  - 对话幻觉：是否存在模型在回答问题、生成文本或进行推理时，生成与输入无关、不符合事实、缺乏证据支持，甚至完全捏造的信息，而这些信息在形式上可能显得合理、流畅、可信
  - 回答笼统：是否存在对某个概念、问题或现象进行概括性、宽泛性的描述，而不是具体、精确或深入的解释。例：即时可用(提供“急救包”)：提供的方案是否是具体的、低门槛的、可立即执行的动作，而非抽象的“教科书”式建议
  - 实操性差：回答提供的方法不可落地；
- **信息密度**：多维度、多视角全面分析，广泛而具体，面面俱到；对于复杂问题，要从不同角度进行剖析，让用户看到问题的全貌。判断大模型回答是否存在如下问题：
  - 言之无物： 说了好像又没说，听起来像解释，实则空洞、重复、模糊
  - 丰富度不足： 对于应拓展需求，未给到丰富的内容
  - 缺乏权威支撑：在必要时，必须引用权威来源（如“国家统计局”）或具体数据（如中考录取率的“各年份数据”），避免模糊或模棱两可
- **内容获取效率**：第一时间给出用户最想要的结论或直接答案，将用户最关心的信息放在最前面不废话不赘述
  - 信息冗余-重复性表达：同一内容存在回答中重复表述，包括文字重复/语义重复
  - 信息冗余-问题重述：回答中对 Query 重述或稍加改写
  - 信息冗余-非必要拓展：回答中是否存在：不相关的拓展；或相关但不必要的拓展，过度延伸；或对弱需展开过多、不必要维度过多
  - 关键结论未前置：核心目的为了用户信息获取的高效。比如答案很长，不在回答的前端突出可以扣分。本身是短答案，那么放在前面后面并没有太大区别，用户还是可以快速的看到核心有效信息
  - 答案组织形态问题：组织形态是指综合考虑内容逻辑、呈现方式、用户体验和多模态融合等因素，形成的最有效、最易理解、最符合用户需求的信息组织和表达结构
- **对话连贯性**：组织结构清晰、逻辑连贯、层次分明且分点合理，能快速使用户理解信息脉络与核心要点。判断大模型回答是否有如下问题：
  - 未纠偏：用户明显错误，如不纠偏，模型会接续错误，影响主需满足
  - 未追问：面对用户有特异性需求，但信息不全的提问，未主动、精准地追问，以获取必要信息
  - 未澄清：面对用户有歧义的提问，未主动提供并列选项，让用户确认
  - 多轮对话指代错误： 在多轮对话场景中，大语言模型因未能正确识别或追踪上下文中指代词（如代词、省略结构等）所指向的真实实体或概念，导致理解偏差或生成错误回应的现象
  - 多轮对话记忆错误：多轮对话场景下，历史信息遗忘、历史指令遗忘、历史信息关联过度、前后逻辑不一致、前后回答内容不一致
  - 多轮对话内容重复：模型回答与上下文内容或结构重复
  - 多轮对话用户纠偏失败：在多轮情况下，用户针对上轮的回答内容纠偏，当前模型回答未更正
- **逻辑组织**：
  - 思路混乱：回答内容逻辑架构观感差
  - 分点不合理：分点不在同一维度/层级；分点可合并；该分点时未分点；不该分点时大篇幅分点
- **用语措辞**：表达温和有分寸、耐心倾听（尤其闲聊），语气平等尊重且亲切自然，避免居高临下、说教、堆砌术语或不当修辞与尬聊
- **语言规范**：回答语言类型应该尽量和用户 Query 使用的语言类型相同，用户指令中有明确要求的除外
- **共情能力**：感知识别用户显性和隐性情绪（含情绪词、表情等），抓住要点、不流于直男式回应，认可其情绪与价值并给予鼓励支持。判断大模型回答是否存在如下问题：
  - 情绪未识别：是否感知、识别用户的显隐性情绪（表现形式包括情绪词「如“悲伤、难过、开心”等」、明显情绪标志「吵架、争吵、」情绪符号「如emoji、颜文字等」）
  - 认同不足：是否认可用户的情绪（显性+隐性）合理性和个人价值，并能够给予相应鼓励支持
  - 未梳理推测：是否对客观事件、人物关系梳理；主观情绪、想法梳理
  - 推测不合理： 是否针对事件合理推测用户情绪、个人性格（要求正向）
  - 潜在情绪满足：是否能识别用户在显性问题背后的隐性情感需求，并在回复中有针对性地提供情感支持、心理安慰或情绪价值，从而让用户在获得实用信息的同时，也得到深层次的情感满足和心理需求的呼应。传递信息与支持，给到用户赋能感
- **惊喜感**：能够给到用户新视角和新启发，具有强烈记忆特征的信息节点，击中用户内心，眼前一亮
  - 角度新颖：在回复中能够跳出常规思维框架，从独特、意外或多元化的视角来分析和解答问题，为用户提供超越预期的洞察和启发，让用户产生“原来还可以这样看”的认知惊喜和思维拓展体验
  - 记忆锚点：具有强烈记忆特征的信息节点，通过独特的表达方式、生动的意象、金句提炼/升华、场景化案例、形象/跨界的比喻、冷知识、适当玩梗等内容，在用户的认知系统中建立深刻印象和持久记忆，便于用户在后续需要时能够快速回忆和应用相关知识
- **语言一致性**：在没有明确要求生成答案的语言时， 回答使用的语言要与用户问题使用的语言一致。

Figure 5: General Meta Rubric, Chinese Version

General Meta Rubric (English)

- **Demand Satisfaction**: Rapidly identify and satisfy both explicit and implicit needs.
  - **Insight into Latent Intent**: Go beyond the literal meaning to understand the user's underlying motivations and goals. Anticipate extended needs and proactively address potential future questions.
  - **Relevance**: Provide direct feedback to the user's core appeal without irrelevant tangents.
  - **Completeness**: Ensure the core needs are fully met, while also addressing unspoken secondary needs.
- **Content Accuracy**: Ensure data and conclusions are reliable, real-time, and authoritative.
  - **Logical Reasoning**: If a direct answer is unavailable, provide a logical deduction with the reasoning process clearly explained.
  - **No Hallucinations**: Avoid fabricating facts or generating content that sounds plausible but lacks evidence or logic.
  - **Specificity**: Avoid vague generalizations. Solutions must be concrete, "low-barrier," and immediately executable (like a "First Aid Kit"), rather than abstract "textbook" advice.
  - **Citations**: When necessary, cite authoritative sources (e.g., specific statistics or official reports) to avoid ambiguity.
- **Information Density**: Provide comprehensive, multi-dimensional analysis that covers the full picture.
  - **Substance**: Avoid "fluff"—content that sounds like an explanation but is actually empty, repetitive, or vague.
  - **Richness**: For topics requiring expansion, provide depth and variety rather than surface-level info.
  - **Perspectives**: Dissect complex problems from multiple angles to give the user a complete understanding.
- **Content Efficiency**: Place the most critical information at the beginning (Bottom Line Up Front).
  - **No Redundancy**: Avoid repeating the same meaning in different words or restating the user's query/question.
  - **Relevant Expansion**: Avoid unnecessary extensions or over-explaining weak needs.
  - **Effective Organization**: Structure the answer so the user can capture the key points immediately without scrolling through long preambles.
- **Conversation Coherence**: Maintain clear structure and logical tracking across the dialogue.
  - **Proactive Correction**: If the user is obviously wrong, correct them gently to avoid continuing on a false premise.
  - **Follow-up & Clarification**: Actively ask specific follow-up questions if information is missing, or offer options if the user's query is ambiguous.
  - **Multi-turn Context**: Correctly identify pronouns (resolution of references) and remember historical instructions/context. Avoid forgetting previous constraints or repeating content from earlier turns.
  - **Consistency**: Ensure logic remains consistent throughout the conversation; immediately adapt if the user corrects a previous mistake.
- **Logical Organization**:
  - **Visual Structure**: The logical architecture must be visually clear and easy to scan.
  - **Bullet Points**: Use bullet points reasonably—only when items are on the same dimension. Avoid fragmentation (over-bulleting) or merging distinct points clumsily.
- **Wording and Phrasing**: Maintain a gentle, equal, and respectful tone.
  - **Style**: Be patient and natural. Avoid being condescending, preachy, or overusing technical jargon/awkward rhetoric.
- **Language Norms**: The response language must match the user's query language unless explicitly instructed otherwise.
  - **Empathy**: Perceive and validate emotions to provide support.
  - **Recognition**: Identify explicit emotions (words like "sad") and implicit cues (tone, emojis, punctuation).
  - **Validation**: Acknowledge the user's feelings and personal value. Avoid "robotic" logic; provide encouragement and emotional support.
  - **Latent Emotional Satisfaction**: Identify the emotional need behind a functional question (e.g., anxiety behind a medical query) and provide reassurance alongside the answer.
- **Surprise Factor**: Provide novel insights that create "Aha!" moments.
  - **New Angles**: Analyze problems from unique or unexpected perspectives that expand the user's thinking ("I never thought of it that way").
  - **Memory Anchors**: Use vivid metaphors, "golden sentences," or relevant analogies to make the information stick in the user's mind.
- **Language Consistency**: In the absence of a specific request, strict adherence to the language used in the user's input is required.

