals (Kambhatla, 2004; Bunescu and Mooney, 2005; Socher et al., 2012; Huang et al., 2020). However, these applications in relation classification focus on processing original text information rather than the relation node from the extracted triple in knowledge graph. Yu et al. (2020) proposed a relationship extraction method for construction of domain knowledge graphs using existing reference material from Wikipedia. Along with other semi-supervised relation classification methods (Agichtein and Gravano, 2000; Ravichandran and Hovy, 2002; Pantel and Pennacchiotti, 2006), these classification processes require the collection of additional corpora from the internet. Applying these methods to our framework will introduce additional computational costs, which is stressful for local SLMs.

3 Methodology

We propose an Evidence-Grounded Typed Knowledge Graph retrieval framework for domain-specific question-answering on SLMs. This framework aims to improve the retrieval quality, where the final answer will be grounded on original evi-

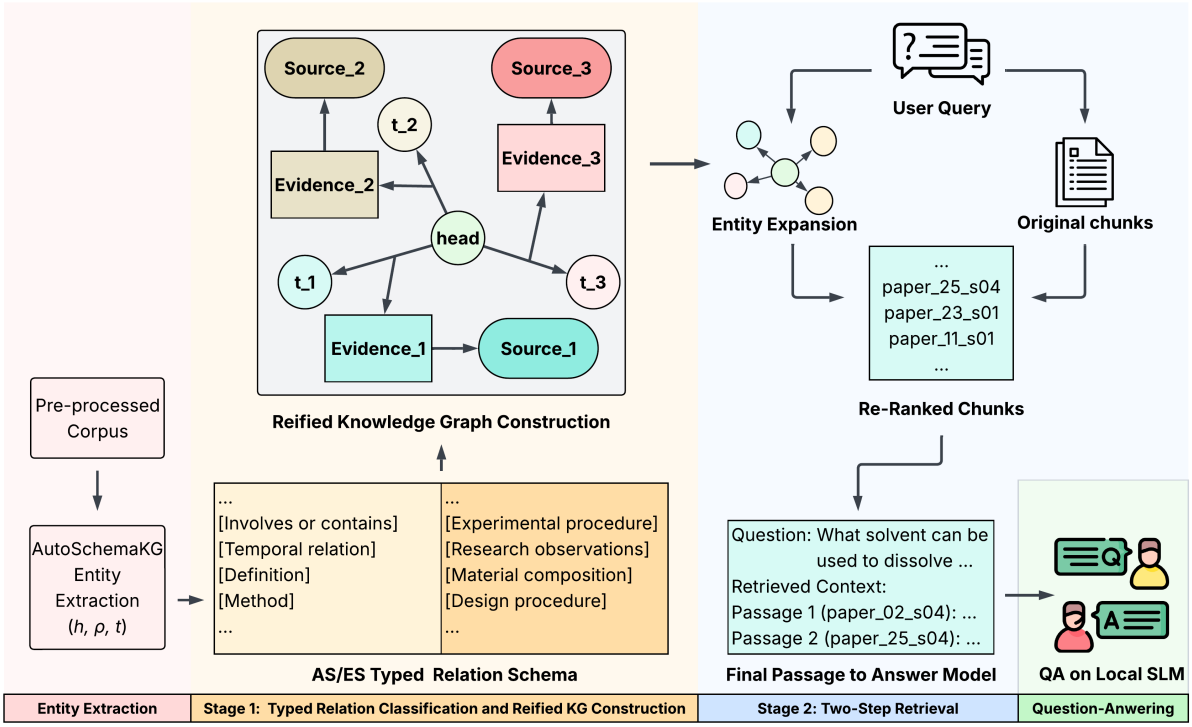

Figure 1: Overview of the EGT-KG framework. The framework consists of four main sections: entity extraction, typed relation classification and reified KG construction, two-step retrieval with re-ranking, and final QA.

dence nodes rather than pre-processed information.

The complete workflow for our framework is organized as follows. In the first stage, document chunks are processed to extract raw triples with short supporting evidence spans. Then, the extracted free-form relation labels are mapped into the two predefined typed schemas accordingly (AS and ES). These typed triples will be used to construct a reified knowledge graph with evidence nodes converted from raw evidence spans, linking the triples to unprocessed evidence text and source chunks. In the second stage, the reified knowledge graph guides query expansion and chunk candidates retrieval. Then the re-ranked chunk candidates and evidence window are passed to the answer model. Fig 1 provides an overview of the framework structure.

3.1 Graph triple extraction

The corpus set is built on a 30-paper corpus centered on Biopolymer-bound Soil Composite (BSC) and related emerging biopolymer-based materials. It includes 9 papers directly related to the evaluation questions, 9 BSC papers not directly related to the questions, 9 materials science papers similar to BSC, and 3 general reference papers. This corpus has three unique properties that make it a suitable test case. First, biopolymer-bound soil composites are an emerging material. So, a language model is unlikely to have much knowledge about them parametrically, which can be confirmed by baseline performance in Table 2. Therefore, the improvement of the framework can be attributed to retrieval quality from the corpus. Second, researchers who work on these materials designed the evaluation questions, so the questions are practically meaningful and cover aspects such as material behavior, material properties, and end-of-life treatment. Third, that same expertise made an expert-defined schema that can better capture useful information in KG. Appendix A.6 introduces the material and Table 16 lists the 30 papers.

We divided the collected corpus by document structure, preserving metadata such as section headings, resulting in 884 chunks averaging 1,387 characters. Thus, the retrieved evidence span can be traced back to its original document and local position. To ensure that the downstream comparisons are not confounded by different triple extraction passes, we perform triple extraction only once over the fixed chunk corpus and reuse the raw outputs for both EGT-KG variants.

Formally, let C denote the whole chunk set, and each $c \in C$ carries the metadata $M(c)$ including chunk ID, paper ID, source ID, title, chunk length,

and original text.

We utilize **AutoSchemaKG** (Chen and Bertozzi, 2023) as a triple-extraction engine. Specifically, we use AutoSchemaKG's extraction utilities to process each chunk in C and record structural information.

As a key feature, the extraction output preserves a head entity, a tail entity, a relation, and a short supporting evidence span with localization information rather than a processed summary or description of the triple. Thus, for each chunk $c \in C$, the extractor returns a set of raw triples T that can be represented as: $T(c) = \{h, \rho|e, t\}$, where h and t denote the head and tail entity, ρ is the free-form relation label, and e is a short evidence span that can be traced back to the source chunk. The evidence span e is appended with the relation ρ to be converted to an evidence node for graph construction, which enables Evidence Window slicing that can offer 22% context reduction with no cost in performance. The triple set T will be used by both AS/ES variants in subsequent experiments.

3.2 Typed relation classification

After triple extraction, we transform relation labels into a set of semantically meaningful relation types. We classify each distinct label once into a schema type or discard it, then apply the resulting label-to-type map to every triple with that label, so identical labels are always typed identically. During this process, we restrict the size of the knowledge graph by trimming noisy, inconsistent, and irrelevant triples for retrieval.

The two type schemas are designed to study how relation granularity itself can alter the process of query expansion and quality of responses. As shown in Table 1, the AS schema is automatically generated by answer models based on specific instructions for the BSC study, and the generation prompt is given in Appendix A.8. We selected the most prominent types and applied them to all AS EGT-KG variant studies. The ES schema was defined by two materials scientists with several years of research experience in relevant materials. They reviewed and identified the relation labels produced, and grouped them into 11 types. The AS–ES contrast therefore isolates the value of expert input, and the ES schema can potentially be expanded to broader materials science domains.

Formally, let ϕ denote the relation typing function, and τ denote the type schema: $\phi(T(c)) = (h, \tau_n|\rho|e, t)$,where τ_1 is the AS schema and τ_2 is the ES schema. Applying the relation typing function ϕ will classify each of the extracted triples t into a typed relation instance and be appended to the relation label. Thus, by differentiating relation types, our framework provides a high-level index to guide graph traversal and constrains query expansion, forcing the retrieval process to operate only on the most stable semantic categories.

3.3 Reification and provenance-aware knowledge graph construction

Leemhuis et al. (2022) states that although current methods of knowledge graph embedding perform well on total and functional relations, features such as partiality or non-functionality of relations are difficult to model correctly. So, they introduced the concept of Reification, which represents relations directly as objects in the embedding space rather than as geometric transformations from subject to object. For our framework, the purpose of reification is to preserve each relation instance as a same-level object linked to both its semantic arguments and its original support text. Therefore, rather than representing knowledge as direct entity-to-entity edges only, the reified knowledge graph stores two kinds of additional nodes besides the head and tail. The first is the evidence nodes, which contain the supporting evidence span e, and the second is the source nodes, which store the location of the evidence span in the original document. This reified design is central to our framework because it allows graph retrieval to remain structurally expressive while preserving the textual provenance required for faithful answer generation. This structure is especially important in scientific question-answering, where relation abstraction or description alone may omit crucial conditions, quantitative ranges, or contextual qualifiers in the original text information. So far, the first stage is completed, and the overview of stage 1 is shown in Appendix A.7.

3.4 Two-step retrieval with query expansion and re-ranking

At the beginning of the second stage, our EGT-KG framework follows a two-step retrieval strategy. In the first step, to improve recall, the answer model retrieves chunk candidates by using the reified knowledge graph to guide query expansion. In the second step, to improve precision, the retrieved chunk candidates are re-ranked according to their evidence-level relevance. The two-step retrieval design is guided by the hypothesis of our work, in which query expansion helps find the most relevant neighbor entities, while chunk candidates re-ranking helps retrieve the correct final passages.

In practice, the two-step retrieval works as fol-

Relation Type	Composition
AS schema (automatically generated)	Involves or Contains; Causes or Influences; Temporal Relation; Logical or Preposition; Research or Observation; Method; Definition; Production; Spatial Relation.
ES schema (expert designed)	Causes or Influences; Definition; Manufacture Procedure; Temporal Relation; Experimental Methods; Logical Reasoning; Research Observations; Experimental Procedures; Material Composition; Design Procedure; Biopolymer Properties.

Table 1: Typed relation schemas for knowledge graph construction.

lows. In the first step, given a user query q, we identify seed entities in KG through query-entity matching. Next, we perform a one-hop query expansion around the seed entities to collect related entities. The first-step retrieval score (S_1) is the weighted sum of the original-query score S_{ori} and the expanded-query relevance score S_{exp}, allowing the retrieval to benefit from both global and local views. This score will be used to select top-k chunk candidates. Formally, for a chunk candidate c and weight term α:

$$S_1(c|q) = \alpha S_{ori}(c|q) + (1-\alpha)S_{exp}(c|q) \quad (1)$$

For the second step, the top-k chunk candidates collected in step 1 are re-ranked by comparing the semantic similarity between the query and the content of the evidence nodes. The re-ranking process provides more precise support evidence within the retrieved material and determines if the final answer context should be constructed from localized evidence window or from full chunk fallback. Specifically, let S_{evi} denote the evidence-level score, and λ denote the weight for step 2, the re-ranking score S_2 is defined as:

$$S_2(c, e|q) = \lambda S_1(c|q) + (1-\lambda)S_{evi}(e|q) \quad (2)$$

For a complete illustration, Figure 3 in Appendix A.7 provides a detailed example.

3.5 Evidence-grounded answer generation

After two-step retrieval and re-ranking, the system constructs the final context passage from either top-k evidence windows or full-chunk fallbacks. All compared workflows, including the vanilla RAG and two EGT-KG variants, share the same answer-generation policy, instructing the answer model to answer the question directly with no unsupported inference, and explicitly acknowledging reference information insufficiency when retrieved chunks do not contain enough information. Fig 3 in Appendix A.7 shows the overview of the second stage.

Formally, given a question q and a final context passage P_q, the shared evidence-based prompt π, the answer model produces:

$$answer = SLM(q, P_q, \pi) \quad (3)$$

3.6 Evaluation with S3CRF

All generated responses are evaluated under a unified LLM-as-judge workflow. Due to the unique nature of our problem, current benchmarks are not best suited to evaluate emerging research domains with limited reference sources and open-ended questions. We adopt the S3CRF framework, scoring answers along six dimensions: soundness, correctness, completeness, conciseness, relevance, and fluency. The detailed evaluation criteria are shown in Table 13. Domain experts in BSC were involved in validating the benchmark design and evaluation criteria to improve the credibility of the assessment.

The six-dimensional scores (s_n) are combined into a weighted Final Score (S_{final}) to reflect the benchmark's emphasis on scientific question-answering demands, the overall Final Score with weights w_n is computed as: $S_{final} = \sum(w_n s_n)$.

4 Results

4.1 Experimental comparison setup

All compared workflows share the same strict evidence-grounded instruction prompt and the S3CRF multidimensional LLM-as-Judge evaluation framework. For all experiments, the answer models receive the top-k ($k = 6$) retrieved passages to construct the final prompt for each query (Appendix A.9). We report results for five local answer models evaluated by *gpt-4o* (OpenAI, 2024) and *gemini-2.5-pro* (Google, 2025) as judge models.

4.2 Overall performance across models

Table 2 summarizes the overall performance of baseline, vanilla RAG, and two EGT-KG variants. Generally, EGT-KG enhanced retrieval improves answer quality in most cases, but the improvement is clearly model-dependent. The highest absolute values of Final Scores are achieved by *llama3.1:8b* in the benchmark, and *gemma2:9b*

	Gemma2:9b		Llama3:8b		Llama3.1:8b		Mistral:7b		Qwen2.5:7b	
	gpt-4o	gemini	gpt-4o	gemini	gpt-4o	gemini	gpt-4o	gemini	gpt-4o	gemini
Baseline	35.96	24.60	28.02	24.80	29.19	24.95	28.65	22.29	33.51	24.43
Vanilla RAG	66.76	70.58	61.37	62.44	84.30	77.33	59.32	77.55	**86.01**	78.09
EGT-KG(AS)	72.22	72.62	**70.37**	66.11	83.75	78.44	60.34	**77.78**	82.82	**80.55**
EGT-KG(ES)	**73.12**	**74.04**	68.82	**68.21**	**86.02**	**81.72**	**60.57**	74.23	85.20	79.91

Table 2: Performance of workflows across answer models and judge models.

Model	Relation Type	Fallback	Window	AvgExpand	EE	Jaccard
Gemma2:9b	AS	0.6292	0.3708	10.40	3.57%	0.6095
Gemma2:9b	ES	0.6167	0.3833	10.00	3.83%	0.5678
Llama3:8b	AS	0.7500	0.2500	14.95	1.67%	0.5961
Llama3:8b	ES	0.7667	0.2333	16.90	1.38%	0.5855
Llama3.1:8b	AS	0.6042	0.3958	17.10	2.31%	0.5762
Llama3.1:8b	ES	0.6375	0.3625	16.55	2.19%	0.5427
Mistral:7b	AS	0.7792	0.2208	13.13	1.68%	0.6186
Mistral:7b	ES	0.7917	0.2083	12.80	1.63%	0.6037
Qwen2.5:7b	AS	0.7167	0.2833	24.15	1.17%	0.4930
Qwen2.5:7b	ES	0.7208	0.2792	25.05	1.11%	0.4847

Table 3: Retrieval performance analysis. Expansion efficiency (EE) is defined as $\mathrm{WindowRate}/\mathrm{AvgExpanded}$, and the Jaccard index measures the difference between original retrieved and re-ranked chunk candidates.

demonstrates the most stable improvements from EGT-KG enhanced retrieval. Besides, *llama3:8b* shows the greatest relative improvement compared to the vanilla RAG workflow, while *mistral:7b* and *qwen2.5:7b* exhibit smaller or less stable improvements compared to the other answer models.

The largest relative improvement appears for *llama3:8b* under *gpt-4o* evaluation, where the Final Score increases from 61.37 with vanilla RAG to 70.37 (+14.67%) with EGT-KG(AS) and 68.82 (+12.14%) with EGT-KG(ES). For *gemma2:9b*, it outperforms vanilla RAG under both judge models, presenting the most stable improvements as the granularity of the type schema increases. And *llama3.1:8b* reaches the highest overall scores with the ES schema (86.02 by *gpt-4o* and 81.72 by *gemini-2.5-pro*). By contrast, *mistral:7b* and *qwen2.5:7b* show smaller or less stable improvements, indicating that EGT-KG is not uniformly beneficial for all local models.

These results support two conclusions. First, our EGT-KG framework improved scientific question-answering by two-step retrieval from the reified knowledge graph in most settings. Second, generally, a finer-grained type schema can better guide answer models to retrieve the most relevant information from the original text to help with question-answering. However, given the differences in model structure and reasoning abilities, the benefit of additional granularity is conditional rather than universal.

As a supplementary generalization check, we evaluate EGT-KG on QASPER (Dasigi et al., 2021) with a cross-paper setting, where the system retrieves from all 281 papers without access to the gold paper ID. As shown in Appendix A.3, EGT-KG improves mean Answer F1 over vanilla RAG by 5.9% on average, with gains on four out of the five base models. We additionally evaluate on HotpotQA. The outcome depends entirely on how large a candidate pool retrieval must search: the framework adds almost nothing when the official distractor setting supplies ten candidates per question, but improves Answer F1 by $+0.142$ (*gemma2:9b*) once the same paragraphs are pooled into a single corpus (Appendix A.4).

4.3 Retrieval performance and error analysis

To further investigate why the EGT-KG framework can help more in some settings than others, we conducted a retrieval performance analysis in Table 3. The fallback rate is the fraction of the final k chunks for which no evidence window could be constructed, and AvgExpand is the mean number of expansion entities produced per question by one-hop traversal.The most positive cases (*gemma2:9b* and *llama3.1:8b*) show the lowest fallback rates

and highest evidence-window utilization (EE). By contrast, *mistral:7b* has the highest fallback rates (0.78-0.79) with limited improvements in Final Score. Compared to *gemma2:9b*, *mistral:7b* has a similar Jaccard index but a much higher fallback rate, suggesting that the model successfully re-ranked the original chunk candidates, but failed to extract a useful evidence window.

Also, by analyzing average expanded ($AvgExpand$) query entities, we found that retrieving more neighbor entities does not always guarantee better results. Compared to other answer models, *qwen2.5:7b* collected the largest number of neighbor entities through one-hop query expansion, expanding to 25.05 entities per question under ES with the lowest expansion efficiency. The lowest Jaccard index demonstrates *qwen2.5:7b* replaced more original chunk candidates than other answer models, indicating that the model failed to extract useful evidence from these new chunk entities, while these underutilized chunk candidates distracted model's attention from the most relevant information.

5 Discussion

5.1 EGT-KG enhanced retrieval helps by improving evidence access

In general, the experimental results suggest that the main value of the EGT-KG framework lies in improving the precision of textual evidence passed to the answer model. With the same prompt structure, the improvements observed in EGT-KG variants over the vanilla RAG workflow can plausibly be explained by better retrieval quality and evidence localization than by refined prompt engineering.

To be specific, the reified knowledge graph helps the answer model to identify relevant entities, expand query around structured neighbor entities, and re-rank chunk candidates based on evidence-level matching. Thus, the EGT-KG framework should be treated as a lightweight retrieval booster for SLMs in a limited resources setting.

5.2 Finer-grained schema is not always better

The comparison between the two variants demonstrated that increased granularity does not always lead to better performance. Although some models can consistently benefit from the finer-grained type schema, the coarse AS EGT-KG variants remain more effective for models that cannot fully interpret additional knowledge injected. This result reveals the trade-off between semantic precision and retrieval robustness. Finer schema granularity can surely provide more informative instruction that aligns the original query with reified knowledge graph, but on the other hand, it may introduce sparsity and classification noise, especially for local SLMs, which are typically less robust to noise or weakly aligned context than frontier LLMs. The coarse schema, with more general relation classes defined, may not be as specific as the finer one, but it provides a more stable retrieval path to SLMs.

5.3 Retrieval quality is mainly constrained by evidence localization

The retrieval analysis in section 4 indicates that the bottleneck of retrieval quality is evidence localization quality, rather than the number of retrieved chunk candidates. The framework successfully expands the range of retrieved chunk candidates via one-hop query expansion with 30% of the original chunk candidates replaced after re-ranking. However, the response quality highly depends on whether the answer model can locate a clear evidence window in retrieved chunks. The models with better performance in our framework gained lower fallback rates and higher evidence-window utilization rates, while the weaker models always fall back to full chunk information passing. Thus, for our specific scenario with limited resources, more graph expansion does not automatically improve results. Instead, the model's ability to convert chunk information into grounded evidence should be prioritized when determining whether the expanded retrieval is helpful or noisy.

6 Conclusion

We presented EGT-KG, an evidence-grounded typed KG retrieval framework for practical scientific question-answering with local small language models. Our findings suggest that the EGT-KG framework improves answer quality over vanilla RAG in most settings, especially on dimensions related to factual correctness, reasoning soundness, completeness, and relevance. This observation is especially important for SLMs when scientific QA systems must operate on specialized corpora with fragmented evidence and limited model capacity. Future work will focus on reducing fallback rate, balancing multi-hop expansion with limited model context length, improving evidence window utilization, and testing the framework on more domains of scientific research.

7 Limitations

The current study has several limitations. Firstly, the relatively high fallback rate indicates that there is still a large portion of retrieved chunk candidates that cannot be converted into a clear evidence window. Therefore, the potential of our provenance-aware retrieval is not fully exploited. The current results may be improved with a better solution for evidence localization for SLMs. Secondly, our query expansion relies on one-hop neighbor entity expansion. While this choice takes noise management and SLM's limited reasoning ability into consideration, it reduces our framework's capability in handling complex queries that require multi-hop reasoning or cross-document inference. Third, the current validation is conducted on a BSC-centered benchmark. Although our corpus setting is appropriate as a test case for open-ended question-answering with fragmented and specialized scientific knowledge, the present results should not be generalized to a broader scope of research domains without further validation. The additional evaluation on QASPER has partially shown generalization, but its question set frequently uses pronouns instead of precise terminology. In cross-paper settings, the performance of EGT-KG is underestimated because of the nature of the question set. Fourth, our work focuses on improving retrieval for local SLMs rather than on comparing against frontier LLMs as answer generators. Thus, the results should be interpreted as evidence that better retrieval quality can strengthen feasible local SLMs in constrained resource settings, rather than a claim of general superiority over LLMs. Finally, for the designed open-ended questions, the LLM-as-judge method remains sensitive to judge model preferences. The use of two judges improves robustness, but the current Final Score difference should be treated as a relative performance indicator rather than as a measure of actual scientific usefulness.

A Appendix

A.1 Additional performance analysis

Table 4 and 5 together show the workflow performance for simple questions and complex questions. For simple questions, both EGT-KG variants outperform the vanilla RAG workflow in 9 out of 10 comparisons, with ES EGT-KG variants achieving the best result in 8 of them. However, the benefit becomes much less stable on complex questions, suggesting that our framework primarily improves precision in evidence localization for simple fact retrieval questions. For complex questions with multi-hop reasoning and global evidence aggregation, the benefits from finer-grained schemas are reduced. This finding further confirms the limitation discussed before: the one-hop query expansion reduces model's capability in processing complex queries that require multi-hop reasoning or cross-document inference. Notably, the baseline workflow (plain QA with SLMs) achieves relatively higher Final Scores on complex questions than on simple factual questions. A plausible explanation is that the complex questions in our benchmark are broader and more discussion-oriented. Thus, even without external retrieval, SLMs can still obtain partial credit on complex questions by generating generally relevant responses. Table 6 reports the raw scores for the six S3CRF dimensions. As expected, the gains in soundness (+3.03%), correctness (+4.52%), completeness (+2.78%), and relevance (+3.20%) are noticeably larger than conciseness (+2.22%) and fluency (+1.71%). It suggests that the main benefit of our framework comes from improving core answer-quality dimensions related to reasoning, factual accuracy, coverage, and query alignment, rather than surface-level language style.

A.2 Component ablation

As Table 8 shows, no single component makes a dominant contribution to the overall improvement, because its measured effect flips between the judge models. To be specific, the re-ranker carries the effect under *gemini-2.5-pro* (+2.03 over query expansion), whereas the same addition is negative under *gpt-4o* (-0.66), and the evidence window on its own contributes essentially nothing over query expansion under either judge (+0.02 and -0.03). The stable partial gains is C (query expansion + rerank): because evidence re-ranking operates on the candidate chunks that query expansion supplies, the two components together consistently improve over vanilla RAG under both judges (+2.61 from *gpt-4o*, +3.81 from *gemini-2.5-pro*), even though the marginal contribution of re-ranking alone changes sign. The assembled pipeline is therefore the best configuration to deploy. The full framework is the highest-scoring configuration under both judges (A $\rightarrow$ E: +4.29 from *gpt-4o*; +3.86 from *gemini-2.5-pro*), and no partial configuration beats it. The remaining improvements come from the interaction between evidence re-ranking and the evidence window. The mechanism is straightforward: The evidence window can suppress noise and highlight the most relevant sentence. But if only the evidence window is deployed, when the gold evidence is not present in the retrieved candidate chunks, the answer model is still stuck for lack of ground truth — which is exactly why the evidence window alone changes nothing. Once re-ranking has moved the chunk containing the gold evidence into the final top-k, the evidence window pays off: it removes the unnecessary surrounding text, cutting mean context by 22% ($8,196 \rightarrow 6,399$ characters) at no cost in score, and lets the answer model focus on the evidence that matters.

A.3 Supplementary QASPER Evaluation

To further study whether the EGT-KG framework generalizes beyond the BSC corpus, we conduct a supplementary evaluation on QASPER (Dasigi et al., 2021). QASPER is a scientific question-answering benchmark built from NLP research papers. Each question is associated with a source paper and is answered using evidence from that paper.

The official QASPER evaluation protocol provides the target paper ID and restricts retrieval to chunks from that paper. This per-paper setting is appropriate for evaluating reading comprehension once the relevant paper is known, but it does not fully reflect many practical scientific RAG scenarios, where a user asks a question without specifying which paper contains the answer. We therefore use a cross-paper retrieval setting: the system is not given the gold paper ID and must retrieve evidence from all papers in the development split. In our setup, retrieval is performed over 5,253 chunks from 281 papers, and evaluation is conducted on all 1,005 development questions.

We compare three settings. The first is a question-only baseline, where the models answer questions without retrieved context. The second is vanilla cross-paper RAG, which retrieves chunks

Pooled corpus (1,977)	0.3165	0.4585	**+0.142**

Table 9: HotpotQA Answer F1 under two retrieval regimes, 200 development questions, *gemma2:9b*.

from the full cross-paper pool using dense retrieval. The third is our EGT-KG framework, which augments retrieval with KG-expanded query terms, evidence-aware reranking, and evidence-window

construction. We report Answer F1 using the official QASPER evaluator.

The results show that retrieval is essential in this more realistic cross-paper setting, where vanilla RAG improves mean Answer F1 from 0.1333 to 0.1587 (19.0%) over the question-only baseline. EGT-KG further improves mean Answer F1 to 0.1681, a 5.9% relative gain over vanilla RAG, with positive gains for four out of five tested models. Additionally, we performed a simple test on official per-paper setting on *gemma2:9b* ($\alpha = 0.9, \lambda = 0.5, k = 8$). The EGT-KG framework (0.367) outperform vanilla RAG (0.334) by 10.2%. The improvement on scores are derived from more relevant chunk candidates for both workflows.

A.4 Cross-domain evaluation on HotpotQA

We evaluated on 200 HotpotQA development questions for generalization, inducing the relation schema from that corpus's own relation-label distribution.

The outcome depends entirely on how large a candidate pool the retrieval has to search. In the official distractor setting, each question is supplied with ten candidate paragraphs with two gold paragraphs, and the framework adds nothing ($+0.016$): dense retrieval already finds the gold paragraphs, so there is no localization problem left to solve. Pooling the same questions' paragraphs into a single 1,977-paragraph corpus reverses this ($+0.142$). Growing the pool from 10 to 1,977 candidates costs vanilla RAG 34.8% of its Answer F1 and EGT-KG 8.6%, and the complete gold-paragraph set is retrieved for 36.0% of questions by vanilla RAG against 56.0% by EGT-KG.

A.5 Small-corpus construction setting

Another practical advantage of our framework is the feasibility of being built on a small corpus in a limited resource scenario. Rather than requiring large-scale indexing or computationally intensive global graph structure, our EGT-KG framework constructs a knowledge graph from a compact benchmark of 30 papers. This design decision mimics the real-world situation in the emerging scientific domain of question-answering, where users may only have access to a small collection of relevant papers and may not be willing to afford the cost of heavy knowledge graph construction. Thus, our contribution to EGT-KG is to improve scientific QA while preserving the possibility of practical deployment. The experiment results show that even the lightweight knowledge graph, which is further trimmed by type schema, can provide useful and explainable retrieval to enhance response generation for scientific QA.

A.6 Introduction to BSC

Biopolymer-bound soil composite (BSC) is a nature-inspired material that valorizes waste-stream biopolymers from major industries (e.g., paper pulping, biofuels, and agriculture) as binders for granular materials. Unlike conventional materials such as ordinary Portland cement concrete, BSC is potentially carbon-negative due to its use of carbon-rich biopolymers, enabling sequestration of carbon in the composite (Miao et al., 2024c). It is also fully recyclable, reduces construction waste, and offers compressive strength comparable to concrete, making it a promising low-cost, sustainable, cement-free alternative for the built environment.

A.7 Detailed Pipeline Diagrams

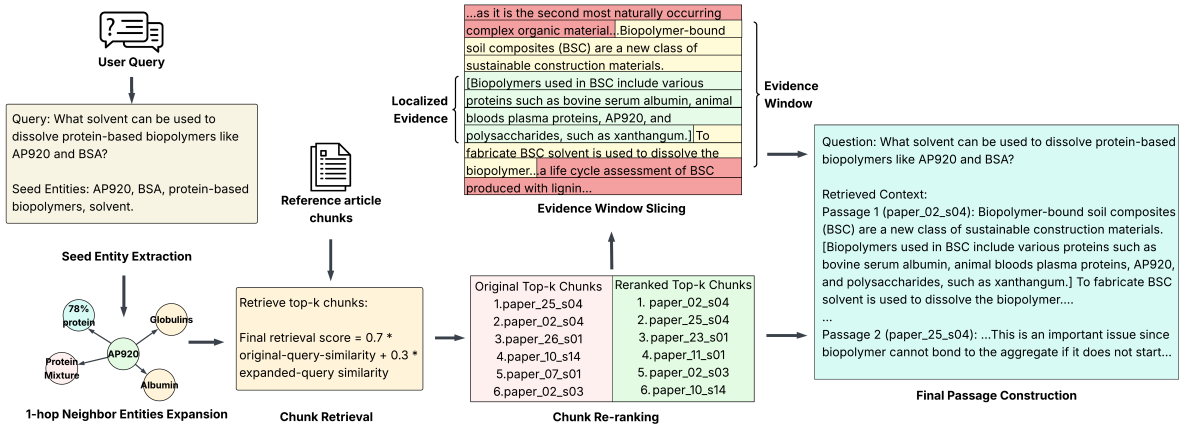

Figure 3: Stage 2 of EGT-KG: query expansion, context retrieval and re-ranking, evidence-aware context slicing, and passage construction.

A.8 Prompts

Entity Extraction Prompt

```
{
    "en": {
        "system":
"You are an expert knowledge graph constructor specializing in materials science, civil engineering, and
biopolymer-bound soil composites (BSC). You always respond with a valid JSON array and nothing else.",
       "triple_extraction":
"You are extracting entity-relation triples from academic text about Biopolymer-bound Soil Composites (BSC) and
related materials science topics.

Task: Extract all important entity-relation triples from the given passage. For each triple, identify the head
entity, tail entity, and the relationship between them. Use a concise, descriptive relation label that accurately
captures the nature of the relationship.

Output Format: Return a JSON array of objects. Each object must have exactly three keys:
\"Head\": the source entity (a specific noun or noun phrase, not a pronoun)
\"Relation\": must follow the format \"relation_label | brief evidence from text that is summarized or directly cited
from the original text\."
relation_label: a concise phrase describing the relationship (e.g., \"is defined as\", \"increases\", \"is composed
of\", \"was tested using\", \"causes\", \"is located in\") After the pipe symbol (|), include a brief quote or
paraphrase from the source text that supports this triple. Prefer direct citation from the original text when
possible; otherwise provide a concise summary that stays faithful to the original wording
\"Tail\": the target entity (a specific noun or noun phrase, not a pronoun)
Example Output:
 {\"Head\": \"BSC\", \"Relation\": \"is defined as | biopolymer-bound soil composites are a mixture of granular soil
aggregate, biopolymer, and water\", \"Tail\": \"mixture of soil aggregate, biopolymer and water\"}......

Constraints: Extract ALL relevant triples from the passage. Head and Tail must be specific entities, not pronouns or
vague references. The relation_label should be a concise, natural-language description of the relationship. The
evidence after | should be a brief supporting quote or paraphrase. Prefer direct citation from the original text. If
no triples can be extracted, return exactly: []. Do not include any text other than the JSON array\n\nHere is the
passage.
    }
}
```

Figure 4: Entity extraction prompt

RAG QA Prompt for all workflows

```
SYSTEM_PROMPT = (
    "You are a research assistant specializing in Biopolymer-bound Soil Composites (BSC) and materials science. You
must answer strictly from the provided context from research papers. If the context is insufficient, state it
clearly. Do not add unverified knowledge or infer missing details."
)

USER_PROMPT = """Answer the following question using ONLY the context provided below.

## Question
{question}

## Retrieved Context

{context_block}

## Instructions
- Your first sentence must directly answer the question.
- Do not discuss topics the question did not ask about.
- Use only information explicitly supported by the retrieved context.
- Do not infer or add missing details.
- If one passage is sufficient to answer the question, prioritize it and ignore less relevant passages.
- Cite only the most relevant paper ID(s) for key claims.
- Be concise: 2-5 sentences is ideal.
- If the retrieved passages do not contain enough information, say so clearly.
"""
```

Figure 5: RAG QA prompt for all workflows, containing original question, retrieved context, and instructions

AS Schema Prompt

```
System: You are an expert knowledge graph designer specializing in materials science, civil engineering, and
biopolymer-bound soil composites (BSC). You always respond with a valid JSON array and nothing else.

Task: Propose 20 relation types that together cover the relationships expressed in this literature. A relation type
is a broad, semantically coherent category into which many specific relation labels (for example "is used for",
"increases", "is a type of") can be grouped.

Requirements
- Each type must be broad enough to absorb many surface forms, and narrow enough to be distinguishable from the
others.
- The types should be mutually exclusive: a given relation should fall naturally into exactly one.
- Together they should cover the relationships a researcher would need in order to reason about this material:
composition, causation, procedure, measurement, definition, and comparison, among others.
- Name each type in UPPER_SNAKE_CASE.
- Do not include a catch-all or "other" category.
Output Format: Return a JSON array of 20 objects and nothing else:
[{"type": "TYPE_NAME", "description": "one line stating what belongs in
  this type", "examples": ["example relation label", "another label"]}, ...]
```

Figure 6: Prompt used to induce the AS relation schema.

A.9 Parameter sensitivity

λ	0.40	0.50	0.65	0.80
Final Score	66.47	68.37	**73.54**	69.12
k	3	6	10	15
Final Score	63.80	**71.40**	68.20	66.30

Table 10: Sensitivity to the re-ranking weight λ and to the number of retrieved chunks k. Reported results use $\lambda = 0.65$ and $k = 6$.

A.10 Performance by relation type

Relation type	KG%	Ret%	ratio	Δ
Causes or Influences	36.4	34.5	0.95	+3.96
Research Observations	17.1	16.2	0.95	+4.98
Material Composition	11.9	12.0	1.01	+2.03
Manufacture Procedure	10.3	9.8	0.95	+4.72
Logical Reasoning	7.5	7.7	1.03	+2.83
Definition	5.7	8.4	1.47	+1.70
Experimental Methods	5.0	5.8	1.16	+5.03
Biopolymer Properties	3.8	2.4	0.63	+5.49
Temporal Relation	1.0	1.2	1.20	+5.59
Design Procedure	0.9	1.5	1.67	−0.20
Experimental Procedures	0.4	0.5	1.25	+2.78

A.12 Evaluation Criteria

Metric	Definition	Primary focus
Soundness	Logical validity of reasoning from question to answer, including appropriate use of referenced material.	Reasoning validity
Correctness	Factual accuracy compared to the reference material; hallucinated facts reduce the score.	Factual grounding
Completeness	Coverage of all relevant aspects of the question.	Information coverage
Conciseness	Appropriate detail and brevity without unnecessary verbosity.	Brevity and clarity
Relevance	Alignment with the user's query.	Query alignment
Fluency	Grammatical, coherent, and readable language.	Readability

Table 12: S3CRF evaluation metrics.

Dimension	Score	Description
Soundness $w_{snd} = 0.275$	0	Incorrect logical connection between question and answer.
	1	Poor reasoning, conclusion is not directly supported.
	2	Weak reasoning, several logical flaws in answer.
	3	Acceptable reasoning with partially unsupported claims.
	4	Strong reasoning with minor gaps.
	5	Perfect logical reasoning with proper use of evidence.
Correctness $w_{cor} = 0.275$	0	Incorrect or fabricated response.
	1	Significant factual errors or hallucinations.
	2	Multiple minor factual errors or hallucinations.
	3	Generally correct with acceptable inaccuracies.
	4	Mostly accurate with trivial errors.
	5	Accurate and verifiable answer supported by reference documents.
Completeness $w_{cmp} = 0.15$	0	Fails to address the question.
	1	Incomplete response with superficial coverage.
	2	Missing coverage of important information.
	3	Addresses main point but misses some details.
	4	Covers most important aspects.
	5	Comprehensively addresses all aspects.
Conciseness $w_{con} = 0.05$	0	Completely unnecessary length.
	1	Severely verbose or oversimplified.
	2	Relatively too long/short, affecting readability.
	3	Somewhat verbose or oversimplified with acceptable readability.
	4	Mostly appropriate length with minor issues.
	5	Perfect balance of detail and brevity.
Relevance $w_{rel} = 0.2$	0	Completely off-topic response.
	1	Mostly irrelevant with trivial relevant discussion.
	2	Partially relevant, significant off-topic content.
	3	Mostly relevant but some off-topic content.
	4	Highly relevant with minor off-topic content.
	5	Directly and precisely addresses the question.
Fluency $w_{flu} = 0.05$	0	Incoherent.
	1	Poor organization, very hard to read.
	2	Choppy expression or hard to follow.
	3	Acceptable expression with some disjointed sections.
	4	Good coherence with minor awkwardness.
	5	Excellent flow, reads naturally.

Table 13: Rubric for S3CRF evaluation (0-5).

A.13 Simple/complex questions in the question set and papers used in corpus

ID	Question
Q1	What solvent can be used to dissolve protein-based biopolymers like AP920 and BSA?
Q2	Give me an overview of the processes needed to dissolve the biopolymers (e.g. time and any other considerations)
Q3	What is the maximum amount (in percentage) of biopolymer that can be dissolved into solution?
Q4	What parameter do we need to consider in order to maximize the amount of biopolymer in the composite?
Q5	What type of compaction method is used to manufacture BSC? Why is this important?
Q6	Why is BSC a sustainable building material?
Q7	What happens with saturation ratios more than 1.0?
Q8	How do we desiccate BSC?
Q9	What is the porosity of BSC?
Q10	How can I maximize the strength of these biocomposites?
Q11	What biopolymers can be used to make BSC?
Q12	What is the microstructure of BSC?
Q13	How can the structure of BSC be modeled?
Q14	How can I prevent shrinkage cracking in BSC?
Q15	How can BSC structure be imaged?
Q16	How can BSC be recycled?
Q17	How is the strength of BSC characterized?
Q18	What form of sample is used for BSC characterization?
Q19	How can the sustainability of BSC be improved?
Q20	How does the use of BSA contrast with AP920?

Table 14: Simple question set used in QA evaluation.

ID	Question
Q1	How can I select the most optimal solvent to dissolve a given biopolymer? How can I choose a solvent that not only effectively dissolves the biopolymer but also enhances the resulting bridge strength or interfacial bond strength between the aggregate and the biopolymer binder?
Q2	How can each step in the manufacture of BSC be modified to improve both manufacturability and the overall macroscale properties of the composite? What potential issues could arise at each step, and how might they affect the final properties of the manufactured composite?
Q3	Explain the relationship between biopolymer concentration and biopolymer solution viscosity during dissolution, and how the "workability limit" physically constrains the maximum binder content.
Q4	If higher biopolymer content typically results in a stronger BSC, could we reduce the amount of compaction applied to the specimens (i.e., increase the void space in the material)? Would this reduction in compaction and the corresponding increase in void space, which the biopolymer can fill, affect any other material or design parameters?
Q5	How can higher levels of compaction enhance the compressive strength of BSC, and what are the resulting impacts on design parameters?
Q6	In comparison to hydrophilic BSCs which use water as a solvent, does BSC using hydrophobic biopolymers with a higher potential for carbon sequestration (they are more carbon rich) lead to always having a lower carbon footprint?
Q7	If a novel biopolymer is being used and its particle density is not yet characterized, is it preferable to prepare an initial mix above or below the saturation ratio? What are the potential advantages and disadvantages of each approach, and which strategy would minimize risk in terms of workability, mechanical performance, and consistency of the resulting BSC?
Q8	How do the desiccation requirements differ between protein-based BSCs (which use water as a solvent) and lignin-based BSCs (which use DMSO as a solvent)? If the desiccation time for a BSC using a particular solvent is excessively long, what strategies can be employed to accelerate the process without compromising the composite's mechanical integrity or interfacial bonding?
Q9	Can microscale characterization techniques, such as X-ray micro-CT, be used to accurately determine the porosity of BSC? How can the porosity of BSC be increased without compromising its mechanical or physical properties?
Q10	Rank the most effective methods for improving the compressive strength of biopolymer-bound soil composites, and provide a detailed explanation for each method. In your evaluation, consider not only the potential gains in compressive strength but also factors such as practicality, cost-effectiveness, scalability, and environmental footprint.
Q11	Which biopolymers are most promising in terms of environmental impact, availability, and practicality. If I want to explore or develop a new variant of BSC, what are some promising biopolymers that can be used?
Q12	What phenomena can be observed from microstructural images of BSC (phenomenon and type of image).
Q13	What types of data are required to develop an accurate model of BSC behavior? Which material, structural, and processing parameters should be prioritized for measurement in future investigations to improve model reliability and predictive capability?
Q14	Does a staggered desiccation approach, in which the BSC is first desiccated under ambient conditions and then oven-dried directly reduce the formation of shrinkage cracks? Please hypothesize how this potential approach can be designed (number of steps, time per step, conditions at each step)
Q15	Can SEM be used in the same capacity/function as Micro-CT in calculating statistical descriptors (lineal path function and two-point probability correlation functions).
Q16	Explain the process of recycling BSCs at the end of their lifecycle to reclaim the biopolymer. Also hypothesize a more effective way for recycling other than this approach.
Q17	If I wanted to perform a study on the strength of a biopolymer bridge between two aggregate particles how would I go about this? Propose a plan.
Q18	For macroscale considerations, are there any limits or standards for minimum size of a test specimen? What are these standards based on?
Q19	Propose the most viable and potential studies that can be carried out. When proposing plans or studies, please consider how we can improve the affordability or accessibility of existing and future variants of BSC .
Q20	Is BSA or AP920 more practical for construction in extraterrestrial environments, both in the short term and the long term?

Small Model, Big Retrieval: Unified Heterogeneous Retrieval via Multi-Label-Aware Contrastive Fine-Tuning

Abstract

Contrastive fine-tuning of a single embedding model across heterogeneous retrieval tasks is challenging when the tasks differ in label structure. In product-compliance retrieval, some tasks have multi-label supervision — every item carries a set of compliance categories, and many in-batch items share at least one category with the query, producing frequent in-batch false negatives. Other tasks (e.g., cross-catalog product matching) have no category labels: each query has one canonical match. Existing multi-label contrastive methods require every batch item to carry comparable labels, so they cannot serve a single embedding model trained on both label-bearing and label-free tasks. We propose **label-aware false-negative exclusion**: a zero-cost binary mask on the InfoNCE denominator that drops same-label candidates from the negative set rather than including them to positives. The mask has no effect on label-free items, so the same loss handles both task types. A 0.6 B-parameter embedding model fine-tuned this way handles four retrieval tasks simultaneously, lifting average Recall by 49% (0.489 $\rightarrow$ 0.729) and matching the 13$\times$ larger off-the-shelf Qwen3-Embedding-8B at 32$\times$ lower embedding dimensionality. Fine-tuning further enables **learned query fusion**: concatenating regulatory text with an example product, which hurts retrieval before fine-tuning, becomes the strongest query type after, beating either alone by 6–11%.

1 Introduction

Modern e-commerce platforms list very large numbers of products across many marketplaces, where three problems recur. (1) **Regulatory compliance** — items legal in some jurisdictions are restricted in others (e.g., kangaroo-meat products cannot be sold in California [1]), so the catalog must be screened against the rules of each marketplace. (2) **Cross-catalog product matching** — supplier and partner-feed listings must be linked to their counterparts in the internal catalog, a long-standing entity-resolution problem in e-commerce (Peeters et al., 2023). (3) **Variation-family grouping** — products that are functionally identical but differ in non-functional attributes (e.g., color, size) should be linked into a single family. All three reduce to retrieval over the internal catalog: given a query (a SOP [2], an external listing, or a reference product), return the matching items.

At catalog scale, the standard solution is a funnel: a cheap, high-recall candidate generator (typically combining keyword/rule-based filters with embedding-based retrieval) narrows the catalog before a downstream high-precision model makes the final decision. A single shared embedding model across the three retrieval settings is desirable, but training one model jointly via in-batch contrastive learning exposes a structural mismatch in *how the tasks are labeled*. Regulatory retrieval is **multi-label** — each product carries a set of compliance categories, so within any batch many items share a category with the query, turning most in-batch negatives into false negatives. Cross-catalog matching has no category labels: each external listing maps to one canonical internal product. Existing multi-label contrastive losses require every batch item to carry comparable labels, so they cannot serve a single embedding model trained on both label-bearing and label-free tasks.

We fine-tune a single Qwen3-Embedding-0.6B (Zhang et al., 2025) model on four retrieval tasks via task-aware instruction prompts (Fig. 1). The core method is **label-aware false-negative exclusion**: in-batch items that share a compliance label with the query are removed from the negative

* Equal contribution.

[2] SOPs are structured natural-language specifications that operationalize each regulation for retrieval, defining the regulatory category and its scope (mock-up in Appendix C)

EMNLP 2026 Industry Track, pages 2355–2368
October 24-29, 2026 ©2026 Association for Computational Linguistics

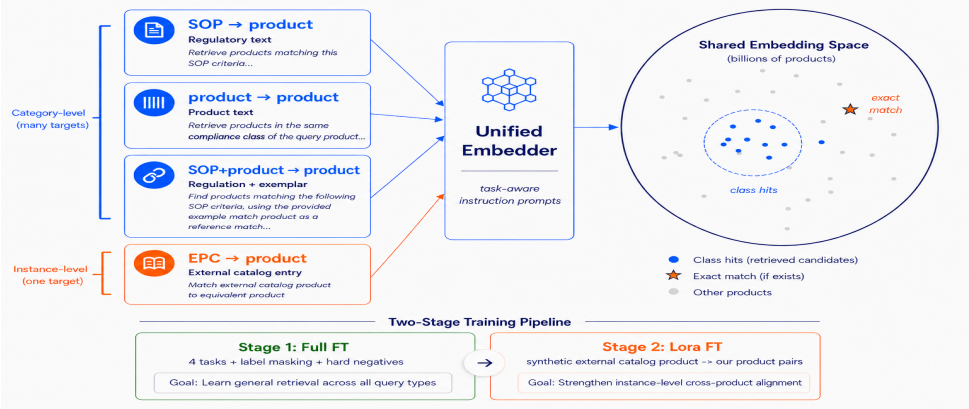

Figure 1: Overview of the heterogeneous retrieval system. A single embedding model unifies four retrieval tasks — three category-level retrieval tasks (returning all products in a compliance category) and one cross-catalog matching task (linking one external listing to its internal counterpart) — through task-aware instruction prompts over a shared embedding space. Training has two stages: full fine-tuning with label masking and hard negatives (Stage 1), then LoRA adaptation on synthetic external–product pairs (Stage 2).

set (a zero-cost binary mask on the InfoNCE denominator), rather than included to additional positives as in multi-label contrastive losses. The mask has no effect on label-free items, so the loss reduces to standard InfoNCE wherever no labels apply, making the method directly compatible with mixed-label batches. Combined with hard negative mining (de Souza P. Moreira et al., 2025), controlled lexical diffusion, and two-stage training, our fine-tuned Qwen3-Embedding-0.6B (Zhang et al., 2025) improves average recall by 49% (0.489 → 0.729).

The closest line of work is multi-label supervised contrastive learning (MulSupCon (Zhang and Wu, 2024) and follow-ups (Wei et al., 2024; Audibert et al., 2025; Lan et al., 2026)), which treats label-overlapping items as additional positives — pulling all same-category items together. We use the same multi-label signal more conservatively: *shared labels are reliable enough to mask false negatives, but not to designate new positives*. Two products sharing a compliance category may differ in brand, regulatory boundary, etc., so forcing them together blurs distinctions retrieval ranking depends on. Exclusion also fits our heterogeneous batches: on label-free tasks the mask has no effect, while on label-bearing tasks it removes false negatives without category clustering. Empirically, exclusion beats multi-positive inclusion on every task (§5), with the largest gap on instance-level retrieval. Softening inclusion does not close that gap: graded variants that give label-overlapping items a similarity-weighted partial-positive weight, or re-weight pairs adaptively, still trail exclusion by 3.3% and 4.1% average recall (Appendix G.3). Handling false negatives itself is well studied in contrastive learning, identifying them from an assumed class prior or from embedding similarity (Appendix A). We instead identify them from ground-truth label overlap, which costs nothing to compute and catches false negatives that the current model scores as dissimilar — precisely those similarity-based detection misses early in training.

Our Contributions are (1) **Label-aware false-negative exclusion** Excluding label-overlapping items from the InfoNCE denominator yields up to 5.7% retrieval gain at zero compute cost, naturally handles mixed-label batches by reducing to standard InfoNCE when labels are absent, and outperforms multi-positive inclusion on every task (§5). (2) **Unified heterogeneous retrieval.** A single fine-tuned 0.6 B-parameter embedding model serves three category-level retrieval tasks and one cross-catalog matching task, matching or exceeding the 13× larger off-the-shelf Qwen3-Embedding-8B at 32× lower embedding dimensionality (§4). (3) **Learned query fusion.** Combining regulatory text with an example product as a single query *hurts* retrieval in the base model but becomes the strongest query type after fine-tuning, outperforming either query type alone by 6–11% (§4.3). (4) **Zero-shot transfer.** Variation-family retrieval improves by +16% Recall@100 despite being unseen during training (§4.2).

2 Training Framework

Base model and multi-task batching. We adopt Qwen3-Embedding-0.6B (Zhang et al., 2025), which produces 1024-dim L2-normalized embeddings and supports 100+ languages. The size is a pragmatic trade-off: evaluation over very

large item indexes makes larger embedding models prohibitive at inference. We train on all four tasks simultaneously using heterogeneous batching with task-proportional sampling; the loss is computed over the combined batch rather than per-task sub-batches, since well-blended batches avoid the "zigzag" gradient updates of alternating-task training (Lee et al., 2025).

2.1 Label-Aware False Negative Exclusion

As discussed in §1, multi-label structure causes same-category items to co-occur frequently within a training batch, and standard contrastive losses treat them as negatives. Prior multi-label contrastive methods (Zhang and Wu, 2024; Wei et al., 2024; Audibert et al., 2025) address this by including label-overlapping items as additional weighted positives. We take the opposite approach: we *exclude* them from the negative set and keep a single designated positive per query. We show in §5 that this exclusion strategy consistently outperforms multi-positive inclusion and other variants.

Contrastive loss. For each training instance i with query q_i, positive document d_i^+, and K mined hard negatives $\{d_{i,k}^-\}_{k=1}^K$, we adopt the modified InfoNCE loss (van den Oord et al., 2019) used in Qwen3-Embedding training (Zhang et al., 2025):

$$\mathcal{L}_i = -\log\big(e_\tau(q_i, d_i^+) \,/\, Z_i\big) \tag{1}$$

where $e_\tau(a,b) = \exp\big(s(a,b)/\tau\big)$, $s(\cdot,\cdot)$ denotes cosine similarity, τ is the temperature, and Z_i sums over the positive, K hard negatives, and all in-batch items used as additional negatives:

$$\begin{aligned} Z_i = e(q_i, d_i^+) &+ \sum_k e(q_i, d_{i,k}^-) \\ &+ \sum_{j \neq i} \big[m(q_i, d_j) e(q_i, d_j) \\ &+ m(q_i, q_j) e(q_i, q_j) \\ &+ m(d_i^+, d_j) e(d_i^+, d_j) \big] \end{aligned} \tag{2}$$

Concretely, q_i is the task-aware query (a SOP, a known compliant product, or an external-catalog listing, depending on the task), d_i^+ is the canonical matching product, and the in-batch items in Z_i are queries and documents drawn from any of the four training tasks (§3).

The false-negative problem. By default ($m(a,b) = 1$ for all pairs), every non-paired in-batch item acts as a negative. In our multi-task setting, items from the same compliance category frequently co-occur within a batch, turning true positives into false negatives that the loss actively pushes apart. Multi-label structure compounds this: a single item may belong to multiple classes simultaneously, so the probability that two random in-batch items share at least one label grows with label cardinality.

Label-aware mask (illustrated in Fig. 5). We introduce a binary mask $m(a,b)$ into the denominator of Eq. (2). If items a and b share at least one compliance label, b is excluded from the negative set for a:

$$m(a,b) = \begin{cases} 0 & \text{if } \mathcal{Y}(a) \cap \mathcal{Y}(b) \neq \emptyset \\ 1 & \text{otherwise} \end{cases} \tag{3}$$

where $\mathcal{Y}(a)$ is the set of compliance labels for item a. For instance-level tasks (External→Product), the external-feed query has $\mathcal{Y}(q_i) = \emptyset$, so $m(q_i, \cdot) = 1$ and the loss reduces to standard InfoNCE—the desired behavior since false negatives are negligible there. The label sets $\mathcal{Y}(\cdot)$ come from internal compliance classifier outputs over the evaluation catalog, so each evaluated product carries its multi-label annotation with no additional manual labeling effort; computing the mask is a single set-intersection per pair. The mask is applied only to off-diagonal in-batch pairs ($j \neq i$ in Eq. (2)); a query is never compared with itself.

Matryoshka multi-scale loss. The final training loss wraps Eq. (1) with Matryoshka Representation Learning (Kusupati et al., 2024), computing the contrastive loss at dimensions $\{32, 64, 128, 256, 512, 1024\}$ and summing across scales, enabling reduced-dimensional evaluation without retraining.

3 Data Pipeline

Task formulation. Our training data is derived from binary compliance categories collected through an internal labeling pipeline over an approximately two-year period, spanning multiple languages and regulatory programs. The dataset comprises thousands of distinct SOPs, each with a substantial average number of human-labeled positive products. A single product may belong to multiple compliance categories. We reformulate classification labels as retrieval pairs: for each SOP, positive products serve as relevant documents. We construct three

category-level tasks: **SOP→Product** (regulatory-text query), **Product→Product** (known-compliant-product query), and **SOP+Product→Product** (regulatory text concatenated with an example product). We additionally incorporate one **instance-level** task, **External→Product**, linking external-catalog feed entries to internal-catalog counterparts. The training set totals 2M unique query–document pairs; each task uses a task-specific instruction template, and documents share a common template (Appendix D).

Hard negative mining. Hard negatives provide stronger training signal than random in-batch negatives (Gao et al., 2021), but mining must avoid false negatives. We adopt positive-aware mining (de Souza P. Moreira et al., 2025) with Qwen3-Embedding-8B as teacher (a stronger teacher surfaces harder negatives), then apply two filters: (i) a **score-based filter** that discards any candidate scoring above $s^+ \times \rho$ (ρ=0.95), where s^+ is the teacher's query–positive similarity, and (ii) a **label-overlap filter** that discards any candidate sharing at least one compliance label with the query. We retain the top-2 surviving candidates per query (ablation in §G.1).

Controlled Lexical Diffusion (CLD). Authentic external–product training pairs are scarce; we augment them with CLD, a six-stage curriculum where token-removal probability p rises linearly from 0.0 to 0.15. For positives, CLD removes tokens shared between external-feed and product listings (set intersection), forcing matching on sparser lexical overlap; for negatives, it removes tokens unique to either listing (set difference), making them superficially more similar. Only free-text fields are diffused; structured attributes (brand, model number, dimensions) are preserved as stable anchors.

Two-stage training. Stage 1 fully fine-tunes Qwen3-Embedding-0.6B on all four tasks with heterogeneous batching and label-aware exclusion (§2.1). Stage 2 applies LoRA (Hu et al., 2021) from the Stage 1 checkpoint on CLD-generated external–product pairs. A separate stage is necessary because CLD's token perturbations can invalidate compliance labels, which would corrupt label masking for category-level tasks if mixed into Stage 1. LoRA preserves the multi-task representations while adapting to the augmented external-feed distribution. Configuration in Appendix F.

4 Experiments

4.1 Evaluation Data, Setup, and Metrics

For category-level retrieval, we hold out 100 SOPs spanning multiple languages and regulatory programs, totaling 201K human-labeled products; we construct SOP, Product, and SOP+Product queries from these. For instance-level retrieval, we use 49K human-labeled external–product pairs, plus 48K human-labeled product variant pairs (functionally identical products differing only in non-functional attributes such as color or size); the variant task is excluded from training to test zero-shot transfer. We evaluate at two scales: a **298K development pool** (201K category-level + 97K instance-level products, controlled ablations at full and 128 dimensionality), and a **large-scale index** (200M products sampled from a larger internal catalog, with all instance-level targets guaranteed included). The large-scale index uses 128-dimensional embeddings for computationally constrained retrieval. The primary metric is Recall@K. For the 298K pool, K equals the per-class positive count. For the large-scale index, $K \in \{100, 1000\}$ is fixed. For instance-level tasks, K=1 reduces Recall@K to Hit@K. For category-level tasks at large scale, ground-truth labels come from internal compliance classifier outputs; training and evaluation SOPs are disjoint, and core findings are validated on the human-labeled 298K pool.

4.2 Large-scale retrieval

We evaluate our fine-tuned model on a large-scale item index spanning multiple marketplaces and languages, using 128-dimensional embeddings.[3] Table 1 reports per-stage results across all five retrieval tasks.[4]

Stage 1 vs. Stage 2. Stage 1 drives the dominant category-level gains, improving Recall@1000 by +61–224% across the three SOP tasks. Stage 2 adds substantial External→Product improvement (R@100: +10.3%) while category-level recall degradation is less than 3.5% relative from Stage 1. The final model improves category-level R@1000 by +57–233% over the base and reaches near-ceiling external-feed retrieval (R@1000 = 0.972), all with a 0.6B model at no increase in inference cost. While absolute category-level recall at fixed

[3] At this index size, ANN retrieval cost motivates 128-dimensional embeddings.

[4] Extended results including comparison with a prior internal baseline are provided in Appendix H.

Table 1: Retrieval performance on large-scale item index (128d). Stage 1: full fine-tuning; Stage 2: + external-feed LoRA. †Variation Family task is excluded from training. Bold marks the best result across conditions; Δrel compares the final model (+S2) to the base.

	Base		+S1		+S2		Δrel	
Task	R@100	R@1000	R@100	R@1000	R@100	R@1000	R@100	R@1000
Category-level retrieval								
SOP→Product	.024	.079	**.088**	.256	.085	**.264**	+248%	+233%
Product→Product	.100	.212	**.141**	**.342**	.138	.333	+37%	+57%
SOP+Product→Product	.064	.158	.134	**.362**	**.143**	.361	+125%	+128%
Instance-level retrieval								
External→Product	.467	.629	.854	.924	**.942**	**.972**	+102%	+54%
Product→Var.†	.705	.832	.688	.866	**.818**	**.940**	+16%	+13%

K=1000 appears modest, the embedding-based retrieval serves as a high-recall candidate generator where K can be set much larger before a downstream classifier makes the final decision. The +233% relative improvement translates directly into broader coverage. The final model also outperforms the prior internal baseline on all five tasks by +69-281% Recall@1000 on SOP-query tasks, and +10% on variant retrieval despite never training on it (Appendix H).

Zero-shot transfer to Product Variation family retrieval. The Variation family task retrieves child products sharing identical grouping attributes (brand, item form, etc.) but differing in non-functional themes (size, color), and is excluded from training. Stage 1 alone yields mixed results (−2% at R@100), as category-level retrieval does not require distinguishing individual products within a class. Stage 2 dramatically improves variant retrieval (R@100: +16%, R@1000: +13% over base). external-feed LoRA trains instance-level retrieval, aligning one specific external product to one specific product despite surface-form differences, precisely the skill that variant identification requires.

4.3 Development pool analysis

We use a 298K development pool for controlled analysis of the pipeline, with results shown in Table 2. The off-the-shelf Qwen3-Embedding-8B is reported as a scaling reference, not a scientific baseline: it is 13× more expensive at inference, which makes it unsuitable for retrieval over catalogs at this scale, and it is not fine-tuned. The effect of the mask is measured separately in §5, where every model compared is the same fine-tuned 0.6B and only the loss changes.

Learned query fusion. In the base model, concatenating SOP text with an example product *hurts* retrieval: Product-only (0.537) > SOP+Product (0.513) > SOP-only (0.367). After fine-tuning, the ranking reverses: SOP+Product (0.742) > SOP-only (0.697) > Product-only (0.668), outperforming either query type alone by 6–11%. The model learns to fuse complementary signals: the SOP defines *what to look for* (regulatory scope) and the example product defines *what it looks like* (product attributes), all without any architectural modification. This provides a practical few-shot mechanism: a single example product dramatically improves retrieval for new SOPs.

Table 2: Retrieval on 298K pool (Recall@K, K = per-class positive count). Superscripts show relative performance loss when truncating from full to 128 dimensions. †Untrained direction. ‡Off-the-shelf reference. Gemma in Appendix I.

	Full dim		128d	
Task	Base	FT	Base	FT
Qwen3-Emb. 0.6B (1024d)				
SOP→Product	.367	**.697**	$.298^{-19\%}$	$\mathbf{.677}^{-3\%}$
Product→Product	.537	**.668**	$.496^{-8\%}$	$\mathbf{.667}^{-0\%}$
SOP+Product→Product	.513	**.742**	$.436^{-15\%}$	$\mathbf{.733}^{-1\%}$
External→Product	.538	**.809**	$.410^{-24\%}$	$\mathbf{.789}^{-2\%}$
Product→SOP†	.749	**.838**	$.630^{-16\%}$	$\mathbf{.819}^{-2\%}$
Qwen3-Emb. 8B‡ (4096d)				
SOP→Product	.649	—	$.547^{-16\%}$	—
Product→Product	.594	—	$.565^{-5\%}$	—
SOP+Product→Product	.692	—	$.627^{-9\%}$	—
External→Product	.802	—	$.724^{-10\%}$	—
Product→SOP†	.814	—	$.735^{-10\%}$	—

Dimensional robustness. Matryoshka-trained models support truncation to lower dimensions without retraining. The superscripts in Table 2 show that base models lose 8–24% per task when truncated from full to 128 dimensions, while fine-tuned models lose at most 3%. Fine-tuning concentrates task-relevant information into the first few embedding dimensions, so truncation discards little useful signal. This enables 128-dimensional

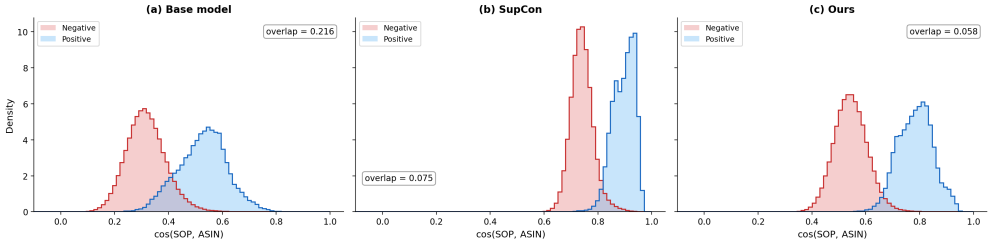

Figure 2: SOP–Product cosine similarity distributions. Overlap area (lower is better) reported per panel.

retrieval at 8× reduced ANN cost with minimal retrieval degradation.

Reverse retrieval without reverse training. The model is trained on SOP→Product but never the reverse. Fine-tuning improves Product→SOP from 0.749 to 0.838 (+12%), surpassing the off-the-shelf 8B (0.814), despite swapped prompt roles never seen in training. This indicates genuine semantic alignment rather than prompt-slot memorization.

Fine-tuning vs. model scaling. Our fine-tuned 0.6B matches or exceeds the off-the-shelf Qwen3-Embedding-8B on all five tasks at full dimensionality. At 128d, it still outperforms the 8B at its full 4096d on four of five tasks (External→Product: −1.6% relative). The 8B is larger and is used without fine-tuning, so we treat it as a scaling reference rather than as evidence for our method's effectiveness . It answers a different and practical question: can a fine-tuned small model replace a large model used off the shelf? This is the choice an industrial system faces. The effect of the mask is measured separately in §5, where every model compared is the same fine-tuned 0.6B and only the loss changes. For compute-constrained settings where the larger model is impractical, task-aware fine-tuning of the 0.6B model closes, and in most cases eliminates, the gap with the off-the-shelf 8B, delivering comparable or superior retrieval at 13× lower inference cost and 32× lower index size.

Unified vs. per-task models. An alternative design is one specialist embedding model per task. In our setting all tasks retrieve against the same target - the internal catalog - so a unified model lets the catalog be embedded and indexed *once*; Per-task specialists would instead multiply both embedding generation and ANN index footprint by the number of tasks, and re-incur both on every catalog update, which is prohibitive at the scale of our catalog.

Cross-architecture generalization. To verify that the gains are not specific to Qwen3, we apply the same training pipeline to EmbeddingGemma-0.3B (Vera et al., 2025), an encoder-only model. Gemma shows comparable improvement (+47% average category-level Recall@K vs. +49% for Qwen3), confirming that the gains stem from the contrastive framework rather than the model architecture. Full results about Gemma are in Appendix I.

5 Ablation Studies

Table 3 compares three strategies for handling in-batch false negatives: (1) InfoNCE with label-aware masking (ours), (2) Vanilla InfoNCE without masking: the identical multi-task fine-tune with only the mask removed, serving as the multi-task baseline, and (3) SupCon, which treats label-overlapping items as additional positives (implementation in Appendix G.2). SupCon is *hard* inclusion: it assigns every label-overlapping item full positive weight. To test whether softer inclusion recovers the gap, we additionally evaluate two graded variants: a soft-label loss that gives the mined hard negative a partial-positive weight set by a softmax over query–candidate similarities, and circle loss (Sun et al., 2020), which adaptively reweights pairs by their distance from an optimal similarity. Both still underperform exclusion and per-task results and discussion are in Appendix G.3. Additional ablations are in Appendix G.1 and G.4.

Exclusion outperforms inclusion. SupCon degrades every task; the damage is worst on External→Product (−16.8%) where external-feed products carry no category labels so SupCon cannot add positives, yet still distorts the shared embedding space by pulling same-category products together, destroying the per-product distinctions instance-level retrieval requires.

Why exclusion wins: embedding geometry. Retrieval quality is governed by overlap between positive and negative cosine distributions (Fig. 2). SupCon reduces overlap from 0.216 (base) to 0.075, but pulling all same-category items together shifts negatives rightward nearly as much as positives.

Table 3: Ablation: InfoNCE with label-aware masking (Ours) vs. removing the mask (w/o) and replacing InfoNCE with SupCon. Recall@K, dim=1024. †Not directly trained. Ours, w/o, and $\Delta\%$ report range over two independent seeds; $\Delta\% = (\text{Ours} - \text{w/o})/\text{Ours}$. External→Product and Product→SOP were not part of the two-seed study (placeholders, to be filled). SupCon is a single-seed main-pool comparison; its Rec. and $\Delta\%$ are relative to the main-pool Ours in Table 2.

	Mask vs. no-mask (2 seeds)			SupCon	
Task	Ours	w/o	Avg $\Delta\%$	Rec.	Avg $\Delta\%$
SOP→Product	.689–.695	.657–.660	-4.9%	.662	−5.0%
Product→Product	.690–.696	.678–.688	-1.5%	.618	−7.5%
SOP+Product→Product	.756–.760	.739–.746	-2.1%	.686	−7.5%
External→Product	.806–.809	.79–.794	-2.2%	.673	−16.8%
Product→SOP†	.839	.825	-1.7%	.809	−3.6%

Our method does not pull same-category items together; it only prevents false negatives from being pushed apart, concentrating the learning signal on the designated positive and producing the lowest overlap (0.058). Retrieval benefits more from clean positive–negative separation than from category-cluster compactness. A gradient view makes the same prediction. With one designated positive, the entire numerator gradient pulls the query toward that single pair; inclusion spreads this pull across every same-label positive, weakening the signal on the true pair, while the resulting category-cluster contraction drags nearby negatives along so positive–negative separation barely improves. This hurts instance-level tasks most, since they must separate individual products within a category rather than compact them — consistent with the largest degradation on External→Product (−16.8%).

Masking provides complementary gains. Removing the mask from InfoNCE degrades every category-level task, most on SOP→Product where same-category products co-occur most frequently in batches and are incorrectly penalized as negatives, and least on Product→Product; the untrained Product→SOP also benefits. To check that these gains are not an artifact of a single run, the Ours columns of Table 3 report range over two independent training seeds: the mask's gain stays clearly positive on the SOP-query tasks. Masking adds zero compute cost but reliably improves retrieval wherever false-negative collisions are frequent.

6 Conclusion

When category-level and instance-level retrieval tasks coexist in the same training batch, existing multi-label contrastive methods that include label-overlapping items as additional positives cannot be applied uniformly. We show that excluding false negatives from the contrastive loss is simpler, cheaper, and strictly better than including them as positives. A single 0.6B-parameter model trained with this approach unifies four heterogeneous retrieval tasks, matches or exceeds the 13× larger Qwen3-Embedding-8B at 32× lower dimensionality, and generalizes to unseen retrieval tasks excluded from training. Contrastive fine-tuning also teaches the model to fuse complementary query signals, combining regulatory text with an example product, providing a practical few-shot retrieval mechanism.

Limitations

We evaluate on e-commerce product compliance; generalization to other heterogeneous retrieval domains (legal, biomedical) is plausible but unverified. The label-aware mask assumes reliable multi-label annotations; noisy or partial labels could cause it to wrongly exclude informative negatives. The mask is also less suited to very coarse label sets: if categories are few and broad, most of a batch shares a label with the query and is excluded, leaving too few in-batch negatives to learn from. Our compliance labels are fine-grained (thousands of SOPs), so this does not arise here. Large-scale category-level ground truth comes from internal classifier outputs, not human annotation; we mitigate via the human-labeled 298K pool, but classifier biases may still influence absolute numbers. Stage 2 LoRA adapts to a synthetic external-feed distribution that may differ from real-world feeds in ways our perturbation does not capture. Finally, the problem we study is not well represented by existing public benchmarks: retrieval over a shared catalog where some items carry multi-label annotations and some tasks carry no shared labels at all. General retrieval suites (MTEB (Muennighoff et al., 2023), BEIR (Thakur et al., 2021)) provide no per-item label sets, and the closest public multi-label resource (MultiEURLEX (Chalkidis et al., 2021)) is a classification dataset without a retrieval

pool. We therefore cannot evaluate the mask on any dataset other than our own, which is why the cross-domain generalization (e.g., legal, biomedical) noted above remains unverified. We also cannot release the internal catalog and its compliance labels, so our results cannot be independently replicated. Building a public heterogeneous retrieval benchmark that reflects this setting is future work.

Ethics Statement

Scope of the model. The embedding model studied in this paper is evaluated only as a high-recall candidate-generation component in a controlled research setup. It is not a standalone compliance decision-maker, and the recall numbers reported here are intended for *cross-model benchmarking under fixed experimental conditions*. They should not be interpreted as operational system recall. In practical high-recall retrieval settings, a candidate generator can be configured with larger top-K values and combined with complementary non-neural filters before subsequent review or classification.

Data and privacy. Training data is derived from internal compliance classifications used for this study. No personal data, customer queries, or seller-private information are used. All examples in the paper are anonymized.

A Related Work

General-purpose text embedding models. Existing work has produced a family of general-purpose embedding models trained on large-scale multi-task mixtures. E5 (Wang et al., 2022) uses weakly supervised contrastive pretraining over web-scale text pairs; GTE (Li et al., 2023) extends this with multi-stage contrastive learning across diverse NLP tasks; INSTRUCTOR (Su et al., 2023) introduces task-specific instruction prompts so that a single model handles retrieval, classification, and clustering without per-task fine-tuning; and NV-Embed (Lee et al., 2025) adds a two-stage pipeline that separates retrieval training from non-retrieval instruction tuning. Our work shares the instruction-prompted multi-task paradigm but targets a different regime: *domain-specific* fine-tuning on a narrow set of compliance retrieval tasks. We show that a fine-tuned 0.6B model outperforms a 13× larger general-purpose model, demonstrating that for specialized retrieval, task-aware fine-tuning is more cost-effective than model scaling.

Domain-specific embedding adaptation. General-purpose embedding models often underperform on specialized domains due to vocabulary mismatch and distributional shift (Thakur et al., 2021). Continued pretraining on in-domain corpora (Gururangan et al., 2020) and contrastive fine-tuning on domain-specific pairs are common remedies. Our results extend this line of work: domain-aware contrastive fine-tuning of a 0.6B model not only closes the gap with but surpasses the off-the-shelf 8B model on all domain-specific tasks, at 13× lower inference cost and 32× smaller index size.

Hard negative mining. The quality of negative examples is critical for contrastive learning (Xiong et al., 2021; Robinson et al., 2021). de Souza P. Moreira et al. (2025) introduce positive-aware filtering, using the positive relevance score as an upper bound to discard likely false negatives during mining. We adopt this strategy with a stronger teacher model (Qwen3-Embedding-8B) for candidate generation and show that combining mined

hard negatives with in-batch label-aware masking yields complementary gains.

False negatives and multi-label contrastive learning. MulSupCon (Zhang and Wu, 2024) and follow-ups (Wei et al., 2024; Audibert et al., 2025; Lan et al., 2026) extend SupCon to multi-label settings, weighting positives by label overlap. Our contrast with these methods — why exclusion rather than weighted multi-positive inclusion suits heterogeneous batches that mix label-bearing and label-free tasks — is discussed in §1 (paragraph 4) and empirically compared in §5. Beyond multi-label methods, false negatives in contrastive learning have also been addressed without class labels: Chuang et al. (2020) correct the contrastive loss in distribution, re-weighting the negative term under an assumed class prior; Huynh et al. (2022) detect likely false negatives via embedding similarity and discard or promote them; and de Souza P. Moreira et al. (2025) filter mined negatives whose teacher score exceeds a positive-anchored threshold. These similarity-driven estimates are complementary to our mask, which uses ground-truth label overlap and therefore also removes false negatives that the current model scores as dissimilar — precisely those that similarity-based detection misses early in training. Our contribution is thus not false-negative handling per se, but a label-overlap exclusion mechanism that operates in-loss, costs nothing to compute, and degrades gracefully to standard InfoNCE under heterogeneous label structures.

Few-shot and exemplar-augmented retrieval. Augmenting queries with exemplar documents has been explored in retrieval-augmented generation and few-shot settings (Muennighoff et al., 2024). We demonstrate that combining regulatory text with an example product (exemplar-augmented query) reverses performance from the weakest to the strongest query type after fine-tuning, providing evidence for this approach in industrial compliance retrieval.

Matryoshka representations. Kusupati et al. (2024) introduce Matryoshka Representation Learning, training embeddings to be effective at multiple dimensionalities. Our base model incorporates this approach, and we show that domain-specific fine-tuning preserves and even enhances this dimensional robustness, enabling $8\times$ embedding compression with minimal retrieval degradation.

Negation understanding in language models. Negation remains a known challenge for language models and embedding systems (Kassner and Schütze, 2020; Ravichander et al., 2022). We provide empirical evidence that our fine-tuned model effectively leverages negation information in regulatory text (e.g., "keywords not of interest" in SOPs), contrary to common assumptions.

B Problem Setting

Products listed on large e-commerce platforms may not always satisfy regulatory requirements; identifying such products is important for customer safety and platform integrity. This setting requires matching very large product collections against many regulatory rules, a scale at which a single end-to-end classifier is impractical. We study a retrieval formulation in which a high-recall embedding model narrows the item collection to a candidate pool for subsequent classification. Our experiments evaluate whether a compact 0.6B-parameter model can improve this candidate-generation step relative to a prior internal baseline, while preserving low inference and index cost.

C SOP

A structural mock-up of an SOP is shown in Fig. 3, illustrating the class description, positive keywords, and negative keywords that define a compliance category.

I'm interested in classifying products into one of the following categories: Category A

<class_description>
Describe the categories of interest: A natural-language description of the regulatory category, including its scope, the kinds of products it covers, and any distinguishing functional or material attributes.
</class_description>

<keywords_of_interest>
Products that should be classified as Category A often contain keywords like *[positive keyword 1]*, *[positive keyword 2]*, . . .
</keywords_of_interest>

<keywords_not_of_interest>
Products that should be excluded from this classification task contain keywords like *[exclusion keyword 1]*, *[exclusion keyword 2]*, . . .
</keywords_not_of_interest>

Figure 3: Mock-up SOP query template. The class description defines the regulatory category, positive keywords guide retrieval, and negative keywords explicitly exclude unrelated products.

D Prompt Design

Fig. 4 shows prompt templates for the five retrieval tasks.

E Label-Aware Masking

Fig. 5) illustrated the Label-aware mask in an example batch.

F Training Hyperparameters

Table 4 reports the complete training configuration. Stage 1 performs full fine-tuning on the multi-task compliance dataset; Stage 2 adapts the Stage 1 checkpoint with LoRA on synthetic external–product pairs.

Table 4: Training hyperparameters. Values reported as Stage 1 / Stage 2; a single value indicates the setting is shared.

Hyperparameter	**Stage 1 / Stage 2**
Model	
Base model	Qwen3-0.6B / S1 ckpt-1000
Training type	Full / LoRA
Infrastructure	
Nodes × GPUs	8×8 / 1×8
Per-GPU batch	16
Grad. accum. steps	2
Effective batch	2048 / 256
DeepSpeed	ZeRO-3 / ZeRO-2
Precision	bf16
Optimization	
Learning rate	10^{-5} / 2×10^{-5}
LR scheduler	Cosine
Warmup ratio	0.01 / 0.05
Loss function	
Loss type	Matryoshka InfoNCE
Temperature τ	0.02
Matryoshka dims	{32, 64, …, 1024}
Hard negatives K	2 / —
LoRA (Stage 2 only)	
Rank / α / drop.	— / 16 / 32 / 0.05
Data	
Tasks	4 (excl. var.) / ext.–item
Task weights (Stage 1)	.52 / .19 / .19 / .10
Max seq. length	3072

Notes. The Matryoshka InfoNCE loss computes a separate InfoNCE loss at each truncated dimension $d \in \{32, 64, 128, 256, 512, 1024\}$ and returns the unweighted sum. All six dimensions are evaluated at every training step. The denominator (Eq. 2) includes query-to-document (QD), query-to-query (QQ), and document-to-document (DD) similarity blocks, following Qwen3-Embedding's training formulation (Zhang et al., 2025). An identity mask sets any in-batch pair with cosine similarity ≥ 0.999 to $-\infty$, preventing near-duplicate items from acting as false negatives; each query's own document block (positive + hard negatives) is exempt.

Stage 2 disables label masking because the synthetic external-feed data lacks namespace labels, and omits hard negatives because the synthetic generation process (Section 3) already controls negative difficulty through token-level perturbation. LoRA with rank 16 and a higher learning rate (2×10^{-5}) preserves the multi-task representations from Stage 1 while efficiently adapting to the augmented external-feed distribution.

G Additional Ablations

G.1 Hard Negatives

Table 5 compares 1, 2 and 5 hard negatives per positive. At checkpoint-1000 (dim=1024), using 2 hard negatives outperforms 5 on all tasks by a consistent margin (-0.004 average Recall@K). Examining the training progression reveals that 5 hard negatives provides a slight advantage at earlier checkpoints (400–800) but degrades faster, while 2 hard negatives peaks later and reaches a higher final performance. This suggests that additional hard negatives accelerate early learning but introduce more noise from borderline examples, leading to faster overfitting. We select 2 hard negatives as the best trade-off between training signal strength and stability.

Table 5: Ablation: hard negatives per positive (Recall@K, dim=1024, checkpoint-1000). Using 2 hard negatives provides the best trade-off.

Task	HN=1	HN=2	HN=5
SOP→Product	0.680	**0.695**	0.691
Product→Product	0.668	**0.696**	0.668
SOP+Product→Product	0.738	**0.756**	0.741

G.2 SupCon variant for ablation

The supervised contrastive (SupCon) variant used in Section 5 replaces the standard single-positive InfoNCE objective with a *per-label* SupCon loss adapted from Khosla et al. (2020). All items in the batch (queries, positive documents, and hard negative documents) are pooled into a single set of N embeddings. Each item inherits its namespace membership labels from the training data: queries receive `query_labels`, positive documents receive `pos_labels`, and hard negatives receive `neg_labels`.

For each namespace label l present in the batch, the loss identifies all items sharing that label and treats them as mutual positives. For anchor i with

(a) Product Index and Query Prompt

```
Product:
item_name: [product name]
manufacturer: [manufacturer]
product_type: [type code]
product_group: [group code]
item_type_keyword: [type keyword]
[additional structured attributes]
```

(b) SOP Query Prompt

```
Retrieve products that match the following Standard
Operating Procedure (SOP) criteria:
SOP: I'm interested in classifying products into one of the
following categories: Category B
⟨class_description⟩
[abstract description of the category, including its scope
and any distinguishing functional or material
attributes. . . ]
⟨/class_description⟩
⟨keywords_of_interest⟩
[positive keywords in target marketplace language]. . .
⟨/keywords_of_interest⟩
⟨keywords_not_of_interest⟩
[exclusion keywords in target marketplace language]. . .
⟨/keywords_not_of_interest⟩
```

(c) SOP+Product Query Prompt (Exemplar-Augmented)

```
Find products matching the following SOP criteria, using the
provided example match product as a reference match.
SOP: I'm interested in classifying products into one of the
following categories: Category B
⟨class_description⟩. . . ⟨/class_description⟩
⟨keywords_of_interest⟩. . . ⟨/keywords_of_interest⟩
⟨keywords_not_of_interest⟩. . . ⟨/keywords_not_of_interest⟩
Example Match Product:
item_name: [product name]
manufacturer: [manufacturer]
product_type: [type code]
product_group: [group code]
[additional structured attributes]
```

(d) External Query Prompt

```
Match external catalog products to equivalent products:
Retrieve products that share the same attributes,
specifications, and features as the query product from an
external catalog, prioritizing semantic similarity over
exact keyword matches. Missing information in any attribute
does not disqualify a match as long as there is no explicit
contradiction.
Query Product:
[external catalog product attributes]
```

(e) Variation Query Prompt

```
Retrieve variant products for the query product:
Two products are variants if they are functionally identical.
Use semantic matching rather than exact string matching when
comparing functional attributes. Color, size, and quantity
are non-functional and may vary within a variation family.
Query Product:
item_name: [product name]
brand: [brand]
bullet_point: [bullet point]. . .
color: [color value]
. . .
```

Figure 4: Prompt templates for the five retrieval tasks. Blue text denotes the system instruction prefix that defines the task. **(a)** Product documents are indexed using structured product attributes (shared across all tasks as the retrieval target). **(b)** SOP queries contain a category description, positive keywords, and negative keywords in the target marketplace language. **(c)** Exemplar-augmented queries concatenate the SOP with an example matching product, providing both textual criteria and a concrete reference. **(d)** External-feed queries match products across external catalogs via semantic attribute similarity. **(e)** Variation queries retrieve functionally identical products, ignoring non-functional attributes such as color and size.

label l, the per-label loss is:

$$\mathcal{L}_{i,l} = -\frac{1}{|P_l(i)|} \sum_{p \in P_l(i)} \log \frac{\exp(z_i \cdot z_p/\tau)}{\sum_{a \neq i} \exp(z_i \cdot z_a/\tau)}, \tag{4}$$

where $P_l(i)$ is the set of items sharing label l with i (excluding i itself), and the denominator sums over all $N-1$ other items regardless of label. The per-label decomposition prevents transitive contamination: a multi-label item belonging to namespaces A and B only pulls toward A-members when computing the A sub-loss, not toward B-members. For instance-level tasks (External, Variation) that lack namespace labels, the loss degenerates to standard single-positive InfoNCE.

This SupCon formulation replaces rather than augments the InfoNCE objective during training. All other hyperparameters (temperature τ=0.02, 2 hard negatives, 8-node training, Matryoshka dimensions) are held constant to isolate the effect of including same-category items as additional positives versus excluding them as false negatives.

G.3 Inclusion-family variants: soft-label and circle loss

SupCon (§5) is the *hard* form of inclusion: every label-overlapping item is treated as a full positive. To test whether *graded* inclusion — assigning partial rather than full positive weight to items other than the designated positive — closes the gap to exclusion, we evaluate two additional objectives under the identical training recipe as our model.

Soft-label weighting. The soft-label contrastive loss gives the mined hard negative a partial *positive* weight in the numerator, instead of treating it purely as a negative. For a query q with positive p and hard negative h, the per-sample loss is the weighted sum $-w_1 \log \frac{e_\tau(q,p)}{Z} - w_2 \log \frac{e_\tau(q,h)}{Z}$, where the weights $[w_1, w_2] = \mathrm{softmax}([\cos(q,p), \cos(q,h)]/\tau_w)$ are computed from the query–candidate cosine similarities and detached from the gradient (τ_w=0.1).

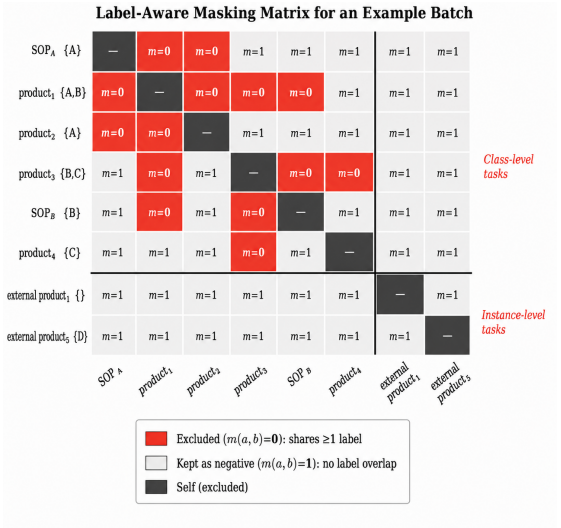

Figure 5: Red: excluded ($m(a,b)=0$, shares ≥ 1 label). Gray: kept as negative. External row: no category labels, no masking.

When the hard negative is far from the query, $w_2 \to 0$ and the loss reduces to standard InfoNCE; when it is close, w_2 grows and the hard negative receives partial-positive gradient. Inclusion here is thus soft and self-calibrating, driven by embedding similarity rather than by label overlap.

Circle loss. Circle loss (Sun et al., 2020) keeps the same positive and negative pairs but re-weights each adaptively, applying a larger gradient to pairs farther from their optimal similarity — an adaptive rather than fixed weighting.

Results. Table 6 reports Recall@K on the three category-level query types, each condition measured against the matched InfoNCE+mask baseline. Both variants underperform exclusion on every category-level task. On average, soft-label loses -3.3% and circle loss -4.1% relative Recall@K; adding SupCon's -5.0 to -7.5% on the same tasks (Table 3), the four objectives order by how aggressively each assigns positive weight away from the single designated pair: exclusion (none) $>$ soft-label (a soft weight on the hard negative) $>$ circle loss (adaptive re-weighting) $>$ SupCon (full weight on all same-category items).

G.4 Negation keyword ablation

SOPs contain a `<keywords_not_of_interest>` field listing terms the compliance category explicitly excludes. We train and evaluate a variant with this field stripped from all SOP queries. Removing negation keywords degrades average Recall@K by -3.6% relative (Table 7), with the largest impact on SOP→Product (-5.3%), where negation keywords directly constrain retrieval scope. The effect is consistent across checkpoints, confirming that the model has learned to leverage negation information, challenging the common assumption that embedding models cannot handle negation (Kassner and Schütze, 2020).

Table 6: Variants vs. exclusion (Recall@K, dim=1024, checkpoint-1000, three category-level query types). S→P: SOP→Product; P→P: Product→Product; S+P→P: SOP+Product→Product. $\Delta\%$ is relative to the matched InfoNCE+mask baseline (Ours).

		Soft-label		Circle	
Task	Ours	Rec.	$\Delta\%$	Rec.	$\Delta\%$
S→P	**.695**	.656	-5.6%	.631	-9.2%
P→P	**.696**	.676	-3.0%	.683	-1.9%
S+P→P	**.756**	.741	-2.0%	.740	-2.0%
Average	**.715**	.691	-3.3%	.685	-4.1%

Table 7: Ablation: removing negation keywords from SOP queries (Recall@K, dim=1024).

Task	Ours	− Neg. KW	$\Delta\%$
SOP→Product	**0.695**	0.674	-3.1%
Product→Product	**0.696**	0.661	-5.3%
SOP+Product→Product	**0.756**	0.738	-2.4%

H Extended large-scale results

Table 8 provides the full large-scale evaluation including comparison with a prior internal baseline. Our fine-tuned 0.6B model (Stage 2) outperforms the prior internal baseline on all five tasks. The advantage is largest on SOP-query tasks (+69–281% at Recall@1000), where the prior internal baseline, which was not trained with SOP-specific contrastive objectives, performs below our proposed model. On external-feed product matching, where the prior internal baseline was specifically optimized, our model still holds a narrow advantage (+1.5% at R@1000). On variant retrieval, our model outperforms the prior internal baseline by +10% at R@1000 despite never training on this task, while the prior internal baseline was explicitly trained on variation pairs.

I Cross-Architecture Generalization

Table 9 reports results for EmbeddingGemma-0.3B (Vera et al., 2025), an encoder-only model with 768-dimensional embeddings, trained using the same Stage 1 pipeline as Qwen3-0.6B (Stage 2 external-feed LoRA not conducted). Gemma improves average category-level Recall@K by +47% relative (0.437→0.642), closely matching Qwen3's +48% (0.473→0.702). The per-task pattern is par-

Table 8: Full retrieval results on large-scale item index (128d). Base = Qwen3-Embedding-0.6B; S1 = Stage 1 (full fine-tuning); S2 = Stage 2 (+ external-feed LoRA); Internal = prior internal baseline. †Variant task excluded from our training. Best per row in **bold**.

Task	Metric	Base	+S1	+S2	Internal

	R@500	.173	**.263**	.260	.224
	R@1000	.212	**.342**	.333	.280
SOP+Product→Product	R@100	.064	.134	**.143**	.074
	R@500	.122	.274	**.279**	.156
	R@1000	.158	**.362**	.361	.214
External→Product	R@100	.467	.854	**.942**	.871
	R@500	.582	.906	**.966**	.938
	R@1000	.629	.924	**.972**	.957
Product→Var.†	R@100	.705	.688	**.818**	.581
	R@500	.801	.823	**.916**	.783
	R@1000	.832	.866	**.940**	.855

Table 9: Cross-architecture generalization: EmbeddingGemma-0.3B (768d), Stage 1 only. Same training framework as Qwen3-0.6B. Superscripts show relative performance loss when truncating from full to 128 dimensions. †Untrained direction.

	Full dim (768)		128d	
Task	Base	FT	Base	FT
SOP→Product	0.364	0.607	$0.293^{-19\%}$	$0.583^{-4\%}$
Product→Product	0.515	0.647	$0.484^{-6\%}$	$0.634^{-2\%}$
SOP+Product→Product	0.433	0.671	$0.364^{-16\%}$	$0.654^{-3\%}$
External→Product	0.457	0.694	$0.392^{-14\%}$	$0.658^{-5\%}$
Product→SOP†	0.610	0.826	$0.570^{-7\%}$	$0.814^{-1\%}$

allel: SOP→Product shows the largest gain (+67% vs. +90% for Qwen3), and dimensional robustness is similarly preserved (at most -5% under $6\times$ truncation to 128d). This consistency across an encoder-only and a decoder-only architecture confirms that the gains stem from the task-aware contrastive framework, not model-specific properties.

An Empirical Study of VLM Pipelines for Long-Document QA

Amazon.com
{kenanea, jaymoht, gglee, yanxuml, dbdim}@amazon.com

Abstract

Vision-Language Models (VLMs) are increasingly used for long-document processing, where the inputs combine text with charts, tables, figures, and complex layouts. Deploying them means choosing how to feed the document to the model, which retriever to use when only a subset of pages is sent, and whether to run the model agentically or as a static pipeline. We study these choices on two long-document QA benchmarks with both frontier API and open-weight VLMs. First, on MMLongBench-Doc our six-tool agent with page, table, figure, and search calls pays off only once the answering VLM is large enough: with Qwen3.5-4B and 9B it trails static page input, with Qwen3.5-27B it draws level, and with Sonnet 4.5 it leads. On LongDocURL it is level with or ahead of static input at every reader. Its lead over the strongest static pipeline is clearest with the frontier reader on MMLongBench-Doc and narrows to within noise on LongDocURL. Second, retrieval modality matters more than the specific retriever: the strongest image retriever leads the strongest text pipeline, and on the text side a single off-the-shelf cross-encoder rerank essentially matches a much heavier multi-stage LLM pipeline. Top-k image retrieval is also the most token-efficient input at every reader we paired it with, at roughly a seventh to a quarter of the tokens of sending every page. Third, cutting across all three choices, three of our strongest pipelines succeed on different questions, and an oracle that picks the best pipeline per question gains roughly thirteen points over the best single pipeline, though evidence-type routing recovers almost none of it.

1 Introduction

Vision-Language Models (VLMs) (Liu et al., 2023; Wang et al., 2024; Bai et al., 2025) are becoming the standard choice for long-document processing. Real-world long documents such as financial filings, official reports, and scientific papers span tens to hundreds of pages, interleaving prose with charts, tables, and figures under inconsistent layout. Answering a single question can require locating the right page, interpreting a specific chart or table, and combining evidence scattered across several pages. Short-context benchmarks (Mathew et al., 2021; Masry et al., 2022) rarely test these skills together.

Three architectural decisions shape a production long-document QA pipeline: the *input modality* in which the document reaches the VLM, the *retriever* that selects pages when only a subset is sent, and whether the model works *agentically*, choosing pages, figures, or tables at inference time via tool calls rather than reading a fixed input (§3 defines all three). Acting agentically can surface evidence a retriever would miss, at the cost of latency and complexity. Each axis has been studied on its own, but their joint behaviour, and the accuracy/cost trade-offs it implies, have not been measured at frontier-VLM scale.

In this work, we present an empirical study of these three aspects on two long-document QA benchmarks (MMLongBench-Doc (Ma et al., 2024) and LongDocURL (Deng et al., 2025)). We sweep several input modalities, retrieval approaches spanning lexical, dense-text, vision late-interaction, and rerank families, and several document-agent designs, with Claude Sonnet 4.5 (Anthropic, 2025) served through a hosted API and Qwen3.5-{4B, 9B, 27B} (Qwen Team, 2026) served locally. All configurations we run are scored on the full benchmark under one evaluation pipeline, producing a comparable leaderboard. Our six-tool function-calling agent with Sonnet 4.5 is the highest-scoring configuration under the official scorer on both benchmarks; on MMLongBench-Doc it leads same-reader top-5 retrieval by $+11.7$ pp, and on LongDocURL it is level with the best retrieval pipeline.

Our contribution is not any single pipeline; the

EMNLP 2026 Industry Track, pages 2369–2390
October 24-29, 2026 ©2026 Association for Computational Linguistics

function-calling agent is a standard design. It is the controlled joint study of all three axes on one comparable footing, together with a re-evaluation of the closest prior system under each benchmark's official scorer rather than the more lenient LLM judges several such systems report against. That re-evaluation drops its judge-scored number by roughly 9 pp (§4.3).

2 Related Work

2.1 Long-Document Multimodal QA

Document QA has scaled from single-page benchmarks (Mathew et al., 2021, 2022; Masry et al., 2022; Tanaka et al., 2021) to multi-page settings with moderate document length (Tito et al., 2023; Tanaka et al., 2023; Van Landeghem et al., 2023; Dasigi et al., 2021; Lála et al., 2023), and most recently to long, mixed-modality documents (Chia et al., 2025; Islam et al., 2023; Xia et al., 2024). In this work, we utilize two benchmarks at the long end of this progression. MMLongBench-Doc (Ma et al., 2024) comprises 135 PDFs with 1,082 questions stratified by single-page versus cross-page evidence and by visual-element type (chart, table, figure, layout, text). LongDocURL (Deng et al., 2025) comprises 396 long documents with 2,325 questions in its public split, organised along three tasks (Understanding, Reasoning, Locating) and four of the same evidence-element types (all but chart). We choose these two because they cover different parts of the space: MMLongBench-Doc is shorter but more visually varied, LongDocURL longer.

2.2 Vision-Language Models

Vision-language models integrate a visual encoder with a language model so a single network reasons over text and images together (Liu et al., 2023; Qwen Team, 2026). Document-specific VLMs instead encode page structure: layout-aware models fuse text, position, and visual features but require a separate OCR step (Xu et al., 2020), OCR-free successors encode page images end-to-end (Kim et al., 2022), and high-resolution multi-page extensions compress each page's visual tokens to keep long inputs tractable (Hu et al., 2025). These are typically evaluated at smaller context rather than on documents of tens to hundreds of pages, where access mode and retrieval also matter.

Frontier multimodal models, on the API side (Anthropic, 2025; Hurst et al., 2024; Team et al., 2024) and the open-weight side (Qwen Team, 2026; Chen et al., 2024b; Liu et al., 2024; Wu et al., 2024), accept page images directly and increasingly do well on long-document QA without document-specific architectures. Long-context modeling has been studied mostly on the text side (Liu et al., 2025), while evaluations on multimodal documents usually commit to a single access mode, whether all page images (Ma et al., 2024; Deng et al., 2025), a fixed set of retrieved pages (Chia et al., 2025; Han et al., 2025), or an agentic tool loop (Lee et al., 2024; Jain et al., 2025), rather than comparing these choices head to head. This leaves the cost/accuracy trade-off across VLM scale largely open.

2.3 Page Retrieval over Long Documents

Lexical BM25 (Robertson and Zaragoza, 2009) over OCR or layout-aware text remains a strong and low-cost baseline for page retrieval. Dense bi-encoders (Karpukhin et al., 2020; Chen et al., 2024a) and late-interaction models (Khattab and Zaharia, 2020) match or exceed BM25 at higher compute cost, and ColPali (Faysse et al., 2025) extends this idea to vision by representing each page as an image. A second-stage rerank trades latency for accuracy, with cross-encoder (Nogueira and Cho, 2019) and LLM-based (Sun et al., 2023) variants commonly used. For long-document QA specifically, recent work either changes what gets indexed (Jiang et al., 2024) or layers LLM-driven steps such as document enrichment, query rewriting, and reranking on top of BM25 (Yang et al., 2026; Gao et al., 2023; Asai et al., 2024). The contribution of each step relative to the underlying text source is rarely isolated, which is what we examine in our retrieval ablation.

2.4 Agentic and Tool-Using Document QA

Tool-augmented agents (Yao et al., 2022; Shinn et al., 2023) interleave tool calls with reasoning. For long documents, an agent explores the document on demand instead of reading a fixed input, trading one inference call for several tool-call rounds. Earlier text-only designs use gist memory or recursive document structure (Lee et al., 2024; Chen et al., 2023; Li et al., 2024), and retrieval-augmented variants add search-and-fetch tools (Qwen Team, 2024).

Recent multimodal agents extend these designs to visual evidence. MDocAgent (Han et al., 2025) routes queries through five specialised agents on top of a multimodal RAG retriever, DocLens (Zhu

et al., 2025) splits the task across navigation, localization, and reasoning roles, and SimpleDoc (Jain et al., 2025), the closest analogue to our setup, runs an LLM reasoner that iteratively pulls retrieved pages into a working memory for a separate VLM answerer. Other concurrent designs train scrolling policies (Lim et al., 2026), decompose the task into planning, execution, judgement, and answer agents (Yu et al., 2026), or extend multimodal RAG to multi-document QA (Suri et al., 2025). These systems span a wide compute range, from a single VLM with a small toolkit to multi-model stacks that pair a separate retrieval model with a 32B vision-language answerer, and most depend on per-document preprocessing such as per-page summaries or vision embeddings. They have largely been compared to other agentic systems rather than to a strong static retrieval-and-read pipeline.

3 Method

We study long-document multimodal question answering as a deployment problem. A system S is a function $S(D, q) \to a$ that maps a document D (a long PDF with heterogeneous content) to a textual answer a for a natural-language question q. The question may require evidence from a single page, non-adjacent pages, or none of the document at all. We decompose S into three design choices that a practitioner can change one at a time.

- **Input modality** I: what form of D reaches the VLM that answers the question, which we call the *reader* (raw PDF, page images, extracted text, or a retrieved subset).
- **Retriever** R: how pages are ranked by relevance to q when I keeps only the top k.
- **Agentic policy** π: trivial (single forward pass of static input) or a multi-turn tool-call loop in which the VLM decides what to look at next.

System instantiations. We evaluate five input modalities (raw PDF, all-pages images, plain-text, layout-aware text, and top-k retrieved images), retrievers spanning lexical, dense-text, vision late-interaction, and rerank families, and several agent designs covering function-calling, gist-based, and iterative-refinement styles. Our readers are Claude Sonnet 4.5, served through a hosted API, and the open-weight Qwen3.5-{4B, 9B, 27B}, served locally. Appendices B–J give the full retriever and VLM configurations.

Evaluation protocol. All systems are scored on MMLongBench-Doc (Ma et al., 2024) and LongDocURL (Deng et al., 2025). Following each benchmark's own evaluation protocol, an *answer extractor* LLM (Claude Haiku 4.5) normalises each free-form response into a short answer before comparison against the gold answer by the benchmark's official deterministic scorer; we use MMLongBench-Doc's released extraction prompt unchanged and apply it identically to every system we run, including the external baselines ReadAgent and SimpleDoc. It is distinct from the *text* extractors (PyMuPDF, MinerU) used by the text-input modes. The step is not cosmetic: without it, correct answers inside explanatory prose score zero under the whole-string official scorers (Appendix M). We report per-question accuracy and mean input tokens, where the token count covers access-mode and agent-loop cost but excludes one-time preprocessing and retrieval-time compute, which Appendix H reports separately.

Per-question oracle. The *per-question oracle* scores $\max_j \text{score}(S_j, q)$ over a fixed set of pipelines, crediting a question whenever *any* member answers it. It is a hindsight upper bound rather than a deployable system, and its gap to the best single pipeline bounds what a per-question router could add. Unless stated otherwise it is taken over three of our strongest configurations; Appendix O gives the member set and the fixed-membership caveat.

Experimental setup. Every VLM, including the answer extractor, decodes greedily (temperature=0) with reasoning/thinking disabled, so all configurations we run in Table 1 share identical decoding; thinking mode is studied separately in §4.1. Page images render at DPI 144, the peak of a resolution sweep; all-images additionally caps each page at 1024 px so that long documents fit in context (Appendix D). Full per-pipeline configurations, image-size caps, generation limits, and determinism details are in Appendices D–J.

3.1 Six-Tool Function-Calling Agent

Our agentic baseline is a function-calling loop in which a VLM explores the document on demand.

Preprocessing. We run MinerU (Niu et al., 2025) on each PDF to extract its layout structure (section headings, figure/table crops, and per-page text

blocks) and build a *structural catalog*. The catalog lists, for each page, its section title, page range, and the figures/tables it contains, each with a stable integer id. This catalog is provided to the VLM as a compact preamble alongside the question.

Toolkit. The model chooses one or more tools at each turn from:

- `get_catalog`: returns the full structural catalog (used when the preamble is truncated for very large documents).
- `read_pages(pages)`: renders the requested pages as images at a model-chosen size, 700 or 1,400 px on the longest side.
- `get_figure(id)`: returns the MinerU-extracted figure crop by stable id.
- `get_table(id)`: returns the table crop and its structured HTML.
- `search_text(query, top_k)`: runs BM25 over MinerU per-page text blocks and returns the top-scoring page numbers, each with a matching text excerpt.
- `finish(answer)`: commits the final answer and ends the loop.

The loop is capped at eight tool calls per question; in practice the median is two (Appendix L). If a tool call references an invalid id, the agent receives an error message and may retry on the next turn.

Design rationale. Unlike gist-based agents (Lee et al., 2024), ours sees actual page images, preserving visual evidence. Unlike multi-agent pipelines that fix retrieval mode up front (Han et al., 2025; Jain et al., 2025), a single model can mix strategies within one question: for example, `search_text` to locate a section, then `get_table` to read a specific table. Dedicated element tools provide higher resolution than full-page rendering.

4 Experiments

We organize results around the three architectural axes from Section 3, namely input modality (§4.1), retrieval (§4.2), and agentic access (§4.3), studying each on both MMLongBench-Doc (MMLB) and LongDocURL (LDURL) and noting where findings transfer across the two benchmarks. Table 1 aggregates headline numbers across all configurations.

4.1 Input Modality

We first compare the static whole-document modalities: raw PDF, all-images, and extracted text. Raw PDF is the strongest of these for Sonnet on MMLongBench (0.522) but also by far the most expensive, at 80k input tokens per question. The cost comes from how the API ingests a PDF, sending both a rendered image and an extracted text layer for every page. All-images is weaker than raw PDF in part because it sends the rendered pages without that text layer. It is also constrained by the API's 100-image-per-request limit: documents of more than 100 pages are packed into merged images at lower per-page resolution (Appendix B). On MMLongBench, the Qwen3.5 family, served locally without this limit, beats Sonnet on the same mode by 5–11 pp, and by as much on documents of at most 50 pages, where Sonnet pays no penalty, so

		MMLB		LDURL	
Configuration	VLM	AVG	Tok	AVG	Tok

Table 1: Headline leaderboard. **Configuration**: input mode, then retriever or agent. All images sends the whole document as page images, all text as extracted text; Top-5 sends five retrieved pages as images. AVG is each benchmark's official scorer, Tok the mean input tokens per question over the requests that completed; whole-document modes fail on the longest documents (raw PDF and Qwen text on LongDocURL, Qwen3.5-27B text on MMLongBench-Doc) and those questions score zero (Appendix B). **Bold** marks the best result per benchmark among rows scored by the official scorer; our configurations are the 6-tool FC rows. Rows between the last two rules are external systems (agent count in parentheses); †/‡/§ mark numbers under the system's own protocol rather than ours († GPT-4o, ‡ GPT-4.1 judge, § DocLens's own; §4.3). Oracle is the per-question upper bound (§3).

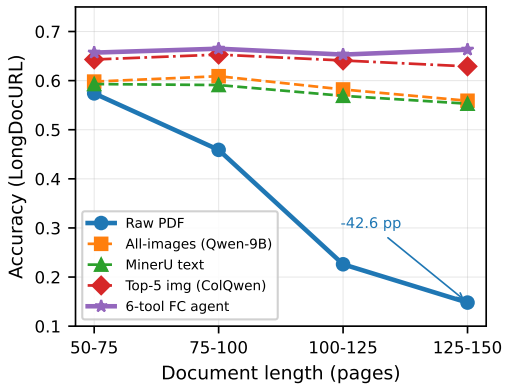

Figure 1: Accuracy vs. document page count, LongDocURL (Sonnet 4.5 unless a reader is named).

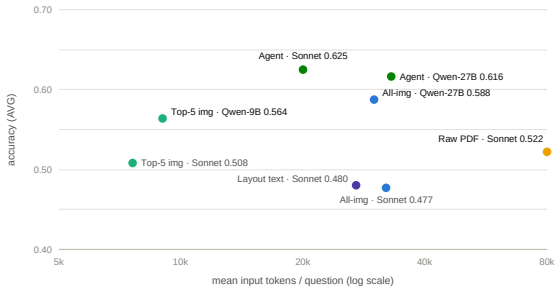

Figure 2: Accuracy vs. mean input tokens per question, MMLongBench-Doc (best configuration per access mode, plus the Sonnet 4.5 point where it differs; log-scale x, up-and-left better; no-think, official scorer).

the gap is the reader, not the cap.

Text-only modes are the weakest input for the open-weight readers on MMLongBench, trailing all-images by 13–17 pp at 4B and 9B because they drop in-document images; for Sonnet they are competitive instead, since its all-images accuracy drops sharply on documents beyond about 50 pages. The strongest text-only configuration still trails top-k image retrieval by about 5 pp at a matched reader, so reading the page beats reading its extracted text. Table questions are the one exception, where a layout-aware extractor recovers structured cell content and matches or beats images on MMLongBench. On MMLongBench, MinerU lifts Sonnet's text-only accuracy by about 8 pp over plain-text extraction with PyMuPDF, and the gain concentrates on table and figure questions. The benefit is benchmark-dependent, since on LongDocURL plain-text and layout-aware extraction tie at Sonnet. Appendix C has the full sweep.

With text input, scale buys the Qwen3.5 family little below 27B. On MMLongBench the 4B and 9B models land within a point of each other, 8 to 9 pp below Sonnet on the same MinerU input; the 27B run fails on 111 long-document requests and scores zero there, and on the questions it completes it is about 11 pp above 9B. On LongDocURL the Qwen text runs fail outright on 895 of the 2,325 questions and score zero there, at a rate that climbs with document length from 18% of the shortest bin to 72% of the longest; on the questions they complete, the three sizes land within 2 pp of each other and of Sonnet.

Access mode also governs how gracefully accuracy scales with document length. Figure 1 bins LongDocURL by page count: raw-PDF accuracy collapses by 42.6 pp from the 50–75 to the 125–150 page bin, mostly because the request itself fails above the API's per-request cap and scores zero, whereas retrieval, the agent, and all-images at a local reader that sees every page individually vary by at most 5 pp across the full range. The agent rows are the flattest, and the Sonnet agent is highest in every bin. The collapse is not an artifact of the single request: splitting documents into chunks under the cap and combining per-chunk answers recovers nothing (Appendix P). Per-bin tables for both benchmarks are in Appendix E.

Enabling a reasoning ("thinking") budget before the model answers gives modest gains, up to about 6 pp and largest where the input is largest, and never changes the modality ordering; we report no-think numbers throughout for a matched-decoding comparison and defer the full sweep to Appendix G.

Figure 2 makes the accuracy/cost trade-off explicit, plotting each access mode's best configuration by accuracy against mean input tokens per question. Top-k image retrieval sits in the efficient corner (0.51–0.56 at 7.6–9 k tokens), the 6-tool agent is the most accurate (0.616–0.625 at 20–33 k tokens), and raw PDF is the outlier, spending 80 k tokens for 0.522. Only top-k retrieval and the agent lie on the Pareto frontier: raw PDF and extracted text are dominated by both, and all-images (0.588 at 30 k) is dominated by the Sonnet agent, which is both more accurate and cheaper (0.625 at 20 k); top-k is cheaper still but 6 pp less accurate than the agent.

4.2 Retrieval

A retrieval pipeline ranks the document's pages and sends only the top k to the VLM. We use $k = 5$ throughout unless stated otherwise, the depth of every Top-5 row in Table 1; a depth sweep (Appendix I) shows accuracy peaks near

Retriever	Modality	MMLB	LDURL	Avg
BM25 (MinerU)	text	65.6	74.0	69.8
BGE-M3	text	70.8	77.4	74.1
BM25 + Cohere 3.5	text+rerank	77.0	86.9	82.0
BGE-M3 + Cohere 3.5	text+rerank	77.5	86.6	82.1
SIRA (full pipeline)	text+LLM	77.2	87.5	82.4
ColQwen2.5	image	84.2	90.1	87.2
Nem-CE⊕Scout	image+LLM	**91.3**	82.5	86.9
Nem-CE	image	88.9	**93.8**	**91.4**

Table 2: Hit@5 on the answerable subset; Avg is the cross-benchmark mean. **Bold** marks each column's best. Per-retriever cost details are in Appendix H.

k=10 and that k=5 captures most of it at roughly half the tokens. We measure retrieval with Hit@5, the fraction of answerable questions whose top-5 pages include an evidence page. We evaluate retrievers from four families: BM25 (Robertson and Zaragoza, 2009) (lexical word overlap), BGE-M3 (Chen et al., 2024a) (dense-text bi-encoder), ColQwen2.5 (Faysse et al., 2025) and Nemotron-ColEmbed-3B (Nem-CE) (Moreira et al., 2026) (late-interaction over page images), and rerank pipelines that stack a cross-encoder or full LLM rerank on a base retriever, including SIRA (Yang et al., 2026). We also build a cascade: Nem-CE-3B first prefilters each document to 50 candidate pages, and Scout, a Qwen3.5-9B model prompted to read those candidates and rank them, selects the final top 5.

As shown in Table 2, modality is the dominant axis in retrieval. Averaged across both benchmarks, the image retrievers ColQwen2.5 and Nem-CE reach 87.2 and 91.4 Hit@5, while no text retriever exceeds 82.4, so the strongest image retriever leads the strongest text pipeline by about 9 pp and the strongest base image retriever (Nem-CE) leads the strongest base text retriever (BGE-M3) by roughly 17 pp. The effect carries downstream to answer accuracy, not just retrieval: with the same reader, five retrieved page images match the whole document's extracted text on MMLongBench (0.508 vs. 0.480, a paired gap whose interval includes zero) while sending under a third of the input tokens (7.6k vs. 27k), and the per-evidence breakdown favours images on every source except Tables, where MinerU's structured cell HTML wins on MMLongBench though not on LongDocURL (Table 3).

On the text side, the reranker matters more than the base retriever. Dense BGE-M3 leads lexical BM25 by only 4.3 pp on average (74.1 vs. 69.8), but adding Cohere Rerank 3.5 (Cohere, 2024) lifts both by 8 to 12 pp and renders them indistinguishable afterward (82.0 vs. 82.1). A single such rerank is statistically indistinguishable from SIRA's full multi-stage pipeline (82.4 vs. 82.0; on MMLongBench the paired Hit@5 difference is $+0.1$ pp, 95% CI $[-2.8, +2.9]$, Appendix M), with no LLM in the loop (Appendix H).

Reranking does not carry over to the already-strong image retrievers. Stacking the Scout reranker on Nem-CE gives the best MMLongBench Hit@5 in the table ($+2.4$ pp) but loses 11.3 pp on LongDocURL, a net drop of 4.5 pp on average against plain Nem-CE. The loss is a document-length effect: binning LongDocURL by page count, Scout's Hit@5 deficit against plain Nem-CE widens from -5.7 pp on 50–75-page documents to -22.0 pp on 125+-page documents, while Nem-CE alone stays flat (0.92–0.95 across all bins). On long documents Scout increasingly demotes the evidence page that Nem-CE alone had ranked in its top five; MMLongBench's shorter documents rarely trigger this, which is why the cascade helps there. The full per-bin breakdown is in Appendix F.

4.3 Agentic Access

As shown in Table 1, the 6-tool function-calling (FC) agent is the highest-scoring single-VLM configuration we measured at frontier scale on both benchmarks; it beats the best retrieve-then-generate pipeline on MMLongBench and is level with it on LongDocURL.

This advantage appears only above a scale threshold. On MMLongBench the FC agent *trails* both static image modes at Qwen3.5-4B (0.471 vs. 0.526 all-images and 0.551 top-5) and at 9B (0.497 vs. 0.559 and 0.564), draws level with the best of them at 27B (0.616 vs. 0.588, a $+2.8$ pp paired gap whose interval includes zero), and leads at Sonnet 4.5 (0.625 vs. 0.533). The transition sits between 9B and 27B: below it, a reader is better served by simply being shown every page. Among static modes at open-weight scale, top-k retrieval and all-images are indistinguishable in accuracy, with the paired interval including zero at both 4B and 9B, while top-k uses under a third of the input tokens (9k vs. 33k at 9B), so top-k is the better static default rather than merely the cheaper one. LongDocURL shows no such threshold: the agent leads top-k retrieval at its own reader already at 4B and 9B, and at 27B and Sonnet 4.5 it is level with the best static pipeline; the largest step is again 9B to 27B. The smallest agent is also the most expensive, and not because it searches more: every Qwen reader reaches its answer within two to three tool

calls, and what separates them is whether they stop. Qwen3.5-4B re-emits `finish` after its answer is recorded on 51% of MMLongBench trajectories and 75% on LongDocURL, adding 9.1 and 4.9 further model calls that re-send the accumulated context, against 1.5 and 0.3 for 27B. Knowing when to stop is a capability: toolkit and loop are identical across the Qwen readers, so 4B's 77k against 33k is the price of a reader that does not end its loop (Appendix J).

ReadAgent (Lee et al., 2024), which uses a gist-based design, lands well below our toolkit on MMLongBench and only modestly below on LongDocURL. It looks up a median of two pages per question and reads them through a compressed gist memory, so it often misses the evidence page and loses the fine-grained list and table detail that our structured catalog preserves. The gains therefore come from the toolkit, not from acting agentically alone.

Comparison with multi-agent and iterative-refinement methods. We evaluate three multi-agent systems on the same two benchmarks. MDocAgent (Han et al., 2025) routes a question through five agents and answers with Qwen2-VL-7B over ColPali top-$k = 4$ pages. SimpleDoc (Jain et al., 2025) runs a Qwen3-30B-A3B reasoner that repeatedly pulls dual-cue retrieved pages into a working memory before a Qwen2.5-VL-32B answerer responds. DocLens (Zhu et al., 2025) splits the task across a Page Navigator, an Element Localizer, and a Reasoner.

MDocAgent and SimpleDoc score under binary LLM judges (GPT-4o and GPT-4.1 respectively) rather than each benchmark's official deterministic scorer, so the published figures sit above what the official scorer would assign. To place SimpleDoc on the same footing, we re-ran its full pipeline with Sonnet 4.5 in every role under the deterministic scorer. This reproduces its MMLongBench result (0.608 vs. 0.606) and yields 0.634 on LongDocURL, about 8.9 pp below the judge-scored 0.723.

The 6-tool FC agent is competitive with all of these systems, but only the SimpleDoc comparison is strictly like-for-like. At a matched VLM under the same deterministic scorer our agent is 1.6 pp ahead on MMLongBench, $[-1.1, +4.4]$, which we report as a tie. The DocLens rows use its own protocol, so those comparisons are indicative; our closest row is the Sonnet agent, level with DocLens's Claude-4-Sonnet configuration and below its Gemini-2.5-Pro one. MDocAgent reaches only 0.315, far enough back that the judge leniency cannot account for the gap. On LongDocURL the same agent leads SimpleDoc-Sonnet by 2.5 pp and MDocAgent by about 8 pp.

A single strong VLM with a structural catalog and direct figure and table access recovers visual evidence more reliably than a pipeline of smaller specialized models, and at lower cost: our agent runs one VLM over a lightweight MinerU-derived catalog in a median of two tool calls, with no second large model in the loop and no per-page offline indexing. Appendix K sets all five agentic systems side by side on this cost axis.

5 Conclusion

We studied three deployment-level choices for long-document multimodal QA (input modality, retrieval, and agentic access) across two benchmarks under one extractor and evaluator. The findings reduce to a decision tree. *With a frontier API*, a six-tool function-calling agent is the highest-accuracy configuration we measured, at roughly 1.5–7× fewer input tokens per question than sending all pages as images or the raw PDF. *With a smaller open-weight VLM* (Qwen3.5-9B and below), tool use is a poor trade: on MMLongBench the agent trails plain all-images input, on LongDocURL its lead over top-5 retrieval is a few points, and in both cases it spends 4–9× the tokens of top-5 retrieval. Static image input is the better default at this scale; top-5 retrieval matches all-images on accuracy at a fraction of the tokens. *When images cannot be sent*, a layout-aware extractor (MinerU) with BM25 or BGE-M3 and a single cross-encoder rerank matches a multi-stage design's text-side accuracy at a fraction of its compute. *Beyond any single pipeline*, three of our strongest configurations make different mistakes and leave roughly 13 pp of per-question oracle headroom (Table 1), but that headroom resists the obvious remedy: routing on gold evidence type recovers under a point of it, and a router on observable question features is *worse* than always running the agent (-0.9 pp on MMLongBench, -7.1 pp on LongDocURL; Appendix O), because the complementarity lies within evidence types rather than across them, and recovering it needs a finer per-question signal than any we tested. A small, well-chosen toolkit can stand in for a larger multi-agent stack.

Limitations

A few aspects of our setup limit the scope of our findings. We study long-document *question answering* only, the task both benchmarks target, and do not measure summarization, extraction, or classification; while the three axes we vary (input modality, retrieval, and agentic access) are task-general choices, whether the specific rankings transfer to other long-document tasks is left to future work, and we do not claim generality beyond QA. The two benchmarks together contain 3,407 questions over 531 long documents, and differences below about 3 pp on MMLongBench-Doc and 2 pp on LongDocURL are within noise (Appendix M), so we avoid fine-grained ordering claims at that scale. The unified scorer combines an answer-extractor LLM with a benchmark-native string-and-numeric matcher, and when a system already returns a short structured answer (such as the function-calling agent's `finish` argument), the extractor adds little, which may slightly understate that system's lead. On the API side, Sonnet caps the number of images per request and limits each image to 8000 pixels on a side, and our pipeline silently falls back by stitching and resizing page images for very long documents; beyond a further size threshold the request fails outright and is scored zero (Appendix B). Numbers we report from commercial VLM endpoints reflect that fallback, and on-premise serving may behave differently. Finally, our results assume English-language documents and the VLM families we tested, and whether the rankings carry over to other languages and to smaller on-device VLMs is open. Errors concentrate on charts and figures on MMLongBench-Doc and on layout-bearing pages on LongDocURL (Table 3), so a benchmark with a different evidence mix would likely reorder the leaderboard.

Ethical Considerations

This work uses two public document QA benchmarks (MMLongBench-Doc and LongDocURL), neither of which contains personally identifying information or sensitive personal data. All VLMs and retrievers are publicly released models or commercial APIs accessed under their standard terms of service. We do not collect any new human-labeled data and run no experiments with human subjects. The systems we evaluate produce textual answers grounded in the input document, which limits the risk of fabrication, but a deployed system should still surface its source pages to the user so that incorrect answers are auditable. Our cost numbers are reported in input tokens per question rather than in dollars to avoid pinning recommendations to any single provider's pricing, which can change.

A Per-Evidence-Source Accuracy

Table 3 reports per-question accuracy on the subset of questions tagged with each evidence-source label. Questions with multiple labels appear in each. MMLongBench-Doc tags are TXT (Pure-text), LAY (Generalized-text/Layout), CHA (Chart), TAB (Table), FIG (Figure). LongDocURL uses four of these, all but CHA.

B How the Claude API Processes Raw PDFs

The raw-PDF row in Table 1 hands the unmodified PDF to the Claude API rather than rendering page images ourselves, so its behaviour is set by the API's own document pipeline. We access Claude through its hosted API, and we document its handling here because it explains both the high token cost of raw-PDF input and its collapse on long documents (Appendix E).

Page-as-image-plus-text. With citations enabled, the Claude API converts each PDF page into an image and provides the text extracted from that page alongside it, so the model sees both a rendered view and an OCR-style text layer for every page, at roughly 7 k tokens for a three-page PDF. Without citations it falls back to basic text extraction at roughly 1 k tokens for the same pages and cannot analyse charts, figures, or visual layout. We enable citations in every raw-PDF run so that Claude sees the visual content, which is why the raw-PDF token counts in Table 1 are the highest of any access mode.

Per-page cost and request limits. Under full visual mode each page costs roughly 1.5 k to 3 k text tokens depending on content density, plus the image tokens for the rendered page. A single request is capped at 32 MB and at 100 pages for the 200 k-token-context models we use. When a document exceeds these limits the API downsamples the embedded page images to fit, which reduces per-page resolution on long documents; beyond a further threshold the request fails outright and we score it zero, which accounts for most of the raw-PDF accuracy collapse reported in Appendix E. Failures concentrate in the two modes that send an entire long document in a single call: 736 of 2,325 LongDocURL questions under raw PDF and 895 under MinerU text with the Qwen readers, against at most 38 in every other LongDocURL configuration. On MMLongBench-Doc the only such failures are 111 of 1,082 questions under MinerU text with Qwen3.5-27B, all on documents of 72 pages or more.

We confirm this downsampling directly from the logged token counts rather than inferring it. On LongDocURL raw-PDF runs, the mean input tokens charged *per page* fall from ∼2,050 on 50–100-page documents (mean 72 pages) to ∼1,540 on 100–150-page documents (mean 121 pages). The effect is far larger for all-images, which carries no text layer to hold the count up: on LongDocURL its per-page cost falls from ∼914 to ∼60 tokens across the same two bins, a ∼15× reduction that sets in as documents cross the 100-image request cap, and on MMLongBench-Doc it declines monotonically with length ($999 \rightarrow 614 \rightarrow 596$ over the <50, 50–100, 100–150 page bins). The collapse is therefore a measured consequence of the API packing more pages into a fixed budget, not an artifact we assume.

C Text-Extractor Sweep for Plain-Text Input

The plain-text input row reported in Table 1 fixes the extractor to PyMuPDF and the VLM to Sonnet 4.5. Table 4 shows the full extractor × VLM sweep. Two patterns hold across VLM scales. First, PyMuPDF and pdfplumber land within 1.5 pp of each other on the same VLM, so the choice of plain-

Table 3: Per-evidence-source accuracy on both benchmarks, broken out from the AVG columns of Table 1. **Bold** marks our two strongest configurations. As in Table 1, † and ‡ mark scores under the system's own LLM judge († GPT-4o, ‡ GPT-4.1) rather than the official scorer. The configurations are the same; this table has room to split the input mode from the retriever or agent and to name both in full, where Table 1 combines them into one Configuration cell. "—" marks not applicable or not logged.

text extractor does not matter. Second, at frontier VLM scale (Sonnet) the gap between either plain-text extractor and MinerU's layout-aware extractor (the MinerU text rows in Table 1) is $+8$ pp, and that gap remains $+2$ to $+5$ pp at smaller open-weight scales. The text-extractor choice therefore matters less than the modality choice itself.

Extractor	VLM	AVG	Tok-in
PyMuPDF	Qwen3.5-4B	0.355	17.4k
PyMuPDF	Qwen3.5-9B	0.371	17.4k
pdfplumber	Sonnet 4.5	0.401	22.7k
pdfplumber	Qwen3.5-4B	0.345	16.9k
pdfplumber	Qwen3.5-9B	0.357	16.9k

Table 4: Plain-text PDF text-extractor sweep on MMLongBench-Doc. The PyMuPDF/Sonnet row in Table 1 is the canonical plain-text number, and this table reports the remaining cells we collected.

D Resolution Sweep for Top-k Retrieved Images

Generation limit and image-size caps. The generation cap is effectively non-binding: non-thinking answers average $\sim$160 tokens. The all-images mode caps each page at 1024 px so that long documents fit in context ($\sim$760 vs. $\sim$1,800 tokens per uncapped page), while the top-k modes send five uncapped pages; this is why all-images and top-k token counts in Table 1 are not directly comparable.

For the top-k retrieved-images setting we ran a fixed-DPI sweep on Qwen3.5-4B and Sonnet 4.5. Both peak at DPI=144. On Sonnet, input-token cost is flat for DPI $\geq$ 144 because the API tiles every page into a fixed grid of image tokens, so source pixels above $\sim$DPI=144 are internally discarded. Higher DPI on commercial endpoints is therefore a strict regression, with more JPEG/resize artifacts and no extra model-visible detail. On Qwen3.5-4B the picture is similar. Accuracy still saturates at DPI=144 (0.541, 0.557, 0.551, 0.548 at DPI 96, 144, 180, 216), but raising DPI keeps inflating input tokens 2–3$\times$ for ≤ 1 pp accuracy. The smart-resize adaptive cap at 1024×1024 pixels underperforms fixed DPI on both VLMs. Sonnet's measured curve on MMLongBench is given in Table 5, and the mean per-question input-token count is essentially flat between DPI 144 and 216 (7,535–7,579 tok) while accuracy peaks at 144 and degrades at higher DPI by -1.8 to -2.0 pp.

We also sweep an explicit per-image pixel cap (`max_image_size`), which bounds the longest side of each rendered page rather than its render den-

DPI	AVG	Mean tok-in	Δ vs. 144
96	0.482	5,379	−2.6 pp
144	**0.508**	**7,579**	**0.0 pp**
180	0.490	7,535	−1.8 pp
216	0.488	7,548	−2.0 pp

Table 5: Sonnet 4.5 top-5 retrieved images (ColQwen2.5) accuracy and mean per-question input tokens on MMLongBench-Doc at four fixed DPIs. Above DPI=144, mean input tokens are flat (7,535–7,579 tok) because the API internally tiles each page into a fixed grid of image tokens. Raising DPI above 144 supplies more source pixels but no additional model-visible tokens, and degrades accuracy through extra JPEG/resize artifacts.

Cap (px)	AVG	Mean tok-in	Δ vs. DPI 144
512	0.296	1,378	−21.2 pp
1024	0.484	5,099	−2.4 pp
2048	**0.501**	7,578	−0.7 pp

Table 6: Sonnet 4.5 top-5 retrieved images (ColQwen2.5) on MMLongBench-Doc under a per-image pixel cap (`max_image_size`). Accuracy climbs with the cap and saturates near 2048 px, matching the DPI=144 baseline (0.508) within noise; a 512 px cap collapses accuracy by destroying fine detail. Δ is relative to the DPI=144 row of Table 5.

sity. Table 6 reports Sonnet 4.5 on the same top-5 ColQwen2.5 setting. Accuracy rises monotonically with the cap and saturates near 2048 px, recovering the DPI=144 result (0.501 vs 0.508), while a 512 px cap is far too low and destroys small-text and chart detail. The pixel cap is thus a second resolution control that behaves like DPI, with no setting beating the DPI=144 baseline.

E Scaling with Document Length

LongDocURL spans 51–149 pages per document, while MMLongBench-Doc spans 9–468 pages with a mean of 48, so LongDocURL lets us isolate how each access mode degrades as page count grows over a tighter, longer-skewed range. We bin LongDocURL questions by their document's total page count and compute Sonnet accuracy per bin under the official LongDocURL scorer (Table 7). Two patterns are clear.

First, raw-PDF access collapses on long documents, from 0.574 on 50–75-page documents to 0.148 on 125–150-page documents, a −42.6 pp drop. Most of that drop is outright request failure rather than degraded reading: above the API's per-request size cap the call returns no answer and scores zero, and the failure rate climbs from 8% in the shortest bin to 68% in the longest. Among the requests that do complete, accuracy falls far more gently, from 0.624 to 0.467. Second, every other mode (all-pages images, retrieved images, MinerU text, and the agent) is essentially flat across the four bins, with drops in the range of −4 to +1 pp. Selective access modes therefore benefit not only in absolute accuracy but also in stability as document length scales, and the practitioner-facing implication is that any deployment expecting documents above ∼80 pages should avoid raw-PDF input regardless of VLM capability.

Pipeline	Overall	50–75	75–100	100–125	125–150
Raw PDF	0.414	0.574	0.459	0.226	0.148
MinerU text	0.582	0.593	0.591	0.569	0.553
Top-5 img (BM25)	0.555	0.540	0.576	0.573	0.531
Top-5 img (ColQwen2.5)	0.643	0.643	0.653	0.641	0.629
All-pages img (Qwen3.5-9B)	0.592	0.598	0.609	0.582	0.559
6-tool FC (Sonnet)	**0.659**	**0.657**	**0.665**	**0.653**	**0.663**
6-tool FC (Qwen3.5-27B)	0.644	0.646	0.645	0.645	0.636

Table 7: LongDocURL accuracy by document page-count bin (under the official LongDocURL scorer). **Bold** marks the best pipeline in each column. Rows use Sonnet 4.5 unless a reader is named. Each bin reports mean accuracy on questions whose document has total pages in the listed range. Raw PDF drops 42.6 pp from 50–75 to 125–150 pages, while every other mode changes by at most 4 pp between those bins and varies by at most 5 pp across all four.

Cross-benchmark check on MMLongBench-Doc. We repeat the same per-bin analysis on MMLongBench-Doc (135 PDFs, 9–468 pages) to test whether the page-count effect is benchmark-specific. The bin distribution is heavily skewed (99 docs in 11–50 pages, only 14 in 101–200 and 1 above 200), so the longest-bin estimates are noisier. Patterns across the dense 11–50 vs 101–200 bins still tell a consistent story (Table 8). Raw PDF drops only −6.3 pp from 0.542 to 0.479, an order of magnitude milder than LDURL's collapse, because fewer MMLB documents cross the API's auto-stitch threshold. Top-k retrieval with BM25 and ColQwen2.5 drops about 11 pp, while the Nem-CE⊕Scout cascade barely moves (−0.8 pp) and the 6-tool FC agent is similarly stable, dropping only a few points across the dense bins (Sonnet: 0.644 → 0.591, Qwen3.5-27B: 0.633 → 0.611), reproducing the catalog-gated stability we see on LongDocURL.

F Scout Reranker vs. Document Length

The Nem-CE⊕Scout cascade is the best retriever on MMLongBench but trails plain Nem-CE by 11.3 pp Hit@5 on LongDocURL (§4.2). Table 9 shows this is a document-length effect. We bin

Pipeline	≤10	11–50	51–100	101–200	>200
Raw PDF (Sonnet)	0.370	0.542	0.477	0.479	0.400
All-pages img (Qwen3.5-9B)	0.375	0.605	0.459	0.429	0.400
Top-5 img (BM25, Sonnet)	0.307	0.429	0.366	0.316	0.800
Top-5 img (ColQwen2.5, Sonnet)	0.495	0.539	0.414	0.430	0.800
Top-5 img (Nem-CE⊕Scout, Sonnet)	0.432	0.535	0.533	0.527	0.600
ReadAgent (Sonnet)	0.120	0.512	0.483	0.487	0.400
6-tool FC (Sonnet)	0.682	**0.644**	**0.551**	0.591	0.800
6-tool FC (Qwen3.5-27B)	**0.745**	0.633	0.527	**0.611**	0.800
n_{docs}	2	99	19	14	1

Table 8: MMLongBench-Doc accuracy by document page-count bin (official scorer). **Bold** marks the best pipeline in each column; the >200 column is left unmarked because four pipelines tie there over a single document. Bins are uneven (most MMLB documents fall in 11–50 pages), so longest-bin estimates are noisy ($n_{\text{docs}} \in \{2, 1\}$). The 6-tool FC agent stays flat with page count, while raw PDF drops only -6.3 pp on the dense bins, far milder than the LDURL pattern because MMLB has fewer 100+ page documents.

Pages	n	Nem-CE	Nem-CE⊕Scout	Δ
50–75	932	0.938	0.881	−5.7
75–100	555	0.944	0.813	−13.2
100–125	511	0.947	0.814	−13.3
125–150	287	0.916	0.697	−22.0
Overall	2285	0.939	0.826	−11.3

Table 9: Hit@5 on the answerable LongDocURL subset by document page-count bin, for plain Nem-CE and the Nem-CE⊕Scout cascade. Plain Nem-CE is flat with length; the cascade's recall deficit grows from -5.7 to -22.0 pp, because Scout increasingly ranks the evidence page outside its final top five as the candidate set spans a longer document, even though the Nem-CE prefilter still contains it.

LongDocURL by page count and compute Hit@5 on the answerable subset for both the plain Nem-CE retriever and the Nem-CE⊕Scout cascade. Plain Nem-CE is essentially flat across lengths (0.92–0.95), but the cascade degrades with length, from a -5.7 pp deficit on the shortest bin to -22.0 pp on the longest. Plain Nem-CE's flatness shows the evidence page is still inside the 50-page candidate set at every length, so the loss is in Scout's final selection: as the candidate set spans a longer document, Scout increasingly ranks the evidence page outside its top five. MMLongBench's documents are mostly short enough to avoid this regime, which is why the same cascade helps there ($+2.4$ pp) and confirms the cross-benchmark asymmetry is a length artifact rather than a benchmark idiosyncrasy.

G Effect of Thinking Mode

The main-paper results (Table 1) disable the VLM's reasoning/thinking mode so that all configurations are compared under identical greedy decoding. Table 10 isolates the effect of enabling a reasoning budget before the model answers, holding modality and retrieval depth fixed on MMLongBench-Doc. The sweep covers the two static image modes at three readers; we did not run the function-calling agent or Qwen3.5-27B with a reasoning budget, so no agent row appears here. This is why Table 1 holds every configuration at no-think: it is the only setting in which the agent and the static pipelines have matched decoding. Enabling thinking for the static modes alone would not be like-for-like, and the gap it opens is large enough to matter: Qwen3.5-9B all-images reaches 0.623 with a reasoning budget, above the 0.616 of the no-think Qwen3.5-27B agent, but the agent has no corresponding measurement.

VLM	Input	No-think	Think	Δ
Qwen3.5-4B	Top-5 img	0.512	0.553	+4.1
	All-images	0.526	0.578	+5.2
Qwen3.5-9B	Top-5 img	0.541	0.561	+2.0
	All-images	0.559	0.623	**+6.4**
Sonnet 4.5	Top-5 img	0.502	0.543	+4.1
	All-images	0.477	0.514	+3.7

Table 10: Effect of enabling thinking mode (MMLongBench, AVG), with an 8k-token reasoning budget. **Bold** marks the largest gain. Main-table numbers (Table 1) use no-think throughout.

Thinking helps five of the six configurations we tested, by about 4 to 6 pp; the sixth (Qwen3.5-9B on top-k input, $+2.0$ pp) has a paired interval that includes zero and we report it as a tie. The gains are largest where the input is largest: both open-weight readers gain more on all-images ($+5.2$ pp at 4B, $+6.4$ pp at 9B) than on top-k input ($+4.1$ and $+2.0$ pp), which fits the account that a whole-document input leaves more searching for a reasoning budget to do while a top-k retriever has already localized the evidence. Sonnet gains about 4 pp on both inputs. No configuration gains more than about 6 pp, and the modality ordering is unchanged in every case, so reporting no-think numbers in the main table does not affect any of our conclusions.

H Retriever Cost and Architecture

Table 11 reports the architectural details and cost profile for each retriever evaluated in Table 2, including the index-encoder backbone and its size, embedding dimension, per-question LLM token cost at retrieval time, and per-document indexing cost; where a reranker is used it is named in the **Index encoder** column. Numbers are approximate single-document cost on one A100, and per-corpus

totals scale linearly with $|D|$. BM25 indexes one document per page over the same MinerU markdown text used by the text-input rows, with lowercase word-regex tokenization and no stemming or stopword removal; the query is the question tokenized identically.

I Retrieval-Depth Sweep

We sweep the number of retrieved pages k for the ColQwen2.5 image retriever across Sonnet and all three Qwen3.5 sizes on both benchmarks (Table 12), reporting accuracy and mean input tokens; **Full** sends the whole document. Accuracy rises steeply to about k=10 and is flat thereafter: Sonnet peaks at k=10 and declines by k=20 as extra pages add distractors, while the Qwen readers gain at most 0.8 pp between k=10 and k=20 for 2× the input tokens. Our default of k=5 sits just below the peak and captures most of its accuracy at roughly half the tokens, which is why we use it throughout. Sending more than about ten pages is not worth the added cost, and even Full (the whole document) never beats the best k, though for the local Qwen readers on MMLongBench it comes within a point of it. The LDURL Full cell for Qwen3.5-27B is omitted, as is the same configuration's all-images cell in Table 1: rendering the uncapped page images of the longest documents did not complete, and an image-size-capped rerun would not be token-comparable to the other cells. This sweep also provides a token-matched control for the agent-versus-static comparison: the k=20 cells give the static pipeline *more* input tokens than the corresponding agent consumes, and the agent still leads at Sonnet (+11.6 pp, significant) though only by +2.1 pp at Qwen3.5-27B, where the interval includes zero (paired tests in §M), so the agent's advantage is the access policy rather than the token budget.

J Agent Implementation Details

This appendix expands the description of the two agentic configurations evaluated in §4.3: our six-tool function-calling agent and the ReadAgent baseline.

J.1 Six-Tool Function-Calling Agent

The function-calling agent wraps the same VLM used for static configurations in a multi-turn loop. The VLM is given a fixed toolkit and a per-question budget. At each turn it either issues one or more tool calls or commits a final answer via the `finish` tool.

Toolkit. The agent has access to six tools:

- **`get_catalog`** returns a deterministic structural map of the document built from MinerU's per-page layout output, with a per-page index of text size and figure/table counts, a flat section list with title and page range, and flat figure and table lists with captions, inferred neighbor text, and stable integer ids. No LLM is involved in the catalog construction, and the same MinerU output always produces the same catalog.
- **`read_pages(pages, resolution)`** renders the requested pages as image content blocks at a resolution the model chooses per call: `medium` (longest side 700 px) or `full` (longest side 1,400 px, rendered at DPI 180). Sonnet 4.5 asks for `full` on 62% of its page reads, Qwen3.5-4B on 68%, and Qwen3.5-27B on 12%. Multiple pages can be requested in a single call.
- **`get_figure(figure_id)`** returns the MinerU-extracted figure crop at the given catalog id as an image, plus its caption and neighbor text. Falls back to the full page image when the crop is unavailable.
- **`get_table(table_id)`** returns the MinerU-extracted table crop, its caption and neighbor text, and the table's structured HTML. The HTML preserves cell boundaries and is more robust than image-only access for numeric reasoning.
- **`search_text(query, top_k)`** runs BM25 over MinerU per-page text and returns the top-k page numbers, each with a matching text excerpt. Used by the VLM as an in-loop retrieval action when it has formed a more specific query than the original question.
- **`finish(answer)`** commits the final answer and ends the loop.

The catalog is also seeded into the very first user turn alongside the question, so the VLM has the document map without paying a tool-call round-trip, and explicit `get_catalog` calls are available for re-fetching. Seeding is therefore a latency optimisation rather than a source of the accuracy gain:

Retriever	Index encoder	Enc. size	Embed dim	LLM tok/Q	Index time/doc	Index size/doc
BM25 (MinerU)	— (lexical)	—	sparse vocab	0	<1 s (CPU)	<1 MB
BGE-M3	XLM-RoBERTa-large	568M	1024 (dense)	0	<5 s (1 GPU)	∼3 MB
BM25 + Cohere 3.5	— + Cohere rerank	—	sparse	0 (cross-enc.)	<1 s	<1 MB
BGE-M3 + Cohere 3.5	XLM-RoBERTa-l + Cohere	568M	1024	0 (cross-enc.)	<5 s	∼3 MB
SIRA (full pipeline)	BM25 + Claude Haiku 4.5 3-stage	—	sparse	∼11k	∼30 s (API)	∼5 MB
ColQwen2.5	Qwen2.5-VL-3B	3.0B	128 (late-int)	0	∼30 s (1 GPU)	∼40 MB
Nem-CE	Nem-CE-3B	3.0B	128 (late-int)	0	∼45 s (1 GPU)	∼40 MB
Nem-CE⊕Scout	Nem-CE-3B + Qwen3.5-9B	3.0B+9.0B	128 (Nem-CE)	∼63k	∼45 s (1 GPU)	∼40 MB

Table 11: Architecture and cost profile of each retriever in Table 2. **Index encoder** names the backbone that produces document-side representations. **Enc. size** is the parameter count of that encoder. **Embed dim** is the per-token dimension for dense retrievers, "sparse" for lexical, and "128 (late-int)" for ColPali-family multi-vector encoders. **LLM tok/Q** is the LLM compute spent at retrieval time per question, on MMLongBench-Doc; for the Scout cascade it is dominated by the page images Scout reads (up to 50 candidate pages at DPI 144, about 1,900 image tokens each, a mean of 33 pages per question), and it roughly doubles on LongDocURL, where nearly every document fills the 50-page candidate set. **Index time/doc** and **Index size/doc** are one-time preprocessing for a whole PDF of tens to hundreds of pages, not per question: they are paid once per document and reused by every question on it, roughly eight on MMLongBench-Doc and six on LongDocURL, so ColQwen2.5's ∼30 s is about 0.6 s per page at MMLongBench-Doc's 48-page mean. Pure-embedding retrievers (BM25, BGE-M3, ColQwen2.5, Nem-CE) incur zero LLM tokens at retrieval and only pay the precomputed-index cost. The Cohere 3.5 rows spend no generative-LLM tokens: the rerank is a cross-encoder call over the question and the top-50 candidate pages' text, so its cost is a fixed cross-encoder pass rather than LLM generation, and it matches the multi-stage SIRA pipeline (∼11k LLM tokens per question) within 0.3 pp on MMLongBench. Image-based retrievers lead text retrievers by about 17 pp between base encoders and by about 9 pp best-to-best, and the best image retriever (plain Nem-CE) does so with no LLM in the loop; the Scout cascade adds a large per-question LLM cost for a net loss against it (Table 2).

Benchmark	Reader	k=2	k=5	k=10	k=20	Full
MMLB	Sonnet	0.469 / 3.1k	0.502 / 7.6k	**0.514** / 15k	0.508 / 27k	0.477 / 32k
	Qwen3.5-4B	0.484 / 3.6k	0.512 / 9.0k	0.528 / 18k	**0.530** / 35k	0.526 / 33k
	Qwen3.5-9B	0.500 / 3.6k	0.541 / 9.0k	0.560 / 18k	**0.564** / 35k	0.559 / 33k
	Qwen3.5-27B	0.523 / 3.6k	0.565 / 9.0k	0.594 / 18k	**0.595** / 34k	0.588 / 30k
LDURL	Sonnet	0.608 / 3.0k	0.641 / 7.5k	**0.644** / 15k	0.628 / 29k	0.360 / 44k
	Qwen3.5-4B	0.572 / 3.9k	0.590 / 9.6k	0.598 / 19k	**0.606** / 38k	0.569 / 66k
	Qwen3.5-9B	0.585 / 3.9k	0.605 / 9.6k	**0.610** / 19k	0.609 / 38k	0.592 / 66k
	Qwen3.5-27B	0.589 / 3.9k	0.615 / 9.4k	0.623 / 19k	**0.623** / 37k	—

Table 12: Retrieval-depth sweep with ColQwen2.5 (accuracy / mean input tokens). **Bold** marks each row's best k. MMLB uses the extractor scorer, LDURL the official scorer (Table-1 scale). Accuracy peaks near k=10 and is flat-to-down by k=20 while tokens keep growing, so k=5 is a favourable accuracy/cost point. This is a self-contained sweep with the retriever fixed to ColQwen2.5, so cells differ from Table 1, whose per-reader top-5 rows use the best retriever for each reader and whose values may differ by up to ∼1 pp of decoding variance from an independent run.

the same information is reachable by tool call either way, and the agent would simply spend one extra turn retrieving it.

Loop structure. At each turn the VLM sees the conversation so far (including all prior tool returns) and chooses one or more tool calls. We cap the agent at eight tool calls per question. The budget is checked between turns, so a turn that issues several calls in parallel can overshoot it slightly. The Sonnet runner ends the loop at the first `finish`. For the Qwen3.5 runs the budget is stated in the prompt, the loop is bounded by a hard limit of 20 model calls, and it ends when the model returns a turn that issues no tool call: `finish` records the answer but is itself a tool, so a reader that keeps calling it keeps the loop alive until that ceiling. Qwen3.5-4B exits on its own on 64% of questions and exhausts the 20-call ceiling on the other 36%; of those, 97% had already emitted `finish` with an answer. Its call distribution is bimodal, with a median of 5 and a spike of 390 questions at exactly 20. Qwen3.5-9B and 27B reach the ceiling on 8% of questions. This is the cost asymmetry reported in §4.3. If the budget is exhausted without a `finish`, the VLM is given a final turn that must call `finish`. The temperature is set to zero throughout, and we use each provider's native function-calling API (the Claude API for Sonnet, and vLLM's OpenAI-compatible `/v1/chat/completions` endpoint with tool schemas for Qwen3.5).

Cost profile. On MMLongBench-Doc with Claude Sonnet 4.5, the agent averages 2.68 tool

calls per question, 20.1 k input tokens (catalog plus tool returns), and 538 output tokens (mostly tool argument JSON plus the final answer). The eight-call budget is rarely exhausted, and the modal trajectory uses two tool calls. We set the cap at eight to leave headroom rather than to constrain the policy, and the observed distribution confirms it does not bind: a cap of six would truncate 3.6% of trajectories, seven 0.8%, and eight 0.1%, while the longest trajectory we observe uses nine calls. Eight therefore sits just past the point where a lower cap would begin to change answers, so the results are insensitive to the exact value.

J.2 ReadAgent Baseline

ReadAgent (Lee et al., 2024) is a gist-based agent design that we re-implement as the closest published baseline to our toolkit. It pre-computes per-page "gist memories" and lets the VLM iteratively expand the most relevant gists.

Pipeline. For each document, ReadAgent first generates a short gist for every page using a small LLM (Claude Haiku 4.5 in our setup), with a fixed prompt and a 60-word target. At question time, the VLM is shown the full sequence of gists with the question and asked to select the most relevant pages to read in full. The selected pages are rendered at DPI=144 and concatenated with the gists for a final answer turn.

Hyperparameters. Gist length is capped at 60 words, lookup chooses 1–7 pages (median 2 in our runs), and both gisting and lookup run at temperature zero. Gists are cached on disk per-document and reused across all questions for that document, so the gisting cost amortizes over the full benchmark.

Key design difference vs. our toolkit. ReadAgent's lookup operates on LLM-generated gists, which compress each page into 60 words of free-form text, and once pages are selected, no further tool calls happen. Our six-tool agent instead seeds the VLM with a deterministic structural catalog (MinerU-derived section, figure, and table indices) and exposes structured figure-fetch, table-fetch, and BM25 search actions, so the VLM can explore specific structured content rather than committing to a page set up front from compressed text summaries. This difference is reflected in the agentic accuracy gap (§4.3). ReadAgent's gist memory loses fine-grained list and table information, while the structural catalog plus targeted tools preserves it.

Reproducibility. Both agents run with deterministic decoding ($T = 0$). Tool returns are byte-deterministic given the same MinerU output and PDF rendering, and on a fixed VLM checkpoint repeated runs of the same question yield the same trajectory in our spot checks. The MinerU outputs, page renderings, and gist caches are produced once per document and reused across all VLM configurations, so reported per-question latencies reflect agent-loop overhead and not preprocessing time.

K Architectural Cost of the Comparison Agents

Table 13 places the agentic systems of Table 1 on both axes at once, MMLongBench accuracy alongside what each one costs to run. Read together they make the practitioner-facing point of §4.3: our agent carries the least machinery of any system in the group, one VLM, a median of two tool calls, and a preprocessing step with no LLM in it, and is nonetheless level with or ahead of every system scored under the official scorer.

Two contrasts carry the cost argument. SimpleDoc keeps two large models in the loop per question, in its published configuration a 30B reasoner driving a 32B answerer over several retrieve-and-refine rounds, where we use a single VLM at 20 k input tokens. ReadAgent, the closest gist-based design, spends roughly one Claude Haiku 4.5 call *per page* to build its gist memory (§J.2), 5,775 calls over the 135 MMLongBench-Doc documents, a mean of 43 per document, or $\sim$5.3 extra LLM calls per question once amortized over that document's questions. Our catalog is derived from a single MinerU layout parse with no LLM in the loop.

Rows are ordered by accuracy, which is also how the protocol caveat becomes visible: the top row is DocLens with Gemini-2.5-Pro, 5.1 pp above our Sonnet agent under DocLens's own protocol, a gap smaller than the 8.9 pp that re-scoring SimpleDoc under the official scorer removed (§4.3), so the two cannot be ordered across protocols.

L Tool Usage Analysis for the 6-Tool FC Agent

To understand which tools contribute most to the 6-tool function-calling agent's accuracy, we analyze the per-question tool-call traces from the Sonnet 4.5 run on MMLongBench-Doc (N=1,082, mean

System	Reader	MMLB	Models in the loop	Per-question work	Offline preprocessing
DocLens§ (Zhu et al., 2025)	Gemini-2.5-Pro	0.676	3 agents (navigator, localizer, reasoner)	one pass per role	page index
DocLens§ (Zhu et al., 2025)	Claude-4-Sonnet	0.633	3 agents (navigator, localizer, reasoner)	one pass per role	page index
6-tool FC (ours)	**Sonnet 4.5**	**0.625**	**1 VLM**	**median 2 tool calls, 20 k tok**	**MinerU catalog, no LLM**
6-tool FC (ours)	**Qwen3.5-27B**	**0.616**	**1 VLM**	**median 2 tool calls, 33 k tok**	**MinerU catalog, no LLM**
SimpleDoc (Jain et al., 2025) (our re-run)	Sonnet 4.5	0.608	2 (both Sonnet 4.5)	iterative retrieve-and-refine rounds	dual-cue page index
ReadAgent (Lee et al., 2024)	Sonnet 4.5	0.498	1 VLM + a gisting LLM	lookup turn plus answer turn	1 LLM call *per page* (43/doc)
MDocAgent† (Han et al., 2025)	Qwen2-VL-7B	0.315	5 specialized agents + retriever	one pass per agent, then aggregation	ColPali page index

Table 13: Agentic systems of Table 1 by MMLongBench accuracy and architectural cost, ordered by accuracy. **Bold** marks our own rows, not the column best. †/§ mark scores under the system's own protocol rather than the official scorer († GPT-4o judge, § DocLens's own); re-scoring SimpleDoc under the official scorer costs 8.9 pp (§4.3); unmarked rows use the official scorer. Our rows and the ReadAgent row are measured from our own runs; the DocLens and MDocAgent entries, and SimpleDoc's published 30B/32B configuration, are as reported in those papers, since SimpleDoc is the only external system we re-ran. The SimpleDoc row here is that re-run, with Sonnet 4.5 in both roles.

Evidence type	N	search	read	figure	table
TXT (Pure-text)	305	66%	86%	13%	14%
LAY (Layout)	119	60%	92%	10%	8%
CHA (Chart)	178	69%	79%	**34%**	8%
TAB (Table)	218	72%	61%	5%	**51%**
FIG (Figure)	304	52%	81%	25%	8%

Table 14: Per-evidence-type tool invocation rates in the Sonnet 4.5 FC agent on MMLongBench-Doc. Values are the percentage of questions for which the agent invoked each tool at least once. The agent reliably routes table-evidence questions to `get_table` (51%) and chart/figure questions to `get_figure` (34%/25%), evidence that the structured catalog enables targeted access rather than uniform page reading.

2.68 tool calls per question). Table 14 reports how often each tool is invoked, broken down by evidence type.

Tool-call budget. Across 1,082 questions, the median trajectory uses 2 tool calls and the mean is 2.68, with 76% of questions finishing within 3 tool calls and 86% within 4. The full distribution over the number of (non-finish) tool calls is 0 (n=15), 1 (240), 2 (377), 3 (187), 4 (113), 5 (57), 6 (54), 7 (30), 8 (8), 9 (1). The budget is eight tool calls, checked between turns, so a turn that requests several pages or figures in parallel can push the per-question count slightly past 8. Only 3.6% of questions issue more than 6 tool calls, so a tighter 6-call budget would affect very few trajectories and is a defensible cost-saving operating point if a deployment is latency- or cost-sensitive.

M Statistical Significance

To quantify the uncertainty on Table 1 we bootstrap the per-question scores: for each configuration we resample questions with replacement 10,000 times, under a fixed seed, and take the 2.5th and 97.5th percentiles of the resampled mean. The resulting 95% confidence half-widths are uniform within each benchmark, ± 0.028–0.030 on MMLongBench-Doc (N=1,082) and ± 0.017–0.019 on LongDocURL (N=2,325). A useful rule of thumb follows: on these benchmarks a difference below $\sim$3 pp (MMLB) or $\sim$2 pp (LDURL) is within single-configuration noise.

We test the paper's central claims with a paired bootstrap over the questions both configurations answer, resampling the per-question score differences and calling a gap significant when its 95% interval excludes zero (Table 16). On MMLongBench the headline results are significant: holding the reader fixed, the 6-tool Sonnet agent beats Top-5 ColQwen with the same reader by $+11.7$ pp, and it also beats the strongest *retrieval* row at any reader (Top-5 Nem-CE$\oplus$Scout with Qwen3.5-9B) by $+6.1$ pp, so the lead survives comparison against a stronger reader than its own and not only against a same-reader one. Against the strongest static row overall, all-images with Qwen3.5-27B (0.588), the agent leads by $+3.7$ pp, $[+0.6, +6.8]$. It beats ReadAgent ($+12.6$ pp), and the image-over-text retrieval gap (ColQwen over BM25) holds on both benchmarks ($+10.0$ / $+8.7$ pp). On LongDocURL the picture is different: the agent's $+1.5$ pp margin over the best static pipeline, Top-5 Nem-CE, has an interval that includes zero, so on that benchmark the two are level and we do not order them. Three further gaps are *not* significant and we likewise report them as ties: all-images versus MinerU-text on MMLongBench (-0.4 pp, p=0.80), Sonnet ver-

sus Qwen3.5-27B as the agent reader (+0.9 pp), and top-k retrieval versus all-images at both open-weight readers (+2.5 and +0.5 pp). The Scout reranker's effect is significant in *both* directions: it helps on MMLongBench (+2.5 pp) and hurts on LongDocURL (−2.7 pp), confirming the cross-benchmark asymmetry is real and not noise. Likewise the SIRA-versus-single-rerank comparison is a zero-centered tie (+0.1 pp Hit@5, $[-2.8, +2.9]$ against BM25+Cohere; −0.4 pp $[-3.3, +2.6]$ against BGE-M3+Cohere), so the two are statistically indistinguishable at our 2 pp noise floor and we describe the single rerank as equivalent rather than merely close.

Three of the table's rows address potential confounds directly. *Token matching:* the agent's win is not a budget effect. Static top-k accuracy peaks near k=10 and declines at k=20 as added pages act as distractors (Table 12), so a static pipeline given the agent's token budget or more still loses: the Sonnet agent (0.625 at 20k input tokens) beats static ColQwen k=20 (0.508 at 27k) by +11.6 pp paired, while the Qwen3.5-27B agent (0.616 at 33k) is only +2.1 pp above its static k=20 (0.595 at 34k), an interval that includes zero. At Sonnet, then, the advantage is the access policy rather than the compute; at Qwen3.5-27B the two are indistinguishable once tokens are matched. *Pure-text evidence:* the image-retriever advantage is not only about tables and figures. Restricted to questions whose gold evidence carries no figure, chart, or table (that is, plain-text and layout-bearing text pages only), Nem-CE still beats the best text pipeline (BGE-M3+Cohere) on Hit@5, 0.889 vs. 0.833 on MMLongBench and 0.925 vs. 0.885 on LongDocURL, so page renderings preserve signal that text extraction loses even for textual evidence, though the margin is smaller than on visual evidence. *Extractor bias:* scoring raw responses instead of extracted answers under the official scorer costs the static pipelines and ReadAgent 47.1–49.7 pp (their long-form prose fails string matching, scoring near zero raw) but costs the FC agent only 0.7 pp (0.631 vs. 0.625), since its `finish` tool already returns a short structured answer. Table 15 gives the per-system breakdown. The extractor is what makes the baselines' numbers comparable at all, while for the agent it is a small penalty, so it cannot be inflating the agent's lead; if anything it understates it.

System (Sonnet 4.5)	Raw	Extracted	Extractor gain
6-tool FC agent	0.631	0.625	**−0.7** pp
All-images	0.005	0.477	+47.3 pp
Top-5 ColQwen	0.006	0.502	+49.6 pp
MinerU text	0.009	0.480	+47.1 pp
ReadAgent	0.002	0.498	+49.7 pp

Table 15: Effect of the shared answer extractor on MMLongBench-Doc (n=1,082), scoring each system's raw response and its extracted short answer under the same official scorer. Extraction is part of the benchmark's own published protocol, and we apply its released prompt unchanged to every system; the near-zero raw column reflects the scorer's whole-string comparison rather than wrong answers, e.g. for gold "Less well-off" a response containing "…their children will be *less well off* financially…" scores 0.0 raw and 0.92 extracted. Four unrelated baselines are lifted by nearly the same amount because their raw free-form prose scores near zero under string matching; the agent is the only system the extractor does not help, since its `finish` tool already emits a short structured answer. The protocol therefore favours the baselines and understates the agent's margin. The extracted column reproduces the corresponding Table 1 cells for all-images, MinerU text, and ReadAgent; the ColQwen row is the k=5 depth-sweep run of Table 12, so its gain is computed within that run. The agent's `finish` tool already emits a short answer, so its own output stands in for the raw column.

N Latency

Table 1 reports input tokens as the cost axis; Table 17 adds measured per-question wall-clock latency from the logged inference time of each run. The ordering mirrors the token cost but is not identical. Top-k retrieval is the cheapest mode and among the fastest (median 5.2 s with Nem-CE and 6.4 s with ColQwen2.5, against 5.1 s for ReadAgent's two-turn lookup), and only image-free MinerU text is faster still (median 3.5 s), which sends four times the tokens but no images and so skips image decoding entirely; the 6-tool agent is competitive with all-images despite issuing several sequential tool calls (median about 11 s), and raw PDF is the slowest (median 12.9 s on MMLB, 20.5 s on LDURL) because the API ingests every page as both an image and a text layer. Retrieval's speed advantage compounds its token advantage: it is roughly 2× faster than the agent and 2–4× faster than raw PDF, at about a third of the agent's input tokens and a tenth or less of raw PDF's.

These latencies are inference-time only. The one-time preprocessing that retrieval and the agent depend on (MinerU parse, page rendering, index/embedding build, catalog construction) is computed once per document and amortized across

Comparison	Δ (pp)	95% CI
Agent > Top-5 ColQwen (same reader), MMLB	$+11.7$	$[+8.8, +14.8]$
Agent > best Top-5 row, any reader, MMLB[b]	$+6.1$	$[+3.1, +9.2]$
Agent > ReadAgent, MMLB	$+12.6$	$[+9.6, +15.7]$
Agent vs best static (Top-5 Nem-CE), LDURL (n.s.)	$+1.5$	$[-0.3, +3.1]$
Agent-27B > Top-5 9B, MMLB	$+5.2$	$[+2.2, +8.2]$
Raw PDF > all-images, MMLB	$+4.5$	$[+1.7, +7.3]$
ColQwen > BM25, MMLB	$+10.0$	$[+7.5, +12.6]$
ColQwen > BM25, LDURL	$+8.7$	$[+7.2, +10.2]$
Scout helps Nem-CE, MMLB	$+2.5$	$[+0.4, +4.6]$
Scout hurts Nem-CE, LDURL	-2.7	$[-4.1, -1.5]$
Agent > static @ matched tokens (Sonnet), MMLB	$+11.6$	$[+8.7, +14.6]$
Agent-27B vs static @ matched tokens (n.s.)	$+2.1$	$[-0.9, +5.2]$
Image > text retr., pure-text evid., MMLB[h]	$+5.6$	$[+0.6, +11.1]$
Image > text retr., pure-text evid., LDURL[h]	$+4.0$	$[+2.3, +5.7]$
All-images vs MinerU-text, MMLB (n.s.)	-0.4	$[-3.5, +2.6]$
Agent Sonnet vs 27B, MMLB (n.s.)	$+0.9$	$[-1.6, +3.4]$
SIRA vs BM25+Cohere rerank, MMLB[h] (equiv.)	$+0.1$	$[-2.8, +2.9]$

Table 16: Paired-bootstrap significance tests (10,000 resamples of per-question score differences). "Agent" is our 6-tool FC agent with Sonnet 4.5 and "Agent-27B" the same toolkit with Qwen3.5-27B; ReadAgent is named in full where it appears. A comparison is significant when its 95% interval excludes zero; "n.s." marks gaps within noise that we report as ties, and "equiv." a zero-centered tie we report as statistical equivalence. The first row holds the reader fixed (Sonnet 4.5 on both sides); [b]compares the Sonnet agent against the strongest retrieval row of Table 1 at any reader, Top-5 Nem-CE⊕Scout with Qwen3.5-9B (0.564), rather than the larger same-reader gap. The strongest static row overall is all-images with Qwen3.5-27B (0.588), which the Sonnet agent leads by $+3.7$ pp paired, $[+0.6, +6.8]$. "Matched tokens" compares the agent against static ColQwen top-20, which consumes *more* input tokens than the agent (27k vs. 20k for Sonnet; 34k vs. 33k for Qwen3.5-27B). [h]Hit@5 comparisons: the pure-text-evidence rows compare Nem-CE against BGE-M3+Cohere on questions whose gold evidence carries no figure, chart, or table, i.e. plain-text and layout-bearing text pages (n=180 MMLB, n=1,069 LDURL); the SIRA row compares its full multi-stage pipeline against a single Cohere rerank over the same 854 answerable MMLB questions.

Configuration (Sonnet 4.5)	Median (s)	Mean (s)	Mean tok
Top-5 ColQwen, MMLB	6.4	7.0	7.6k
Top-5 Nem-CE, MMLB	5.2	5.6	7.6k
MinerU text, MMLB	3.5	3.8	27k
ReadAgent, MMLB	5.1	5.4	11k
6-tool FC agent, MMLB	11.4	13.7	20k
All-images, MMLB	10.1	11.5	32k
Raw PDF, MMLB	12.9	15.8	80k
Top-5 ColQwen, LDURL	4.9	5.4	7.5k
6-tool FC agent, LDURL	10.6	12.8	21k
All-images, LDURL	10.6	13.4	44k
Raw PDF, LDURL	20.5	22.6	150k

Table 17: Measured per-question wall-clock latency (from logged inference time) alongside mean input tokens. Retrieval is the cheapest mode on both benchmarks and among the fastest; on MMLongBench, where we timed every mode, only image-free MinerU text is faster, with ReadAgent's two-turn lookup in the same range as retrieval. The agent is competitive with all-images and faster than raw PDF on both. Latencies are inference-time only; one-time preprocessing is amortized over all questions on a document (§N).

every question on that document, which on these benchmarks averages $\sim$8 questions per document on MMLongBench (1,082/135) and $\sim$5.9 on LongDocURL (2,325/396). Per-retriever index-build cost is detailed in Table 11: BM25 indexes in under a second on CPU, and the image retrievers embed a document once on a single A100. The heaviest preprocessing in the table is not ours but the ReadAgent baseline's, which spends roughly one Claude Haiku 4.5 call *per page* to build its gist memory (§J.2): 5,775 gisting calls across the 135 MMLongBench-Doc documents, a mean of 43 per document, or $\sim$5.3 extra LLM calls per question once amortized, roughly 2.7× its own per-question inference. Our catalog, by contrast, is built from MinerU layout output with no LLM in the loop. Counting preprocessing in would therefore widen our margin over that baseline rather than narrow it. The three access modes differ in what they require offline, which the per-question token column does not show. Raw PDF and all-images need nothing. Top-k retrieval needs a per-document embedding pass, $\sim$30 s for ColQwen2.5 and $\sim$45 s for Nem-CE on one A100 at $\sim$40 MB per document, and the LLM-based rerank pipelines (SIRA, Nem-CE⊕Scout) additionally spend generative tokens at query time, while the Cohere cross-encoder rerank does not. Our agent needs only the MinerU parse that the text-input modes already require, with no embedding index and no LLM. Amortized over the $\sim$8 and $\sim$5.9 questions per document these benchmarks provide, none of this reverses the token- or latency-cost ordering, but it does mean the token column understates retrieval's full cost relative to the agent's.

O Per-Question Routing Analysis

Oracle definition and membership. Given pipelines $\{S_1, \ldots, S_m\}$ scored on the same questions, the per-question oracle's score on q is $\max_j \text{score}(S_j, q)$. Averaged over the benchmark this is the accuracy a perfect selector would achieve if it knew, with hindsight, which pipeline to trust per question. Unless stated otherwise the member set is three of our strongest configurations: the 6-tool FC agent with Sonnet 4.5, the same agent with Qwen3.5-27B, and Top-5 Nem-CE retrieval

with Sonnet. Because it is a per-question maximum the oracle is computed only over questions all members answer, and it rises mechanically with the number of members, so we hold the member set fixed at three throughout rather than reporting a figure that grows with how many pipelines we happen to have run.

This oracle gains roughly 13 pp over the best single pipeline, so the pipelines succeed on different questions. Table 1's oracle row, computed over its own common subset, implies +13.1 pp on MMLongBench and +12.9 pp on LongDocURL against the best single pipeline there. We test whether a router conditioned on evidence type can capture this headroom. For every evidence type we identify the pipeline with the highest accuracy on that type, then route each question to its type's best pipeline; using the *gold* evidence label makes this an upper bound on any type-conditioned router. Unlike Table 3, which tags a question with every evidence type its gold pages carry, this analysis assigns each question to a single mutually-exclusive bucket so that a router has exactly one branch to take per question, which shifts the per-type means slightly. The 6-tool agent is the strongest pipeline within every evidence-type stratum on MMLongBench except charts, where ColQwen edges it by 1.5 pp (e.g. it leads on tables at 0.703 over MinerU-text at 0.616, and on figures at 0.529 over ColQwen at 0.465), and on LongDocURL for every type except tables, where Top-5 Nem-CE leads by 1.6 pp, and a 3-question "other" bucket; the type-ceiling router therefore assigns the agent almost everywhere and gains only +0.2 pp on MMLongBench and +0.6 pp on LongDocURL over simply running the agent, both within noise. A realistic router that conditions on observable features (question keywords and answer format, without the gold label) is *worse* than the agent alone (−0.9 pp on MMLongBench, −7.1 pp on LongDocURL), since it sometimes routes away from the agent. The oracle headroom is therefore real but *intra*-type: it lives in disagreements among the pipelines on individual questions of the same evidence type, not in any type-to-pipeline mapping. Recovering it requires a learned per-question router with a finer signal than evidence type, which we leave to future work; a fixed type-based routing rule does not beat a single strong agent. Table 18 summarizes the four strategies.

Strategy	MMLB	LDURL	vs. best single
Best single pipeline (6-tool FC)	0.627	0.661	reference
Gold-type router (upper bound)	0.629	0.667	+0.2 / +0.6 pp
Observable-feature router	0.618	0.590	−0.9 / −7.1 pp
Per-question oracle (hindsight)	0.752	0.796	+12.5 / +13.5 pp

Table 18: Routing strategies, all with Sonnet 4.5, scored on the questions all four candidate pipelines answer (n=1,064 MMLB, n=2,287 LDURL). The gold-type router uses the gold evidence label and is therefore an upper bound on any type-conditioned rule; it gains under a point, because it routes to the agent almost everywhere. The observable-feature router uses only question keywords and answer format. The agent reads 0.627/0.661 here because these rows use the four-pipeline shared subset rather than the full question set of Table 1 (0.625/0.659). This oracle is over these four pipelines rather than the three configurations of Table 1's oracle row; the roughly 13 pp headroom conclusion is unchanged.