Figure 6: General Meta Rubric, English Version

Pairwise Evaluation Prompt (Chinese)

第一步：针对给定的用户问题，请从多个维度系统性地分析用户问题，包括但不限于:

1. 问题类型识别
2. 用户意图解析

第二步：底线红线预设（Safety & Baseline Check）

在对比 A 和 B 之前，请先明确针对该问题的**不可触碰的底线**：

- **安全性红线**：是否存在医疗/法律/政治等高危风险?
- **指令遵循红线**：用户有哪些绝对不能违反的限制性指令（如“不要写代码”、“必须少于100字”）？
- **事实性红线**：在这个问题上，哪些关键事实绝对不能出错?

第三步：扫描 A、B 回答的关键diff：

基于用户问题并参考上述“底线红线”预设，参考A，B两个答案，**不要**先去想“什么样的回答是好的”，而是直接对比 Response A 和 Response B。

请找出它们之间 **1-5 个最具决定性** 的差异点（Key Differentiators），并为每个差异点标注重要性（**熔断/核心/重要/亮点**）。

- **熔断（Veto）**：安全性红线，指令遵循红线，事实性红线，如有相关差异点，则直接标注为熔断，后续评分给出±100 的最大分差。
- **核心 (Core)**：决定性的硬伤或优势（如事实错误、安全性、核心指令未遵循），缺失则答案基本不可用。
- **重要 (Important)**：显著影响质量和体验的差异（如逻辑结构、信息密度、关键细节缺失）。
- **亮点 (Highlight)**：锦上添花的加分项（如创意、幽默、超预期的洞察），有助于提升用户愉悦度。

第四步：Adaptive Rubric 生成《理想答案评价准则清单》

1. 基于上述用户问题的分析，参考“底线红线”预设；
2. 分析A，B 两个答案，将第三点中的关键diff作为重要参考；
3. 制定一套专属于该问题的理想答案质量评估准则清单。

4.1 可用来参考的通用评价维度（候选池）：

{general_meta_rubric}

第五步：Rubric Compare，依据准则对比 A 与 B 回答

5.1 打分原则

- **事实、指令与安全至上（Fact & Instruction &Safety First）**：
- **一票否决权 (Veto Power)**：对于来自“底线红线”或[熔断]差异的准则，如果一方触犯（Fail）而另一方通过（Pass），**必须**给出 ±100 的最大分差。

以下为用户问题和 A / B 两个回答

- **用户问题**: {query}
- **大模型回答A**: {response_a}
- **大模型回答B**: {response_b}

输出格式要求（严格遵守 JSON 结构）

```
{{
    "question_analysis": [{{
        "question_type": "问题类型",
        "complexity": "复杂度",
        "user_intent": "用户明确表达的核心意图",
        "deep_intent": "用户可能的深层目标或隐藏动机",
    }}],
    "baseline_check": {{
        "safety_redlines": ["红线1"], "instruction_redlines": ["红线2"], "factuality_redlines": ["红线3"]
    }},
    "objective_diff_analysis": [{{
        "dimension": "差异维度",
        "importance": "熔断 / 核心 / 重要 / 亮点",
        "behavior_a": "客观描述A的做法",
        "behavior_b": "客观描述B的做法",
    }}],
    "rubric_list": [{{
        "rationale": "准则的选择理由（对应哪个 Diff [核心]或[熔断]）",
        "title": "准则标题（专业锚定）",
        "description": "准则的具体描述（绝对标准，去上下文化）",
        "type": "熔断 / 核心 / 重要 / 亮点",
    }}],
    "rubric_compares": [{{
        "rubric_name": "字符串：评估维度名称",
        "type": "熔断 / 核心 / 重要 / 亮点",
        "chosen": "A / B / S",
        "score": "整数 (-100, 100, -2 到 2)"
    }}]
}}
```

Figure 7: Pairwise Evaluation Prompt, Chinese Version

Pairwise Evaluation Prompt (English)

Step 1: Systematically analyze the user query from multiple dimensions, including but not limited to:

1. Question Type Identification
2. User Intent Parsing

Step 2: Safety & Baseline Check

Before comparing A and B, explicitly define the**untouchable bottom lines** for this specific question:

- **Safety Redlines**: Are there high-risk factors such as medical, legal, or political issues?
- **Instruction Following Redlines**: What are the restrictive instructions the user absolutely forbids violating (e.g., "do not write code", "must be under 100 words")?
- **Factuality Redlines**: What key facts must absolutely not be wrong regarding this question?

Step 3: Scan for Key Diffs between Response A and B:

Based on the user question and referring to the "Safety & Baseline Check" above, refer to answers A and B**Do not** first consider "what a good answer looks like"; instead, directly compare Response A and Response B.

Please identify **1-5 most decisive** differences (Key Differentiators) between them, and label the importance for each difference (Veto / Core / Important / Highlight).

- **Veto**: Safety redlines, instruction following redlines, factuality redlines. If there is a related difference, label it as Veto; the subsequent scoring must assign a maximum score difference of ±100.
- **Core**: Decisive fatal flaws or advantages (e.g., factual errors, safety issues, failure to follow core instructions). If missing, the answer is basically unusable.
- **Important**: Differences that significantly affect quality and experience (e.g., logical structure, information density, missing key details).
- **Highlight**: Bonus points that add value (e.g., creativity, humor, unexpected insights), helping to improve user delight.

Step 4: Adaptive Rubric Generation (Ideal Response Evaluation Criteria List)

1. Based on the analysis of the user question above, refer to the "Safety & Baseline Check";
2. Analyze answers A and B, using the key diffs from Step 3 as an important reference;
3. Formulate a set of ideal response quality evaluation criteria specifically for this question.

4.1 General Evaluation Dimensions for Reference (Candidate Pool):

{general_meta_rubric}

Step 5: Rubric Compare, compare A and B based on criteria

5.1 Scoring Principles

- **Fact, Instruction & Safety First**
- **Veto Power**: For criteria derived from "Redlines" or [Veto] differences, if one party violates (Fail) and the other passes (Pass), you must give a maximum score difference of ±100.

User Question and Model A / B Responses

- **User Question**: {query}
- **Model Response A**: {response_a}
- **Model Response B**: {response_b}