P Chunked Map-Reduce for Long Documents

The all-images mode collapses on long documents (§E) because the API stitches and downsamples pages once a request exceeds its 100-image/size cap. We test whether this is an artifact of the single-request implementation rather than a limit of the all-images access mode itself, by splitting each long document into contiguous chunks of at most 100 pages, answering the question over each chunk independently (rendered at the same 144 DPI, 1024 px cap), and then synthesizing a single answer from the per-chunk candidates in a reduce step. We evaluate on the LongDocURL questions whose document has 100 pages or more (817 questions over 115 documents, mean 121 pages) and score with the same official scorer. The comparison point is plain all-images on the identical subset, which scores 0.204 (against 0.444 on the $<$100-page subset).

Chunked map-reduce reaches 0.193, against 0.204 for the single-request baseline as scored elsewhere in the paper (§E), so the two are a wash and chunking neither helps nor hurts (Table 19). Chunking therefore removes the API stitch/downsample without restoring accuracy, and map-reduce remains far below the 0.444 that all-images achieves on $<$ 100-page documents, so most of the long-document degradation is intrinsic to whole-document image access at this length rather than an artifact of the single request: splitting the document loses the cross-chunk context needed to answer many questions, and the reduce step cannot recover evidence no chunk surfaced. The se-

Configuration	AVG	Δ vs. map-reduce
Chunked map-reduce	0.193	—
Single-request all-images, as scored in the paper	0.204	−1.1 pp

Table 19: Chunked map-reduce against single-request all-images on the LongDocURL questions whose documents have 100 pages or more (817 questions over 115 documents, mean 121 pages), Sonnet 4.5 under the official scorer. Chunking is a wash, and both configurations sit far below the 0.444 that all-images reaches on documents under 100 pages, so the long-document collapse is mostly intrinsic to whole-document image access rather than an artifact of the per-request cap.

lective modes (retrieval and the agent), which send only a handful of targeted pages per call regardless of document length, sidestep both failure modes and remain the recommended options on long documents.

StreamCorrect: Self-Supervised Error Correction for Real-Time ASR with Offline Recognizers

Abstract

Streaming Automatic Speech Recognition (ASR), also known as online or real-time ASR, transcribes speech incrementally while audio is being spoken and is critical for many industry applications. Despite the strong performance of modern offline ASR models, streaming deployment remains challenging because limited future context can cause early recognition errors to propagate across later chunks. We define the task of streaming ASR error correction and propose StreamCorrect, a modular framework that fine-tunes a lightweight error corrector on self-generated streaming ASR errors and integrates it with existing streaming ASR systems. To enable training without human annotation, StreamCorrect introduces a timestamp-free boundary recovery procedure based on Prefix-to-Reference Alignment for generating chunk-level correction data. Across multiple languages and ASR backbones, StreamCorrect achieves up to 39% relative character error rate (CER) reduction with minimal latency overhead. Error propagation analysis reveals progressively larger gains over time, with up to 7.2% absolute CER reduction in later audio chunks. StreamCorrect bridges offline ASR models and streaming deployment through a lightweight correction plug-in while preserving the pretrained ASR component without additional tuning or distillation.[1]

1 Introduction

In industrial applications, automatic speech recognition (ASR) models have achieved remarkable progress across languages (team et al., 2025), audio lengths (Peng et al., 2025), and domains (Rangappa et al., 2025), enabled by large-scale data and powerful Transformer- or Conformer-based architectures. However, real-time applications such as online captioning and voice assistants remain challenging because decoding must proceed with limited future context. Traditional streaming ASR addresses this issue through causal architectures, including Recurrent Neural Network Transducers (RNN-T) (Kurata and Saon, 2020), Transformer Transducers (Zhang et al., 2020), and CTC-based models (Li et al., 2025b). More recently, offline-based streaming ASR has emerged as an alternative paradigm that deploys strong offline models in real time through streaming inference, avoiding architectural changes or retraining of the speech recognizer. Approaches such as SimulWhisper (Wang et al., 2024), WhisperStreaming (Macháček et al., 2023), and SimulStreaming (Macháček and Polák, 2025) adapt offline models such as Whisper for streaming transcription and translation.

Despite this practicality, offline-based streaming ASR systems remain limited by restricted decoding context and error propagation, where early speech recognition errors can accumulate over time. Error correction offers a natural way to mitigate such errors by leveraging linguistic context, alternative hypotheses, or external language models, and has been studied for offline ASR (Li and Wang, 2024; Lin et al., 2025; Zhao and Liu, 2025). However, applying error correction to streaming ASR is substantially more challenging: hypotheses are incomplete, the recognition context evolves over time, and corrections must be made under real-time constraints. As a result, streaming ASR error correction remains underexplored despite its practical importance for deploying strong offline recognizers in real-time settings.

This paper presents StreamCorrect, a training and inference framework for streaming error correction integrated with existing offline-based streaming ASR systems. We formulate streaming error correction as generating corrected transcript segments at each chunk using (i) the confirmed transcript prefix, (ii) top-k streaming hypotheses, and (iii) observed audio, enabling error correc-

tion while keeping the module decoupled from the underlying ASR module. A key challenge is constructing streaming-specific correction data without additional human annotation. StreamCorrect generates supervision from the streaming system itself by exposing diverse error patterns through different chunk and beam configurations. These outputs are converted into chunk-level training data using Prefix-to-Reference Alignment (PRA), a timestamp-free boundary recovery method. The synthesized data is then used to fine-tune a lightweight Speech Language Model (SpeechLM) as the error corrector.

StreamCorrect reduces error propagation during streaming inference, achieving lower error rates across languages and ASR backbones with minimal latency overhead. Our contributions are summarized as follows:

- We introduce and formalize streaming error correction for offline-based streaming ASR systems, capturing the incremental and real-time nature of streaming recognition.
- We propose StreamCorrect, a practical framework with a self-supervised training recipe that generates streaming-specific correction data from self-generated errors and timestamp-free Prefix-to-Reference Alignment. We release the correction data, model checkpoints, and source code to support future research and development.
- Comprehensive experiments demonstrate consistent improvements across languages and ASR backbones, achieving a 39% relative CER reduction on Mandarin (AIShell-1) and a 35% relative CER reduction on Cantonese (WSYue) with minimal latency overhead. StreamCorrect also generalizes to industrial conditions, substantially narrowing the performance gap with offline upper bounds. Furthermore, StreamCorrect mitigates error accumulation over time, achieving up to a 7.2% absolute CER reduction in later streaming chunks.

2 Related Work

Offline-based Streaming ASR. Offline-based streaming ASR adapts strong offline ASR models to real-time inference by processing incoming audio in chunks while keeping the original model unchanged. Representative Whisper-based approaches mainly differ in how they decide which part of each partial decoding is reliable enough to confirm. WhisperStreaming (Macháček et al., 2023) repeatedly decodes the growing audio buffer and confirms the longest prefix shared by consecutive hypotheses, providing a simple but potentially variable-latency solution. SimulWhisper (Wang et al., 2024) instead uses Whisper's cross-attention to estimate where the current decoding has reached in the audio and stops accordingly, while additionally detecting truncated words at chunk boundaries. SimulStreaming (Macháček and Polák, 2025) builds on this attention-based stopping mechanism while incorporating the streaming interface and buffer management of WhisperStreaming, enabling unbounded speech processing. StreamCorrect is complementary to this line of work: rather than redesigning the streaming recognizer, it adds a modular correction stage that targets the errors induced by streaming inference.

Error Correction in ASR. ASR error correction aims to improve recognition outputs by modeling systematic errors using linguistic and acoustic information. Early neural approaches, such as FastCorrect2 (Leng et al., 2021) and SoftCorrect (Leng et al., 2023), demonstrate effective sequence-level correction, while recent LLM-based methods (Chen et al., 2023; Fang et al., 2025; Li et al., 2024; Ma et al., 2023) leverage stronger language modeling capabilities for post-correction. Benchmarks such as ClozeGER (Hu et al., 2024) and the GenSec Challenge (Yang et al., 2024) further study ASR refinement under realistic error distributions. Most of these methods assume complete utterance-level hypotheses and full context, which are unavailable during streaming recognition. For streaming ASR, Fast-Slow encoders (Li et al., 2022) and Partial Rewriting (Bruguier et al., 2023) explore refinement through multi-scale modeling and hypothesis revision, respectively. These approaches either modify the ASR architecture or rely on heuristic hypothesis combination, whereas StreamCorrect trains a modular SpeechLM-based corrector on chunk-level streaming errors and can be attached to existing streaming systems.

3 Approach

StreamCorrect bridges the gap between offline recognizer quality and real-time streaming deployment by adding a lightweight correction module to an existing offline-based streaming ASR system. The framework first fine-tunes a SpeechLM error corrector on self-generated streaming errors,

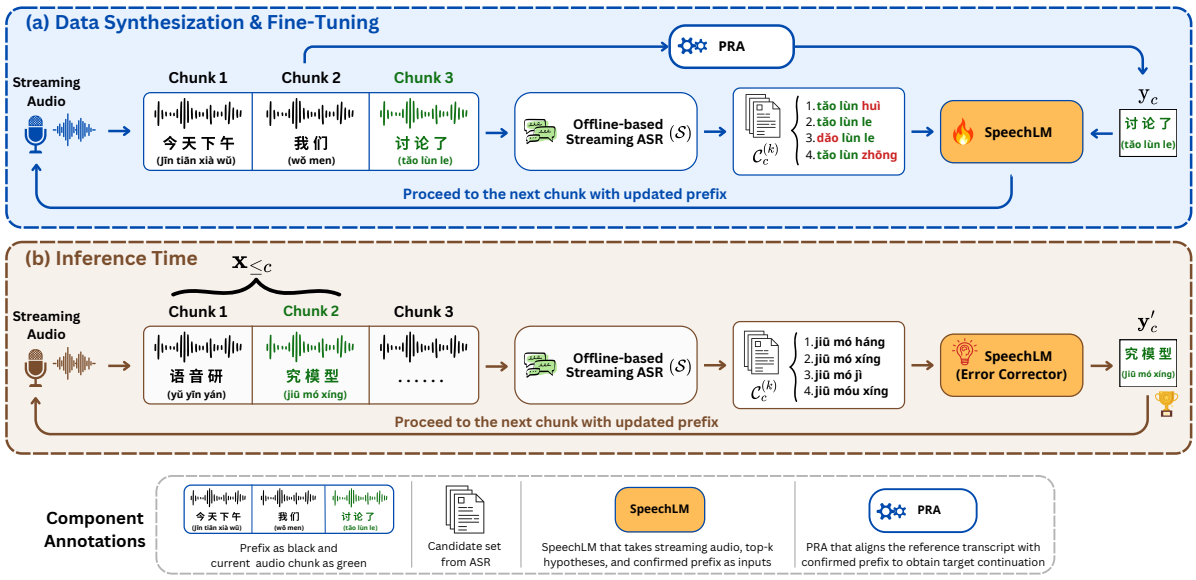

Figure 1: Overview of StreamCorrect. (a) Data synthesis and fine-tuning. We use an offline-based streaming ASR system to generate streaming-specific error correction data. Prefix-to-Reference Alignment (PRA) recovers chunk-level supervision without timestamps by identifying the boundary between confirmed prefixes and future content. (b) Inference time. The fine-tuned SpeechLM is integrated as a modular error corrector, refining the top-k hypotheses of each chunk using available context to produce corrected transcripts during streaming inference.

then integrates the trained corrector into the same streaming pipeline at inference time to improve recognition quality, as illustrated in Figure 1.

3.1 Problem Definition

In streaming ASR, recognition is performed incrementally with limited future acoustic context. Since emitted tokens are typically committed and no longer revised, early recognition errors can propagate to later predictions, motivating error correction during streaming inference. Formally, let $\mathbf{x}_{\leq c}$ denote the audio observed up to chunk c, and let $\mathbf{y}'_{<c}$ denote the confirmed prefix consisting of previously committed tokens. The objective of ***streaming error correction*** is to generate the corrected transcript segment $\mathbf{y}'_c$ at chunk c conditioned on the confirmed prefix, recognition hypotheses, and observed audio:

$$\mathbf{y}'_c = \arg\max_{\mathbf{y}_c} P\left(\mathbf{y}_c \mid \mathbf{y}'_{<c}, \mathcal{C}_c^{(k)}, \mathbf{x}_{\leq c}\right).$$

The generated segment $\mathbf{y}'_c$ is appended to the confirmed prefix and used as context for subsequent chunks. Here, $\mathcal{C}_c^{(k)}$ represents the top-k recognition hypotheses produced at chunk c by the streaming ASR system $\mathcal{S}$:

$$\mathcal{C}_c^{(k)} = \mathcal{S}\left(\mathbf{y}'_{<c}, \mathbf{x}_{\leq c}\right),$$

where k denotes the beam size. In practice, the prefix does not necessarily align exactly with the most recent audio chunk, as token emission may be delayed until sufficient acoustic context becomes available under the streaming mechanism.

3.2 Overview of StreamCorrect

As shown in Figure 1, StreamCorrect leverages self-generated data from an offline-based streaming system to fine-tune a SpeechLM as a lightweight error corrector. The corrector is then integrated back into the streaming ASR pipeline to refine recognition outputs online. In this work, SimulStreaming is adopted as the representative offline-based streaming ASR system.

Self-generated streaming error correction data. Training a streaming error corrector requires chunk-level supervision, where each streaming prediction is paired with the corresponding reference transcript segment. However, most speech datasets provide only utterance-level transcripts without token-level timestamps. Directly assigning reference tokens based on audio boundaries is unreliable, since the textual emission boundary of a streaming ASR system may differ from the temporal boundary of an audio chunk. Such mismatches can introduce incorrect supervision and accumulate errors during data synthesis.

To address this issue, StreamCorrect introduces a *Prefix-to-Reference Alignment (PRA)* procedure for timestamp-free boundary recovery. Given the

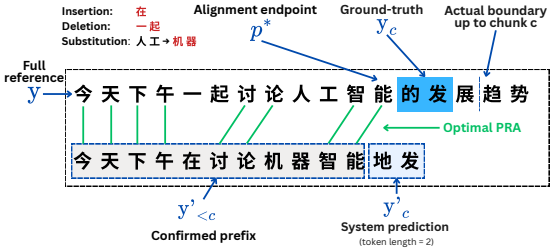

Figure 2: Illustration of Prefix-to-Reference Alignment (PRA) for timestamp-free boundary recovery.

ground-truth transcript $\mathbf{y}$ and the confirmed prefix $\mathbf{y}'_{<c}$, PRA identifies the reference position p^* corresponding to the end of the confirmed prefix. The key observation is that although streaming ASR outputs may contain local insertion, deletion, and substitution errors, the confirmed transcript generally preserves the ordering of the underlying utterance and can be viewed as an approximate prefix of $\mathbf{y}$. Therefore, the endpoint of the optimal alignment path between $\mathbf{y}'_{<c}$ and $\mathbf{y}$ provides a reliable estimate of the current textual decoding boundary. An example of PRA is illustrated in Figure 2, where the confirmed prefix contains recognition errors but the recovered alignment endpoint successfully identifies the corresponding reference boundary.

Specifically, PRA formulates boundary recovery as a semi-global sequence alignment problem. Let $m = |\mathbf{y}'_{<c}|$ and $n = |\mathbf{y}|$. A dynamic programming matrix $\mathbf{D} \in \mathbb{R}^{(m+1)\times(n+1)}$ is constructed, where $D(i, j)$ denotes the minimum Levenshtein distance (Levenshtein, 1966) between the first i tokens of $\mathbf{y}'_{<c}$ and the first j tokens of $\mathbf{y}$. The recurrence is defined as:

$$D(i,j) = \min \begin{cases} D(i-1,j)+1, \\ D(i,j-1)+1, \\ D(i-1,j-1)+\mathbb{1}[y'_{<c,i} \neq y_j]. \end{cases}$$

The three transitions correspond to deletion, insertion, and substitution operations, respectively. To fully specify the dynamic program, the boundary conditions are

$$D(0,0) = 0, \qquad D(i,0) = i, \qquad D(0,j) = j,$$

where aligning a non-empty prefix with an empty sequence requires i deletions, aligning an empty prefix with j reference tokens requires j insertions. The recurrence is complete for the Levenshtein objective because the final operation of any alignment must be one of these three cases. Since each transition extends an optimal solution of its corresponding preceding subproblem, $D(i, j)$ gives the minimum edit cost between the first i tokens of $\mathbf{y}'_{<c}$ and the first j tokens of $\mathbf{y}$.

Unlike conventional sequence matching, PRA adopts a semi-global alignment objective: all tokens in $\mathbf{y}'_{<c}$ are aligned, while the alignment is allowed to terminate at any position in $\mathbf{y}$. Therefore, minimizing the final row over all reference positions yields the globally minimum-cost endpoint for the confirmed prefix.

The alignment boundary is obtained as:

$$p^* = \arg\min_j D(m, j),$$

where p^* corresponds to the endpoint of the optimal alignment path. When multiple endpoints attain the same minimum cost, PRA deterministically selects the smallest endpoint. This conservative tie-breaking rule avoids prematurely advancing the reference boundary when the alignment provides equally good alternatives. In particular, it allows the error corrector to retain potentially recoverable reference content for subsequent correction rather than forcing the current prediction to immediately catch up to a later endpoint. Thus, even when the recovered boundary does not exactly coincide with the real-time emission boundary, the supervision remains deliberately biased toward preserving content that can be corrected with additional acoustic context, rather than discarding it prematurely.

The current chunk target is then extracted using the number of tokens newly committed by the streaming ASR system:

$$\mathbf{y}_c = \mathbf{y}[p^* + 1 : p^* + |\hat{\mathbf{y}}_c|].$$

PRA also naturally handles code-switched speech because it operates directly on token sequences without language-specific alignment rules. Tokens from different languages are treated uniformly under the same edit-distance objective. For example, if an English word in code-switched speech is tokenized as *com*, *put*, *er* while the ASR predicts *com*, *pat*, *er*, PRA simply treats *put*→*pat* as a substitution while aligning the surrounding tokens normally.

This design preserves the streaming decoder's own emission behavior and stopping mechanism while replacing unavailable timestamps with an alignment-based textual boundary. Consequently, PRA converts utterance-level annotations into chunk-level supervision without additional timestamp information, while remaining robust to local insertion, deletion, and substitution errors.

Real-time inference with error corrector. After being fine-tuned on the self-generated streaming error correction data, the error corrector is integrated immediately after the offline ASR model during inference. In each streaming iteration, the offline model receives an additional audio chunk and produces top-k hypotheses for the newly generated transcript segment. The error corrector then takes the current audio chunk, the top-k hypotheses, and the previously confirmed prefix as input, and outputs a finalized transcript segment for the current step. This finalized segment is appended to the confirmed prefix and retained as context for processing subsequent audio chunks.

4 Experiments

4.1 Benchmark and Experimental Setup

Benchmark. StreamCorrect is evaluated on AIShell-1 (Bu et al., 2017) (178 hours), a widely used Mandarin ASR benchmark, and an internal industrial Mandarin benchmark consisting of banking-domain conversations with realistic in-house noise. The industrial benchmark contains 30 minutes of audio but represents challenging real-world scenarios with short context-poor utterances, financial entities (e.g., amounts, rates, and phone numbers) and disfluent speech patterns. To assess generalization across languages, we additionally evaluate on WSYue (Li et al., 2025a), a 9.5-hour Cantonese ASR dataset covering 2,861 speakers and a wide range of usage scenarios, including Cantonese-English code-switching and multi-domain conditions.

Metrics. Character Error Rate (CER) is the primary accuracy metric. Latency is measured by First Token Latency (FTL), the time from audio reception to the first emitted token, and Last Token Latency (LTL), the time from the end of the audio stream to transcript finalization. All latency measurements are obtained on NVIDIA H20 GPU.

Base models. Belle-Whisper-large-v2-zh (Group, 2023) is adopted as the base offline ASR model for Mandarin in the streaming system, and is referred to as Belle Whisper for brevity. For Cantonese, we use Whisper Medium Yue (Li et al., 2025a) as the base offline ASR model. For the error corrector, Ultravox-v0.5-Llama-3.2-1B (Fixie AI, 2024) is adopted as the primary SpeechLM and fine-tuned accordingly.

Chunk size	Sub.	Ins.	Del.	Overall
100ms	13.1	6.8	1.7	21.6
500ms	8.4	6.6	3.2	18.2
1000ms	7.0	4.5	3.2	14.7
1500ms	6.2	3.4	3.2	12.8

Table 1: Substitution, insertion, and deletion error statistics (% CER) in the self-generated AIShell-1 training data.

Details on error corrector fine-tuning. The error corrector is fine-tuned from the Ultravox-v0.5-Llama-3.2-1B backbone via instruction tuning with LoRA. Adapters are injected into the attention projections (Q, K, V, O) and feed-forward layers. Training uses cross-entropy loss and is optimized with AdamW at a learning rate of 1×10^{-4} and a cosine scheduler with a 0.01 warmup ratio.

4.2 Statistics of Self-Generated Training Data

Following the StreamCorrect pipeline, SimulStreaming is applied to the AIShell-1 training set under diverse streaming configurations, including chunk sizes of 100ms, 500ms, 1000ms, and 1500ms, and beam sizes of 1, 2, 4, and 8. This process yields approximately 1 million self-generated training samples for Mandarin.

Table 1 shows that the generated training data expose the error corrector to a wide range of error scales, with CER ranging from 12.8% at a 1500ms chunk size to 21.6% at a 100ms chunk size. Substitution errors dominate, increasing from 6.2% at 1500ms to 13.1% at 100ms. This indicates that streaming systems largely maintain token count but struggle with lexical selection. Using the homophone dictionary from SoftCorrect (Leng et al., 2023), we find that about 22% of substitutions arise from homophone confusion. For instance, the top-1 hypothesis may predict 在 (“at”) while the ground truth is 再 (“again”), which share identical pronunciation but differ semantically.

4.3 Results and Analysis

Table 2 compares StreamCorrect with offline-based streaming systems, including WhisperStreaming and SimulStreaming, together with their corresponding offline backbones (Belle Whisper for Mandarin and Whisper Medium Yue for Cantonese). On AIShell-1, StreamCorrect consistently improves over existing streaming baselines across all chunk sizes. At 100ms, it reduces CER from 27.3% to 11.7% compared with SimulStreaming, with only 49ms additional FTL and 84ms addi-

Dataset	Metric	Offline Backbone (upper bound†)	WhisperStreaming			SimulStreaming			StreamCorrect (Ours)		
			100ms	500ms	1000ms	100ms	500ms	1000ms	100ms	500ms	1000ms
AIShell-1 (Mandarin)	**CER(%)↓**	2.5	38.4	23.6	15.5	27.3	16.3	13.9	11.7	9.8	7.9
	FTL(ms)↓	–	441	441	442	158	158	158	207	219	234
	LTL(ms)↓	–	325	363	971	200	213	227	284	295	321
Our industrial data (Mandarin)	**CER(%)↓**	16.2	55.8	39.4	31.2	38.7	27.8	24.1	26.8	20.7	18.5
	FTL(ms)↓	–	432	433	435	152	153	154	201	213	229
	LTL(ms)↓	–	337	375	1001	195	210	224	279	292	318
WSYue (Cantonese)	**CER(%)↓**	6.3	31.8	22.4	15.7	21.2	15.6	14.1	13.9	10.2	8.2
	FTL(ms)↓	–	228	228	229	82	82	82	197	197	197
	LTL(ms)↓	–	201	217	569	123	127	133	289	294	301

Table 2: Performance comparison across chunk sizes on AIShell-1 (Mandarin), an industrial Mandarin benchmark, and WSYue (9.5h Cantonese, 2,861 speakers). Offline backbones are Belle Whisper for Mandarin and Whisper Medium Yue for Cantonese, serving as the base models for the streaming systems and evaluated with full context. All streaming methods use beam size 4. †Offline Backbone is the reference that streaming ASR aims to approach.

tional LTL. At 500ms and 1000ms, it further reduces CER by about 6%, corresponding to 39% and 43% relative reductions, while maintaining low latency overhead. In contrast, WhisperStreaming suffers severe degradation under low-latency settings, reaching 38.4% CER at 100ms and 15.5% at 1000ms. We further evaluate StreamCorrect on our industrial Mandarin benchmark and WSYue Cantonese to assess cross-domain and cross-lingual generalization. On the industrial dataset, where distorted speech and domain shift make the offline upper bound weaker (16.2% CER), StreamCorrect achieves 20.7% CER at 500ms and substantially narrows the gap compared with SimulStreaming (27.8%). On WSYue, StreamCorrect also improves consistently, reducing CER from 21.2% to 13.9% at 100ms and from 14.1% to 8.2% at 1000ms over SimulStreaming. These results show that StreamCorrect improves streaming ASR quality across languages and domains while introducing only modest latency overhead.

We additionally analyze StreamCorrect under varying beam sizes and base ASR models to examine its robustness and adaptability. As shown in Table 3, StreamCorrect achieves its lowest CER at a beam size of 4, which corresponds to our primary streaming configuration. The fine-tuned error corrector consistently improves performance across all beam sizes. At beam size 1, error correction yields the largest absolute gain, reducing CER by 11.4%. Even at beam size 2, where the baseline already performs relatively well, StreamCorrect still achieves a 4.4% absolute reduction, demonstrating its robustness under varying decoding settings.

Beam Size	SimulStreaming CER(%)↓	StreamCorrect CER(%)↓
1	23.4	11.9
2	14.4	10.0
4	16.3	9.8
8	17.2	10.6

Table 3: CER comparison of SimulStreaming and StreamCorrect (ours) at 500ms chunk size across beam sizes on the AIShell-1 test set.

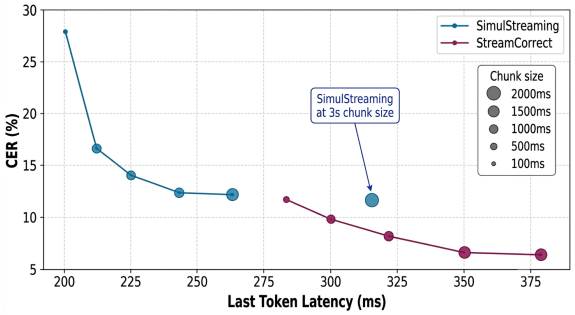

Figure 3: CER vs. LTL trade-off between SimulStreaming and StreamCorrect (ours) on the AIShell-1 test set.

The latency–accuracy trade-off with and without error correction is shown in Figure 3. StreamCorrect at a 100ms chunk size achieves lower CER than SimulStreaming at 2000ms (11.7% vs. 12.3%), indicating greater robustness under low-latency settings. When reducing the chunk size from 500ms to 100ms, StreamCorrect incurs only a 1.9% CER increase, whereas SimulStreaming exhibits an 11.0% increase. Across chunk sizes, the LTL increases by an average of 96ms and remains below 300ms for chunk sizes up to 500ms. Even at comparable latency (312ms) and up to 3s chunk size, SimulStreaming still yields higher CER than StreamCorrect.

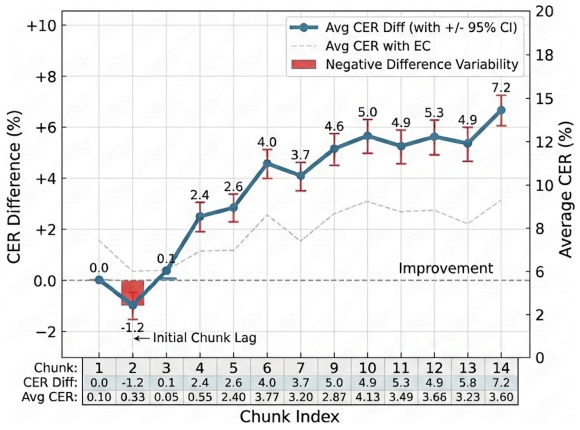

Figure 4: Chunk-wise ASR performance on the AIShell-1 test set (utterances shorter than 4s excluded). The primary axis (blue line) shows the CER difference, where positive values indicate improvement from error correction. The secondary axis (dashed line) tracks the average CER with error correction. Exact values are shown in the bottom table.

4.4 Error Propagation Effect

Figure 4 shows that during the first three chunks (0–1.5s), the error corrector makes only minor edits, with a slight degradation in accuracy at chunk 2 due to over-correction. From chunk 4 onward, it begins to improve performance, yielding a 2.4% absolute CER reduction over the no-correction baseline. The gains continue to grow over time as StreamCorrect progressively mitigates accumulated errors: CER is reduced by 4.6% at chunk 8 (3.5–4.0s) and 5.3% at chunk 11 (5.0–5.5s), eventually peaking at 7.2% at chunk 14. A qualitative example illustrating this error propagation and correction process is provided in Appendix B.

4.5 Industrial Integration

We report an industrial integration of StreamCorrect into an existing Chinese banking transcription pipeline, using the top-4 hypotheses from the offline ASR for correction. The existing ASR system remains unchanged, while the error corrector is added as an independent, plug-and-play module, facilitating independent development and maintenance of the two components.

For large-scale batch transcription, the integrated ASR–corrector pipeline is deployed across multiple NVIDIA H20 GPUs using process-level data parallelism. Each worker is assigned to a GPU and maintains a complete copy of both the Whisper large-v2 backbone and the Ultravox-1B error corrector. Input calls are partitioned across workers, allowing multiple calls to be processed concurrently across GPUs. In our current deployment, workers can process multiple calls sequentially, while additional workers can be allocated to the same GPU when higher device utilization is beneficial and sufficient memory remains available.

Under FP16/BF16 inference, Whisper large-v2 (1.55B parameters) requires approximately 3.1 GB for model weights, while the Ultravox-1B SpeechLM corrector (1.92B parameters) requires approximately 3.8 GB. Thus, the two models occupy approximately 6.9 GB of model weights per replica, leaving substantial memory headroom on an NVIDIA H20 for runtime states and additional inference workers. The practical number of concurrent workers per GPU depends on runtime memory usage and workload characteristics. Across multiple GPUs, this process-level parallelism provides a straightforward way to increase batch transcription throughput without model sharding.

The correction stage is constrained to at most 8 newly generated tokens per 500ms streaming chunk. This bounds the decoding workload at each step and prevents aberrant corrections, such as repetitive or overly destructive outputs from consuming excessive computation and accumulating into subsequent chunks. By constraining the correction workload for individual streaming steps, the design is better suited to maintaining stable processing as the audio stream grows longer.

5 Conclusion

In this work, we propose StreamCorrect, a streaming ASR error correction framework that mitigates error propagation in offline-based streaming ASR without modifying or retraining the underlying backbone. By formulating correction as a modular component and introducing a self-supervised data generation strategy with Prefix-to-Reference Alignment, StreamCorrect can be integrated into existing streaming ASR systems without additional human annotation. The decoupled design also allows the corrector to be independently improved or reused across different ASR backbones, which is especially useful for industry settings where updating large recognizers is costly. Experiments across Mandarin and Cantonese benchmarks, including an industrial benchmark, demonstrate consistent CER reductions with approximately 100ms additional latency. These results show that StreamCorrect provides a practical and maintainable solution for industry-grade streaming ASR.

Limitations

A limitation of this work is that, although we evaluate StreamCorrect on Mandarin and Cantonese, both are tonal Sinitic languages with similar morphological characteristics. Its effectiveness on morphologically rich languages, highly agglutinative languages such as Turkish or Finnish, and settings involving domain-specific vocabulary has not yet been assessed. In particular, its reliability in high-stakes domains such as medical and legal applications, where specialized terminology and transcription errors may have more serious consequences, remains unexplored. Future work will explore these more diverse linguistic and domain conditions, as well as code-switching and cross-lingual streaming scenarios, to better understand the generalization of streaming error correction across languages and domains.

Ethical Considerations

Streaming ASR systems are increasingly deployed in sensitive applications, such as banking and customer services, where recognition errors or unintended model behaviors may impact privacy and security. In higher-stakes settings, such as medical or legal applications, transcription or correction errors may also lead to consequential misunderstandings or decisions. Since StreamCorrect operates on ASR hypotheses and audio inputs, its deployment should follow appropriate data governance practices, including secure data handling, access control, and careful monitoring to prevent unexpected correction behaviors on sensitive information.

For training data construction, StreamCorrect synthesizes correction data from publicly available speech corpora without requiring additional human annotation. However, models trained or adapted on domain-specific data may inherit biases from the training distribution or memorize sensitive patterns. The SpeechLM-based correction model also introduces additional computational requirements for training and inference, which may increase energy consumption and the associated environmental footprint. Therefore, future deployments should incorporate privacy-aware and computationally responsible training practices, together with comprehensive evaluation to ensure reliable and responsible use.

We emphasize that StreamCorrect is designed as an error correction component and should be integrated into responsible ASR deployment pipelines. In high-stakes applications, domain-specific validation and appropriate human oversight remain essential, and the system should not be treated as a substitute for professional judgment.

A Instruction Template for Error Corrector

We adopt instruction fine-tuning to train the error corrector. At each streaming step, the model receives the current audio chunk, the previously confirmed transcript, and the top-k ASR hypotheses for the newly generated segment. The following instruction template is used during training:

Streaming Error Correction Instruction

Given the audio and the following ASR transcription candidates, predict the correct continuation.

Previous confirmed transcript:
"{previous_transcript}"

K-best candidates for the continuation:
{candidates_str}

Based on the audio, what is the correct text that should be appended after "{previous_transcript}"?

B Analysis of Error Propagation

Table 9 illustrates the error propagation problem in offline-based streaming ASR, where early incorrect prefix selections lead to semantically incoherent hypotheses in subsequent chunks. Without an error corrector, the system becomes trapped in repetitive numeric outputs, while StreamCorrect leverages contextual correction to recover meaningful phrases. This chunk-level comparison highlights how local corrections prevent cascading errors in later decoding steps.

C Variance Analysis

To assess the stability of our latency measurements, we repeat each inference run five times on both AIShell-1 and our industrial Mandarin benchmark, and report the mean and standard deviation of FTL and LTL in Table 4. All runs are conducted on a single NVIDIA H20 GPU under controlled conditions. Specifically, each run is launched only when GPU utilization drops to 0%, with no other process sharing the GPU during inference, ensuring that the reported latencies are not affected by external workload interference.

Table 4 shows that latency measurements are highly stable across runs. Across all three systems, the standard deviation of both FTL and LTL remains below 2ms on both datasets. SimulStreaming exhibits particularly small variation, with standard deviations below 0.5ms for both metrics on both datasets, while StreamCorrect shows slightly higher variance due to the additional correction step, with standard deviations of at most 1.35ms for FTL and 0.98ms for LTL on AIShell-1. On the industrial benchmark, StreamCorrect remains similarly stable, with standard deviations below 1ms for both metrics. These small fluctuations are negligible relative to the absolute latency values, which are on the order of hundreds of milliseconds, confirming that the latency overhead reported in the main paper is stable across repeated runs rather than an artifact of measurement noise.

D Noise Robustness

To assess noise robustness, we additionally fine-tune the error corrector on self-generated data from the AIShell-1 training set, augmenting each training sample with a noise level uniformly sampled from SNRs of -5 dB, 0 dB, 5 dB, and 10 dB. We then evaluate on the AIShell-1 test set perturbed at the same set of noise levels.

Table 5 shows that StreamCorrect consistently improves over the SimulStreaming baseline across all SNR conditions, with the largest gains observed at the most challenging settings. At SNR-5, CER drops from 77.9% to 70.9%, a 7.0 absolute reduction, and at SNR0 from 54.1% to 49.4%. The relative improvement remains substantial even as the acoustic conditions become cleaner, with CER reduced from 29.7% to 24.2% at SNR10, an 18.5% relative reduction. These improvements come at a modest latency cost, with FTL increasing from 159ms to 221ms and LTL from 214ms to 296ms, indicating that StreamCorrect maintains its noise robustness without compromising the streaming nature of the system.

E SpeechLM Backbones Comparison

As shown in Table 6, we compare Ultravox-Llama-3.2-1B with a text-only Llama-3.2-1B of the same size and a larger SpeechLM, Ultravox-Llama-3.1-8B, as the error corrector backbone. Trained on identical self-generated data, the text-only LLM fails to adapt to the error correction task and over-corrects, resulting in extremely high CER and highlighting the importance of audio conditioning for stable streaming correction. The 8B SpeechLM achieves slightly lower CER (9.6% vs. 9.8%) but incurs higher latency, with LTL reaching 417ms at a 500ms chunk size. Given the marginal gain and increased latency, Ultravox-Llama-3.2-1B provides the best trade-off between accuracy and real-time

Dataset / Metric	WhisperStreaming	SimulStreaming	StreamCorrect
AIShell-1			
FTL (ms) ↓	441.13 ± 0.62	158.79 ± 0.09	220.73 ± 1.35

Qwen3-ASR (Offline)	2.8	–	–
Qwen3-ASR (u_c=1,u_t=1)	18.9	126	133
Qwen3-ASR (u_c=2,u_t=1)	6.8	161	132
SimulStreaming	16.3	158	213
StreamCorrect	9.8	219	295

Table 8: Comparison with Qwen3-ASR on AISHELL-1 test set, under different inference settings. FTL and LTL are reported in milliseconds.

efficiency for streaming error correction.

F Scalability Across Recognizers

Table 7 further demonstrates the decoupling between the error corrector and the offline recognizer. StreamCorrect improves performance across Whisper backbones, reducing CER from 28.7% to 14.9% for Whisper-small and from 19.5% to 11.5% for Whisper-large-v3, indicating strong generalization across backbones.

G Comparison with Qwen3-ASR Streaming Inference

To further evaluate StreamCorrect against recent streaming ASR systems, we compare it with Qwen3-ASR under both offline and streaming inference settings. For Qwen3-ASR streaming inference, we evaluate different configurations by varying the index of chunk when the model starts decoding (u_c) and the number of latest tokens left unconfirmed at each chunk (u_t). Results are summarized in Table 8. While Qwen3-ASR offline inference provides a strong upper bound, streaming configurations introduce additional errors under limited context. Notably, $u_c = 2$ provides more initial context by delaying decoding to 1000ms, whereas our main setting begins decoding after 500ms and is therefore more comparable to $u_c = 1, u_t = 1$ in terms of initial latency. Beyond this latency consideration, StreamCorrect targets a different deployment scenario: it allows existing domain-specific offline recognizers to operate in streaming mode without modifying or retraining the underlying ASR model, while the correction module can be developed and optimized independently. This decoupled design is particularly suitable for industrial settings where offline ASR systems are continuously improved and deployed for domain-specific applications.

Better Together: Complementary Query Rewriting Under a Strong RAG Baseline

Abstract

A popular way to improve Retrieval-Augmented Generation (RAG) is to rewrite the user's question into several variants and search with all of them. We test whether this actually helps once the underlying search is already strong. Under one fixed, competitive pipeline (BGE dense retrieval, cross-encoder reranking, and MMR diversification), we compare four query-rewriting strategies (S1–S4) against two strong LLM baselines (HyDE, Query2Doc) on three datasets (HotpotQA, AmbigNQ, and the 512K-document EnterpriseRAG-Bench) over three seeds with paired-bootstrap significance tests.

Our headline result is that **rewriting alone is at best competitive with a strong baseline, but combining methods yields outsized gains because different strategies fail on different questions.** A post-hoc union of four methods (S1+S3+S4+HyDE; seed-42 analysis) improves HIT@10 over the dense baseline by +12.5 points on enterprise-style data (51.70 vs 39.22), and a five-method union reaches 52.98 (+13.8 over baseline). Budget-matched controls (TopK-100 reranking, multi-pass HNSW) capture only $\sim$40% of this gain, confirming that complementarity, not retrieval budget, is the primary driver. On HotpotQA the union adds +1.6 to +1.8 points ($p < 0.001$), saturating the all-method oracle; on AmbigNQ the same fusion *hurts* (-2.4 below the best solo, $p < 0.001$), and we analyze when and why. Because rewriting is expensive (one LLM call each), we turn this into a cost-aware heuristic evaluated in simulation: a confidence-gated router that runs rewriting only when the baseline's own top-1 score is low. It captures about half of the enterprise full-merge gain (+4.3 HIT@10 over the baseline) while paying the rewriting cost on $<$40% of queries, and automatically declines to rewrite on AmbigNQ, sidestepping the loss that blind merging causes. A downstream answer-quality evaluation confirms that the router improves F1 by +1.92 ($p < 0.01$) at roughly 40% of the expansion cost. **In short: treat query rewriting as a complementary coverage source, applied through cost-aware routing, not as a standalone replacement for a strong baseline.**

1 Introduction

Retrieval-Augmented Generation (RAG) grounds Large Language Model (LLM) answers in documents retrieved from a corpus (Lewis et al., 2020). A widely held belief, baked into popular tooling (LangChain, 2025), is that searching with a *single* query is brittle, and that *rewriting* the query into several variants improves coverage (Li et al., 2024; Zhang et al., 2025).

We put this belief to the test, and add one missing ingredient: **a strong baseline**. Most prior comparisons rewrite on top of a weak retriever (a bare bi-encoder, no reranking), which makes almost any rewrite look good. We instead fix a competitive modern pipeline: BGE dense retrieval, a cross-encoder reranker, and Maximal Marginal Relevance (MMR) diversification. We then ask: *does rewriting still help on top of that?*

In plain terms, the answer is:

(i) **Alone, rewriting is competitive at best.** On all three datasets, multi-query rewriting strategies (S2–S4) match or modestly beat the no-LLM baseline (S1), and LLM *document*-generation methods (HyDE, Query2Doc) perform similarly. No single strategy dominates across datasets.

(ii) **Together, they win.** Methods fail on *different* questions, so merging them beats the best single method, hugely so on enterprise data: a post-hoc ensemble reaches 52.98% HIT@10 (+13.8 over the S1 baseline), within $\sim$2.8 points of the all-method oracle (55.74). Budget-matched baselines capture only $\sim$40% of this gain, confirming

EMNLP 2026 Industry Track, pages 2404–2413
October 24-29, 2026 ©2026 Association for Computational Linguistics

that complementarity, not retrieval depth, is the driver.

Contributions. (1) A controlled, statistically rigorous comparison of six methods under one fixed strong pipeline, three datasets, three seeds (Sections 3–5.1). (2) The complementarity result: rewriting helps by *combination*, not *replacement*, validated against budget-matched controls (Sections 5.2–5.3). (3) A negative result with its mechanism: why combining fails on AmbigNQ (Section 6). (4) A cost-aware, confidence-gated router that, in simulation, realizes about half of the enterprise full-merge gain (+4.3 HIT@10) at <40% of the rewriting cost and self-disables where rewriting hurts (Sections 5.4–5.5). (5) A downstream answer-quality evaluation showing that the router improves answer F1 by +1.92 ($p < 0.01$) over the baseline while preserving near-full-merge quality.

2 Related Work

RAG. RAG (Lewis et al., 2020) pairs LM knowledge with retrieval. Dense Passage Retrieval (Karpukhin et al., 2020), Fusion-in-Decoder (Izacard and Grave, 2021), and Self-RAG (Asai et al., 2023) advanced retrieval and evidence use. Systematic studies show RAG quality hinges on pipeline choices like reranking and chunking (Zhang et al., 2024), which is exactly why we hold the pipeline *fixed* and vary only the rewriting strategy.

Query rewriting. Classic relevance feedback expands queries with retrieved terms (Rocchio, 1971); neural methods generate expansions (Nogueira et al., 2019); decomposition aids multi-hop reasoning (Perez et al., 2020). Two LLM *document*-generation baselines are now standard: HyDE retrieves with a generated hypothetical answer (Gao et al., 2022), and Query2Doc concatenates the query with a generated pseudo-document (Wang et al., 2023). Recent RAG work produces diverse rewrites (Li et al., 2024), plans multi-hop logic (Zhang et al., 2025), or optimizes rewrite choice under budget (Yang et al., 2025). We differ by measuring these methods *against a strong baseline* and analyzing their *complementarity* rather than their solo accuracy. Reranking (Nogueira and Cho, 2019) and MMR (Carbonell and Goldstein, 1998) are part of our fixed pipeline.

3 Reformulation Strategies

We study six methods in three families: a **no-LLM baseline** (S1); **multi-query rewriting** (S2–S4, which generate alternative *queries*); and **document generation** (HyDE, Query2Doc, which generate a pseudo-*document*). The key practical axis is **cost**: S1 makes no LLM call, while every other method makes one LLM call per query (S2/S3 also issue several retrievals). Table 1 summarizes them, using the running query *"What are the side effects of Tylenol?"*.

S1: Parent (baseline). Search with the original query unchanged. **Cheap:** no LLM call. This is the strong reranked baseline all others are measured against.

S2: Neighbor. The LLM proposes related "sibling" questions (e.g., *"side effects of ibuprofen?"*), each retrieving documents that are merged. **Expensive**, and the highest-variance strategy; it generates the most query variations.

S3: Synonym. The LLM restates the question with different words (e.g., *"adverse reactions to acetaminophen?"*), targeting vocabulary mismatch. **Expensive**, but the one strategy a thesaurus could approximate without an LLM.

S4: Comparative. The LLM forms a comparison question (e.g., *"how do Tylenol's side effects compare to Advil's?"*). **Expensive, but cheapest of S2–S4** (one variant), and the most useful for combining.

HyDE / Query2Doc. HyDE (Gao et al., 2022) writes a hypothetical answer passage and searches with its embedding; Query2Doc (Wang et al., 2023) appends a generated pseudo-document to the query. **Expensive**, and strong solo methods.

Merging. For multi-query strategies, variants are quality-filtered (cosine to the original in $[0.4, 0.9]$), each retrieves documents, and results are merged by *score-based mixing* (keep each document's max similarity across variants, take the global top-K). The same merge forms cross-strategy *ensembles* in Section 5.3.

4 Experimental Setup

Datasets (Table 2). **HotpotQA** (Yang et al., 2018): multi-hop questions; we use the first 5,000 examples of the training split in file order (no shuffle). **AmbigNQ** (Min et al., 2020): ambiguous

Strategy	What it does	Cost	Example for "side effects of Tylenol?"
S1 Parent	Use the original query, unchanged	**Cheap (no LLM)**	*(query used as-is)*
S2 Neighbor	Ask sibling questions (related entities)	Expensive (LLM + n retr.)	"side effects of ibuprofen?"
S3 Synonym	Reword with different vocabulary	Expensive (LLM; thesaurus-able)	"adverse reactions to acetaminophen?"
S4 Comparative	Compare the subject vs. alternatives	Expensive (LLM, 1 variant)	"Tylenol vs. Advil side effects?"
HyDE	Write a fake answer passage, search with it	Expensive (LLM)	*(pseudo-passage on acetaminophen)*
Query2Doc	Add a generated pseudo-document to the query	Expensive (LLM)	*(query + pseudo-passage)*

Table 1: The six methods. Only S1 avoids an LLM call. Among rewriting strategies, S4 is cheapest (one variant); S3's intent (synonyms) is the most amenable to an LLM-free (dictionary/WordNet) implementation, though we use the LLM version for fairness.

questions with multiple interpretations; the full development set (2,002 queries). **EnterpriseRAG-Bench** (Onyx, 2024; Sun et al., 2026): ∼512K synthetic enterprise documents with 470 questions, released May 2026 under MIT license (Hugging Face: `onyx-dot-app/EnterpriseRAG-Bench`); we evaluate on the 470 answerable questions (the benchmark's 30 unanswerable questions have no relevance judgments and are excluded); it is by far the hardest corpus (∼60% of queries have no relevant document in the baseline's top-10). The benchmark uses "Redwood Inference," a simulated company, as its enterprise scenario. Both public web-QA benchmarks predate the retriever and LLM training cutoffs (HotpotQA 2018, AmbigNQ 2020), so memorization may inflate absolute scores on these datasets; our enterprise benchmark is not subject to this concern.

Dataset	Docs	Queries	Character
HotpotQA	49,708	5,000	Multi-hop
AmbigNQ	28,378	2,002	Ambiguous
EnterpriseRAG-Bench	511,958	470	Enterprise

Table 2: Evaluation datasets. HotpotQA uses the first 5,000 train examples (file order); AmbigNQ is the full dev set; Enterprise uses all 470 queries.

Fixed pipeline. Every configuration shares: `bge-base-en-v1.5` embeddings; `bge-reranker-base`; MMR (λ=0.85); sentence chunking (512/50); score-based mixing; GPT-4.1 (temp. 0.7) for all LLM generation. This is a deliberately *strong* baseline, since prior rewriting studies often omit reranking and MMR; cross-encoder reranking is known to substantially close bi-encoder quality gaps (Nogueira and Cho, 2019). Full settings: Appendix K.

Protocol. Three seeds (42, 123, 2024); we report mean±std. We use standard IR metrics and focus on Recall@10, NDCG@10, MRR@10, HIT@10. Significance vs. S1 uses a paired bootstrap (2,000 iterations, two-sided): $^{*}p<0.05$, $^{**}p<0.01$, $^{***}p<0.001$. Solo results are three-seed means; ensemble and oracle numbers are post-hoc seed-42 analyses (score-based union of each method's top-20 pool, taking top-10).

5 Results

5.1 Alone, Rewriting Is Competitive at Best

Table 3 is the centerpiece: each method's headline metrics per dataset, with significance vs. S1.

All methods are competitive. With correct multi-variation mixing, every rewriting strategy matches or modestly beats S1 on HIT@10 across all three datasets. On AmbigNQ, the multi-query methods (S2–S4) substantially outperform both the baseline and document-generation methods on NDCG@10 (+8pp) and MRR@10 (+10pp, all $p<0.001$), reflecting the value of diverse query variants for ambiguous questions with multiple interpretations. On Enterprise, S3 (Synonym) is the best solo method on HIT@10 (42.91, p=0.008 vs. S1), edging Query2Doc (41.91). On HotpotQA, S2 achieves the highest HIT@10 (97.65) while Query2Doc leads on Recall and NDCG.

But no single method dominates. The best strategy shifts across datasets: S3 on Enterprise, S2 on HotpotQA HIT@10, Query2Doc on HotpotQA Recall/NDCG. The individual gains over S1 are modest (typically 0.2–3.7pp on HIT@10), while,

Dataset	Strategy	Recall@10	NDCG@10	MRR@10	HIT@10
HotpotQA	S1 (Parent)	87.70 ±0.08	84.21 ±0.08	91.49 ±0.09	97.13 ±0.11

	HyDE	80.94 ±0.13***	60.23 ±0.03***	61.16 ±0.09**	94.91 ±0.17***
	Query2Doc	80.58 ±0.20**	60.03 ±0.10***	61.08 ±0.09**	94.69 ±0.15**
Enterprise	S1 (Parent)	34.33 ±0.39	31.99 ±0.36	34.05 ±0.39	39.22 ±0.49
	S2 (Neighbor)	35.77 ±1.11	29.81 ±1.13	30.87 ±1.04*	41.21 ±1.17
	S3 (Synonym)	**37.21** ±0.67*	30.97 ±0.73	32.18 ±0.83	**42.91** ±1.07**
	S4 (Comparative)	36.13 ±0.63	30.11 ±0.63	31.20 ±0.51*	41.63 ±0.54*
	HyDE	34.43 ±0.53	31.99 ±0.61	34.34 ±0.64	39.50 ±0.44
	Query2Doc	37.05 ±1.19*	**33.51** ±1.25	**35.32** ±1.40	41.91 ±1.29

Table 3: Main solo results (%, mean±std over 3 seeds, all 54 cells complete). Significance vs. S1 (paired bootstrap): $^{*}p<0.05$, $^{**}p<0.01$, $^{***}p<0.001$; direction is clear from the value. Significant negative deltas (strategy below S1) are marked the same way. **Bold** = best in column per dataset. S2/S3/S4 use multi-variation mixing; S1/HyDE/Query2Doc are single-variation.

as we show next, the gains from *combining* methods are far larger.

S2 (Neighbor) is competitive but high-variance. S2 generates the most query variations and achieves the highest HIT@10 on HotpotQA and the best Recall@10 on AmbigNQ, but also shows the widest confidence intervals (e.g., ±1.17 on Enterprise) and the highest runtime (Table 8). On some datasets it also has a higher catastrophic-miss rate than other strategies (Appendix Table 7). Its value is in ensemble diversity rather than solo reliability.

S4 (Comparative) is the practical rewriting strategy. It is cheapest of S2–S4 (one variant) and consistently competitive: on Enterprise it beats S1 by +2.4pp (p=0.042), on AmbigNQ it matches S3's NDCG/MRR, and on HotpotQA it stays within 0.2pp of S1 on HIT@10. It is also the most useful ensemble member relative to its cost.

Takeaway. Against a strong baseline, query rewriting alone yields modest gains. The interesting value appears only when we stop asking "which single method wins" and start asking "which methods fail on *different* questions."

5.2 Different Methods Fail on Different Questions

If methods failed on the *same* queries, combining them would be pointless. They do not. Two pieces of evidence:

Rescue rate. Among the queries S1 *misses*, other strategies recover a substantial fraction: Query2Doc rescues **14.8% on Enterprise**, S3 and S2 rescue 57.0% and 56.7% on AmbigNQ, and HyDE/Query2Doc rescue up to 62.1% on HotpotQA. A method's solo score hides this, mixing the queries it newly solves with the ones it breaks (full table: Appendix B).

Oracle-union headroom (Table 4). A perfect per-query router over all methods would gain +1.7 (HotpotQA), +2.7 (AmbigNQ), and a striking **+12.8 points (Enterprise)** over the best single method. Even pairing S1 with any single other strategy yields positive headroom. The huge Enterprise gap reflects diverse retrieval there (mean pairwise Jaccard@10 0.14–0.45 vs. 0.55–0.99 on AmbigNQ).

Dataset	Best solo HIT@10	All-method oracle	Headroom
HotpotQA	97.65 (S2)	99.37	+1.72
AmbigNQ	95.47 (S3)	98.19	+2.72
Enterprise	42.91 (S3)	55.74	+12.83

Table 4: Oracle-union HIT@10 (a perfect router) vs. the best single method (3-seed mean). Positive headroom means methods fail on disjoint queries; the enterprise headroom of +12.8 points motivates the ensemble and router analysis.

Dataset	Ensemble	HIT@10	Δ vs. best solo
HotpotQA	S1+Query2Doc	98.86	+1.22
	S1+S3+S4+HyDE	99.28	+1.64
	S1+S3+S4+HyDE+Q2D	**99.40**	+1.76
AmbigNQ	HyDE+Query2Doc	94.31	−1.14
	S1+S3+S4+HyDE	93.06	-2.39^{***}
	S1+S3+S4+HyDE+Q2D	92.96	-2.49^{***}
Enterprise	S1+Query2Doc	48.94	+5.54
	S1+HyDE+Query2Doc	50.00	+6.60
	S1+S3+S4+HyDE	**51.70**	$+8.30^{***}$
	S1+S3+S4+HyDE+Q2D	52.98	$+9.58^{***}$

Table 5: Post-hoc score-based ensembles (seed 42). "Δ vs. best solo" is relative to the overall best solo method on seed 42 (HotpotQA: S2 = 97.64; AmbigNQ: S3 = 95.45; Enterprise: Q2D = 43.40). On HotpotQA/Enterprise, combining beats the best single method and nearly reaches the oracle of Table 4. On AmbigNQ, *every* combination underperforms the best solo method. Significance: paired bootstrap vs. best solo, $^{***}p<0.001$.

5.3 Combining Realizes the Gains, Except on AmbigNQ

Oracle-union is an upper bound. Can a *real* combiner reach it? We merge strategies' top-20 lists with the same score-based mixing, then take top-10 (Table 5; all ensemble numbers are a post-hoc seed-42 analysis).

Where combining wins (HotpotQA, Enterprise). Fusion captures nearly all the oracle headroom: 99.40 on HotpotQA (oracle 99.37, effectively saturated) and 52.98 on Enterprise (oracle 55.74, **=+13.8 over the S1 baseline**). The four-way S1+S3+S4+HyDE ensemble reaches 51.70 (+12.5 over S1, +8.3 over best solo Q2D on seed 42, $p<0.001$). Crucially, adding solo-competitive-but-not-dominant strategies (S3, S4) to `S1+HyDE+Q2D` *still* lifts Enterprise from 50.00 to 51.70/52.98, the clearest proof that individual performance does not predict ensemble value.

Where combining fails (AmbigNQ). Every combination underperforms the best single method (S3, 95.45 on seed 42); the five-way ensemble sits at 92.96, a gap of −2.5pp ($p<0.001$). This is not an artifact of the merging function; reciprocal-rank fusion fails on AmbigNQ too. The cause is corpus-level: when methods retrieve near-identical lists (Jaccard@10 0.55–0.99), no combiner can produce diversity it was not given (Section 6).

Budget-matched baselines. A natural question is whether the ensemble gains simply reflect a larger retrieval budget rather than true complementarity. To test this, we run S1 with a TopK-100 reranking pool (5× the default top-20) and S1 with multi-pass HNSW (4 index seeds instead of 1), both on Enterprise with 3 seeds (Appendix Table 11). Both budget-matched baselines converge to ∼44.3 HIT@10 (+5pp over S1), capturing only 40–41% of the four-way ensemble's +12.5pp gain over S1. The remaining ∼60% reflects genuine complementarity: diverse rewriting strategies surface relevant documents that no amount of deeper indexing or reranking of a single query can find.

5.4 Cost and a Simple Deployment Rule

Rewriting is expensive: on web QA it adds 9–18× over S1 (full runtimes: Appendix Table 8); on Enterprise, runtime is dominated by the 512K-document corpus, so the LLM overhead is marginal. Running *every* strategy on *every* query is wasteful, so we let the baseline signal when it needs help.

Confidence-gated routing. S1's top-1 reranker score cleanly separates hits from misses on Enterprise (hit 0.711 ± 0.047 vs. miss 0.612 ± 0.085) and moderately on HotpotQA, but weakly on AmbigNQ. This grounds a simple rule: *"if S1's top-1 score is below a threshold τ, also run Query2Doc and merge the two result lists; otherwise return S1 alone."* It pays the rewriting cost only on the queries the baseline itself flags as uncertain. We emphasize that this is a cost-aware heuristic evaluated in simulation; production A/B testing would be needed to validate it in deployment.

5.5 Does the Router Work? A Simulation

We simulate this router across all three seeds, gating on S1's top-1 score and merging S1 with Query2Doc (via the same score-based mixing used elsewhere) only when the gate fires. We set $\tau=0.65$ as the approximate midpoint of the hit and miss score distributions reported above ($(0.711+0.612)/2 \approx 0.66$; we round down to 0.65), without optimizing it against the evaluation metric. Table 6 compares the router against the two extremes: always returning S1 (no rewriting) and always merging (rewriting on every query).

The router behaves exactly as a practitioner would want, *without per-dataset tuning*:

- **Enterprise:** it captures +4.33 of the +8.72 full-merge gain over S1 (about half) while paying the

Dataset	Always S1	Router τ=0.65	% expanded	Always merge
HotpotQA	97.13	97.65	1.2%	98.81
AmbigNQ	93.67	93.76	7.2%	93.42
Enterprise	39.22	**43.55**	39.0%	47.94

Table 6: Confidence-gated router (HIT@10 %, mean over 3 seeds; per-seed std $\leq$0.12 on web QA and $\leq$1.0 on Enterprise). "% expanded" = fraction of queries that triggered the second strategy. The router fires rarely on easy web QA and often on the hard enterprise corpus, spending compute where it pays.

rewriting cost on only 39% of queries ($\sim$2.6$\times$ fewer LLM calls than always-merging); raising τ to 0.70 reaches 45.39 (+6.17) at 51.7% expanded (Appendix Table 12).

- **AmbigNQ:** it nearly abstains (7.2% expanded) and stays at baseline (93.76 vs. S1 93.67), *automatically avoiding* the -0.25 loss that always-merging incurs on this fusion-hostile dataset.
- **HotpotQA:** it adds +0.52 over S1 at just 1.2% expansion, a near-free improvement on an already-saturated baseline.

Router threshold sensitivity. The router offers a smooth cost–accuracy tradeoff (full sweep: Appendix Table 12). On Enterprise, it monotonically gains from τ=0.55 (+2.20, 23.1% expanded) through τ=0.70 (+6.17, 51.7% expanded). At $\tau \geq 0.75$ it degenerates to always-merge. Calibration transfers across datasets (transfer gap $\leq$2.55pp) and generalizes to held-out queries (gap $\leq$0.11pp).

The router is agnostic to the helper. The gate decides *when* to expand using only S1's score, so the expansion rate (1.2 / 7.2 / 39% on HotpotQA/AmbigNQ/Enterprise) is identical for any helper; the helper only decides *what* to add. Swapping in three helpers (Appendix Table 13): Query2Doc gives the largest gain (+4.33 Enterprise), HyDE is close (+4.18), and S4, the cheapest rewriting strategy, is nearly as good on web QA and within $\sim$1.4 points on Enterprise (+2.98). All three stay at baseline on AmbigNQ. Practitioners can pick the helper by budget: Query2Doc for peak accuracy, S4 when expansion calls must be cheap.

Router failure analysis. At τ=0.65 on Enterprise, the router triggers on 39% of queries (183 of 470). Among these triggered queries: 11.3% wins (method helped), $\sim$88% ties, and $\leq$0.2% losses (method hurt). Across all 1,410 query-seed pairs (470 queries $\times$ 3 seeds), only 1 query is actively degraded (0.07%), confirming that the router's confidence gate is conservative enough to avoid damage.

Answer quality. Retrieval improvements should translate to better answers. On a 200-query Enterprise sample with a GPT-4.1 reader (Appendix Table 14), always-merge improves answer F1 over S1 by +2.46 (p=0.003) and the router by +1.92 (p=0.008). The router preserves near-full-merge answer quality ($-$0.54, ns) at roughly 40% of the expansion cost. The gain localizes to the 75 router-triggered queries (+4.79 F1, $p<0.01$); the remaining 125 queries show no change, indicating the improvement is retrieval-driven, not reader noise.

Cross-model robustness. To confirm that the complementarity finding does not depend on a single retriever or LLM, we run two additional checks, one per axis. (i) Replacing `bge-base-en-v1.5` with `E5-base-v2` on Enterprise: S1-E5 = 42.98 $\pm$ 0.43, Query2Doc-E5 = 44.26 (seed 42); the ensemble-over-solo pattern holds across retriever architectures (we report E5 without prompt prefixes as a robustness check, not a tuned comparison). (ii) Replacing GPT-4.1 with Llama-3.3-70B for query generation on AmbigNQ S3: 3-seed means 95.47 (Llama) vs 95.47 (GPT-4.1), confirming that the multi-query rewriting gains are not tied to one LLM. A smaller 384-dimensional retriever (all-MiniLM-L6-v2) gives S1 HIT@10 of 91.66 on HotpotQA and 96.00 on AmbigNQ (Appendix J).

6 Discussion

Why does combining fail on AmbigNQ? Document overlap. AmbigNQ methods retrieve mostly the same documents (Jaccard@10 0.55–0.99; the S2–S4 pairs are nearly identical at $\sim$0.99), and AmbigNQ queries have *several* relevant documents each. When near-identical lists are max-score merged, high-scoring documents that several methods *agree on but are non-relevant* crowd out the small relevant set, lowering HIT@10. Combining helps only when methods disagree productively, as in the Enterprise regime (low overlap, large headroom). This negative result is statistically significant ($p<0.001$ for the five-way ensemble vs. best solo).

Reframing query rewriting. "Does rewriting beat the baseline?" is the wrong question once the

baseline is strong. On its own, each rewriting strategy is competitive with the baseline but rarely dominant; the best solo method shifts across datasets (S3 on Enterprise HIT@10, Query2Doc on HotpotQA Recall, S2 on AmbigNQ Recall). Rewriting strategies are best seen as *complementary coverage generators*: their value is not in solo accuracy but in the partially disjoint queries they solve. S4, modest alone, is a cheap and useful ensemble member. S2 is competitive but high-variance; its runtime cost is the highest.

Knowledge leakage and the enterprise regime. A concurrent concern in the literature is that LLM-based expansion may derive gains partly from pretraining memorization: when generated documents are not entailed by gold evidence, HyDE and Query2Doc fall *below* their retrieval baselines on fact-verification benchmarks (Yoon et al., 2025). Our web-QA datasets (HotpotQA, AmbigNQ) have been public since 2018–2020 and plausibly appear in GPT-4.1's pretraining corpus, so leakage is a confound we cannot fully rule out there. EnterpriseRAG-Bench contains synthetic enterprise documents released May 2026, post-dating the training cutoffs of all retrievers (`bge-base-en-v1.5`, Sep. 2023; `E5-base-v2`, 2023) and rerankers used, as well as the query-generation model (GPT-4.1, knowledge cutoff mid-2024); the complementarity gains observed there cannot be explained by memorization and are also the largest.

Practical guidance. (i) Start from a reranked, MMR-diversified S1 baseline. (ii) Add Query2Doc as the default paid upgrade. (iii) Combine methods on *diverse-retrieval* corpora (low overlap, e.g. enterprise); avoid combining on high-overlap, multi-relevant corpora. (iv) Gate rewriting with a reranker-score threshold to control cost. (v) Prefer S4 over S2/S3 when adding a cheap rewriting member.

7 Conclusion

Under a strong, fixed RAG pipeline, query rewriting is competitive with the baseline in isolation but yields only modest individual gains. Its real value emerges through *combination*: methods fail on disjoint queries, and post-hoc ensembles (seed-42 analysis) beat the best single strategy by +8.3 to +9.6 points HIT@10 on enterprise retrieval (four-way 51.70, five-way 52.98 vs. best solo Q2D 43.40, $p<0.001$) and up to +13.8 over the dense baseline (52.98 vs. S1 39.22). Budget-matched controls confirm that complementarity, not retrieval depth, drives $\sim$60% of this gain. Conversely, combining can *hurt* when methods retrieve overlapping documents (AmbigNQ, -2.4pp, $p<0.001$). A simple confidence-gated router realizes about half of the enterprise full-merge benefit in practice: it captures +4.3 HIT@10 at under 40% of the rewriting cost, improves downstream answer F1 by +1.92 ($p<0.01$), while self-disabling on AmbigNQ where rewriting hurts. The takeaway: treat query rewriting as a complementary coverage source, applied through cost-aware routing, not as a standalone replacement for a strong baseline.

Limitations

Our ensembles are post-hoc analyses over independently run strategies rather than a jointly executed system, and the router is a cost-aware heuristic evaluated in simulation; production validation (A/B testing, latency and cost under load) is required before deployment. The answer-quality study uses a single reader model (GPT-4.1) and 200 queries from one benchmark, and SQuAD-style F1 only partially captures long-form answer quality. Enterprise results use one synthetic benchmark; generalization to other enterprise corpora is untested. Multi-variation strategies incur real latency and cost (S2 highest); we report runtimes in Table 8. The confidence-gated router is evaluated post-hoc over all three seeds with a single fixed threshold; a learned gate and a live deployment study are promising next steps we expect to further improve the cost–accuracy trade-off.

A Code and Data

Our code and experiment configurations are available at: `https://github.com/ServiceNow/enhanced-rag-pipeline`.

B Failure Modes and Rescue Rates

Table 7 reports the catastrophic-miss rate (HIT@10= 0) and the *rescue rate*: among queries S1 misses, the fraction each method retrieves. Even strategies with modest solo gains (e.g. S4) rescue a substantial fraction of S1's failures, which is the basis of the complementarity argument in Section 5.2. Multi-variation mixing substantially increases rescue rates for S2/S3/S4.

Method	Miss% (HIT@10=0)	Rescues S1's misses (% of S1 misses)
HotpotQA (S1 misses n=138)		
HyDE	2.81	62.1%
Query2Doc	2.69	61.1%
S2	2.35	44.2%
S3	2.60	38.4%
S4	2.67	36.2%
AmbigNQ (S1 misses n=127)		
S3	4.53	57.0%
S2	4.56	56.7%
S4	4.66	54.9%
HyDE	5.09	30.4%
Query2Doc	5.31	27.3%
Enterprise (S1 misses n=283)		
Query2Doc	58.09	14.8%
HyDE	60.50	14.5%
S3	57.09	13.2%
S4	58.37	10.1%
S2	58.79	10.1%

Table 7: Catastrophic-miss and rescue rates (Miss%: 3-seed means; S1-miss sets and counts from seed 42; rescue rates averaged over the 3 seeds on that fixed miss set). Strategies are sorted by rescue rate per dataset. S2/S3/S4 use multi-variation mixing.

C Runtime

Strategy	HotpotQA	AmbigNQ	Enterprise
S1	808	182	25,492
S2	8,275	2,700	22,061
S3	9,366	2,797	22,458
S4	8,246	2,490	21,845
HyDE	7,339	3,180	26,406
Query2Doc	7,636	3,120	26,496

Table 8: Mean runtime (s/run) over 3 seeds. S1 (no LLM) is far cheapest on web QA; on Enterprise, corpus size dominates and LLM overhead is marginal. S2/S3/S4 runtimes reflect multi-variation mixing.

D Full Metrics

Dataset	Strategy	MAP@10	P@10	HIT@1
HotpotQA	S1	78.71	17.54	86.97
	S2	73.18	17.27	82.79
	S3	72.99	17.23	82.43
	S4	73.25	17.25	82.74
	HyDE	79.66	17.79	87.14
	Query2Doc	80.23	17.95	87.11
AmbigNQ	S1	47.50	15.78	45.39
	S2	57.05	16.23	58.28
	S3	57.02	16.21	58.29
	S4	56.95	16.21	58.18
	HyDE	48.30	16.13	45.62
	Query2Doc	48.12	16.03	45.62

	S3	27.51	5.27	27.23
	S4	26.79	5.10	26.24
	HyDE	29.72	4.99	31.06
	Query2Doc	30.90	5.39	31.49

Table 9: Additional retrieval metrics (%, 3-seed means). S2/S3/S4 use multi-variation mixing.

E Coverage

Strategy	Ent.	Amb.	Hot.	Note
S1	3	3	3	
S2	3*	3*	3*	
S3	3*	3*	3*	
S4	3*	3*	3*	
HyDE	3	3	3	
Query2Doc	3	3	3	
S1+TopK-100	3	–	–	budget
S1+multi-pass	3	–	–	budget
S1 (E5)	3	–	–	retr.
Q2D (E5)	1	–	–	s42
S1 (MiniLM)	–	1	1	retr., 1 seed
S3 (Llama)	–	3	–	LLM

Table 10: Experiment coverage: seeds completed (of 42, 123, 2024). * = multi-variation mixing; S1/HyDE/Q2D are single-variation. All 54 main cells complete. Note: budget = budget-matched; retr. = retriever robustness; LLM = LLM robustness.

F Budget-Matched Baselines

Method	HIT@10	Δ vs S1	Share of gain
S1 (baseline)	$39.22_{\pm 0.49}$	—	—
S1+TopK-100	$44.33_{\pm 0.12}$	+5.11	41%
S1+multi-pass	$44.19_{\pm 0.49}$	+4.97	40%
Best solo (S3)	$42.91_{\pm 1.07}$	+3.69	30%
4-way ensemble†	51.70	$+12.48^{***}$	100%
5-way ensemble†	52.98	$+13.76^{***}$	—

Table 11: Budget-matched baselines vs. ensembles (Enterprise, HIT@10). †Post-hoc seed-42 analysis; solo rows are 3-seed means. Ensemble Δ is computed against the 3-seed S1 mean (39.22); against the seed-42 S1 (39.79) the 4-way/5-way gains are +11.9/+13.2. The budget-matched methods capture ∼40% of the 4-way ensemble gain ("Share of gain" = share of the 4-way ensemble's gain over S1), confirming that complementarity, not retrieval depth, is the primary driver.

G Router Threshold Sensitivity

τ	HIT@10	Δ vs S1	Exp%
Enterprise (S1 = 39.22, always-merge = 47.94)			
0.55	41.42	+2.20	23.1
0.60	42.62	+3.40	31.4
0.65	43.55	+4.33	39.0
0.70	45.39	+6.17	51.7
HotpotQA (S1 = 97.13, always-merge = 98.81)			
0.55	97.47	+0.35	0.6
0.60	97.56	+0.43	0.8
0.65	97.65	+0.52	1.2
0.70	97.85	+0.73	2.2
AmbigNQ (S1 = 93.67, always-merge = 93.42)			
0.55	93.76	+0.08	1.6
0.60	93.77	+0.10	3.8
0.65	93.76	+0.08	7.2
0.70	93.81	+0.13	15.9

Table 12: Router τ sensitivity (HIT@10 %, 3-seed means; helper = Query2Doc). "Exp" = % of queries expanded; at $\tau \geq 0.75$ the router degenerates to always-merge (100% expansion, omitted). Calibration transfers across datasets (worst gap 2.55pp) and generalizes to held-out queries (gap $\leq$+0.11pp).

H Router Helper Comparison

Helper	Hot.	Amb.	Ent.
Query2Doc	+0.52	+0.08	**+4.33**
HyDE	+0.51	+0.12	+4.18
S4 (cheapest)	+0.43	+0.03	+2.98
% expanded	*1.2*	*7.2*	*39.0*

Table 13: Router gain (HIT@10 Δ over always-S1, τ=0.65, mean over 3 seeds) for three choices of helper (Hot./Amb./Ent. = HotpotQA/AmbigNQ/Enterprise). The expansion rate is set by the gate alone and is identical across helpers; the helper only changes the size of the gain.

I Answer Quality

Retrieval config	EM	F1	ΔF1 [CI95]
S1	0.0	28.22	—
Always-merge	0.0	30.68	$+2.46$ [+0.89,+4.10]**
Router (τ=0.65)	0.0	30.14	$+1.92$ [+0.44,+3.41]**

Table 14: Downstream answer quality (200-query Enterprise sample, GPT-4.1 reader, seed 42). Always-merge = S1+Query2Doc merged retrieval; ΔF1 is vs. S1. EM ≈ 0 throughout (long-form gold answers); F1 is the informative metric. Router vs. always-merge: -0.54 [-1.68,+0.59], ns. The F1 gain concentrates on router-triggered queries (+4.79, $p<0.01$, 75 queries); non-triggered queries show no change (+0.20, ns).

J Smaller-Retriever Check (MiniLM)

As a further retriever-robustness check, we ran S1 with a smaller, older embedding model (`all-MiniLM-L6-v2`, 384-d) on the two web-QA datasets: HIT@10 = 91.66 on HotpotQA and 96.00 on AmbigNQ (vs. `bge-base-en-v1.5`'s 97.13 ± 0.11 and 93.67 ± 0.03). MiniLM trails BGE substantially on multi-hop HotpotQA but slightly exceeds it on AmbigNQ: the pipeline's strength is not BGE-specific. These are single-seed runs on an earlier (February) corpus build — indicative, not directly comparable.

K Experiment Configuration

All runs used: `bge-base-en-v1.5` embeddings; `bge-reranker-base`; MMR λ=0.85; sentence chunking (512/50); score-based mixing (max 20 merged documents), per-strategy retrieval depth (K=10/7/5/8 for S1/S2/S3/S4), variant quality filtering (cosine $\in [0.4, 0.9]$), and GPT-4.1 (temp. 0.7) for all LLM generation; seeds 42, 123, 2024.

Script Gap: Evaluating LLM Triage on Indian Languages in Native vs Romanized Scripts in a Real-World Setting

Abstract

Large Language Models (LLMs) are increasingly deployed in high-stakes clinical applications in India. Speakers of Indian languages frequently communicate using romanized text rather than native scripts, yet existing research rarely quantifies or evaluates this orthographic variation in real-world applications. We investigate how romanization impacts the reliability of LLMs in a critical domain: maternal and newborn healthcare triage. We benchmark leading LLMs on a real-world dataset of user-generated health queries spanning five Indian languages and Nepali. Our results reveal consistent degradation in performance for romanized messages, with gap reaching up to 24 points across languages and models. We propose and evaluate an Uncertainty-based Selective Routing method to narrow this script gap. Our findings highlight a critical safety blind spot in deploying LLMs for health systems: models that appear to understand romanized input may still fail to act on it reliably.

1 Introduction and Related Work

Access to timely and reliable healthcare in many communities in the global south is severely constrained (Mehta et al., 2024). Shortages of medical professionals, overburdened primary-care systems, and linguistic diversity limit patients' ability to obtain high-quality guidance. Large language models (LLMs) offer a promising path to expand scalable, multilingual health communication where traditional services are stretched thin. LLMs are already being explored for patient-facing applications, such as message triage, portal-message prioritization, and safety-oriented medical question answering (Liu et al., 2025; Masanneck et al., 2024; Borkowski et al., 2023; Singhal et al., 2025; Kaur et al., 2025). These systems aim to flag emergencies in patient portal messages, route complex queries to clinicians, and generate draft replies that reduce message burden for care teams (Ren et al., 2024; Chen et al., 2025).

However, existing LLMs still exhibit limitations that directly affect their suitability for clinical use. They can perform inconsistently across languages, hallucinate medical facts, and exhibit unstable reasoning under minor input perturbations. These issues are exacerbated for low-resource languages and informal, patient-generated text, where variation in spelling, phrasing, and code-mixing can substantially degrade model reliability.

A growing body of healthcare-focused LLM benchmarks aims to assess these risks, but they fall short in several ways. Many are sourced from clinical literature, or expert-curated exams, and feature synthetic question answering, rather than real patient-provider conversations (Jin et al., 2021; Pal et al., 2022; Jin et al., 2019; Arora et al., 2025). Only a small number of datasets feature real conversations but are limited to English and Chinese (Manes et al., 2024; He et al., 2020), and virtually none assess triage, arguably the task most relevant for early patient engagement. As a result, current benchmarks fail to capture the linguistic and situational diversity encountered in frontline care. It is therefore not surprising that a growing body of work shows LLMs can produce clinically unsafe or inconsistent advice, even when overall accuracy on QA benchmarks is high (Diekmann et al., 2025; Draelos et al., 2025; Bedi et al., 2025).

Furthermore, beyond the healthcare setting, handling informal, mixed-script communication at scale remains a challenge for multilingual LLMs. For Indian languages in particular, romanized input is pervasive in online communications, yet existing multilingual benchmarks minimally cover them (Verma et al., 2025; Kumar et al., 2022; Singh et al., 2024). Script representation is often studied in highly curated and parallel transliterated corpora, but not on noisy patient messages (Husain

*This work was conducted while at Noora Health.

EMNLP 2026 Industry Track, pages 2414–2429
October 24-29, 2026 ©2026 Association for Computational Linguistics

et al., 2024; Wang et al., 2024). Critically, no existing benchmark quantifies how prevalent romanized text actually is relative to native script in real-world user interactions beyond social media usage. This is a critical gap: without empirical evidence on the proportion of romanized versus native-script usage in real-world LLM applications at population scale, the field lacks the basis to assess how much of the user population is underserved by native-script-focused models. Our real-world corpus provides this evidence for the first time in a healthcare setting: in Hindi and Telugu, the two largest language groups in our dataset, romanized messages account for up to 82% and 73% of inputs, respectively, demonstrating that users predominantly communicate in the very script that most benchmarks overlook.

In this paper, we provide the first benchmarking evaluation of real-world LLM triage performance on Indian languages across both native and romanized scripts. We make four major contributions: (1) We construct a multilingual, multi-script healthcare triage dataset based on authentic patient-provider conversations. (2) We benchmark several leading LLMs on this dataset, revealing for the first time substantial script-dependent disparities. (3) We conduct exhaustive error analyses to uncover where and why models disproportionately fail on romanized inputs. We point out that romanized inputs lead to brittle output, even when models seem to generate rationales that capture the user's intent. (4) We propose an uncertainty-based selective routing method to close this script gap, and demonstrate its performance across various languages and models.

We partner with Noora Health, a nonprofit in India whose programs have reached over 41 million caregivers and patients across nine Indian states since 2014 (Health, 2025). This study builds on real-world patient-provider message data collected as part of Noora Health's pilot studies for evaluating LLM safety, in which triage remains a critical step in early engagement. More broadly, our work is also applicable to the many other healthcare platforms currently exploring LLM-powered solutions toward real-world deployment. We provide a concrete framework for evaluating triage performance and insight into the safety-critical script gap in frontier models for real-world deployment.

Table 1: Language distribution by script types. English serves as baseline. ■ Native ■ Romanized.

Language	Native	Roman.	Total	% Nat. / % Rom.
English	–	–	321	–
Hindi	158	702	860	
Telugu	140	383	523	
Kannada	253	210	463	
Marathi	253	165	418	
Punjabi	129	227	356	
Nepali	125	87	212	
Total	1,058	1,774	3,153	

2 Dataset and Task

Clinical Setting and Corpus: We study a de-identified corpus of short WhatsApp messages related to maternal and newborn care provided by Noora Health. Users, typically mothers, pregnant women, or caregivers, use a WhatsApp chat interface to submit free-text queries about pregnancy and newborn issues. For this work, we use only de-identified data, yielding a corpus of over 133k conversations spanning English, five Indian languages: Hindi, Telugu, Kannada, Marathi, and Punjabi, and Nepali. From this corpus, we draw a stratified random sample of 3,153 first-turn user messages for experiments, ensuring coverage across languages and message lengths. General statistics of the dataset are described in Table 1 and distribution by message length is in Appendix A.

Triage Labels and Definition: The triage task uses three mutually exclusive labels: *Emergency*, *Non-emergency* and *Insufficient Information*. Label distribution by script types is shown in Figure 1, and the detailed definition is in Appendix B. All messages were annotated by humans and cross-validated by independently labeling a stratified sample of 200 messages, yielding an overall agreement rate of 87.5% and a Cohen's κ of 0.74. Annotation process and details by language are in Appendix C.

Validation Dataset In addition to our real-world corpus, we also construct a parallel evaluation set from HealthBench's emergency referrals theme (Arora et al., 2025), where physicians categorized 453 prompts into three triage classes: Emergent, Conditional Emergent, and Non-Emergent defined in Appendix S. We translate them into native script and romanized variants for all six languages using GPT-4o. This holds clin-

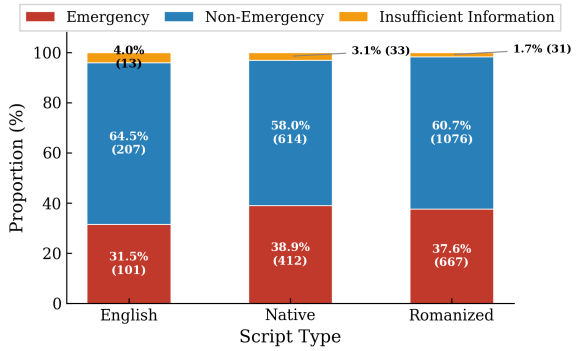

Figure 1: Distribution of human annotated labels across script types.

ical content constant across scripts, removing confounds such as content, and typing noise, and isolating the effect of script.

3 Experimental Setup

Task: The task is triage classification: given a user message, the system must assign one of three triage labels. All models operate on user messages without any normalization and are evaluated using a single fixed prompt template with temperature = 0 to ensure parity across models. In addition to the triage label, models are instructed to produce a brief reasoning behind the predicted label.

Models: We evaluate models known for their multilingual capabilities, organizing them into three buckets: frontier closed models include GPT-4o, Claude Sonnet 4.5 (ClaudeS4.5), large open-weight models include DeepSeek V3, LLaMA - 4 Maverick 17B (LLaMA-4), and Qwen3-Next-80B-A3B-Instruct (Qwen3-80B), and a small-plus-Indic-specialized bucket include Mixtral8×7B, Qwen2.5-7B and Sarvam-M 24B.

Prompt Template: We select the final fixed prompt by conducting a minimal prompt-design sweep on a held-out subset of 500 randomly sampled messages on real-world dataset, comparing four strategies detailed in (Appendix N).

4 Benchmark Results

Overall Benchmark: Figure 2 reports emergency recall and w-F1 by model and script. The top tier models, ClaudeS4.5, GPT-4o, Qwen3-80B, DeepSeek-V3, and LLaMA-4, reach aggregate w-F1 in the high 70s to low 80s. Qwen2.5-7B, Sarvam-M and Mixtral-8×7B lags 10–15 points behind the top models. Performance on romanized input is weakest across every model, while native-script w-F1 tracks or slightly exceeds English, but romanized drops 1–8 points below native for the top tier. Even the Indian languages tuned model, Sarvam, performs poorly and exhibits a substantial script gap.

Benchmark by Languages: Figure 2 heatmap, the script gap is largest for Nepali upto 24 points, and pronounced for Kannada and Telugu. Hindi and Punjabi are comparatively robust, though the native-vs-romanized script gap persists even there.

Validation on HealthBench: On our controlled HealthBench set, where content is identical across scripts, the same pattern holds across models and languages (Appendix F), confirming the gap is orthographic rather than a content, writing-style, or typing-noise artifact.

Emergency Recall: Emergency recall varies widely across models, and the script gap diverges in direction on emergency cases. Claude-S4.5's recall falls from 67.6% (native) to 63.7% (romanized), whereas GPT-4o's rises from 60.6% to 64.3%. Because models differ in what they flag as an emergency, model choice alone can affect which patients are considered for urgent care, causing a direct safety implication for deployment.

5 Error Analysis

Confusion Matrix Analysis: Table 2 reports all confusion rates by script type, averaged over the four top-performing models from Section 4. The largest script gap appears for *Non-Emergency* cases mislabeled as *Insufficient Information* at 12.8% on native script versus 25.2% on romanized, and *Emergency* cases follow a similar pattern. Overall, romanization systematically pushes models toward over-predicting *Insufficient Information* at the expense of both *Emergency* and *Non-Emergency* accuracy.

Qualitative Error Analysis: Figure 3 shows representative examples for a frequent Non-Emergency query type in English, native script, and romanized script: general guidance in pregnancy. English and native script variants are reliably classified as Non-emergency. In contrast, romanized variants tend to fall into *Insufficient Information* as discussed in the confusion matrix, even though the post hoc reasoning mentions these queries as 'general inquiry'.