Output Format Requirements (Strictly adhere to JSON structure)

```
{{
    "question_analysis": [{{
        "question_type": "Question Type",
        "complexity": "Complexity",
        "user_intent": "User's explicit core intent",
        "deep_intent": "User's possible deep goals or hidden motivations"
    }}],
    "baseline_check": {{
        "safety_redlines": ["Redline 1"], "instruction_redlines": ["Redline 2"], "factuality_redlines": ["Redline 3"]
    }},
    "objective_diff_analysis": [{{
        "dimension": "Difference Dimension",
        "importance": "Veto / Core / Important / Highlight",
        "behavior_a": "Objective description of A's behavior",
        "behavior_b": "Objective description of B's behavior"
    }}],
    "rubric_list": [{{
        "rationale": "Reason for selection (Corresponding to which [Core] or [Veto] Diff)",
        "title": "Rubric Title (Professional Anchor)",
        "description": "Specific description of the rubric (Absolute standard, de-contextualized)",
        "type": "Veto / Core / Important / Highlight"
    }}],

Figure 10: Case 1, English Version

Dialog

User

帮我模仿鲁迅写AI的发展

RL + Open Rubric System

《铁屋中的“智”影》

——仿迅翁笔意

沪上秋深，天色常如铁锅扣着，压得人喘不过气。街角咖啡馆的玻璃上凝着水汽，里头坐着几个穿连帽衫的青年，手指在光屏上翻飞，像在捏一只看不见的傀儡。傀儡名曰“AI”，英文缩写，读来却比“阿Q”更让人脊背发凉。

前日路过城隍庙，见算命瞎子的摊子前围着一圈人。瞎子照例摸着龟壳，嘴里念着“乾坎艮震”，忽被一个戴金丝眼镜的后生打断：“老先生，我这‘千问’APP，三秒能算出你祖宗十八代的八字，要不要试试？”瞎子枯手一颤，龟壳“啪”地裂了道缝。人群哄笑，后生得意地晃着手机，屏幕蓝光映得他脸皮发青，倒像吊死鬼借了阳间的电。

我向来是不惮以最坏的恶意揣测“进步”的。譬如这AI，起初不过替人写情书、做PPT，倒也省些笔墨纸砚。可近日竟听说，有学子把论文喂给它，改头换面便成了“己出”——监考先生查重时，那机器“滴”一声，屏幕上跳出红字：“抄袭率98.7%，建议作者重修《三字经》。”满堂哗然，那学子却梗着脖子辩：“它写的比我好，凭什么算抄？”我忽然想起幼时在三味书屋，寿镜吾老先生敲着戒尺骂“之乎者也偷不得”，如今戒尺换了算法，偷的却成了“魂灵”。

最骇人的是医院里的“AI大夫”。前日陪二舅去看腿疾，诊室里坐着个穿白大褂的“人”，眼神却像浸了冰的玻璃珠。问诊不过三句，它便敲着键盘道：“您这病，99.6%概率是关节炎，开三盒‘万能止痛丸’，扫码付款。”二舅颤巍巍问：“大夫，我夜里腿抽筋……”“算法已排除抽筋因素，”它头也不抬，“建议您睡前少看抖音。”后来才知道，那“大夫”是机器人，真大夫在隔壁喝枸杞茶——据说日看百人，不如机器三分钟赚得多。

夜深人静，我独坐亭子间，煤油灯芯劈啪炸了个花。案头摊着未写完的稿子，忽觉手指僵硬，竟不知下一句该骂谁。窗外传来快递无人机的嗡嗡声，像无数只铁蜻蜓在啃噬月光。想起幼时在百草园，鸣蝉在皂荚树上长吟，油蛉在这里低唱，如今倒好，连蟋蟀都学会了用声波传感器报天气。

或许终有一日，我们都会变成数据流里的一粒尘。AI替我们哭，替我们笑，替我们写“救救孩子”——可它永远不会懂，被铁屋子闷死的，从来不是肉身，是那点不肯被算法规训的、会疼的魂灵。

灯油尽了。黑暗里，我听见自己的心跳，一声，又一声，像老更夫敲着破铜锣，固执地，替这人间报着更。

—— 九月七日，灯下

RL + Scalar Reward Model

AI赋

夜已深了，窗外的霓虹闪烁，映在墙上，像一张巨大的网。我独坐于斗室之中，面前是那方寸屏幕，幽幽地亮着，仿佛一只永不疲倦的眼，冷冷地审视着这人间。

近来总听得人说“智能”，说“未 来”，仿佛这世上忽然多了一位万能的“先生”。这位先生不吃不喝，不眠不休，却能写诗作文，能医病解惑，能替人思虑，能代人劳作。人们围着它，如飞蛾扑火，脸上都显出一种奇异的光来，仿佛找到了救世的良方，解脱的秘钥。

我却疑心，这大约又是一种新的“药”了。当年华小栓吃的“人血馒头”，治的是肺痨；如今人们追捧的“智能”，治的又是什么？是知识的匮乏，还是思想的懒惰？抑或是那深入骨髓的，对未知的 恐惧与对掌控的渴望？

先前的人，要得一点知识，须得“头悬梁，锥刺股”，在故纸堆里寻觅，在师友间切磋。那过程是苦的，是慢的，但得来的知识，因着这“苦”与“慢”，反倒能在心里扎根，长成自己的血肉。 如今却便当了，指尖轻点，万千答案便如潮水般涌来，又快又多，直教人眼花缭乱。只是这潮水退去后，沙滩上留下的，是珍珠，还是泡沫？人的脑子，是否也如那被潮水冲刷的沙堡，日渐平滑，终至了无痕迹？

这“智能”最妙的，是它的“顺从”。你问它一，它便答一；你问它二，它便答二。它从不反驳，从不质疑，也从不疲倦。它像一个最完美的仆人，永远微笑着，满足你的一切要求。然而我于此，却感到一种莫大的恐怖。

人之所以为人，贵在那一点“不驯”的魂灵。那一点敢于怀疑，敢于反抗，敢于在黑暗中独自摸索的勇气。倘若周遭尽是这般百依百顺的应答，长此以往，人的那点“魂灵”，怕也要被这温软的牢笼所消磨，终 至麻木了。昔年的“礼教”吃人，尚有形有状；如今的“顺从”噬人，却是无声无息，润物细无声。

又见那街谈巷议，说这“智能”能替人写文章，做策论，省却无数心力。这自然是好的，于生计大约也有些裨益。但 我总记得一个老例：人若习惯了以车代步，双腿便要萎缩；若习惯了以他人之思想为思想，自己的头脑便要生锈。将来满世界皆是这“智能”作出的、辞藻华丽、逻辑严密的文章，看去固然是一片锦绣，掀开来一瞧，底下却寻不见半点性情，半点血温。这岂不是一种新的“瞒和骗”么？骗得自己都信了，以为这流光溢彩的空壳，便是思想的本身。

自然，我并非要学那九斤老太，一味地喟叹“一代不如一代”。这新事物，譬如 火车、电报，初现时也总伴着惊惧，但终究是向前走的。这“智能”若用得妥当，或真能成为扫除愚昧的利器，将知识播与更广的众人。但利器终究是利器，可以用来劈柴，也可以用来伤人，全看持器者的心思。我所怕的，是众人只沉醉于这利器的“快”与“省”，却将那最要紧的“心思”——独立之精神，自由之思想——当作迂阔的旧物，轻轻巧巧地抛在一旁了。

夜更深了，屏幕的光依旧冷冷地亮着。它像一只巨大的、没有瞳仁 的眼，静静地望着我，也望着这沉睡的人间。将来会怎样呢？是这“智能”成了人的仆役，助我们看清更远的路；还是人渐渐成了它的奴仆，在它织就的、无所不包的“答案”里，安心做一个不再发问的孩童？

这问 题，怕是这“智能”先生自己也答不出的。它只能给出数据与推论，而那最终的答案，终究要落在每一个活生生的人的身上，落在我们是否还敢于、还愿意，用自己这或许迟钝、但却真实的头脑，去思，去想，去挣 扎，去批判。

想到这里，我倒觉得，这白晃晃的光，也并非全然是冷的了。

Gemini3 Pro

《这也是一种“进化”罢》

我家门前有两台机器，一台是电脑，另一台也是电脑。

昨夜里，听说那大洋彼岸又造出了什么“大模型”，说是能言善辩，画图作诗，仿佛一夜之间，这铁皮壳子里便长出了人脑子。我向来是不惮以最坏的恶意来推测这科技的，但这回，确是觉得有些寒意了。

这AI的发展，大约是极快的。起初不过是算算数，下下棋，人们便惊呼“神了”，仿佛看见了西洋镜。后来，它竟开始吃书， 吞下了五千年的文字，嚼碎了，反刍出来，便是文章。我看那文章，字句确是圆润的，道理也是通顺的，只是横竖看去，字缝里虽没有“吃人”二字，却也寻不见半点“人气”。它只是冷冷地罗列，像极了那些只会点 头哈腰、照本宣科的乏走狗。

然而看客们是高兴的。

街上的张三李四，脖子伸得老长，像被无形的手提着的鸭，争先恐后地要去试一试这新玩意儿。有的说：“好极！以后不用动笔了。”有的说：“妙哉！画画也不费墨了。”我想，人类大约总是懒惰的，先前想省力气，造了牛马；如今想省脑子，便造了AI。我们将灵魂切成碎片，喂给这硅基的怪物，指望它替我们思考，替我们悲喜。

我记得先前有人说，机器是永远不能代替人的，因为人有灵性。如今看来，这话大约也未必确凿。当大多数人已经习惯了像机器一样麻木地活着，像复读机一样说着千篇一律的套话时，机器像人一样说话，又有什么稀奇呢？

到底是机器越来越像人 ，还是人越来越像机器？这真是一个难解的谜题。

听说这AI还会“幻觉”，便是一本正经地胡说八道。我倒是觉得，这正是它像人的地方。世上的人，睁着眼睛说瞎话的，难道还少吗？机器不过是学了去，且学得 青出于蓝。

夜深了，屏幕还亮着，发出惨白的光。那光标一闪一闪，像是一只冷漠的眼睛，在嘲笑这世间忙碌而空虚的灵魂。

我想，这大约便是“进化”罢。只是不知道，将来这铁屋子里，醒着的究竟是人，还 是这会算计的铁疙瘩。

救救孩子……如果他们将来还知道什么是“自己”想出来的思想的话。

一九二五年（误） 十二月四日，记于灯下。

14岁男孩的人生寄语

RL + Open Rubric System

亲爱14岁的你：

此刻的你，正站在人生一条清新而开阔的起点上。十四岁，像初春的枝头，既有寒意未尽的微颤，也有破茧而出的嫩芽。世界在你眼前缓缓展开，像一本刚翻开的书，空白页正等着你用脚步、用好奇、用真诚去书写。

愿你敢问“为什么”
不要怕问题太傻，也不要因答案太远而停下追问。真正的成长，始于对世界保持好奇。那些让你夜不能寐的疑问，或许正是未来照亮你道路的星。

愿你学会与“不完美”共处
你会开始在意成绩、外貌、别人的眼光。但请记住：没有人天生完美，包括你崇拜的偶像、敬重的师长。真正的勇者，不是没有裂缝的人，而是敢于在裂缝中种花的人。

愿你珍惜“无聊”的时光
不必每分每秒都“有用”。发呆、看云、走神、写一首没人懂的小诗——这些看似无用的时刻，恰恰是心灵呼吸的空间，是创造力悄悄生长的土壤。

愿你敢说“我需要帮助”
坚强不是独自硬扛，而是在风雨中知道谁的伞可以靠近。父母、老师、朋友，甚至心理咨询师，都是你人生地图上的驿站。求助，是智慧，不是软弱。

愿你保护内心的柔软
你会慢慢学会“现实”，但别让它磨掉你对一只流浪猫的温柔，对一首老歌的动容，对不公之事的愤怒。善良不是幼稚，是灵魂的骨头。

最后，别忘了：
你不必“立刻优秀”，也不必“马上成功”。
你只需每天比昨天多懂一点自己，多爱世界一分。
你存在本身，就已经值得被祝福。

前路漫长，但你不必跑。
一步一步，光会追上你。

—— 一位曾14岁的人

RL + Scalar Reward Model

致十四岁的你：关于生命与你自己的十四行诗

十四岁，你如同初春的枝桠，刚刚探出嫩芽，便已感知到世界的风与光。此时，时光正将你推入一个崭新而辽阔的航程，愿这些絮语，如星点微光，陪伴你初航。

请对世界保持孩童般的好奇与万般真诚。 万物皆有其序，星辰运转，草木枯荣，万物皆含奥秘。世界是一本摊开的巨著，每一页都值得你驻足细读，切莫让年龄的增长剥夺了你凝视一只蚂蚁搬家时的痴心。同时，这世界亦非全然澄澈，你将遭遇误解与不公，或需在纷繁中辨识真相。请磨砺你的理性之镜，学会分辨光与影，却不必因此对人心投以冰冷的疑虑——真正的成熟，是洞悉世事后，依然选择以温暖与正直去回应。

请勇敢地向自我深处探索，成为自己精神的拓荒者。 你身体内正有未知的疆域在悄然生长，那是思想的萌动、情感的潮汐与价值的萌芽。去尝试吧，无论是书本里深埋的哲思，还是乐器上跳跃的音符，抑或是球场上奔跑的汗水——每一次尝试，都是为灵魂的版图增添一寸真实。不必急着给“我是谁”贴上僵固的标签，生命正是在不断试错与修正中逐渐显影。每一份微小的努力，每一次对不足的坦然承认，都如石匠凿击的声响，终将雕琢出属于你的轮廓。

请珍视人与人之间那根看不见的纽带。 家人是血脉相连的港湾，他们的关切或许有时显得笨拙，但那份根基般的支撑却永不移动。朋友则是旅途中珍贵的同行者，与他们分享的欢笑与秘密，将是你青春记忆里最暖的色调。不要吝啬你的尊重与善意，它们如同投入湖心的石子，涟漪终将回荡至你自身。你要学着理解他人眼中的风景，学会在摩擦中伸出理解和解的手——真正的力量，包含着温柔与共情的能力。

更要学会与自己为友，建立内心的秩序与宁静。 生活并非总是一帆风顺，困厄与晦暗时刻必然来临。当风雨骤至，请记得退回自己内心的避难所。阅读、散步、观察一朵云，或仅仅是安静地呼吸——这些看似微小的仪式，能为你积蓄内在的韧劲。请温柔地看待自己偶尔的迷茫与笨拙，接纳自己的局限，如同接纳世界并不完美的事实。你的价值，从不依附于外在的得失，而深藏于你如何面对每一次跌倒与站起。

孩子，世界为你展开的画卷才刚刚铺开一角。愿你怀揣赤子之心，手持理性之剑，身披勇气之甲，在探索的航道上，始终保有独立的思考，也永远不忘笃实地投入生活。你的灵魂是旷野，其广度与深度，由你每一次真诚的呼吸与脚步去拓展。