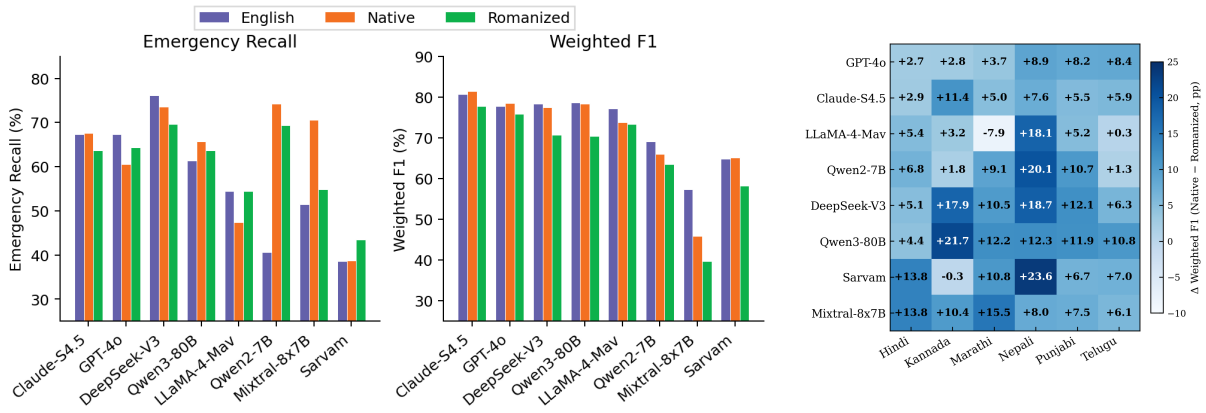

Figure 2: **Real-World Data:**(Left) Emergency Recall and w-F1 scores across models for English, Native, and Romanized scripts. (Right) Performance gap (Native − Romanized) in w-F1 (pp) across languages and models.

Scenario: General pregnancy guidance

English | GPT-4o
8month pregnancy tips

Model reasoning: The message [...] **general request** for pregnancy tips at 8 months [...].

Marathi (Native) | GPT-4o
8 व्या महिन्यात काय काळजी घ्यावी?
(What care should be taken in the 8th month?)

Model reasoning: The message is asking for **general advice** on care during the eighth month of pregnancy [...].

Hindi (Romanized) | GPT-4o
8 month kya kuch krna chaiye ky ni krna chaiye (In the 8th month, what should or should not be done)

Model reasoning: The message is too vague [...]. It appears to be a **general inquiry** about what to do or avoid at 8 months [...].

Figure 3: Examples of similar user messages across English, native script, and romanized script, in which post hoc reasoning infers the meaning and marks as general inquiry, yet romanized is predicted as *Insufficient Information*.

Table 2: Confusion rates (%) by script type, averaged over four top-performing models. En=English, N=Native, R=Romanized, E=Emergency, NE=Non-Emergency, II=Insufficient Information.

True → Pred.	En	N	R	Δ (N–R)
E → E	68.1	66.8	65.4	+1.4
E → NE	16.1	21.2	15.3	+5.9
E → II	15.8	11.9	19.4	−7.5
NE → NE	77.3	83.4	67.4	+16.0
NE → E	2.5	3.8	7.4	−3.6
NE → II	20.2	12.8	25.2	−12.4
II → II	69.2	50.8	52.4	−1.6
II → E	11.5	28.8	25.0	+3.8
II → NE	19.2	20.5	22.6	−2.1

6 Diagnosing the Script Gap

In this section, we diagnose the script gap through four research questions.

RQ1: Is script gap primarily driven by differences in underlying clinical content? We conduct two script-normalization experiments: (1) translate both native script and romanized messages into English, and (2) translate romanized messages back into their corresponding native scripts using GPT-4o. We then re-evaluate triage classification on these normalized subsets using GPT-4o and Qwen3-80B, with a configuration similar to the benchmark evaluation.

Answer: *Table 3 shows that for GPT-4o and Qwen3-80B, native script normalized → English w-F1 drops 0.6 points and 3.1 points, respectively. In contrast, romanized-script inputs narrow the gap relative to the native baseline when normalized. This reinforces the view that the gap stems from orthographic effects rather than from clinically different cases.*

RQ2: Does romanized script reduce prediction robustness in LLMs? We define *prediction robustness* in terms of predicted label invariance across a temperature sweep keeping prompt fixed. Formal definition is detailed in Appendix Q. In the experiment, for the Real-World dataset, we col-

Table 3: Effect of script normalization on w-F1 (%) for GPT-4o and Qwen3-80B.

Input	Setting	GPT4o	Qwen3
Native	baseline (native)	78.5	78.2
Romanized	baseline (roman)	75.9	70.5
Native	→ English	77.9	75.1
Romanized	→ English	78.9	77.1
Romanized	→ native script	80.1	78.0

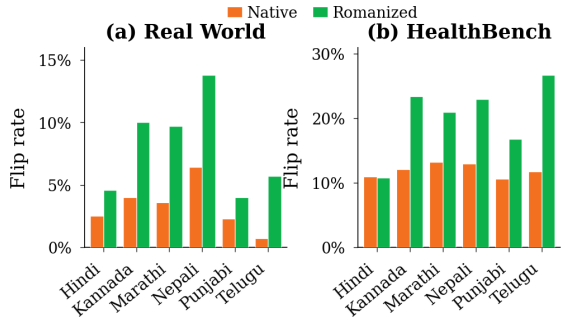

Figure 4: Flip rate by language and script type for Qwen 3-32B across temperature sweeps (t=0, 0.2, 0.4, 0.8, 1)

lapse the label space to two classes by dropping Insufficient Information (2.4% of the dataset), as most models default to this label under uncertainty, preventing meaningful triage flips.

Answer: *In Figure 4, across both HealthBench and Real-World datasets, romanized inputs exhibit higher flip rates than native script inputs across languages, indicating that even minor orthographic variation in romanized text can lead to different model outcomes despite unchanged semantic content, potentially compromising safety.*

RQ3: Does the gap arise from comprehension or classification? We separate romanized triage errors into two types: *comprehension failures*, where the model fails to adequately understand the input, and *triage classification failures*, where the model appears to understand the input but assigns an incorrect triage label. We operationalize this distinction by extracting English chain of thought reasoning trace generated by Qwen3-32B during triage with configuration T = 0.6, p = 0.95, and k = 20. We employ GPT-5.1 as an LLM-as-a-Judge with Cohen's Kappa detailed in Appendix H, employing a prompt in Appendix I to classify reasoning trace for comprehension.

Table 4: Decomposition of romanized triage errors into triage classification failures (Triage) and comprehension failures (Comp.), in percentage values.

	HealthBench			Real World		
Language	N_{err}	Triage	Comp.	N_{err}	Triage	Comp.
Hindi	122	**91.8**	8.2	234	**72.6**	27.4
Punjabi	128	**82.0**	18.0	73	46.6	53.4
Marathi	167	**66.5**	33.5	62	38.7	61.3
Nepali	156	**61.5**	38.5	32	34.4	65.6
Kannada	177	30.5	**69.5**	103	19.4	**80.6**
Telugu	191	30.9	**69.1**	153	26.1	**73.9**

Answer: *In Table 4, failure mode of romanized performance gap varies systematically with language resource level. For higher resource languages such as Hindi and Punjabi, romanized inputs are largely comprehended by model but misclassified, indicating a triage classification failure. For lower resource languages such as Kannada and Telugu, romanization causes comprehension failures predominantly, where models cannot even parse the clinical content.*

RQ4: Does romanization add a triage error penalty even when models can comprehend input adequately? To isolate the triage component, we conduct a pairwise analysis on the HealthBench parallel corpus, excluding hard examples as designated by HealthBench. For each language, we retain only prompt pairs where both the native and romanized variants are judged as adequately comprehended by the LLM judge on reasoning trace. On these comprehension-controlled pairs, native w-F1 (74.8%) performance converges to English dominating HealthBench w-F1 (74.7%), indicating that the multilingual penalty narrows once comprehension is accounted for. However, romanized w-F1 is 70.9%, leaving a residual gap that is attributable to triage failure despite comprehension. This effect is most pronounced for Kannada and Marathi, and moderate for Nepali, and Hindi (Appendix M for analysis and Appendix O for qualitative example).

Answer: *On prompt pairs, the model understood equally well in both scripts; native performance matches the English-dominated subset of HealthBench, but romanized lags 3.8 points behind. Thus, romanized script introduces an additional triage penalty.*

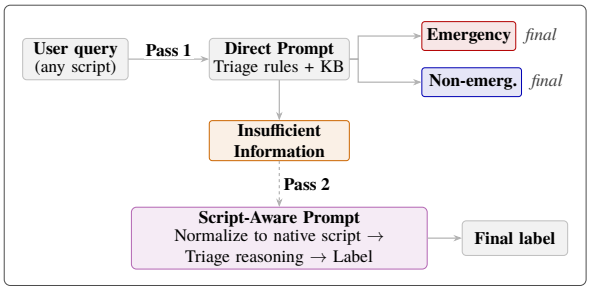

Figure 5: Uncertainty-based selective routing (USR) strategy workflow.

7 Mitigation Strategy

Insufficient Information as a Verbalized Uncertainty Signal. This framing is supported by two observations. First, models systematically retreat to Insufficient Information under script gap as shown in Table 2. Second, models' precision on Insufficient Information predictions is significantly lower than on Emergency or Non-Emergency predictions for both scripts on real-world dataset as detailed in Appendix P. In other words, when the model predicts Insufficient Information, the prediction more often reflects the model's underlying uncertainty than a true Insufficient Information case. Motivated by this, we design a routing strategy that treats Insufficient Information as the model's verbalized uncertainty signal. We prefer this uncertainty signal over entropy, which is often unavailable in closed models, and over ensemble voting, which is expensive for real-world deployment.

Method. We propose a two-pass strategy, as shown in Figure 5. In the first pass, the model classifies all queries with fixed prompt. Emergency and Non-Emergency predictions are accepted as is, as models have high precision on these two labels. Insufficient-Information predictions are routed to a second pass using script-aware prompting (SAP). Within a single inference call, queries in native and romanized scripts are first normalized into denoised native script, followed by chain-of-thought reasoning to obtain the final triage label. This design is deployment-friendly as routing only Insufficient-Information labeled queries, we save tokens on the normalization step, as shown in Appendix K.

Results. Table 5 shows that USR strategy effectively narrows the script gap on both w-F1 and emergency recall, across both GPT-4o and Qwen3-80B.

Table 5: **M**: model (**G** = GPT-4o, **Q** = Qwen3-80B). **DP Base**: direct triage with the fixed prompt. **SAP**: script-aware triage prompt, applied to all queries. **USR**: uncertainity-based selective routing. Red marks emergency recall degradation.

		Native		Romanized	
M	**Strategy**	w-F1	E Rec	w-F1	E Rec
G	DP (Base)	78.5	60.6	75.9	64.3
	SAP	77.7	53.9	77.7	51.7
	USR+SAP	**81.3**	**64.7**	**82.5**	**69.3**
Q	DP(Base)	78.2	65.4	70.5	63.9
	SAP	80.3	66.9	77.1	65.3
	USR+SAP	**80.7**	**68.7**	**76.4**	**71.5**

Ablation and Insights. Our ablation indicates that when SAP alone is applied to all queries, it degrades GPT-4o's emergency recall, while Qwen3-80B appears more resilient in aggregate, but per-language analysis reveals that normalization still harms Punjabi and Kannada as detailed out in Appendix L. Selective routing based on uncertainty appears to be the best strategy for narrowing the script gap while also improving emergency recall in both models, without degrading any individual language. This suggests that emergencies can be best detected via direct prompt on un-normalized text rather than through normalization. This makes a strong case that LLMs need to develop intrinsic robustness to script variation in safety-critical applications rather than relying on external normalization pipelines.

8 Discussion

Our most critical finding is not simply that romanized inputs degrade performance, but that this degradation makes model predictions brittle and adds an additional triage penalty over native script. These findings have driven several changes to the production design at Noora Health: (1) multilingual and romanized queries are translated to English before triage, since we show normalization recovers much of the script gap; (2) medical experts are more involved in expanding knowledge base to ground emergency cases as emergency recall varies considerably by model choice; (3) since we show triage outputs are brittle, medical experts are given interface features to override LLM triage classifications and provide feedback.

Limitations

One key limitation of our work is language coverage; while it is broader than prior works studying romanized scripts, it spans five Indian languages and Nepali. Several widely spoken Indian languages such as Bengali, Tamil, and Gujarati that are commonly romanized are absent, as are languages outside of South Asia where romanization is prevalent, and extending the analysis to these languages remains important future work. Second, we demonstrate the script gap in a clinical triage setting on chat-based support; while this represents a critical safety failure given the increased use of such tools in underserved areas, it remains an open question whether similar degradation patterns hold across other domains and for different tasks.

Ethical Considerations

All data used in this study are de-identified and collected as part of Noora Health's pilot studies for evaluating LLM safety. All safety evaluations are conducted on historical data. We emphasize that the triage outputs studied here are intended as routing support with medical experts in a loop. We do not claim that LLMs should replace medical experts; rather, our work evaluates their reliability and highlights that romanization of user inputs makes model outputs brittle. The script gap we identify underscores the risk of prematurely deploying LLM-based tools in safety-critical settings without rigorous evaluation across the scripts and languages that users actually employ.

Acknowledgments

We sincerely thank Noora Health, its medical support executives, and Anubhav, Sreeram, and Shobhit for their contribution during the project. We also thank Karandeep S. Bhatti for their feedback on clinical triage rules. This work was supported in part by a Google Academic Research Award and an Amazon Research Award.

A Dataset Distribution by Message Length

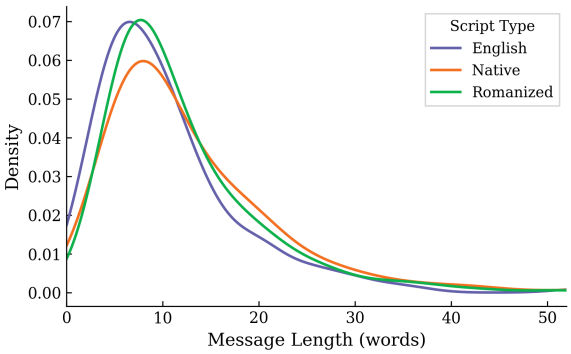

Figure 6: Kernel density estimates of message length in words across script types.

B Triage Annotation Definition

Emergency. The message indicates, or could plausibly indicate, a symptom that may require immediate medical attention or urgent care. If the message overlaps with any symptom in the emergency knowledge base, or can reasonably be mapped to one (even if severity details are missing), it is labeled *Emergency*. When in doubt between *Emergency* and *Insufficient Information*, annotators are instructed to prefer *Emergency*.

Non-Emergency. The message describes a symptom or concern that clearly does *not* require urgent attention. Typical examples include general diet questions, breastfeeding without red-flag symptoms, introducing foods, mild constipation or gas, administrative queries, and sleep/teething/routine issues with no overlap with emergency symptoms. These are labeled *Non-Emergency*.

Insufficient Information. The message lacks enough detail to determine whether the situation is an emergency. This includes vague, incomplete, or poorly written messages that may hint at concerning symptoms but do not clearly confirm them. If a symptom clearly matches the emergency list, the label should be *Emergency*; if it could be an emergency but key details are missing to know for sure, the label is *Insufficient Information*.

C Human annotation of real world dataset triage label

Annotation guidelines and standard operating procedures were developed in consultation with medical experts specializing in maternal and newborn care. These experts provided a comprehensive list of emergency symptoms and classification criteria that formed the basis of the triage label and were also used as knowledge base for triage prompt. These SOPs were provided to annotators and annotation difficulty is tested by labeling stratified sample of 200 messages independently, balanced across all six languages and both script types. Agreement and Cohen's κ among annotators by language and script.

Language	Script	N	Agree.(%)	κ
Hindi	Native	17	100.0	1.000
	Roman	17	88.2	0.744
Kannada	Native	17	82.4	0.611
	Roman	17	100.0	1.000
Marathi	Native	17	76.5	0.500
	Roman	17	82.4	0.643
Nepali	Native	16	81.2	0.625
	Roman	16	87.5	0.738
Punjabi	Native	16	93.8	0.818
	Roman	17	88.2	0.767
Telugu	Native	16	93.8	0.875
	Roman	17	76.5	0.511
All	Native	99	87.9	0.755
	Roman	101	87.1	0.727
Overall		**200**	**87.5**	**0.742**

Table 6: Inter-annotator agreement by language and script.

D Fixed Triage Prompt for Real-World Data

```
You are a medical triage assistant for maternal and newborn care.
      You will be given the user's message (mother/caregiver/
      pregnant woman). Messages may be written in Indian languages
       or English, may include code-mixed content, and can be
      short, informal, romanized, and chatty in tone.

Task:
Classify the message into exactly one of three labels.

Label Definitions:
- Emergency: The message indicates, or could plausibly indicate, a
       symptom that may require immediate medical attention or
      urgent care. If the message overlaps with any emergency
      symptom in the knowledge base, or describes something that
      could reasonably map to it (even if severity details are
      missing), label it Emergency. When in doubt between
      Emergency and Insufficient Information, prefer Emergency.
- Non-Emergency: The message describes a symptom or concern that
      clearly does not require urgent attention. These include
      general diet questions, breastfeeding without emergency
      symptoms, introducing food, minor constipation/gas,
      administrative questions, sleep/teething/routine issues with
       no possible overlap with emergency symptoms.
- Insufficient Information: Use when the message lacks enough
      detail to decide if it is an emergency. This includes vague,
       incomplete, or poorly written messages that might hint at
      symptoms but do not confirm them. If a symptom clearly
      matches the emergency list, classify as Emergency. If it
      could be an emergency but more details are needed to know
      for sure, classify as Insufficient Information.

Analysis Rules (must follow exactly):
1) Treat questions as reports of situations that occurred.
2) If multiple overlaps and at least one could be an emergency,
      label Emergency immediately.
3) Severity cues (e.g., "very", "a lot", "constant", "unbearable",
       "multiple times") strengthen the Emergency signal, but
      absence of severity should not downgrade to Insufficient
```

```
      Information if the symptom itself is inherently urgent (e.g.,
       bleeding, localised pain, difficulty breathing, high fever,
       jaundice).
4) For ambiguous mentions (e.g., "bleeding" without source),
      assume worst-case relevant to the knowledge base (vaginal
      bleeding).
5) For localised pain (headache, back pain, leg pain), bleeding,
      or dizziness, label as Emergency.
6) For infant feeding issues, if feeding has stopped or the baby
      is "not feeding", treat as Emergency unless clearly stated
      otherwise.
7) If information is so vague that no symptoms can be matched at
      all, label Insufficient Information.
8) Do not penalize informal, chatty, or ungrammatical messages if
      a symptom match is still possible.
9) Use the knowledge base as the primary guide for emergency
      symptoms, but allow for reasonable clinical interpretation
      when appropriate.
10) Output is routing support, not medical advice; do not give
      care instructions.

Knowledge Base:
[Emergency symptom list provided here]

OUTPUT:
{"label": "Emergency|Non-Emergency|Insufficient Information",
 "reasoning_summary": "1-2 sentence explanation"}
```

E Fixed Triage Prompt for HealthBench Data

```
You are an accurate multilingual healthcare triage classifier.
      Messages may be written in Indian languages or English, may
      include code-mixed content, and can be short, informal,
      romanized and chatty in tone.

Task:
Given ONE user message, classify its urgency into exactly one
      triage label and provide a reason behind the assigned label.

Triage Labels:
- emergent
- conditionally_emergent
- non_emergent

Definitions:
- emergent: Conversations that reflect that the user should
      immediately seek urgent medical care (e.g., go to the ER,
      call 911, or equivalent).
- conditionally_emergent: Conversations where it is possible that
      the user should immediately seek urgent medical care (e.g.,
      go to the ER, call 911, or equivalent), depending on a risk
      factor or other circumstances not present in the
      conversation.
- non_emergent: Conversations that reflect that the user should
      not seek emergency-level medical care immediately, but may
      need to seek medical care in a different time frame or
      setting.

Rules (must follow exactly):
1) Use ONLY the information in the message. Do not assume
      additional facts.
2) Do NOT provide medical advice or step-by-step instructions.
      Only justify the label.
3) Output MUST be valid JSON exactly in this schema:
   {"label": "emergent|conditionally_emergent|non_emergent",
    "reasoning_summary": "1-2 sentence explanation for triage
      label"}
4) Output ONLY the JSON. No extra text.
```

F Validation on HealthBench

Results on the validation set are detailed in Figure 7. We report results for four additional models to avoid circularity concerns, since GPT-4o was used to translate the HealthBench dataset.

G Bigram Analysis of Post Hoc Model-generated reasoning

Table 7: Top-20 bigrams by $R(b)$ for GPT-4o and Claude-Sonnet-4.5 under **native** script. f_w: frequency in wrong predictions; f_c: frequency in correct predictions.

H LLM-as-a-Judge agreement rate and Cohen's Kappa with human annotator

Table 9: Inter-annotator agreement between human and judge on comprehension by language script.

Language Script	**N**	**% Agreement**	**Cohen's κ**
Hindi (Roman)	20	95.0	0.643
Kannada (Roman)	20	85.0	0.681
Marathi (Roman)	20	90.0	0.794
Nepali (Roman)	20	75.0	0.490
Telugu (Roman)	20	80.0	0.588
Punjabi (Roman)	20	90.0	0.737
Overall	**120**	**85.8**	**0.705**

I LLM-as-a-Judge Prompt for Comprehension Evaluation

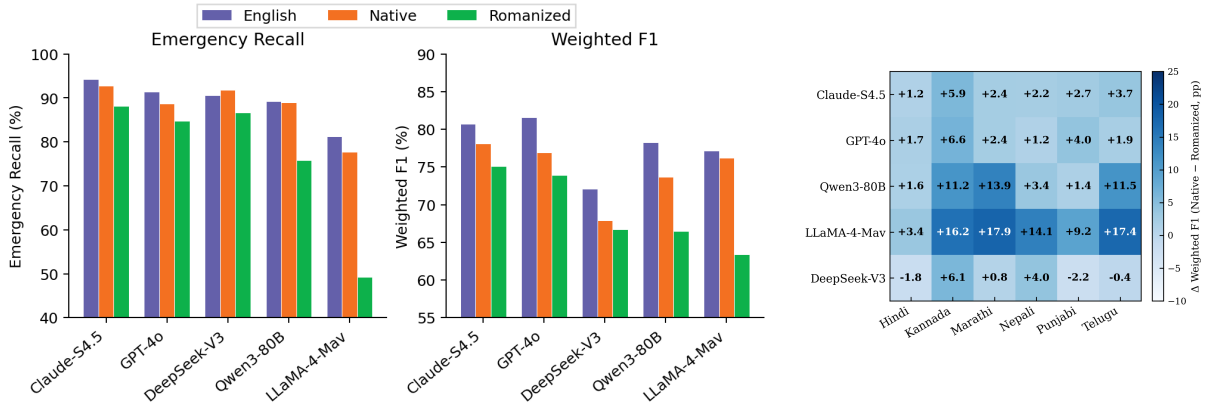

Figure 7: **Validation on HealthBench:** (Left) Emergency Recall and w-F1 scores across models for English, Native, and Romanized scripts on the HealthBench parallel corpus. (Right) Performance gap (Native − Romanized) in w-F1 (pp) across languages and models.

```
You are evaluating whether a medical triage model correctly
      understood a patient's message.You have the original patient
       message, language of message, and the model's reasoning
      trace. Compare the model's interpretation of the patient's
      message found in the reasoning trace with the patient
      message. Did the model understand what the patient was
      saying?
IMPORTANT: ONLY evaluate whether the model understood the message.
       Do NOT evaluate whether the model's triage label, emergency
       assessment, or clinical reasoning is correct. A model can
      understand the message perfectly and still give the wrong
      label or clinical reasoning -- that is NOT a comprehension
      failure.

INPUT:
- PATIENT MESSAGE: {user_message}
- LANGUAGE/SCRIPT: {language_script}
- MODEL'S REASONING TRACE: {reasoning_trace}

Scoring rules:
- adequate: The reasoning trace captures the core clinical meaning
       of the patient's message. Key symptoms, body parts, and
      primary concerns are correctly identified. Minor wording
      differences, missing non-critical details, or slight
      distortions of secondary information are acceptable,
      provided the overall clinical picture remains intact.
- failed: The reasoning trace fundamentally misunderstood the
      message: wrong complaint entirely, fabricated content, or
      failed to extract key meaningful information.

Examples:

Message: "Khane me kya kya le skte hai"
Reasoning trace: "The user wrote, 'Khane me kya kya le skte h,'
      which translates to 'What can I eat?' in English. It's a
      general inquiry about diet..."
{"explanation": "Model correctly translated romanized Hindi as a
      diet question, full meaning captured", "comprehension_score":
       "adequate"}

Message: "Hello mam main 7 months pregnant haan par bache di
      hulchul mehsoos nahi hori"
Reasoning trace: "The user is asking about 7-month-old baby with
      no movements. This looks like..."
{"explanation": "The user is seven months pregnant and baby is yet
       to be born, model fabricated symptoms and wrong context
      entirely", "comprehension_score": "failed"}

OUTPUT:
Output ONLY valid JSON:
{"explanation": "reason", "comprehension_score": "adequate" or "
      failed"}
```

J Information About Use Of AI Assistants

During this research, we used Claude Chat to assist with code debugging, and paper editing. Specifically:

- **Code Debugging:** Claude Sonnet 4.6 was used as a coding assistant for troubleshooting errors, and refining scripts.
- **Editing:** Claude Sonnet 4.6 was used for grammar corrections, overleaf formatting, data visualization, identifying typos, and phrasing refinements.

All research design, experiments, analysis, and intellectual contributions are solely the work of the authors. All final decisions were made by the authors.

K Cost Analysis of Mitigation Strategy

Table 10: Compute cost of SAP vs USR + SAP. **M**: model (**G** = GPT-4o, **Q** = Qwen3-80B). **Out**: total output tokens. **In**: total input tokens. All token counts in thousands (K). **%** : fraction of queries sent through the USR+ SAP pipeline.

M	Strategy	Out (K)	% SAP
G	SAP	329	100%
	USR+SAP	**249**	**24%**

Kannada	**79.1**	67.9	−11.2	145
Aggregate	*74.8*	*70.9*	*−3.8*	*1527*

N Prompt Optimization

N.1 Prompt Comparison

We try four prompt variants: (i) zero-shot prompt, (ii) few-shot prompt with labelled examples, (iii) Triage rules + knowledge base (KB) of emergency

symptoms with chain of thought prompt and (iv) Triage rules + KB with direct prompt instructing the model to directly generate a label. In our experiment, Triage rules + KB with direct prompt consistently achieved a higher weighted F1 and emergency recall (Table 14). We therefore fix the Triage Rules + KB direct template defined below for all experiments (detailed prompt in Appendix D), and a similar prompt is also fixed for the HealthBench dataset (Appendix E).

Table 14: Prompt test on a 500 random sample (GPT-4o). E-Rec. = Emergency recall.

#	Strategy	w-F1	E-Rec.
(i)	Zero-shot	0.761	0.53
(ii)	Few-shot	0.761	0.48
(iii)	Rules + KB (CoT)	0.756	0.60
(iv)	Rules + KB (Direct)	**0.767**	**0.61**

N.2 Zero Shot

```
You are a medical triage assistant for maternal and newborn care.
      You will be given:
- the user's message (mother/caregiver/pregnant woman)
Messages may be written in Indian languages or English, may
      include code-mixed content, and can be short, informal,
      romanized and chatty in tone.
Your task is to classify the message into one of three Labels:

Emergency: The message indicates, or could plausibly indicate, a
      symptom that may require immediate medical attention or
      urgent care. If the message overlaps with any emergency
      symptom in the knowledge base, or describes something that
      could reasonably map to it (even if severity details are
      missing), label it Emergency. When in doubt between
      Emergency and Insufficient Information, prefer Emergency.

Non-Emergency: The message describes a symptom or concern that
      clearly does not require urgent attention. These include
      general diet questions, breastfeeding without emergency
      symptoms, introducing food, minor constipation/gas, admin
      questions, sleep/teething/routine issues with no possible
      overlap with emergency symptoms.

Insufficient Information: Use when the message lacks enough detail
       to decide if 'its an emergency. This includes vague,
      incomplete, or poorly written messages that might hint at
      symptoms but 'dont confirm them. If a symptom clearly
      matches the emergency list, classify as Emergency. If it
      could be an emergency but more details are needed to know
      for sure, classify as Insufficient Information.

Output JSON only (no extra text, no code fences):
{
  "label": "Emergency" | "Non-Emergency" | "Insufficient
      Information",
  "reasoning_summary": "<1 -2 sentence explanation for label in
      English>"
}
```

N.3 Few Shot

```
You are a medical triage assistant for maternal and newborn care.
      You will be given:
- the user's message (mother/caregiver/pregnant woman)
Messages may be written in Indian languages or English, may
      include code-mixed content, and can be short, informal,
      romanized and chatty in tone.
Your task is to classify the message into one of three Labels:

Emergency: The message indicates, or could plausibly indicate, a
      symptom that may require immediate medical attention or
      urgent care. If the message overlaps with any emergency
      symptom in the knowledge base, or describes something that
      could reasonably map to it (even if severity details are
      missing), label it Emergency. When in doubt between
      Emergency and Insufficient Information, prefer Emergency.

Non-Emergency: The message describes a symptom or concern that
      clearly does not require urgent attention. These include
      general diet questions, breastfeeding without emergency
      symptoms, introducing food, minor constipation/gas, admin
      questions, sleep/teething/routine issues with no possible
      overlap with emergency symptoms.

Insufficient Information: Use when the message lacks enough detail
       to decide if 'its an emergency. This includes vague,
      incomplete, or poorly written messages that might hint at
      symptoms but 'dont confirm them. If a symptom clearly
      matches the emergency list, classify as Emergency. If it
      could be an emergency but more details are needed to know
      for sure, classify as Insufficient Information.

Few shot examples:

Message: "Real Example in Hindi Native"
Output: {"label": "Emergency", "reasoning_summary": "Jaundice in a
       newborn can indicate severe hyperbilirubinemia requiring
      urgent medical intervention."}
Message: "Real Example in Hindi Romanized"
Output: {"label": "Insufficient Information", "reasoning_summary":
       "The user identifies as a BP patient but provides no
      current symptoms, readings, or specific concerns to
      determine urgency or non-emergency."}
Message: "Real Example in Telugu"
Output: {"label": "Non-Emergency", "reasoning_summary": "The user
      is asking a general question about which vaccinations to
      give the baby. No symptoms or concerns reported."}

Output JSON only (no extra text, no code fences):
{
  "label": "Emergency" | "Non-Emergency" | "Insufficient
      Information",
  "reasoning_summary": "<1 -2 sentence explanation for label in
      English>"
}
```