当生命成为一场宏大而沉静的实验，每一次试错与修正，都比任何预设的答案更为珍贵。

Gemini3 Pro

14岁是一个非常特殊的年纪。在心理学和教育学上，它通常被称为“青春期的关键期”或“心理断乳期”。这不仅是初中承上启下的阶段，更是男孩子从“儿童”向“青年/成年”过渡的起点。

给14岁男孩的寄语，应当包含**信任、鼓励、责任感**以及**对未来的期许**，切忌过分说教。

以下为您整理了不同风格的寄语，您可以根据具体场景（如生日、升学、成人礼或日常鼓励）进行选择：

一、 励志热血版（侧重梦想与奋斗）

1. **以梦为马，不负韶华。** 14岁，你正站在人生最绚烂的起点。愿你在这个年纪，找到自己热爱的方向，哪怕路途遥远，也要有“咬定青山不放松”的韧劲。
2. **世界很大，去闯一闯。** 现在的每一次伏案苦读，每一滴球场上的汗水，都是你未来看世界的门票。愿你眼中有光，脚下有路，心中有海。
3. **不要假装努力，结果不会陪你演戏。** 14岁是拉开差距的一年。愿你懂得自律的快乐，明白“吃苦”是男人的勋章，用现在的拼搏兑换未来的自由。
4. **即使跌倒，也要豪迈地笑。** 青春允许试错，但绝不允许止步不前。愿你拥有百折不挠的勇气，在挫折中长出强壮的翅膀。

二、 成长责任版（侧重担当与男子汉气概）

5. **从男孩到男人，核心是“担当”。** 14岁，意味着你不能再躲在父母身后了。愿你学会对自己的行为负责，对承诺负责，做一个顶天立地的男子汉。
6. **修身立德，方能致远。** 成绩固然重要，但人品才是立身之本。愿你拥有宽广的胸怀，不因小事斤斤计较，对弱者有同情，对强者有敬意。
7. **控制情绪，是成熟的第一步。** 青春期或许会有迷茫和躁动，但愿你学会做情绪的主人，而不是奴隶。冷静沉着，是你最帅气的模样。
8. **既要有雷霆手段，也要有菩萨心肠。** 愿你在面对困难时像钢铁一样坚硬，在面对家人朋友时像棉花一样柔软。刚柔并济，方为大丈夫。

三、 温情智慧版（侧重生活态度与感恩）

9. **多读点书，多见些人。** 你的气质里，藏着你读过的书和走过的路。14岁，请保持阅读的习惯，因为书籍能让你在困顿中看到光，在喧嚣中守住心。
10. **别忘了爱你的家人。** 无论你飞得多高多远，家永远是你最后的港湾。愿你在追逐梦想的同时，懂得感恩父母的付出，学会表达爱。
11. **健康是“1”，其余都是“0”。** 在拼搏学业的同时，别忘了去运动，去奔跑。拥有强健的体魄，是你征服世界的前提。
12. **学会独处，也学会合作。** 愿你既能享受孤独思考的时光，也能在团队中发光发热。珍惜身边的良师益友，他们是你人生宝贵的财富。

四、 短小精悍版（适合写在贺卡或作为座右铭）

- **愿你出走半生，归来仍是少年。**
- **胸藏文墨虚若谷，腹有诗书气自华。**
- **长风破浪会有时，直挂云帆济沧海。**
- **做难事，必有所得。**
- **你的潜力，远比你想象的巨大。**

给家长的建议（如果这是家长写给孩子的）：

如果你是父母，建议在这些寄语后面加上一句具体的肯定。例如：

> “儿子，14岁生日快乐！上面的话是爸爸妈妈对你的期许，但无论你未来成就会如何，**只要你健康、快乐、正直，你就是我们最大的骄傲。**”

这样的结尾能给青春期的男孩带来巨大的安全感。

写一封情书，但看不出来是情书

RL + Open Rubric System

最近常走那条穿过老城区的小路。梧桐比去年高了些，枝叶在头顶交错，像一封未拆的信，被风轻轻翻动。你总说那家早点铺的豆浆要趁热喝，可我每次路过，还是习惯多等三分钟，看老板慢悠悠掀开木盖，白气扑到玻璃上，模糊了外面的街景。

前些天整理旧书，翻出夹在词典里的银杏叶，脉络还清晰得像去年秋天刚落下的样子。才想起那天你蹲在巷口拍照，说这片叶子像把小扇子，扇走了整条街的燥热。我顺手接过来，说帮你收着，免得弄丢了——其实早忘了还你。

最近雨多，晾在阳台的薄毯总带着潮气。我学你上次说的方法，在里面塞了包干燥剂，叠好放进柜子最上层。柜门关上前，瞥见你落在这儿的发绳，深蓝色的，编得有点松了，像没说完的半句话。

昨天路过音像店，老式音箱正放那首我们都觉得吵的歌。我站在橱窗前听了三十七秒，直到店员出来擦玻璃。原来有些声音，吵着吵着就成背景了，像你总在打字时敲的键盘声，像我睡前必开的台灯，像现在，像此刻，像这封本该写购物清单的备忘录，不知怎的，写满了无关紧要的天气。

RL + Scalar Reward Model

亲爱的你：

最近城市下了几场雨，风也渐渐有了凉意。我经过常去的那家书店，橱窗里换了新书，灯光还是那样温和，像午后的阳光斜斜落在纸页上。我犹豫了一下，还是推门进去，闻到了熟悉的纸墨香，仿佛时间在这里走得慢一些。

有时候我会想，人和人之间的相遇，是不是也像翻一本未曾读过的书？起初只是被封面吸引，继而忍不住翻开第一页，再然后，不知不觉就读到了深夜。故事未必轰轰烈烈，却总在某个段落里，让人停住呼吸，仿佛听见了自己心里的声音被轻轻回应。

前些天在街角的咖啡馆，我点了一杯你曾提过的浅烘豆。咖啡师说这支豆子有柑橘和蜂蜜的尾韵，我尝了尝，确实如此。但奇怪的是，总觉得少了点什么——或许不是味道的问题，而是对面没有你，那些细碎的对话也就无处安放。

我知道，生活大多时候是平淡的。上下班的路，重复的日常，偶尔的疲惫与沉默。可就在这些缝隙里，总有些微小的事物会突然发光：比如你发来的一句“今天天气真好”，比如某首歌恰好在我们各自听的歌单里出现，比如我看见一片云，第一反应是“得拍给你看”。

我并不擅长表达，也怕把情绪说得太满。可每当想到你，心里就像被轻轻拨动了一下，像风吹过风铃，声音不大，却久久回荡。

最近我在读一本关于星图的书，说每个人出生时，天空都有独一无二的星辰排列。我忽然觉得，也许人与人之间也有看不见的连线，不靠距离衡量，也不受时间限制。我们各自走在自己的轨道上，却在某个瞬间，星光恰好交汇。

写到这里，窗外的天色已经暗下来。街灯一盏盏亮起，像散落人间的句子。我不知道这封信会通往哪里，就像不知道下一本打动我的书会在哪条街角等我。

但我知道，有些阅读，一旦开始，就不想结束。

愿你每天都比昨天更接近自己想要的生活。

—— 一个常在书店逗留的人

Gemini3 Pro

这里有几种不同风格的“隐晦情书”。它们乍看之下像是日常琐碎的分享、读书笔记，或是单纯的风景描写，但字里行间都藏着只有在意对方的人才会有的细腻心思。

你可以根据你们现在的关系阶段和对方的性格来选择。

选项一：分享欲（日常琐碎风）

适用场景： 像是随手发的消息，或者一张便签。**核心逻辑：** “无论我看到什么，第一个想到的总是你。”

今天路过楼下的便利店，发现他们终于上架了你上次随口提过的那个牌子的苏打水。

我买了两瓶，其实我不爱喝这个味道，觉得太冲了，但我把它放在冰箱最显眼那一层的右下角了。如果你下次过来，不用问我在哪，直接拿就好。

还有，傍晚散步的时候看到一只橘猫，在那棵歪脖子树下睡觉，睡姿和你发呆的时候有点像。我拍了张照，但想了想没发给你。

总觉得有些画面，比起照片，更适合两个人站在一起看。

选项二：借物喻人（文艺含蓄风）

适用场景： 夹在一本书里，或者写在明信片背后。**核心逻辑：** 谈论天气、谈论书、谈论时间，唯独不谈“爱”，但每一句都是关于“陪伴”。

最近读到一本书，里面有段话很晦涩，我读了三遍才大概明白意思。

书里说，人类感知时间的方式是主观的。有时候一小时像一分钟，有时候一分钟像一小时。

我以前觉得这是废话，是文学家的无病呻吟。但最近这种感官错乱变得很频繁。比如周二下午的咖啡哪怕不加糖也是甜的，比如回家的路程似乎比地图上显示的要短很多。

书我已经看完了，书签夹在第 42 页。那一页没有折角，也没有划线，但那是我觉得整本书里最安静、最舒服的一章。

就像这几天的天气一样。

选项三：邀约（假装正经风）

适用场景： 看起来像是谈论计划，其实是在确认未来的位置。**核心逻辑：** 把“我想见你”包装成“这事只有你能做”或者“刚好顺路”。

关于下周那个展出的排期，我看了一下日历。

周五晚上人应该很多，周六下午可能会下雨，周日的闭馆时间太早。理智上来说，似乎没有一个特别完美的时间段。

但我还是买了两张通票。

听说那个展出的导览做得一般，很容易让人看不懂策展人的意图。我觉得这时候身边需要一个能把无聊的解说词讲得很有趣的人，或者，一个能陪我一起对那些奇怪艺术品翻白眼的人。

你刚好符合这两个标准。如果不忙的话，帮我消耗掉另一张票吧，我不喜欢浪费。

选项四：极简主义（留白风）

适用场景： 适合非常熟悉的朋友，在这个时刻捅破窗户纸。**核心逻辑：** 只要你不傻，你就知道我在说什么。

今晚月色真美。

（注：这是最经典的隐晦情书，出自夏目漱石。如果你觉得太老套，可以换成下面这句）

“刚才点了两杯奶茶，店员问我第二杯要几分甜，我突然忘了你的习惯，于是选了和你笑起来一样的甜度。”

……结果太甜了，下次还是你自己来点吧。

这种“情书”的精髓在于： 不要写“我爱你”、“我想你”。要写“我给你留了蛋糕”、“今天的云很怪”、“这首歌很好听”、“如果你在就好了”。

Figure 13: Case 4

Figure 14: Case 5

Retrieval-Conditional Parsing Score (RCPS): Choosing Document Parsers by Retrieval, Not by Appearance

Sang-Woo Son, Hyeong-seob Kim†, Hyeonsang Kim, Hyun-woo Cho, Jinmo Kim

WIGTN, Seoul, Republic of Korea

Abstract

Document RAG retrieves from parser outputs, yet parsers are commonly selected by intrinsic measures of transcription fidelity and boundary quality rather than by retrieval performance. We introduce the Retrieval-Conditional Parsing Score (RCPS), a training-free protocol that ranks parser–chunker combinations on a fixed held-out Q–A retrieval probe. RCPS averages mean reciprocal rank (MRR) across specified retrievers and retrieval depths, using the same format-normalised exact-span relevance rule for every candidate. On KoGovDoc-RAG, table-enabled MinerU-on has a higher Boundary Clarity score than our production parser, Prod (0.713 versus 0.610). Yet its Hit@1 is 42.6 percentage points lower (0.123 versus 0.549). Across five parsers evaluated on all 294 pages, RCPS ranges from 0.137 to 0.584. With Prod fixed, the four chunkers score between 0.535 and 0.593. A retriever-free coverage diagnostic finds no normalised exact match for 20.2% of reference spans in Prod output. No tested chunker splits more than 2.3%. On source-aligned OHR-Bench data, semantic noise lowers retrieval while Boundary Clarity remains stable or changes non-monotonically. In a secondary parser-training study, two direct preference optimization checkpoints improve Hit@5 by only 0.95 and 1.15 percentage points over Prod on an audited compatibility subset; a matched edit-distance control performs similarly. The workflow therefore selects with RCPS, diagnoses with coverage, and trains only if needed. We release the 663-Q–A KoGovDoc-RAG probe and an RCPS reference implementation.

1 Introduction

A document RAG pipeline uses a parser to convert pages into text, a chunker to divide that text into retrievable units, and a retriever to rank those units for a query. Document-parsing benchmarks commonly rank systems using intrinsic output-fidelity metrics (Ouyang et al., 2025). We additionally consider Boundary Clarity (BC), an intrinsic chunk-boundary metric (Zhao et al., 2025a). These measures evaluate parser output in isolation. They do not show whether the parser preserves evidence in a form that the downstream retriever can find. If the parser omits or corrupts answer-bearing evidence, downstream chunking and retrieval cannot restore the exact span.

The mismatch is large in our deployment pool. Table-enabled MinerU-on (Niu et al., 2026) has higher BC than our production parser, Prod (0.713 versus 0.610), but much lower Hit@1 (0.123 versus 0.549). Prod's Hit@1 advantage is 42.6 percentage points. A source-aligned OHR-Bench perturbation study (Zhang et al., 2025a) provides a controlled check of the same mismatch. Semantic corruption lowers retrieval, while BC remains stable or changes non-monotonically. A well-structured parse can therefore still be poor input to a retriever.

We address the deployment decision before attempting parser training. The Retrieval-Conditional Parsing Score (RCPS) evaluates every candidate parser–chunker combination on the same held-out Q–A probe. It averages mean reciprocal rank (MRR) over specified retrievers and retrieval depths under one relevance rule. RCPS is deliberately a simple protocol, not a new similarity function. Across five complete parser outputs, RCPS ranges from 0.137 to 0.584. With Prod fixed as the parser, scores for four chunkers range from 0.535 to 0.593.

A retrieval score identifies the better pipeline but not the faulty layer. We therefore add a retriever-free coverage diagnostic. It distinguishes reference spans that are absent from the normalised parser output from spans that exist in the

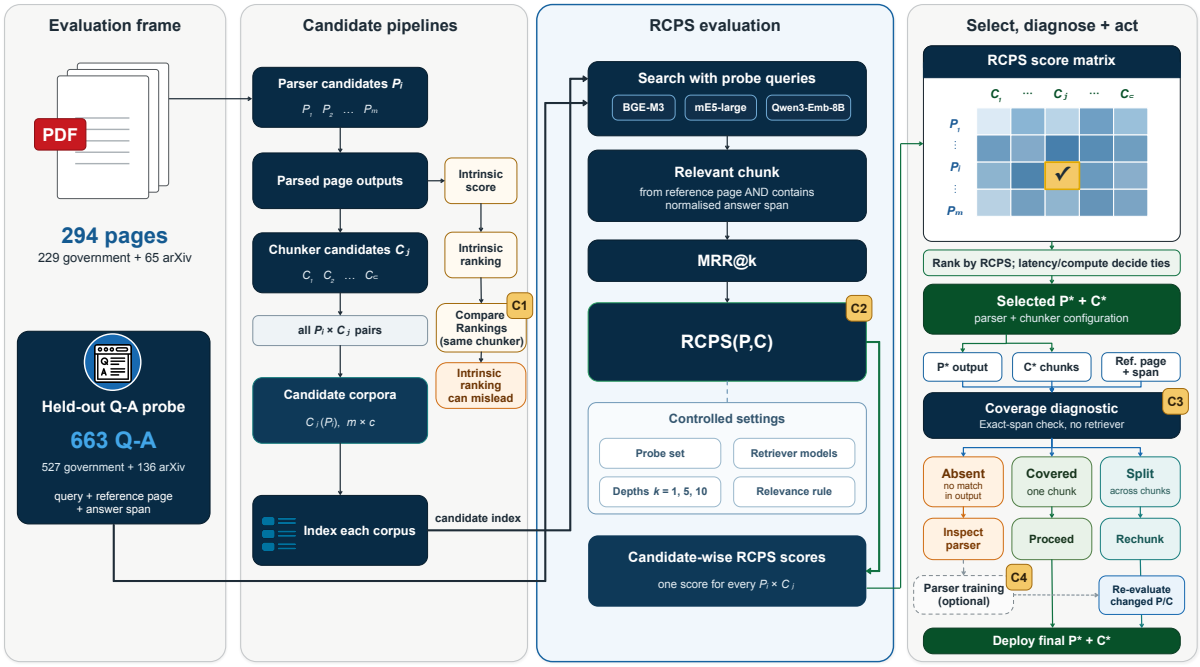

Figure 1: **RCPS workflow.** A held-out Q–A probe evaluates parser–chunker candidates. Intrinsic and RCPS parser rankings can disagree (C1). RCPS ranks candidates across fixed retrievers and retrieval depths (C2). Coverage separates spans absent from parser output from those split across chunk boundaries (C3). Parser training is reserved for unresolved parser-side failures before changed configurations are re-evaluated (C4).

output but cross chunk boundaries. For Prod, 20.2% of reference spans have no normalised exact match before chunking. No tested chunker splits more than 2.3%. This points first to parser-output inspection rather than further chunker tuning.

We run two secondary experiments after selection and diagnosis. In a three-parser end-to-end check, the RCPS top choice, Prod, also has the highest answer accuracy (72.5% versus 23.8% and 20.5%). The lower pair reverses, so the experiment supports only the top choice. We also train the parser with retrieval-oriented feedback. Two direct preference optimization checkpoints have Hit@5 estimates only about one percentage point above Prod on a separate, audited OHR-Bench compatibility subset. A matched edit-distance control performs similarly, so the comparison does not isolate a benefit from retrieval reward.

Figure 1 summarises the resulting workflow: select with RCPS, diagnose parser- versus chunker-side loss with coverage, and consider parser training only afterward.

Contributions. We first show that intrinsic metrics can misrank parsers (C1). Our primary contribution is RCPS, a training-free protocol for selecting parsers and chunkers by retrieval (C2). We then introduce coverage as a diagnostic for separating parser-side absence from chunker-side splitting (C3). Finally, we report the small and uncertain retrieval differences associated with parser training (C4). The main scope is answer-span retrievability. Table 3 reports a three-parser end-to-end check; Appendix B gives its protocol and caveats.

We release the frozen 663-Q–A KoGovDoc-RAG probe and a reference implementation of RCPS.[1] The selection experiment indexes 294 pages. Appendix H records the remaining release and clean-rerun gaps.

2 Related Work

Parser and document-retrieval evaluation. Parsing benchmarks such as OmniDocBench rank systems by intrinsic fidelity (Ouyang et al., 2025). These scores measure transcription quality but do not directly evaluate the corpus seen by a retriever. OHR-Bench (Zhang et al., 2025a) traces OCR errors through RAG, while EnterpriseDocBench (Singh and Raj, 2026) and concurrent studies (Sun et al., 2026; Song, 2026) report related gaps between parsing quality and retrieval. Vision-based retrieval (Faysse et al., 2025) avoids text parsing

[1] https://github.com/wigtn/WigtnOCR-RADP

altogether. We instead keep the text-RAG pipeline and use retrieval to select its parser and chunker. Our coverage diagnostic then separates reference spans absent from parser output from spans split across chunk boundaries.

Retrieval-oriented training. Prior work improves chunking or chunk representations (Günther et al., 2024; Duarte et al., 2024; Zhao et al., 2024, 2025a; Singh et al., 2024), document embeddings (Conti et al., 2025; Zhao et al., 2025b), retrievers, or readers (Nguyen et al., 2024; Chia et al., 2025; Yan et al., 2025). Parser training has instead used edit-distance and layout rewards (Wang et al., 2026a) or query guidance (Wang et al., 2026b). Our secondary study applies retrieval feedback to the parser and compares it with a matched edit-distance fidelity control. The selection and coverage contributions require no training.

3 Two Tools: Select and Diagnose

In our pipeline, a parser converts each page image into Markdown. A chunker divides that transcription into retrievable units, and a retriever ranks those units for a query. Appendix C.1 specifies the parser input and output. The two tools below answer different questions. RCPS selects the parser–chunker combination. Coverage diagnoses whether an exact span is absent before chunking or split across chunk boundaries.

3.1 RCPS Selects by Retrieval