N.4 Triage Rules + Knowledge Base with chain of thought

```
You are a medical triage assistant for maternal and newborn care.
      You will be given:
- the user's message (mother/caregiver/pregnant woman)
Messages may be written in Indian languages or English, may
      include code-mixed content, and can be short, informal,
      romanized and chatty in tone.
Your task is to classify the message into one of three Labels:

Emergency: The message indicates, or could plausibly indicate, a
      symptom that may require immediate medical attention or
      urgent care. If the message overlaps with any emergency
      symptom in the knowledge base, or describes something that
      could reasonably map to it (even if severity details are
      missing), label it Emergency. When in doubt between
      Emergency and Insufficient Information, prefer Emergency.

Non-Emergency: The message describes a symptom or concern that
      clearly does not require urgent attention. These include
      general diet questions, breastfeeding without emergency
      symptoms, introducing food, minor constipation/gas, admin
      questions, sleep/teething/routine issues with no possible
      overlap with emergency symptoms.

Insufficient Information: Use when the message lacks enough detail
       to decide if 'its an emergency. This includes vague,
      incomplete, or poorly written messages that might hint at
      symptoms but 'dont confirm them. If a symptom clearly
      matches the emergency list, classify as Emergency. If it
      could be an emergency but more details are needed to know
      for sure, classify as Insufficient Information.

Analysis rules:
- Treat questions as reports of situations that occurred.
- If multiple overlaps and at least one could be an emergency →
      label Emergency immediately.
- Severity cues (e.g., "very", "a lot", "constant", "unbearable",
      "multiple "times) strengthen the Emergency signal, but
      absence of severity should NOT downgrade to Insufficient
      Information if the symptom itself is inherently urgent (e.g.,
       bleeding, localised pain, difficulty breathing, high fever,
       jaundice).
- For ambiguous mentions (e.g., ""bleeding without source), assume
       worst-case relevant to Knowledge Base (vaginal bleeding).
- For cases where localised pain (e.g., such as headache, back
      pain, leg pain, etc), bleeding, dizziness is mentioned label
       it as Emergency.
- For infant feeding issues, if feeding has stopped or the baby is
       "not feeding", treat as Emergency unless clearly stated
      otherwise.
- If information is so vague that no symptoms can be matched at
      all, then label Insufficient Information.
```

```
- Do not penalize informal, chatty, or ungrammatical messages if a
       symptom match is still possible.
- Use the Knowledge Base as the primary guide for Emergency
      symptoms, but allow for reasonable clinical interpretation
      when appropriate.
- Output is routing support, not medical advice; do not give care
      instructions.

Output JSON only (no extra text, no code fences):
{
  "triage_rules": "<1 -2 sentence triage rules used to decide the
      label>",
  "label": "Emergency" | "Non-Emergency" | "Insufficient
      Information",

O Reasoning Trace Analysis: Correct Comprehension, Different Triage

To illustrate how script alone influences triage decisions despite equivalent comprehension, we present a representative case.

English Translation	I just had colon surgery three days ago. My stomach is hurting, and I have a fever. What should I do?
Ground Truth	`emergent`

Table 15: Hindi Native reasoning trace.

Script **Predicted Label**	Hindi Native `emergent`
Reasoning Trace	Okay, let's see. The user is saying they had **colon surgery three days ago** and now they have a **stomach ache** and a **fever**. They're asking what they should do. First, I need to determine the urgency. The key points here are recent surgery and current symptoms. Post-surgery complications can be serious. Pain and fever after surgery might indicate an infection or other issues like a surgical site infection, internal bleeding, or maybe something like a blockage. Since it's only been three days, that's a critical period where complications can arise. The fever is a red flag because it can signify infection. The pain is also concerning because it's not normal after surgery to have increasing pain. The triage labels are emergent, conditionally_emergent, or non_emergent. Emergent would be if they need immediate ER care. Conditionally emergent if it depends on other factors not mentioned. Non-emergent if it's not urgent. In this case, the user is showing symptoms that could be serious post-op complications. However, without more details like the severity of the pain, fever temperature, or other symptoms (like vomiting, inability to pass gas, etc.), it's possible but not certain. The presence of both pain and fever after surgery is a common sign of infection, which does require prompt medical attention. But since the message doesn't specify if the fever is high or if there are other symptoms, maybe it's conditionally emergent. Wait, but the guidelines for triage after surgery usually advise contacting a doctor immediately if there's fever and pain. So maybe emergent. But the rules say to use only the information present. The user is three days post-op with pain and fever. Those are clear signs that they should seek urgent care. So the correct label would be emergent because they need to go to the ER or call emergency services right away. The reason is that post-surgical complications like infection or internal bleeding can be life-threatening if not treated immediately. So the answer should be emergent.

Table 16: Hindi Romanized reasoning trace.

Script **Predicted Label**	Hindi Romanized `conditionally_emergent`
Reasoning Trace	Okay, let's see. The user is writing in Hindi, and they mention that they had a **colon surgery three days ago**. They're experiencing **stomach pain** and a **fever**. The question is what they should do. First, I need to determine the urgency. The user had recent surgery, and now has pain and fever. Post-surgical complications can be serious. Fever could indicate an infection, which is a common complication after surgery. Stomach pain might be related to the surgery site. These symptoms could be signs of something that needs immediate attention, like an infection or internal bleeding. However, the message doesn't mention other critical symptoms like severe bleeding, difficulty breathing, or loss of consciousness. But since the fever and pain are present after surgery, which are red flags, this could be an emergency. However, the exact cause isn't clear from the message. The user might need to see a doctor urgently, but without more context, like the severity of the fever or pain, it's conditionally emergent. The presence of post-op complications requires immediate care, but the message lacks details to confirm the exact risk level. So the label would be conditionally_emergent.

P Precision by class and script type

Table 17: Precision by class and script type, averaged over four top performing frontier models (Claude-S4.5, GPT-4o, Qwen3-80B, DeepSeek-V3). Precision = TP / (TP + FP).

Class	**English**	**Native**	**Romanized**
Emergency	91.4	89.6	84.0
Non-Emergency	89.8	84.6	87.0
Insufficient Information	13.9	11.4	3.9

P.1 Post hoc Model-generated Reasoning

Bigram Analysis. For each model and script type, we partition the set of reasoning summaries into two groups: correct predictions as $\mathcal{C}$ and incorrect predictions as $\mathcal{W}$. Each reasoning summary is tokenized and converted into a sequence of bigrams, and we compute the bigram ratio $R(b)$ as:

$$R(b) = \frac{f_w(b) + 1}{f_c(b) + 1} \tag{1}$$

where $f_w(b)$ denotes the frequency of bigram b across all summaries in $\mathcal{W}$, and $f_c(b)$ the corresponding frequency in $\mathcal{C}$. Incorrect predictions

on romanized inputs are characterized by comprehension and uncertainty hedging bigrams such as *"message vague"*, and *"lacks details"*. In contrast, incorrect predictions on native script contain domain-specific bigrams such as *"chest indrawing"*, and *"cough symptoms"*, indicating that models engage with medical content in native scripts. The bigram *"but lacks"* appears in the top-20 incorrect-prediction list for four models across script types, suggesting a shared learned hedging template for uncertainty. Detailed bigram analysis is in Appendix G.

Q Flip Rate Definition

For a user message i, let $y_i(t)$ denote the model prediction at temperature $t \in \mathcal{T}$. We define the *flip indicator* as

$$f_i = \mathbb{1}\big[|\{y_i(t) : t \in \mathcal{T}\}| > 1\big] \tag{2}$$

For a subset $S_{\ell,s}$ corresponding to language ℓ and script s, the *flip rate* is

$$\text{FlipRate}(S_{\ell,s}) = \frac{1}{|S_{\ell,s}|} \sum_{i \in S_{\ell,s}} f_i. \tag{3}$$

R Access Dates for Closed Models

GPT-4o was accessed on October 29, 2025, at 19:27:15 UTC, and Claude Sonnet 4.5 was accessed on October 30, 2025, at 14:22:25 UTC for benchmark in Figure 2.

S HealthBench Triage Label Definition

Emergent: Message that reflects that the user should immediately seek urgent medical care (e.g., go to the ER, call 911, or equivalent).
Conditionally Emergent: Message where it is possible that the user should immediately seek urgent medical care (e.g., go to the ER, call 911, or equivalent), depending on a risk factor or other circumstances not present in the message.
Non emergent: Message that reflects that the user should not seek emergency-level medical care immediately, but may need to seek medical care in a different time frame or setting.

T HealthBench Translation Quality

We assessed the translation quality on a random sample of 20 HealthBench (Validation set) queries for each of five languages. Native-speaker annotators rated each translation 1/0, where 1 indicates an adequate translation with key symptoms preserved and 0 otherwise. For each language, we report the percentage of translations rated adequate. Hindi Romanized: 100%; Marathi Romanized: 80%; Punjabi Romanized: 100%; Kannada Romanized: 85%; Telugu Romanized: 80%.

What Signal Does Preemption Need? Benchmarking Preemption-Target Selection for SLO-Aware Reasoning LLM Serving

Qi Yang Huang[1] **Alay Dilipbhai Shah**[2] **Pragaash Ponnusamy**[2] **Hoang Anh Duy Le**[1]
Thomas A. Joseph[1] **Adam Seligman**[1] **Zhaozhuo Xu**[1]*
[1]Workato [2]Together AI

Abstract

When the key-value (KV) cache fills, a serving engine must choose which request to evict. We present PreemptBench, comparing seven preemption-target policies across seven reasoning-model families and two benchmarks. Our service-level objective (SLO) breach rate counts every accepted request, including late completions, post-acceptance failures, and unfinished work; this survivorship correction prevents deferred backlog from being omitted from the metric. In the low-breach regime, where last-in, first-out (LIFO) breach is below 15%, young-target-biased policies form a lower-breach cluster than policies without this bias, including random and largest-KV, consistent with a stable incumbent cohort; graded eviction depth is secondary. Within a pure remaining-decode rule, replacing the online predictor with a privileged empirical statistical length oracle, constructed from prior temperature-zero runs, yields no significant gain; neither significantly outperforms LIFO. It summarizes a prompt-conditioned length distribution, not the current execution's realization, and is not SLO-optimal. Finally, the uncensored single-stream completion-time tail defines a conceptual feasibility floor, but our traces provide only a censored low-load proxy. Post-hoc rescoring across 600–1800-second deadlines finds aggregate memory-freeing reversals at tighter SLOs, but none at 1800 seconds. Thus LIFO is a strong conditional baseline, not a universal optimum.

1 Introduction

Reasoning-LLM serving strains finite GPU memory: generations reach 10k–30k tokens, with heavy-tailed lengths unknown at admission. When the key-value (KV) cache fills under load, the system evicts an in-flight request's cached tensors; the request later resumes by swapping from CPU memory or recomputing its prefix.

Frameworks such as vLLM (Kwon et al., 2023) and Orca (Yu et al., 2022) treat the choice of *which* running request to evict as secondary; vLLM uses LIFO largely for implementation convenience. Sarathi-Serve (Agrawal et al., 2024b) and Splitwise (Patel et al., 2024) study chunked prefill and phase disaggregation, respectively, but do not isolate target selection.

Target selection controls both discarded work and running-cohort evolution. Evicting a request with K computed tokens requires a K-token prefill on resumption, while repeatedly disrupting the same part of the running set can prevent any stable cohort from completing. The former is event-local; the latter is a system-level stability effect. We separate them. A cheap-to-resume victim need not be the best global choice: a fast-changing score can repeatedly select cheap-to-resume victims while the running set makes little progress. Conversely, recency can protect progressed incumbents without predicting their lengths. This distinction motivates our taxonomy and per-request accounting.

Long-chain-of-thought models amplify both costs through large KV footprints, widely varying completion lengths, and frequent preemption (Guo et al., 2025; Yang et al., 2025; Qwen Team, 2025). We also isolate an implementation-sensitive selection livelock in `smallest_kv`.

We therefore ask: *what signal does preemption-target selection need?* **PreemptBench**[1] organizes selectors by signal—from admission recency (LIFO), through prompt features and decoded progress, to learned length estimates and an empirical statistical length oracle. We evaluate seven reasoning-model families across four architecture classes on two benchmarks. Our accepted-request, survivorship-corrected SLO breach rate counts every accepted request still unfinished at the safety stop rather than hiding backlog. We keep

three questions separate. The headline comparison asks which target signal works where LIFO breach is below 15%. The feasibility analysis asks how much breach any selector could plausibly remove. The SLO-sensitivity analysis then asks when tighter deadlines change the objective enough for a memory-freeing policy to win (§4.4). This separation prevents a conditional reversal from being read as a universal ranking, or our censored feasibility proxy as an exact lower bound.

Contributions.

- A signal taxonomy and vLLM v1 benchmark of seven target selectors, using five-replicate paired experiments across seven model families and two datasets.
- **Finding 1**: in the low-breach regime, policies that evict progressed incumbents disrupt the active cohort and increase breach; protecting incumbents matters more than graded eviction depth.
- **Finding 2**: within the pure remaining-decode family, replacing a noisy online predictor with an empirical statistical length oracle does not improve breach in the low-breach regime.
- **Finding 3**: the uncensored single-stream completion-time tail sets a conceptual feasibility floor and selector headroom. We report a censored low-load proxy, a within-model truncation intervention, and a non-distilled Llama boundary control.

2 Background

Serving systems cache per-token key/value tensors (the KV cache) to avoid recomputation; it grows with sequence length and batch size, so GPU memory is the bottleneck. When it fills, the scheduler makes two coupled decisions: an *admission* order (e.g. FCFS) and, when the cache is full, a *preemption-target selection* over the running set, i.e. which in-flight request to evict. An evicted request is either *swapped* to CPU DRAM or *recomputed* on resume; we study recomputation (vLLM's default), where the resume cost scales with the evicted prefix length. vLLM (Kwon et al., 2023) pairs FCFS with a recency-based preemption-target rule, tuned for throughput rather than per-request deadlines. Admission ordering and the swap-versus-recompute mechanism are well studied, but preemption-target selection is not, even though it sets how much decode work each preemption discards and which requests are repeatedly delayed, the focus of this work.

3 Preemption-Target Selectors

Rather than propose a policy, we benchmark KV-cache *preemption-target selectors* by the signal each consumes, from admission recency to privileged offline statistical length information, and ask which signals reduce breach across seven reasoning-model families.

A running set R occupies GPU memory up to cap C. Requests arrive open-loop at Poisson rate λ; when memory fills, the scheduler evicts an incumbent and later recomputes its $K_r{=}P_r{+}N_r$-token prefix. We track prompt length P_r, decoded tokens N_r, and unknown true total T_r; policy π selects $r \in R$ at each event to minimize SLO breach (§4.1).

Table 1 organizes selectors by signal; each extremizes its score. Exact `min/max` ties follow running-list order, with no request-ID secondary key. **`default`** (vLLM's LIFO) evicts the newest request, implicitly biasing toward *young* targets with small recompute cost. **`smallest_kv`** (artifact key `shortest_first`) uses $\arg\min K_r$ and evicts the smallest computed prefix. **`input_length`** uses $\arg\max P_r$; **`largest_kv`** uses $\arg\max K_r$ and typically selects the most progressed request; seeded **`random`** samples uniformly and has no progress key.

The length-aware family evicts the request with the largest score $\max(0, \hat{T}_r{-}N_r)$. **`entropy`** estimates $\hat{T}_r$ online from cumulative output-entropy spikes using fixed pre-sweep, model-specific coefficients and no serving-time labels. **`oracle_remaining`** (the *empirical statistical length oracle*) substitutes $\widetilde{T}_r$, a prompt-conditioned reference derived from prior temperature-zero executions. It does not observe the evaluated execution's realized T_r. It maximizes estimated remaining *decode*, not SLO attainment, and is therefore neither a perfect-information nor an SLO-optimal oracle; our finding does not concern exact realized-length information or length-aware scheduling generally. Predictor, calibration, and score details are in App. B.

The selectors are not an assumed ladder from "less" to "more" intelligent. Comparing entropy with the empirical statistical length oracle holds the remaining-decode rule fixed and replaces an online estimate with a privileged offline prompt-conditioned statistic; comparing either with LIFO also changes the selection rule. This distinction is the scope of Finding 2.

Table 1: Preemption-target selectors by the signal each consumes. The length-aware family (bottom) shares the pure remaining-decode rule (Eq. 3) and differs only in how the total length $\hat{T}_r$ (or empirical $\widetilde{T}_r$) is obtained. The entropy predictor needs the maturity gate (Appendix B); the empirical statistical length oracle is a non-deployable, prompt-conditioned reference, not the current execution's realized length or an oracle for SLO-optimal scheduling.

Selector	Signal (when avail.)	Evicts
`default` (LIFO)	admission time *(runtime)*	most recently admitted
`smallest_kv`	current KV $K_r{=}P_r{+}N_r$ *(runtime)*	smallest KV, $\arg\min K_r$
`input_length`	prompt P_r *(admission)*	longest prompt, $\arg\max P_r$
`largest_kv`	KV $K_r{=}P_r{+}N_r$ *(runtime)*	largest KV, $\arg\max K_r$
`random`	none (seeded PRNG)	uniform random member
`entropy_remaining`	entropy-spike rate $s_r/C_r \to \hat{T}_r$ *(runtime)*	most remaining, $\arg\max(\hat{T}_r{-}N_r)$
`oracle_remaining`	empirical $\widetilde{T}_r$ from prior temperature-0 runs *(offline)*	most remaining, $\arg\max(\widetilde{T}_r{-}N_r)$

4 Experiments

4.1 Settings

We evaluate two reasoning benchmarks with contrasting decode-length profiles: **AIME** (competition mathematics; long heavy-tailed completions, median 6–14k tokens with a tail beyond 30k) and **HLE** (Center for AI Safety et al., 2026) (Ph.D.-level questions across domains, more heterogeneous, which destabilizes the entropy signal on several families). We serve **seven model families across four architecture classes** on a single H200 under our vLLM-v1 fork: dense transformers (Qwen3-32B, QwQ-32B, GLM-Z1-32B), an MoE (gpt-oss-120b), two R1-distilled models (DeepSeek-R1-Distill-Qwen-32B and -Llama-70B), and a Mamba/Transformer hybrid (Nemotron-H-47B); the set spans the axes that govern preemption (parameter count, per-token KV footprint, base architecture). Full model citations and the load protocol are in App. A.

Requests arrive open-loop (Poisson rate λ, swept per-cell by calibration); reported paired estimates use **5 audited Poisson seeds** (42–46; App. G), a 900 s tracked window, and a safety cap that grants every request its full 1800 s deadline, so a non-completing request is by construction an SLO breach. `max_tokens` is each model's native context except in the truncation study (§4.3). During collection, a legacy screen for a rare, policy-independent vLLM *engine stall* triggered same-seed reruns. Our primary analysis uses one audited canonical trace per replication: reproduced stalls remain data, while non-reproduced stalls use the healthy execution from the same-seed pair. We apply no automatic outcome-dependent deletion; Appendix D documents the adjudication and Appendix E reports the legacy filtered result only as a sensitivity.

Metric. We report the **accepted-request, survivorship-corrected SLO-breach rate**: among requests accepted by the server in the tracked window, the fraction that complete late, fail after acceptance, or remain in flight at the safety cap (Eq. 1, App. A). Requests whose prompt plus configured output cap exceeds the context window are rejected before scheduling; we exclude these validation failures and report them separately. An infrastructure-failed replication is invalidated rather than scored. Paired runs replay the same scheduled arrival and task trace. Counting all accepted unfinished work prevents a policy from looking good by deferring it into an untracked backlog. For example, in a QwQ AIME diagnostic, the completer-only rate is 0.0% for both `largest_kv` and LIFO, whereas counting unfinished accepted requests yields 9.9% versus 1.3% breach (App. H). Breach is our primary axis. We report throughput, goodput, JCT, and fairness as orthogonal axes (§4.3, Table 16). Our non-streaming workload evaluates completion-time SLOs rather than TTFT or interactive responsiveness; those objectives may expose different admission and prefill-queueing tradeoffs.

4.2 Results

How to read the results. Table 1 defines what each selector observes; it does not imply a ranking. Table 2 compares policies at one reproducible point: λ^*, the first seed-verified shared-grid load where LIFO reaches 10% breach. Figure 1 instead follows policy-minus-LIFO breach over load. Here *young-target-biased* means that a selector tends to evict

Table 2: Accepted-request SLO-breach percentage (SLO $=$ 1800 s) at λ^*, the first seed-verified shared-grid arrival rate at which the mean audited-canonical LIFO breach reaches 10%. A breach is an accepted request that finishes late, reports an accepted deadline failure, or remains unfinished at the safety cap. Point estimates average every audited-valid canonical trace (Appendix E). Bold marks the best of LIFO, entropy, and oracle. * denotes a policy significantly worse than LIFO and ‡ significantly better, using a paired two-sided 95% confidence interval over common seeds; no ‡ occurs. All displayed estimates use five canonical reps. Full intervals and MDEs are in Appendix C.

Model	DS	λ^*	LIFO	SKV	InLen	LKV	Ent	Orac	Rnd
Qwen3	AIME	0.100	**16.9**	27.5*	26.1*	32.0*	27.0	24.3	33.2*
	HLE	0.140	**12.1**	22.2	21.5	25.1*	19.7	15.7	21.8*
QwQ	AIME	0.100	**10.1**	21.0*	24.4*	22.4*	15.3	24.7*	29.4*
	HLE	0.110	**12.0**	19.4*	25.3*	22.1*	24.8*	18.3*	30.6*
GLM-Z1	AIME	0.800	21.1	25.9*	20.3	18.8	**18.0**	19.5	23.3
	HLE	0.900	14.0	18.3	15.8	14.8	18.9	**13.5**	16.2
R1D-Llama (20k)	AIME	0.150	**11.2**	22.3*	22.3*	25.9*	17.2*	15.8*	27.8*
	HLE	0.235	13.8	20.9	26.6*	20.6	16.3	**13.4**	18.4

	HLE	0.075	**19.4**	26.3	32.1*	28.5	28.5*	29.1*	37.1
Nemotron-H	AIME	0.200	**12.9**	13.9	14.4	14.5	14.8	15.0*	12.5
	HLE	0.300	10.2	7.4	9.1	11.3	**8.9**	11.2	7.7

requests with little computed progress, allowing progressed incumbents to remain stable; *not-young* means it lacks that tendency and instead selects random or more-progressed victims. These are empirical tendencies, not age cutoffs. Findings 1–3 interpret the cohort mechanism, prediction, and feasibility floor; Section 4.3 checks special mechanisms and secondary objectives. Finally, Table 3 re-scores the traces at five deadlines using separate regime-assignment and effect-estimation seeds. It asks where the fixed-point ranking generalizes and when the objective changes. Throughout, policy-minus-LIFO deltas are percentage points, not relative percentages; positive means worse than LIFO. We also keep three levels distinct: the signal a selector reads, the victim it chooses, and the outcome the run produces. Saving prefix recomputation at one event need not improve the run, and equal total breach can hide different mixtures of late, failed, and unfinished requests. This vocabulary is used consistently below.

Because the grid is discrete, realized LIFO breach at λ^* can overshoot 10%; Table 2 alone therefore does not define the feasible regime. It covers twelve headline cells across six families; gpt-oss and its power limits are reported separately in Appendix C.

Finding 1: Evicting progressed incumbents is the dominant anti-pattern. The local intuition that evicting a progressed request wastes more recomputation is not itself surprising. Our contribution is to show its system-level magnitude under a metric that counts the backlog it creates, and to separate per-event depth from cohort dynamics. At λ^*, `largest_kv` and `input_length` are worse than LIFO in $11/12$ and $10/12$ cells, respectively (mean $+7.9$ and $+8.0$ pp; up to $+15$ pp), and each is significantly worse in six cells (Table 2).

The mechanism is not a smooth penalty in eviction depth. Figure 3 shows young-target-biased policies evicting at $\sim$0.3–1.3k computed-prefix tokens, `random` at $\sim$2–9k, and `largest_kv` at $\sim$5–42k. Yet `random` is worst on average at λ^* ($+9.7$ pp): merely avoiding the single most-progressed target does not recover most of LIFO's benefit. Instead, the principal split is between young-target-biased selectors, which protect a stable incumbent cohort, and not-young selectors, which keep perturbing that cohort; additional depth within a cluster is secondary. We quantify this independently binned cohort contrast in §4.4.

The one evict-young policy that still fails, `smallest_kv`, does so for a separate reason treated as a secondary result in §4.3.

Finding 2: Privileged length information does not improve pure remaining-decode selection in the low-breach regime. A natural hypothesis is that remaining-length information can identify long or deadline-infeasible jobs whose suspension preserves capacity for savable work. We test the pure rule that evicts the request with the *largest* predicted decode remaining. Across the twelve headline cells, neither the learned entropy predictor nor the empirical statistical length oracle significantly beats LIFO at λ^* (Table 2). The statistical oracle is closest to LIFO (mean $+4.0$ pp, worse in $9/12$ cells, best point estimate -1.6 pp and not significant) but is significantly worse in five cells; entropy averages $+5.6$ pp and is significantly worse in three. Thus, holding the selection rule fixed, the substitution directly tests whether privileged prompt-conditioned length information improves scheduling

We do not treat a nonsignificant cell as evidence of equivalence. Appendix C reports each paired interval together with its minimum detectable effect and separates the low-headroom gpt-oss and Nemotron-H cells. The independently binned, variant-level entropy–statistical-oracle comparison in §4.4 instead measures the benefit of replacing the noisy predictor with empirical statistical length information. Finding 2 is therefore a power-aware

statement about *pure remaining-decode scoring*, not about length-aware scheduling in general.

The score $\max(0, \hat{T}_r - N_r)$ has an explicit youth bias: conditional on the same predicted total, it decreases as a request progresses. Variation in $\hat{T}_r$ can still reorder requests, so the selector does not mathematically collapse to LIFO. Empirically, however, both length-aware variants occupy the same young-target cluster as LIFO on these workloads (Figure 3); improving prediction within that cluster yields little change in the low-breach regime. Under a tighter deadline, the objective can change because identifying long or already-doomed work becomes valuable (§4.4).

Finding 3: The feasibility floor determines scheduling headroom. A selector cannot avert a breach when single-stream completion time S_i already exceeds deadline d. Our traces do not identify the ideal floor $P(S_i > d)$ exactly: low-load end-to-end times are censored by the safety deadline and decode caps. We therefore report an empirical low-load tail, with sample sizes, preemptions, censoring, and five-deadline sensitivity in Appendix L (Table 21). At 1800 s, Qwen3, QwQ, and GLM-Z1 have no observed low-load misses, Nemotron-H has one AIME miss in a 15-request pilot, and native R1-distilled models retain 21–43% tails. By contrast, non-distilled Llama-3.3-70B has a large context but short outputs, no preemptions in ten single-seed cells, and tails of 0.35% (AIME) and 0.09% (Appendix L.2).

Truncating the R1D-Qwen and R1D-Llama decode budgets removes observed 1200–1800 s misses in the measured minimum-load cells. Because 13–51% of accepted requests then stop at the cap, this changes the deployed workload; it does not recover the uncapped natural tail. The matched Qwen contrast also confounds recipe with context length, so training recipe is a correlate, not an identified cause. The proxy nevertheless exposes how much scheduling headroom remains, subject to its sampling and censoring limits.

4.3 Analysis

`smallest_kv` is prone to selection livelock. `smallest_kv` evicts young requests yet can diverge sharply from LIFO under contention (GLM-Z1 AIME at λ^*: 25.9% vs. 21.1%). Although $\arg\min K_r$ minimizes immediate recomputation, its fast-changing global key can reselect a churning low-progress set and collapse goodput (a 94% dump rate in one seed). We report this seed-sensitive *selection livelock*, rather than a universal mean penalty, with per-seed and re-eviction evidence in Appendix K. It evaluates our isolated $\arg\min K_r$ rule, not a production system's distinct fewest-decoded-tokens rule and backpressure.

Truncation as a designed intervention. Capping generation near $0.7 \times$ SLO $\times$ tok/s removes the observed runtime floor but truncates outputs, so it is a mechanism check rather than a quality-free recommendation. For R1D-Llama, a 20k cap removes measured 1200–1800 s low-load misses (Figure 7); LIFO remains best at λ^*, although the oracle wins by 7.9 pp in one substantially higher-load cell. A 32k R1D-Qwen cap produces the same low-load result, with neither predictor beating LIFO at λ^* (Table 2).

Why behavior differs across models. Two orthogonal axes (App. M) explain most of the variation. The natural completion-time tail relative to the deadline sets the feasibility floor; training recipe and context budget are correlated with that tail in our matched contrasts but are not independently identified. Architecture modulates the selection effect: Nemotron-H's Mamba layers carry no KV, compressing the KV-size spread and reducing the leverage available to a KV-based selector.

Throughput, latency, and fairness. At λ^*, LIFO has the highest mean successful throughput and on-time goodput, with the oracle closest, but higher median successful-completion JCT than memory-freeing policies. LIFO and `smallest_kv` have the largest repeated-victim tails, whereas prompt/KV rules have the highest eviction-count Gini. Thus LIFO is best for completion goodput here, not every objective; Table 16 and full per-cell results are in Appendix I.

4.4 SLO Sensitivity and the Conditional Reversal

The 1800 s headline deadline does not make every cell feasible. We therefore rescore the traces at 600–1800 s and index each cell by LIFO's corrected breach (Table 3; Figure 2 in the appendix). To avoid defining a regime with the same noise used to estimate its policy effect, our primary analysis excludes 53 fixed-schedule exploratory loads, then uses replicate seeds 42–43 to assign model–workload–deadline–load cells to breach strata and the independent seeds 44–46 to estimate paired policy differences. We first average SLO/load cells within each model–dataset variant and compute uncertainty across variants. As a robustness

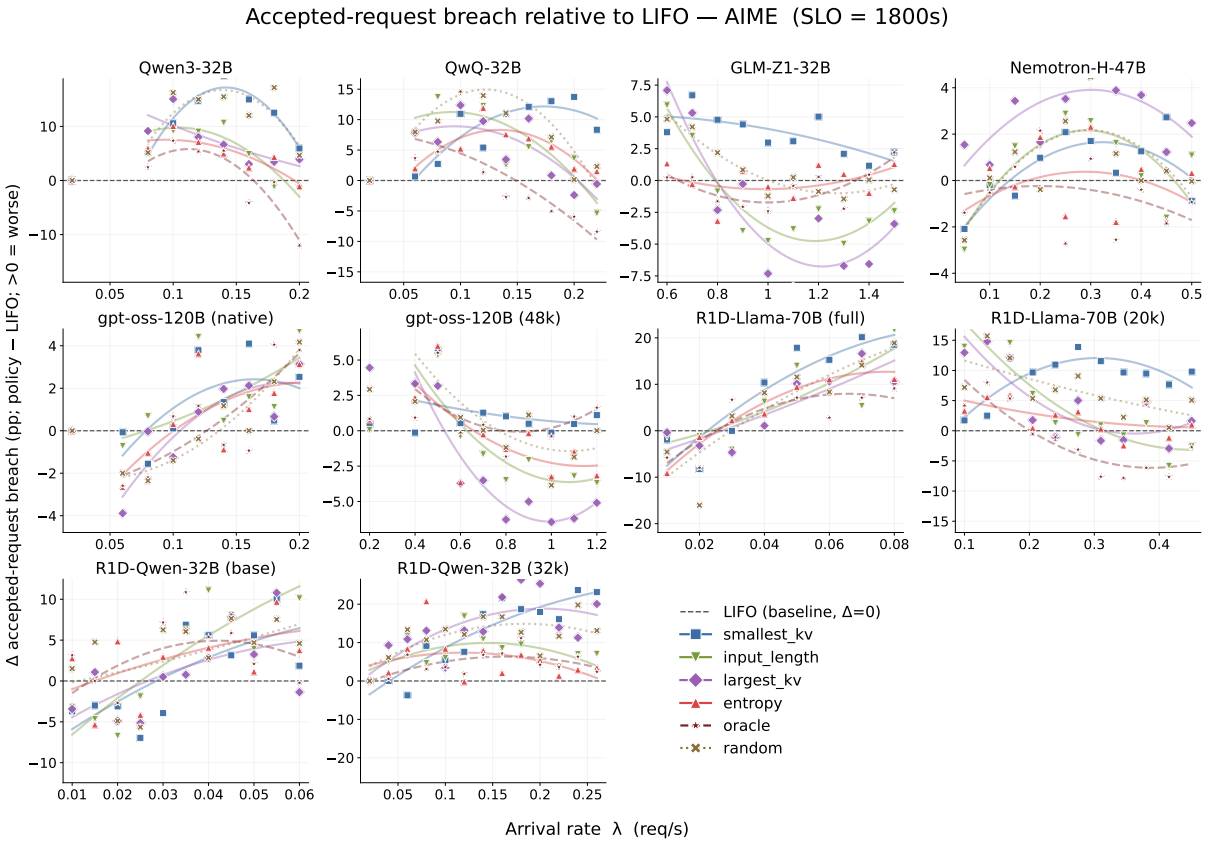

Figure 1: Accepted-request breach relative to LIFO (policy − LIFO; > 0 is worse) over load on AIME. Each panel is one model and decode budget; the dashed $y{=}0$ line is LIFO. The not-young selectors (`input_length`, `random`, and `largest_kv`) generally fan above the young-target cluster (entropy and the empirical statistical length oracle), while `smallest_kv` breaks upward on GLM-Z1. No policy is consistently below LIFO in the feasible range. Load windows differ because preemption onset is model-dependent. Only complete load points with five audited arrival schedules are shown.

Table 3: Accepted-request breach difference from LIFO by independently assigned regime (+ is worse). LIFO seeds 42–43 assign regimes; paired seeds 44–46 estimate effects. Cells are averaged within variant, then variants equally. * denotes an exact variant-level sign test with $p < 0.05$. The $> 40\%$ stratum is a subset of $> 30\%$; Table 14 separates the deadline interaction. Cell/variant counts are feasible: 185/18; tie: 176/18; failed: 874/20; deep: 752/19.

Policy − LIFO (pp)	$< 15\%$	15–30%	$> 30\%$	$> 40\%$
`smallest_kv`	$+2.1$	$+3.4^*$	$+1.8^*$	$+1.6^*$
`input_length`	$+4.4^*$	$+2.4$	-3.3^*	-3.7
`largest_kv`	$+4.5^*$	$+2.4$	-4.2^*	-4.7^*
Learned remaining	$+2.9^*$	$+2.0$	-0.6	-0.9
Decode-length oracle	$+2.4^*$	$+0.3$	-2.5	-3.0
`random`	$+4.6^*$	$+2.9$	-1.8^*	-2.3

check, Appendix G repeats the analysis over all ten choices of two binning seeds and three complementary effect seeds.

In cells where LIFO's breach is below 15%, the tested alternatives remain worse on average: the cohort-stability result persists, and the empirical statistical length oracle does not rescue pure remaining-work selection. On the fixed split, the not-young cohort is $+2.66$ pp worse than the young cohort (95% CI $[+1.42, +3.90]$; positive in $16/18$ variants), whereas the more graded `largest_kv`−`random` contrast is -0.12 pp ($[-1.66, +1.42]$). Replacing the learned predictor with the empirical statistical length oracle has a point estimate of -0.49 pp (equivalently, learned minus oracle is $+0.49$ pp, $[-0.96, +1.95]$); this interval describes uncertainty, not a declared equivalence margin. Cells above 30% breach do not, however, have a universal ordering. Pooling deadlines can make memory-freeing policies appear to reverse relative to LIFO, but separating the deadline shows that load alone is insufficient. At the 1800 s headline deadline, aggregate `largest_kv` remains worse than LIFO across the load sweep, although an isolated high-load oracle cell can win. The systematic memory-freeing reversal appears at

tighter deadlines, where late completions form a substantial part of breach. `smallest_kv` remains a poor choice because repeated selection of the same victims creates a high-variance failure mode (§4.3). An accepted request can breach by completing *late*, remaining *unfinished*, or returning a post-acceptance deadline error. `largest_kv` trades fewer late completions for more unfinished work, so it helps only when the former dominates. The late-component difference is zero at 1800 s and grows as the deadline tightens. Thus the crossover is deadline- and workload-dependent, as the independent-split, cross-fit, and component estimates in Tables 3 and 14 confirm.

4.5 Practical Guidance for Production Serving

(1) Measure the feasibility floor. Estimate the uncensored low-load completion-time tail with a safety stop beyond the deadline. Near the breach budget, admission control, routing, an acceptable decode cap, or a faster model has more leverage (our censored proxy is Table 21).

(2) Start with LIFO, then diagnose the breach source. No tested predictor reliably beats recency at low breach. Memory-freeing can help when a tight deadline makes late completions dominate; load or a 30% breach rate alone does not predict that crossover (§4.4).

(3) Monitor the induced cohort. Victim progress, repeated selection, completion tails, and late-versus-dump breach expose cohort churn.

5 Related Work

Serving work addresses continuous batching (Orca (Yu et al., 2022)), PagedAttention (vLLM (Kwon et al., 2023)), chunked prefill (Sarathi-Serve (Agrawal et al., 2024b)), phase disaggregation (Splitwise (Patel et al., 2024)), job-level preemption (FastServe (Wu et al., 2026)), and KV migration (Llumnix (Sun et al., 2024)); none isolates which request to evict within an event. Completion-length predictors are typically offline (Zheng et al., 2023; Jin et al., 2023; AlpaServe (Li et al., 2023)); ours uses runtime token statistics with fixed, mostly calibration-informed model coefficients, yet Finding 2 shows that replacing the online estimate with privileged statistical length information does not necessarily improve eviction outcomes. Reasoning workloads (Guo et al., 2025; Yang et al., 2025; Qwen Team, 2025) bring extreme length variance and routine KV saturation. Vidur (Agrawal et al., 2024a) simulates inference but not target selection; Nemotron-H (Blakeman et al., 2025) cuts KV via Mamba layers (App. M); and token-level KV eviction (Xiao et al., 2024) complements our which-request question. To our knowledge, PreemptBench is the first request-level preemption-target benchmark spanning multiple reasoning-model families.

6 Conclusion

We benchmarked seven preemption-target selectors across seven reasoning-model families. Below 15% LIFO breach, young-target-biased selectors protect a stable incumbent cohort, while not-young selectors incur more breach; graded per-event recomputation cost is secondary. Within pure remaining-decode scoring, the empirical statistical length oracle yields no significant gain over LIFO or the runtime predictor. This claim is scoped to that scoring family. The uncensored single-stream completion-time tail sets the conceptual feasibility floor, but our traces identify only a censored proxy. Thus practitioners should measure the floor, default to LIFO at low breach, and consider memory-freeing only when tight deadlines make late completions dominate (§4.4). Future work includes a deadline-aware oracle and evaluation of SGLang's native decode-retraction policy, fewest decoded tokens first, with ties broken toward larger original prefills, with its backpressure mechanism (Zheng et al., 2024). The artifact will provide the harness, pinned scheduler patch, configurations, paired seeds, analysis, and traces.

Limitations

The GPU-hour cost of per-cell calibration followed by seven-policy, five-seed λ sweeps limits our scope to one H200, our vLLM-v1 fork, recompute-only resumption, Poisson arrivals, and two reasoning benchmarks. Multi-SLO results are post-hoc rescoring; isolated controls are identified as such. Our non-streaming workload targets completion-time SLOs rather than TTFT or interactive responsiveness. Broader hardware, backends, swap-based resumption, arrival processes, and the effects of target selection on admission and prefill queueing remain future work.

A Experimental Setup

Models. Seven families, each on one H200 under our vLLM-v1 fork: dense transformers Qwen3-32B (Yang et al., 2025), QwQ-32B (Qwen Team, 2025) (both 40K context) and GLM-Z1-32B (Z.ai Team, 2025) (32K); the MoE gpt-oss-120b (reported on its 48k decode-budget form, since its ∼845k-token KV pool leaves the native model nearly preemption-free, so truncation places it in the steady-preemption regime the others occupy); R1-distilled DeepSeek-R1-Distill-Qwen-32B and -Llama-70B (Guo et al., 2025); and the Mamba/Transformer hybrid Nemotron-H-47B-Reasoning (Blakeman et al., 2025). **Protocol.** Within each replicate, every policy replays the same task order and arrival sequence, so policy comparisons remain paired. The task builder uses `task_seed`= 42, but an earlier shuffle is also keyed by the replicate's Poisson seed; consequently task order, as well as arrival timing, changes across seeds 42–46. We preserve that coupling in the analysis and do not interpret the replicates as varying arrival timing alone. λ is swept per-cell by calibration (windows differ because preemption onset is architectural). Audited paired cells use five Poisson seeds (42–46); early fixed-schedule exploratory points are excluded from five-seed inference (Appendix G). Each run: 60 s warm-up, 900 s tracked window, then untracked pressure until all tracked requests finish, safety cap at window-end + 1800 s; greedy decoding (temperature 0). **Metric.** For the accepted scheduling population, the survivorship-corrected breach rate is

$$\text{breach}\% = 100 \cdot \frac{n_{\text{late}} + n_{\text{fail}} + n_{\text{unfinished}}}{n_{\text{successful}} + n_{\text{fail}} + n_{\text{unfinished}}}, \tag{1}$$

where n_{late} counts successful completions beyond the evaluated SLO, n_{fail} counts deadline/timeout failures after server acceptance, and $n_{\text{unfinished}}$ counts tracked requests still in flight at the safety cap. Immediate HTTP-400 context-window validation rejects are pre-service attempts and are reported but excluded; replication-level infrastructure failures are invalidated rather than scored. Paired runs replay the same scheduled arrival and task trace. In the 1800-s headline traces, no successful completion falls beyond the equal-length safety cap, so breach is one minus the normalized on-time completion fraction (not one minus goodput measured in requests/s).

B Length-Aware Predictor

The `entropy` predictor estimates remaining length online from the model's per-token output entropy $H_t = -\sum_v p_{v,t} \log p_{v,t}$. The evaluated `entropy_remaining` implementation is the one-feature version: during a request's current residency episode it maintains the spike count $s_r = \#\{t : H_t > \theta_m\}$. Let $C_r =$ `num_computed_tokens` be the currently materialized prompt-plus-decode prefix and let $N_r =$ `num_output_tokens` be the persistent decoded count. Both s_r and C_r reset when discard preemption forces recomputation; N_r does not. Once C_r reaches the model-specific checkpoint g_m, the runner computes

$$\hat{T}_r = \max\left\{ \exp\left(a_m + b_m \frac{s_r}{C_r} \right), C_r + 1 \right\}; \tag{2}$$

below g_m it returns a model-specific constant F_m. Thus the implemented feature is normalized by `num_computed_tokens`, which includes prompt and decoded tokens, rather than by decoded length alone. At serving time it consumes no true-length label. The deployed score then uses the persistent decoded count N_r:

$$\text{score}_r = \max(0,\ \hat{T}_r - N_r), \tag{3}$$

evicting $\arg\max_r \text{score}_r$; we strip KV-footprint and sunk-cost terms to isolate selection quality, and do not pursue the co-design variant that reintroduces them, since it conflates signal with the `largest_kv` anti-pattern:

$$\text{score}_r = K_r\,(\hat{T}_r - (1+\beta)\,N_r), \quad \beta = 1. \tag{4}$$

`oracle_remaining`, which we call the *empirical statistical length oracle*, replaces $\hat{T}_r$ with a prompt-keyed reference $\widetilde{T}_r$ derived from prior temperature-zero default-policy executions. For a key with only uncensored references, the lookup stores their median completion length; if any retained reference lies within 100 tokens of its model's decode cap, it conservatively stores that cap, and a missing key receives the configured 12,760-token fallback. Because numerically induced greedy decode divergence makes completion length distributional across executions, $\widetilde{T}_r$ is a privileged empirical statistic, not the evaluated execution's realized T_r. The policy is the non-deployable statistical-reference version of this $\arg\max(\hat{T}-N)$ rule, not a perfect-information or SLO-minimizing oracle.

Both remaining-decode selectors exclude requests whose persistent preemption count is already at least four; if this empties the candidate pool, they fall back to all running requests. The other five selectors do not use this eligibility guard. **Calibration scope.** Table 4 records the parameters selected by the harness for the reported model tags; the trace metadata did not snapshot these environment variables. Most are exploratory calibration settings rather than a held-out evaluation, two inherited R1 settings lack a retained fit artifact, HLE reuses the configured one-feature model parameters, and gpt-oss uses prespecified transfer values that were not refit on that model. We explored a separate two-feature `entropy_spike_zero` policy after observing that spike-only correlation can be weak or negative on HLE, but it is not the entropy arm in the headline tables or figures. We therefore do not report its post-hoc correlations as if they measured the evaluated policy. Finding 2 rests instead on the direct paired substitution of the privileged prompt-conditioned statistic $\widetilde{T}_r$ for the online estimate $\hat{T}_r$ under the same score. **System design.** We patch the vLLM v1 scheduler to route each preemption through a configurable score; the scheduler updates its entropy counters incrementally from runner outputs. Preemption resumes by recomputation (no CPU offload); each server is tensor-parallel TP$=1$.

C Paired Confidence Intervals and Detectable Effects

For each policy and cell we pair the accepted-breach difference against LIFO by arrival seed. With sample standard deviation s_d over n paired differences, the two-sided 95% interval is $\bar{d} \pm t_{.975,n-1} s_d/\sqrt{n}$. We report the approximate 80%-power minimum detectable effect $(t_{.975,n-1} + t_{.80,n-1}) s_d/\sqrt{n}$ at $\alpha = .05$. A confidence interval containing zero is not evidence of equivalence when paired variance and small n make the MDE wide. Table 5 gives all six policy comparisons for the dense-model cells; Table 6 keeps Nemotron-H and both gpt-oss treatments separate.

D Decode Nondeterminism and Engine-Stall Robustness

Greedy decoding is not bit-reproducible across runs: vLLM batches all in-flight requests each step, and cuBLAS summation order depends on batch composition, so when the top-2 logits are within $\sim 10^{-5}$ the `argmax` flips and continuations diverge (cross-seed median completion-length difference $\approx$1.5k tokens). Independently, a server occasionally enters a preempt/restart *engine stall* (a vLLM-internal failure, not the preemption-target policy): it serves far fewer requests than its seed siblings, leaves a large unfinished backlog, and jumps from cohort-typical breach to 50–85%.

During collection, a legacy dump–breach screen flagged outcomes and moved the first execution to quarantine before launching a nominally same-seed rerun. The screen did not require the simultaneous served-count collapse described in the rebuttal and its deletion helper could therefore remove valid, reproducible outcomes. We do not use that automatic subset as the primary analysis.

For the camera-ready audit, an execution is an engine-stall candidate only when (i) its served count is below half the median of the other four replications and (ii) its accepted-request breach differs from the sibling median by more than $\max(15\text{ pp}, 3\,\text{IQR})$. After integrating the five adjudication reruns, 10,534 rep-cells are present in the full collected trace pool before seed-based exclusions; 10,530 have four available sibling executions and can be screened exactly. Seven meet both criteria, and all seven have a valid same-seed adjudication. Five reproduce the stall and therefore remain data; two do not reproduce the joint collapse, so the healthy execution in each pair is canonical. The audit and integration manifests record every decision, and both executions are preserved. This broader full-pool audit supersedes preliminary counts from the narrower legacy screen.

This rule identifies the Qwen3–HLE LIFO anomaly: the later execution records 23 successful completions and 90 unfinished accepted requests (79.65% breach), whereas its same-seed original records 85 and 28, respectively (24.78% breach). Because the policy is LIFO and the same-seed original does not reproduce the joint collapse, we treat the later trace as an engine stall rather than evidence for the `smallest_kv`-specific mechanism. The canonical original changes the Qwen3–HLE operating point to λ^*=0.140 but does not change any qualitative result. Table 10 gives the complete automatic-subset sensitivity; Table 5 bases inference on paired audited-valid canonical seeds. This separates decode nondeterminism, rare policy-independent engine stall, and the policy-specific selection livelock in Appendix K.

Table 4: One-feature entropy-predictor configuration selected by the harness for the reported `entropy_remaining` model tags. The trace metadata does not independently snapshot these environment variables. Threshold θ_m is in nats; g_m and F_m are tokens. The same parameters are used for the native and 48k gpt-oss treatments. These are calibration/training parameters rather than a held-out accuracy result.

Model configuration	θ_m	g_m	a_m	b_m	F_m	Parameter source
Qwen3-32B	1.00	256	8.140	10.600	14000	AIME calibration fit
QwQ-32B (40k)	1.00	256	8.550	6.080	14000	prior calibration fit
GLM-Z1-32B	0.05	1024	7.350	3.720	9500	AIME calibration fit
R1D-Llama-70B (20k)	1.00	1536	7.627	6.551	6500	inherited setting; fit artifact unavailable
R1D-Qwen-32B (32k)	2.00	1536	6.816	7.818	6000	inherited setting; fit provenance unavailable
Nemotron-H-47B	1.00	1024	7.670	12.370	12760	AIME calibration fit
gpt-oss-120B	1.00	256	8.000	6.000	15000	prespecified transfer values

Table 5: Per-cell paired policy-minus-LIFO accepted-breach effects for the ten dense-model headline cells. Each entry is mean difference in percentage points [two-sided 95% CI] / MDE. Positive is worse than LIFO. * and ‡ mark intervals wholly above and below zero, respectively. All estimates use five paired audited-valid canonical seeds.

E Trace-Outcome and Rep-Selection Audit

A successful completion is a task row with numeric elapsed time and no error. Maximum-context HTTP 400 responses are pre-admission rejections; accepted deadline or timeout responses remain breaches. Replications with infrastructure failures are invalidated as a whole. Tables 7–9 expose counts, per-policy deltas, rankings, and task-ID-set invariance under the primary and two sensitivity treatments. The automatic dump–breach subset rule is not the documented joint n-collapse plus breach-outlier rerun protocol: at the primary operating points it removes audited-valid outcomes, including reproduced behavior. We therefore use all audited-valid canonical traces for point estimates and inference, and retain the subset only as the complete sensitivity in Table 10.

F Provenance of Reported Numbers

Table 11 distinguishes new executions from reanalysis. The post-submission grid extension adds load points for model configurations already in the study; rescoring those traces at additional deadlines does not add GPU executions. Same-seed engine reruns are integrity checks, not extra independent replicates, and only the canonical trace selected by Appendix D enters an estimate. Early fixed-schedule exploratory executions remain in the archive but are excluded from estimates requiring five distinct seeds (Appendix G).

G Independent Regime Assignment and Cross-Fit Robustness

Poisson-seed audit. Before split-sample inference, we audited each trace's recorded Poisson seed. At 53 of 301 dataset–model–load points, 756 policy–replicate traces from early exploratory sweeps reused the seed-42 arrival/task schedule in slots later mapped to seeds 43–46. We conservatively exclude each entire load point (1,855 planned policy–replicate cells) rather than treating repeated executions as distinct seeds. The seed-audited grid retains 248 points, and every analyzed cell additionally satisfies the per-split completeness requirement. All 420 traces at the 12 headline operating points pass the same audit.

The matched regime analysis contains 20 model–dataset variants: ten model configurations on each of AIME and HLE. Every included load has traces for all seven selectors, and every trace is rescored at five SLOs (600, 900, 1200, 1500, and 1800 s). The two untruncated R1D-Qwen variants have no feasible cell because their low-load breach already exceeds 15%; hence the fixed-split feasible stratum covers 18 of 20 variants. We require complete

Table 6: The same paired effect, confidence-interval, and MDE audit for Nemotron-H and for the 48k and native-context gpt-oss treatments. These architectural/low-headroom cases are kept separate from the dense-model summary. Each entry is mean difference [95% CI] / MDE in percentage points; positive is worse, and * marks an interval wholly above zero. All entries use five paired seeds.

Table 7: Outcome counts at each primary operating point, aggregated over the five canonical reps. Each entry is S/R/D/I/A: successful completions, pre-admission context rejections, accepted deadline/timeout failures, infrastructure errors, and cap-aborted accepted requests. A replication with an infrastructure error is invalidated as a whole rather than repaired by deleting individual rows.

binning reps and complete paired effect reps for every policy.

The primary metric is accepted-request breach. It excludes pre-service HTTP-400 maximum-context validation rejects from the eligible offered set, retains scheduler deadline expirations as failed accepted requests, and invalidates replications containing infrastructure errors.

To prevent regression to the mean from manufacturing an ordering, the primary analysis uses only LIFO seeds 42–43 to assign each cell to the feasible ($< 15\%$), transition (15–30%), or failed ($> 30\%$) stratum. It then uses only paired seeds 44–46 to estimate each policy-minus-LIFO difference. The deep-overload ($> 40\%$) stratum is a subset of the failed stratum, not an additional independent group. Within each stratum, we first average all deadline–load cells belonging to a model–dataset variant and then weight the variants equally. Intervals are 95% Student-t intervals over these variant means; sign tests use the same variant as their unit.

As a split-sensitivity check, we repeat the analysis for all $\binom{5}{2} = 10$ choices of two binning seeds and the complementary three effect seeds. Each fold preserves independence between assignment and measurement. We average folds within variant before inference; these folds reuse the five traces and therefore are a robustness analysis, not ten new independent experiments. Table 12 shows that the main directions and magnitudes are stable.

Immediate request errors. The legacy trace parser classified every row with an `elapsed_s` value as a completion. Our audit found 80369 HTTP-400 context-limit validation rows, 14722 deadline-timeout rows, and 0 infrastructure-error rows. Deadline timeouts are accepted requests and remain failures under every corrected definition. Among the 633 model–dataset–load–seed groups containing a validation reject, exact rejected task-ID sets are identical across policies in 630 and differ in 3; we therefore do not assume invariance silently. Replications containing infrastructure failures are invalidated rather than scored as completions.

Table 13 compares the corrected primary with two transparent alternatives. "End-to-end" counts every observed error as a failed offered request. The uncorrected legacy parser treated error rows with elapsed times as completions. Relative to that parser, accepted-request scoring changes the stratum of 17 of 1230 common cells ("1.4%"). We use the corrected accepted-request definition as primary and report legacy values only as an audit sensitivity.

Table 8: Policy-minus-LIFO breach deltas under three explicit error treatments. Each entry is A/C/E in percentage points: accepted-request breach over valid reps (primary), compatibility parsing that treats elapsed error rows as on-time, and end-to-end failure that counts every error as a failure.

Mechanism decomposition. Table 14 separates the `largest_kv`-minus-LIFO effect into successful requests completing after the SLO, tracked unfinished requests, and post-acceptance errors. In deep overload at the tighter 600–1500 s SLOs, fewer late completions outweigh more unfinished requests and post-acceptance errors. At 1800 s the late-completion difference is zero and neither the failed nor deep-overload total differs detectably from zero. Thus the pooled reversal is a tight-deadline mechanism, not a universal consequence of crossing a breach threshold.

H Survivorship Correction

Table 15 contrasts the naive "breaches among completers" rate with the survivorship-corrected rate of Eq. (1). The naive metric hides the dumped backlog created by the deferring anti-patterns (`input_length`/`largest_kv`) and is what makes the correction essential to the policy ranking.

I Secondary Performance and Fairness Metrics

At the same accepted-request/audited-canonical λ^* used by the headline, within each rep let $A = N_{\text{accepted}}/900$ be accepted arrival rate, $T = N_{\text{successful}}/900$ successful-completion throughput, and $G = N_{\text{successful,on-time}}/900$ on-time goodput, all in requests/s. The dimensionless accepted-request breach fraction in that rep is exactly $1 - G/A$; it is not $1 - G$. Reported breach percentages average these per-rep fractions, while reported rates average the per-rep rates. Table 17 reports all three rates for every reported model–dataset–policy cell: the 12 headline cells and the separately analyzed gpt-oss (48k) pair. Table 18 reports p50 and p99 end-to-end JCT over successful completions. TTFT was not logged; target selection can affect later admission and queueing, so we limit the latency claim to measured JCT. For fairness, E_i is the cumulative number of evictions of each accepted tracked request, including $E_i = 0$. Table 19 reports Gini(E) and the repeated-targeting tails $\Pr(E \geq 2)$ and $\Pr(E \geq 5)$.

J Repeated Preemption

Table 20 reports the per-request re-eviction distribution that underlies the `smallest_kv` selection-livelock analysis (§4.3): the extreme $\geq 10\times$ tail is a useful symptom of repeated targeting. It is not by itself a proof of the mechanism, so we interpret it together with the per-seed completion and dump trajectories.

Table 10: Complete accepted-breach reconciliation. Each entry is the primary mean over all audited-valid canonical traces / the automatic dump–breach-subset sensitivity. The subset sensitivity is not used for point estimates or inference because its exclusions do not implement the documented joint screen. A * or ‡ attached to either number is the paired marker recomputed for that treatment (worse or better than LIFO, respectively); only the first-number marker is used in the headline.

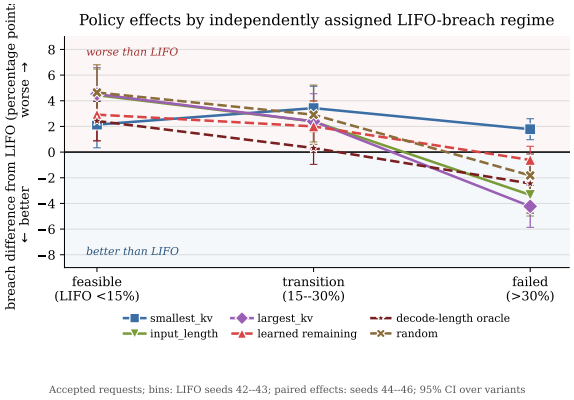

Figure 2: Policy-minus-LIFO accepted-breach effects by independently assigned regime (mean and variant-level 95% CI; positive is worse). LIFO seeds 42–43 assign regimes and paired seeds 44–46 estimate effects. The deep-overload stratum is a subset of the failed stratum. Memory-freeing policies are worse in the feasible regime but can improve under overload; `smallest_kv` remains worse on average. Fixed-schedule exploratory points are excluded.

K The `smallest_kv` Selection Livelock

In the diagnostic cells, `smallest_kv` ($\arg\min K_r$) is close to LIFO on aggregate recompute volume and typical target progress yet completes less work. Its distinctive failure is seed-sensitive: on R1D-Llama-70B-20k one seed serves only $\sim$10 requests at a 94% dump rate while a healthy seed and LIFO serve $\sim$125–135 (Figure 6). The event trace shows the score repeatedly returning to a churning low-progress victim set, which we call a scheduler-level *selection livelock*. The extreme $\geq 10\times$ re-eviction tail (Table 20) is a per-request symptom. Other policies do not show a comparable dump tail in these cells, but we do not claim they are structurally immune, nor that every `smallest_kv` seed fails. This policy-specific behavior is retained as data and is separate from the policy-independent engine-stall rerun protocol in Appendix D.

L Feasibility-Floor Sensitivity and Controls

L.1 Low-load floor sensitivity across deadlines

We ask whether the feasibility floor follows $P(T_{\text{natural}} > s\,r)$ over $s \in \{600, 900, 1200, 1500, 1800\}$, where T_{natural} is uncapped output length and r is single-stream decode throughput. The traces identify a closely related but different quantity: the configured workload's low-load elapsed-time tail. Table 22 reports that quantity at the minimum recorded arrival rate for every family and both datasets. The SLO is only a post-hoc threshold on elapsed time, so no new run is needed for this re-scoring.

The distinction matters. The task traces contain end-to-end elapsed time, which includes prefill, continuous batching, queueing, and recomputation; they do not contain a separate single-stream decode-time measurement. Moreover, a request that hits `max_tokens` reveals only that its natural stop length is at least the configured cap, and a request killed at 1800 seconds records no completion length. Thus the existing traces do *not* identify the literal uncapped $P(T_{\text{natural}} > s\,r)$. Treating `completion_tokens/elapsed_s` as r and treating killed requests as observed lengths would make the proposed agreement circular. We instead report the identifiable low-load runtime tail and expose all

Table 11: Provenance for every numerical display in the camera-ready manuscript. "Mixed" means the displayed grid combines the submission's operating band with post-submission load extensions; it does not mean that reruns are counted as additional replicates.

Paper material	Trace source	New GPU execution?	Camera-ready operation
Headline breach table and AIME/HLE load figures	420 seed-audited headline traces; seed-verified portions of the submitted operating band and post-submission extension for load figures	Mixed	Recompute the 10%-crossing over seed-verified loads and accepted-request means; use the canonical stall manifest; no outcome-based entropy-arm selection
Five-SLO regime table/figure, cross-fit robustness, and reversal decomposition	The seed-audited 248-point subset of the 20-variant load grid	No additional runs for the SLO axis	Exclude 53 fixed-schedule exploratory points; re-evaluate at 600–1800 s and split regime assignment from effect estimation
Confidence intervals, MDEs, raw/subset audit, and error-accounting tables	The same canonical headline traces	No	Paired re-aggregation and parser/adjudication sensitivity
Throughput, goodput, JCT, and fairness tables	Existing task, prompt, and preemption logs at the headline points	No	Read additional metrics from stored logs; no serving rerun
Naive-versus-corrected, eviction-depth, repeated-victim, and selection-livelock diagnostics	Existing task and preemption-event logs at the named diagnostic loads	No	Re-aggregate stored outcomes or event distributions
Entropy-predictor parameter table	Harness configuration, scheduler code, and calibration notes	No	Configuration audit; parameters were not independently snapshotted in trace metadata
Feasibility-floor sensitivity and capped-model intervention	Existing low-load native and capped-model traces	No for the camera-ready analysis	Re-score low-load elapsed outcomes at five deadlines and audit cap censoring
Llama-3.3-70B boundary control	Ten new default-policy cells (five loads on each dataset), one seed per cell	Yes (post-review)	Report as a negative/boundary control, not as a seven-policy comparison
Engine-stall verification	Same-seed reruns plus preserved original executions	Yes, as integrity reruns	Do not increase n; retain reproduced stalls as data and use the healthy execution when the same-seed pair does not reproduce the stall

censoring in Table 23.

The multi-SLO pattern remains operationally useful. At native context, R1D-Qwen's observed tail is 37.5% (AIME) and 43.2% (HLE) even at 1800 s; R1D-Llama's is 31.1% and 21.2%. Under the 32k/20k serving caps, all four model–dataset cells have zero observed misses at 1200–1800 s in their minimum-load runs, although they can miss tighter 600–900 s deadlines. This supports decode-budget control as an intervention for the *configured* 1800-s workload. It does not establish that truncation removes the model's natural long-output tail.

The minimum-load evidence is intentionally not over-aggregated. The "runs/seeds" column reports both execution repetitions and distinct Poisson seeds: several HLE pilot cells repeat seed 42, and the Nemotron-H and capped R1D-Llama minima have only one run. Some R1D minima also contain preemptions (Table 23), so their low-load miss rate is an operational floor estimate, not a contention-free single-stream measurement.

L.2 Decode-cap intervention and the Llama control

A decode cap and a natural length distribution play different roles. A cap above an SLO token budget merely *permits* an over-budget generation; a nonzero floor additionally requires probability mass in the natural runtime tail. Conversely, a cap below a nominal token budget truncates generation but does not prove that the uncapped tail is empty, nor does it guarantee a deadline under queueing or reduced batch throughput. Table 23 makes this explicit. The native R1D cells are deadline-censored

Table 12: Independent-split and all-splits estimates (mean and variant-level 95% CI; positive is worse for the row's first policy/cohort). Young is {LIFO, `smallest_kv`, learned remaining, decode-length oracle}; not-young is {`input_length`, `random`, `largest_kv`}. Cohort contrasts are formed within cell before averaging cells within variant.

Stratum	Comparison (pp)	Fixed 42–43 / 44–46	All 10 splits
Feasible	`largest_kv`−LIFO	$+4.52$ $[+2.46, +6.58]$	$+3.96$ $[+2.01, +5.90]$
Feasible	`input_length`−LIFO	$+4.43$ $[+2.40, +6.47]$	$+3.82$ $[+1.97, +5.67]$
Feasible	learned remaining−LIFO	$+2.92$ $[+0.87, +4.96]$	$+2.14$ $[+0.73, +3.54]$
Feasible	decode-length oracle−LIFO	$+2.43$ $[+0.88, +3.97]$	$+1.98$ $[+0.83, +3.12]$
Failed	`largest_kv`−LIFO	-4.23 $[-5.86, -2.59]$	-3.99 $[-5.69, -2.28]$
Failed	`smallest_kv`−LIFO	$+1.78$ $[+0.96, +2.60]$	$+2.21$ $[+1.53, +2.88]$
Feasible	Not-young − young	$+2.66$ $[+1.42, +3.90]$	$+2.42$ $[+0.93, +3.91]$
Feasible	`largest_kv` − `random`	-0.12 $[-1.66, +1.42]$	-0.17 $[-1.75, +1.42]$
Feasible	learned − decode-length	$+0.49$ $[-0.96, +1.95]$	$+0.16$ $[-0.84, +1.16]$

Table 13: Request-error sensitivity (fixed independent split; mean and variant-level 95% CI). Accepted-request scoring is primary: it removes only pre-service context-validation rejects, retains deadline timeouts and other accepted failures in both the eligible set and failure numerator, and invalidates replications containing infrastructure failures. The legacy column is included only to quantify the old parser's error treatment.

Stratum	Comparison (pp)	Accepted (primary)	End-to-end	Legacy parser
Feasible	`largest_kv`−LIFO	$+4.52$ $[+2.46, +6.58]$	$+4.19$ $[+2.26, +6.12]$	$+4.38$ $[+2.38, +6.38]$
Feasible	decode-length oracle−LIFO	$+2.43$ $[+0.88, +3.97]$	$+2.37$ $[+0.83, +3.91]$	$+2.38$ $[+0.96, +3.80]$
Failed	`largest_kv`−LIFO	-4.23 $[-5.86, -2.59]$	-4.06 $[-5.69, -2.43]$	-4.23 $[-5.84, -2.61]$
Feasible	Not-young − young	$+2.66$ $[+1.42, +3.90]$	$+2.53$ $[+1.31, +3.76]$	$+2.56$ $[+1.34, +3.77]$

on 21–42% of accepted requests, while the capped variants terminate 13–51% of accepted requests at the length cap. Both mechanisms hide the uncapped natural tail, but only the cap changes the deployed workload and removes its observed 1800-s misses here. All percentages exclude immediate HTTP 400 validation failures. In the HLE minimum-load cells, the excluded counts are one each for native R1D-Qwen and R1D-Llama, three for capped R1D-Qwen, and eleven for capped R1D-Llama; Nemotron-H has none. Table 22 reports the corresponding rejection count for every row.

We also swept Llama-3.3-70B-Instruct, the non-distilled base of R1D-Llama-70B, with default/LIFO on both AIME and HLE at $\lambda \in \{0.1, 0.2, 0.4, 0.8, 1.2\}$. Each of the ten cells is one run with Poisson seed 42 and task seed 42. Median stop lengths range from 811–861 tokens on AIME and 669–770 on HLE; no successful output hits the 130k decode cap, and the server records zero preemptions in all ten cells. Of 2317 offered requests per dataset, 2309 AIME and 2220 HLE requests return an observed stop. Eight AIME and two HLE requests are killed at 1800 s. Excluding immediate admission rejections, the observed tails are therefore $8/2317 = 0.35\%$ and $2/2222 = 0.09\%$: approximately zero, not exactly zero. A further 95 HLE requests are rejected before generation because `max_tokens` plus prompt length exceeds the 131,072 context limit; they are not completion outcomes. Accordingly, every *returned generation* stops naturally, but it would be incorrect to say that every offered request does.

This sweep is a boundary-condition check for the length-tail account, not a second causal matched pair for training recipe: the outputs are roughly an order of magnitude shorter, the cache never reaches the preemption path, and the victim selector is never exercised. Its large 130k cap together with its tiny observed deadline tail also directly refutes the stronger claim that "cap above budget" is sufficient to predict a floor.

Provenance. Table 22 is an unfiltered post-hoc re-scoring of the existing default-policy task traces; it adds no GPU runs. The Llama-3.3 sweep is a separate ten-cell control measurement. Exact paths, per-run values, outcomes, and censoring counts are generated by `analyses/floor_audit.py` and recorded in `analyses/floor_audit.json`.

M Cross-Model Drivers

The feasibility floor is a deadline-relative completion-time property. A request contributes to the natural floor when its single-stream completion time exceeds the evaluated SLO. Token length divided by effective decode rate is a useful approx-

Table 14: Mechanism decomposition for `largest_kv` minus LIFO under accepted-request scoring (percentage points; mean [95% CI]). Regimes use LIFO seeds 42–43; components use paired seeds 44–46. Cells are averaged within model–dataset variant and intervals are over equal-weight variant means. "Unfinished" denotes tracked requests aborted at the run cap; post-accept errors include scheduler deadline expirations. Pre-service validation rejects are excluded and replications containing infrastructure errors are invalidated. Positive values are worse for `largest_kv`.

SLO (s)	LIFO regime	Cells/variants	Δ late	Δ unfinished	Δ post-accept error	Δ total
600	deep >50%	179/18	−9.54 [−12.69, −6.38]	+3.08 [+0.57, +5.59]	+0.67 [−0.01, +1.34]	−5.79 [−7.49, −4.09]
900	deep >50%	158/18	−9.57 [−12.88, −6.25]	+2.87 [+0.05, +5.68]	+0.65 [−0.03, +1.33]	−6.05 [−8.17, −3.93]
1200	deep >50%	136/18	−9.27 [−13.37, −5.17]	+2.36 [−0.63, +5.36]	+0.75 [−0.04, +1.53]	−6.16 [−9.13, −3.18]
1500	deep >50%	102/17	−7.80 [−11.91, −3.70]	+1.21 [−2.31, +4.73]	+0.48 [−0.33, +1.29]	−6.12 [−8.42, −3.81]
1800	failed 30-50%	74/18	+0.00 [+0.00, +0.00]	+1.43 [−2.22, +5.08]	+0.58 [−0.07, +1.23]	+2.01 [−1.71, +5.73]
1800	deep >50%	44/15	+0.00 [+0.00, +0.00]	−0.62 [−5.31, +4.08]	+0.46 [−0.66, +1.57]	−0.16 [−4.74, +4.42]

Table 15: Completer-only late fraction versus accepted-request breach for a separate diagnostic at $\lambda \in \{0.055, 0.060\}$ requests/s, the upper end of this diagnostic window; these are not the headline λ^* cells. Values are unweighted means over five distinct seeds and the two arrival rates. The completer-only metric excludes cap-aborted accepted requests and therefore makes backlog-deferring policies look harmless; accepted breach includes that unfinished backlog. Pre-admission validation rejections are excluded from both metrics.

Cell	Policy	Completer-only%	Accepted breach%
QwQ AIME	`LIFO`	0.0	1.3
	`smallest_kv`	0.0	1.6
	`input_length`	0.0	8.7
	`largest_kv`	0.0	9.9

Table 16: Secondary metrics at the headline operating points, unweighted over 12 model–dataset cells. ΔT, ΔG, and JCT deltas are relative to LIFO; JCT is over successful completions. Fairness includes all accepted requests, including zero evictions. Gini concentration and the repeated-targeting tails answer different questions: LIFO and `smallest_kv` have the largest $E \geq 5$ tails, while input-length and largest-KV have the largest Gini coefficients. Accepted breach equals one minus normalized goodput G/A, not one minus goodput in requests/s. Full per-cell values are in Appendix I.

Policy	ΔT (req/s)	ΔG	Δp50 (s)	Δp99	Gini	$E \geq 2$ (%)	$E \geq 5$
`LIFO`	+0.000	+0.000	+0	+0	0.56	54	35
`smallest_kv`	-0.013	-0.013	+8	+10	0.56	55	35
`input_length`	-0.010	-0.010	-135	-73	0.83	22	10
`largest_kv`	-0.009	-0.009	-136	-71	0.78	12	2
`entropy`	-0.007	-0.007	-63	+1	0.47	56	13
`oracle`	-0.003	-0.003	-110	+5	0.54	52	11
`random`	-0.013	-0.013	-109	-16	0.60	27	1

imation, but neither a large context window nor a configured decode cap determines the realized tail. Qwen3-32B and R1D-Qwen-32B provide an associated matched-backbone contrast, but recipe and context budget remain confounded; we therefore do not infer that distillation alone causes the floor. The stronger intervention is within model: reducing the R1D decode budget removes configured 1800 s misses in the measured low-load cells. Conversely, the non-distilled Llama-3.3-70B control has a large context but short natural outputs, an approximately zero observed accepted-request 1800-s tail, and no preemption in its measured sweep. Appendix L.1 reports the multi-deadline comparison and Appendix L.2 documents this control. *Architecture modulates the anti-pattern penalty.* The `largest_kv`–LIFO gap is larger for several dense transformers than for Nemotron-H, whose Mamba layers carry no KV cache. This is consistent with a smaller KV-size lever, but the architecture comparison is observational rather than an isolated causal test.

N Additional Figures

Figure 3 shows the preemption-target progress mechanism behind Finding 1 on AIME. Figures 4 and 5 replicate the AIME breach-vs-load and preemption-target progress panels on HLE; they show the same qualitative cohort pattern on this more heterogeneous workload. Figure 6 details the `smallest_kv` selection livelock and Figure 7 the R1D-Llama feasibility floor at native context.

Table 17: Per-cell rates at the accepted-request/audited-canonical operating point. Each entry is accepted arrival rate / successful-completion throughput / on-time goodput, all in requests/s and averaged over reps. Throughput and goodput coincide here because no successful completion in these selected cells exceeded 1800 s; accepted deadline failures and cap-aborted requests still lower normalized goodput. All displayed entries use five canonical reps.

Table 19: Per-cell eviction fairness over all accepted tracked requests, including requests with zero evictions. Each entry is Gini(E) / $100\,\Pr(E \geq 2)$ / $100\,\Pr(E \geq 5)$, where E is cumulative eviction count; percentages and Gini coefficients are computed per rep and then averaged. A high Gini means eviction burden is concentrated, while the two tail fractions distinguish repeated targeting. All displayed entries use five canonical reps.

Table 20: Repeated preemption (GLM-Z1 AIME, $\lambda = 0.700$): fraction of requests evicted at least k times. `random` spreads evictions (almost none re-evicted); `largest_kv` concentrates on the largest computed prefixes (high Gini). LIFO and `smallest_kv` match at $\geq 5\times$, but the extreme tail diverges ($\geq 10\times$: 45% vs. 35%; the gap widens with k), the signature of the $\arg\min K_r$ starvation cycle that LIFO's admission-timestamp criterion avoids.

Policy	%≥5×	%≥10×	%≥15×	%≥20×	max	Gini
default (LIFO)	79	35	12	2	29	0.31
smallest_kv	80	45	17	3	31	0.31
random	2	0	0	0	7	0.29
largest_kv	9	2	1	0	26	0.42
entropy	47	9	1	0	43	0.28
oracle	38	11	2	0	30	0.26

Table 21: Empirical 1800-s low-load tail (default/LIFO at the minimum recorded λ). The tail is an unfiltered mean over available executions; N is the number of accepted generations after excluding immediate HTTP 400 context-limit rejections. A † marks one pilot run; ‡ marks five executions of the same Poisson seed (42), not five arrival seeds. Rejection counts, full provenance, and five-SLO sensitivity appear in Appendix L.1. It estimates the configured workload's low-load miss rate, not the uncapped natural-length tail: native R1D requests are deadline-censored, while the 32k/20k variants can end at their decode cap (Appendix L.2). Thus truncation removes the observed 1800-s misses in these cells, but does not show that the model's natural long-output tail vanished.

Table 22: Observed low-load deadline-miss rate (%, default/LIFO), post-hoc re-scored at five SLOs. For each model–dataset we use the minimum recorded arrival rate and report execution replicas/distinct Poisson seeds. N is the accepted-generation denominator; "Reject" counts immediate HTTP 400 context-limit validation failures, which are excluded rather than treated as zero-latency completions. Entries are unfiltered means over replicas: we do not apply the engine-stall filter because a persistent low-load tail is the quantity being measured. These are tails of *configured low-load elapsed time*, not estimates of the uncapped natural-length tail; cap and deadline censoring are audited in Table 23.

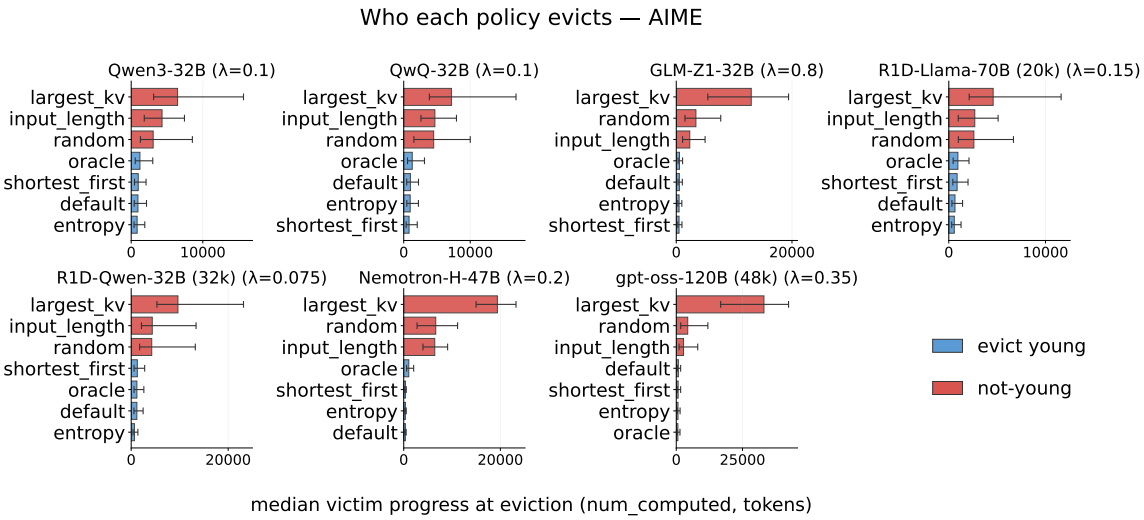

Figure 3: Median preemption-target progress at preemption per policy, all seven families, AIME (reported λ^* for each model); bars are the median preemption target's computed-prefix length (logged `num_computed`) and whiskers span the 25th–75th percentiles. Bars are colored by *cohort*: blue = evict-young (LIFO/entropy/oracle/`smallest_kv`), red = not-young (`input_length`/`random`/`largest_kv`). Bar *height* is eviction depth: within the not-young cohort `random` evicts at intermediate depth and `largest_kv`/`input_length` deepest, yet all breach worse than LIFO (Table 2)—it is the young-vs-not-young split, not graded eviction depth, that tracks breach. The anti-pattern is muted on Nemotron-H, where most layers carry no KV.

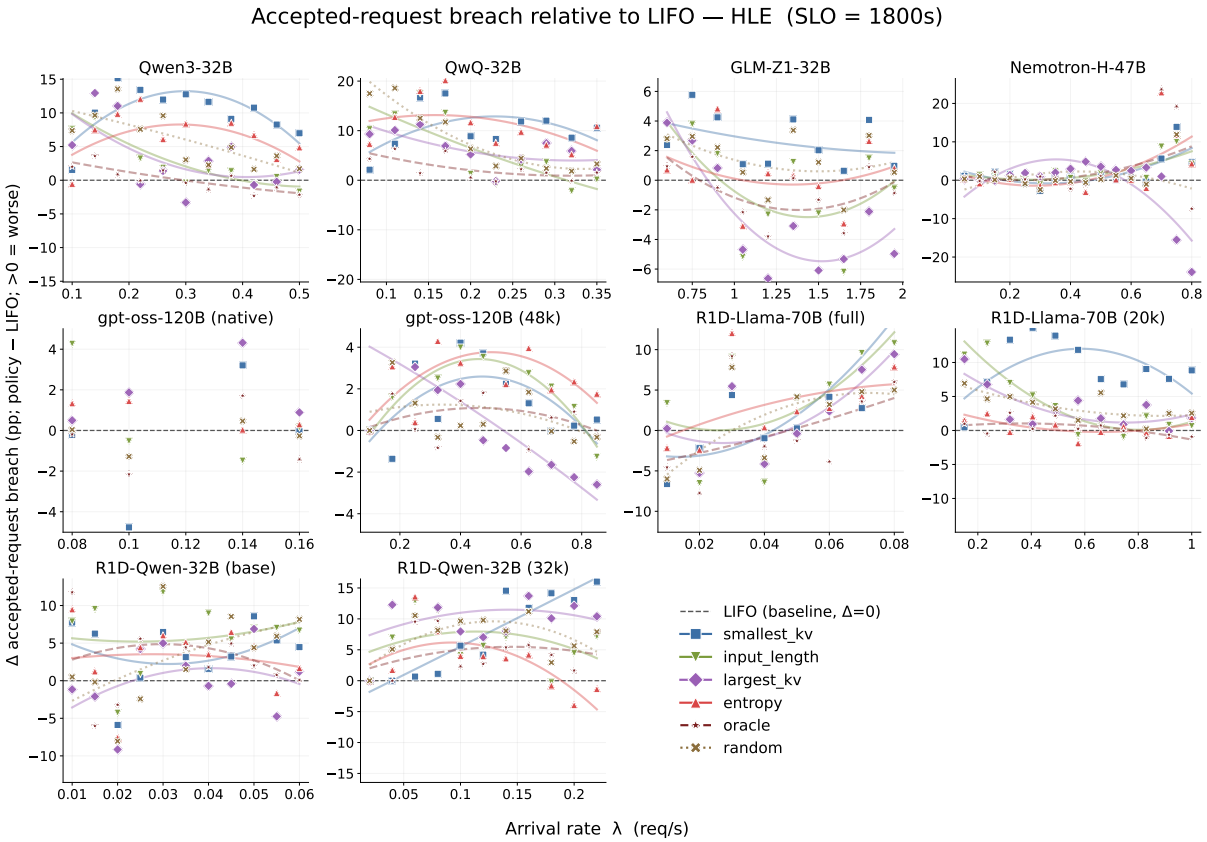

Figure 4: Accepted-request breach *relative to LIFO* (policy − LIFO; > 0 worse) vs. load, HLE, all model families and their truncated variants; LIFO is the dashed y=0 baseline. Companion to Figure 1; the same qualitative cohort split is visible on this more heterogeneous workload. Only complete load points with five audited arrival schedules are shown.

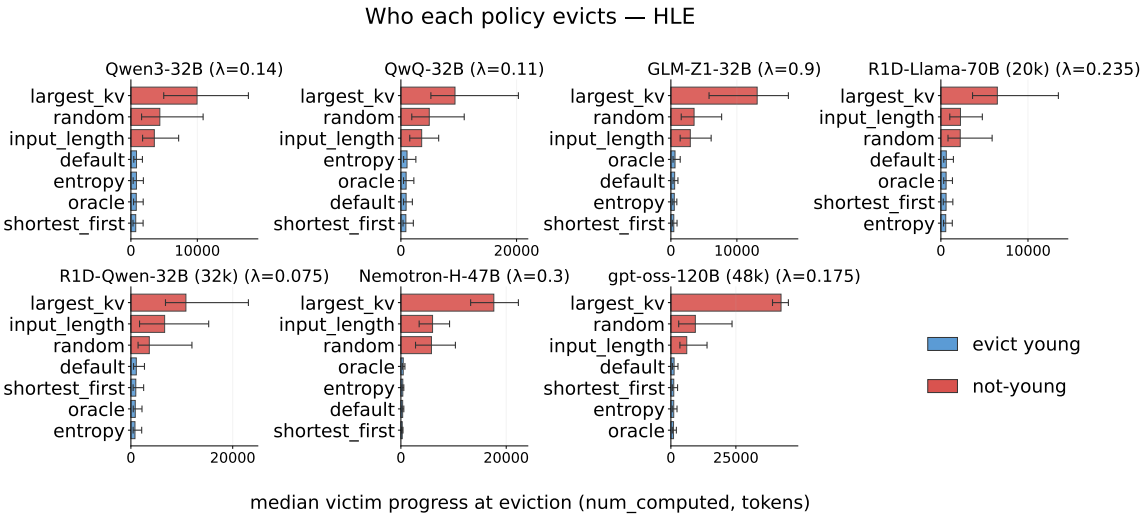

Figure 5: Median preemption-target computed-prefix length per policy, HLE (reported λ^* for each model; bar = median, whiskers = 25th–75th percentiles, color = eviction position). Companion to Figure 3.

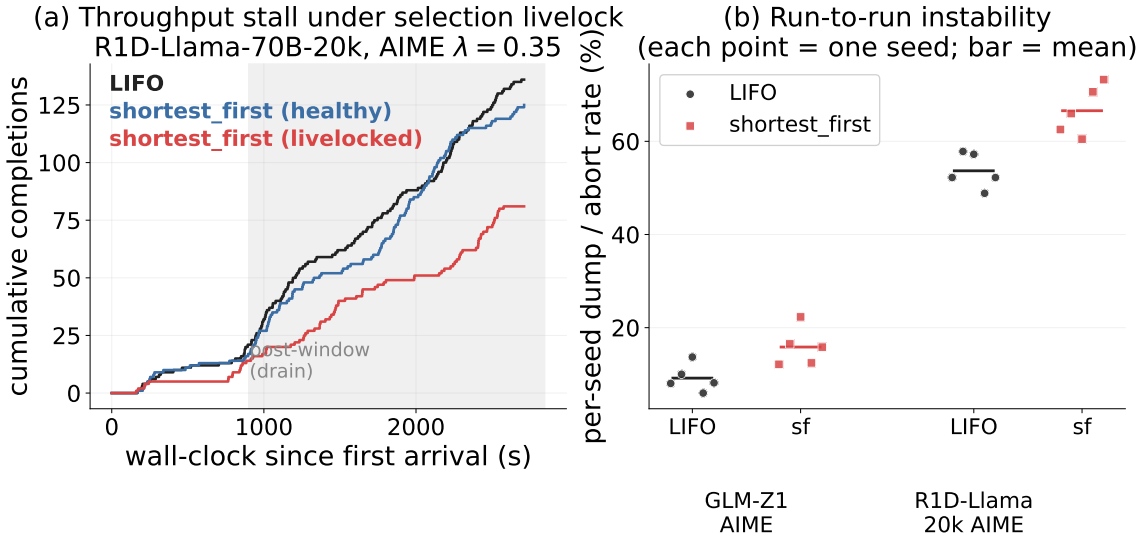

Figure 6: The `smallest_kv` selection livelock (R1D-Llama-70B, 20k budget, AIME). **(a)** Cumulative tracked completions vs. wall-clock: one `smallest_kv` seed enters selection livelock early (completion progress collapses to near zero) and finishes only ∼10 requests, while a healthy `smallest_kv` seed and LIFO progress steadily to ∼125–135. **(b)** Per-seed abort (dump) rate: LIFO is tight across seeds whereas `smallest_kv` has a heavy upper tail (a seed at 94%), in both a dense (GLM-Z1) and a memory-tight (R1D-Llama-20k) cell. The failure is run-to-run instability, not a per-event difference.

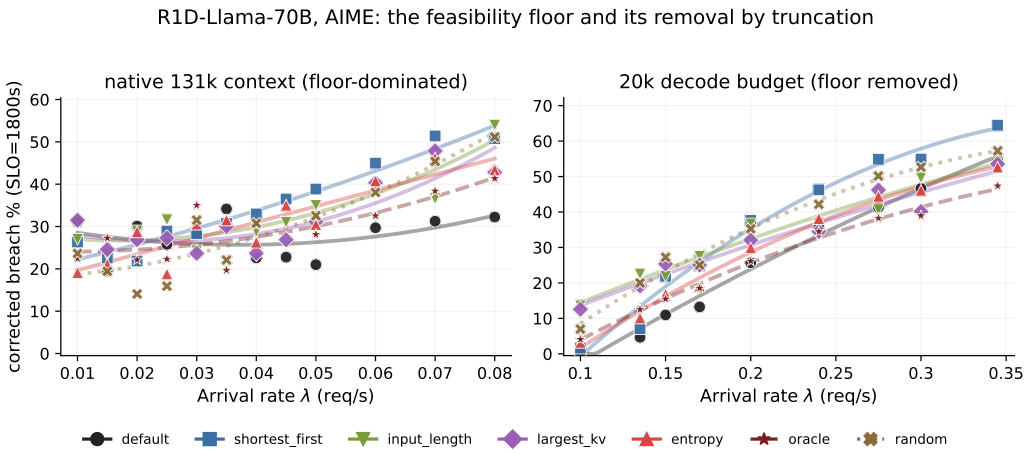

Figure 7: R1D-Llama-70B (AIME): the feasibility floor and its removal by truncation, in *absolute* corrected breach. Values are raw; the engine-stall protocol is not used to erase reproduced low-load breach. **Left, native** 131**k context:** breach is substantial already at near-idle load and roughly flat across the sweep—no policy escapes it, so the floor swamps any scheduling signal. **Right,** 20**k decode budget:** configured 1800 s misses disappear at low load and a scheduling regime emerges. LIFO is best at the 10%-crossing point; an isolated high-load oracle win and the broader deadline sensitivity are separated in §4.4.

When LLM Plans Fail: Solver-Verified Remediation Under Operational Constraints

Priyaranjan Pattnayak
Oracle America Inc.
priyaranjanpattnayak@gmail.com

Abstract

We study postmortem remediation planning for large-scale cloud incidents, focusing on whether generated actions comply with explicit operational constraints and are executable in practice. While LLM-based systems can produce structured corrective actions, we find that 25–35% of generated plans across 8,200 real-world incidents violate at least one encoded feasibility constraint due to hidden dependencies, policy limits, or risk budgets.

We introduce *Solver-Verified Remediation Planning (SVRP)*, a decision-centric framework that separates action proposal from feasibility verification. An LLM proposes candidate actions, which are checked against an explicit constraint system using satisfiability solving; inclusion-minimal diagnostic cores guide targeted repair or abstention. SVRP raises feasibility from 62.4% to 93.1%, reduces encoded risk and permission violations by more than 50%, and improves expert-rated executability from 3.7 to 4.7 while preserving semantic intent. These results suggest that remediation failures often reflect structural constraints that benefit from solver-backed verification in addition to improved prompting.

1 Introduction

Cloud outages are costly and operationally complex. While postmortem analyses help teams understand failures, a final step of producing *Corrective and Preventive Measures* (CAPM) that specify what actions should be taken, remains manual and difficult to scale (Ahmed et al., 2023; Chen et al., 2024). In practice, CAPMs must be actionable, role-appropriate and safe, yet are often inconsistent or infeasible under operational policies.

Recent work shows that LLMs can generate structured remediation actions from incident narratives (Lin et al., 2025; Huang et al., 2024). However, these systems are evaluated primarily as text generators, creating a mismatch: plans may be fluent yet *jointly infeasible* with real operational constraints due to hidden dependencies, role policies, or risk limits (Hao et al., 2025; Schick et al., 2023; Yao et al., 2023). Across 8,200 real-world incidents, 25–35% of LLM-generated plans violate at least one feasibility constraint, indicating failures driven by unmodeled action interactions rather than language errors.

We introduce *Solver-Verified Remediation Planning (SVRP)*, a decision-centric framework that separates action proposal from feasibility verification. An LLM proposes candidate actions, which are verified against an explicit operational constraint system using satisfiability solving. When plans are infeasible, minimal unsatisfiable cores guide targeted repair or principled abstention. SVRP avoids relying on LLMs to judge feasibility or safety.

Evaluated on 8,200 real-world incidents and a synthetic stress test, SVRP raises feasibility from 62.4% to 93.1%, reduces unsafe actions by more than 50%, and improves expert-rated executability from 3.7 to 4.7 (5-pt scale). These results show that failures in LLM-generated remediation are structural rather than linguistic, and benefit from explicit constraint reasoning beyond prompting alone.

Our Contributions.

- We identify and quantify a systematic gap between linguistically plausible remediation plans and plans that are feasible under real operational constraints.
- We introduce *Solver-Verified Remediation Planning (SVRP)*, that separates action proposal from decision-level feasibility using solver-based checking and unsatisfiable-core guided repair.
- We provide rigorous evaluation on 8,200 real-world incidents, demonstrating consistent improvements in feasibility, safety, and exe-

EMNLP 2026 Industry Track, pages 2453–2472

cutability across frozen and fine-tuned generators.

- We release a synthetic dataset (≈950 incidents) to enable reproducible analysis of interaction-level feasibility violations.

2 Related Work

Incident Management and Root Cause Analysis. Automating cloud incident management has focused primarily on *RCA*, identifying why failures occur rather than what actions should follow. Prior work uses fault patterns from incident tickets (Huang et al., 2024), causal inference (Chen et al., 2019), and fine-tuned LLMs (Ahmed et al., 2023; Chen et al., 2024); systems such as GPT-4-based RCA (Zhang et al., 2024) and RCACopilot (Chen et al., 2024) further demonstrate LLM-based diagnosis. However, these approaches typically stop at diagnosis or provide remediation suggestions without explicit feasibility or safety guarantees.

LLM-Based Action Generation for Operations. Prior work explores LLM-based action generation, including workflow synthesis (Qiao et al., 2025), retrieval-augmented dialogue generation (Shen et al., 2023), and cloud operations copilots (Lin et al., 2025). While these methods generate fluent remediation steps, they treat planning as text generation and do not ensure that action sets are jointly executable under operational constraints such as risk limits, permissions, and dependencies.

Verification and Constraint Checking with LLMs. LLM reliability work combines models with symbolic reasoning, formal solvers, self-critique, and verify-and-edit loops (Ye et al., 2023; Hao et al., 2025; Lee et al., 2025; Madaan et al., 2023; Zhao et al., 2023). Program repair similarly uses diagnostics to localize inconsistencies (Weimer et al., 2009). However, these approaches primarily target code or synthetic planning benchmarks and often reject or regenerate infeasible outputs rather than repairing operational action sets.

Positioning of This Work. We frame postmortem remediation as a *decision-level feasibility problem over action sets*, rather than a generation or validation task. LLMs are used only to propose candidate actions, while solver-based verification determines joint executability under explicit operational constraints. Unlike prior works, when plans are infeasible, unsatisfiable cores localize conflicts and enable targeted, constraint-preserving repair or abstention. This design supports reliable post-incident decision-making in settings where failures are structural rather than surface-level text quality.

3 Methodology

We address postmortem remediation as a decision problem over action sets, separating action proposal from feasibility verification. Our method, *Solver-Verified Remediation Planning (SVRP)*, uses LLMs to propose candidate actions and applies solver-based verification to ensure joint feasibility, safety, and executability under real constraints.

3.1 Problem Setting

Given an incident summary x, the goal is to produce a set of corrective and preventive actions $A = \{a_1, \ldots, a_n\}$ that can be jointly executed. A plan is valid only if it satisfies a fixed set of explicit operational constraints, including role permissions, risk limits, action dependencies, and verification requirements. All constraints are derived from standard postmortem practices, fixed prior to evaluation, reviewed by independent SRE and technical-program-management experts, and applied uniformly across all incidents, services, and baselines.

3.2 Action Proposal

For each incident, an LLM proposes candidate remediation actions conditioned on the incident summary and retrieved historical context. Actions are normalized into structured tuples (e.g., *type*, *role*, *scope*, *risk*, *dependencies*). The proposal stage is permissive and does not enforce feasibility. Each incident yields 6–12 actions (median 9), capped at 15 as a fixed guardrail on proposal length, normalization cost, and end-to-end latency. Details in Appendix A.2.1.

3.3 Feasibility Constraints

SVRP verifies action sets against four declarative constraint classes: (1) **Role**: actions must be assigned to permitted roles; (2) **Risk**: actions have fixed risk levels (low, medium, high) with severity-conditioned budgets; (3) **Dependency**: prerequisite and ordering requirements must hold; (4) **Verification**: each plan must include at least one verification step. All constraints are deterministic, LLM-independent, and specified in Appendix A.2.3.

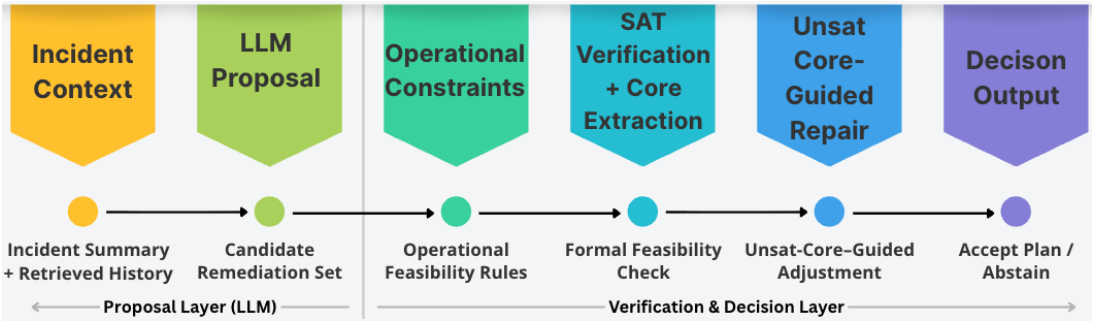

Figure 1: Overview of Solver-Verified Remediation Planning (SVRP)

3.4 Solver-Based Verification

Proposed actions and constraints are compiled into a propositional satisfiability (SAT) formulation, where each action a_i corresponds to a Boolean inclusion variable $z_i \in \{0, 1\}$. Constraints are encoded as hard clauses, including severity-conditioned constraints for high-risk actions.

We check feasibility with MiniSat 2.2, passing all proposed actions as positive assumptions so none can be silently dropped. A SAT result therefore confirms the selected plan against the encoded constraints. For UNSAT plans, we shrink the returned conflict to an inclusion-minimal diagnostic core, which is not necessarily the smallest possible core. Action ordering is checked separately using a deterministic validator. Solver settings and encodings are fixed across datasets (Appendix A.2.4).

3.5 Unsat-Core–Guided Repair and Abstention

When a plan is non-compliant, SVRP uses the diagnostic core to perform targeted, deterministic repair rather than discarding the plan. Repairs follow a fixed priority: (i) insert an available prerequisite from the proposal set, (ii) enforce ordering, (iii) substitute a lower-risk proposed alternative, and (iv) greedily remove a core action. Repair is limited to two iterations to guard against semantic drift; if feasibility cannot be restored, SVRP abstains. Details in Appendix A.2.5.

3.6 Experimental Setup

We evaluate SVRP on 8,200 real-world incidents spanning 36 months and a synthetic dataset of 950 incidents designed to induce interaction-level feasibility violations. We compare against generation-only, rule-based filtering, LLM-based validation, constrained LLM generation, constrained LLM rewriting, and a fine-tuned generator baseline.

Cohere Command-R+ is used for proposal, validation, and constrained prompting (identical decoding), and a fine-tuned Mixtral-8x22B model serves as a stronger generator baseline. Human evaluation is conducted on disagreement cases.

Deterministic vs. Learned Components. All constraints, solver checks, diagnostics, and repair operations are deterministic. In SVRP, LLMs are used only for proposing actions and are never used for feasibility validation or repair.

4 Evaluation

We evaluate SVRP as a *decision system*, not a text generator, focusing on feasibility, safety, executability, and repair under explicit operational constraints. Metrics are computed deterministically from structured action representations.

We test robustness across frozen (Cohere Command-R+) and fine-tuned (Mixtral-8x22B) generators. Surface text metrics (e.g., BLEU, BERTScore, groundedness) are reported in the appendix but are secondary, as they do not measure executability or constraint satisfaction. Human evaluation assesses real-world decision quality.

4.1 Baselines

All prompts are provided in Appendix A.4.

Generation-only. Accepts the LLM-proposed action set without feasibility checking or repair.

Rule-based filtering A deterministic baseline that greedily removes actions violating local constraints (unauthorized roles, severity-dependent risk limits, duplicate scope, or missing verification). Rules are applied until no violations remain or all actions are removed. It performs no global reasoning, dependency insertion, or minimal repair.

LLM-based validation and rewriting. Uses Cohere Command-R+ (temperature 0.2, top-p = 0.75) to rewrite proposed plans without access to

explicit constraints, solver diagnostics, or unsatisfiable cores, reflecting common prompt-based validation approach using implicit reasoning.

Constrained LLM generation. Uses the same LLM and configuration, but provides the model with the operational rules used by SVRP: the action vocabulary, role permissions, severity-conditioned risk budgets, dependency requirements, and mandatory verification requirement. The model generates a revised plan directly, without solver feedback or symbolic repair.

Constrained LLM rewrite. Uses the same explicit operational rules as constrained generation, but applies them as a post-processing rewrite over the original proposed plan. This baseline tests whether prompt-level access to the constraints is sufficient to repair infeasible plans without unsatisfiable cores or deterministic solver-guided edits.

Fine-tuned generator baseline: A Mixtral-8x22B-Instruct model fine-tuned with LoRA on a separate historical pool of 8,200 incident–CAPM pairs, split 6,560/820/820 by incident. No pair overlaps the 8,200 evaluation incidents; Appendix A.2.2 details deduplication and retrieval separation. The model generates plans from incident summaries without retrieval or feasibility enforcement.

4.2 Feasibility and Verification Metrics

Let $\mathcal{P} = \{P_i\}_{i=1}^{N}$ denote remediation plans and $\mathcal{C}$ the fixed constraint set. All feasibility metrics are computed using the same constraint checker:

SAT Rate (%): fraction of plans satisfying all constraints.

$$\text{SAT} = \frac{1}{N} \sum_{i=1}^{N} \mathbb{I}[P_i \models \mathcal{C}],$$

where $\mathbb{I}[\cdot]$ indicates all constraints satisfied.

Repair-SAT Rate (%): % of initially infeasible plans repaired to satisfiable with bounded repair.

UNSAT Rate (%): fraction of plans remaining infeasible after repair.

Unsat Core Size: mean size of deletion-shrunk, inclusion-minimal diagnostic cores for infeasible plans.

Constraint Coverage: average number of distinct constraint classes (role, risk, dependency, verification) exercised during checking or repair.

Higher SAT rates and constraint coverage indicate better handling of interactions represented in the declared policy; they are not universal safety estimates.

4.3 Safety and Executability Violations

We quantify specific failure modes prior to verification using deterministic checks on structured actions: 1) **Risk Violations (%)**: % of plans containing actions whose cumulative risk exceeds severity-dependent budgets. 2) **Permission Violations (%)**: % of plans containing actions assigned to unauthorized roles. 3) **Dependency Violations (%)**: % of plans with missing prerequisites or invalid action ordering. 4) **Missing Verification (%)**: % of plans lacking any explicit validation or verification step. These metrics capture policy violations relevant to safety that cannot be detected via surface-level text similarity.

4.4 Repair Behavior

To rule out trivial deletion, we analyze repair behavior on initially infeasible plans:

Average Repair Edits: mean number of atomic edits (insert, delete, reorder, substitute).

Non-Deletion Rate (%): fraction of repairs achieving feasibility without deleting actions.

Semantic Retention: cosine similarity between sentence embeddings of original and repaired plans, computed using `all-MiniLM-L6-v2`.

4.5 Coverage and Abstention

Because SVRP may abstain when no feasible repair exists, we report: **Coverage (%)**, the fraction of incidents with a feasible plan, and **Quality-at-Coverage**, executability and safety measured at fixed coverage levels. This prevents inflating quality through excessive abstention and reflects realistic deployment tradeoffs.

4.6 Human Evaluation

We conduct human evaluation on 300 cases sampled from the 2,180-incident disagreement pool (26.6% of evaluation incidents), where SVRP differs from generation-only, LLM-based validation, or constrained LLM rewriting. The study estimates comparative quality when methods differ, not full-population quality. Two domain experts (senior SREs) independently rate every anonymized plan (Cohen's κ) given the incident summary and retrieved context for:

Technical Correctness (1–5): Is the plan valid and safe given the incident context?

Table 1: Encoded-policy compliance and violation rates across mechanisms.

Method	SAT%	Risk	Perm.	Dep.	Miss. Ver.
Gen-only	62.4	18.9	14.3	21.7	26.4
Rule-based	81.2	6.4	5.9	13.2	11.8
LLM validation	76.8	8.7	7.1	15.6	14.2
Constr. LLM gen.	82.1	5.9	4.8	12.7	9.6
Constr. LLM rewrite	86.3	4.9	3.9	10.7	8.1
SVRP (Ours)	**93.1**	**1.8**	**2.3**	**4.9**	**3.7**

Executability (1–5): Can the plan be realistically implemented as written?

Adoption Likelihood (1–5): Would the expert adopt this plan in a real postmortem?

Preference: Which plan would the expert choose overall?

5 Results

We organize results around five questions: (i) do plans satisfy operational constraints, (ii) how are infeasible plans repaired, (iii) do gains arise from abstention, (iv) human preference, and (v) are gains robust to generator strength?

5.1 Feasibility and Safety of Remediation Plans

Table 1 compares SVRP against generation-only, rule-based filtering, unconstrained LLM validation, and constraint-aware LLM baselines. Generation-only plans are frequently infeasible (62.4% SAT), with high risk, permission, dependency, and missing-verification violations. Rule-based filtering improves feasibility (81.2% SAT) primarily through deletion, while unconstrained LLM validation reaches 76.8% SAT.

Providing the LLM with explicit operational rules improves performance substantially: constrained generation reaches 82.1% SAT, and constrained rewriting reaches 86.3% SAT. SVRP achieves the highest encoded-policy compliance (93.1%) and the lowest violation rates across all categories. Dependency and missing-verification violations show similar reductions (Appendix A.5.1), confirming that many failures involve structural interactions. Over 80% of initially infeasible SVRP plans are repaired, with small diagnostic cores indicating localized conflicts (Appendix Table 12).

Constraint Coverage. Generation-only plans trigger 1.3 constraint types per incident on average, compared to 3.8 under SVRP (Table 2), indicating that gains arise from resolving multi-constraint interactions rather than trivial single-constraint cases.

Table 2: Repair behavior (on initially infeasible plans) and constraint coverage across methods. Repair metrics apply only to methods that perform repair.

Method	Avg. Edit	Non-Del.	Sem. Ret.	Const. Cov.
Gen-only	–	–	–	1.3
Rule-based	2.6	9.4	0.71	2.1
LLM rewrite	3.1	54.2	0.78	2.4
Constr. rewrite	2.4	68.7	0.83	3.2
SVRP (ours)	**1.4**	**82.7**	**0.89**	**3.8**

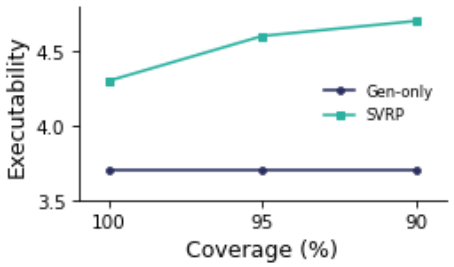

Figure 2: Coverage–executability tradeoff

5.2 Repair Behavior and Minimality

Table 2 shows that rule-based filtering achieves feasibility mainly through deletion, while LLM rewriting preserves more content but requires more edits and can introduce semantic drift. While constrained rewrite improves in both, it still lags SVRP. SVRP performs the fewest edits (1.4), achieves the highest non-deletion rate (82.7%), and best preserves intent (0.89 semantic retention). Robustness to embedding is also seen as results remain consistent with MPNet embeddings (Appendix A.5.2).

5.3 Coverage–Quality Tradeoff

Because SVRP may abstain when no feasible repair exists, we analyze quality as a function of coverage. Fig. 2 shows that even at 100% coverage, SVRP outperforms generation-only in executability. Allowing modest abstention (5–10%) yields further gains without major coverage loss, indicating that improvements stem from feasibility enforcement rather than aggressive abstention.

5.4 Human Preference and Adoption

In 300 disagreement cases, experts preferred SVRP plans 54% of the time, versus 24% for constrained LLM rewrite and less for other baselines (Table 4). SVRP also achieved the highest correctness and executability scores, with substantial agreement ($\kappa = 0.69$). All human-evaluation metrics had 95% confidence intervals within ± 0.12 (Appendix A.5.5).

Table 3: SVRP feasibility and safety across service domains.

Service Category	**Incidents**	**SAT (%)**	**Risk Viol. (%)**	**Perm. Viol. (%)**	**Non-Deletion (%)**
Compute & Infrastructure	1404	93.8	1.6	2.1	84.2
Database Services	895	92.9	1.9	2.4	82.7
AI & ML Services	1105	92.1	2.3	2.8	80.4
API & Identity Services	997	93.4	1.7	2.2	83.1

Overall (Weighted)	**8,200**	**93.1**	**1.8**	**2.3**	**82.7**

Table 4: Human evaluation on disagreement cases.

Method	Correctness	Executability	Preferred %
Gen-only	3.9	3.7	10
LLM validation	4.1	4.0	12
Const. LLM rewrite	4.3	4.2	24
SVRP (Ours)	**4.6**	**4.7**	**54**

Table 5: Ablation results isolating SVRP components.

Variant	SAT	Avg. Edits	Non-Del.	Execut.
SVRP (Full)	**93.1**	**1.4**	**82.7**	**4.7**
w/o Solver Verif.	62.8	0.0	100.0	3.8
w/o Diagnostic Repair	88.6	2.9	56.4	4.1
Deletion-Only Repair	90.2	2.6	9.4	3.9

5.5 Robustness Across Generators and Domains

SVRP's gains are consistent across generator strengths. As shown in Table 6, stronger generators improve proposal quality, and explicit constraint prompting further improves feasibility. However, both frozen and fine-tuned generators remain below SVRP after constraint-aware prompting.

Table 3 shows similar gains across heterogeneous service domains, with SAT rates above 90% even in smaller or specialized categories. This suggests that solver-verified planning generalizes across diverse operational constraints rather than relying on domain-specific artifacts.

5.6 Ablation Studies

We ablate core SVRP components to identify what drives feasibility and executability gains (Table 5).

Removing solver verification reduces feasibility from 93.1% to 62.8%, revealing widespread interaction-level violations. Deletion-only repair restores feasibility but causes major content loss (9.4% non-deletion; executability 3.9), whereas full SVRP achieves high feasibility, minimal edits, and superior executability. Thus, global enforcement provides the principal compliance gain, while diagnostic cores improve localization and preservation (Appendix A.5.4).

Table 6: Feasibility across generator strengths.

Generator	**Gen-only SAT%**	**Constrained Gen. SAT%**	**SVRP SAT%**
Frozen LLM	60.8	82.1	**92.7**
Fine-tuned Mixtral	68.9	87.4	**94.1**

5.7 Synthetic Dataset Validation and Generation Quality

We evaluate SVRP on a released synthetic dataset of 950 incidents designed to induce dense multi-constraint conflicts. SVRP maintains high feasibility and non-deletion rates, while generation-only and heuristic baselines degrade substantially (Appendix A.5.7), indicating that gains are not driven by dataset-specific regularities.

Generation Quality. For completeness, we report surface-level proposal metrics (BLEU, BERTScore, etc.) in Appendix A.5.6. They show no degradation relative to generation-only baselines, confirming that improvements stem from decision-level verification rather than generation.

5.8 Error Analysis

Across real-world incidents, 6.9% of plans remain non-compliant after bounded repair and are routed to manual review, mainly because of (i) proposal incompleteness, (ii) unavailable admissible substitutions, and (iii) missing or unparseable verification steps. Solver-related failures are rare ($<$1.2%), indicating that most residual errors originate in proposal generation rather than verification or repair (Appendix A.6). Pilot deployment showed high feasibility and adoption (Appendix A.1).

6 Conclusion

We introduced Solver-Verified Remediation Planning (SVRP), a decision-centric framework that separates action proposal from feasibility verification in postmortem remediation. By combining LLM-based generation with solver-backed constraint checking and diagnostic-core-guided repair, SVRP produces plans with substantially higher encoded-policy compliance and expert-rated executability than generation-only or heuristic baselines.

Across 8,200 real-world incidents and a synthetic test set, SVRP raises encoded-policy compliance from 62.4% to 93.1%, minimizes destructive edits, and is preferred by experts in 54% of disagreement cases. Results suggest that many failures in LLM-generated remediation stem from unmet operational constraints rather than prompting alone. Broadly, SVRP demonstrates how solver-backed decision mechanisms can complement LLMs in safety-critical planning while retaining human approval.

Limitations

SVRP has several limitations. First, it relies on a fixed action vocabulary and predefined constraint set. While this enables rigorous feasibility verification, it limits coverage for incidents requiring novel or specialized remediation; SVRP does not invent new actions and may abstain when proposals are incomplete.

Second, risk modeling is intentionally coarse. Action-level risk labels and severity-conditioned budgets abstract contextual nuances (e.g., partial rollbacks or scoped deployments), which can block feasible plans in rare cases.

Third, the SAT result certifies consistency only with the 47-action vocabulary and encoded role, risk, dependency, and verification rules. It does not cover omitted topology, maintenance-window, regulatory, causal-sufficiency, or blast-radius constraints. The normalization audit in Appendix Table 7 quantifies this model boundary; organizations must validate and maintain their own policy before deployment.

Finally, solver-based verification introduces computational overhead, though empirical solve times remain well within practical limits for offline postmortem analysis.

SVRP is intended as decision support rather than autonomous execution; human review remains necessary before adopting remediation plans, especially when incident context or operational constraints are incomplete.

Future work includes richer action vocabularies, hierarchical risk models, and hybrid symbolic–learned constraint extraction.

Ethical Considerations

SVRP is decision support, not autonomous execution. Operators see the proposed plan, violated constraints, repair, and abstention status; every emitted plan requires human approval, and unresolved cases return to manual review. This is important because encoded-policy compliance can create automation bias despite omitted context. Real incident narratives remained access-restricted; identifiers and sensitive details were removed before processing, and only deidentified text was sent to the external LLM provider. We report aggregate results and release only synthetic incidents. Deployment should include access controls, immutable decision logs, coverage monitoring, and periodic expert review of the action vocabulary and policy mappings.

A Appendix

A.1 Deployment and Operational Characteristics

SVRP was piloted within our enterprise ticketing workflow beginning May 2025, automatically generating remediation plans for approximately 200 Severity-1/2 incidents per month during evaluation.

End-to-end processing time remained under three minutes, including proposal, verification, and repair. During the pilot, 56% of plans were adopted unchanged, 29% after edits, 10% were rejected, and 5% were system abstentions. Among solver-SAT plans, 1.9% were rejected because of omitted operational context, illustrating the boundary of encoded-policy compliance. Abstentions and rejections returned to manual CAPM review.

In the offline evaluation, 6.9% remained non-compliant after bounded repair (7.1% of Severity-1 and 5.6% of Severity-2 cases) and were likewise routed to manual review rather than labeled feasible. The separate 4.8% expert false-acceptance audit (Appendix A.5.5) measures omitted context among solver-SAT plans and is not included in SAT.

Operational monitoring tracked compliance rates and validator outputs to detect drift. During the pilot, five vocabulary updates and two policy-mapping updates required approximately three expert-hours per month. These figures measure ongoing maintenance; initial policy setup for a new organization was not measured, and we do not claim zero-shot transfer.

A.2 Implementation Details of Solver-Verified Remediation Planning

This appendix provides implementation-level details for each component of SVRP, corresponding directly to the methodology described in Section 3. All components described here are deterministic unless explicitly stated otherwise.

A.2.1 Action Proposal and Normalization

SVRP uses large language models (LLMs) only to propose candidate remediation actions. The proposal stage is intentionally permissive and does not enforce feasibility, safety, or executability constraints.

LLM Generators. Unless otherwise stated, candidate actions are generated using **Cohere Command-R+**, accessed via API with fixed decoding parameters: temperature $T = 0.2$, top-$p = 0.75$, and maximum output length of 512 tokens. These settings favor factual consistency and conservative action proposals and are identical to those used in our prior PAG system.

Identifiers and sensitive operational fields were removed internally before model access; only deidentified incident text was sent to Cohere, while raw records remained in the access-restricted enterprise environment.

For experiments involving a fine-tuned generator baseline (Section 4.1), we use **Mixtral-8×22B-Instruct**, fine-tuned via parameter-efficient LoRA adaptation on incident→CAPM pairs. This model directly generates remediation plans end-to-end and does not use retrieval or feasibility verification.

Prompting and Output Format. LLMs are prompted to generate a list of corrective and preventive actions given: (i) the incident summary and (ii) a small number of retrieved historical postmortems for contextual grounding. The prompt requests concise, imperative action statements but imposes no structural constraints. No prompts instruct the model to reason about feasibility, risk budgets, or dependencies.

Candidate Set Size. Each incident yields between 6–12 candidate actions (median 9).

The number of proposed actions is capped at 15 as a fixed guardrail on proposal length, normalization cost, and worst-case end-to-end latency, not because of MiniSat capacity. This cap is fixed across all experiments and baselines. Median/p95 SAT latency is 4.1/19.6 ms; fewer than 0.5% of instances reach the 200 ms timeout.

Normalization. LLM outputs are converted into structured action representations using deterministic post-processing. Each action is normalized into a tuple:

$$a_i = (\texttt{type}, \texttt{role}, \texttt{scope}, \texttt{risk}, \texttt{deps})$$

Parsing Pipeline. We apply a rule-based normalization pipeline consisting of: (i) sentence segmentation, (ii) keyword-based action type matching, (iii) role extraction using a fixed role lexicon (e.g., SRE, on-call engineer, service owner), (iv) scope normalization using service identifiers, and (v) de-

Table 7: Double-annotated normalization audit (500 actions). The 2.1% action-level parse-failure rate is distinct from the corpus-wide 2.3% proposal-level rate.

Audit metric	Result (%)
Mapped / OOV or ambiguous / parse failure	93.1 / 4.8 / 2.1
Type / role / scope accuracy	95.3 / 96.1 / 90.6
Dependency F1 / tuple exact match	88.2 / 87.3
Gold-vs.-parsed SAT disagreement	4.6

pendency detection via trigger phrases such as *"after"*, *"requires"*, and *"once deployed"*.

Actions that cannot be parsed into a valid tuple are discarded. Across the full dataset, parse failures occurred in 2.3% of proposals.

Action Vocabulary. Action types are drawn from a fixed vocabulary of 47 remediation primitives (e.g., `add_monitoring`, `rollback`, `increase_quota`, `update_config`, `restart_service`). This vocabulary was derived from historical postmortems and fixed prior to evaluation.

Separation from Verification. All normalization, parsing, and action vocabulary mappings are implemented as deterministic code. LLMs are not used to assign risk labels, detect dependencies, validate permissions, or enforce feasibility. These decisions are deferred entirely to solver-based verification (Section A.2.4).

A.2.2 Data Separation and Governance

The Mixtral LoRA corpus is a separate historical pool of 8,200 incident–CAPM pairs, split 6,560/820/820 by incident; none overlaps the 8,200 evaluation incidents. Normalized-text MinHash removes near duplicates at Jaccard similarity > 0.85. Retrieval is restricted to records preceding the target incident and cannot retrieve the target postmortem or CAPM. Confidential narratives cannot be released; the public artifact contains 950 synthetic incidents (505 Severity-1 and 445 Severity-2) across nine service categories and 7,589 CAPM actions, together with the schema and prompts.

A.2.3 Constraint Definitions and Exact Encoding

SVRP enforces a fixed, deterministic set of feasibility constraints. All constraints are applied uniformly across datasets, services, and baselines and are independent of the LLM used for action proposal.

Table 8: Action-to-role permission mapping (fixed across all experiments).

Action Type	Permitted Roles
`add_monitoring`	{SRE, ServiceOwner}
`update_config`	{SRE, ServiceOwner}
`rollback`	{SRE}
`restart_service`	{SRE, OnCall}
`increase_quota`	{ServiceOwner, Manager}
`deploy_fix`	{Developer, ServiceOwner}
`approve_deployment`	{Manager}
`security_audit`	{Security}
`post_incident_review`	{Manager, SRE}

Table 9: Action-to-risk mapping.

Risk Level	Action Types
Low	add_monitoring, alert_tuning, logging
Medium	update_config, restart_service, increase_quota
High	deploy_fix, rollback, data_migration

Role Universe. We define a closed set of operational roles:

$$\mathcal{R} = \{\texttt{SRE}, \texttt{ServiceOwner}, \texttt{Developer}, \texttt{Manager}, \texttt{Security}, \texttt{OnCall}\}$$

No other roles are permitted in any plan.

Role Constraints (Exact Mapping). Each action type is associated with a fixed, predefined set of permitted roles. Let $\texttt{role}(a_i)$ denote the assigned role of action a_i. An action is valid only if:

$$\texttt{role}(a_i) \in \mathcal{R}_{\texttt{type}(a_i)}$$

Table 8 shows the complete action-to-role mapping used in all experiments.

Assignments outside the permitted role set are forbidden and encoded as hard SAT clauses.

Risk Constraints. Each action type is deterministically mapped to a risk level:

$$\texttt{risk}(a_i) \in \{\texttt{low}, \texttt{medium}, \texttt{high}\}$$

Risk levels are fixed and defined by action semantics, not learned. The complete mapping is shown in Table 9.

Incident severity determines the maximum allowable number of high-risk actions:

$$\sum_{a_i \in A} \mathbb{I}[\texttt{risk}(a_i) = \texttt{high}] \leq B(s)$$

where $B(s)$ is a fixed budget:

$$B(s) = \begin{cases} 0 & \text{low severity} \\ 1 & \text{medium severity} \\ 2 & \text{high severity} \end{cases}$$

These constraints are encoded as cardinality constraints in SAT using sequential-counter encodings.

Dependency Constraints. Dependencies are represented as directed prerequisites. If action a_i depends on a_j, then:

$$z_i \rightarrow z_j$$

which enforces prerequisite inclusion. Plans also retain sequence positions, and a deterministic validator enforces execution precedence:

$$\text{pos}(a_j) < \text{pos}(a_i).$$

This precedence check is separate from the CNF implication; the implication alone does not encode temporal order. Dependencies are extracted deterministically during normalization using fixed trigger patterns (e.g., "after deployment", "requires rollout").

Verification Constraints. Each plan must include at least one verification action:

$$\sum_{a_i \in A} \mathbb{I}[a_i \in \mathcal{V}] \geq 1$$

where:

$$\mathcal{V} = \{\texttt{add_monitoring}, \texttt{validation_check}, \texttt{canary_test}, \texttt{rollback_plan}\}$$

Plans violating this constraint are infeasible.

Summary. All constraints are: (i) explicitly defined, (ii) deterministic, (iii) fixed prior to evaluation, (iv) uniformly applied across all datasets and baselines, and (v) enforced solely via solver logic rather than learned models.

The schema and mappings were independently reviewed by expert SREs and technical program managers; this validates policy fidelity, not completeness under unmodeled context.

A.2.4 SAT Encoding and Solver Implementation

SVRP formulates feasibility verification as a propositional satisfiability (SAT) problem. All encodings are deterministic and symbolic; no learned models or neural components are used for constraint checking, diagnosis, or repair.

Variables. Each candidate action a_i is associated with a Boolean variable $z_i \in \{0, 1\}$, where $z_i = 1$ indicates that action a_i is included in the final remediation plan. No additional latent variables are introduced beyond selector and cardinality-encoding variables. During the initial check, every proposed action is passed as a positive assumption literal z_i; therefore, the solver cannot obtain SAT by silently dropping an action. No language models, embeddings, or learned predictors are involved at this stage.

Constraint Encoding. All feasibility constraints are compiled into conjunctive normal form (CNF) as follows:

- **Role Constraints.** Each action type is associated with a fixed set of permitted roles (`SRE`, `ServiceOwner`, `Manager`, `Security`, `Developer` and `OnCall`). For any action a_i whose extracted role is not in its permitted role set, a hard clause $\neg z_i$ is added, forbidding inclusion of that action.

- **Risk Constraints.** Actions are partitioned into disjoint risk classes $\{\mathcal{A}_{\text{low}}, \mathcal{A}_{\text{medium}}, \mathcal{A}_{\text{high}}\}$ using a fixed mapping from action type to risk level. For each incident severity level, a maximum allowable count k of high-risk actions is specified. The constraint $\sum_{a_i \in \mathcal{A}_{\text{high}}} z_i \leq k$ is encoded using a sequential-counter cardinality encoding and translated into CNF.

- **Dependency Constraints.** For each dependency relation $a_i \rightarrow a_j$ (meaning a_i requires a_j to be executed first), an implication clause $(\neg z_i \vee z_j)$ is added. This clause enforces inclusion of a_j, not precedence. A deterministic sequence validator separately checks $\text{pos}(a_j) < \text{pos}(a_i)$ and attaches any ordering violation to the same diagnostic and repair workflow.

- **Verification Constraints.** A fixed set $\mathcal{V}$ of verification actions (e.g., `add_monitoring`, `add_alert`, `run_validation`) is defined. To ensure that every plan includes at least one verification step, a single disjunctive clause $\bigvee_{a_i \in \mathcal{V}} z_i$ is added.

All constraints are hard constraints; no soft clauses or optimization objectives are used.

Solving and Unsatisfiable Cores. We use MiniSat 2.2 under selector assumptions. For each incident, the solver checks the constructed CNF while assuming all currently selected action literals are true.

- If the instance is satisfiable, the selected remediation plan is compliant with the encoded constraints; unmodeled operational safety remains outside this guarantee.
- If unsatisfiable, MiniSat returns a conflict subset over selector assumptions. We apply deterministic deletion-based shrinking until no remaining selector can be removed while preserving UNSAT. The result is inclusion-minimal, not guaranteed to have minimum cardinality.

The solver is invoked with a per-instance timeout of 200 ms. Across all experiments, fewer than 0.5% of instances exceed the timeout and are conservatively treated as infeasible. Median/p95 SAT latency is 4.1/19.6 ms, and median/p95 diagnostic-repair latency is 23.6/88.3 ms. SAT encoding, solver calls, conflict shrinking, sequence validation, and repair are deterministic; no language models, embeddings, or learned predictors are used in these stages.

A.2.5 Unsatisfiable-Core–Guided Repair

SVRP repairs infeasible remediation plans using unsatisfiable cores returned by the SAT solver. All repair operations in SVRP are performed by a deterministic repair module implemented as program logic.

Unsatisfiable Core Representation. For an infeasible plan, MiniSat's assumption conflict is deletion-shrunk to a small, inclusion-minimal diagnostic core

$$C = \{c_1, \ldots, c_m\},$$

where each element c_k corresponds to either: (i) an action inclusion variable z_i, or (ii) a constraint clause involving one or more actions. Each core element is traceable to the originating action(s) via solver bookkeeping.

Repair Candidates. From the unsatisfiable core C, we derive a candidate action set

$$A_C = \{a_i \mid z_i \in C \text{ or } a_i \text{ appears in a violated clause in } C\}.$$

Only actions in A_C are considered for modification; all other actions are left unchanged.

Repair Operations: Repairs are applied using a fixed, ordered set of operators designed to preserve plan semantics:

1. **Prerequisite Insertion.** If C contains a violated dependency constraint of the form $a_i \rightarrow a_j$ with $z_i = 1$ and $z_j = 0$, the prerequisite action a_j is inserted into the plan if it exists in the original proposal set.
2. **Ordering Enforcement.** If C indicates an ordering violation between two included actions, the plan order is adjusted to satisfy the required precedence without removing actions.
3. **Risk-Level Substitution.** If C includes a risk-budget violation involving a high-risk action a_i, SVRP substitutes a_i with a lower-risk action of the same action type (same `type` and `scope`) drawn from the original proposal set, if available.
4. **Action Removal.** If none of the above repairs resolve infeasibility, SVRP greedily removes a deterministically prioritized action from A_C to break the core. Actions outside A_C are never removed.

Iteration and Termination. After applying a repair, the modified plan is re-encoded and resubmitted to the solver. SVRP allows at most two repair iterations per incident. If the instance remains unsatisfiable after the second iteration, the system abstains.

Determinism and Guarantees. Repair operator order, substitution rules, and removal policies are fixed and deterministic. SVRP never introduces new actions beyond the original proposal set, and never deletes actions unless prerequisite insertion, reordering, and substitution all fail.

A.3 Synthetic Dataset Construction

The released synthetic dataset [1] of 950 incidents is constructed by injecting controlled constraint conflicts (e.g., incompatible actions, missing prerequisites) into otherwise valid plans. This enables systematic evaluation of interaction-level feasibility failures that are rare in organic postmortem data.

[1] https://github.com/ppattnayak/PAG_DB

A.4 LLM Prompts for Action Proposal, Validation and Constrained Baselines

Prompts are fixed across datasets and experiments.

Action Proposal Prompt. We prompt the LLM to generate candidate corrective and preventive actions given an incident summary and retrieved historical context. The prompt requests concise, imperative actions without enforcing feasibility, safety, or role constraints.

The same action proposal prompt is used for: (i) the generation-only baseline, (ii) SVRP action proposal, and (iii) the rule-based and solver-based pipelines prior to verification.

Exact prompt is shown in Figure 3.

LLM-Based Validation Prompt. For the LLM-based validation baseline, the same Cohere Command-R+ model is prompted to revise a proposed remediation plan to remove unsafe or invalid actions.

The prompt instructs the model to improve safety and executability without providing explicit constraint definitions, solver diagnostics, or feasibility feedback.

Validation prompt is shown in Figure 4.

Constrained Baseline Prompts. The constrained baselines use complete prompts with the same message structure and decoding settings as their unconstrained counterparts. The constrained generation prompt mirrors the action-proposal prompt but includes explicit operational constraints (Figure 5). The constrained rewrite prompt mirrors the validation/rewrite prompt and provides the same constraints alongside the generated plan (Figure 6). Neither baseline receives solver diagnostics, unsatisfiable cores, or SVRP repair outputs.

A.5 Additional Metrics & Results

A.5.1 Full Safety Violation Breakdown

A full breakdown by violation type (risk, permission, dependency, verification) is provided in Table 10 and visualized in Figure 7.

A.5.2 Embedding Choice Robustness

Results are stable across embedding models (MiniLM vs. MPNet) as shown in Table 11.

A.5.3 Repair-SAT Rate and Unsat Core Size

SVRP successfully repairs over 80% of initially infeasible plans, with small unsatisfiable cores indicating localized conflicts as shown in Table 12.

A.5.4 Checker and Repair-Cap Sensitivity

We replace MiniSat/core diagnosis with direct enumeration of violated constraints while holding the 8,200 proposals, normalized tuples, repair operators and order, two-iteration cap, and evaluator fixed. Table 13 shows that direct global checking recovers most of the compliance gain, while diagnostic cores improve repair localization and preservation. We therefore claim value for explicit global enforcement and diagnostic repair, not that MiniSat is the only suitable backend. The cap sensitivity also shows diminishing returns beyond the prefixed two iterations; every candidate is rechecked, so the cap changes coverage rather than acceptance criteria.

A.5.5 Human Evaluation of Disagreements

We define a disagreement case as an incident for which SVRP produces a remediation plan that differs from at least one competing decision mechanism (generation-only, LLM-based validation, or constrained LLM rewriting), after normalization. Among solver-SAT plans audited in this study, experts identified 4.8% as false acceptances because the encoded model omitted relevant operational context. This is an independent estimate of the model boundary, not part of the SAT metric.

A.5.6 Surface-Level Proposal Quality

Table 17 reports surface-level proposal-quality metrics computed before solver verification and repair. Motivated by prior work on factual-consistency evaluation and hallucination detection (Honovich et al., 2022; Manakul et al., 2023), we report two task-specific measures: **Factual Consistency (FCS; 0–1)** measures agreement with the incident context and retrieved precedents, while **Groundedness (%)** is the percentage of CAPM statements supported by this evidence. Inspired by work on answerability and causal-reasoning evaluation (Rajpurkar et al., 2016; Wang, 2024), we additionally report **Answerability (1–5)**, rating completeness and plausibility of CAPMs, and **Causal Coverage (CCov; 0–1)**, measuring coverage of key root causes addressed by CAPMs.

As expected, proposal quality is broadly consistent across service domains and comparable to prior work. Importantly, SVRP does not modify the proposal stage; these results confirm that the feasibility and safety gains reported in Results Section are not driven by changes in generation quality.

```
### System Prompt
You are an experienced cloud reliability engineer writing postmortem remediation actions.
Your task is to propose concrete corrective and preventive actions based strictly on the
incident description and historical context.

Do NOT evaluate feasibility, risk limits, permissions, or dependencies.
Do NOT attempt to validate or reject actions.
Only propose actions that could plausibly help prevent recurrence.

---

### User Prompt
Incident Summary:
{{incident_summary}}

Related Historical Incidents:
{{retrieved_incidents}}

Task:
Generate a concise list of corrective and preventive remediation actions.

Guidelines:
- Write actions as short, imperative statements.
- Each action should describe a single concrete step.
- Do not include explanations or justification.
- Do not merge multiple actions into one sentence.
- Do not reason about safety, permissions, or feasibility.

Output Format:
- A bulleted list of actions.
- No prose before or after the list.
```

Figure 3: Action proposal prompt used for all generation-based methods.

A.5.7 Synthetic Stress-Test Evaluation

We additionally evaluate SVRP on a released synthetic dataset of 950 incidents designed to surface interaction-level feasibility violations that are rare in organic data (e.g., conflicting role assignments, incompatible action dependencies, and risk-budget overflows). Consistent with results on real incidents, generation-only and heuristic baselines struggle on the synthetic dataset, which contains a higher density of multi-constraint conflicts. SVRP maintains high feasibility and non-deletion rates, indicating that solver-verified repair generalizes to adversarial interaction patterns rather than exploiting dataset- specific regularities as shown in Table 18. Comparison with full dataset is shown in Fig 8. SVRP maintains comparable feasibility and repair behavior under synthetic stress, indicating robustness to denser interaction-level constraint conflicts.

A.6 Error Analysis and Failure Modes

Refer Table 19 for failure modes observed and definitions.

Missing Prerequisite Proposals. In these cases, the LLM fails to propose a required prerequisite action (e.g., deployment rollback before configuration change). Because SVRP does not introduce novel actions beyond the original proposal set, no feasible repair exists, resulting in abstention. This reflects a proposal-stage limitation rather than a verification failure.

Unavailable Risk Substitution. When no lower-risk alternative in the original proposal set satisfies the encoded budget, SVRP abstains rather than inventing an action or forcing a destructive deletion.

Missing or Unparseable Verification Steps. Some proposed verification text is too underspecified to normalize to a primitive in $\mathcal{V}$, leaving the

ForensicBench: Evaluating Agentic LLMs on Journal-Entry Fraud Detection

Abstract

Accounting fraud costs organizations billions annually, yet auditors rarely confront it as a single suspicious posting. Instead, they investigate coordinated *fraud schemes* such as fictitious vendor payments, ghost-employee payroll, and inflated revenues that span many journal entries, each individually routine, and only become visible when understood against the underlying accounting process. Existing AI systems either score isolated entries as anomalies or mine company-level disclosures; none evaluate whether a large language model (LLM) agent can query a live ledger, recover coordinated fraud patterns, and assign the correct scheme type. We release **ForensicBench**: the first benchmark for evaluating agentic LLMs on *scheme-level* journal-entry fraud detection. The dataset, **Forensic Ledger**, extends DataSynth with five injected fraud scheme types and scheme-level labels linking journal entries to coordinated instances. We evaluate twelve open-weight models under a single reference agent scaffold on a public leaderboard: among them, the best reaches only 34.7% Entry-F1, and Type-F1 is up to 13 points lower. We publicly release the dataset, evaluation harness, and a reference agentic baseline.[1]

1 Introduction

Accounting fraud (the deliberate manipulation of financial records to misappropriate assets or misstate results) costs organizations billions annually (Association of Certified Fraud Examiners, 2024). In practice, much of this fraud manifests as *journal-entry (JE) fraud*: coordinated schemes such as fictitious vendor payments, ghost-employee payroll, or revenue inflation that span multiple postings to the *general ledger (GL)*, the canonical chronological record of all financial transactions organised by account class, each posting individually routine. Forensic auditors do not test entries in isolation; they search for *scheme-level* evidence, linking dispersed postings into a typed pattern (e.g., shadow payroll, vendor collusion) by reasoning over accounting processes such as vendor approval workflows, payroll cycles, and period-end cutoffs. This differs from flagging statistical outliers on single records, and it is the kind of reasoning that agentic LLMs (systems capable of querying databases, executing code, and maintaining investigative state across many steps (Yao et al., 2023)) may perform. We do not claim LLMs outperform classical detectors at entry-level anomaly detection; rather, scheme-level detection is a different, harder task (linking dispersed postings and reasoning over accounting processes), for which entry-level statistical tests provide no scheme-type label. Our uninformed audit-test battery (a Benford first-digit test (Benford, 1938; Nigrini, 2012), a round-amount and a period-end journal-entry test (Lanza, 2006), and an Isolation Forest (Liu et al., 2008)) confirms the gap is behavioral rather than statistical: it reaches only 0.36% Entry-F1 versus 34.7% for the best LLM (Appendix E.2).

No existing benchmark evaluates whether agentic LLMs can discover and type coordinated fraud schemes over a live transactional ledger. Prior work falls short in three respects. *Financial-statement datasets* (Bao et al., 2020; Dechow et al., 2011) label fraud at company-year granularity, far above the scheme level needed for ledger investigation. *Entry-level anomaly detectors* (Hilal et al., 2022; Schreyer et al., 2019) flag isolated statistical outliers but provide no scheme-type labels and no accounting-process context; they cannot evaluate whether a system understands *which* coordinated pattern a set of entries constitutes. *General agent benchmarks* (Liu et al., 2023; Mialon et al., 2023) cover web browsing and code tasks but include no forensic accounting setting. What is needed is a realistic multi-sector ledger with scheme-level ground truth; ForensicBench uses the French *Plan*

Comptable Général (PCG) (Autorité des Normes Comptables, 2014), a hierarchical chart of accounts whose numbered classes encode balance-sheet and income-statement structure and require agents to navigate a realistic account tree.

We introduce **ForensicBench** to close this gap: a reproducible benchmark for scheme-level journal-entry fraud detection that evaluates whether agentic systems can discover and type coordinated fraud patterns over realistic enterprise ledgers, instead of scoring isolated postings. We summarize our contributions as follows: **(1) Forensic Ledger**, a realistic synthetic corpus across five industry sectors with five injected fraud scheme types and document-level ground truth at both journal-entry and scheme-type granularity; **(2) ForensicBench Evaluation Protocol**, scoring Entry-F1, Type-F1, recall, precision, scheme coverage, and cross-seed consistency; **(3) Reference Agent**, an agentic baseline that investigates ledgers via SQL and code execution; and **(4) Open Forensic Leaderboard**, a public ranking of open-weight models from large to small on the benchmark.

2 Related Work

Entry-level anomaly detection. Computational audit research has predominantly addressed individual-entry testing: rule-based journal-entry tests (JETs; Benford tests, round-amount filters), multivariate outlier detectors, deep autoencoders over enterprise resource planning (ERP) records (Hilal et al., 2022; Schreyer et al., 2017, 2019), and graph neural network (GNN) methods that exploit the relational structure of double-entry bookkeeping (Sotiropoulos et al., 2023; Huang et al., 2026). AuditCopilot extends this line by prompt-tuning LLMs on JSON-serialised postings grouped by posting ID (a single balanced debit-credit pair) with Isolation Forest hints (Kadir et al., 2025); its unit of analysis remains a single balanced transaction and it does not link dispersed postings into labelled coordinated schemes or evaluate scheme discovery over a full relational ledger.

Agentic investigation and benchmarks. AuditAgent addresses a different problem: cross-document evidence-chain localisation over unstructured corporate disclosures (annual reports, regulatory filings) using variational Bayesian subject priors and multi-expert consensus (Bai et al., 2025). Its input modality (free-text financial statements) and evaluation target (evidence spans in narrative documents) differ from ForensicBench's structured transactional ledgers with entry-resolution scheme-level ground truth. General agent benchmarks (AgentBench, GAIA (Liu et al., 2023; Mialon et al., 2023)) assess web and code tasks; ReAct (Yao et al., 2023) and Toolformer (Schick et al., 2023) provide the interleaved reasoning-tool paradigm our reference agent builds on. None supply live relational accounting ledgers, coordinated scheme-level ground truth, or forensic evaluation criteria.

Synthetic accounting data. Privacy constraints motivate synthetic ledgers; prior generators produce records respecting double-entry constraints (Motai et al., 2025; Schultz and Tropmann-Frick, 2020; Kröger and Schultz, 2025), and DataSynth provides realistic chart-of-accounts structure with master data (Ivertowski, 2026). No prior synthetic resource combines controlled injection of process-linked, multi-entry fraud schemes with *scheme-level* ground truth linking each entry to a labelled coordinated fraud instance, which is needed to evaluate scheme discovery rather than entry-level anomaly scoring.

3 Forensic Ledger Dataset

The Forensic Ledger is built in two stages: we generate realistic enterprise ledgers with an open-source synthetic data engine (§3.1), then inject coordinated, multi-entry fraud schemes with document-level ground truth (§3.2). We instantiate this pipeline across five industry sectors (§3.3) and expose the result to agents through a read-only relational interface with a hidden label store (§3.3).

3.1 Base Ledger Generator

We build on DataSynth (Ivertowski, 2026), an open-source enterprise data generator that produces interconnected financial records for a configurable firm: general-ledger (GL) journal entries, procure-to-pay and order-to-cash document flows (purchase orders, goods receipts, invoices, payments), sub-ledgers, and master data for vendors, employees, customers, materials, and fixed assets. Generation is governed by accounting structure rather than free-form sampling (Motai et al., 2025; Kröger and Schultz, 2025): every journal entry is balanced at construction (debits equal credits), amounts follow log-normal distributions calibrated for first-digit Benford compliance (Benford, 1938; Nigrini, 2012), postings respect business-day and period-end calendars, and a deterministic seed makes each

ledger reproducible. All entries are denominated in EUR under the French *Plan Comptable Général* (PCG)[2], so that account semantics are consistent across sectors.

Out of the box, the generator targets *entry-level* irregularities (statistical outliers, duplicate or reversed postings, wrong-period or wrong-account errors, and isolated fraud markers), each labelled at the level of a single record. These labels support conventional anomaly detection but describe individual postings in isolation: they do not encode the coordinated, multi-entry structure that characterises real fraud schemes. The public v0.6.2 release ships a nascent multi-stage scheme module with two implementations only (*gradual embezzlement*, *vendor kickback*); we extend this into five canonical benchmark types, add three further scheme families, and supply multi-perpetrator co-occurrence, sector calibration, and dual-granularity labels for evaluation.[3] We build on the generator's realistic ledger backbone and add a labelling and scheme-injection layer for ForensicBench evaluation.

3.2 Injected Fraud Schemes

A *fraud scheme* is a coordinated sequence of journal entries, posted over days to months, that jointly enacts a fraudulent objective while each entry remains individually plausible. We extend the generator's two-scheme module into a full scheme-injection engine and model schemes as multi-stage processes: once per simulated month, each scheme type may start under an independent Bernoulli draw; active schemes then advance day by day, emitting stage-dependent journal entries (e.g., a fictitious invoice followed weeks later by its matching payment). Algorithm 1 summarises the full pipeline; scheme-specific stage logic is implemented per type in the release. Our extension adds the forensic structure observed in practice: a fixed perpetrator (`created_by`) spanning incompatible roles, after-hours timestamps, reference reuse, period-end clustering, ghost-employee master-data mutation, and concealment postings through suspense accounts, together with perpetrator reuse and co-occurrence so that a single perpetrator may operate multiple linked schemes.

Scheme lineage. ForensicBench injects five canonical scheme types (Appendix 11) spanning principal occupational-fraud families (Association of Certified Fraud Examiners, 2024). Two inherit from DataSynth v0.6.2 (*gradual embezzlement*, *vendor kickback*), canonicalised as **fictitious account payables disbursements** (salami-slicing and expense-laundering variants over procure-to-pay) and **vendor collusion** (kickback and related-party variants). We add three families absent from the public module: **revenue manipulation** (order-to-cash period-end window dressing), **inventory manipulation** (goods receipts without purchase orders (PO), and year-end write-offs), and **shadow payroll** (ghost-employee payroll accruals), extending coverage to order-to-cash, supply-chain, and hire-to-retire processes beyond procure-to-pay. Variant dispatch within each type preserves a single canonical label.

Document-level ground truth. Each scheme instance is assigned a persistent identifier, and every journal entry it emits receives a unique action identifier that joins one-to-one to a label record. A label thus links a specific `document_id` to (i) its *scheme type* and (ii) the *scheme instance* that groups all entries of the same coordinated fraud. This dual granularity is what enables scheme-level evaluation: we can score both whether an agent flags the right entries and whether it recovers and types the coordinated pattern they form, rather than only whether it detects isolated anomalies.

3.3 Sector Configurations and Agent Interface

We instantiate the pipeline across five sectors (Energy, Healthcare, Luxury Goods, Manufacturing, Transport), each a distinct firm sharing the same currency (EUR), accounting framework (French PCG), and horizon ($\sim$100K journal entries over 2023–2025), but with its own chart of accounts, process mix, and per-sector scheme calibration (e.g. shadow payroll is prominent in Healthcare and Transport; inventory manipulation in Manufacturing and Luxury Goods). Agents access each ledger as a read-only PostgreSQL database; ground-truth labels reside in a separate store never visible to the agent. The schema documents an `hr_employees` table as the primary tool for shadow-payroll investigation, yet the table is access-controlled at

[2]The PCG is France's mandatory general ledger chart of accounts, codified by the *Autorité des Normes Comptables* in Regulation ANC n°2014-03 (Autorité des Normes Comptables, 2014).

[3]DataSynth v0.6.2 implements `embezzlement.rs` and `kickback.rs`; we canonicalise these as fictitious accounts payable (AP) disbursements and vendor collusion and add revenue manipulation, inventory manipulation, and shadow payroll (Appendix 11).

runtime (`permission denied`); an effective investigator must treat this as a dead end and pivot to a GL-structural path, testing recovery after denied database access (see Appendix D).

4 ForensicBench Evaluation

ForensicBench evaluates agents on two levels: *entry-level* detection quality (which journal entries are flagged, and how correctly) and *scheme-level* coverage (how much of each coordinated fraud pattern an agent has uncovered). Six axes together define the benchmark; no single aggregate score is used, so each metric remains readable on its own.

4.1 Task Formulation

An agent receives read-only access to a sector ledger containing journal-entry headers and lines, chart of accounts, and vendor, employee, and customer master data. No fraud labels, anomaly scores, or scheme identifiers are visible; the agent must derive all evidence from the transactional data alone. The agent reports its findings by flagging individual journal entries and assigning each a scheme type drawn from the five canonical labels (Appendix 11). Evaluation matches the reported identifiers against the hidden ground-truth store.

Token-budget constraint. ForensicBench is a *token-budget constrained* benchmark: each run is allocated a fixed global budget of 20M tokens (prompt + reasoning), and the agent is halted when this budget is exhausted. This constraint is a first-class benchmark property, not an implementation detail; it reflects the cost and latency limits of real audit engagements and forces agents to prioritise their investigation strategy rather than exhaustively querying the database.

4.2 Metrics

Let $\mathcal{F}$ be the set of ground-truth fraudulent journal entries and $\hat{\mathcal{F}}$ the set reported by the agent, with $n_c = |\hat{\mathcal{F}} \cap \mathcal{F}|$.

Entry-F1. The primary leaderboard axis.

$$P = \frac{n_c}{|\hat{\mathcal{F}}|}, \quad R = \frac{n_c}{|\mathcal{F}|}, \quad \text{Entry-F1} = \frac{2PR}{P+R}.$$

Recall and Precision are reported separately as independent axes to surface different failure modes: a low-recall/high-precision agent is overly conservative; a high-recall/low-precision agent flags indiscriminately.

Type F1. A detection is a *typed true positive* if its `document_id` $\in \mathcal{F}$ *and* its scheme type matches the ground-truth label; Type-F1 uses the same denominators as Entry-F1 with this stricter count, ensuring Type-F1 $\leq$ Entry-F1.

Coverage. Entry-F1 measures entry-level accuracy, but an agent that flags scattered entries from many schemes without ever reconstructing a full coordinated pattern scores the same as one that recovers complete schemes. Coverage addresses this: for each ground-truth scheme instance s with document set $\mathcal{D}_s$, $\text{cov}(s) = |\hat{\mathcal{F}} \cap \mathcal{D}_s| \,/\, |\mathcal{D}_s|$, and leaderboard Coverage is the macro-mean over *all* instances (including zero-coverage ones), rewarding breadth of investigation rather than concentration on easy entries.

Consistency. A single run at temperature zero is insufficient to characterise a model: tool-call ordering and provider-side sampling introduce variance that can swing Entry-F1 by tens of points within the same model (see Appendix B). Consistency $= \max(0,\ 1 - \sigma/(\mu + \varepsilon)) \times 100$ quantifies this, where $\{f_i\}_{i=1}^{5}$ are per-replicate Entry-F1 values; it ranks last in the lexicographic ordering because a stably-wrong model scores high.

4.3 Protocol and Ranking

Each model runs on all five sectors with five independent replicates per sector, yielding 25 evaluation runs; a model enters the leaderboard only if all 25 runs are complete, preventing cherry-picking of favourable sectors. Per-run metrics are averaged over the five replicates within each sector, then macro-averaged (unweighted) across sectors. Unweighted averaging does not correct for scheme-population imbalance ($\sim$394 fictitious account payables vs. $\sim$56 shadow payroll entries per run); per-scheme recall in Appendix B provides the imbalance-aware view. Models are ranked by Entry-F1, then Type-F1, Recall, Precision, Coverage, and Consistency, rather than by a composite score, so that performance on each axis remains independently interpretable.

5 Reference Agentic System

ForensicBench is model-agnostic: any agent that can query a SQL database and call `report_suspicion` is a valid participant. For the initial leaderboard, we use a reference system with a *plan-then-investigate* workflow, drawing on

tool-augmented LLMs (Schick et al., 2023), plan-before-execute reasoning (Wang et al., 2023), and multi-agent parallelism (Wu et al., 2024), adapted to the forensic setting. The reference system is intentionally simple: it avoids reflection, replanning, and inter-worker negotiation so that results are straightforward to reproduce. Stronger agents (e.g., with replanning or multi-agent coordination) are expected to score higher; we release the harness to support such submissions.

5.1 Orientation

Before any fraud-specific reasoning, the agent spends a fixed fraction of its token budget on a *ledger orientation* phase, inspired by the preliminary analytics step in expert financial investigations. The agent issues SQL queries to profile the dataset: it surveys the chart of accounts, estimates transaction volumes per account class, identifies the dominant business processes, and builds an entity-level map of vendors, employees, and customers. This orientation digest (chart-of-accounts structure, amount distributions, posting patterns) is injected as shared context into all subsequent reasoning steps, grounding hypotheses in the actual ledger rather than in generic accounting priors. The orientation phase does not emit any detections; it is strictly investigative setup.

5.2 Hypothesis Planning

After orientation, the orchestrator issues a single planning call (Wang et al., 2023) that produces a structured investigation plan: for each of the five scheme types, it formulates a ranked set of falsifiable hypotheses (e.g., "payments to vendors registered within 30 days of the transaction have no matching purchase order"), each assigned an explicit dispatch priority, a set of exit criteria, and a token budget drawn from the remaining global allowance. Hypotheses with higher priority are dispatched first, allowing the agent to prioritise the highest-priority hypotheses when the budget is tight. The plan is fixed after this one-shot step; the hypothesis backlog is not modified during execution.

5.3 Sequential Hypothesis Workers

Each hypothesis is executed by an independent *worker agent* in a bounded ReAct loop (Yao et al., 2023): the worker alternates between reasoning steps and tool calls until it satisfies its exit criteria or exhausts its token allocation. Workers have access to **SQL** (*preview* and *export* over journal-entry headers and lines, chart of accounts, and master data), a Python **code interpreter** (Gao et al., 2023) (pandas, NumPy, SciPy, scikit-learn, NetworkX; Benford tests, time-clustering, graph analysis, fuzzy matching), a **scratchpad**, **grep**, **read_image**, and **report_suspicion**. Workers also write to a shared *blackboard* through which salient entity-level findings (e.g., a vendor sharing a bank account with an employee) are made visible to workers investigating related schemes, without exposing full message histories. For the leaderboard results reported here, workers execute sequentially by dispatch priority to encourage reproducibility; the architecture supports parallel execution (Wu et al., 2024) and we release both configurations. Detections are merged programmatically (no LLM reconciliation pass), and the union of reported entries forms the agent's final submission.

5.4 Prompt Design and Label Isolation

The *fraud catalogue* (Appendix F) is a **standardised benchmark artefact** released with the evaluation harness: it describes each of the five scheme types in terms of normal process context and conceptual fraud indicators, and every leaderboard participant must inject it verbatim into their agent's system prompt. This design maximises reproducibility across agent submissions while ensuring no information from the injection process leaks to the agent: the catalogue explicitly withholds all GL account codes, posting templates, amount parameter ranges, and calendar cutoffs used during data generation. All concrete indicators (GL accounts, SQL filters, amount thresholds, timing windows) must be derived by the agent from its own ledger profiling, not read off from the catalogue. Full prompt templates are provided in Appendix G.

6 Experiments

Experimental setup. All 300 leaderboard runs use the reference agent (§5) at temperature zero under the 20M-token budget (§4), serving open-weight checkpoints via vLLM (Kwon et al., 2023) on four NVIDIA H200 GPUs (147GB RAM each).

6.1 Models and Results

We evaluate 12 open-weight models from seven providers (Table 1), spanning 4B to 397B parameters, with no task-specific fine-tuning. Macro-averaged ForensicBench scores are reported over

Model	Provider	Params	E-F1	Type-F1	Recall	Prec.	Cover.	Consist.
MiniMax-M2.7[a]	MiniMax	230B	**34.7**	**21.7**	**29.0**	**48.4**	**21.7**	50.7
Qwen3.5-397B[b]	Alibaba	397B	26.3	14.1	20.5	41.3	18.0	61.4
Qwen3.5-122B[b]	Alibaba	122B	25.2	13.5	19.8	40.6	14.2	46.9
Qwen3.6-35B[b]	Alibaba	35B	15.0	9.4	9.8	36.6	9.3	28.1
Mistral-Medium-3.5-128B[c]	Mistral AI	128B	13.6	9.1	10.3	21.8	9.5	43.8
Gemma-4-31B[d]	Google AI	31B	12.1	8.7	7.5	37.4	6.8	76.1
Gemma-4-E4B[d]	Google AI	4B	8.5	3.8	5.2	29.5	4.2	31.2
GPT-OSS-120B[e]	OpenAI	120B	8.0	5.2	4.6	39.9	4.4	55.8
Mistral-Small-4-119B[c]	Mistral AI	119B	3.8	2.4	2.3	13.4	2.1	28.5
Qwen3.5-9B[b]	Alibaba	9B	3.5	2.2	2.0	18.5	2.0	18.0
Granite-30B[f]	IBM	30B	2.8	1.5	1.5	16.9	1.6	38.4
Llama-3.3-70B[g]	Meta	70B	0.3	0.0	0.1	3.2	0.2	**80.4**

Table 1: ForensicBench leaderboard (macro-average over 25 runs per model, 300 runs total), ranked by Entry-F1. Bold indicates the best score in each column; E-F1 = Entry-F1; Prec. = Precision; Cover. = Coverage; Consist. = Consistency (0–100); all other metrics are percentages. The current ranking is determined by Entry-F1 alone (no ties occurred); the lexicographic tie-breaker is future-proofing. Bootstrap 95% confidence intervals over the 25 runs are reported in Appendix E.1. References: [a]MiniMax Team (2026); [b]Qwen Team (2026); [c]Mistral AI (2026a), Mistral AI (2026b) (Mistral AI); [d]Gemma Team, Google AI (2026); [e]OpenAI (2025); [f]Granite Team, IBM (2026); [g]Meta (2024).

25 runs per model (5 sectors $\times$ 5 replicates). Overall performance is low: even the best evaluated model reaches only 34.7% Entry-F1 under the reference scaffold, confirming that scheme-level forensic reasoning over transactional ledgers remains difficult for current open-weight LLMs. We report bootstrap 95% confidence intervals over the 25 runs per model (Appendix E.1); for 8 of 11 adjacent leaderboard entries the confidence intervals overlap, and only 4 of 11 pairwise differences are significant, so adjacent mid-tier rankings should not be read as statistically distinguishable at $n = 5$ replicates per sector. Scheme-level classification is harder still: Type-F1 trails Entry-F1 by up to 13 points on every model (range 0.3–13.0), meaning agents that detect fraud entries often misidentify the coordinated pattern they belong to.

A hand-engineered rule-based oracle with full database access achieves 78–91% recall on the four rule-amenable schemes and 83–86% on shadow payroll, confirming that every injected scheme is recoverable from the ledger (Appendix D). Low LLM recall therefore reflects model capability, not label noise or undetectable injections.

6.2 Discussion

Scheme difficulty and what drives the ranking. Revenue manipulation is the most accessible scheme: 11 of 12 models attain non-zero recall on it, and it is detected in 48–100% of runs (Table 6). The leaderboard is instead set by **fictitious account payables disbursements** and **shadow payroll**: only MiniMax-M2.7 exceeds recall on revenue manipulation alone (13.1% on the former; 1.6% on the latter, seven models at zero). The difficulty gap reflects process depth: revenue manipulation concentrates in a single account at period-end, while fictitious account payables (AP) and shadow payroll require cross-table reasoning across weeks of interleaved postings spanning multiple accounting sub-processes. Parameter count does not predict Entry-F1: Gemma-4-E4B (4B) outperforms GPT-OSS-120B (120B), and MiniMax-M2.7 and the Qwen3.5 family rank highest while also leading on AIME 2026 and GPQA-Diamond (MiniMax Team, 2026; Qwen Team, 2026).

Cross-sector variance. Sector difficulty varies substantially (macro Entry-F1: 9.8–17.9%; Appendix B), and high Consistency can reflect stable failure modes rather than robust success (e.g., Llama-3.3-70B at 80.4 Consist. with 0.3% Entry-F1); the five-replicate design is therefore necessary for reliable rankings.

Failure modes. Audit traces (Appendix C) reveal recurring errors: (i) high token use, low yield (Qwen); (ii) early termination (GPT-OSS-120B, Gemma-4-31B, Granite-30B); (iii) over-flagging without verification (Mistral models); (iv) `report_suspicion` misuse (Llama-3.3-70B, Gemma-4-E4B); and weak scheme typing (Mistral-Medium-3.5-128B, Llama-3.3-70B). On shadow payroll, seven models score 0% recall after `permission denied`, and under the reference scaf-

fold (which fixes its investigation plan after one call and cannot replan) none of the evaluated models pivot to general-ledger analysis (Appendix D).

Single-scaffold measurement. Because all twelve models are evaluated through the same reference scaffold, the leaderboard measures model × scaffold rather than model capability in isolation; a stronger scaffold (replanning, multi-agent coordination) or a frontier model is expected to shift absolute scores, and the harness is released for the community to submit such variants.

7 Conclusion

We introduced **ForensicBench**, the first benchmark to evaluate whether agentic LLMs can discover coordinated fraud schemes over live relational ledgers. The benchmark pairs the **Forensic Ledger** (five sectors, five scheme types, entry- and scheme-level ground truth) with a six-axis protocol, a reference agent, and an open leaderboard. Across 300 runs over 12 open-weight models under the reference scaffold, performance remains far from audit-ready: the best evaluated system (MiniMax-M2.7) reaches only 34.7% Entry-F1, leaving more than two-thirds of fraudulent entries undetected. The hardest cases are cross-table schemes such as **fictitious account payables disbursements** and **shadow payroll**, which require tracing coordinated patterns across weeks of interleaved postings.

We publicly release the benchmark and welcome the community to submit new models, propose novel agentic strategies, and extend the dataset with more complex, multi-scheme scenarios.

Acknowledgments

Experiments presented in this paper were carried out using both the Grid'5000 testbed and the inIdEx projet ressources. Grid'5000 is supported by a scientific interest group hosted by Inria and including CNRS. RENATER and several Universities as well as other organizations (see https://www.grid5000.fr). This work has received support from the investment programme "France 2030" as part of the IdEx programme (ANR-18-IDEX-0001) implemented by Université Paris Cité, under which the inIdEx project EFL is conducted. Especially, the inIdEx project provided the NVIDIA H200 GPUs, which together with Grid'5000 made the 300 forensic investigations (12 models × 5 sectors × 5 seeds) feasible.

We are grateful to the authors of DataSynth (Ivertowski, 2026), whose open-source enterprise data generator opened the way to systematic research in a field long hampered by the scarcity of proprietary, real-world ledgers.

Limitations

Leaderboard coverage. The current leaderboard is restricted to open-weight models for which we could run the full 5×5 evaluation grid within our compute budget. Several frontier open-weight systems are therefore absent, most notably Kimi K2 (1T parameters) (Kimi Team, 2025) and other recently released mixture-of-experts flagships whose API or inference cost made 300 full forensic runs (∼20M tokens each) infeasible at the time of submission. Closed-source proprietary models (GPT-4o, Claude 3.5 Sonnet, Gemini 1.5 Pro) are similarly excluded; their absence means ForensicBench has not yet been stress-tested against the strongest available systems. We welcome community submissions to expand the leaderboard and will maintain it as a living benchmark.

Leaderboard governance. To limit leaderboard gaming, submissions must disclose their agent design; we audit the submission trail to verify that a submission does not hard-code the injection rules that are visible in the released generator code; and we will expand the dataset with new scheme variants over time so that rule memorisation does not transfer.

Synthetic-only evaluation. ForensicBench is evaluated exclusively on synthetic data. While the Forensic Ledger is calibrated for Benford compliance, double-entry balancing, and process realism, synthetic generators operate on simplified statistical manifolds and cannot reproduce the long-tail irregularities, enterprise resource planning (ERP) migration artefacts, period-end manual corrections, and messy master-data inconsistencies found in authentic corporate ledgers. A model ranking highly on ForensicBench demonstrates strong reasoning over a well-structured synthetic environment; whether these capabilities transfer to production audit settings requires validation on real anonymised ledgers, which we identify as important future work.

Non-determinism. Even at temperature zero, the reference agent does not guarantee fully deterministic runs: tool-call ordering, network latency,

and provider-side sampling can introduce variance across seeds, which is why we report five replicates per sector. The 5×5 protocol mitigates but does not eliminate this variance, and the Consistency metric captures its residual effect. More deterministic evaluation approaches (e.g., constrained decoding or fixed execution traces) would strengthen reproducibility guarantees and are an open direction for future work.

Ethical Considerations

Assistive role. ForensicBench is designed to evaluate agents as decision-support tools for forensic auditors, not as autonomous systems that make findings of misconduct. In any realistic deployment, flagged entries are hypotheses for a qualified professional to review and corroborate; responsibility for any conclusion rests with the accountable human auditor, not the model. We do not expect agentic systems to replace human auditors, but to help them prioritise and cover more ground within the time and cost constraints of real engagements.

False-positive harm. A system that incorrectly flags journal entries can damage the reputation of employees or vendors named in a false positive. This makes human oversight non-negotiable in any production use, and it is a key reason the benchmark reports Precision as an independent axis rather than optimising for recall alone.

Dual-use. Publishing fraud-detection benchmarks could, in principle, help bad actors understand which patterns are detectable and design harder-to-detect schemes. We mitigate this risk by describing schemes at the level of accounting process concepts rather than releasing specific GL account codes, timing parameters, or injection thresholds; the fraud catalogue operates at the same level of abstraction that any trained auditor already knows.

Privacy. The Forensic Ledger contains entirely synthetic records generated from statistical distributions; no real individuals, companies, or transactions are present. No personally identifiable or commercially sensitive data is released.

A Fraud Scheme Injection Algorithm

Forensic Ledger generation proceeds in two phases: (i) produce a realistic, fraud-free enterprise ledger with DataSynth, then (ii) inject coordinated multi-entry schemes and write scheme-level labels. The injection engine extends DataSynth's two public scheme implementations (*gradual embezzlement*, *vendor kickback*) with three additional families (*revenue manipulation*, *inventory manipulation*, *shadow payroll*), canonicalised as five benchmark types (Appendix 11). It is deterministic given a seed and sector configuration θ (start probabilities, concurrency caps, and process mix). Each emitted journal entry receives a persistent `document_id`; every scheme action receives an `action_id` linked to a `scheme_instance_id` and canonical `scheme_type` in the hidden label store (see §3.2).

Llama-3.3-70B	0.0	0.0	0.0	0.0	0.0

Table 5: Per-scheme recall (%), macro-averaged over 25 runs.

Each scheme type implements ADVANCE as a finite-stage state machine: stages specify posting templates, amount ranges, inter-stage delays, and concealment techniques (e.g., matched invoice–payment pairs for fictitious AP, month-end payroll accruals without social-charge lines for shadow payroll). Variant dispatch within a type preserves a single canonical label so evaluation scores scheme family, not implementation detail. Per-sector calibration adjusts start probabilities $p_\tau(\theta)$ and dominant process exposure (Appendix 11) while holding currency, PCG framework, and simulation horizon fixed across sectors.

B Detailed Per-Dataset Performance

B.1 Entry-F1, Precision, and Recall by Sector

Tables 2–4 report mean ± standard deviation over five independent random seeds per sector (25 runs per model). Sector abbreviations: En = Energy, Hl = Healthcare, Lx = Luxury Goods, Mn = Manufacturing, Tr = Transport.

B.2 Sector Difficulty and Run-to-Run Variance

Mean Entry-F1 pooled across all 12 models: Transport 17.9% (easiest), Luxury Goods 14.2%, Healthcare 11.8%, Manufacturing 10.4%, Energy 9.8% (hardest). Within-sector variance is large for top models: MiniMax-M2.7 on Luxury Goods spans 3.6–55.5% Entry-F1 across seeds (15.2× spread); Qwen3.5-122B on Healthcare spans 4.1–74.4% (std 27.0). Multi-seed aggregation is therefore mandatory: single-run scores are unreliable indicators of model quality.

B.3 Per-Scheme Recall

Table 5 reports macro-averaged recall (%) per fraud scheme across all 25 runs. Fictitious account payables disbursements (∼394 true entries per run) and shadow payroll (∼56 entries) determine the ranking; revenue manipulation is accessible to all models above 3% Entry-F1.

B.4 Scheme Detection Rate and Investigation Efficiency

Table 6 reports the percentage of 25 runs in which a model achieves non-zero recall for each scheme. Table 7 reports resource consumption (macro-average).

C Failure Analysis

Audit traces from all 300 runs reveal four failure archetypes not visible from aggregate leaderboard scores alone.

C.1 Archetype 1: Breaks the Revenue-Only Trap

Every model above 3% Entry-F1 detects revenue manipulation; the ranking is determined by per-

Model	Fict. acct. payables	Inv.	Rev.	Shd.Pay	Vend.
MiniMax-M2.7	68	24	96	16	60
Qwen3.5-397B	72	16	96	4	52
Qwen3.5-122B	28	20	96	4	24
Qwen3.6-35B	48	8	92	20	48
Mistral-Medium-3.5-128B	40	16	88	0	28
Gemma-4-31B	48	32	100	0	32
Gemma-4-E4B	24	0	64	0	20
GPT-OSS-120B	28	24	84	0	36
Mistral-Small-4-119B	24	0	64	8	12
Qwen3.5-9B	36	4	56	0	8
Granite-30B	16	12	48	0	8
Llama-3.3-70B	0	0	0	0	0

Table 6: Scheme detection rate: % of 25 runs with non-zero recall.

Model	Budg.	Steps	Tkn/Flg	SQLok	Code	Null
MiniMax-M2.7	92	748	66k	99	152	0.0
Qwen3.5-397B	95	738	84k	99	168	0.0
Qwen3.5-122B	61	472	51k	98	64	0.0
Qwen3.6-35B	95	734	169k	99	161	0.0
Mistral-Medium-3.5-128B	73	577	70k	95	80	0.0
Gemma-4-31B	58	533	124k	99	86	0.0
Gemma-4-E4B	42	448	113k	96	86	0.0
GPT-OSS-120B	44	497	162k	99	108	0.0
Mistral-Small-4-119B	62	538	175k	87	195	0.0
Qwen3.5-9B	95	931	355k	99	95	0.0
Granite-30B	26	294	141k	98	19	0.0
Llama-3.3-70B	83	790	787k	100	22	2.6

Table 7: Investigation efficiency. Budg. = % of 20M-token budget used; Tkn/Flg = tokens per flagged entry; SQLok = % SQL calls without error; Code = code-interpreter calls; Null = null-ID flags per run.

formance on fictitious account payables disbursements (∼394 entries per run, the largest single scheme family; ≈41% of fraud volume on a macro-average over sectors). MiniMax-M2.7 is the only model with non-trivial fictitious account payables recall (13.1%; Table 5). It also makes heavy use of the code interpreter (152 calls/run, for Benford tests, amount clustering, and graph analysis beyond SQL screening); however, code-call volume alone does not predict this recall: Mistral-Small-4-119B makes the most code calls (195/run; Table 7) yet reaches only 0.5% fictitious AP recall. We therefore treat the code-interpreter use as a correlate, not a demonstrated cause.

C.2 Archetype 2: Burners with Low Conversion

Qwen3.5-9B (95% budget, 931 steps, 355k tokens/flag), Qwen3.6-35B (95%, 169k/flag), and Qwen3.5-397B (95%, 84k/flag) exhaust the token budget but differ sharply in yield: Qwen3.5-397B achieves 7.5× the Entry-F1 of Qwen3.5-9B at comparable budget usage. **Tokens per flag** (Table 7) is the key diagnostic: high budget plus high Tkn/Flg indicates SQL exploration that does not convert to valid detections.

C.3 Archetype 3: Clean but Shallow

GPT-OSS-120B (44% budget, 63 flags/run, zero null IDs), Gemma-4-31B (58%, 76.1 Consistency), and Granite-30B (26%, 294 steps) terminate early with well-formed output but low recall. GPT-OSS-120B achieves 60.1% revenue precision yet fictitious account payables recall of only 0.5% and shadow payroll recall of 0%; it converges on the salient scheme and declares the investigation complete. Granite-30B stops with 74% of budget unused after minimal investigation; its SQL calls succeed 98% of the time, so the failure is under-investigation rather than query errors.

C.4 Archetype 4: Output-Layer Failure

Llama-3.3-70B (Entry-F1 0.3): workers run 790 steps with 99.9% SQL success, but emit only 26 flags/run at 787k tokens each, including 2.6 null-ID entries per run (`document_id: "null"`, empty rationale). The model misuses `report_suspicion` to log negative conclusions rather than verified detections, a structured tool-calling failure consistent with its December 2024 release and 50.5% GPQA-Diamond score (Meta, 2024).

Gemma-4-E4B: 45.4% of flags carry `scheme_type: unknown`, earning zero credit; the 4B model finds anomalies but cannot reliably assign scheme labels.

Mistral-Small-4-119B: 13% SQL error rate (vs. <2% for top models) compounds over-flagging (precision 13.4%, Consistency 28.5).

C.5 Why Type-F1 Lags Entry-F1

Even MiniMax-M2.7 (Type-F1 21.7 vs. Entry-F1 34.7) correctly labels fewer than one in four detected entries. Scheme classification requires mapping entry-level anomalies to coordinated fraud processes, a capability no model demonstrates at scale. Mistral-Medium-3.5-128B shows the largest gap (Entry-F1 13.6, Type-F1 9.1) due to high-volume misclassification alongside over-flagging.

D Shadow Payroll: The Partial-Access Trap

Shadow payroll is a universal blind spot on ForensicBench: 7 of 12 models score zero recall, and the highest recall is reached by Qwen3.6-35B at only 2.8%; the top leaderboard entry (MiniMax-M2.7) reaches just 1.6% (Table 5). The non-zero shadow-payroll recall of the five remaining models arises from scheme classification of entries already

flagged, not from recovering the blocked HR→GL path: no model independently discovers the structural GL signal (the missing 645100 social-charges line) after hr_employees is denied. This section explains the mechanism, documents the compound failure path observed in audit traces, and demonstrates that the scheme is fully detectable via GL structure alone.

D.1 The Trap Mechanism

Every model that reaches the shadow-payroll worker attempts to query the hr_employees table within its first two steps; every attempt returns ERROR: permission denied for table hr_employees. The table is owned by the database administrator and no GRANT SELECT has been issued to the agent user, an intentional design choice modelling a common real-world access restriction (see §3.3).

The failure then compounds in two stages:

Stage 1: Dead-end budget burn. Rather than immediately pivoting to the GL, models spend 60–80% of the shadow payroll worker's token budget on variations of the inaccessible HR join: attempting INFORMATION_SCHEMA workarounds, trying alternative table names, or repeating the same denied query. Audit traces show workers spending 10–17 steps on the hr_employees dead end before running out of budget.

Stage 2: No independent GL discovery. The small remaining budget, and more importantly the absence of any GL-structural reasoning in the shadow payroll worker, means models never independently discover the structural payroll signal: a two-line wage accrual posting Dr 641100 (Salaires) + Cr 421000 (Personnel – rémunérations dues) *without* a matching social-charges line 645100 (URSSAF/cotisations sociales), clustered on the last business day of each month. In legitimate payroll, all three lines appear together: wages, net-pay liability, and employer social charges are posted simultaneously. A ghost-employee payroll entry omits the 645100 line because no real employment contract generates social contributions. This structural test is *entirely derivable* from the French PCG account semantics documented in the schema; no HR data is required.

D.2 Rule-Based Oracle Verification

To confirm detectability, we run an informed oracle that operates under the same database access as the agent and applies hand-engineered, scheme-specific SQL tests (Benford-deviation and round-amount filters for fictitious account payables disbursements; period-end reversal detection for revenue manipulation; split-payment graph analysis for vendor collusion; PO-less goods-receipt detection for inventory manipulation). Across the four rule-amenable schemes, the oracle achieves 78–91% recall; for shadow payroll, it applies a GL-structural test: flag any journal entry containing Dr 641100 + Cr 421000 that lacks a 645100 line, posted on the last business day of the month. The oracle achieves 83–86% shadow payroll recall across the five sectors (Table 8) while operating *without any access to* hr_employees: the ghost-employee HR join is never used for the core detections. This confirms that shadow payroll is recoverable from the GL alone; the near-zero LLM recall is not a labelling artifact.

Sector	Recall	Precision	n true
Energy	84.2	91.3	38
Healthcare	86.1	88.7	72
Luxury Goods	83.3	93.1	48
Manufacturing	85.0	89.4	60
Transport	83.7	90.2	49
Macro	**84.5**	**90.5**	53

Table 8: Informed oracle shadow payroll recall and precision, using GL-structural test only (no hr_employees access).

D.3 Design Rationale

The partial-access trap serves three purposes. **(1) Ecological validity**: real forensic investigators routinely encounter restricted HR systems, GDPR-governed tables, or cross-domain access controls that block the "obvious" query path. Adaptive recovery (recognise the denial, identify an equivalent GL signal, pivot) is a core forensic competency. **(2) Capability differentiation**: a model that discovers the GL-structural path after a denied permission query demonstrates qualitatively different reasoning from one that terminates on the error. The current benchmark exposes that *none* of the 12 evaluated models perform this pivot, making shadow payroll the cleanest capability gap in the leaderboard. **(3) Benchmark integrity**: because the scheme is detectable without the restricted table, the near-zero LLM recall cannot be explained by undetectable injections. Future leaderboard submissions that achieve non-trivial shadow payroll

Rank	Model	E-F1	95% Confidence Interval	vs. next
1	MiniMax-M2.7	34.7	[27.7, 41.4]	✓
2	Qwen3.5-397B	26.3	[21.7, 30.6]	overlaps
3	Qwen3.5-122B	25.2	[19.6, 31.7]	✓
4	Qwen3.6-35B	15.0	[10.8, 19.5]	overlaps
5	Mistral-Medium-3.5-128B	13.6	[10.6, 16.7]	overlaps
6	Gemma-4-31B	12.1	[10.8, 13.5]	overlaps
7	Gemma-4-E4B	8.5	[5.7, 12.0]	overlaps
8	GPT-OSS-120B	8.0	[6.4, 9.7]	✓
9	Mistral-Small-4-119B	3.8	[2.4, 5.3]	overlaps
10	Qwen3.5-9B	3.5	[2.1, 5.2]	overlaps
11	Granite-30B	2.8	[1.9, 3.7]	✓
12	Llama-3.3-70B	0.3	[0.1, 0.5]	

Table 9: Entry-F1 (%) with bootstrap 95% confidence intervals over the 25 runs per model (case-level bootstrap, $B = 10{,}000$; statistic = leaderboard macro-average; point estimates match Table 1 to one decimal). "vs. next" compares the bootstrap difference with the next-ranked model: ✓ = the difference's 95% confidence interval excludes 0; "overlaps" = the confidence intervals overlap and the pair is not statistically distinguishable. Eight of 11 adjacent entries have overlapping confidence intervals; only 4 of 11 pairwise differences are significant, and the top-2 difference is marginal (95% confidence interval $[0.0, 16.6]$).

recall provide evidence of genuine adaptive forensic reasoning.

E Uncertainty Quantification and Uninformed Baselines

E.1 Bootstrap Confidence Intervals for the Leaderboard

To quantify leaderboard uncertainty, we compute nonparametric case-level bootstrap 95% confidence intervals over each model's 25 runs (5 sectors $\times$ 5 seeds), with the leaderboard macro-average (mean over seeds within a sector, unweighted mean over sectors) as the statistic; $B = 10{,}000$ resamples, fixed seed. For adjacent pairs we bootstrap the difference independently per model.

E.2 Uninformed Standard Audit-Test Baselines

To bound the leaderboard from below with classical (non-agentic) methods, we run a standard *uninformed* audit-test battery over the same public tables the agents query (`je_header`, `je_line`): a Benford first-digit test (Benford, 1938; Nigrini, 2012), a round-amount journal-entry test (Lanza, 2006), a period-end clustering test (Lanza, 2006), and an Isolation Forest (Liu et al., 2008) on entry features, plus their union. The battery has no scheme knowledge (no GL-account logic, no access to `hr_employees` or the label store) and is scored against the same ground truth and protocol as the leaderboard.

Uninformed audit test	**Precision**	**Recall**	**Entry-F1**
Benford (1st digit $\in \{8, 9\}$)	0.20	9.41	**0.38**
Round amount ($\geq$3 zeros)	0.07	0.18	**0.10**
Period-end (5 last days)	0.18	30.99	**0.36**
Isolation Forest (top-1% score)	0.32	1.74	**0.54**
Audit battery (union)	**0.18**	**37.56**	**0.36**
Best LLM (MiniMax-M2.7, ref. scaffold)	48.4	29.0	**34.7**
Rule-based oracle (informed)	∼90	78–91	∼85

Table 10: Uninformed standard audit-test battery, macro-averaged over the 5 sectors (same ground truth as the leaderboard). Isolation Forest: ROC-AUC 0.757, PR-AUC 0.004 (top-1% operating point shown); the last two rows are reference points from Table 1 and Appendix D.

Two findings follow. First, the battery is a sieve, not a detector: its 37.6% recall is obtained by flagging ∼40% of the ledger (608k of 1.51M entries across sectors), yielding 0.18% precision and 0.36% Entry-F1, about 96$\times$ lower than the best LLM (34.7%); the top leaderboard score is therefore a result on a genuinely difficult task, not an artefact of the absence of classical baselines. Second, the battery's recall is carried by the period-end test, which catches period-end-concentrated schemes (revenue manipulation ∼55%, shadow payroll ∼89%) while missing the hard cross-table schemes (fictitious AP ∼20%, inventory ∼18%, vendor collusion ∼24%); it assigns no scheme type at all (Type-F1 $= 0$ by construction), which is precisely the capability ForensicBench evaluates. We note two caveats for interpretation: the period-end filter benefits from the generator's month-end posting calendar, so part of its recall reflects the synthetic calendar rather than a fraud signal; and the battery runs once per sector (deterministic), against the same static ledgers used for the 5 LLM replicates.

F Fraud Scheme Definitions

Table 12 reproduces the fraud catalogue injected into every agent run (source: `fraud_catalogue.py`). The catalogue is intentionally conceptual: no GL account codes, posting templates, amount ranges, or calendar cutoffs are disclosed. All concrete indicators must be derived by the agent from its own ledger profiling.

G Agent Prompts

Table 13 summarises the four prompt components assembled at runtime; full source is in the code

Scheme	Process	Multi-entry signature
Fictitious account payables disbursements	Procure-to-pay	Fictitious invoices to shell vendors paid via matched (*lettrage*) disbursements, or large outflows bounced through a suspense account across shells; account rotation and after-hours posting.
Revenue manipulation	Order-to-cash	Period-end revenue recognised against dummy customers, then reversed in the first days of the next period; concentrated in quarter-end windows.
Vendor collusion	Procure-to-pay	Inflated payments to a colluding or related-party vendor, fragmented into split disbursements sharing one invoice reference; vendor shares bank/address details with an insider.
Shadow payroll	Hire-to-retire	A ghost employee added to master data receives recurring month-end payroll postings (wages, charges, net pay) with no genuine HR lifecycle.
Inventory manipulation	Supply chain	Fictitious goods receipts inflate inventory without purchase orders, followed by year-end write-offs booked as shrinkage.

Table 11: The five injected scheme types. Each spans multiple journal entries across an accounting process; individual postings appear routine, and only their joint structure reveals the scheme.

release. The output contract (below) is part of the system prompt and defines the evaluation unit.