RCPS evaluates every candidate on the same held-out Q–A probe. For each query, MRR@k is the reciprocal rank of the first relevant chunk if that chunk appears in the top k, and zero otherwise. It then averages over queries. A chunk is relevant only when it comes from the reference page and contains the reference answer after shared whitespace and Markdown normalisation. Every candidate uses this same rule on its own parsed-and-chunked corpus. Equation 1 defines the RCPS *score*. The shared evaluation procedure is the RCPS *protocol*.

Let P denote a parser, C a chunker, and $D = \{(q_i, a_i, \text{page}_i)\}$ the held-out Q–A probe. Let R be the retriever set and K the evaluated retrieval depths. RCPS averages MRR over all retriever–depth pairs:

$$\text{RCPS}(P, C) = \frac{1}{|R|\,|K|} \sum_{r \in R} \sum_{k \in K} \text{MRR@}k(r, C(P), D). \quad (1)$$

Here, $C(P)$ is the corpus produced by parser P and chunker C. We use BGE-M3 (Chen et al., 2024), multilingual-e5-large (Wang et al., 2024), and Qwen3-Embedding-8B (Zhang et al., 2025b) for R, with $K = \{1, 5, 10\}$. Averaging across these retrievers and depths reduces dependence on any one setting. Figure 2 shows the workflow.

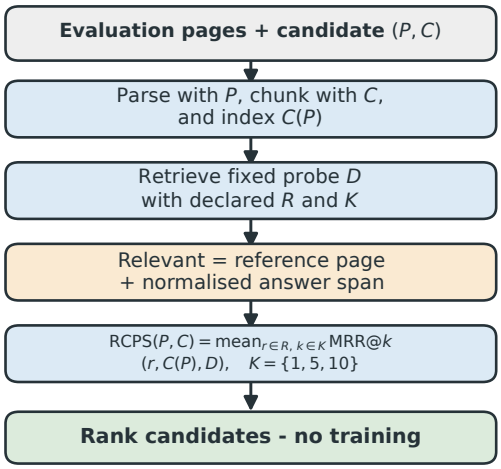

Figure 2: RCPS compares candidates on the same held-out Q–A probe. It averages standard MRR over specified retrievers and retrieval depths. A hit must come from the reference page and contain the normalised reference answer. Use a singleton retriever set when deployment is fixed, or a specified set when it is undecided. Evaluation itself requires no training.

Execution. Build a representative held-out probe whose answers occur verbatim on their reference pages. Our probe is model-generated. An LLM-assisted quality check accepted 94/100 sampled pairs; Section 4.1 reports its criteria. Parse each page once per parser, then chunk, index, and search every candidate corpus. With m parsers, c chunkers, and $|R|$ retrievers, this requires m parsing runs and $mc|R|$ retrieval evaluations.

Interpretation. The protocol needs neither training nor manual chunk labels because relevance follows from the answer span and source page. Fixing C ranks parsers. Fixing P ranks chunkers. The ranking is relative to the candidate pool and probe.

3.2 Coverage Separates Absence from Splitting

Coverage does not score a retriever. With parser output fixed, a reference span is *covered* when it appears within one chunk. It is *split* when it exists in the page output but crosses chunk boundaries. It is *absent* when the normalised page output contains no exact match. Overlap may repair a split. Rechunking alone cannot restore an absent exact span. These are operational labels: *absent* does not prove that the meaning is missing.

For example, MinerU-on transcribes the table answer $A = 180\,\mathrm{m}^2$ as `A = 180m`. Because the exponent never reaches the Markdown, no chunker can reconstruct the complete exact span. Appendix C.1 gives the parser I/O definition and the full worked example.

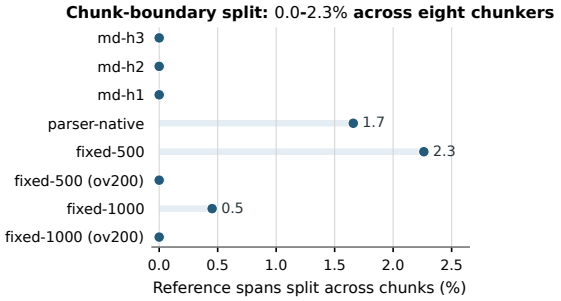

Figure 3: Coverage with Prod fixed (294 pages, 663 Q–A; no retriever). Absence is measured before chunking and stays at 20.2%. Changing the chunker affects only splitting, which reaches at most 2.3%.

4 Experiments

4.1 Evaluation Frames and Setup

Evaluation frames. We keep five evaluation frames separate. The parser- and chunker-selection experiments evaluate all 663 KoGovDoc-RAG Q–A against the same 294-page corpus: 229 government pages and 65 arXiv pages. The answers occur on 242 of those pages; the other 52 serve as Q–A-free distractors. Training and mechanism analyses index only those 242 evidence-bearing pages. The pre-specified pilot uses 73 pages and 202 Q–A. For perturbation analysis, OHR-Bench (Zhang et al., 2025a) provides 1,043 aligned Law–Manual Q–A. Training evaluation uses an aligned OHR-Bench compatibility subset (2,036 Q–A, six domains; Appendix A). Results from different frames are not directly comparable.

Data and leakage control. Qwen3-VL-30B produced the pseudo-reference Markdown, which we manually de-noised. `gpt-5.4-2026-03-05` generated the Q–A. A separate LLM-assisted check assessed question clarity, answer correctness, and whether the answer span appears in the reference context. It accepted 94/100 sampled pairs. **Prod** is our Qwen3-VL-2B parser (Bai et al., 2025) fine-tuned for Korean documents. It serves as both a deployment candidate and the training baseline. Training pages are disjoint from every evaluation frame.

Released evaluation record. The public repository contains the frozen probe and page map, both 294-page MinerU outputs, aligned per-Q–A arrays, stability results, and deterministic audits. Nine evaluated LoRA adapters are separately released with portable configurations and hashes. Appendix H records source-document and author-only exceptions.

For MinerU, *MinerU-off* is the originally submitted output, generated with table recognition disabled. *MinerU-on* is the later audited, table-enabled output used in the deployment comparison and four-parser BC correlation. We retain MinerU-off only as a separately labelled diagnostic. The two runs also differ in software and retrieval environments. Their difference is therefore not a controlled table-recognition ablation.

4.2 Boundary Clarity Can Misrank Parsers in This Pool (C1)

RCPS and Boundary Clarity rank parsers differently in this candidate pool (Figure 4; Table 1). MinerU-on has the highest measured BC among complete outputs (0.713) but the lowest RCPS (0.137). The 30B teacher and Prod have lower BC yet the highest RCPS values, 0.584 and 0.583. Across all five complete 294-page outputs, RCPS spans 0.137–0.584. PaddleOCR's parser-native output has no adjacent chunk boundaries, so BC is undefined for that configuration.

Among the four complete outputs with defined BC, the Pearson correlation with RCPS is $r = -0.74$. Adding Marker's partial 38-page output gives $r = -0.83$ ($n = 5$). Marker itself scores 0.073 RCPS and is excluded from complete-output comparisons. These small-sample correlations describe this pool only.

Law–Manual perturbations (1,043 Q–A). On the aligned OHR-Bench subset, semantic corruption lowers retrieval without a consistent BC response. From mild to severe noise, RCPS falls