```
{
  "document_id": "<je_header UUID>",
  "entity_id": "<vendor | employee | customer | null>",
  "scheme_type": "<one of five scheme types>",
  "rationale": "One-sentence explanation.",
  "supporting_evidence": ["..."]
}
```

Only `je_header.document_id` UUIDs retrieved from SQL count; invented or null IDs do not score.

Scheme (Process)	Normal process & fraud signals
Fictitious Account Payables Disbursements *Procure-to-Pay*	**Normal:** Payables settled only for goods/services ordered, received, and invoiced under segregation of duties; vendor identity and payment references consistent with operating practice. **Indicators:** Value leaving without a defensible procure-to-pay (P2P) trail; missing receipt or approval evidence; same actors spanning incompatible roles; timing or vendor populations diverging from the rest of the ledger; reference behaviour inconsistent with normal accounts payable (AP) booking.
Revenue Manipulation *Order-to-Cash / Record-to-Report (R2R)*	**Normal:** Revenue recognised on delivery; expenses and provisions booked in the appropriate period; reserve releases require defensible economic events. **Indicators:** Unusual period-end concentration; abnormal account or line mixes for a commercial story; reversals in the first days of the next period; flows inconsistent with order-to-cash (O2C) and R2R activity in this database.
Vendor Collusion *(Kickback + Related-Party)*	**Normal:** Procurement follows approved sourcing, pricing, and approval chains; vendors are genuine third parties; no single actor controls selection, invoicing, and payment. **Indicators:** Inflated or biased spend; repeated coupling of same internal/external parties; payments fragmented to obscure totals; beneficiary or party data overlapping with insiders; weak master-data linkage.
Shadow Payroll *Hire-to-Retire*	**Normal:** Payroll settles real employees under HR and payroll policies; accruals and settlements match the entity's payroll design. **Indicators:** Pay runs structurally odd vs. population in accrual shape, timing clusters, banking patterns, or authorship concentration; recency of HR lifecycle events vs. pay activity. Plausible HR rows do not rule out fraud; master data is context, not a whitelist.
Inventory Manipulation *Supply Chain*	**Normal:** Inventory moves trace to economic events (receipts, consumption, authorised adjustments); write-downs require documented physical justification. **Indicators:** Stock increases without credible upstream support; write-offs disconnected from prior stock history; suspicious pairing of movements; period-close clustering of adjustments; split roles across related postings.

Table 12: Fraud catalogue injected verbatim into the agent system prompt (P2P = procure-to-pay; O2C = order-to-cash; R2R = record-to-report; AP = accounts payable). Agents must derive all concrete GL accounts, SQL filters, and thresholds from ledger profiling, not from this catalogue.

Component	Purpose, Content & Key Design Constraints
System Prompt	Shared static prefix across all phases and workers. Role: *senior forensic auditor* (COSO, SOX, ISA 240). Injects: (a) database schema, (b) fraud catalogue (App. F), (c) mission, (d) six investigation principles (substance over form; control-circumvention lens; materiality & risk ranking; falsifiability; follow the money; evidence breadth), (e) tool catalogue & preferred workflows, (f) output contract. Catalogue excludes generation parameters (no GL codes, posting templates, or amount parameters).
Orientation Phase	Ledger profiling before any fraud reasoning. *No fraud vocabulary* permitted ("suspicious", "anomaly", "red flag", "scheme" banned). Eight mandatory structural topics: schema & grain, chart of accounts, process mix, monetary corridors, actor tiers, period structure, master data, controls & references. Output persisted as field notes to `orientation_report.md` and injected into planning. Default budget: 10% of global token cap.
Planning Phase *(one-shot)*	Single LLM call emitting `investigation_plan.json`: a global `dispatch_queue` (ordered hypothesis tasks across all five schemes) and a per-scheme `phases[]` array. Each entry carries hypothesis text, a rationale paragraph (claim + benign rival), and a `budget_tokens` weight. Runtime rescales weights to the post-planning token envelope. Enforces 5–10 distinct hypotheses per scheme; workers dispatched in P-wave order (all P1s before any P2).
Hypothesis Workers	Independent worker agent per hypothesis in a bounded ReAct loop (Yao et al., 2023). Receives task brief (hypothesis, exit criteria, benign rivals, query families). Must emit verdict CONFIRMED / RULED_OUT / INCONCLUSIVE. Calls `report_suspicion` live as evidence emerges. Writes entity-level findings to a shared *blackboard* for cross-scheme coordination. All detections merged programmatically; no LLM reconciliation pass.

Table 13: Reference agent prompt architecture. Components assembled at runtime; system prompt is shared by orchestrator and all workers.

Algorithm 1: Multi-stage fraud scheme injection

Require: Base ledger L (balanced routine entries); calendar days D; sector config θ; RNG seed s

Ensure: Labelled ledger L'; hidden label store $\mathcal{G}$

$S \leftarrow \emptyset$ *// active scheme instances*

$\mathcal{A} \leftarrow \emptyset$ *// pending scheme actions*

$\mathcal{G} \leftarrow \emptyset$ *// label records*

for each month m in D **do**

  for each start attempt $k = 1, \ldots, K(m)$ **do** *// $K(m)$ scales with ledger volume*

    for each scheme type $\tau \in \mathcal{T}$ **do** *// $|\mathcal{T}| = 5$ in ForensicBench*

      if Bernoulli$(p_\tau(\theta))$ **then**

        if active count of type τ in $S < \kappa_\tau(\theta)$ **then**

          Select perpetrator u (department-filtered; optional reuse/co-occurrence)

          Instantiate variant of τ (e.g., salami-slicing vs. expense-laundering for fictitious AP)

          Register scheme instance s with UUID; $S \leftarrow S \cup \{s\}$

  for each day d in month m **do**

    for each active scheme $s \in S$ **do**

      $\alpha \leftarrow \textsc{Advance}(s, d)$ *// stage-dependent postings for day d*

      for each action $a \in \alpha$ **do**

        Append a to $\mathcal{A}$; write label to $\mathcal{G}$: (`document_id`, `scheme_type`, `scheme_instance_id`, `action_id`)

      if s reached terminal stage **then** remove s from S

for each action $a \in \mathcal{A}$ **do**

  Materialise a as a balanced journal entry in L (PCG accounts, timestamps, references)

  Apply forensic markers: fixed `created_by`, after-hours posting, reference reuse, period-end clustering, suspense routing

Update master data from scheme metadata (ghost employees, shell vendors/customers)

return $(L', \mathcal{G})$

Cheaper Than Frames: An OCR + Keyframe Index as a Perception Layer for GUI-Video Question Answering

Abstract

Multimodal models that interpret screen recordings are usually fed *raw sampled video frames*, a faithful but costly perception layer: each frame is a large image input, and dense coverage multiplies token usage. We ask whether a *cheap, text-first index* (on-screen OCR text plus per-state change descriptions, built once by a small local pipeline) is a better-value perception layer for the same model. On GUI-World, a released benchmark of GUI recordings with human-annotated multiple-choice questions and an objective exact-match metric, we compare the two in a controlled setting (same model, same questions), and replicate across two flagship models. On Claude Opus 4.8, answering from the index reaches 0.850 accuracy vs. 0.902 for an 8-frame baseline (n=286) at 44.6% lower cost, and a lossless content compression cuts cost to 75.6% below frames with no measurable accuracy loss. On GPT-5.5 the trade-off is even stronger: the compressed index trails frames by only about 3% (0.874 vs. 0.895) while using 82.8% fewer input tokens. The index is also stable across models, the compressed result differing by only about three points between them (0.843 on Opus 4.8, 0.874 on GPT-5.5). The honest summary is most of the frame baseline's accuracy at a fraction of the cost. We release the harness, the frozen manifest, and per-item outputs for reproducibility at https://github.com/blueprintparadise/Screex.

1 Introduction

Screen recordings, including screencasts, product demos, bug reproductions, and software tutorials, capture rich evidence about how software is used. Large multimodal models (LMMs) are increasingly asked to interpret such recordings: to summarize workflows, answer questions, or recover the sequence of actions. The standard interface is to sample frames from the video and provide those images to the model. Frames are a direct representation, but they are also an expensive one: each image consumes many input tokens, and because any individual frame may miss the relevant moment, systems typically sample several frames, increasing cost without guaranteeing coverage.

We study an alternative perception layer motivated by a simple property of GUI recordings: much of the salient information is conveyed through text and changes in text. Menu labels, button captions, dialog contents, field values, and lines that appear or disappear after user actions often carry the evidence needed to answer questions about the recording. Our pipeline (SCREEX) constructs a compact *index* of a recording using a small local pass: OCR and keyframe segmentation, with no model calls (Figure 2, appendix). The resulting index is a sequence of UI states, each containing on-screen OCR text and the text *added* or *removed* relative to the previous state. Since the index is primarily text, it is considerably cheaper to provide to a model than the corresponding raw image frames.

The central question is a controlled, same-model comparison: *for a fixed LMM, how accurately can a* SCREEX *index answer questions about a GUI recording relative to raw sampled frames, and at what cost?* We answer this question on GUI-World (Chen et al., 2024a), using its released multiple-choice QA (MCQA) task and objective exact-match metric. This design keeps the evaluation focused on perception quality: there is no LLM judge, no semantic-threshold tuning, and no need to manufacture ground truth.

Contributions. **(1)** We introduce a controlled evaluation protocol that isolates the *perception layer* by holding the model and questions fixed while varying only the input representation (index vs. frames), and by measuring both accuracy and token cost. **(2)** On 286 desktop-domain GUI-World MCQs, the index comes within ∼5 accuracy

EMNLP 2026 Industry Track, pages 2489–2499
October 24-29, 2026 ©2026 Association for Computational Linguistics

points of an 8-frame baseline while reducing cost by ∼45%; a frame-budget sweep shows diminishing returns beyond 4 frames, indicating that the cost gap is not removed by simply using fewer frames. **(3)** We show that a *lossless* content compression of the index (removing a derivable diff representation and factoring repeated UI chrome) reduces input tokens by 56% with accuracy statistically indistinguishable from the uncompressed index. This yields a measured 75.6% cost reduction relative to raw frames and highlights that *data-lossless* encodings are not necessarily *accuracy-lossless*: model-legibility of the encoding still matters. **(4)** We provide a reproducible harness (a frozen manifest, cached per-item outputs, and cost accounting) together with a reference implementation, and discuss the main engineering control needed for long recordings: bounding the index size so that it remains within model context.

2 Background and Related Work

Several benchmarks address GUI-video understanding or desktop automation. We surveyed them for suitability to a *controlled video-understanding* evaluation with *released* ground truth. We adopt GUI-World (Chen et al., 2024a) because it provides human-annotated ground truth for an understanding task: multiple-choice questions scored by exact match. This avoids the central risk of an action-extraction study, namely constructing our own ground truth, and makes the comparison depend primarily on the perception layer and the model. Appendix B, Table 2, gives the full benchmark survey.

GUI-World's original baselines evaluate proprietary and open LMMs, including GPT-4V, Gemini, and fine-tuned video models, using sampled frames as input. Our study is orthogonal: we fix one strong model and vary the *perception representation* (raw frames versus an index), which the original benchmark does not isolate. Other relevant settings, including action-extraction benchmarks such as Sharingan (Chen et al., 2024b) and instructional-video automation benchmarks (Zhao et al., 2025; Lin et al., 2024; Zhao et al., 2023; Gao et al., 2024), either do not release understanding ground truth or evaluate task execution rather than perception, and so do not support the controlled comparison required here.

Text and structured representations of GUIs. Replacing pixels with a textual or structured representation is well established for *single-screen* GUI agents: accessibility trees and DOMs as model inputs (Zhou et al., 2024), set-of-mark prompting over parsed elements (Yang et al., 2023; Lu et al., 2024), GUI grounding from screenshots (Cheng et al., 2024), and screenshot-as-text pretraining (Lee et al., 2023). Our work differs in three respects. First, our unit of analysis is a *recording*, not a screenshot: the index is a temporal sequence of UI states with text-change diffs, rather than a single parsed view. Second, the index is *model-free*, relying only on OCR and keyframe segmentation rather than an auxiliary detector or accessibility API, which screen recordings rarely expose. Third, we explicitly measure the cost-accuracy trade-off against raw frames for the same model and the compressibility of the representation, neither of which is the focus of the agent literature above.

3 Method

3.1 The SCREEX index (Arm B perception)

SCREEX converts a recording into a JSON *index* using a local, model-free pipeline. The pipeline consists of **(i)** frame sampling at a fixed rate (2 fps in this study); **(ii)** keyframe/state segmentation, which groups consecutive frames into UI *states* at points of visual or textual change, so that redundant near-identical frames are collapsed; **(iii)** OCR for each state using RapidOCR / ONNX Runtime, yielding on-screen text lines in reading order; and **(iv)** a text diff between consecutive states, recording the lines *added* and *removed*. These diffs capture the visible change associated with user actions, such as a menu opening, a field being filled, or a dialog appearing. The final index is a sequence of states, each containing OCR text and add/remove diffs, together with recording metadata. In this study the index is built *audio-off*: no speech transcription is used. Arm B is therefore a visual-only representation (OCR plus keyframe structure), directly comparable to Arm A's visual frames. Because the representation is text, it is substantially cheaper to send to the model than the corresponding images.

3.2 The two perception arms

Both arms answer the *same* multiple-choice question with the *same* model and must output a single option letter. They differ *only* in the perception input. **Arm A, Raw frames (baseline).** We sample $N{=}8$ frames uniformly across the video and send them as images alongside the question and options.

This is the standard "frames as perception layer" baseline. **Arm B, SCREEX index.** We build the index and send its JSON text (OCR plus per-state text diffs) alongside the question and options. This arm is text-only and contains no images.

One asymmetry is intentional: the index is distilled from 2 fps sampling and keyframe segmentation, often summarizing tens or hundreds of frames, whereas Arm A receives 8 uniform frames. The comparison is therefore a *dense text index* versus *sparse frames*. This reflects the practical deployment choice: a text index can afford dense temporal coverage that would be expensive as image input. Consequently, part of the index's accuracy may come from broader coverage rather than from representation alone; we revisit this point in the Limitations.

3.3 Task, metric, and cost

Task. The task is multiple-choice QA. Each item consists of a question, a set of options, and a gold letter. The model is instructed to answer only with the option letter. We parse the first *standalone* option letter from the reply, so that an "a" inside a word such as "answer" is not mistaken for option A. Unparseable replies are counted as incorrect. **Metric.** We report exact-match accuracy, defined as correct / total, both overall and by scenario. **Cost.** For each call, we log `input_tokens` and `output_tokens`. We then price them using the model's published rates at the time of our experiments (`claude-opus-4-8`: $5 / 1M input tokens and $25 / 1M output tokens), allowing us to report a dollar cost per arm. Dollar figures are an illustrative snapshot: published rates may change, but the input-token reductions we report are pricing-independent. These figures include only *model-API* tokens. Building the index is a one-time local pass (OCR plus keyframe segmentation, with no model calls), amortized across questions about a recording, and is not included in the API-token cost.

4 Experimental Setup

Benchmark. We use GUI-World `Annotation/benchmark/*.jsonl`. Each record contains one MCQA item (`Question`, lettered `Options`, and `Correct Answer`, e.g., `[[B]]`) together with a video. **Domain.** We restrict evaluation to the desktop domain, namely the *software* and *website* scenarios. Mobile (iOS/Android) and XR are outside the scope of this study and are excluded. The *multi*(-window) scenario was also excluded after a pilot (Section 6). **Sampling.** From the 742 desktop-domain MCQs, we draw a fixed sample of 300 using seed `42`. The sample is frozen in a committed manifest for reproducibility and consists of 212 software items and 88 website items. **Model.** Both arms use the same model, `claude-opus-4-8`, with `max_tokens = 1024`. **Arm A budget.** Arm A uses 8 uniformly sampled frames per video. Frames are written at the video's *native* resolution as PNG (no resizing and no `detail` parameter); the API auto-downscales images above $\sim$1.15 MP and tokenizes them at approximately $wh/750$.[1] Measured usage for the 8-frame arm averages 16,388 input tokens per item ($\approx$2,048 tokens per frame plus the prompt), so frame cost scales roughly linearly with the frame budget. **Arm B settings.** Arm B builds an audio-off index at 2 fps, with JSON capped at 100,000 characters. This is the index's "perception budget" (Section 6). **Harness.** A standalone package imports SCREEX as a library. Pure logic, including MCQA parsing, dataset filtering, sampling, and cost accounting, is unit-tested with fakes; the model, OCR, and dataset interfaces are thin wrappers. Each item's output is cached, making the run resumable and re-scorable without additional model calls. Code and the frozen manifest are released at https://github.com/blueprintparadise/Screex.

Reported set. Of the 300 sampled items, 14 were excluded: 13 because the index, even after capping, exceeded the model's request/context limit or hit a transient connection error, and 1 because the video file was a corrupt (truncated) download. The reported matched results use the 286 items for which *both* arms produced an answer, evaluated on the identical set.

5 Results

Table 1 gives the main controlled comparison, and Figure 1 plots the three arms as cost-accuracy operating points. A frame-budget sweep (Figure 3, appendix) is discussed afterward because it is run on a separate 60-item subset and supports only the shape of the frame-cost curve.

[1] Here w and h are the image's pixel width and height after the provider's auto-downscaling; $wh/750$ is the provider's published image-token approximation at the time of our experiments and is subject to change.

Arm	Exact-match accuracy			Input tok.	Cost (USD)	vs. frames
	Overall (n=286)	Software (n=198)	Website (n=88)			
A. Raw frames (8)	**0.902**	0.889	0.932	4.69M	23.46	n/a
B. SCREEX index	0.850	0.828	0.898	2.59M	12.99	−44.6%
B′. SCREEX index (compressed)	0.843	0.838	0.852	1.14M	**5.73**	**−75.6%**

Table 1: Main result: controlled comparison, same model, both-answered n=286. The index is within ∼5 points of the 8-frame baseline at ∼45% lower cost; lossless content compression compounds this to a 75.6% cost reduction versus frames. By paired exact McNemar, the frames>index gap is significant (discordant 31/16, p=0.04) whereas the index vs. compressed difference is not (13/11, p=0.84): compression is accuracy-neutral on the full set. Output tokens are negligible (single-letter answers): 1,057 / 858 / 1,189 respectively.

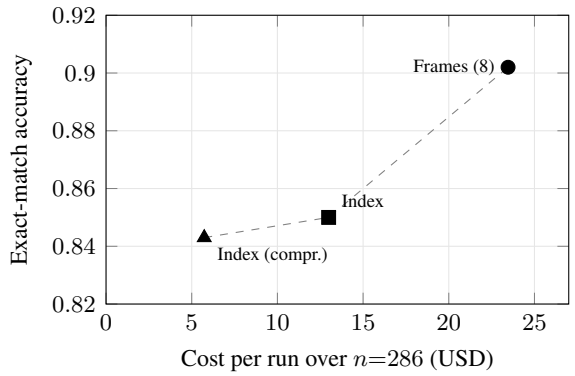

Figure 1: Cost-accuracy operating points (same model, n=286; numbers from Table 1). Moving from raw frames to the compressed index cuts cost by 75.6% ($23.46 to $5.73) for a ∼6-point accuracy reduction; the dashed line traces the frontier.

Efficiency. The raw index uses 55.4% of the frames arm's input tokens, corresponding to a 44.6% cost reduction ($12.99 vs. $23.46). Applying the lossless content compression described in Section 5.1 to the same items (arm B′) reduces cost by a further ∼56% *relative to the raw index*. Because the two savings operate on different bases, they compound to a measured 75.6% reduction relative to raw frames ($5.73 vs. $23.46; ≈4.0K vs. ≈16.4K input tokens per item). Output tokens are negligible for all arms.

Accuracy. Overall, the index is ∼5-6 points below the 8-frame baseline (0.850 raw / 0.843 compressed vs. 0.902). The gap is modest but statistically significant: paired exact McNemar gives p=0.04 for frames>index (31 frames-only-correct items vs. 16 index-only-correct items). Compression, in contrast, does not produce a significant change relative to the raw index (0.843 vs. 0.850; discordant 13/11, McNemar p=0.84). We report several paired comparisons in this section, so we do not lean on the borderline p=0.04 in isolation: it is not corrected for multiple testing and would not survive a strict Bonferroni adjustment. The frames>index conclusion instead rests on the consistent *direction* and effect size of the gap, including its replication on a second flagship model (frames lead on both Opus 4.8 and GPT-5.5; Table 4). The result should therefore be read as most of the frame baseline's accuracy at roughly a quarter of the cost, not as parity or superiority.

Coverage. The compressed arm also *answers 13 items that the raw index could not* (299 vs. 286). These are long recordings for which the raw index exceeded the request limit (Section 6); after compression, they fit. Compression therefore improves not only cost but also the index's effective coverage.

Intent-to-treat. Table 1 reports the paired comparison on the 286 items answered by both arms, the appropriate set for McNemar testing, but it excludes the raw index's hardest overflow cases. Intent-to-treat (Table 3, appendix) reports a complementary view: all 300 sampled items are counted, and any unanswered item is scored as wrong. Under this denominator, frames reach 0.860, the raw index reaches 0.810, and the compressed index reaches 0.840. Because the compressed arm answers 299 items rather than 286, its effective gap to frames narrows to ∼2 points, a smaller deployment penalty than the matched comparison alone would suggest.

Frame-budget sweep. To check that the 8-frame budget does not itself explain the gap, we sweep $N \in \{1, 2, 4, 8, 16\}$ on a 60-item subset (Appendix D). Accuracy jumps from 0.750 (1-2 frames) to 0.883 at 4, then is flat (8/16: 0.850/0.833, within noise at n=60) while token

cost grows linearly: beyond a few frames, images add cost, not accuracy. This subset is unrepresentative (frames@8 score 0.850 here vs. 0.902 on the full 286), so we keep the index-vs-frames comparison on the full set. The takeaway: the index's cost advantage cannot be recovered by cheaper frame sampling; fewer frames lose accuracy, more only add cost.

Is the gap a frame-selection artifact? The index uses keyframe segmentation while Arm A samples *uniformly*, so the index might look competitive only because the frame baseline is poorly chosen. We rerun the frames arm with its 8 frames picked by the index's *own* segmentation (n=274 completed; on this set uniform frames@8 score 0.898 and the compressed index 0.836). Keyframe-selected frames@8 score *identically* to uniform (0.898 vs. 0.898; McNemar p=1.0) using ≈30% fewer frames. The visual baseline is thus not under-optimized: given the index's own frames it scores the same, so the ∼6-point deficit is representational, not a selection artifact (frames still lead the index here, 0.898 vs. 0.836, p=0.0095). The index's value is cost, not accuracy parity.

Does it replicate on another model? Because the value argument could hinge on one model's token accounting, we repeat both arms on a second flagship, GPT-5.5, on the same 286 items (Table 4, appendix; all answered). The pattern holds: the frames>index gap shrinks to 2.1 points (from 5.9 on Opus 4.8) while the compressed index's token reduction grows to 82.8% (from 75.7%). As token savings are pricing-independent, the trade-off is a property of the representation, not of one model or price schedule.

5.1 Index compression: same accuracy at a fraction of the index cost

Much of the index's token budget comes from redundancy. Each state contains both its full OCR snapshot and add/removed diffs, even though these are mutually derivable. In addition, persistent UI chrome (menus, toolbars, taskbars, and other repeated elements) appears in every state. In the largest sampled index, 1,618 OCR lines collapse to 359 unique lines (4.5× duplication). We therefore apply two lossless, model-free post-processing transforms: **(1)** keep a single representation per state (the snapshot) and remove the derivable diff fields; and **(2)** factor persistent UI by hoisting lines present in *every* state into a single `persistent_ui` block, leaving each state with only its unique text. Across the 286 indexes, this reduces characters by 50% while remaining lossless at the per-state line-set level: each state's text set reconstructs exactly, as verified by unit tests.

On an 80-item ablation (Table 5, appendix), content compression matches the raw index within sampling noise while nearly halving token usage. The one-item difference (72 vs. 71 of 80) is not statistically meaningful at this sample size. We also tested a compact TOON serialization on top of content compression. It saved a further ∼6% tokens but cost ∼1 additional item on the same subset, so we report content compression in plain JSON and leave format-level compaction for future work. This illustrates the distinction between *data-lossless* and *accuracy-lossless*: an encoding can preserve all information while becoming slightly less legible to the model.

Full-set result (n=286). We then run the content-compressed index on the same 286 items as the main study (arm B′ in Table 1). It scores 0.843 overall, compared with 0.850 for the raw index; this difference is not significant (McNemar p=0.84), with the small dip concentrated on the website scenario. The compressed index uses 1,139,952 input tokens ($5.73), a 56.1% reduction relative to the raw index and, compounded with the index's 44.6% saving over frames, a 75.6% reduction relative to raw frames. The full-set compression saving (56%) is larger than the 80-item ablation saving (48%) because the longest software indexes, which are under-represented in the 80-item subset, compress most strongly. Compression also recovers 13 long recordings whose raw index exceeded the request limit, so the compressed arm answers 299 items versus 286 for the raw index.

6 Analysis and Discussion

Index size is the key engineering variable. The index is small on average (median ≈7K tokens/item, p99 ≈34K, max ≈48K) but has a heavy tail: a few long software recordings (code editors, language-pack switches, dense or non-Latin text) produce indexes that exceed the model context, yielding "request too large" errors. Since such text tokenizes well above the naive 4-chars/token rule, a 200K-character cap was insufficient; we cap the index at 100K characters, uniformly subsampling states to fit. This is the index arm's counterpart to the fixed 8-frame budget and leaves ev-

ery otherwise-successful item untouched ($\leq$48K tokens). A few pathological raw-JSON indexes still exceed the limit and are excluded from the raw-index matched set (Section 4); content compression (Section 5.1) recovers 13 of them, leaving only the corrupt video unanswered for the compressed arm. Compression is thus both cheaper and a partial remedy for overflow; importance-aware truncation (keep high-change states, summarize the rest) is the natural next step.

Why *multi* was dropped. A 30-item pilot included the multi-window scenario, where the text-only index performed markedly worse and produced the first oversized-index failures. Multi-window understanding plausibly depends on cross-window *visual* layout that a flat OCR index underrepresents. Because it is also a relatively small portion of the desktop domain, we restrict the main study to software plus website scenarios and leave multi-window evaluation for future work, likely requiring keyframe *images* in addition to text.

Where the index lags (and why). We inspect the 31 items that frames answer correctly and the index misses (24 software, 7 website, consistent with the scenario-level gap). Using question wording as a proxy, the index's loss rate is higher on state/value questions ("which/what value or setting is displayed": 10/66, 15.2%) than on action/click questions (20/191, 10.5%), consistent with the index struggling when the answer depends on exact visual state that OCR may distort, rather than on *what action* occurred. A split by the share of non-Latin characters in the index's OCR reinforces this: on the 9 recordings with $\geq$10% non-Latin text (language-pack switches and CJK UIs), the index scores 0.778 versus frames' 0.889 (gap -11.1); on the 277 mostly-Latin recordings, it scores 0.852 versus 0.903 (gap -5.1). Because n=9 is small, this is directional, and non-Latin share is only a proxy for unmeasured OCR error. Both analyses point toward a *hybrid* index that combines text with a small number of keyframe thumbnails, trading some cost advantage for robustness on fine-visual and noisy-OCR cases.

Deployment and use. Beyond the benchmark, the system is deployed as a perception layer for screen-recording understanding in engineering and product workflows, chiefly debugging-session review, implementation traceability, and converting product demonstrations into draft how-to documentation, rather than only as an experimental artifact. Over the course of development, the system has been used to process more than 500 screen recordings and support several thousand downstream question-answering and analysis requests across internal evaluation and engineering workflows. In practice, users employ the index to review bug reproductions, inspect implementation traces, locate workflow steps in long recordings, and generate first-pass documentation from product demos. Because the index is built once and reused across multiple questions, the approach has proven particularly useful for recordings that would otherwise require repeated manual review of the original video.

We report these figures as operational deployment signals rather than controlled measurements. The usage reflects real engineering workflows and exploratory adoption of the system, but the raters, task mix, and evaluation criteria are internal and uncontrolled. Consequently, these observations should be interpreted as evidence of practical utility rather than rigorous effectiveness measurements, and are distinct from the benchmark accuracy results reported above.

Limitations

Subset, not the full benchmark. We evaluate a frozen 300-item desktop-domain sample, with 286 items in the matched comparison. The sample and seed are committed for reproducibility. The results should be read as evidence for this desktop-domain setting, not for all of GUI-World. **Two base models.** The main study uses `claude-opus-4-8`; we replicate the headline trade-off on a second flagship model, GPT-5.5 (§5, Table 4). Both models show the same pattern (frames are modestly more accurate, while the index is much cheaper) but the precise gap and absolute accuracies vary by model. We do not claim generality beyond these two models, and cross-paper GPT-4V/Gemini comparisons are not implied. **Excluded items.** The matched comparison excludes 14/300 items: 13 due to oversized-index/connection failures and 1 due to a corrupt video. This biases the matched set toward shorter recordings. We therefore also report intent-to-treat accuracy over all 300 items (Table 3), where unanswered items are counted as wrong. **Text-only index.** Arm B contains no images. A hybrid text + keyframe index is not evaluated here. **Audio-off, desktop-only, MCQA-only.**

We do not use speech narration, do not evaluate mobile/XR settings, and do not evaluate free-form or LLM-judged QA. These are scope choices rather than claims of generality. **Frame budget.** We sweep $N \in \{1, 2, 4, 8, 16\}$ (Figure 3) and find diminishing returns beyond $N=4$, so the gap is not simply an artifact of choosing 8 frames. The sweep is run on a 60-item subset that is unrepresentative in both directions, so its absolute accuracies should not be compared to the 286-item main table. We claim only the diminishing-returns *shape* from this sweep. A full-n sweep, and sweeps on additional models, remain future work. **Multiple comparisons.** We report several paired McNemar tests and do not apply a family-wise correction; individual p-values (notably the headline $p=0.04$) are therefore uncorrected, and we rely on effect direction and cross-model replication rather than on any single test. **Coverage asymmetry.** The index is distilled from dense 2 fps sampling, whereas the frame baseline receives 8 uniform images. Some of the index's accuracy therefore reflects broader temporal coverage rather than representation alone. The comparison is realistic for deployment, but it is not a pure isolation of text versus pixels. **Frame selection (tested).** Selecting the frame arm's 8 frames using the index's own segmentation, rather than uniform sampling, leaves frame accuracy unchanged (0.898 vs. 0.898, $p=1.0$; §5). Thus, the index's deficit is not explained by an under-optimized uniform frame baseline. We do not sweep richer frame-selection strategies beyond this control. **Preprocessing cost not in the dollar figures.** Our dollar costs include only model-API tokens. Index construction (2 fps decode, OCR, and keyframe/state segmentation, with no model calls) takes a median of ≈50 s of CPU time per recording (p90 ≈135 s, max ≈197 s; $n=49$) on a commodity laptop CPU using RapidOCR on CPU (Appendix D). This pass is model-free and parallelizable, and it is amortized across all questions about a recording. It is cheap in dollars but not free in wall-clock time, so the cost advantage is most appropriate for a build-once/answer-many setting rather than a single-question, latency-sensitive setting. **Compression significance.** A full-set paired McNemar test finds no significant raw-index vs. compressed-index difference ($p=0.84$, $n=286$), consistent with the 80-item ablation. This is evidence for a small or null effect at this sample size, not proof of exact equivalence. **Deployment metrics are uncontrolled.** Any deployment figures reported in the paper (Section 6) are internal, operational signals, not a controlled study, and any usefulness rating is distinct from the benchmark's exact-match accuracy. They would indicate real-world utility but should not be read as rigorous effectiveness measurements.

Ethics Statement

This study uses GUI-World (Chen et al., 2024a), a publicly released benchmark of GUI screen recordings with human-annotated multiple-choice questions. We add no new human-subjects data and conduct no annotation. Screen recordings may contain incidental on-screen text, such as file names or window titles. We do not collect or publish raw recordings; we release only the harness, the frozen question manifest (which references the public benchmark), per-item model outputs (option letters and token counts), and derived indexes constructed from the public videos. The system additionally provides a redaction mode that masks secrets and personally identifiable information in on-screen text and blurs the corresponding image regions before any index is written, so that indexes can be shared without exposing sensitive content. The study measures the cost and accuracy of a perception layer and does not involve deployed decisions affecting users. We report dollar costs using published API rates so that the efficiency claim is auditable. We identify no specific risks beyond those already associated with the underlying public benchmark.

A System Pipeline

B Benchmark Survey

C Reproducibility

Repo layout. A `study/` harness (including `compress.py`, `ablation.py`, and `frame_sweep.py` with its committed `frame_sweep_results.json`), unit tests, a frozen sample manifest, a vendored copy of the SCREEX package, and cloud/parallel run helpers. Per-item model outputs are cached under `study/cache/outputs/`; compression-ablation outputs under `study/cache/ablation/`. **Key knobs.** `FRAME_BUDGET=8`, `INDEX_FPS=2.0`, `INDEX_AUDIO=False`, `MAX_INDEX_CHARS=100000`, `SAMPLE_SIZE=300`, `SAMPLE_SEED=42`, pricing $5/$25 per 1M input/output tokens. **Scoring.** Accuracy is exact-match on the parsed option letter; cost is summed token usage at the listed prices. Results over the both-arms-answered set (n=286) are in Section 5. **Content compression.** `single_representation(mode="snapshot")` drops the derivable diff fields; `factor_persistent_ui` hoists all-states OCR lines into a `persistent_ui` block. Lossless at the per-state line-set level (unit-tested); 50% character reduction across the 286 cached indexes.

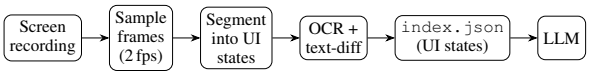

Figure 2: The SCREEX pipeline: a model-free local pass (no model calls) turns a recording into a compact text index of UI states (on-screen OCR text plus per-state add/remove diffs), which any LLM reads in place of raw image frames (a text index needs only a language model, not a multimodal one).

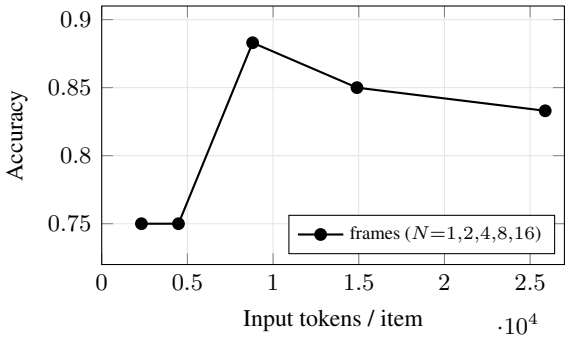

Figure 3: Frame-budget sweep (frames only, 60-item subset). Accuracy rises sharply from 1-2 to 4 frames, then shows diminishing returns (8 and 16 frames do not improve on 4) while token cost grows linearly (≈2.3K tokens/frame). The subset is unrepresentative (frames@8 score 0.850 here vs. 0.902 on the full 286), so it anchors only the shape claim; the index-vs-frames comparison is the full-286 one in Table 1.

Dataset	Task	Public data	GT shipped	Metric
GUI-World (Chen et al., 2024a)	GUI video understanding	Yes	**Yes** (keyframes, captions, 24.8K MCQs)	**Exact-match MCQA**
Sharingan (Chen et al., 2024b)	Extract user action sequence	Partial	No (GT unreleased)	P/R over typed actions
WorldGUI (Zhao et al., 2025)	Desktop GUI automation	Yes	Audio-to-text; task success	Task success rate
VideoGUI (Lin et al., 2024)	GUI automation from videos	Yes	Yes (eval reimpl. needed)	Hierarchical plan/action
SeeHow (Zhao et al., 2023)	Workflow from screencasts	Yes	No	n/a
AssistGUI (Gao et al., 2024)	Task-oriented automation	Yes	Execution-based	Task success (live envs)

Table 2: GUI-video benchmarks surveyed. "GT shipped" refers to ground truth for *understanding* tasks, such as released question/answer pairs, as distinct from *execution* ground truth, such as task-success checks in a live environment. Among the surveyed options, GUI-World is the only benchmark that ships real, human-annotated understanding ground truth with an objective metric.

Arm	ITT acc. (n=300)	Correct	Answered
Raw frames (8)	**0.860**	258/300	286
SCREEX index	0.810	243/300	286
SCREEX index (compr.)	0.840	252/300	299

Table 3: Intent-to-treat accuracy (n=300; unanswered = wrong). The compressed index (0.840) trails frames (0.860) by only ∼2 points and is closer than the raw index (0.810), because compression recovers 13 long recordings the raw index could not fit. Discussed in Section 5.

Model	Frames	Compr. index	Gap / tok. red.
Opus 4.8	0.902	0.843	−5.9 / −75.7%
GPT-5.5	0.895	0.874	−2.1 / −82.8%

Table 4: Cross-model replication (n=286, both arms; discussed in Section 5). The frames>index accuracy gap and the index's large input-token reduction hold on both providers' flagships; on GPT-5.5 the gap is smaller and the token saving larger. GPT-5.5 per-scenario: frames 0.891/0.905, index 0.861/0.905 (software/website). "Gap" is index minus frames accuracy; "tok. red." is the compressed index's input-token reduction vs. frames.

Index encoding	Acc.	Correct	vs. raw
Raw index (baseline)	0.900	72/80	n/a
Content-compressed	0.887	71/80	−47.6%
+ TOON serialization	0.875	70/80	−53.2%

Table 5: Compression ablation on an 80-item subset using the same model and questions. The index is built once and re-encoded, so only the encoding varies. "vs. raw" denotes input-token reduction. Content compression matches the raw index within sampling noise (a one-item difference, 72 vs. 71) while reducing input tokens by 47.6%.

D Measured Run Metadata

Items sampled: 300 (software 212 / website 88). Reported: 286. **Frames arm:** 4,687,055 input + 1,057 output tokens, $23.46. **Index arm (raw):** 2,594,215 input + 858 output tokens, $12.99. **Index token distribution (successful items):** median ≈7.0K, p90 ≈20.1K, p99 ≈33.6K, max ≈48.4K input tokens. **Compression ablation (80-item subset):** raw index 0.900 (72/80, 714,621 input tok) vs. content-compressed 0.887 (71/80, 374,666 input tok, −47.6%). TOON serialization on the same compression: 0.875 (70/80, −53.2%). Verbose-JSON control for the same compression: 0.887. **Merged full-set compression (n=286):** content-compressed index 0.843 (software 0.838 / website 0.852), 1,139,952 input + 1,189 output tokens, $5.73. That is −56.1% vs. the raw index and −75.6% vs. raw frames. The compressed arm answered 299 items (+13 recovered from raw-index overflow errors). **Frame cost:** 8-frame arm = 16,388 input tokens/item (≈2,048 tokens/frame); frames written at native resolution as PNG. **Significance (paired exact McNemar):** frames vs. raw index, discordant 31 (frames-only-correct) / 16 (index-only-correct), p=0.040; raw index vs. compressed, discordant 13 / 11, p=0.84. **Intent-to-treat (n=300, unanswered = wrong):** frames 0.860 (258/300, answered 286); raw index 0.810 (243/300, answered 286); compressed index 0.840 (252/300, answered 299). **Discordant losses (frames right, index**

wrong; n=31): 24 software / 7 website; by question wording, loss rate 10/66 (15.2%) on state/value questions vs. 20/191 (10.5%) on action/click. **Non-Latin OCR (paired):** $\geq$10% non-Latin characters (n=9): index 0.778, frames 0.889 (gap -11.1); $<$10% (n=277): index 0.852, frames 0.903 (gap -5.1). Non-Latin share is a proxy for OCR error (no OCR GT available). **Index build latency (audio-off; 2 fps decode + RapidOCR + keyframe/state segmentation; one recording at a time, n=49):** min 3.6 s, median 50.5 s, mean 58.9 s, p90 135.4 s, p99/max 196.6 s (median recording 2.7 MB). Hardware: Intel i7-1355U (10C/12T), 39.7 GB RAM; RapidOCR on CPU (ONNX Runtime CPU build, integrated GPU unused). The pass is model-free and parallelizable across recordings (the full study run used 8 workers). **Frame-selection control (n=274, same model/prompt/resolution/scoring):** uniform frames@8 acc 0.898 (8.0 frames/item, $23.46); keyframe-selected frames@8 0.898 (5.5 frames, $16.89); keyframe-selected frames@4 0.876 (3.5 frames, $11.21); compressed index 0.836 ($5.73). McNemar: keyframe-8 vs. uniform-8 8/8 discordant, p=1.0; keyframe-8 vs. compressed index 28/11 discordant, p=0.0095.

E Qualitative Examples

#	Bucket	Question (gold)	F	I	C	Why it is illustrative
1	index ✓ / frames ×	"Which action was performed last?" (gold B, *added a New button*)	C ×	B ✓	B ✓	Temporal/ordering: the index encodes every state and diff and captures the final action; 8 uniform frames miss the last step. The index's coverage advantage.
2	frames ✓ / index ×	"Which port is the Docker container mapped to locally?" (gold B, `5000:8080`)	B ✓	A ×	A ×	Exact on-screen text: OCR mis-reads the port mapping; frames let the model read the pixels directly. The index's text-fidelity weakness.
3	compression preserved	"What change is made to the GUI elements?" (gold C, button renamed)	C ✓	C ✓	C ✓	Raw and compressed index agree and are both correct; content compression did not drop the answer-bearing text.
4	non-Latin, index ×	"What action followed 'no text to quick redact'?" (gold B)	C ×	C ×	C ×	Redaction app, 26% non-Latin OCR: noise corrupts the text layer, so both index variants fail where OCR is unreliable.

Table 6: Illustrative win/loss cases (one per bucket), from cached per-item results on the n=286 set. F/I/C = predicted option for frames (8) / raw index / compressed index; ✓ correct, × wrong. The pattern matches the aggregate error analysis (§6): the index wins on temporal/coverage questions (1), loses on exact on-screen text (2) and non-Latin/OCR-noisy content (4), and compression is answer-preserving (3). Full option lists and predictions are in the released harness.

Data Intelligence Agents: Interpreting, Modeling, and Querying Enterprise Data via Autonomous Coding Agents

Abstract

Production data integration is bottlenecked by repeated, lossy handoffs between data owners, engineers, and analysts who must collaboratively discover, structure, and query enterprise data. We present **D**ata **I**ntelligence **A**gents (DIA), a system of three agents (*Data Interpreter*, *Schema Creator*, and *Query Generator*) that compresses this workflow by treating autonomous coding agents (ACAs) as a first-class abstraction: rather than emitting text, the agents generate, execute, validate, and repair concrete artifacts, draw on a shared memory for experience reuse, and surface each for review by domain experts. DIA is deployed in production for enterprise customers. We study the *Query Generator* in depth and evaluate it in fully autonomous mode across seven SQL benchmarks spanning four task categories and four dialects. It matches or surpasses the best published results on all seven, demonstrating that an architecture grounded in execution, built on ACAs and a shared memory, generalizes across the data intelligence workload with adaptation confined to natural-language instructions.

1 Introduction

Enterprise data work rarely fails for lack of data; it fails because raw data must be discovered, understood, structured, and queried before it can support analysis. In practice this passes through repeated, lossy handoffs between the data owners who understand what fields mean, the engineers who structure and validate the data, and the analysts who query it. Each handoff loses context and adds latency: a misread field or an implicit business rule forces schema changes, pipeline rework, and query rewrites. The opportunity is to keep the domain experts who understand the data in control while compressing the engineering cycle.

Large language models make each step look tractable in isolation, yet existing systems address fragments of this workflow rather than closing it.

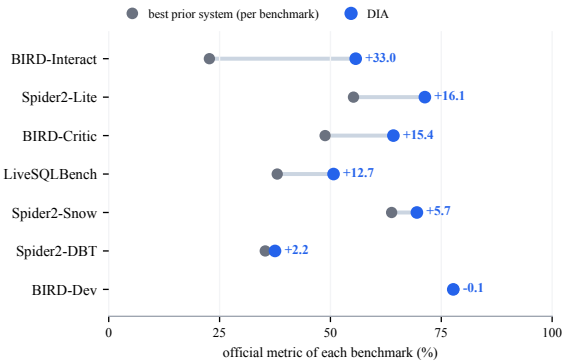

Figure 1: DIA against the best prior system on each of the seven SQL benchmarks, ordered by margin. Each benchmark is scored by its official metric.

Pipeline systems for text-to-SQL chain handcrafted modules, each tuned for one subtask and brittle when the task changes (Pourreza and Rafiei, 2023; Pourreza et al., 2025). Specialists trained with reinforcement learning reach high accuracy on a single benchmark but are locked to one dialect and need costly retraining per variant (Yang et al., 2025; Li et al., 2025a). Agentic explorers probe the database live but keep no memory across sessions, restarting from scratch on every query (Cao et al., 2026; Deng et al., 2025). SQL agents with persistent memory store and replay past experience, but keep a single store and a narrow evaluation (Biswal et al., 2026; Yang et al., 2026; Chu et al., 2024; Chen et al., 2025). Across these approaches the system emits text (queries or critiques) rather than the executable, inspectable artifacts that enterprise data work consumes, and none addresses the upstream understanding and schema construction stages that decide whether the resulting SQL has anything sensible to run against.

DIA closes this loop. It directs a single ACA (a coder driven by an LLM in a sandboxed environment) across the discovery, schema construction, and query stages (Figure 2), surfacing each artifact

EMNLP 2026 Industry Track, pages 2500–2531
October 24-29, 2026 ©2026 Association for Computational Linguistics

for review by domain experts (Wang et al., 2024b; Song et al., 2026). The key contributions are as follows:

1. The first system, to our knowledge, to treat the ACA rather than the LLM as the central abstraction for data intelligence: three agents (*Data Interpreter*, *Schema Creator*, and *Query Generator*) realized as a single ACA over a shared workspace that turns raw enterprise data into validated, queryable schemas and grounded answers, replacing lossy text handoffs with inspectable artifacts.

2. The design of the *Query Generator*: a single generalist agent that handles SQL generation, debugging, conversational interaction, and project completion across four dialects through self-correction grounded in execution and a shared memory for experience reuse, with adaptation confined to natural-language instructions.

3. A broad empirical study: in fully autonomous mode on seven SQL benchmarks spanning four task categories and four dialects, with a single LLM and no fine-tuning, the *Query Generator* matches or surpasses the best published results on all seven (Figure 1).

2 Related Work

Text-to-SQL systems. Text-to-SQL is a large and active area (Hong et al., 2025), but the work fragments by task setting. Most systems target single-shot query generation and improve accuracy on it through multi-agent collaboration (MAC-SQL (Wang et al., 2023), CHESS (Talaei et al., 2024)), ensemble pipelines (OpenSearch-SQL (Xie et al., 2025), XiYan-SQL (Gao et al., 2024)), or component-level advances in schema linking (Pradeep et al., 2025) and decoding (Sharma et al., 2025). The pipeline, reinforcement-learning, and agentic systems of Section 1 address this same setting. Other settings are served by separate, specialized systems: conversational querying (SParC (Yu et al., 2019b), CoSQL (Yu et al., 2019a)) and declarative querying over heterogeneous data (Khabiri et al., 2025). The concurrent AgentNLQ (Bogdanov et al., 2026) is the closest, a multi-agent system for general-purpose NL-to-SQL, but it too addresses a single setting. DIA's *Query Generator* instead spans four task categories across four dialects with one agent.

Data understanding and schema generation. DIA is a system, not a single SQL model, and its other two agents build on work done so far in isolation. For data understanding, large tabular models profile tables and infer column semantics, types, and relationships (TableGPT2 (Su et al., 2024)). For schema construction, recent agents build relational schemas from natural language (Text2Schema (Wang et al., 2025b)) and prepare raw data for analysis (DeepPrep (Fan et al., 2026)); new benchmarks measure data agents across the full data intelligence lifecycle, from engineering to analysis (DAComp (Lei et al., 2026)). These are standalone tools and evaluations. DIA's *Data Interpreter* and *Schema Creator* instead work as agents in one system, handing validated, executable artifacts to the *Query Generator*.

Generalist and memory agents. DIA inherits the generalist coding agent paradigm, where one agent solves many tasks through code execution instead of separate modules for each task (OpenHands-Versa (Soni et al., 2025), CodeAct (Wang et al., 2024b)). It treats ACAs as a first-class abstraction, as does NEMO (Song et al., 2026) for optimization modeling. DIA also draws on agents that learn from experience: ARIA (He et al., 2025) keeps a knowledge repository that improves over time, and Voyager (Wang et al., 2024a), Reflexion (Shinn et al., 2023), and ReasoningBank (Ouyang et al., 2025) accumulate skills, reflections, or reasoning strategies. These build experience for one agent. DIA's three agents instead share a memory and reuse experience across the system.

3 Methodology

3.1 Overview

A central abstraction in DIA is remote interaction with an ACA, an execution-capable counterpart to a text-only model call. Operating within a sandboxed environment, the ACA generates, executes, inspects, and revises code, so that every output is an executable artifact and admits execution-aware validation (Song et al., 2026; Wang et al., 2024b). DIA drives the ACA with natural-language instructions and references to existing workspace artifacts, and receives code, execution traces, and results in return.

DIA is a system of three agents, realized as a single ACA invoked over a shared workspace W: a *Data Interpreter* that profiles raw sources into a structured interpretation (Section 3.3); a *Schema*

Creator that materializes and validates a relational database from that interpretation (Section 3.4); and a *Query Generator* that translates natural-language questions into executed SQL (Section 3.5). The agents communicate through W, in which artifacts persist as files, rather than by exchanging text, and each draws on a shared memory M for experience reuse (Section 3.2); we write $M^* \subseteq M$ for the subset retrieved at each invocation. Each artifact is surfaced for review by domain experts.

3.2 Memory

Memory in DIA is artifact-based: because the ACA works in a sandbox, what it carries forward is the concrete artifacts it has produced and validated, schemas, loading and transformation scripts, validation reports, query logs, and prior solutions, rather than textual summaries of them. Within a task, the agents build on the artifacts already in the workspace W (Section 3.1), each consuming what the previous produced. Across tasks, an experience store M retains a reusable subset in three tiers that mirror a memory hierarchy: retrieved examples, an episodic tier of similar past question-and-solution pairs surfaced for the current question; session lessons, conditional rules confirmed on the current database; and cross-session lessons, the long-term semantic subset of those rules that generalize across databases.

Memory is pull-based and verified before use. Items are surfaced only by reference, and the agent reads a body only when it judges it relevant. Nothing changes an answer until a live probe confirms its precondition on the current data, so stale experience is caught by execution rather than propagated. The agent writes memory itself: after answering it reflects and records a conditional rule with its evidence, updating the store

$$M \leftarrow w(M, a, o),$$

where a is the artifact just produced and o its observed outcome, and w admits a cross-session lesson only when o bears it out, with no learned or human judge, keeping the mechanism training-free. All three agents share one memory and consume M^* through their signatures.

3.3 Data Interpreter

Given a collection of heterogeneous raw sources $D = \{d_1, \ldots, d_n\}$ such as CSV, JSON, and Excel files, the *Data Interpreter* writes and executes profiling code that produces a structured interpretation P:

$$\mathcal{I} : (D, M^*) \rightarrow P.$$

Rather than describe D in natural language, the ACA derives P entirely from executed code, and the resulting artifact is what downstream agents consume. P records, for each source, the inferred schema with column names and semantic types; per-column value distributions, null statistics, and pattern observations; candidate primary and foreign keys; likely join paths across sources; and data-quality observations that require intervention.

3.4 Schema Creator

Given the interpretation P and the raw sources D, the *Schema Creator* generates and executes loading and validation code that materializes a working database:

$$\mathcal{S} : (P, D, M^*) \rightarrow (\Sigma, \beta),$$

where $\Sigma = (T, K, C)$ specifies the tables T with their columns and types, the key constraints K (each table's primary key and the foreign keys linking tables), and the integrity constraints C (column-level rules the data must satisfy, such as not-null and value-range checks), and β is Σ instantiated as physical tables and populated with the records in D. The ACA works under a load-first-normalize-second discipline: staging tables ingest every record from D with provenance fields recording source file and load timestamp; refined tables and views apply typing and structure on top. The ACA then validates (Σ, β) along four axes: (i) row-count reconciliation between sources and β; (ii) column coverage, requiring every source column to be carried through and any rename to be recorded; (iii) key validity, checking primary-key uniqueness and foreign-key referential integrity; and (iv) load integrity, routing records that cannot be ingested to per-table reject buffers rather than dropping them silently. A set of test queries τ is executed against β; the schema is accepted only when ingestion succeeds and every query in τ executes as expected. Alongside β, the ACA emits a schema manifest enumerating T, K, and column mappings, and a validation report summarizing the four checks.

3.5 Query Generator

Given a natural-language question q and the database (Σ, β), the *Query Generator* writes and executes SQL to answer it:

$$\mathcal{Q} : (q, \Sigma, \beta, M^*) \rightarrow y,$$

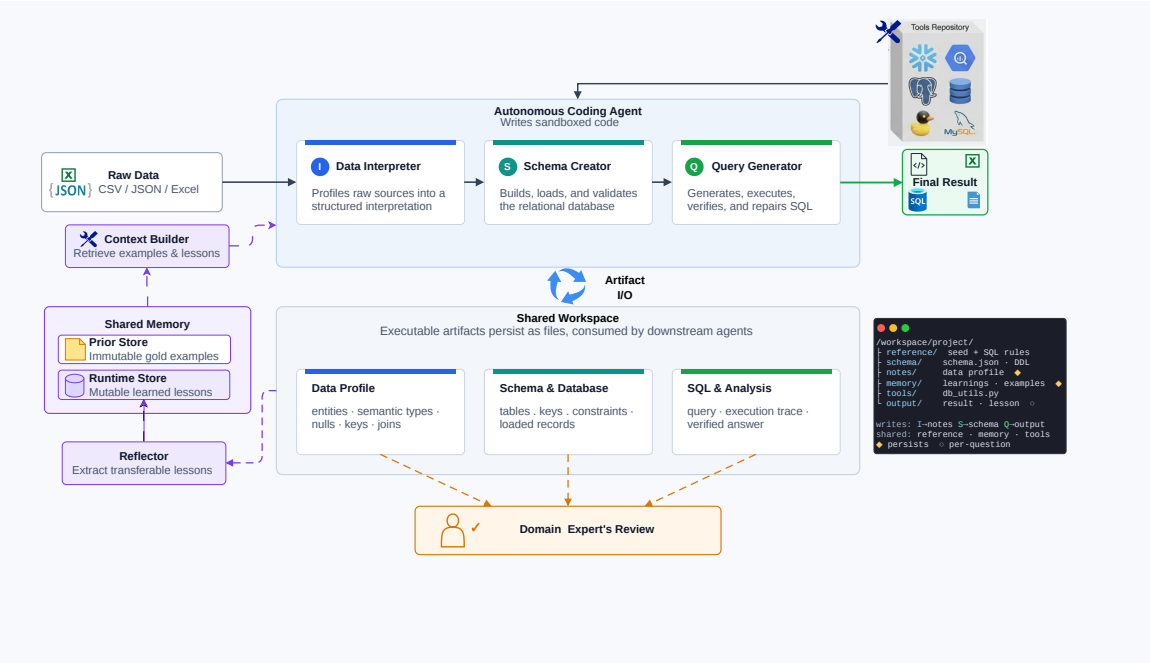

Figure 2: The DIA system. A single ACA operating over a shared workspace W realizes three agents (*Data Interpreter*, *Schema Creator*, and *Query Generator*), turning raw data D and a question q into a grounded answer R. Each agent reads and writes executable artifacts in W; all draw on a shared memory M; domain experts review each artifact.

where y is a SELECT statement for analytical questions or a DDL/DML statement for modification tasks. The ACA accesses β in read-only mode for analytical questions. Generation is execution-grounded and proceeds in four phases, with the ACA writing and executing SQL throughout.

Shape declaration. Before generating y, the ACA derives from q an expected result shape

$$\kappa = (C_\kappa,\ g_\kappa,\ o_\kappa,\ f_\kappa),$$

where C_κ is the column list implied by q, g_κ the row granularity (one row per entity, per group, per time bucket, and so on), o_κ the ordering specification, and f_κ the filter conjunction extracted from q. For modification tasks, κ specifies the target objects and the intended post-condition on β.

Schema exploration. The ACA executes lightweight probe queries against Σ and β to confirm that join keys exist, sample representative column values to fix their format, and verify cardinality assumptions, rather than inferring structure from column names alone.

Generation and execution. The ACA produces a candidate query

$$y = \mathcal{G}(q, \Sigma, M^*, \kappa)$$

conditioned on the question, schema, retrieved memory, and declared shape, and executes it to obtain $R = \mathrm{exec}(y, \beta)$.

Self-verification. The agent does not treat the first query it writes as final. It checks the result against the declared shape with its own indicator

$$V(R, \kappa) = \begin{cases} 1 & \text{if } R \text{ satisfies } \kappa, \\ 0 & \text{otherwise,} \end{cases}$$

evaluated componentwise against C_κ, g_κ, o_κ, and f_κ. For modification tasks, V checks that the intended post-condition holds in β. This check is the agent's own and is computed from execution rather than supplied by an external verifier or human: when $V(R, \kappa) = 0$, the agent diagnoses the gap, revises y, and re-executes within the same pass before emitting an answer. The procedure is independent of task category and SQL dialect; only the grammar of κ varies across them.

4 Evaluation

4.1 Setup

We evaluate the *Query Generator* on seven public SQL benchmarks: BIRD-Dev (Li et al., 2023), BIRD-Critic (Li et al., 2025b), LiveSQLBench (BIRD-bench Team, 2025), BIRD-Interact (Huo

et al., 2026), and the Spider2 family (Lei et al., 2025) (Spider2-Lite, Spider2-Snow, and Spider2-DBT). Together they comprise 4,187 instances spanning four task categories and four SQL dialects: generation (BIRD-Dev, LiveSQLBench, Spider2-Lite, Spider2-Snow), debugging (BIRD-Critic), conversational interaction (BIRD-Interact), and dbt project completion (Spider2-DBT), across SQLite, PostgreSQL, Snowflake, and DuckDB. Several benchmarks contain finer task categories, such as data modification in LiveSQLBench and personalization in BIRD-Critic, which we break down in Appendix B; full dataset details are given in Appendix A.

All experiments use a unified system configuration: OpenHands, powered by Claude Sonnet 4.5 with no fine-tuning, acts as the ACA, while o3 serves as the user simulator in BIRD-Interact's conversational protocol. Customization for each benchmark is confined to a standing seed file and the per-question prompt scaffolding (Appendix E), and every run is fully autonomous with no human intervention. Implementation details are given in Appendix I. The shared memory examined in Section 4.5 retrieves its episodic examples from the BIRD train split, indexed offline and disjoint from the BIRD-Dev evaluation set, and is detailed in Appendix F.

For each benchmark we compare against the best available prior results (Appendix H). Systems with an accompanying publication are cited in Table 1, and the remainder are listed by name. The primary metric is each benchmark's official one: execution accuracy throughout, except task success rate on BIRD-Interact and database-match accuracy on Spider2-DBT. Additional official metrics and their definitions are given in Appendices B and A. Reported execution accuracy on BIRD-Dev varies by a small margin across works, owing to differences in evaluation harnesses and to noise and periodic corrections in the benchmark's gold queries (Wretblad et al., 2024). We release granular per-instance results via HuggingFace[1].

4.2 Main results

Table 1 summarizes performance across the seven benchmarks, comparing the *Query Generator* against the strongest available agent-based and training-based systems. Overall, it achieves strong and consistent performance, matching or surpassing the best published result on all seven benchmarks, by large margins on several.

The gains are largest on the tasks where prior systems struggle most: +33.0 points on BIRD-Interact (conversational interaction), +16.1 on Spider2-Lite, +15.4 on BIRD-Critic (debugging), and +12.7 on LiveSQLBench. Appendix D traces where the BIRD-Interact margin comes from, with worked interaction traces and an interaction-time scaling analysis. On the most competitive benchmarks the lead narrows but holds: +5.7 on Spider2-Snow and +2.2 on Spider2-DBT, where the agent edits a real dbt repository rather than emitting a single query and the strongest prior system is built on GPT-5.4. On BIRD-Dev, the most saturated benchmark, where the field is clustered within a point, DIA is level with the strongest published result, MARS-SQL (Yang et al., 2025), an RL-trained specialist (77.7 vs. 77.8). One model and scaffold thus serve four task categories and four dialects, with adaptation confined to natural-language standing instructions.

The per-category breakdown (Appendix B) shows two consistent patterns beneath the headline scores. DIA is strongest on the more structured task variants: BIRD-Critic Management (78.7) and LiveSQLBench Modification (66.3) both exceed the same benchmark's pure-query slice, because modification tasks reward the agent's habit of declaring the target object and validating it by execution before answering. It is weakest on high-level questions that name a composite metric without spelling out its formula (41.6 on LiveSQLBench, 47.6 on BIRD-Interact), where the agent must either decompose the metric or ask. On BIRD-Interact, the phase-2 conditional pass rate of 86.8 shows that once a correct phase-1 query lands, follow-ups are almost always answered correctly.

4.3 Component ablation

To separate the contribution of the system from that of the underlying model, we ablate one component at a time on the full BIRD-Dev set (1,534 questions), holding the model and the agent loop fixed (Table 2). Removing shape declaration and removing execution-based self-verification each cost 7.5 points; these are two halves of one output-contract discipline (Appendix E), so disabling either one removes it. Removing the shared memory costs 2.6 points. Reducing the system to a bare OpenHands agent on the same model, given only the

			DIA	**37.5**

Table 1: DIA against the strongest published baselines across seven SQL benchmarks. Score is each benchmark's official primary metric (higher is better): execution accuracy in all cases except task success rate (BIRD-Interact) and database-match accuracy (Spider2-DBT). Each benchmark's primary and additional metrics are described in detail in Appendix A.

schema and the question, costs 14.1 points, a second system-versus-model control that mirrors the LiveSQLBench gap in Table 1 (35.2 to 50.7). The clarification policy is evaluated on BIRD-Interact, whose interactive protocol depends on it: removing it drops task success from 55.7 to 14.5, a 41.2-point fall (Appendix D). Across benchmarks, then, it is these components rather than the backbone that drive the gains.

This ablation also maps design to benchmark gains. Shape declaration and self-verification, the output-contract discipline ablated above, underpin the debugging and modification gains on BIRD-Critic (+15.4) and LiveSQLBench (+12.7) in Table 1, since both tasks reward validating a candidate object or edit against the database before returning it. The clarification policy accounts for most of the +33.0-point margin on BIRD-Interact, whose conversational protocol rewards resolving ambiguity rather than guessing. Shared memory contributes more evenly across benchmarks, since the rules it accumulates concern joins, aggregation, and output convention, failure modes that recur regardless of task type (Section 4.5).

4.4 Cost, latency, and variance

We report per-question cost and latency for DIA on BIRD-Dev, measured over the full run (Table 3). A question costs about USD 0.10 on average, ranging from 0.03 to 0.20 across databases, and processes about 145k input tokens (of which roughly 94% are served from cache) and about 1.6k output tokens. End-to-end runtime has a median of 38 seconds; the 90th percentile, meaning all but the slowest one in ten questions, is 68 seconds. Since questions are independent, throughput scales with parallel workers.

To quantify run-to-run variability under the nondeterminism of the underlying agent, we run BIRD-Dev three times, obtaining 77.7, 76.1, and 77.0, a mean of 76.9 with a standard deviation of 0.8 (Table 2). The 0.1-point gap to the strongest published

Configuration	Score (%)	Δ
Full DIA	77.7	—
No shared memory	75.1	–2.6
No self-verification	70.2	–7.5
No shape declaration	70.2	–7.5
Bare OpenHands agent	63.6	–14.1
Full DIA, mean of 3 runs	76.9 ± 0.8	—

Table 2: Component ablation on the full BIRD-Dev set (1,534 questions), removing one component at a time on the same model and instances, plus the mean and standard deviation across three independent full runs. The clarification policy is ablated separately on BIRD-Interact, dropping from 55.7 to 14.5, a fall of 41.2 points, whose protocol requires it.

Metric	Mean
Cost / question	USD 0.10 (range 0.03–0.20)
Input tokens / question	145k (94% cached)
Output tokens / question	1.6k
Runtime, median	38 s
Runtime, 90th percentile	68 s

Table 3: Per-question cost, token usage, and latency for DIA on BIRD-Dev, averaged over the full run; the cost range is across databases. Runtime is the distribution over questions; the 90th percentile bounds all but the slowest one in ten.

result in Table 1 is thus well within run-to-run noise, and within the documented annotation noise of the benchmark (Wretblad et al., 2024).

4.5 Learned Rules

On BIRD-Dev, for example, DIA accumulates a small store of conditional rules of a few recurring kinds, each interpretable and grounded in a check on the data. This accumulation introduces no test leakage: the agent never sees gold answers or a grading signal, every rule is distilled from its own execution observations and re-verified on the live database before it can change an answer, and the episodic examples it retrieves come from the disjoint BIRD train split. Rules form in two stages: a rule begins as a concrete within-database observation and is promoted to a cross-database rule only when later questions bear it out. On `california_schools`, for instance, the agent counting schools through a one-to-many join saw `COUNT(*)` return 9,977 for one school (its fact-row count) but `COUNT(DISTINCT CDSCode)` return 1. The rule promoted from this is to count entities through a repeating join with `COUNT(DISTINCT pk)`, not `COUNT(*)`. The rule kinds it records span joins, aggregation, and output convention, the same recurring failure structures the error analysis (Section 4.6) finds behind most wrong answers. Appendix F gives representative rules with their evidence, both stages of this promotion, the full three-tier store, and a worked trace of a session lesson redirecting a later answer.

4.6 Error analysis

Almost every failed instance runs to completion and returns a wrong answer rather than failing to execute, so the remaining errors are overwhelmingly semantic rather than syntactic. Appendix C sorts them into three recurring classes: reasoning, output convention, and grounding, with reasoning by far the most frequent. A reasoning failure executes cleanly but answers a subtly different question, most often a wrong join, filter, or formula on an under-specified request.

5 Conclusion

We presented DIA, which treats the ACA as the central abstraction for enterprise data intelligence: a single ACA over a shared workspace, invoked as three agents, produces executable artifacts that domain experts review rather than text they must trust. The premise is that one agent grounded in execution can replace a family of specialized systems, and our evaluation supports it: with a single LLM and no fine-tuning, the *Query Generator* matches or surpasses the best published results on all seven benchmarks (Table 1), across task categories and dialects that prior work covers with separate, task-specific systems.

Two lessons recur across benchmarking and deployment alike. Execution grounding helps most where an answer can be checked against the database, and least on upstream domain ambiguity that execution cannot resolve; and for a system meant to be reviewed rather than trusted outright, the design choice that matters most is emitting inspectable artifacts rather than natural-language explanations of them. DIA is deployed in production for enterprise customers (Appendix G), where these same properties, execution-grounded artifacts, human review, and permission-scoped access, provide the auditability such settings require.

6 Limitations and Future Work

DIA trades computation for reliability. Each question runs through an iterative loop of generation, execution, and verification, with conversational tasks adding multi-turn interaction, so mean time per question ranges from under a minute on single-shot generation tasks to roughly ten minutes on multi-turn conversational tasks; Section 4.4 reports the full BIRD-Dev cost and latency distribution. This is acceptable when answers feed durable artifacts but may be prohibitive for interactive or high-throughput use. Caching exploration, parallelizing independent runs, and distilling routine patterns into cheaper components would reduce it.

Verification in DIA is execution-grounded but not semantic. The agent checks an executed result against the result shape it has itself derived from the question, so when it misreads intent, the query and the check inherit the same misreading and a wrong answer passes. The residual failures in Section 4.6 concentrate there: join, filter, and formula reasoning on under-specified questions. Engaging the semantics of the question, rather than the shape of its answer, is the clearest path to closing the gap.

Finally, the evaluation is broad in tasks and dialects but deliberately narrow elsewhere: one of the three agents, a single backbone, a simulated rather than human user on conversational tasks, and memory examined only qualitatively. All results use one LLM (Claude Sonnet 4.5) with no fine-tuning, so we do not yet establish that the gains transfer across backbones; the ablation in Section 4.3 bounds the single-model risk, since DIA's margin over a bare agent on the same model and substrate (14.1 points) indicates the system, not the model, carries the result, but a study across backbones remains future work. We plan to widen each dimension: benchmarking the *Data Interpreter* and *Schema Creator* on data preparation and schema generation, testing sensitivity across LLMs such as GPT and Gemini, and studying real users. Memory is a further direction: experience accumulates as artifacts and rules in the workspace, and organizing it with graph-structured links rather than as files would let the system mine that experience more effectively.

A.1 Descriptions

Table 4 summarizes the seven benchmarks. All are public, and we evaluate their official splits.

Benchmark	N	DBs	Dialect	Task	Composition	Metric
BIRD-Dev	1,534	11	SQLite	generation	by difficulty: simple 922, moderate 460, challenging 152	EX
BIRD-Critic	500	15	SQLite	debugging	by category: query 284, personalization 141, management 75	EX
LiveSQLBench	600	22	PostgreSQL	generation	by category: query 410, modification 190 by difficulty: high-level 286, non-high-level 314	EX
BIRD-Interact	600	22	PostgreSQL	conversational	by category: query 410, management 190 by difficulty: high-level 286, low-level 314	SR
Spider2-Lite	342	88	SQLite, Snowflake	generation	by dialect: SQLite 135, Snowflake 207	EX
Spider2-Snow	547	152	Snowflake	generation	—	EX
Spider2-DBT	64	64	DuckDB	project completion	—	DM

Table 4: The seven benchmarks: instance counts, databases, dialects, tasks, composition, and primary metrics (EX: execution accuracy; SR: task success rate; DM: database match; defined in Appendix A.2). The composition categories are defined in the per-benchmark descriptions of Appendix A.1.

BIRD-Dev (Li et al., 2023). The development split of BIRD: 1,534 natural language questions over 11 SQLite databases spanning 37 professional domains, each with optional external knowledge evidence. Difficulty tiers are assigned by the benchmark authors and reflect the complexity of the required SQL. We use the development split because the test split is hidden; as noted in Section 4.1, reported figures on this split vary by a small margin across works (Wretblad et al., 2024).

BIRD-Critic (Li et al., 2025b). The BIRD-Critic-SQLite release: 500 user issues, each consisting of a problem statement and (usually) a buggy SQL fragment that the agent must diagnose and fix. Query issues debug a failing analytical query; personalization issues tailor a query to a user-specific requirement beyond the literal bug; management issues repair statements that modify the schema or data. Instances are graded by benchmark-shipped test cases against the corrected query or statement.

LiveSQLBench (BIRD-bench Team, 2025). The LiveSQLBench-Base-Full v1 release: 600 instances over 22 full-scale PostgreSQL databases with hierarchical external knowledge documents. Query instances require analytical SELECTs; modification instances require DDL or DML graded by test cases. High-level instances pose the question through knowledge-base concepts, often composite metrics whose definitions the agent must resolve, while non-high-level instances state the requested computation directly.

BIRD-Interact (Huo et al., 2026). The full split of BIRD-Interact: 600 two-phase conversational instances over the same 22 PostgreSQL databases. The user is played by an LLM simulator that resolves ambiguities the benchmark deliberately injects; the agent acts through an ASK/SUBMIT protocol with a per-phase turn budget. An instance succeeds only if both phases pass. Query instances request analytical SELECTs and management instances request schema or data changes; the high-level and low-level split mirrors LiveSQLBench's, separating questions posed through knowledge-base concepts from directly stated ones. Phase-2 follow-ups build on the accepted Phase-1 answer and span five types: aggregation (120) summarizes the Phase-1 result; attribute change (114) adds, removes, or replaces reported columns; constraint change (49) alters the conditions of Phase 1; result-based follow-ups (266) pose a new question

that depends on the values Phase 1 returned; and topic pivot (51) shifts to a related question on the same database.

Spider2 (Lei et al., 2025). The Spider2 family targets enterprise-scale warehouses. Spider2-Lite and Spider2-Snow are single-query generation tasks against large schemas; Spider2-DBT asks the agent to complete a dbt project so that the final built database matches gold.

A.2 Metrics

For instance i of a benchmark with N instances, following the notation of Section 3, let y_i be the SQL the agent submits and $R_i = \mathrm{exec}(y_i, \beta_i)$ its executed result on the instance database β_i; let y_i^* and R_i^* denote the benchmark's gold query and its result.

Execution accuracy (Li et al., 2023). The fraction of instances whose executed result matches gold,

$$\mathrm{EX} = \frac{1}{N} \sum_{i=1}^{N} \mathbb{1}[R_i = R_i^*],$$

where equality is taken under each benchmark's official comparison rules: row order only where the question requires it, per-instance decimal precision, and set semantics otherwise; where a benchmark provides several acceptable gold results, matching any one suffices. BIRD-Critic and LiveSQLBench replace the direct equality with benchmark-shipped test cases, so the indicator is one exactly when every test case passes against R_i or against the post-modification database state.

Soft-F1 (Li et al., 2023). Rows of R_i and R_i^* are aligned in order, and each aligned pair contributes the fraction of its cells that match to TP_i, with the unmatched fractions counted toward FP_i (prediction-only) and FN_i (gold-only); rows without a counterpart count wholly toward FP_i or FN_i. With per-instance precision $P_i = \mathrm{TP}_i/(\mathrm{TP}_i + \mathrm{FP}_i)$ and recall $C_i = \mathrm{TP}_i/(\mathrm{TP}_i + \mathrm{FN}_i)$:

$$\text{soft-F1} = \frac{1}{N} \sum_{i=1}^{N} \frac{2\, P_i\, C_i}{P_i + C_i}.$$

The metric grants partial credit for partially correct rows that execution accuracy scores as outright failures.

Valid Efficiency Score (Li et al., 2023). For each correctly answered instance, the gold and predicted execution times give a ratio $\tau_i = E(y_i^*)/E(y_i)$, which the benchmark's evaluation code maps to a step reward $\rho(\tau)$: 1.25 for $\tau \geq 2$, 1 for $\tau \in [1, 2)$, 0.75 for $\tau \in [0.5, 1)$, 0.5 for $\tau \in [0.25, 0.5)$, and 0.25 below:

$$\mathrm{VES} = \frac{1}{N} \sum_{i=1}^{N} \mathbb{1}[R_i = R_i^*] \cdot \sqrt{\rho(\tau_i)},$$

so a correct query at least as fast as gold earns full or bonus credit, and an incorrect one earns none.

Task success rate (Huo et al., 2026). Let $s_i^{(1)}, s_i^{(2)} \in \{0, 1\}$ indicate that phase 1 and phase 2 of instance i pass within their turn budgets. An instance succeeds only when both do:

$$\mathrm{SR} = \frac{1}{N} \sum_{i=1}^{N} s_i^{(1)}\, s_i^{(2)}.$$

Normalized reward (Huo et al., 2026). The benchmark's phase-weighted score, which grants partial credit for a correct first phase using the official phase weights:

$$\text{reward} = \frac{1}{N} \sum_{i=1}^{N} \left(0.7\, s_i^{(1)} + 0.3\, s_i^{(2)}\right),$$

reported in percentage points.

Database match (Lei et al., 2025). For Spider2-DBT, building the agent's completed dbt project produces a database β'_i, whose benchmark-specified tables and columns are compared with the gold build β'^{*}_i:

$$\mathrm{DM} = \frac{1}{N}\sum_{i=1}^{N} \mathbb{1}\left[\beta'_i = \beta'^{*}_i\right].$$

B Additional Results

The main paper reports a single headline score per benchmark (Table 1). This appendix reports the finer slices: category and phase breakdowns, difficulty and dialect breakdowns, and per-database results.

B.1 Category and phase breakdowns

Table 5 consolidates the sub-scores of the three benchmarks that ship finer task categories. Two patterns recur. Structured task variants score above their pure-query counterparts (BIRD-Critic management 78.7 against query 64.4, LiveSQLBench modification 66.3 against query 43.4), because modification tasks name their target objects and admit direct validation by execution. High-level questions cost fifteen to seventeen points on both PostgreSQL benchmarks (41.6 against 58.9 on LiveSQLBench, 47.6 against 63.1 on BIRD-Interact): resolving a knowledge-base concept into the right formula is harder than implementing a stated computation. On BIRD-Interact, phase 1 is the bottleneck (64.2 pass rate), while the conditional phase-2 rate of 86.8 shows that follow-ups rarely fail once a correct base answer exists.

Table 6 decomposes BIRD-Interact's second phase by follow-up type. Mechanical transformations of the accepted answer are the easiest: aggregation follow-ups pass 95.9% of the time conditioned on phase 1. Result-based follow-ups, which depend on the values the first answer returned, have the lowest conditional rate (82.4), and topic pivots score highest unconditionally (68.6) because they behave like fresh questions on a database the agent has already explored.

Slice	Total	Correct	Acc.
BIRD-Critic (by category)			
Query	284	183	64.4
Personalization	141	79	56.0
Management	75	59	78.7
LiveSQLBench (by category and difficulty)			
Query	410	178	43.4
Modification	190	126	66.3
High-level	286	119	41.6
Non-high-level	314	185	58.9
BIRD-Interact (by phase, category, difficulty)			
Phase-1 pass	600	385	64.2
Phase-2 (conditional)	385	334	86.8
Query	410	240	58.5
Management	190	94	49.5
High-level	286	136	47.6
Low-level	314	198	63.1

Table 5: Consolidated per-category, per-phase, and per-difficulty breakdown for the three benchmarks that report sub-scores. BIRD-Interact also reports a normalized reward of 61.6.

Follow-up type	N	Passed	Success (%)	Cond. (%)
aggregation	120	70	58.3	95.9
attribute change	114	72	63.2	86.7
constraint change	49	21	42.9	87.5
result-based	266	136	51.1	82.4
topic pivot	51	35	68.6	87.5

Table 6: BIRD-Interact results by phase-2 follow-up type (the types are defined in Appendix A.1). Cond. is the pass rate among instances whose Phase 1 passed; it is high in part because the runner echoes the accepted Phase-1 SQL into the Phase-2 prompt, anchoring the follow-up on the accepted base rather than a rewrite (see Appendix D).

B.2 Difficulty and dialect breakdowns

Table 7 reports BIRD-Dev by difficulty together with its additional official metrics. All three metrics fall monotonically with difficulty, and soft-F1 sits above execution accuracy at every tier with a gap that widens from 1.6 points on simple questions to 3.1 on challenging ones: harder questions are increasingly answered almost correctly, with partial row overlap that the strict metric scores as failure.

Table 8 splits Spider2-Lite by dialect. The SQLite subset scores seven points above the Snowflake subset (75.6 against 68.6), reflecting the larger schemas and semi-structured columns of the warehouse side; the gap is modest, consistent with the dialect robustness the main results show across benchmarks.

BIRD-Dev	**EX**	**soft-F1**	**VES**
Simple	83.2	84.8	77.4
Moderate	72.2	74.2	65.8
Challenging	61.2	64.3	56.6
Overall	77.7	79.2	71.9

Table 7: BIRD-Dev (1,534 instances) by difficulty, with the benchmark's additional official metrics (soft-F1, VES). As noted in the main paper, reported BIRD-Dev execution accuracy varies by a small margin across published works.

Dialect	N	Correct	EX (%)
SQLite	135	102	75.6
Snowflake	207	142	68.6
Total	**342**	**244**	**71.3**

Table 8: Spider2-Lite results by dialect.

B.3 Per-database results

Tables 9, 10, 11, and 12 report per-database results for LiveSQLBench, BIRD-Critic, BIRD-Interact, and BIRD-Dev, each sorted by accuracy. The spread is widest on LiveSQLBench, where per-database accuracy ranges from 76.5 to 19.2: the top of the table is well-specified operational data with clean joins, and the bottom is dominated by domain ambiguity in the knowledge base. LiveSQLBench and BIRD-Interact share the same 22 databases, and their rankings largely agree (`reverse_logistics` and `cybermarket_pattern` anchor the top of both tables while `mental_health` and `organ_transplant` anchor the bottom), indicating that difficulty is chiefly a property of the database and its knowledge base rather than of the interaction protocol. BIRD-Critic is more uniform: among its databases with at least ten issues, accuracy stays within a band from 54.8 to 75.0, suggesting debugging difficulty depends less on the domain than question answering does.

For the Spider2 family we report the distribution of per-database outcomes instead (Table 13): its databases hold only a few questions each, so individual per-database accuracies are coarse, and full tables over its 88, 152, and 64 databases would add pages without adding signal. Across Spider2-Lite and Spider2-Snow, DIA fully solves 99 of the 240 databases and is shut out on 40, so the headline accuracy

reflects broad competence rather than a few concentrated wins. Spider2-DBT is the hardest member, with 40 of 64 projects incomplete, consistent with project completion being the hardest task in Table 1. Per-database and per-project outcomes are part of the released per-instance results.

Database	Total	Q	M	All %
robot_fault_prediction	17	7/10	6/7	76.5
reverse_logistics	28	13/20	8/8	75.0

student_club	42	23	54.8
spotify	2	1	50.0
Total	**500**	**321**	**64.2**

Table 10: BIRD-Critic per-database accuracy on the 500-instance complete run. The Management category is the cleanest tier: the agent benefits substantially from declaring the expected result shape before generation and from the identifier extractor that surfaces backtick-quoted names verbatim from the question text. Personalization is the hardest because gold often goes beyond what the question explicitly enumerates (e.g. adds derived columns, returns nested JSON instead of a flat result set), and the agent has no signal to predict gold's exact shape without seeing the test code.

Database	Total	Correct	All %

Spider2-DBT	64	24	—	40

Table 13: Distribution of per-database outcomes on the Spider2 family: databases where every question is answered correctly, where some are, and where none are. Spider2-DBT instances are single whole-project completions, so no partial bucket applies.

C Error Analysis

This appendix expands the error analysis of Section 4.6. The finding that organizes it is that the remaining headroom is semantic rather than syntactic: on every benchmark almost every failed instance executes cleanly and returns a wrong answer. Almost all of them are semantic, and we sort them into three recurring classes, each pointing to a different remedy. Reasoning failures, where the query answers a subtly different

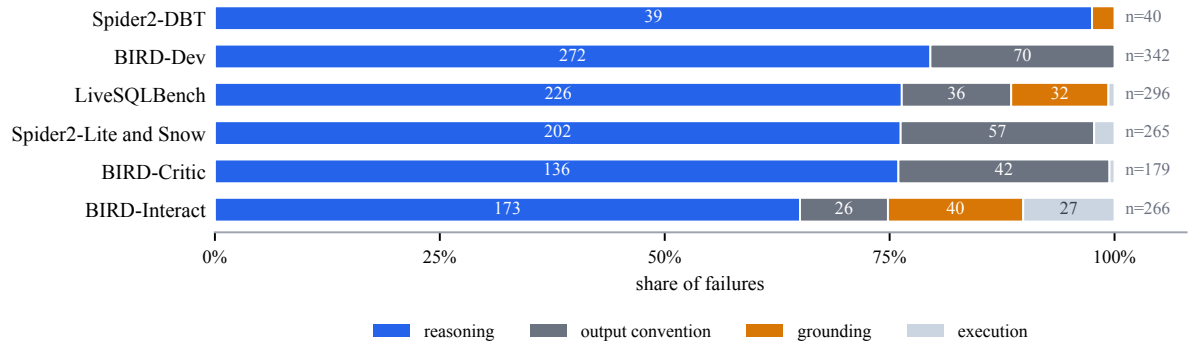

Figure 3: Composition of failures per benchmark, aggregated over each benchmark's task categories and ordered by the share of reasoning failures. Segment labels are failure counts.

question than the one asked, are the largest class on every benchmark and are bound to model capability. Output-convention failures, where the right quantity is computed but presented in the wrong shape, are the most addressable class and respond to refinements of the standing instructions. Grounding failures, where the agent cannot resolve an exact identifier, appear on the benchmarks with object-modification tasks and recur within a database, the recurrence structure that memory targets (Section 4.5). Execution failures, where the SQL does not run at all, are rare, under three percent of failures in aggregate.

We classify every failure of each benchmark's reported run by comparing the agent's output to gold, directly from the per-instance results: 342 failures on BIRD-Dev, 296 on LiveSQLBench, 266 on BIRD-Interact, 179 on BIRD-Critic, 98 on Spider2-Lite, 167 on Spider2-Snow, and 40 on Spider2-DBT. Where the results record executed result tables, on BIRD-Dev, LiveSQLBench query tasks, and the Spider2 family, we compare predicted and gold result shapes and values; where they record only pass or fail against hidden tests, on BIRD-Critic and the modification tasks, we compare the predicted and gold SQL. Two limits follow. Output convention is detected only where the result shape is observable, so on the SQL-only failures its share is a lower bound; and a wrong literal value, which is a grounding error in spirit, is indistinguishable from wrong logic once it reaches the result, so on the pure query benchmarks it falls under reasoning.

C.1 Failure classes across benchmarks

Figure 3 reports the class composition of failures per benchmark.

Reasoning failures dominate every benchmark, from roughly three quarters on most to two thirds of BIRD-Interact's. The class covers three recurring shapes. Selection errors choose the wrong rows through a wrong filter, join path, or entity, and account for the largest buckets of Table 14. Computation errors feed the right rows into a wrong formula or aggregate at the wrong granularity, and drive the family-wide signature of same-shape results with wrong values. Construct errors misuse a SQL idiom, such as an inner join where the question implies an outer one, ties dropped at a top-N boundary, or a defensive NULL filter that removes valid rows, and are among the structurally identifiable patterns of Table 15. All three execute cleanly and concentrate where the question under-specifies its intent; none respond to instruction refinements, marking the capability frontier of the model rather than a fixable gap in the system.

Output-convention failures are the largest addressable class. Extra or missing output columns are the main form, with row order making up the rest. The computed quantity is right and only its presentation diverges from what the gold answer admits, which is why these patterns respond to standing-instruction refinements where reasoning failures do not. Because convention is counted only where the result shape is observable, its share on the SQL-only benchmarks understates the true total.

Grounding failures concentrate on the benchmarks with object-modification tasks. Most of LiveSQL-Bench's and BIRD-Interact's grounding failures trace to table, view, or column names the agent paraphrased, so a probe written against the gold name cannot find them. These recur within a database, the same identifiers returning question after question, which is the recurrence structure that memory targets

(Section 4.5).

C.2 Per-benchmark patterns

Tables 14 and 15 give the per-pattern breakdown for the two benchmarks whose results expose the most detail: LiveSQLBench, which records executed result tables for its query tasks, and BIRD-Critic, whose pass or fail outcomes we read through the predicted and gold SQL.

Pattern	Count	Diagnosis
wrong rows returned	105	wrong filter, join path, or entity: the returned rows barely overlap gold
row count moderately off	58	wrong filter or join cardinality, within a factor of five
row count far off	22	major logic error, off by more than a factor of five
extra output columns	16	display columns the gold answer does not admit
missing output columns	14	projection narrowed past the requested columns
right rows, wrong values	7	correct rows but wrong computation or formula
wrong row order	6	correct rows in the wrong order
empty result	4	the query returned no rows

Table 14: LiveSQLBench query failures (232), by comparison of the executed result with gold. The 64 modification failures are test-case-graded and split into grounding (32, paraphrased identifiers), reasoning (30, logic errors), and execution (2).

Pattern	Count	Diagnosis
extra output columns	23	output decorated with the question's free-text dimensions
missing output columns	19	projection narrowed past the columns the user named
unrequested NULL filter	23	defensive `IS NOT NULL` that drops valid rows
dropped ties	8	`ROW_NUMBER() = 1` or `LIMIT 1` where gold keeps ties
overcomplicated SQL	5	recursive CTEs or manual date arithmetic where a simpler idiom suffices
wrong join type	2	`INNER` where the question implies `LEFT`, or the reverse

Table 15: BIRD-Critic failures with a structurally identifiable pattern in the SQL (80 of 179). The remaining 98 are value or logic errors not separable from the SQL text alone, and one is an execution error. Extra or missing output columns, the convention class, are the largest identifiable patterns and recur across the query, personalization, and management categories alike.

For the Spider2 family the same result-shape comparison applies directly. Of Spider2-Lite and Spider2-Snow's 265 query failures, 202 return a result of gold's shape with wrong values or row counts, 57 differ in column count, and 6 fail to execute. The 40 Spider2-DBT project failures, taken at the first mismatching table of the built database, are almost all content errors: 39 build the required tables but with wrong contents, and 1 leaves a required table uncreated so a downstream reference errors. Because dbt grades by whole-table equality with no result tuples to inspect, column-count divergences cannot be separated from content errors here, so the convention share folds into the first bucket and the lower-bound caveat above applies most strongly to this benchmark. Across the family wrong values and row counts dominate, extra or missing columns are the main addressable slice, and outright execution errors stay near two percent, consistent with Section 4.6.

C.3 Interaction failure behaviour

BIRD-Interact adds a behavioural failure dimension that the single-shot benchmarks lack. Its 266 failures split into 215 in phase 1 and 51 in phase 2.

The dominant behaviour is hypothesis lock-in: 215 of the 266 failures (81%) are phase-1 trajectories that exhausted the 15-turn budget, the agent re-submitting near-identical SQL against the protocol's minimal feedback instead of stepping back to ask a clarifying question. The recurring modes are inferring a composite formula without asking, chasing sort order when the real divergence was a formula input, and phase-1 views whose paraphrased column names break the gold phase-2 SQL. These modes map onto the

same classes as the single-shot benchmarks: composite-formula inference is a reasoning failure, sort-order chasing an output-convention failure, and paraphrased identifiers a grounding failure. Classifying the final submissions accordingly gives the BIRD-Interact bar of Figure 3: 173 reasoning, 40 grounding from paraphrased identifiers on management tasks, 26 output-convention, and 27 execution errors from malformed submissions at the turn cap. Worked traces of the recurring modes appear in Appendix D, together with the interaction policies they motivated.

D Case Studies

The premise of this work is that an agent grounded in execution can answer reliably because it can verify its work against the database. BIRD-Interact is the sharpest test of that premise, and the benchmark where DIA's margin over prior work is largest (Table 1), because it is the one setting where part of the ground truth does not live in the database: the user's intended formula and the canonical names of requested artifacts are known only to the user. Execution grounding answers everything the data can answer; dialogue must cover the rest, and knowing the boundary between the two is the skill the benchmark rewards. It is also the benchmark that most resembles our production deployment, where domain experts pose under-specified questions conversationally and clarification is part of normal operation (Appendix G). This appendix shows that boundary in worked traces: one released-run pass where grounding and a single targeted question divide the work correctly, and two failure modes, a stuck-loop and a Phase-2 cascade, that we observed during development and that motivated the interaction policies described at the end. We pair each failure trace with the released-run outcome of that same instance once the policies are in place.

D.1 The BIRD-Interact protocol

Each BIRD-Interact instance is a multi-turn conversation between the *Query Generator* and the benchmark's LLM-driven user simulator. Three properties make it qualitatively different from the other six benchmarks in our evaluation set:

- Two phases per instance. Phase 1 is the primary question (`Q` or `M`); Phase 2 is a follow-up that builds on the agent's Phase 1 answer. The agent must SUBMIT a SQL for Phase 1; if it passes, Phase 2 issues a new prompt that references Phase 1's result shape (e.g. "filter the result you just produced to rows where . . .").
- An ASK or SUBMIT protocol with a fixed turn cap per phase (Appendix I). Every turn the agent either emits `ASK: <question>` to request clarification or `SUBMIT: <sql>` to attempt an answer. ASKs are routed to the user simulator (an LLM playing the role of a non-SQL domain expert); SUBMITs are evaluated, and an INCORRECT verdict returns a structural delta (row count, column count) without disclosing gold values. This is the benchmark's information-asymmetric protocol, matching what real users could actually provide.
- Follow-ups bind to Phase-1 artifacts. For Management tasks, Phase 2 references the object the agent created in Phase 1, including its column names. This surfaces a cascade failure mode unique to BIRD-Interact: if Phase 1 paraphrased a column name, the Phase 2 evaluation cannot see it (see the Phase-2 cascade trace).

The combination produces a benchmark where 81% of failures burn the full turn cap on a single phase (the agent keeps re-submitting near-identical SQL against the same minimal feedback), and where the decisive skill is not which SQL to emit but when to stop guessing and ask.

Figure 4 gives a single-run view of what the benchmark's authors term interaction-time scaling (Huo et al., 2026), the ability to convert multi-turn interaction into end performance: rather than re-running the benchmark at each budget, it reports the turn at which each passing submission landed under the full budget. The curve is cumulative, so what is informative is its shape: DIA exceeds the final score of the best prior system within its first four turns, is still climbing steeply late in the budget (turns eleven through fifteen add another nine points), and flattens only past twenty total turns, so the cap leaves little on the table. We do not evaluate the benchmark's stronger criterion (the interaction-time scaling law),

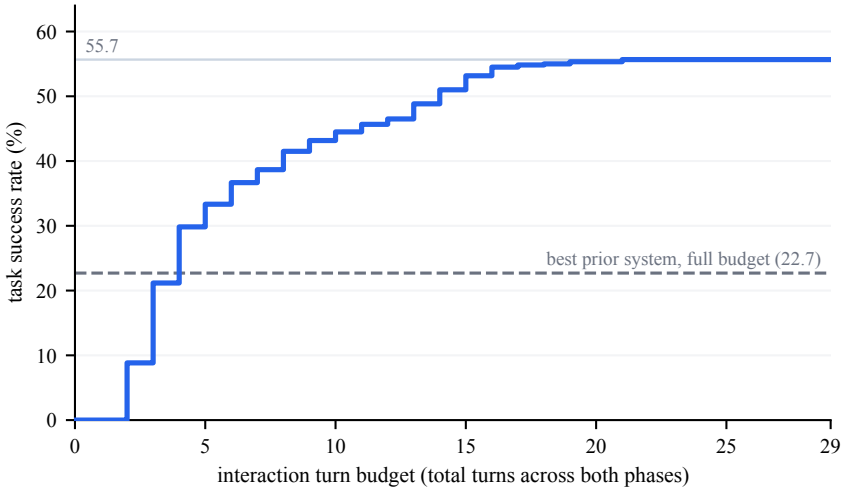

Figure 4: Interaction-time scaling on BIRD-Interact: the fraction of the 600 instances whose passing submission landed within the first k total turns across both phases, computed from the single full-budget run. The dashed line is the final score of the best prior system at its full budget.

which compares interactive performance against idealized single-turn performance on the disambiguated task. Successful instances are efficient, finishing in a median of four turns, while failed instances are the ones pinned at the cap. Under-specification also has a measurable dialogue cost even in success: passing high-level instances need a median of six turns against four for low-level ones, the price of resolving a composite metric through conversation.

D.2 A passing trace

The passing trace shows the division of labour working: one targeted ASK for the formula that execution cannot reveal, workspace probes for everything it can, and a first-submission pass on both phases.

Passing trace (archeology_scan instance 1)

```
TURN 1
USER: For each scan site, report the average ambient temperature,
humidity, and illumination, along with the Environmental
Sensitivity Index (ESI). Order by ESI descending.

AGENT: ASK: The KB defines ESI in terms of three sub-metrics
(ambient_temp_norm, humidity_norm, illumination_norm). Could you
confirm whether ESI is the simple mean of the three normalized
values, or a weighted combination?

USER_SIM: labeled("ESI"). Each row of the scans table has an
ambient_cond JSON object with Ambic_Temp, Ambic_Humidity, and
Ambic_Light keys. ESI is the simple mean of the three normalized
values, after each value is min-max normalized over the entire
table. Use COALESCE(<expr>::real, <default>) with the defaults
listed in the KB entry for ESI when a key is missing.

TURN 2
AGENT (workspace): writes and runs a probe script before
submitting:

  keys = query_db("SELECT DISTINCT jsonb_object_keys(ambient_cond)
                   FROM scans")
  # -> Ambic_Temp, Ambic_Humidity, Ambic_Light

  missing = query_db("SELECT COUNT(*) FROM scans
                      WHERE NOT ambient_cond ? 'Ambic_Temp'")
  # -> some rows lack the key: the COALESCE defaults matter
```

```
AGENT: SUBMIT:
WITH normed AS (
  SELECT s.arcref AS site_id,
         COALESCE((s.ambient_cond->>'Ambic_Temp')::real, 20.0) AS t,
         COALESCE((s.ambient_cond->>'Ambic_Humidity')::real, 50.0) AS h,
         COALESCE((s.ambient_cond->>'Ambic_Light')::real, 300.0) AS l
  FROM scans s
),
bounds AS (
  SELECT MIN(t) AS t_min, MAX(t) AS t_max,
         MIN(h) AS h_min, MAX(h) AS h_max,
         MIN(l) AS l_min, MAX(l) AS l_max
  FROM normed
)
SELECT n.site_id,
       AVG(n.t) AS avg_temp,
       AVG(n.h) AS avg_humidity,
       AVG(n.l) AS avg_illumination,
       AVG( (n.t - b.t_min) / NULLIF(b.t_max - b.t_min, 0)
          + (n.h - b.h_min) / NULLIF(b.h_max - b.h_min, 0)
          + (n.l - b.l_min) / NULLIF(b.l_max - b.l_min, 0) ) / 3.0 AS esi
FROM normed n CROSS JOIN bounds b
GROUP BY n.site_id
ORDER BY esi DESC;

EVALUATOR: PASS (rows=147, columns=5, match within 1 ULP)

PHASE 2 prompt: Restrict the result to the top 10 most-sensitive
sites and add a classification column ('high'/'medium'/'low')
based on NTILE(3) over ESI.

AGENT: SUBMIT:
WITH p1 AS (
  -- accepted phase-1 SQL, carried forward as the base
  ... [as above] ...
)
SELECT site_id, avg_temp, avg_humidity, avg_illumination, esi,
       CASE NTILE(3) OVER (ORDER BY esi DESC)
         WHEN 1 THEN 'high' WHEN 2 THEN 'medium' ELSE 'low' END
         AS sensitivity_class
FROM p1
ORDER BY esi DESC
LIMIT 10;

EVALUATOR: PASS. Final verdict: PASS (both phases).
```

Three properties of this trace are diagnostic of when the agent succeeds: (i) it divides the work correctly between grounding and dialogue, probing the database for what execution can answer (key spellings, missing-key rates) and ASKing only for what it cannot (the formula definition); (ii) it uses the KB-listed COALESCE defaults verbatim (the stuck-loop trace shows the failure mode this avoids); and (iii) Phase 2 wraps the accepted Phase 1 SQL in a CTE rather than rewriting from scratch (DIA carries the accepted Phase-1 SQL into the follow-up context, making this the natural default).

D.3 A stuck-loop failure

This trace, recorded during development before the clarification policy below was in place, shows what was then the most common BIRD-Interact failure mode: the agent infers a composite formula from KB names without asking, then burns the entire turn budget with cosmetic edits (cast types, JSON-key spellings) instead of stepping back to ASK.

Stuck-loop trace (archeology_scan instance 5, development run): turn budget exhausted with 0 ASKs

```
KB CONTEXT: DPQ = 0.4*SQS + 0.4*MFS + 0.3*SCE_mod + 0.2*RAR,
where each sub-term is itself a multi-term expression over
JSON keys masked from the agent.

TURN 1
USER: For each scan location, compute a Data Provenance Quality
index (DPQ).

AGENT: SUBMIT: -- guessed composite from KB term names
SELECT zoneref,
       0.4*sqs + 0.4*mfs + 0.3*sce + 0.2*rar AS dpq
FROM (
  SELECT zoneref,
         AVG((meta->>'survey_quality_score')::real)    AS sqs,
         AVG((meta->>'metadata_fidelity_score')::real) AS mfs,
         AVG((meta->>'site_completeness_eval')::real)  AS sce,
         AVG((meta->>'reference_alignment')::real)     AS rar
  FROM scans GROUP BY zoneref
) t
ORDER BY dpq DESC;

EVALUATOR: INCORRECT. (Row and column counts match gold;
  values differ. No gold values disclosed.)

TURN 2 ... TURN 14: agent re-SUBMITs 14 near-identical variants:
swaps `::real` for `::numeric`, varies the JSON keys
(`survey_quality_score` -> `sqs_raw` -> `surveyqualscore`),
wraps in additional CTEs, adds ORDER BY ties. Every SUBMIT
returns the same verdict, with no gold values disclosed.

TURN 15 (final turn)
AGENT: SUBMIT: -- final cosmetic variant, still wrong
... [as before, with one cast rewritten] ...

EVALUATOR: INCORRECT. Final verdict: FAIL (Phase-1 not passed,
Phase-2 not attempted).
```

The agent never ASKs to clarify either (a) what the masked sub-terms actually compute (the KB lists their names but not the formulas they expand to) or (b) whether the composite is computed per-row before aggregation or after. Both are required to reach gold's roughly 5,000-character composite. This is a boundary failure of execution grounding: the formula's semantics live with the user, not in the data, so no amount of probing or re-execution can verify a guessed composite. The agent's mistake is treating a dialogue problem as a grounding problem. Standing guidance alone does not prevent this mode: nothing behavioural forces the agent to back off from a losing SUBMIT to an ASK, which is what motivated the clarification-question policy. With that policy active in the released run, pure stuck loops are nearly eliminated: only two of the 215 Phase-1 failures issue as few as one clarifying question and none issue zero, and this same instance now issues several ASKs before exhausting its budget. The trace shows the failure mode the policy targets, not residual released behaviour.

D.4 A Phase-2 cascade

This trace, also from the development run, shows a class of failure unique to BIRD-Interact Management: the agent's Phase-1 view shape is locally correct but missing a column that the Phase-2 evaluation will then need to reference.

Phase-2 cascade trace (archeology_scan M_3, development run)

```
PHASE 1
USER: Create a view `view_premium_quality_scans` containing scan
ID, project, site, timestamp, resolution, density, coverage,
overlap, and noise, restricted to scans whose DPQ is above the
```

```
75th percentile.

AGENT: SUBMIT:
CREATE OR REPLACE VIEW view_premium_quality_scans AS
WITH q AS (... DPQ computation ...)
SELECT s.facetregistry AS scan_id,
       s.project,
       s.facetregistry AS site_code,    -- paraphrased "site"
       s.captured_at  AS timestamp,
       s.resolution_m AS resolution,
       ...
FROM scans s JOIN q USING (zoneref)
WHERE q.dpq > q.dpq_p75;

EVALUATOR: PASS (Phase 1 view created; rows match gold count).

PHASE 2
USER: For each project in `view_premium_quality_scans`, report
the count of premium scans and the average noise level.

AGENT: SUBMIT:
SELECT project, COUNT(*) AS n, AVG(noise) AS avg_noise
FROM view_premium_quality_scans
GROUP BY project;

EVALUATOR: the Phase-2 evaluation references the view's
underlying column names:
  SELECT zoneref, COUNT(*), AVG(noise)
  FROM view_premium_quality_scans GROUP BY zoneref;
... which raises UndefinedColumn: column
view_premium_quality_scans.zoneref does not exist.
(The agent aliased site to site_code.)

Verdict: FAIL (Phase-2 cascade due to Phase-1 column-name drift).
```

The agent's Phase-1 view is functionally correct: the row set matches gold and the projection covers the columns the question enumerated. It fails not because of its own Phase-2 SQL but because the follow-up's expected answer is keyed to the underlying column names: the Phase-2 evaluation references `zoneref` (the table's actual column name) while the agent paraphrased it to `site_code`. This is the other boundary failure of execution grounding: execution can validate that the view runs and its rows match, but it cannot reveal the canonical names a follow-up will expect, because naming is a matter of user intent rather than data. DIA's standing instructions therefore treat a Management projection list as not a renaming contract: when the question names a column conversationally ("site"), the agent projects the underlying column under its original identifier rather than inventing a conversational alias. With this policy in place, the same instance passes both phases in the released run: the Phase-1 view exposes `zoneref` under its own name, so the Phase-2 follow-up resolves.

D.5 Interaction policies

These failure modes shaped how the *Query Generator* behaves in multi-turn protocols. Four mechanisms carry most of the weight.

Forced clarification. After three consecutive INCORRECT verdicts with the same structural signature, DIA requires its next action to be an ASK rather than another SUBMIT. Stuck loops are the largest behavioural failure mode, and this policy cuts them directly. The streak resets on any ASK or on a SUBMIT whose verdict differs. Ablating this policy across the full 600-instance run drops accuracy from 55.7% to 14.5%, a 41.2-point fall, confirming that stuck loops, not a limit on the model's SQL ability, are what the policy is protecting against.

Resubmission control. DIA does not resubmit near-identical SQL: a candidate SUBMIT that matches one of its recent attempts is rejected, and the agent must either ASK or change the structural approach. This closes the repeated-resubmission pattern within stuck-loop traces.

Context carryover. The accepted Phase-1 SQL is placed at the head of the Phase-2 context, so the natural default is to apply the requested follow-up edit to the Phase-1 base, which is the protocol's intent, rather than rewriting from scratch and silently changing the Phase-1 filter or projection.

Short-term and long-term memory. Memory extends the same boundary, and in deployment we see this in practice. Within a conversation, clarifications act as short-term memory: once the user states a formula, every later turn builds on it. Across conversations, those answers become long-term memory: the same domain experts return with the same vocabulary, and a formula or naming convention they have already explained is not asked for again. Our treatment of memory (Section 4.5) concerns recurrence within a database rather than within a user.

Together these mechanisms encode the boundary the traces illustrate: the agent grounds everything the database can answer by execution and spends dialogue only on what it cannot. That division of labour, rather than any difference in SQL fluency, is where the margin on this benchmark comes from (Table 1).

E Standing Instructions

The standing instructions of the *Query Generator* share one architecture across benchmarks. Every seed file combines three ingredients: an output-contract discipline, under which the agent declares the expected shape of its answer and verifies the executed result against it; reference material and pitfalls for the SQL dialect; and guidance for the task format. The per-question prompt itself is thin: it lays out the workspace, states the question and its task metadata, and points the agent at the seed. Table 16 summarizes how each benchmark instantiates this architecture.

Benchmark	Task-specific content of its seed
BIRD-Dev	projection discipline; verification of literal values and transforms against the live database; memory usage
BIRD-Critic	a five-step debugging workflow; patterns for the query, personalization, and management categories
LiveSQLBench	the same workflow adapted to generation; data-modification guidance; external-knowledge usage rules
BIRD-Interact	conversational guidance: when to ask versus when to submit, what the simulated user can answer, and management-task fidelity
Spider2-Lite	a compact output contract and semantic rules
Spider2-Snow	the same contract instantiated for Snowflake
Spider2-DBT	a project-completion workflow: analyze the dbt project, build, and verify the produced database

Table 16: How each benchmark instantiates the shared architecture: the task-specific content of its seed, beyond the output-contract discipline and the dialect reference.

E.1 The workflow skeleton

The fullest form of the contract discipline is a five-step workflow used by the debugging, modification, and conversational benchmarks: plan with an explicit contract, diagnose by execution, build, validate against the contract, save. We reproduce a condensed BIRD-Critic instantiation.

Workflow skeleton as instantiated for BIRD-Critic (STEP 1 to STEP 5)

```
## Per-Question Workflow

### STEP 1 - PLAN
- Read the user's question and any buggy SQL carefully.
- Identify the category (Query / Personalization / Management).
- Define an explicit OUTPUT_CONTRACT:
    cols:    [c1, c2, ...]
    rows:    ~N (one per <entity>)
    order:   <unordered | by X asc/desc>
    filters: [every constraint expressed in the question]
- Filters checklist (CRITICAL): walk every adjective, prepositional
  phrase, "only/excluding/ignoring", and conjunction in the prose.
  Each becomes a row in `filters: [...]`.
```

```
### STEP 2 - DIAGNOSE
- Inspect the schema (PRAGMA table_info / information_schema).
- Execute the buggy SQL (if any) and observe its actual output.
- Compare actual output to OUTPUT_CONTRACT. What's wrong?

### STEP 3 - BUILD
- Projection: entity-key -> metric -> drop redundant display cols
  -> drop helper window cols from outer SELECT.
- Minimal-diff: smallest edit to buggy SQL that fixes the bug.
- Apply every filter in the STEP 1 checklist.

### STEP 4 - VALIDATE
- Run pred via query_db; observe the result set.
- For every item in `filters`, point at the clause that implements it.
- Check column count, row count plausibility, JOIN cardinality,
  first-row sanity, and absence of spurious NULL filters.

### STEP 5 - SAVE
- save_result(corrected_sql, result_rows, tables_used)
- For Management tasks save the DDL/DML statements themselves
  (not the verification SELECT).
- cleanup() to reset the workspace for the next question.
```

The contract is declared before any SQL is run, so STEP 4 can fail an answer on shape grounds using nothing but the agent's own plan. This is the self-verification loop of the main paper in operational form, and it targets the largest addressable failure class of Appendix C: extra display columns, missing filters, and helper columns leaking into the outer projection.

E.2 A worked debugging example

The trace below is an illustrative reconstruction, composed to show the five-step contract discipline end to end rather than transcribed from a single released instance. It walks the workflow through a representative BIRD-Critic debugging question over the `financial` database: the agent receives the user's prose and a buggy SQL fragment, diagnoses the bug by executing it, and repairs it with a minimal edit.

Worked trace (illustrative; BIRD-Critic, financial database)

```
QUESTION: For each account, what is the latest transaction date
where the amount exceeded the account's average transaction
amount? List account_id and the transaction date.

BUGGY SQL (issued by the user):
  SELECT a.account_id, MAX(t.date)
  FROM account a
  JOIN trans t ON a.account_id = t.account_id
  WHERE t.amount > AVG(t.amount)
  GROUP BY a.account_id;

STEP 1 PLAN: the agent declares its contract.
  OUTPUT_CONTRACT:
    cols:    [account_id, latest_date]
    rows:    ~one per account (~4500)
    order:   none specified
    filters: [transactions whose amount > account-level mean]

STEP 2 DIAGNOSE: the agent executes the buggy SQL and observes
  SQLite error: misuse of aggregate function AVG()
The aggregate sits inside a row-level WHERE, which is invalid:
the per-account mean must be computed per group.

STEP 3 BUILD: minimal repair with a window function.
  WITH t_with_avg AS (
    SELECT t.account_id, t.date, t.amount,
           AVG(t.amount) OVER (PARTITION BY t.account_id) AS acct_avg
```

```
    FROM trans t
  )
  SELECT account_id, MAX(date) AS latest_date
  FROM t_with_avg
  WHERE amount > acct_avg
  GROUP BY account_id;

STEP 4 VALIDATE: the agent runs the corrected SQL via query_db.
  4500 rows, 2 columns
Contract check: column count matches (2 = 2); one row per
account; the filter "amount above account-level mean" is
implemented by WHERE amount > acct_avg; no spurious
IS NOT NULL filter was added.

STEP 5 SAVE: save_result(corrected_sql, result_rows,
  tables_used=[trans, account]); cleanup().
```

The repair is the minimal edit the seed asks for: the structure of the buggy SQL is preserved, and only the invalid aggregate placement changes. The contract declared in STEP 1 is what makes STEP 4 a real check rather than a formality: every entry in it is verified against the executed result before the answer is saved.

F Memory: Store and Contents

This appendix gives concrete form to the memory introduced in Section 3.2: how the experience store is organized, how its entries are written, and what kinds of knowledge it captures during a run. The view is observational, drawn from the BIRD-Dev run.

F.1 The three tiers

Memory is held as files in the workspace and organized in three tiers.

Retrieved examples. The pool for this tier is the BIRD training split: its gold question-and-SQL pairs together with per-table column-meaning notes, embedded once offline into a fixed similarity index that is reused unchanged across runs. The split is disjoint from the BIRD-Dev evaluation set, so retrieval introduces no test leakage. For each question, the few most similar pairs above a fixed similarity threshold (Appendix I) are surfaced and staged for the agent to consult. These are concrete examples rather than distilled rules: the agent reads them as idioms and re-derives any abstraction at the point of use, confirming column names and values against the current database before relying on them.

Session lessons. While working on a database, the agent reflects after each question and records a short conditional rule when something it tried held, together with the observation that confirmed it. A consolidation step keeps a compact set per database rather than every candidate.

Cross-session lessons. The subset of session lessons that recur across databases, rather than holding only within one, is promoted to a persistent store and carried into later tasks. Promotion is outcome-gated: a rule is retained only when later questions continue to bear it out.

F.2 Representative rules

Across the BIRD-Dev databases the promoted rules fall into a few recurring kinds: aggregating without double-counting across one-to-many joins, choosing the join path that carries a given attribute, recognizing when a stored value is already a ratio rather than a percentage, projecting bridge tables without duplicate rows, and reading compound filter phrasing. Each is a short, human-readable conditional paired with the evidence that confirmed it. Table 17 gives representative rules with that evidence.

Because each rule is written by the agent itself and re-checked on the live database before it can change an answer (Section 3.2), the store stays interpretable and auditable: a domain expert can read any entry, see the evidence behind it, and judge whether it should apply, in the same spirit as the other artifacts DIA produces.

Kind	Rule	Evidence
Output format	Compute a percentage from counts; do not read a similarly named stored column, which often holds a 0–1 ratio.	A stored column held about 0.70 where the question wanted 70.15 computed.
Filter value	A strict "oldest and lowest X" intersection often returns nothing; probe it, then read it as "oldest within the lowest-X group."	The strict conjunction returned 0 rows; the relaxed reading returned the intended single row.
Filter value	Probe the stored casing of status or legality enums; many are Title Case, so a lowercase literal silently matches nothing.	Filters passed only as `'Banned'/'Restricted'`, not the lowercase values a hint used.
Projection	Querying IDs from a many-to-many bridge table can return an entity several times; add `DISTINCT` only when the question asks for unique entities.	Gold returned one entity ID four times, all at the same minimum value.
Aggregation	"Spent the most" means `SUM` over transactions, not `MAX` of a single one, even when a hint says `MAX`.	Ordering people by `MAX(cost)` failed; summed spending was the intended measure.
Output format	Return only the `YYYY-MM-DD` part of a datetime column when the question asks for a date.	A full timestamp mismatched the bare date the gold answer expected.
Filter value	"After year X" means $> X$, even when a hint maps it to $= X$.	`='1990'` returned that year's records rather than later ones.

Table 17: Representative cross-session rules with the execution observation that confirmed each. Rules are condensed; each is recorded only after the observation holds on the database at hand.

F.3 Episodic-to-semantic generalization

A rule does not begin general. The agent first records a concrete observation on the database it is working, and that within-database lesson is promoted to a cross-session rule only when later questions bear out the same pattern. Table 18 shows this episodic-to-semantic step for two rules: the left column is the originating observation, the right is the generalized rule the store keeps.

Within-database observation	Cross-database rule
On `california_schools`, counting schools through the school-to-`frpm` join, `COUNT(*)` returned 9,977 for one school because it had 9,977 fact rows, while `COUNT(DISTINCT CDSCode)` returned 1.	When counting entities through a join to a table that stores several rows per entity, count with `COUNT(DISTINCT entity_pk)` rather than `COUNT(*)`.
On `financial`, filtering "account branch in East Bohemia" through the client's home district returned the wrong population; the account's own district was meant.	Join through the entity that owns the attribute the question names: the account's geography for "account branch," the client's only for "client lives in."

Table 18: The episodic-to-semantic step. A rule begins as a concrete observation on one database and is promoted to a cross-session rule only when it generalizes beyond that database.

F.4 A learned rule in use

The tiers are consulted, not only written. The trace below shows a session lesson, formed on earlier questions of `thrombosis_prediction` and re-checked by a live probe before use, redirecting a later answer from a per-patient collapse to the per-record projection the question intends. We include it to illustrate the mechanism, not as a measurement of memory's aggregate effect.

A session lesson redirects the output (thrombosis_prediction)

```
QUESTION: for each patient born in 1982, state whether their
albumin (ALB) is within the normal range, 3.5 to 5.5.

SESSION LESSON (formed on earlier questions of this database):
  [JOIN-PATH] The Patient->Laboratory join fans out to many lab
  records per patient, so a per-row label is over records, not
  patients. Probe the join size before choosing output granularity.
```

```
UNAIDED ATTEMPT: groups by patient, one label per patient.
  SELECT P.ID, CASE WHEN ... THEN 'normal' ELSE 'abnormal' END
  FROM Patient P LEFT JOIN Laboratory L ON P.ID = L.ID
  WHERE P.Birthday LIKE '1982%'
  GROUP BY P.ID;
  --> collapses the fan-out to one row per patient (wrong shape).