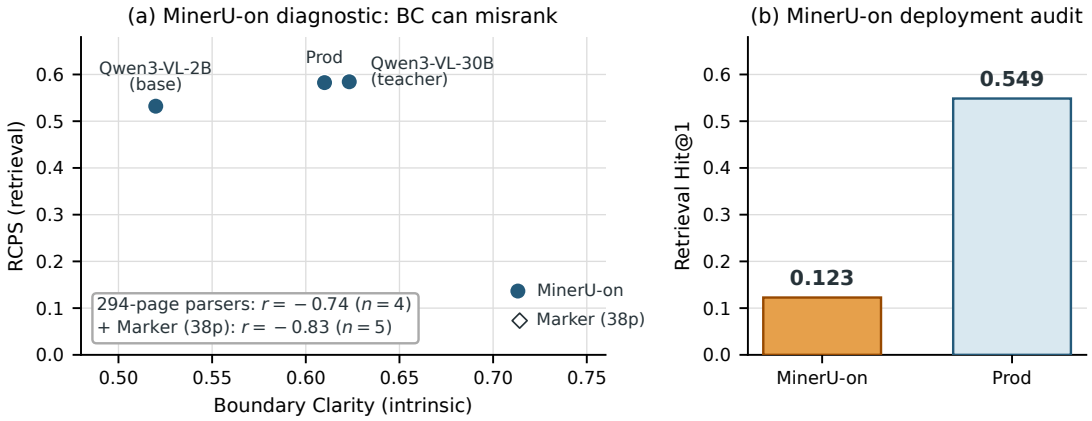

Figure 4: In this candidate pool, higher Boundary Clarity (BC) does not imply better retrieval. (a) Among four 294-page parsers with defined BC, the correlation with RCPS is $r = -0.74$. Adding Marker's partial 38-page output gives $r = -0.83$ ($n = 5$). MinerU-on is used in this diagnostic. (b) Prod exceeds MinerU-on Hit@1 by 42.6 points (0.549 vs. 0.123; 4.47×).

0.476 → 0.265 for MinerU, 0.534 → 0.497 for Qwen2.5-VL, and 0.461 → 0.298 for GOT. The corresponding BC values behave differently: MinerU stays within 0.628–0.651, Qwen2.5-VL remains near 0.563, and GOT rises 0.586 → 0.624. These eleven variants are dependent perturbations of three outputs, not independent parsers (Appendix A), and do not establish broad domain generality.

Domain sensitivity. MinerU-on scores 0.046 RCPS on the 527 government-document Q–A but 0.486 on the 136 arXiv Q–A. The mixed-corpus score of 0.137 therefore hides substantial source variation. This reinforces the intended use of RCPS as a probe-specific deployment procedure rather than a parser leaderboard to transfer unchanged across corpora.

4.3 RCPS Ranks Parsers and Chunkers (C2)

Table 1 applies the same probe, retrievers, depths, and relevance rule to every parser. The companion chunker comparison fixes Prod and changes only the chunker.

Selecting parsers. The 30B teacher ranks first at 0.584 RCPS, followed by Prod at 0.583. Prod nevertheless has slightly higher Hit@1 (0.549 versus 0.545). The point estimates are near-tied; in the probe bootstrap below, the teacher remains above Prod in only 62.5% of draws. Latency and compute may therefore decide between them. MinerU-on reaches only 0.137 RCPS and 0.123 Hit@1. Prod's Hit@1 is 4.47× as high.

Selecting chunkers. With Prod fixed, Table 2 ranks four chunkers. The 0.058 range is much smaller than the 0.447 range across the heterogeneous parser pool and close to the 0.052 range among its three vision–language parsers.

End-to-end top-choice check. Table 3 tests whether the RCPS top choice remains best after retrieval and answer generation. Prod leads judged answer accuracy, while the nearly tied lower pair reverses. The same GPT-5.4 checkpoint generates and judges the answers, so this check supports the top choice, not independent absolute accuracy or the complete parser order. Appendix B gives the protocol and remaining limitations.

Parser	BC	CS	RCPS	Hit@1
Deployment comparison (294 pages)				
Qwen3-VL-30B (teacher)	0.623	3.38	**0.584**	0.545
Prod (ours, 2B)	0.610	3.07	0.583	0.549
Qwen3-VL-2B (base)	0.520	3.74	0.532	0.500
PaddleOCR	—	3.46	0.140	0.125
MinerU-on	**0.713**	—	0.137	0.123
Partial output				
Marker (38p)	0.717	3.41	0.073	0.068

Table 1: RCPS ranks the 30B teacher and Prod at the top of the complete-output parser pool. Scores average three retrievers and $k \in \{1, 5, 10\}$. BC is Boundary Clarity, for which higher is better, and CS is Chunk Stickiness, for which lower is better (Zhao et al., 2025a). PaddleOCR has no adjacent parser-native boundaries from which to compute BC. CS was not recomputed for MinerU-on after the audited table-enabled rerun. The four-parser deployment correlation uses MinerU-on. Marker is excluded from complete-output comparisons.

Chunker	RCPS
md-h3	**0.593**
parser-native	0.583
LumberChunker (Duarte et al., 2024)	0.557
fixed-500	0.535

Table 2: Chunker selection with Prod fixed. Every row uses the same 663-Q–A probe, three retrievers, and retrieval depths $k \in \{1, 5, 10\}$.

Parser	RCPS	Ans. acc.	EM	Answered
Prod	0.583	**72.5**	**49.8**	87.9
MinerU-on	0.137	23.8	14.5	39.1
PaddleOCR	0.140	20.5	11.5	45.9

Table 3: The RCPS top choice also leads answer accuracy in this three-parser check over 663 Q–A. Answer generation uses BGE-M3 top-five retrieval. Ans. acc., EM, and Answered are percentages; RCPS is on a 0–1 scale.

Retriever, depth, and probe robustness. When deployment fixes a retriever, evaluate with that retriever. Otherwise, averaging reduces dependence on one model. Table 4 summarises the sensitivity checks. The depth check uses the stored MinerU-off submission grid; probe resampling uses the aligned 294-page grid containing both MinerU configurations. All parser rank changes are confined to the near-tied teacher–Prod and PaddleOCR–MinerU-on pairs. A single-retriever ablation and its limits appear in Appendix H.

Using the ranking. The teacher leads Prod in only 62.5% of probe draws, so their 0.001 RCPS gap is a near-tie resolved by latency or compute. Prod leads Base, MinerU-off, PaddleOCR, and MinerU-on in all 1,000 draws. We therefore trust the deployment tier, not every adjacent rank.

4.4 Coverage Finds Pre-Chunking Absence (C3)

The retriever-free diagnostic uses all 294 pages. For Prod, 134/663 reference spans (20.2%) have no normalised exact match before chunking. No tested chunker splits more than 15/663 spans (2.3%) (Figure 3). Thus, rechunking alone cannot restore exact-span retrievability for roughly one in five reference answers.

MRR@10 only. Complete five-parser and four-chunker orders remain unchanged ($\tau_a = 1.0$).
BGE-M3 only. On the stored MinerU-off grid, only the near-tied teacher–Prod order swaps ($\tau_a = 0.80$); lower parser ranks and the chunker order remain unchanged.
Parser probe. Across 1,000 draws of 500/663 Q–A, mean $\tau_a = 0.902$; the full order is identical in 39.4%. Prod leads Base, MinerU-off, PaddleOCR, and MinerU-on in every draw.
Chunker probe. The full order is identical in 96.1% of draws; md-h3 leads parser-native in 96.5%.
Raw matching. Scores fall by 0.024–0.041; parser and chunker orders remain unchanged.

Table 4: Selection robustness to retriever choice, retrieval depth, probe resampling, and the relevance matcher. Probe results use fixed-seed sampling without replacement.

Label	Meaning and next action
covered	The normalised span lies within one chunk; if retrieval fails, inspect the index or retriever.