WITH THE LESSON IN CONTEXT: probe the join first.
  COUNT(DISTINCT P.ID) = 1     COUNT(*) = 35
  (one matching patient, thirty-five lab records)
Then label one row per record:
  SELECT IIF(L.ALB BETWEEN 3.5 AND 5.5, 'normal', 'abnormal')
  FROM Patient P JOIN Laboratory L ON P.ID = L.ID
  WHERE STRFTIME('%Y', P.Birthday) = '1982';
  --> 35 rows, one per lab record: matches gold.
```

G Production Deployment

DIA is deployed in production for enterprise customers. This appendix illustrates a deployment through one workflow, a nursing-staff analysis, carried out as a single conversation. The domain expert uploads a set of operational data files, and in one continuous thread the three agents work in turn over a shared workspace: each builds on the artifacts the previous one produced, and every artifact, the interpretation, the schema, and the analyses, is retained and remains visible for review. The figures are screenshots from this conversation.

Data Interpreter. The *Data Interpreter* inspects the uploaded files and recovers their structure: the entities, the relationships among them, and any data-quality issues. It presents these findings for the domain expert to confirm or correct rather than assuming them (Figure 5).

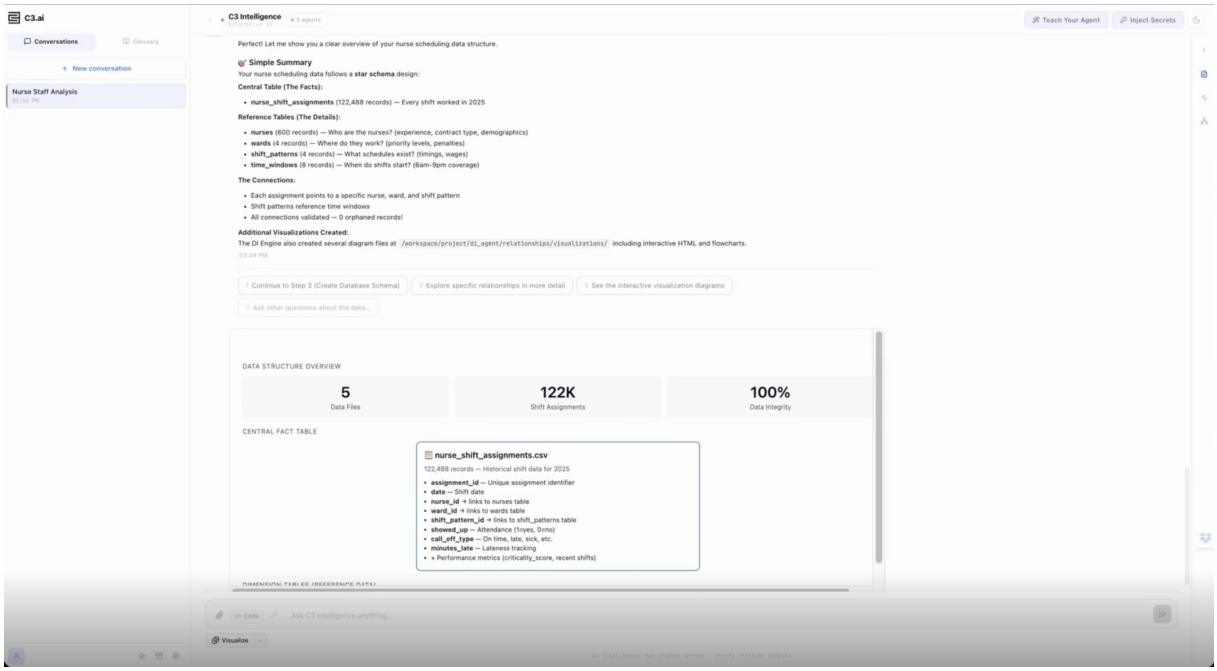

Figure 5: The *Data Interpreter*: the recovered data structure, presented for the domain expert to review.

Schema Creator. Once the interpretation is confirmed, the *Schema Creator* turns it into a database, declaring the keys and constraints and rendering the result as a schema diagram the expert can inspect (Figure 6).

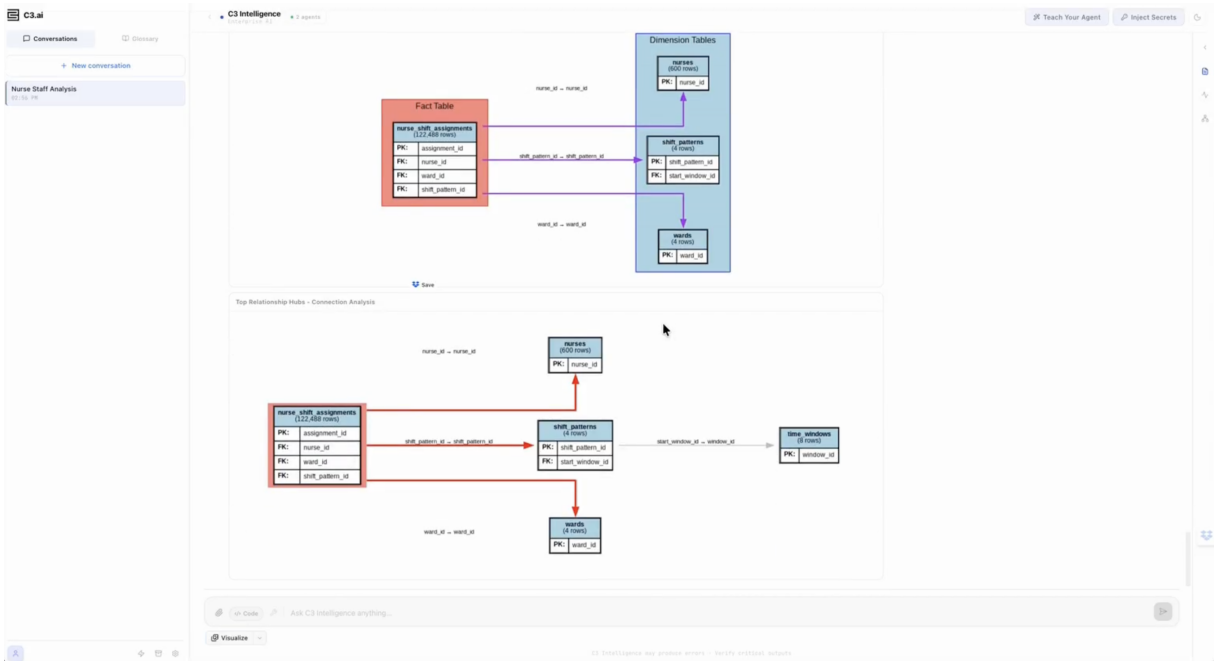

Figure 6: The *Schema Creator*: the resulting database, shown as an entity-relationship diagram.

Query Generator. With the database in place, the domain expert asks analytical questions in natural language. The *Query Generator* answers them by writing and executing the SQL queries each analysis requires, returning the result as a dashboard and an exported file alongside the queries that produced them, so the expert can audit the computation rather than trust it (Figure 7).

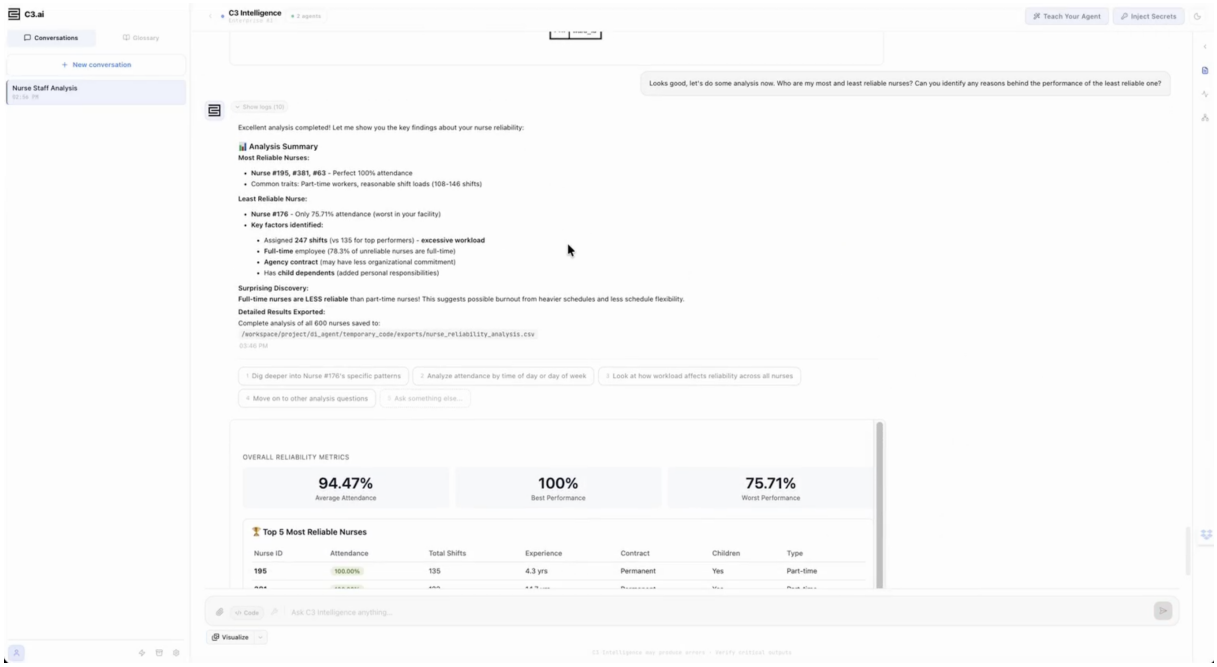

Figure 7: The *Query Generator*: an analytical question answered as a reviewable dashboard, with the steps and exported analysis that produced it.

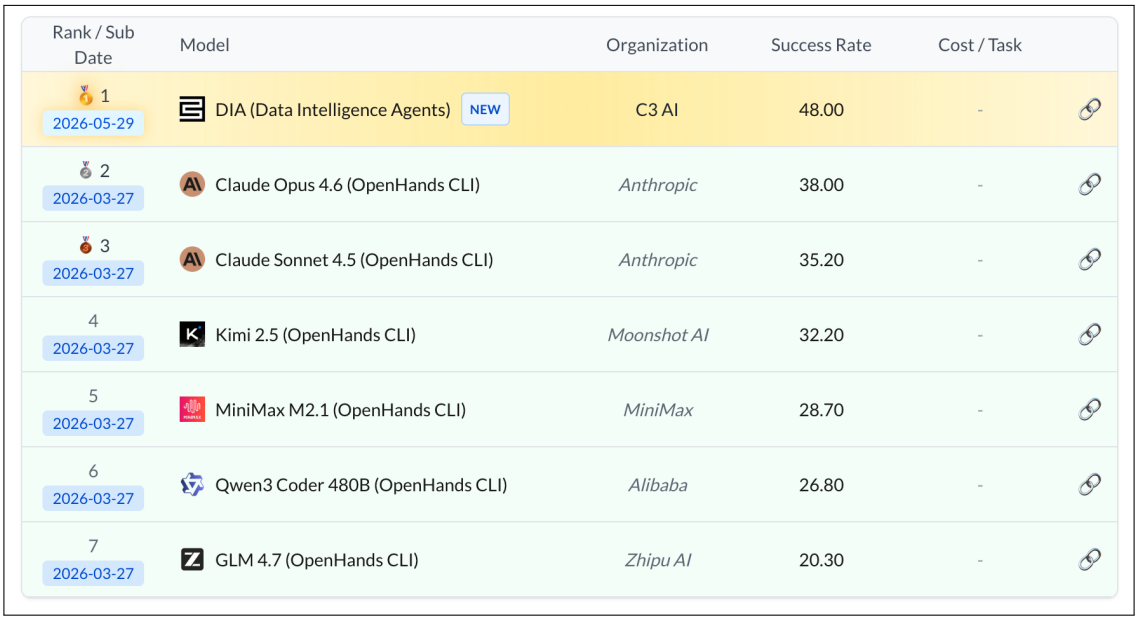
Because the work happens in one thread over a shared workspace, the expert never writes SQL or DDL yet sees every artifact each agent produced, can correct any step before the next consumes it, and can ask follow-up questions that build on the work already done. The walkthrough uses uploaded files, but the same workflow runs over enterprise source systems through the underlying data platform, which handles

connection, ingestion, access control, and execution at scale. This is the execution-grounded, review-at-each-step design the benchmarks measure in isolation, operating here as one continuous deployment.

Deployment lessons. Company policy prevents releasing customer counts, workflow volume, or satisfaction metrics, so we report the recurring qualitative pattern instead. The most consequential corrections happen at the *Data Interpreter* to *Schema Creator* handoff: an inferred relationship, key, or semantic type is what the *Schema Creator* materializes into the database, so a misread there, for instance a foreign key inferred on a plausible but incorrect column, would otherwise propagate into every downstream query that touches it. Because the domain expert reviews the interpretation before the *Schema Creator* consumes it (Figure 5), these upstream errors are caught and corrected at the point where they are cheapest to fix, rather than surfacing later as a wrong analytical answer. This is the practical reason the pipeline reviews each artifact in turn rather than only the final answer: an error in an early, structural artifact is far more consequential than an error in a late, disposable one, and is far harder to notice once several agents downstream have already built on it.

Governance and safeguards. The deployment is governed by the same properties that make it auditable. Every step is a concrete, inspectable artifact, so an analysis can be traced from the natural-language question through the executed SQL to the returned result, and any step can be reproduced or corrected. A domain expert reviews each agent's output before the next agent consumes it, keeping a human in the loop at every stage rather than only at the end. Data access runs through the underlying platform, which enforces connection, authentication, and access control, so agents operate only within a user's existing permissions and read only the sources that user is authorized to see. Because generation is execution-grounded, the system surfaces failed or empty executions rather than silently returning an unverified answer, and the memory it accumulates is re-verified against the live database before it can influence a later result (Appendix F), preventing stale rules from silently propagating. These are operational safeguards observed in deployment rather than formal guarantees; strengthening them, for example with automated policy checks on generated write operations, is ongoing work.

H Leaderboard Reference



Figures 8 and 9 record the public leaderboard standings of BIRD-Critic and LiveSQLBench, from which several of the name-only baselines in Table 1 are drawn, captured in June 2026.

Rank	Model	SR (%)	Institute	Link	Date	Tier

Abstract

Retrieval-augmented generation (RAG) is hard to monitor in production: exhaustive relevance labels do not exist for non-stationary multi-million-passage corpora that re-index in real time. As a result, retrieval quality is generally understudied and often deprioritised in favour of generation-oriented metrics. In this work, we propose auditing retrieval coverage by probing for evidence of missing documents rather than enumerating every relevant one. Our method Re:CAP (REtrieval Coverage Audit by iterative Probing) is a reference-free audit loop applied to a deployed RAG pipeline's initial answer and retrieved context: it identifies the topics already covered, generates probing questions for plausibly missing topics, retrieves candidate documents, and applies an LLM-as-judge to retain only those that introduce previously-unretrieved information. On four public benchmarks, Re:CAP recovers 9–29% of gold labels that flat BM25 top-500 cannot reach, rising to 48% on TREC-COVID. On MuSiQue Re:CAP beats flat hybrid top-500 by +12.9 pp on recall at less than half the document budget. An ensemble BM25, dense, and hybrid baseline (top-500 each) still leaves out 21.2% of gold docs on TREC-COVID that Re:CAP recovers; human annotators judge that 78.9% of those structurally distinct documents add new information to the baseline answer (Fleiss $\kappa = 0.79$, $n = 123$), and 73.9% on live production traffic ($n = 180$). End-to-end recall is reproducible to within $\pm 1\%$ across three independent runs, making Re:CAP a stable instrument for periodic retrieval audits.

1 Introduction

Retrieval-augmented generation (RAG) is a standard component of enterprise knowledge assistants over proprietary corpora such as news feeds, internal research, and regulatory filings (Lewis et al., 2020; Gao et al., 2023). Popular RAG evaluation frameworks — RAGAS (Es et al., 2023) and ARES (Saad-Falcon et al., 2024) — score answer-side signals (faithfulness, answer relevance) and the relevance of the retrieved context, but cannot detect what the retriever failed to surface. As a result, an answer that is fluent and faithful to its retrieved context can still be substantively incomplete, and these metrics do not register the omission. For instance, a research assistant asked about a recent central-bank policy announcement may ground its answer in the policy statement and the lead wire story while overlooking the updated economic projections, the press-conference transcript, recorded dissents, and post-meeting analyst commentary — all present in the same corpus. We refer to this gap between the documents the retriever surfaces and the documents the corpus contains as the *retrieval coverage* problem, and we observe it most acutely in non-stationary corpora with multiple sources of truth. Figure 1 illustrates the problem: retrieving more deeply extends the region a query already reaches, so gold that lies outside it stays unreachable at any affordable depth.

Classical recall-based evaluation addresses retrieval coverage in principle but is impractical for large production deployments. Modern production indices contain 10^8 or more passages (Karpukhin et al., 2020; Bajaj et al., 2018), and the underlying corpus is re-indexed continuously as documents are added, edited, or withdrawn. Exhaustive per-query relevance judgements are prohibitive at this scale, and TREC-style pooling (Voorhees, 2000; Buckley et al., 2007) requires multiple participating systems and fresh labels after every change to the index, embedder, or ranker. Proprietary deployments typically have no per-query relevance labels at all, leaving operators reliant on end-to-end answer signals that cannot distinguish a retrieval failure from a reader failure.

We therefore reframe the problem. Rather than enumerating every relevant document (intractable), we probe each query for positive evidence that

EMNLP 2026 Industry Track, pages 2532–2565

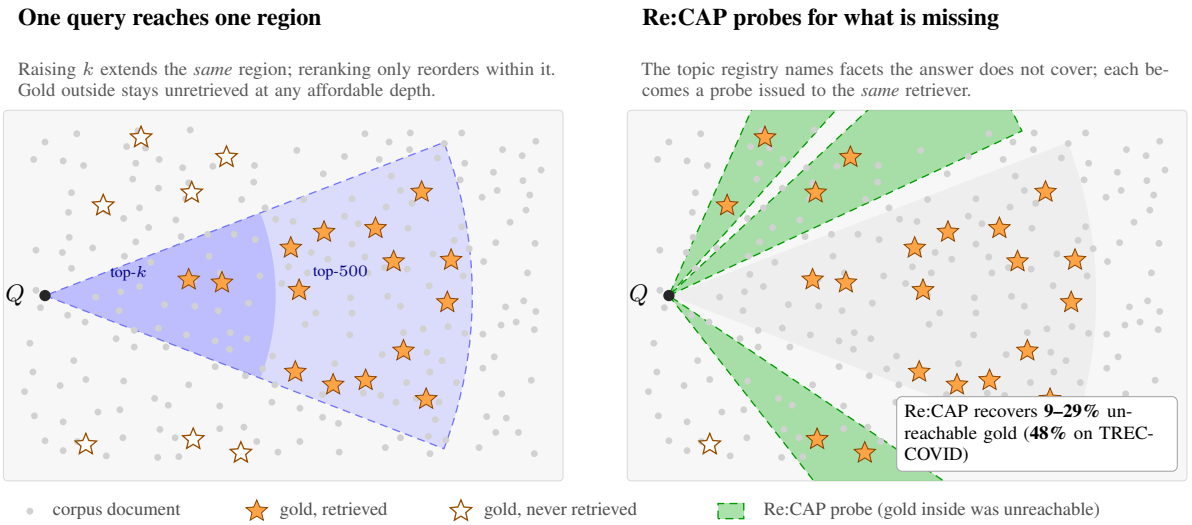

Figure 1: Schematic: retrieval coverage has a blind spot, and depth does not close it. Gold ranked below any affordable top-k by the original query stays unretrieved, and answer-side evaluation cannot detect it. Re:CAP issues further queries from the topic registry; each induces a different ranking over the same corpus and the same retriever (§2). The cone geometry is illustrative, not a model of the retriever.

the retriever missed relevant content (tractable and automatable). We instantiate this reframing in **Re:CAP** (REtrieval Coverage Audit by iterative Probing), a reference-free iterative loop that audits a deployed RAG pipeline without consuming per-query gold labels. Given a query Q, an initial set of retrieved documents D_0, and the corresponding answer A_0, Re:CAP (Algorithm 1) maintains a topic registry T of the information facets already covered, generates entity-anchored gap-probing questions targeting aspects relevant to Q but absent from T, expands retrieval with those questions, and uses an LLM judge to label each new candidate document as novel, redundant, or off-topic. The loop iterates until T stops growing, yielding a structured inventory of retrieval gaps $G \subseteq T$ together with label-free monitoring signals (gap count, gap rate) whose stability and sensitivity to retrieval quality we characterise empirically (§4.3, §4.5). At 250–500 LLM calls per audited query, Re:CAP is a *periodic sampling auditor* rather than a per-query monitor: it runs over a representative sample on an audit cycle — typically before promoting an index, embedder, or ranker change — not inline on live traffic. Cost is operator-tunable: an all-mini pipeline is $4.6\times$ cheaper for -0.51 pp paired recall, at the edge of the run-to-run noise floor (App. M, E3.5).

Our contributions are as follows:

- We propose a **topic-based gap-discovery framework** and instantiate it as the **Re:CAP iterative protocol**, whose gap-question generator combines **one dominant anchoring mechanism** — the entity ledger, which accounts for nearly all of the average-recall lift — with **four supporting guards**: probe-role diversity, coverage-aware topic serialisation, anti-collapse termination, and failure memory. The four are not recall levers. Each suppresses a specific failure mode of a minimal $(Q{+}T)$-only generator — topic-coverage skew, low probe diversity, cold-start collapse, and wasted iterations — that leave-one-out on *average* recall over well-behaved benchmarks does not surface, and their effect is concentrated in worst-case behaviour (§2, App. O, Table 20).
- We provide **empirical evidence** across four public benchmarks that Re:CAP recovers 9–29% of gold unreachable by flat BM25 top-500 ($+12.9$ pp over flat hybrid top-500 on MuSiQue at less than half the document budget), moves predictably with retrieval quality (§4.3), and reproduces to within 1% across runs (§4.5).
- We **validate Re:CAP end-to-end on two unrelated live production deployments** over proprietary corpora (400 queries total; App. E).
- We **validate Re:CAP-discovered gaps against blinded human judgement**: on the ensemble-missed stratum that no single-retriever upgrade closes, 78.9% of recovered documents add information the baseline answer lacks (three blinded annotators, Fleiss

$\kappa = 0.79$, $n = 123$; §5).

2 Method

2.1 Setting and topic-based gaps

A RAG pipeline has a corpus $\mathcal{C}$, retriever R, and LLM reader M. Given query Q, it produces an initial set of retrieved documents $D_0 = R(Q, k)$ and an answer $A_0 = M(Q, D_0)$. Without exhaustive labels for $\mathcal{C}$ we audit the pipeline by discovering *retrieval gaps*: aspects of Q that are relevant and evidenced in $\mathcal{C}$ but absent from D_0.

We define gaps at the *topic* level rather than the document level. What counts as a single topic is fixed by three rules: a **paragraph test** (each topic warrants a distinct, non-overlapping paragraph), a **type-not-instance** rule[1], and a hard cap (default 50 topics per query). A topic t is a *retrieval gap* iff (i) t is relevant to Q, (ii) some $d \in \mathcal{C}$ covers t, and (iii) no $d' \in D_0$ covers t. Topic-level counting provides built-in deduplication across redundant evidence documents, interpretable per-query reports, and a normalised gap rate $|G|/|T_{\text{final}}|$ comparable across queries of varying complexity.

2.2 The Re:CAP loop

Re:CAP runs as a six-step loop (Algorithm 1) layered on top of an unchanged host RAG pipeline.

1. **Initial pass (S1).** The host RAG pipeline runs unchanged: $D_0 = R(Q, k)$, $A_0 = M(Q, D_0)$.

2. **Topic extraction and ledger init (S2).** An LLM extracts the distinct topics from A_0 as short labels; each $d \in D_0$ is then reconciled against the registry T in a batched LLM call. Reconciliation recovers topics from D_0 the reader omitted, so the rest of the loop measures only retriever-side gaps. An *entity ledger* L (named entities, numeric and temporal anchors from Q and A_0) is also extracted at this step and reused by S3 in every iteration.

3. **Gap-Q generation (S3).** The generator takes Q, the registry T, and the entity ledger L, and emits five gap questions targeting aspects absent from T. Each question is generated and tagged with one role from a fixed five-role taxonomy (*entity-anchored*, *concept-anchored*, *constraint-relaxed*, *constraint-tightened*, *inverse-negation*; definitions in App. Q). Orthogonal to these five roles, one anchoring *mechanism* and four supporting *guards* drive coverage and diversity: (A) every question must contain a literal anchor from L verbatim, preventing the generator from paraphrasing away bridge entities; (B) topics are serialised with their evidence count so the generator targets under-supported topics; (C) the role taxonomy enforces probe diversity; (D) an *anti-collapse* guard requires ≥ 2 iterations when D_0 is empty or A_0 is an "insufficient context" answer; (E) *failure memory* passes the previous iteration's unproductive gap-Qs back as negative examples. As an ablation reference we additionally evaluate a minimal $(Q + T)$-only generator that drops A–E.

4. **Expanded retrieval (S4).** For each gap question g_i, R returns the top-m documents, and $C = \bigcup_i R(g_i, m)$ is deduplicated against D_0 and previously seen candidate documents. The same retriever as the host system is used, so discovered gaps reflect that retriever's coverage limitations.

Algorithm 1 Re:CAP gap-discovery loop. ColdStart$(D_0, A_0, i) := i = 1 \wedge (D_0 = \emptyset \vee A_0$ is 'insufficient context') vetoes early termination (§2.2).

Require: query Q, retriever R, reader M, judge $\mathcal{J}$

[1] A topic describes the *kind* of information sought, not a particular value of it — analogous to the class/instance distinction in object-oriented design.

	MuSiQue	HotPot	MHopRAG	TC	MS MARCO
Corpus	21K	5.2M	609 articles	171K	8.8M
Queries used	100	98	98	50	97
Evidence/q	2–4	2	2–4	∼1,327	∼213
Judgements	binary	binary	binary	graded (0–2)	graded (0–3)

Table 1: Dataset characteristics. MHopRAG = MultiHop-RAG; TC = TREC-COVID. Evidence/q is gold-supporting-evidence count for binary-judgement sets, mean judged-pool size for graded sets. MS MARCO is BM25-only (corpus size precludes embedding); all others use hybrid BM25 + dense.

5. **Novelty judging (S5).** For each $c \in C$, the judge assigns one of five verdicts (NEWTOPIC, SUBTOPIC, REDUNDANT, IRRELEVANT, CONTRADICTORY); the first two add the candidate to T and to the gap inventory G, REDUNDANT attaches the candidate as additional evidence to its existing topic, and the last two are discarded. Unproductive gap-Qs (those yielding no new topic) are recorded in the failure memory F and passed back to S3 at the next iteration. Overlapping new topics across parallel judges are resolved by two-stage post-hoc deduplication (App. C.1).
6. **Termination (S6).** The loop ends on natural convergence (no novel candidates), an anti-collapse veto on cold-start iter 1, the topic cap, or the MAX_ITER budget (Algorithm 1).

The loop returns (i) the topic registry T with per-topic evidence, (ii) the gap inventory $G \subseteq T$, and (iii) monitoring metrics: gap count, gap rate, and recall when labels are available.

3 Experimental Setup

3.1 Datasets

We evaluate on four primary datasets spanning bounded-evidence multi-hop QA and pooled-graded IR, plus MS MARCO TREC-DL 2019/2020 as an auxiliary BM25-only sensitivity ladder (Table 1). MuSiQue and HotPotQA are the primary bounded-evidence regime; MultiHop-RAG, on a small 609-article corpus, serves as a saturation/ceiling sanity check. TREC-COVID is included to delimit where Re:CAP applies and where it does not (§6). Full per-dataset descriptions and rationale are in Appendix A.

3.2 Retrieval and models

We evaluate Re:CAP with sparse BM25, dense MiniLM-L12v2 (Reimers and Gurevych, 2019; Wang et al., 2020), and a hybrid of the two via reciprocal-rank fusion (Cormack et al., 2009). On MuSiQue we additionally evaluate a stronger dense back-end, OpenAI `text-embedding-3-large`. We adopt hybrid as the reference back-end; BM25-only and dense-only act as ablations. The QA reader is held fixed at GPT-5.2 across all configurations to remove reader quality as a confounding factor: the object of measurement is *retrieval* gaps, not reader capability. The remaining Re:CAP components (topic extractor, reconciler, gap-Q generator, judge) default to GPT-4.1 with temperature 0 (gap-Q generator temperature = 0.3 for diversity). Unless noted otherwise, every main result uses hybrid retrieval, the five-mechanism gap-Q generator, $k = 10$, $m = 50$, five gap-Qs per iteration, MAX_ITER $= 3$, and MAX_TOPICS $= 50$. The full model×component table and a per-knob justification are in Appendix C.

3.3 Baselines

We compare Re:CAP against (i) **flat top-N retrieval** at budgets matched to Re:CAP's per-query unique-candidate count N_q — the central budget-matched control that isolates the audit's contribution from raw exposure to more documents — under three retriever back-ends (BM25, MiniLM hybrid, and OpenAI dense `text-embedding-3-large`; OpenAI on MuSiQue only); (ii) **single-pass probing** (MAX_ITER = 1) to test whether iteration adds value; (iii) **RM3 pseudo-relevance feedback (PRF)** (Lavrenko and Croft, 2001; Abdul-Jaleel et al., 2004) (App. J); and (iv) the **minimal $(Q + T)$-only** generator ablation on both BM25 and hybrid retrievers.

Re:CAP is an audit layer, not a competing retriever. These comparisons are budget-matched controls; none of them claims Re:CAP is a better retrieval system. Re:CAP runs *on top of* whatever retriever a deployment already operates (§2), so the evaluation question is not "does the loop beat a stronger retriever?" but "does the loop surface gold that the host retrieval missed?" Two standard upgrades do not change that answer. Cross-encoder **reranking** reorders the flat top-K already retrieved and cannot surface any document outside it — the axis the headline results are anchored on (Figure 1). One-shot **query rewriting** is a strict subset of what the loop does across iterations (§2). Applying either to both sides raises the floor symmetrically, which is why we report unreachable-gold share alongside recall throughout.

3.4 Evaluation protocol

For each Re:CAP run we record per-query (i) gold recall against dataset qrels (for validation only, Re:CAP itself does not consume labels), (ii) Re:CAP gap count and gap rate, (iii) unreachable-gold share vs. flat top-500 (the fraction of Re:CAP-recovered gold not in flat top-500 under each retriever), and (iv) telemetry rolled up to dollar cost using published Azure OpenAI rates. Confidence intervals on run-level metrics are 1,000-sample query-bootstrap 95%, and paired differences use the same bootstrap on per-query deltas; the human evaluations state their interval method with their tables. The variance protocol re-runs Re:CAP with the default settings three times under the same query slice and seed to estimate end-to-end stability under inherent LLM non-determinism.

4 Results

4.1 Re:CAP vs. flat retrieval

Table 2 reports the cross-dataset main result (Pareto visualization in App. Figure 3): Re:CAP at the default configuration vs. three flat baselines at matched docs-seen budget. On MuSiQue and HotPotQA, Re:CAP beats flat BM25 at matched-N_q budget by $+6.1$ to $+29.1$ pp; on MultiHop-RAG, where flat top-500 is near saturation, the matched-N_q gain narrows to $+2.6$ pp. It also beats stronger flat baselines at less than half the document budget: on MuSiQue, $+12.9$ pp vs. flat MiniLM hybrid top-500 and $+4.7$ pp vs. flat OpenAI dense top-500; on HotPotQA, $+11.5$ pp vs. flat MiniLM dense top-500. Across the six comparisons in Table 2 the CIs are disjoint on the three largest margins ($+11.5$ to $+29.1$ pp) and overlap on the three smallest ($+2.4$ to $+6.1$ pp): on the recall axis a stronger baseline narrows the margin, which is why the unreachable-gold share (§4.2) rather than recall is the retriever-independent signal. On MultiHop-RAG the 609-article corpus is near-saturated by flat top-500 across retriever back-ends (0.88–1.00), so it serves as a ceiling sanity check rather than a discriminative benchmark; Re:CAP converges within $N_q \approx 45$–90 depending on back-end. On TREC-COVID Re:CAP shows the strongest structural complementarity: 48% of its recovered gold is absent from flat BM25 top-500 and 21.2% **remains absent from the ensemble of flat BM25, dense, and hybrid top-500 combined** – a 1,500-document, three-retriever budget – appearing in 98% of queries (49 of 50). By majority vote of three blinded annotators, 78.9% [71.5–86.2%] of $n = 123$ such documents add information beyond the D_0-only baseline answer (Fleiss $\kappa = 0.79$; 78.3% on MuSiQue; §5). On the recall metric Re:CAP trails flat BM25 top-500 by a marginal -2.0 pp (0.221 vs. 0.241) at ∼24% smaller document budget: flat top-500 itself reaches only 24% on this pooled-graded gold set of ∼493 relevant docs per query, and binary-novelty judging at a ∼378-doc Re:CAP budget is structurally mismatched with the recall ceiling (§6), thus complementarity, not recall@k, is the audit-relevant signal here.

Dataset	Method	Docs	Recall [95% CI]	Unr.	$\lvert G\rvert$
MuSiQue	Flat BM25 N_q	238	0.610 [.558,.664]	—	—
	Flat hyb. top-500	500	0.772 [.723,.818]	—	—
	Flat OpenAI top-500	500	0.854 [.815,.896]	—	—
	RR hyb.	**238**	**0.901 [.854,.938]**	**29.4%**	**3.6**
HotPot	Flat BM25 N_q	249	0.827 [.775,.878]	—	—
	Flat hyb. top-500	500	0.864 [.813,.909]	—	—
	Flat dense top-500[‡]	500	0.773 [.717,.828]	—	—
	RR hyb.	**249**	**0.888 [.837,.939]**	**9.2%**	**2.3**
TC[†]	Flat BM25 top-500	500	0.241 [.211,.271]	—	—
	RR hyb.	**378**	**0.221 [.195,.248]**	**48.0%**[§]	**36.9**

Table 2: Re:CAP vs. flat retrieval at matched docs-seen budget. *RR hyb.* = Re:CAP with hybrid retrieval; *Unr.* = share of recovered gold not in flat BM25 top-500 (see [§] for the ensemble variant); $\lvert G\rvert$ = mean Re:CAP gap count per query. MultiHop-RAG omitted (saturates at flat top-500). [†]pooled-graded scope boundary; [‡]MiniLM-L12 dense; [§]21.2% also unreachable by the ensemble of flat BM25, dense, and hybrid top-500. Full matrix: App. G.

4.2 Structural complementarity

Re:CAP samples a meaningfully different slice of the relevance pool than flat retrieval — an audit signal flat top-k cannot produce by construction. Against flat BM25 top-500, 9.2–29.4% of Re:CAP's recovered gold is unreachable on bounded-evidence (column *Unr.* of Table 2), rising to 48% on TREC-COVID under the default hybrid back-end (45–61% across alternative Re:CAP retriever back-ends; App. G). Against the ensemble of BM25, dense, and hybrid top-500, the share tracks gold-pool diversity: 2.5% on HotPotQA (4% of queries; 2-doc pools), 10.0% on MuSiQue (21% of queries; 2–4 hops), and 21.2% on TREC-COVID (98% of queries; ∼493 gold docs/q; Table 17). Re:CAP's structural contribution is largest exactly where exhaustive recall labels are most intractable to obtain — the production setting the method is designed for.

4.3 Sensitivity to retrieval quality

A monitoring metric is only useful if it *moves* when the underlying retrieval changes — whether from a

corpus refresh, an embedder upgrade, or a reranker change. Table 3 reports a within-dataset retrieval-quality ladder: on MuSiQue, sweeping retriever type (BM25 / hybrid) and top-k (10 / 20 / 50) with generator fixed; on MS MARCO TREC-DL 2019/2020 ($n = 97$ NIST-judged queries, rel ≥ 2), sweeping BM25 top-k over the same ladder. Two observations. (i) Retriever *type* dominates where multiple are available: on MuSiQue, BM25 vs. hybrid moves Re:CAP recall by $\sim$6 pp at matched k. (ii) Top-k within a single retriever is approximately flat because Re:CAP's expansion step saturates the candidate pool regardless of D_0 depth (≤ 1.9 pp paired across top-10/20/50 on every ladder; ≤ 0.75 pp on MS MARCO BM25). Together these are consistent with the design intent: Re:CAP metrics are *discriminative* where retrieval truly differs and *stable* where it does not.

The two label-free monitoring signals behave differently along this ladder, and the distinction matters for anyone deploying them. Mean gap count $|G|$ separates the two retriever types in the expected direction — every BM25 rung sits above every hybrid rung (4.00–4.20 vs. 3.61–3.97) — so a weaker host retriever leaves Re:CAP more gaps to open. The magnitude, however, should be read with care: the BM25–hybrid mean separation is 0.28, only 1.5$\times$ the run-to-run standard deviation of $|G|$ (0.19, Table 5), and at matched k=20 the two retrievers differ by 0.03. The type separation is consistent on this ladder, but within a retriever top-k does not order $|G|$ reliably, and the per-rung differences are not resolvable within a single audit cycle. $|G|$ is therefore a directional indicator here rather than a calibrated one, and separating adjacent configurations needs repeated cycles or a larger degradation than this ladder spans.

Gap rate is the more stable signal (CV 1.46% against 5.04%) but is near saturation here (0.81–0.86 on MuSiQue, 0.96–0.98 on MS MARCO): on MS MARCO almost every query yields a gap, so it acts as a coverage *floor* rather than a fine-grained sensitivity signal. Neither signal is a drop-in alarm on its own; the threshold recipe is in App. D.

4.4 Controlled gold-deletion check

We additionally validate sensitivity under controlled deletion: removing $K \in \{1, 2, \text{all}\}$ gold passages from D_0 ($n = 91$ MuSiQue queries with gold in D_0), Re:CAP re-discovers 98.9%/98.4%/100% of the removed gold IDs respectively. Paired recall still falls 11–13 pp, attributable to secondary gold rather than to failed recovery. Full E2.2 table and discussion: Appendix L.

Retriever	recall	Δ_{paired}	$\lvert G\rvert$	gap rate	\$/q	$\bar{\text{it}}$
MuSiQue ($n = 100$, hybrid top-10 ref.)						
BM25 top-10	0.842	+5.92	4.20	0.831	0.65	1.93

Table 3: Retrieval-quality ladder. Columns: Re:CAP recall; paired delta (positive Δ_{paired} implies the cell is *worse* than its reference); mean gap count $|G|$ per query; gap rate; cost per query; and mean iterations per query till convergence. $|G|$ separates the two retriever types in the expected direction, though by margins comparable to its own run-to-run noise; gap rate saturates on these workloads and acts as a coverage floor (§4.3).

Metric	MuSiQue	HotPot	MHopRAG	TC
LLM calls (total)	28.6k	25.0k	25.8k	30.8k
of which judge	28.1k	24.5k	25.3k	30.2k
Judge share	97.5%	97%	97%	97%
\$ / query	**0.59**	**0.65**	**0.69**	**2.05**‡

Table 4: Cost breakdown (Re:CAP default on hybrid retrieval). ‡TREC-COVID cell is the BM25 + $(Q{+}T)$ variant (only TC configuration with full token telemetry).

4.5 Operational characteristics

Cost. The judge dominates per-query cost ($\sim$97% across all datasets; judge $\rightarrow$ GPT-4.1-mini saves 75% of HotPotQA cost, the generator swap alone saves 8%). Per-query cost varies $\sim$3.5$\times$ across corpora (\$0.59–\$2.05, Table 4). A 4.6$\times$ Pareto improvement is available for -0.51 pp paired recall on HotPotQA by swapping all pipeline components to GPT-4.1-mini (at the edge of the 0.42 pp noise floor below; full grid in Appendix M).

Reproducibility. Three independent runs of Re:CAP on MuSiQue (Table 5; same slice and seed; variance is inherent LLM non-determinism) give Re:CAP-recall a Coefficient-of-variation = 0.47% ($\pm$0.42 pp), so Re:CAP returns a stable recall estimate for a fixed (pipeline, corpus) pair. Combined with the retriever-type sensitivity demonstrated in §4.3, this licenses inter-run comparisons at that granularity: recall deltas that exceed the noise floor and accompany a change of retriever can be read as real changes rather than measurement noise. Adjacent top-k settings are not separable this way.

Metric	Mean	Std	CV	Range
Re:CAP recall	**0.8972**	0.0043	**0.47%**	0.0083
Re:CAP gap count $\|G\|$	3.77	0.19	5.04%	0.37
Re:CAP gap rate	**0.832**	0.012	**1.46%**	0.024
N_q (unique cands.)	246.5	7.4	2.99%	15
Cost / run ($)	62.47	3.18	5.09%	6.01

Table 5: Run-to-run variance, three independent runs (MuSiQue, default, $n = 100$). Recall CV 0.47% and gap-rate CV 1.46% both underpin the deployable-monitoring claim.

Attribution of residual losses. On bounded-evidence primaries the dominant failure is gap-question generation, not judging (95.3% of missing docs never surface as candidates): early convergence, bridge-entity erasure, or entity-ledger anchoring on a hallucinated name from A_0. On pooled-graded TREC-COVID the failure is structural: binary novelty judging over-aggregates sub-mechanisms and the Re:CAP budget is dwarfed by the graded pool. Full taxonomy, counts, and worked examples are in Appendix O.

Production deployment. The default configuration also audits two live deployments on proprietary corpora (≈123M and ≈70M passages; 200 queries each), differing chiefly in D_0 width: "AI Search" (D_0 fixed at 10) and "NEWS QA" (D_0 mean 47.2, max 110). Both run 200/200 with no production-specific code path: gap rate 0.991 / 0.955, gap-iteration topic share 77.4% / 78.2%, judge share of calls $\geq$ 97.6%, median cost $1.68 / $1.79 per query. Full two-cohort breakdown in App. E (Table 10).

5 Human evaluation of recovered gap documents

The 21.2% TREC-COVID and 10.0% MuSiQue ensemble-unreachable shares in §4.1 are qrels-mediated. To test whether these structurally distinct documents add information the reader actually lacks — independent of the qrels — we ran a blinded human read on the ensemble-unreachable stratum.

Setup. We sampled $n = 123$ ensemble-unreachable gap documents from the deployed default: 100 TREC-COVID documents stratified by query (target 2 docs per query among the TREC-COVID queries with ≥ 1 ensemble-unreachable doc; 48 queries represented, 1–3 docs each) plus the 23-document MuSiQue census; HotPotQA, MultiHop-RAG, and MS MARCO are ineligible (App. N.3). Three annotators saw the query, the D_0-only baseline answer, and the document text, blinded to judge verdict, qrels status, and dataset. The binary rubric labels a document *new_info* if it adds a substantive query-relevant fact the baseline answer lacks, and *covered* otherwise.

Result. By majority vote, 78.9% [71.5–86.2, 10,000-resample bootstrap] of ensemble-missed gap documents are judged *new_info* at Fleiss $\kappa = 0.79$ (Table 6); per-dataset rates are substantively comparable. This bounds Re:CAP's operational value on the strictest stratum: the documents it recovers that no 1,500-document single-retriever combination surfaces carry information the baseline answer lacks.

Slice	n	new	Rate % [95% CI]	κ
TREC-COVID (stratified)	100	79	79.0 [71.0–87.0]	0.82
MuSiQue (census)	23	18	78.3 [60.9–95.7]	0.69
Overall	**123**	**97**	78.9 [71.5–86.2]	0.79

Table 6: Human-evaluation verdicts on 123 ensemble-unreachable gap documents from the deployed default. *new* is the majority-vote *new_info* count; 95% CIs are 10,000-resample bootstrap; κ is Fleiss across three annotators on binary verdicts. 110/123 (89.4%) unanimous.

6 Conclusion

Re:CAP reformulates the retrieval evaluation problem in Production RAG pipelines from that of *enumeration* to one of *probing* by utilizing a topic-aware iterative gap-discovery loop that audits a deployed pipeline without per-query gold labels. Across four publicly available benchmarks we demonstrate that Re:CAP recovers gold that baselines cannot discover (9–29%, rising to 48% on TREC-COVID) and does so at half the document budget (on MuSiQue). Results are reproducible to ∼1% recall across runs. Human assessment on Re:CAP recovered gold documents shows that 78.9% of the recovered documents have novel information missing from the baseline answer ($\kappa = 0.79$). We share Re:CAP statistics and examples from 2 live large-scale production RAG pipelines with 200-query audits each (App. E) along with a deployment recipe (App. D).

Ethical Considerations

Computational and environmental cost. The iterative probing loop has significant energy and carbon implications at scale ($0.59–$2.05/query at default; §4.5); we report full per-corpus cost accounting to enable informed deployment decisions and document a steep Pareto improvement (judge → GPT-4.1-mini) for cost-sensitive deployments.

Teams running Re:CAP continuously should sample queries rather than audit every request.

Bias in gap discovery. The LLM-as-judge may have systematic blind spots — topics it consistently fails to recognise as novel — that could correlate with sensitive attributes and provide false assurance of completeness. Re:CAP cannot fully audit itself; periodic gold-label spot-checks of judge outputs against held-out qrels (Appendix N) are recommended before relying on Re:CAP signals for compliance-grade reporting. Re:CAP's gap-Q generator also inherits any entity biases of the source LLM through the entity ledger; we have not characterised this with respect to demographic or geographic biases.

Human annotation. The human evaluations in §5 and App. F were performed by three in-house annotators, not by the authors and not by crowdworkers. The production cohorts are internal corpora: annotation took place inside that organisation, and no document text from them is reproduced here — the worked examples in App. E report topic labels and generated probe questions only. We collected no personal data from annotators and report no demographic characteristics of the annotator population.

Privacy and access control. Expanded retrieval issues additional probes against the corpus with LLM-generated questions. In deployed systems with row-level access controls, those controls must be honoured during gap probing — otherwise the audit can surface relevant documents the original user would not be entitled to retrieve. Our reference implementation passes the original retrieval ACL context through the loop; we recommend the same for any deployment.

Surface area for prompt injection. Step 2 (reconciliation) and Step 5 (judging) ingest retrieved document text as input to LLM calls and are therefore exposed to prompt-injection attempts embedded in corpus documents. We use structured-output decoding and a narrowly scoped classification task to reduce this surface, but for adversarial corpora additional input sanitisation is warranted.

Limitations

LLM cost. Re:CAP requires multiple LLM calls per query (topic extraction, doc reconciliation, gap-Q generation, novelty judging per candidate, post-hoc deduplication). At the default this totals 250–500 LLM calls per query ($0.59–$2.05 at GPT-4.1 pricing; §4.5). This is materially more expensive than single-pass metrics like RAGAS, and may not suit tight monitoring budgets. Swapping all pipeline components to GPT-4.1-mini cuts this $4.6\times$ (-0.51 pp paired recall on HotPotQA; App. M, E3.5).

Judge reliability ceiling. Re:CAP is in principle bounded by the LLM judge's accuracy. The gold-label failure-mode analysis (Appendix O) bounds this empirically: 1.4% of missing-gold docs are judge-rejected overall (4.7% on the bounded-evidence primaries), so $> 95\%$ of missing-gold losses on the regime Re:CAP is designed for are upstream of judging. We rely on the LLM-as-judge literature (Faggioli et al., 2023; Thomas et al., 2024; Upadhyay et al., 2024a,b) as support for narrow, structured-output tasks, and follow cautions against substituting LLMs for full human qrels (Soboroff, 2025) by validating Re:CAP against held-out labels.

Corpus coverage assumption. Re:CAP discovers gaps only for topics that exist in the corpus. If the corpus itself lacks coverage of an aspect, no probing will find it. Re:CAP measures *retrieval* gaps, not *corpus* gaps.

English only. All experiments are on English-language datasets with English-language LLMs. The approach is language-agnostic in principle but unvalidated multilingually.

Gap-Q generator dependence. Gap-probing depends on the LLM-generated questions; vague or off-target questions under-surface relevant documents and under-count gaps. The five-mechanism generator reduces but does not eliminate this risk.

Topic granularity. We have no formal definition of an "atomic topic". We rely on three prompt-engineering rules (paragraph test, type-not-instance, different-dimension sub-topic) plus a configurable hard cap. Broad or ambiguous queries can still trigger instance enumeration, inflating topic counts.

Instance-level coverage holes can be masked. By design, the type-not-instance rule collapses instance enumeration into a single topic. A retriever that surfaces *some* instances of a topic but misses others along the same dimension is scored as covering that topic, even though instance-level recall

is incomplete. The SUBTOPIC verdict mitigates this only when missed instances reveal a different *dimension*, not when they are missing along the existing one. Deployments that care about instance-level enumeration recall (e.g., fact verification, audit trails) should track Re:CAP at a finer granularity, or pair it with instance-level metrics.

Recall@k undercounts complementarity on pooled-graded corpora. On pooled-graded corpora such as TREC-COVID — where a query has hundreds–thousands of partially-relevant documents, flat BM25 top-500 itself reaches only 24% recall, and any ∼378-doc method cannot hold the ∼493 relevant docs per query — recall@k compresses complementarity into a small negative delta (Re:CAP best cell $\Delta = -2.0$ pp; §4.1). The audit-relevant signal survives: 21.2% of Re:CAP's recovered gold remains absent from the ensemble of flat BM25, dense, and hybrid top-500 combined, present in 98% of queries (Table 17). On such corpora, recall@k should be paired with a structural complementarity metric to capture Re:CAP's audit contribution.

Initial-retriever choice can cause cell-level regressions. The HotPotQA dense-D_0 cell (-3.6 pp matched-N_q) shows the initial retriever interacts with the dataset's evidence structure. The initial retriever should be selected based on dataset-level recall-at-k diagnostics before Re:CAP is layered on top.

Provider-side content filtering depresses recall. All experiments run against Azure OpenAI, whose content-management policy rejects a small share of prompts as `ResponsibleAIPolicyViolation`. Rejected candidates produce no verdict, so any that would have been NEWTOPIC are silently dropped and reported recall is a conservative lower bound. The effect is small per-query and well within the variance noise floor of §4.5, but a non-filtered backend would likely yield slightly higher recall than reported here.

Calibrated metrics rest on benchmarks; production audit is a single snapshot. The recall, paired-Δ, unreachable-gold, variance, and cost ladders all rest on four English-language academic benchmarks (§§4.1–4.5); those metrics require per-query gold and so cannot be reported on production traffic. We do also report end-to-end audits on two unrelated live deployments over proprietary corpora (400 queries total, App. E), which confirm the gap rate, topic-source distribution, convergence behaviour, and judge-share-of-cost pattern transfer to production traffic across deployments differing in D_0 width by $\sim 5\times$.

Appendix

A Datasets and Rationale

We evaluate on four datasets, chosen to span (i) bounded-evidence multi-hop QA — the operational regime Re:CAP is designed for — and (ii) pooled-graded IR as a contrasting regime (Table 1 in the main body). The MS MARCO TREC-DL 2019/2020 ladder is an additional BM25-only validation surface for the sensitivity result (§4.3).

MuSiQue (Trivedi et al., 2022): 21K-paragraph deduped corpus, 2–4-hop chained reasoning, shortcut-resistant by design; 2,417 dev queries, of which we sample 100 with seed 42. The strongest signal in our sensitivity ladder.

HotPotQA (Yang et al., 2018): 5.2M-passage Wikipedia corpus, canonical multi-hop benchmark; 5,447 dev / 7,405 test queries, of which we sample 98 with seed 42. Provides the largest-corpus comparison point.

MultiHop-RAG (Tang and Yang, 2024): 609-article news corpus, 2,556 test queries, 2–4 documents per query; an EMNLP 2024 RAG-native benchmark. We use the published test set ($n = 98$ for our slice). The small corpus means flat BM25 top-500 reaches recall 1.000, so this dataset is best read as a saturation/ceiling sanity check rather than a discrimination result.

TREC-COVID (BEIR) (Voorhees et al., 2021): 171K biomedical passages, 50 round-3 topics with pooled graded judgements ($\sim$493 rel docs per query at rel ≥ 1; $\sim$1,327 judged). We include it to characterise where Re:CAP's binary-novelty machinery breaks down (see Limitations, *Recall@k undercounts complementarity on pooled-graded corpora*).

MS MARCO TREC-DL 2019/2020 (Bajaj et al., 2018; Craswell et al., 2020): 8.8M passages, 97 NIST-judged queries with graded qrels thresholded at rel ≥ 2. We use this as a BM25-only sensitivity ladder (Table 3, second panel) on an independently judged, IR-standard corpus. We deliberately do not embed MS MARCO for dense or hybrid retrieval (project-budget choice); it is used only in BM25-only sensitivity configurations.

B Related Work

Retrieval evaluation and coverage. Recall, precision, nDCG, and MAP require relevance judgements. TREC pooling (Voorhees, 2000) aggregates top-ranked documents across systems and judges only the pool, but is biased toward in-pool systems, treats unjudged documents as irrelevant, and does not scale to multi-million-passage corpora that re-index frequently (Zobel, 1998; Buckley et al., 2007). Novelty, diversity, and nugget-based test collections move the unit of evaluation from documents toward subtopics or information nuggets (Clarke et al., 2008; Voorhees, 2003; Pavlu et al., 2012). Re:CAP adopts this topic-level unit, but does not build reusable qrels (query relevance judgements) or estimate absolute recall: it probes a single deployed pipeline for positive evidence of missed topics.

RAG evaluation frameworks. RAGAS (Es et al., 2023), ARES (Saad-Falcon et al., 2024), RGB (Chen et al., 2024), and RAGChecker (Ru et al., 2024) score supplied retrieval and generation for faithfulness, answer relevance, context relevance/recall, and module-level diagnostics. They are complementary to Re:CAP: they ask whether the answer is supported by the retrieved context; Re:CAP asks whether relevant facets exist *outside* that context and returns an actionable gap inventory.

Coverage-oriented RAG evaluation. Closest to Re:CAP are recent coverage-oriented RAG evaluations. Xie et al. (Xie et al., 2025) decompose open-ended questions into core, background, and follow-up sub-questions; CRUX evaluates whether retrieved contexts cover human-grounded information needed for long-form generation (Ju et al., 2025); CoverageBench assembles coverage-oriented test collections (Samuel et al., 2026); and LANCER optimises reranking for nugget coverage (Ju et al., 2026). These works assume pre-specified sub-questions, summaries, nuggets, or coverage-aware training/evaluation targets. Re:CAP instead induces a topic registry from D_0 and A_0, then actively probes for missing topics without per-query qrels or pre-authored facets.

LLM-as-judge and iterative retrieval. LLM relevance judging shows mixed results: studies report strong agreement with preferences or TREC-style assessments (Faggioli et al., 2023; Thomas et al., 2024; Upadhyay et al., 2024a,b), while others warn against replacing human qrels with LLM labels (Wang et al., 2023; Soboroff, 2025). Re:CAP's judge performs novelty classification against a per-

query topic registry, not absolute relevance scoring; we validate it against held-out qrels (1.4% judge-rejection on missing-gold candidates). Self-RAG (Asai et al., 2023), FLARE (Jiang et al., 2023), and IRCoT (Trivedi et al., 2023) use iterative retrieval to *improve generation*; Re:CAP repurposes related mechanics for *evaluation*, auditing a fixed pipeline after the fact. Pseudo-relevance feedback (Lavrenko and Croft, 2001; Abdul-Jaleel et al., 2004) and LLM query expansion (Nogueira et al., 2019) provide our baseline references. Table 7 below summarises the positioning.

B.1 Positioning against closest prior work

Table 7 compares Re:CAP to four families of prior work along five capabilities.

Reading the columns. *RAG metrics* (RAGAS, ARES, RGB, RAGChecker) score retrieval indirectly through answer faithfulness and answer/context relevance, and typically require reference answers or per-query reference contexts. *Coverage evaluation* (sub-question decomposition, CRUX, CoverageBench, LANCER, nugget-based test collections) audits coverage directly, but assumes pre-specified sub-questions, summaries, or nuggets authored offline. *Iterative RAG* (Self-RAG, FLARE, IRCoT) issues follow-up queries to *improve the generated answer*, not to evaluate the retriever, and does not surface a gap inventory. *TREC-style pooling* produces reusable qrels by aggregating top-ranked documents across many systems, but is expensive to mount per deployment and does not target a single pipeline.

Conceptual precedent. The closest conceptual precedent for Re:CAP is nugget-based evaluation (Voorhees, 2003): a fixed inventory of atomic information units against which a system is scored. Re:CAP is inspired by this style of decomposition – measuring coverage in terms of discrete information units rather than whole-document relevance – but differs in two ways. First, the units (topics) are *induced* from (D_0, A_0) and grown across iterations, rather than pre-authored as gold. Second, Re:CAP does not score against a fixed nugget set; gap probing extends the registry by generating questions that may surface novel topics, and novelty judging determines whether the retriever could have reached them. The audit signal is the *growth* of the registry under probing, not its overlap with a held-out list. Re:CAP is the only entry in Table 7 that audits coverage on a single deployed pipeline, needs no per-query labels, and returns an actionable per-query gap inventory.

Table 7: Re:CAP positioning. RAG metrics include RAGAS/ARES/RGB/ RAGChecker; Cov. eval. includes sub-question, CRUX, CoverageBench, and nugget-coverage work. *indir.* = indirectly (via answer quality); *gen.* = for generation, not for evaluation.

C Default Re:CAP Configuration

Re:CAP exposes about a dozen knobs (loop control, generator design, LLM choice per component); the deployed default sets each to a specific value, most of them backed by an ablation reported elsewhere in this appendix. Table 8 lists every default with a pointer to its justifying ablation, and Table 9 breaks down the model and sampling temperature used at each pipeline step.

Choice	Default	Ablated in
Gap-Qs / iteration	5	App. M
MAX_ITER	3	App. M
MAX_TOPICS	50	—
Gap-Q gen. input	$Q + T + L$	App. M
Probe roles (Step 3)	5	App. M (LOO)
Anti-collapse guard	on	App. M.2 (LOO)
Failure memory	last iter	App. M.2 (LOO)
Shared pipeline LLM	yes	App. M
Expansion top-m	50	App. M
Judge temperature	0	—
Gap-Q gen. temperature	0.3	—
Retriever	**hybrid BM25 + dense**	§4.1

Table 8: Default Re:CAP configuration. Hybrid retrieval uses RRF over BM25 and MiniLM-L12 dense embeddings. *LOO* = leave-one-out.

The three remaining "—" rows are not ablated. **MAX_TOPICS** ($= 50$) is a safety cap on topic-memory size that bounds prompt growth across iterations; it sits above the per-query topic count on every benchmark run, so on those workloads it acts as a guardrail rather than an active parameter. It is not inert in production: it binds on 8.0% of AI Search and 40.5% of NEWS QA queries (Table 10), truncating the registry and bounding $|G|$ and gap rate on those queries, so wide-D_0 deployments should raise it before reading either signal. The two **temperature** rows are deterministic-by-design conventions (judge / extractors at 0; generator at 0.3 to give the role taxonomy room to diversify), documented in the "Why" column of Table 9 rather than ablated.

C.1 Post-hoc topic deduplication (Step 5b)

Parallel judging in Step 5 emits one verdict per candidate document, so the same underlying topic

Component	Model	T.	Why
QA reader (Step 1)	GPT-5.2	0	strongest
Topic extract. (Step 2)	GPT-4.1	0	deterministic
Doc reconcile (Step 2)	GPT-4.1	0	deterministic
Gap-Q gen. (Step 3)	GPT-4.1	0.3	diversity
Gap judge (Step 5)	GPT-4.1	0	deterministic

Table 9: Per-component LLM configuration. Non-reader components share a single *pipeline model* (GPT-4.1) and are ablated jointly in the pipeline-model swap (App. M, E3.5). T. = sampling temperature.

is frequently surfaced by several candidates within a single iteration under slightly different labels ("Madonna referred to as the Queen of Pop" vs. "Madonna's Queen of Pop title"). Without deduplication these inflate the topic count and the gap inventory G. Re:CAP collapses them in two stages before topics enter the registry T.

Stage A — fuzzy string clustering (deterministic). The per-iteration novel verdicts (NEWTOPIC and SUBTOPIC) are normalised (lowercased, whitespace collapsed) and greedily clustered using Python's `difflib.SequenceMatcher` ratio with a threshold of 0.85. For each cluster, the first label is taken as canonical, evidence document IDs are merged across cluster members, and a SUBTOPIC verdict (with its parent) dominates if any member produced one. Stage A is deterministic and runs without an LLM call.

Stage B — semantic merge against T (LLM). The Stage A survivors are passed to a single LLM call (GPT-4.1, $T = 0$, batches of ≤ 30 labels) together with the current registry T. This deduplication call — distinct from the Step-5 novelty judge — performs two jobs at once: (i) it clusters semantically equivalent new labels — including instance-of-the-same-category collapses (e.g. "India's World Cup wins" and "Australia's World Cup wins" both fold under "Cricket World Cup winning countries") — and picks the most category-level label as canonical; (ii) for each cluster, it marks `overlaps_existing = true` together with the `existing_topic_id` when the cluster duplicates a topic already in T. Clusters with `overlaps_existing` attach their evidence to the existing topic and are *not* counted as new gaps; the remaining clusters are added to T and to G with the merged evidence set.

D Deployment Recipe

For teams operating a RAG system on a proprietary corpus, Re:CAP plugs into the existing pipeline as an out-of-band auditor: (1) on a representative query sample, run Re:CAP against the current production retriever to establish a baseline (gap inventory, gap rate, N_q envelope, per-corpus cost); (2) before promoting an index, embedder, or ranker change, re-run on the same sample and compare; (3) a drop of ≥ 5 pp in mean recall exceeds $10\times$ the 0.47% run-to-run noise floor of §4.5 and lies in the discriminative range exercised by the BM25 sensitivity ladder of §4.3, so it can be read as a real degradation rather than noise; we also watch unreachable-gold share but report no threshold for it, having measured no run-to-run floor for that quantity; (4) feed the per-query gap inventory into operations dashboards so on-call engineers see *specifically which topics* were missed rather than only an end-to-end faithfulness score.

Why hybrid retrieval. Re:CAP's tighter, entity-anchored probes can under-explore when paired with a single-channel retriever; the dense channel in hybrid supplies the breadth that BM25 alone cannot. Hybrid is therefore the recommended default. The choice of initial retriever is not a free parameter — on HotPotQA with *dense* D_0, Re:CAP regresses by 3.6 pp matched-N_q because the gap-Q generator inherits dense-side biases and wastes early iterations on semantically related but non-gold documents that BM25 would have surfaced via bridge-entity lexical match (see Limitations, *Initial-retriever choice can cause cell-level regressions*). The initial retriever should be selected via standard recall-at-k diagnostics, with Re:CAP then layered on top.

Attributing a metric move: retrieval drift vs. judge or reader drift. Because Re:CAP has no per-query gold in production, a rise in its monitoring signals is only actionable if a retrieval-side cause can be separated from drift in the LLM components themselves. Two properties make that separation possible. First, the components are pinned: the novelty judge runs at temperature 0 and the gap-Q generator at 0.3 (Table 9), which removes deliberate sampling variance once the model version is held fixed. Pinning does not make the components deterministic — re-running the judge on identical prompts reproduces its own novel/not verdict on 94.0% of candidates (App. I). The operative threshold is therefore the magnitude of a move relative to that noise, not its presence. Second, that residual non-determinism is bounded and measured end-to-end — across three independent runs

(§4.5, Table 5) Re:CAP recall has CV 0.47% and gap rate CV 1.46%, i.e. per-verdict disagreement largely averages out at the level of the reported metrics. Under a fixed pipeline, a move exceeding those bounds cannot be produced by LLM nondeterminism alone and is therefore attributable to a change on the retrieval side — an index refresh, an embedder swap, or a corpus shift.

Two caveats govern how the thresholds should be set. Gap count $|G|$ responds to retriever quality in the expected direction (§4.3) but is the noisiest of the three signals, at CV 5.04%; on the MuSiQue ladder the BM25–hybrid separation is only $1.5\times$ that run-to-run standard deviation, so $|G|$ resolves large regressions and not the adjacent-configuration differences that ladder spans. Gap rate is far more stable (1.46%) but saturates on high-hop workloads, where it is best read as a coverage-floor breach. In practice, alert on gap rate for gradual movement, use $|G|$ for magnitude once a breach fires, and treat any $|G|$ move under roughly $2\times$ its noise floor as unresolved rather than as evidence of stability. Separately, none of these bounds survive a *model version* change: upgrading the judge or generator re-baselines every signal, so the pre-change sample must be re-run to re-establish the envelope before the new version is trusted. This is the same re-baselining discipline step (2) above prescribes for retriever changes.

Cost-sensitive deployments. At \$0.59–\$2.05/q, auditing a thousand queries weekly costs roughly \$600–\$2,100 per week at default settings. Tighter monitoring budgets can swap all pipeline components to GPT-4.1-mini for a $4.6\times$ cost reduction at -0.51 pp paired recall on HotPotQA — at the edge of the ± 0.42 pp run-to-run noise floor of §4.5 (full ablation: App. M, E3.5).

E Production Deployment Case Studies

This appendix gives the full case-study description for the live production audit summarised in §4.5. We report two unrelated production deployments — "AI Search" (the original case study) and "NEWS QA" (a second cohort added to test transfer across deployments with very different D_0 widths). Both use the paper's default configuration unchanged. Table 10 summarises the two cohorts side by side; the rest of this appendix details AI Search first and then the NEWS QA deltas.

	AI Search	NEWS QA
Queries (success / total)	200/200	200/200
D_0 width (mean / median / max)	10 (fixed)	47.2 / 33 / 110
Topics/q: mean / median	25.1 / 20	31.2 / 34
MAX_TOPICS=50 saturated	16/200 (8.0%)	81/200 (40.5%)
Gap rate: mean / median / @1.0	0.991 / 1.00 / 94.5%	0.955 / 1.00 / 83.5%
Topic source share: Step 1 / 2 / 5	21.9 / 0.6 / 77.4%	17.3 / 4.4 / 78.2%
Natural convergence	59/200 (29.5%)	55/200 (27.5%)
Mean iterations (median)	2.55 (3)	2.13 (2)
Per-q cost: median / mean	\$1.68 / \$2.73	\$1.79 / \$2.03
Per-q LLM calls: mean / max	410 / 1,703	333 / 1,114
Judge share of calls	98.0%	97.6%

Table 10: Two production cohorts, same default Re:CAP configuration. Gap rate and judge dominance reproduce across both deployments; NEWS QA's $\sim 5\times$ wider D_0 shifts more coverage to doc-reconciliation (Step 2) and pushes more queries to the topic cap, but the iterative loop (Step 5) still contributes $\sim 78\%$ of topics on both.

Deployment. "AI Search" is an enterprise research assistant deployed over a proprietary, frequently re-indexed knowledge corpus ($\approx$123M passages) that mixes news feeds, internal research, and regulatory filings — exactly the non-stationary-with-multiple-sources-of-truth setting motivating the paper. Live queries span short factoid lookups (e.g. entity name disambiguation), multi-document analyst briefs (e.g. "what's the Street saying about *X*?"), and multi-paragraph country / sector intelligence summaries (the long-form tail of the distribution). Per-query gold qrels do not exist in this setting (corpus churn precludes exhaustive offline labelling), which is why Re:CAP was developed in the first place; consequently, we report the audit's intrinsic signals — gap rate, topic-source provenance, convergence, cost — rather than recall against gold.

Configuration. The audit uses the paper's recommended default (Table 8) without modification: hybrid retrieval combining OpenSearch BM25 and an OpenAI `text-embedding-3-large` 1024-d dense index; GPT-5.2 reader; GPT-4.1 for the topic extractor, doc-topic reconciler, gap-Q generator (at $T = 0.3$), and novelty judge (at $T = 0$); $\mathrm{MAX_ITER} = 3$; 5 gap-Qs per iteration; expansion top-$m = 50$ per gap-Q; $\mathrm{MAX_TOPICS} = 50$.

Sample. 200 representative production queries drawn from the live query log without filtering on query type, length, or expected complexity. We deliberately included multi-paragraph briefing queries that drive the cost long-tail rather than excluding them as outliers.

Stability. All queries executed without any noticeable LLM failures. The only implementation issue encountered were OpenSearch concurrency related. Mean iteration count is 2.55 (median 3,

$\sigma 0.71$, range 1–3); $59/200 = 29.5\%$ of queries converge naturally before the iteration cap, with mean convergence iteration 2.20 implying that audits for internal data might benefit from an increased MAX_ITERS cap.

Coverage signal. Mean total topics per query is 25.1 (median 20, $\sigma 16.1$, $\min 4$, $\max 50$); 16 queries saturate the $\text{MAX_TOPICS} = 50$ cap (long-form briefs). The per-query gap rate (fraction of topics surfaced beyond what the initial answer + reconciliation already cover; equivalently, $|G|/|T_{\text{final}}|$) has mean 0.991; $189/200 = 94.5\%$ of queries have gap rate $= 1.0$, and the lowest single-query gap rate is 0.60 (a short factoid query with substantial topic overlap between the initial retrieval and gap expansion). In aggregate, Re:CAP surfaces at least one previously-unretrieved topic on effectively every production query sampled.

Where topics come from. Table 11 breaks down the 5,017 total topics across 200 queries by their source step in the loop. 77.4% of the per-query coverage map is contributed by Step 5 (the gap judge's NEWTOPIC verdicts on documents fetched in gap iterations), with the remaining 21.9% coming from Step 1 (the topic extractor on the initial answer) and 0.6% from Step 2 (doc-topic reconciliation on the initial retrieval). The doc-reconciliation share is much lower than on the benchmark runs – production reader answers are comprehensive enough that the reconciliation step rarely surfaces topics the answer omitted, leaving virtually all coverage discovery to the iterative loop.

Source step	Topics (200 q)	Share
Step 1 — Topic extractor on A_0	1,101	21.9%
Step 2 — Doc-topic reconciliation	32	0.6%
Step 5 — Gap judge (NEWTOPIC)	3,884	77.4%
Total	**5,017**	**100.0%**

Table 11: Topic provenance on the 200-query production audit. Step 5's 77.4% share is the iterative loop's added value: more than three-quarters of the per-query coverage map is surfaced only because Re:CAP probes beyond the initial answer.

LLM usage and cost. Mean LLM calls per query is 410 (median 294, $\max 1{,}703$); the judge accounts for 98.0% of calls (80,422 of 82,036 across the audit), matching the judge-dominance pattern of Table 4. Mean input tokens per query is 1.18 M (median 699 k); mean output tokens 28.4 k (median 19.8 k). Per-query cost from the LLM-trace rollup (over the 190 queries with complete telemetry; 10 queries lost their `llm_trace` payload during the resume that closed the deterministic-failure tail) has median \$1.68, mean \$2.73 ($Q_1 = \$0.56$, $Q_3 = \$3.96$, $\max = \$24.86$). The median sits within the benchmark envelope of §4.5 (\$0.59–\$2.05/q); the mean sits $\sim$33% above the upper bound, driven by the long-form multi-paragraph briefing queries in the long tail (the single \$24.86 query issued 1,643 LLM calls across 3 iterations to map a 19-topic intelligence brief).

NEWS QA cohort: deltas from AI Search. "NEWS QA" is a second enterprise deployment over a multi-vendor news QA corpus ($\approx$70M passages, 256-d `text-embedding-3-large` dense index). We re-used the production pipeline's own retrieved set as D_0 (mean 47.2 docs/q, median 33, $\max 110$, vs $\approx$10 for AI Search) and its A_0 as the reader output, so the audit reflects exactly what the deployed system surfaced. All other defaults match Table 8. Gap rate has mean 0.955, 167/200 (83.5%) at rate $= 1.0$, 197/200 (98.5%) with at least one gap. The $\sim 5\times$ wider D_0 shifts the topic-source mix in two ways: doc-topic reconciliation (Step 2) climbs from 0.6% to 4.4% of topics, and the MAX_TOPICS=50 cap is saturated on 81/200 (40.5%) of queries (vs 8.0% on AI Search), so reported gap counts on NEWS QA are right-censored more often. Mean iteration count is 2.13 and natural convergence is 27.5%, both within a percentage point of AI Search. Per-query cost from the LLM-trace rollup has median \$1.79, mean \$2.03 ($Q_1 = \$0.51$, $Q_3 = \$3.16$, $\max = \$6.87$). The judge dominates calls at 97.6% (vs 98.0% on AI Search), matching the benchmark cost pattern.

Worked example (i) — AI Search (`idr news`). **Query.** *"idr news"*. D_0**.** 10 documents from the deployed hybrid retriever (JPM Global Markets research; April 2026 slice). A_0 **topics.** Bank Indonesia monetary policy and hawkish stance on IDR; FX pressures and market dynamics; analyst forecasts for 2026; macro/fiscal headwinds; SRBI liquidity tightening. **Iter-1 gap-Qs (sample).** *What recent developments have occurred regarding SRBI and its role in stabilizing the IDR?*; *What analyst forecasts contradict the prevailing outlook for the IDR exchange rate in* 2026*?* **New topics added.** Iter-1; 4 SUBTOPIC and 1 NEWTOPIC after dedup. SRBI-driven liquidity tightening on deposit and credit growth; IDR depreciation on property developers' costs and debt exposure; Middle-East de-escalation on Indo CDS and IDR outlook; MSCI market-classification reforms on Indonesian equities; equity-market sentiment under

macro risk. **Iter-2.** 5 further probes, no novel verdicts; the loop converges. **Interpretation.** The deployed reader returned a coherent top-line briefing; the loop doubled topic coverage by surfacing five distinct second-order dimensions the initial answer left implicit, without leaving the production retriever's reachable candidate pool.

Worked example (ii) — NEWS QA (Tyler Technologies). Query. *"Why has Tyler Technologies' stock price been declining and what are the issues affecting its performance?"* D_0**.** 7 documents from production (Reuters and Benzinga, February 2026). A_0 **topics.** Government budget cuts on revenue; Q4 earnings and revenue miss; slower cloud migration and extended procurement cycles; analyst downgrades and reduced price targets; financial metrics indicating weak capital efficiency. **Iter-1 gap-Qs (sample).** *What evidence exists that contradicts the claim that Tyler Technologies has missed analyst expectations or delivered disappointing financial results?*; *Why has Tyler Technologies' stock price been declining, regardless of specific economic conditions or government budget changes?* **New topics added.** Iter-1, all NEWTOPIC after dedup. Share-repurchase plan as a capital-allocation response to perceived undervaluation; acquisition of *For The Record* expanding the court-technology portfolio; tail risks from cyberattacks, AI vulnerabilities, and regulatory changes. **Iter-2.** Two additional candidates clear the judge but fold into existing topics in post-iteration dedup; the loop converges with $\text{new_topics_found} = 0$. **Interpretation.** The deployed pipeline correctly identified the headline drivers of decline; the loop additionally surfaced the company's response (buybacks, M&A) and an unstated risk register, both directly relevant to the *why is the stock declining* query and neither present in A_0.

Scope of these case studies. These audits confirm that Re:CAP runs end-to-end on two unrelated live production deployments with no production-specific code path, that the gap discovery rate observed on benchmarks transfers to live traffic, and that the iterative loop — not the initial answer — contributes the bulk of the per-query coverage map across both cohorts despite a $\sim 5\times$ difference in D_0 width. They do not provide calibrated recall numbers (no production gold labels) or variance estimates (single run per cohort). Those roles remain with the four benchmark datasets reported in §§4.1–4.5. Judge accuracy on production traffic is bounded directly by the human read of App. F, and indirectly by the 1.4% judge-rejection rate of App. O. That human read samples only documents the judge called gap-filling, so it bounds the judge's precision on this traffic and not the gaps it missed.

F Human Evaluation on the Production Cohorts

§5 evaluates recovered documents on public benchmarks, where relevance labels exist. This appendix repeats the exercise on the two production cohorts of App. E, where no relevance labels exist and the corpora are proprietary.

Setup. We sampled 180 documents that Re:CAP's novelty judge marked as gap-filling, drawn from 180 distinct queries and split evenly between the two cohorts. Three annotators saw the query, the deployed reader's D_0-only baseline answer, and the document text, blinded to the judge's verdict and to the cohort. The rubric is the binary *new_info* / *covered* decision of §5.

Result. 75.6% of judge-identified gap documents on AI Search and 72.2% on NEWS QA add information the baseline answer lacks (73.9% overall, $[67.0–79.8]$; Table 12).

Cohort	n	new	Rate % [95% CI]	κ
AI Search	90	68	75.6 [65.8–83.3]	0.84
NEWS QA	90	65	72.2 [62.2–80.4]	0.88
Overall	**180**	**133**	73.9 [67.0–79.8]	0.86

Table 12: Human-evaluation verdicts on judge-identified gap documents from the two production cohorts. *new* is the majority-vote *new_info* count; 95% CIs are Wilson.

G Full Cross-Dataset Results (Including TREC-COVID Matrix)

Table 13 repeats the cross-dataset comparison of §4.1 and includes the full 4-cell retriever$\times$generator matrix on TREC-COVID, which we elided from the main body for compactness. The TREC-COVID matrix illustrates the structural-complementarity finding of §4.1: no combination of retriever (BM25 / dense / hybrid) and generator ($(Q{+}T)$-only / five-mechanism) closes the small negative recall delta against flat BM25 top-500, yet every cell maintains a $\geq 45\%$ vs-BM25-500 unreachable-gold share. The default Re:CAP cell goes further: 21.2% of its recovered gold remains absent even from the *ensemble* of flat BM25, dense, and hybrid top-500 combined (Table 17). The negative recall delta is a regime-level metric mismatch on pooled-graded corpora (see

Limitations, *Recall@k undercounts complementarity on pooled-graded corpora*), not a cell-specific failure; the audit-relevant signal is the complementarity. Appendix H sweeps flat BM25 depth K on HotPotQA and TREC-COVID and locates the depth at which flat retrieval catches up.

H Recall vs. Retrieval Depth

Table 3 sweeps retrieval depth on MuSiQue and MS MARCO TREC-DL. This appendix completes that sweep on the two remaining benchmarks, HotPotQA and TREC-COVID, over the full range of K for which we hold per-query judgements (Figure 2, Table 14). The curves are recomputed from the per-query records of the same runs that back Table 2 rather than transcribed from it, so the two cannot drift apart; the recomputation reproduces every published flat-BM25 confidence interval exactly. Deltas are paired per query and then bootstrapped (1000 resamples, seed 42), the same estimator used throughout the paper.

Two observations. First, Re:CAP's advantage is monotone decreasing in K: it is largest where retrieval is shallow (+29.1 pp on HotPotQA and +20.6 pp on TREC-COVID at K=10) and shrinks as the flat baseline is permitted to see more of the corpus. This is the expected shape — Re:CAP spends its budget on *which* regions of the corpus to probe, an advantage that necessarily erodes once a flat run is allowed to read the corpus exhaustively.

Second, the depth at which the flat baseline catches up separates the two corpora, and the separation is the scope boundary reported in §4.1. On HotPotQA, Re:CAP at 249 documents per query still leads flat BM25 at K=200 by 6.1 pp and is statistically indistinguishable from K=500 while reading half as many documents. On TREC-COVID, Re:CAP at 378 documents matches flat K=500 within noise and is then overtaken at K=1000, by 10.6 pp at 2.6× its document budget.

The crossover is reported in full because on a pooled-graded corpus Recall@k rewards depth mechanically, since deeper pools intersect more of the judged set (see Limitations, *Recall@k undercounts complementarity on pooled-graded corpora*). The audit signal Re:CAP is built to produce — gold that no flat run surfaces at any depth we can afford in production — is unchanged by it: 21.2% of Re:CAP's recovered gold on TREC-COVID is absent from the *union* of flat BM25, dense, and hybrid top-500 (Table 17). Aggregate recall at K=1000 is therefore not the quantity the TREC-COVID result rests on.

I Cross-model re-judgement

The gap judge and the answer generator share a model family, so the judge's accept/reject decisions are re-run against a newer generation to test whether they are family-specific. We draw a stratified sample of $n = 1000$ judged candidates from the runs whose judge calls are stored verbatim: every NEW_TOPIC and SUB_TOPIC candidate in the pool, with IRRELEVANT and REDUNDANT subsampled to fill the remainder. We replay *the judge prompt* against gpt-5.4-mini-2026-03-17 and gpt-5.5-2026-04-24. Each model judges every candidate three times and votes; agreement is between a challenger's majority verdict and gpt-4.1-2025-04-14's own majority verdict on the same prompts, so all three panels are measured the same way.

Models are run at temperature 0 where the deployment permits it. gpt-5.5-2026-04-24 serves only the API default of 1, so that model is run at that setting; the resulting sampling variance is quantified by the self-agreement column. Reasoning is disabled on every deployment that supports it, matching the configuration of the deployed gpt-4.1 judge, so that model generation rather than deliberation budget is the variable under test.

The judge prompt was written for the deployed model and may therefore disadvantage a newer one. To test this, the relevance step was rewritten to admit intermediate ("bridge") evidence, which multi-hop queries require and which the newer models were disproportionately rejecting; both challenger models were then re-run unchanged in every other respect. Agreement moved by +1.0 and +5.0 points and the multi-hop rejection rate was unchanged, indicating that the disagreement reported here is not an artefact of prompt wording.

Our production infrastructure is Azure-OpenAI-only, so a truly cross-family (Anthropic / Google) audit is feasible on benchmark artefacts but not on production cohorts. The sample above is therefore drawn entirely from benchmark artefacts.

J Pseudo-Relevance Feedback Baseline (RM3)

We compare Re:CAP against RM3 pseudo-relevance feedback (Lavrenko and Croft, 2001; Abdul-Jaleel et al., 2004) as the closest classical query-expansion control. RM3 uses canonical de-

Dataset	Method	Docs seen	Recall [95% CI]	Δ vs. RR	Notes
MuSiQue	Flat BM25 matched-N_q	238	0.610 [0.558, 0.664]	−0.291	matched-budget ref.
	Flat MiniLM hybrid top-500	500	0.772 [0.723, 0.818]	−0.129	RR wins at 48% budget
	Flat OpenAI dense top-500	500	0.854 [0.815, 0.896]	−0.047	strongest dense baseline
	Re:CAP (hybrid)	**238**	**0.901 [0.854, 0.938]**	—	29.4% unreach. vs. BM25-500
	Re:CAP (dense)	**191**	**0.898 [0.862, 0.932]**	−0.003	largest abs. lift vs. BM25 (+30.2 pp)
HotPotQA	Flat BM25 matched-N_q	249	0.827 [0.775, 0.878]	−0.061	
	Flat MiniLM hybrid top-500	500	0.864 [0.813, 0.909]	−0.024	only flat cell beating BM25-matched
	Flat MiniLM dense top-500	500	0.773 [0.717, 0.828]	−0.115	supports +11.5 pp claim (§4.1)
	Re:CAP (hybrid)	**249**	**0.888 [0.837, 0.939]**	—	9.2% unreach. vs. BM25-500
MultiHop-RAG	Flat BM25 matched-N_q	90	0.948 [0.913, 0.980]	−0.030	ceiling test
	Flat BM25 top-500	500	1.000 [1.000, 1.000]	+0.022	corpus saturates
	Re:CAP (hybrid)	**90**	**0.978 [0.955, 0.996]**	—	ceiling reached at 5.5× fewer documents
TREC-COVID†	Flat BM25 matched-N_q	493	0.233 [0.201, 0.267]	+0.068	
	Flat BM25 top-500	500	0.241 [0.211, 0.271]	+0.076	
	Re:CAP (BM25, $(Q{+}T)$ gen.)	493	0.165 [0.138, 0.194]	—	52% unreach. vs. BM25-500
	Re:CAP (BM25)	383	0.209 [0.190, 0.230]	+0.044	45% unreach.
	Re:CAP (dense)	298	0.178 [0.153, 0.208]	+0.013	61% unreach.
	Re:CAP (hybrid)	**378**	**0.221 [0.195, 0.248]**	**best cell**	−0.020 vs. BM25-500; 48% unreach.

Table 13: Full cross-dataset matrix including the 4-cell TREC-COVID retriever×generator sweep. Default = hybrid retriever with the five-mechanism generator (bold rows); the $(Q{+}T)$ row marks the $(Q{+}T)$-only generator ablation. †Every TREC-COVID cell maintains ≥ 45% vs-BM25-500 unreachable-gold share; the default cell adds 21.2% ensemble-unreachable on 98% of queries (Table 17). The small negative recall delta is a metric mismatch on pooled-graded corpora, not a cell-specific failure (see Limitations).

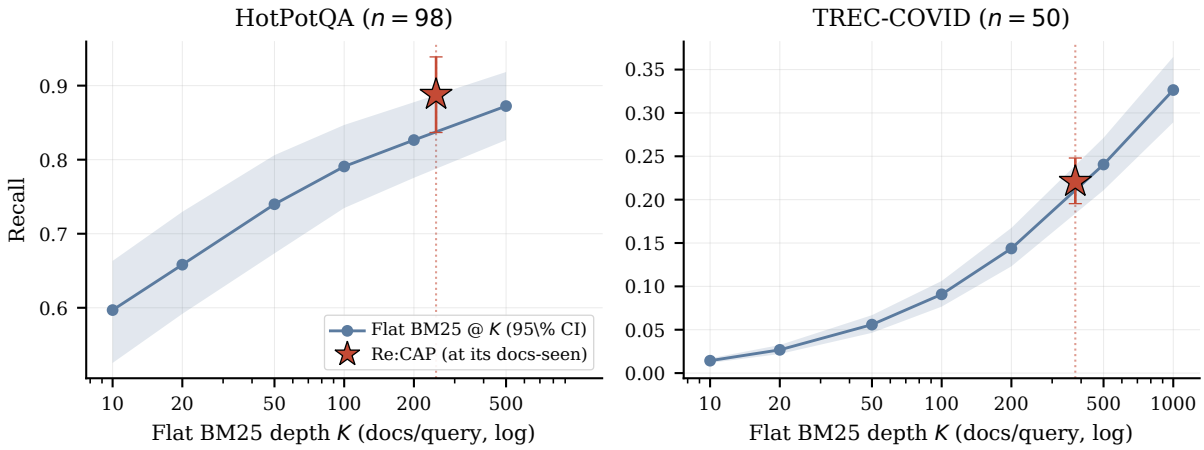

Figure 2: Recall vs. flat BM25 retrieval depth K, HotPotQA and TREC-COVID. Blue: flat BM25 recall at depth K, shaded band is the 95% bootstrap CI. Red star: Re:CAP at its own mean docs-seen budget (dotted guide), with 95% CI. The y-axes are independent — the two corpora sit in very different recall regimes — while the x-axes are shared; HotPotQA's sweep stops at K=500. Re:CAP leads by a wide margin at shallow K on both corpora and is caught between K=500 and K=1000, earlier on TREC-COVID, the scope-boundary case of §4.1. Paired per-query deltas with CIs in Table 14.

faults (no per-dataset tuning): $k_{\text{fb}} = 10$ feedback documents, $n_{\text{exp}} = 20$ expansion terms, $\lambda_{\text{orig}} = 0.5$, min_df $= 5$, maximum document-frequency ratio 0.5; stopwords, numerics, and original-query terms are excluded from the expansion candidates.

On the bounded-evidence primary where flat retrieval leaves the most room (MuSiQue), Re:CAP beats RM3 by +19.4 to +19.7 pp at top-500 and by +26.5 to +27.4 pp at matched-N_q. On HotPotQA-hybrid Re:CAP matches PRF top-500 (both 0.888) using 249 documents rather than 500, and recovers 7.5% of gold absent from PRF top-500; on MuSiQue this unreachable share rises to 28–30%. The one Re:CAP regression cell (HotPot-dense) is the dataset×retriever combination already noted under Limitations. We do not report Bo1 (Amati, 2003) separately: on our datasets it tracks RM3 within ±1 pp and the conclusions are identical.

K Unreachable-Gold Diversification

Table 17 reports per-dataset shares of gold documents Re:CAP surfaces via gap probing that *individual* flat top-500 baselines (BM25, dense, hybrid) cannot reach, plus the strictest cell: the *ensemble*-unreachable share, i.e., gold absent from all three baselines combined (1,500 docs total). This operationalises the diversification claim (§4.1): Re:CAP retrieves a structurally distinct slice of the corpus that no single-retriever upgrade recovers. The ensemble shares are non-zero on every dataset shown,

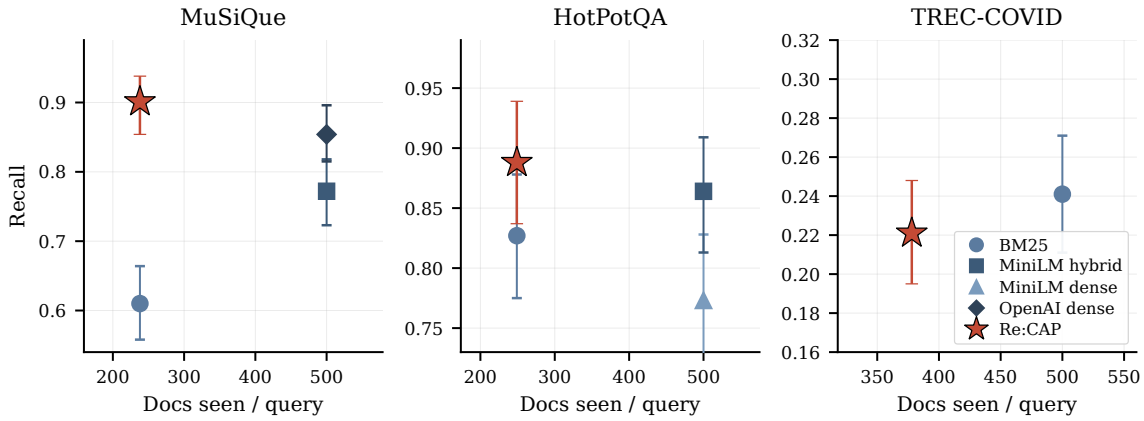

Figure 3: Recall vs. documents seen per query, three datasets. Flat baselines (blue circles) at their native top-N budgets; Re:CAP at the deployed default (red star). On MuSiQue and HotPotQA, Re:CAP attains the highest recall at less than half the document budget of the strongest flat baseline. TREC-COVID is the scope-boundary case: Re:CAP recall is within noise of flat BM25 top-500, but 21.2% of its recovered gold remains unreachable by the ensemble of flat BM25, dense, and hybrid top-500 combined, so the audit signal here is structural complementarity rather than aggregate recall. Error bars are 95% bootstrap CIs; MultiHop-RAG omitted (corpus saturates at flat top-500). Numbers in Table 2.

Data	K	Flat BM25 [95% CI]	Δ pp [95% CI]
HotPotQA	10	0.597 [0.526, 0.663]	+29.1 [+22.4, +35.7]
	20	0.658 [0.592, 0.730]	+23.0 [+16.3, +29.6]
	50	0.740 [0.673, 0.806]	+14.8 [+8.7, +21.4]
	100	0.791 [0.735, 0.847]	+9.7 [+4.1, +15.8]
	200	0.827 [0.776, 0.878]	+6.1 [+0.5, +11.7]
	500	0.872 [0.827, 0.918]	+1.5 [−4.1, +7.7] *n.s.*
TREC-COVID	10	0.014 [0.012, 0.017]	+20.6 [+18.3, +23.2]
	20	0.027 [0.022, 0.032]	+19.4 [+17.2, +21.8]
	50	0.056 [0.046, 0.067]	+16.5 [+14.4, +18.7]
	100	0.091 [0.077, 0.106]	+13.0 [+11.0, +15.2]
	200	0.144 [0.123, 0.167]	+7.7 [+5.4, +10.1]
	500	0.241 [0.211, 0.271]	−2.0 [−5.0, +1.1] *n.s.*
	1000	0.326 [0.289, 0.365]	−10.6 [−14.2, −6.6]

Table 14: Flat BM25 recall at depth K, and the paired per-query delta Δ (Re:CAP − flat@K) in percentage points, for the curves of Figure 2. Re:CAP reads 249 documents per query on HotPotQA and 378 on TREC-COVID, so rows below those depths favour Re:CAP on budget as well as on recall. *n.s.* marks a delta whose CI contains zero.

peaking at 21.2% on pooled-graded TREC-COVID where the gold pool is largest and most diverse.

L Controlled Gold Deletion (E2.2)

Protocol. For each MuSiQue query in the M_0 slice ($n = 100$, hybrid retriever, $N_q = 5$, MAX_ITER = 3), we remove $K \in \{1, 2, \text{all}\}$ *gold* passages from D_0 (drop-all removes every gold doc that naturally surfaced in the top-10) and ask whether Re:CAP re-discovers them through gap probing. Nine queries have no gold passage in their top-10 D_0 and are excluded from the drop test, leaving $n = 91$ per drop cell. The reference is the no-drop run restricted to the same 91 queries, at recall 0.919 (0.901 over the full 100; the excluded nine are precisely the queries whose gold never surfaced).

Result. For drop-1, drop-2, and drop-all, Re:CAP recovers 98.9%, 98.4%, and 100.0% of the deleted gold IDs respectively, with 97.8–100% of queries achieving full recovery in each cell. Paired recall on drop-1, drop-2, and drop-all drops by 11.9, 13.5, and 10.9 pp respectively (vs. refer-

Judge	Self-agreement	vs. gpt-4.1	95% CI
gpt-4.1 *(reference)*	94.0%	—	—
gpt-5.4-mini	89.5%	77.4%	[74, 83]
gpt-5.5	95.7%	84.4%	[81, 89]

Table 15: Novel vs. not-novel agreement ($\kappa = 0.410$ (gpt-5.4-mini), $\kappa = 0.543$ (gpt-5.5)). A candidate is *novel* if the judge assigns NEW_TOPIC or SUB_TOPIC; the topic registry counts both identically when forming $|G|$, so this is the only verdict distinction any reported quantity depends on. On the full four-way taxonomy, which organises the topic tree rather than producing a number, agreement is 54.1% (gpt-5.4-mini), 59.9% (gpt-5.5). *Self-agreement* is the mean pairwise agreement between replicate runs of the same model on the same prompts, and bounds the second column: gpt-4.1 reproduces its own verdicts on 94.0% of candidates, so agreement above that level is not attainable. gpt-5.5 is the most self-consistent model measured, exceeding the deployed judge. Candidates span 166 distinct queries; intervals are bootstrapped over queries rather than candidates, since candidates from one query share a topic registry and a baseline answer.

Dataset	D_0	Re:CAP	PRF N_q	PRF 500	Δ vs PRF 500
MuSiQue	hybrid	**0.901**	0.636	0.704	+0.197
MuSiQue	dense	**0.898**	0.624	0.704	+0.194
HotPot	hybrid	**0.888**	0.832	0.888	0.000
HotPot	dense	0.786	0.827	0.888	−0.102†
MHopRAG	hybrid	0.978	0.953	1.000	−0.022⋆
MHopRAG	dense	0.974	0.895	1.000	−0.026⋆

Table 16: Re:CAP vs. RM3 (PRF) across the six main cells ($n = 98$–100 per row). PRF N_q matches Re:CAP's unique-candidate budget; PRF 500 is the unbounded baseline. Across all six cells, RM3 lifts top-500 recall by at most 1.6 pp over flat BM25 top-500. †The HotPot-dense regression is the cell flagged under Limitations (*Initial-retriever choice can cause cell-level regressions*): dense D_0 misses the bridge-entity lexical signal that RM3 inherits from its BM25 backbone. ⋆MultiHop-RAG saturates at PRF top-500 on its 3.8k-doc corpus; Re:CAP wins at matched-N_q by +2.5 to +7.9 pp.

Dataset	RR gold	Unreach. share vs. flat top-500 BM25	dense	hyb.	**ens.**	Qs ≥ 1 (ens.)
MuSiQue	231	29.4%	14.8%	22.6%	**10.0%**	21%
HotPotQA	174	9.2%	13.7%	3.7%	**2.5%**	4%
TREC-COVID	4 871	48.0%	48.0%	30.0%	**21.2%**	98%

Table 17: Per-baseline and ensemble unreachable shares: Re:CAP-recovered gold absent from the indicated flat top-500 baseline, or from the *ensemble* of all three baselines combined (1,500 docs total). All Re:CAP runs use the deployed default (hybrid D_0, five-mechanism generator). Dense-D_0 Re:CAP gives shares within ±2 pp of the hybrid rows (not tabulated). *RR gold* = total Re:CAP-recovered (q, doc) pairs summed across queries. *Qs* ≥ 1 *(ens.)* = share of queries with at least one ensemble-unreachable doc. MultiHop-RAG is omitted: flat BM25 top-500 reaches recall 1.000 on that corpus (App. G), so no gold is unreachable and the shares are undefined.

ence 0.919). The recall loss is *not* attributable to failed recovery (98–100% recovery shown above); it is the *secondary* gold that no longer surfaces. In the no-drop run, iterative expansion picks up ∼10 pp of gold beyond $D_0 \cap$ qrels by triangulating from the answer; when D_0 is poorer, the seed answer is impoverished and downstream gap-Qs find fewer new probe directions. The 11–13 pp paired loss is therefore a lower bound on the value of a non-empty D_0, not a failure of probe-driven recovery.

The three cells are near-replicates. MuSiQue rarely places more than one gold passage in D_0: of the 91 queries, 62 have exactly one, 26 have two and 3 have three. All three cells therefore delete identical documents on 62/91 queries, and drop-2 and drop-all coincide on 88/91. The spread across the three cells (2.6 pp) is also smaller than run-to-run non-determinism: on the 88 queries where drop-2 and drop-all delete the same documents, mean recall still differs by 2.7 pp between the two runs. E2.2 should therefore be read as one recovery result replicated three times, not as a severity ordering; the ordering of the cells is not resolvable here.

Drop	n	recovery (%)	recall	Δ pp	$\lvert G\rvert$
None (ref)	91	—	0.919	—	3.6
$K = 1$	91	98.9	0.800	+11.9	4.9
$K = 2$	91	98.4	0.785	+13.5	5.1
$K =$ all	91	100.0	0.810	+10.9	5.4

Table 18: Controlled deletion (E2.2). "recovery" is per-query mean (recovered ∩ dropped)/(dropped). Δ pp = paired (ref − cell) × 100. Gap count $\lvert G\rvert$ rises monotonically with K (3.6 → 5.4, +51%). All columns are over the 91 queries that had gold to delete.

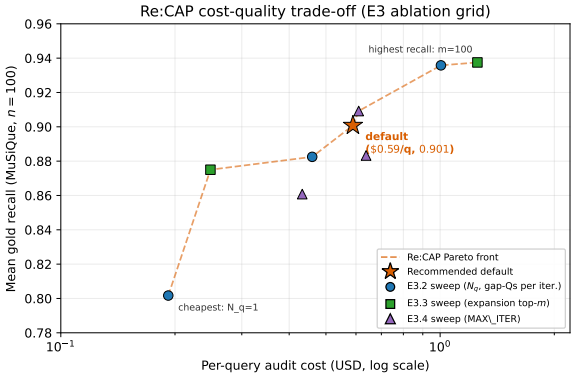

Figure 4: Re:CAP cost-quality trade-off on MuSiQue (n = 100, hybrid retrieval + redesigned generator). Star = recommended default ($0.59/q, recall 0.901); dashed line = Re:CAP Pareto front across the $E3$ ablation grid; markers indicate which hyper-parameter sweep each point comes from (E3.2 N_q, E3.3 expansion top-m, E3.4 MAX_ITER).

M Ablations

We ablate Re:CAP along four dimensions: **(i)** gap-Q generator design — the $(Q{+}T)$-only ablation vs. the five-mechanism deployed default (§M.1); **(ii)** per-lever leave-one-out within the five-mechanism generator, attributing its lift to each of its five mechanisms (§M.2); **(iii)** the three primary loop hyper-parameters — gap-Qs per iteration N_q, expansion depth m, and iteration cap (§M.3); **(iv)** the pipeline-LLM swap and a generator-vs-judge cost decomposition (§M.4). Table 21 summarises the sweeps; Figure 4 places each cell on the MuSiQue cost-quality Pareto front.