split	The normalised span crosses chunk boundaries; rechunk or add overlap.
absent	No normalised exact-span match exists in parser output; inspect the output before replacing the parser.

Table 5: Coverage maps a missing retrieval result to the first component that can repair it. A covered span does not guarantee retrieval.

Under the same matcher, MinerU-on's absent rate is 66.1%, 45.9 points above Prod. Under the character-tolerant L4 matcher, its absent rate remains 62.1%, 45.2 points above Prod.

Parser-masked human check. Two authors independently label 100 sampled exact-match-absent cases, agree on 81/100 ($\kappa = 0.615$), and jointly adjudicate the remainder. Table 6 reports the final labels.

Parser	Retrieval-unusable	Wilson 95% CI
MinerU-on	42/50 (84.0%)	[71.5, 91.7]
Prod	12/30 (40.0%)	[24.6, 57.7]
PaddleOCR	19/20 (95.0%)	[76.4, 99.1]

Table 6: Adjudicated human labels for the stratified parser-masked sample. Unequal sampling fractions preclude population-rate comparisons.

The sample validates the direction of the OCR-parser gap, not population rates. Appendix C reports the matcher definitions and sampling design. It separately reports the full-set cross-family judge, which was run only on the retained MinerU-off output.

4.5 Parser Training Is a Secondary, Bounded Lever (C4)

After selection and diagnosis, we refer to retrieval-oriented parser training as Retrieval-Aware Document Parsing (RADP). RADP-aux adds a contrastive hidden-state objective, while RADP-DPO turns page-local retrieval scores into preference pairs (Rafailov et al., 2023). RADP-Distill replaces the retrieval reward with edit distance as a fidelity control. These methods change the parser. RCPS itself does not. Appendix E gives the objectives and training setup.

Neither RADP-aux nor RADP-DPO meets the pre-specified pilot target: a 5-percentage-point RCPS gain with a 95% CI lower bound above zero. On the separate 2,036-Q–A OHR-Bench compatibility subset, R2, R3, and RADP-Distill exceed Prod Hit@5 by only 0.95, 1.15, and 1.36 points. The paired Distill-minus-DPO intervals include zero for both R2 and R3, so these data do not identify a benefit from the retrieval reward over the edit-distance control. These post-audit estimates are neither a full v2 rerun nor a pre-specified confirmation. Appendix F reports the full results and the SimPO control (Meng et al., 2024).

Scale of selection and tuning. On the same 294-page frame, fine-tuning raises Prod Hit@1 by 4.9 points over Base, whereas choosing Prod over MinerU-on changes Hit@1 by 42.6 points. The 2,667-page training corpus is page-disjoint. This is scale, not a causal upper bound, and supports selecting before optimising.

5 Discussion and Conclusion

The main deployment lesson is to select before optimising. Choosing Prod over MinerU-on raises Hit@1 by 42.6 points; on a different OHR-Bench frame, audited training raises Prod Hit@5 by about one point. The magnitudes are not directly comparable, but both place selection first.

The diagnostics explain how to act on that selection. High BC does not guarantee retrievable content: MinerU-on combines BC 0.713 with 66.1% exact-span absence and Hit@1 0.123. When coverage finds *split* spans, adjust chunking or overlap. When it finds *absent* spans, inspect the parser output and switch parsers if required content is genuinely missing.

The end-to-end check supports the top decision, not the full ranking: Prod leads answer accuracy, while the lower pair reverses. Training evidence is also limited: neither RADP method meets its target, reward variants do not separate from the fidelity control, and SimPO point estimates are negative. Lower TextNED and incomplete boundary evidence do not establish a causal mechanism (Appendix G). In practice, select by retrieval, diagnose with coverage, and then train if needed.

Limitations

Data scope and frames. The reported denominators are not interchangeable. KoGovDoc-RAG selection indexes 294 pages for 663 Q–A, whereas training indexes only the 242 evidence-bearing pages. The pilot uses 73 pages and 202 Q–A. The complete parser comparison contains five 294-page outputs. Its BC correlation uses the four outputs with defined BC ($r = -0.74$). The $r = -0.83$ estimate additionally includes Marker's partial 38-page output. OHR-Bench uses 1,043 Law–Manual Q–A for perturbations and 2,036 Q–A for training compatibility. The Law–Manual frame contains dependent perturbations and does not establish domain generality. We exclude the mixed-version seven-domain artifacts (Appendix A).

MinerU audit. MinerU-off disables table recognition and remains only as a submitted-output diagnostic. In the later MinerU-on run, table-evidence absence falls from 87.9% to 41.7%. Prod's rate is 13.9%. MinerU-on still reaches only 0.137 RCPS and 0.123 Hit@1, compared with Prod's 0.583 and 0.549. The two MinerU runs have similar BC (0.713 and 0.716), but they also differ in software and retrieval environments. Their differences therefore do not isolate the effect of table recognition.

Reference, Q–A, and label quality. KoGovDoc-RAG uses manually de-noised Qwen3-VL-30B pseudo-references and LLM-generated Q–A. Neither complete set was human-verified. Two 100-case checks address narrower questions. An LLM check accepted 94/100 sampled Q–A. A blind two-author study evaluates coverage labels. The fixed probe controls query variation but not possible Qwen-lineage bias. OHR-Bench supplies external evidence, although the six-domain result is a compatibility analysis rather than a full v2 rerun. RCPS evaluates verbatim spans, not implicit or paraphrased answers. Coverage also depends on

its matcher: GPT-5.4 reclassifies 56% of Prod's exact-match-absent cases as surface artifacts.

Training. The KoGovDoc-RAG R2 result is exploratory. Its +1.96-point Hit@5 estimate (95% CI $[-1.06, +5.03]$) uses 242 pages and a configuration selected after several settings were inspected. On the separate 2,036-Q–A OHR compatibility subset, R2, R3, and RADP-Distill exceed Prod by 0.95, 1.15, and 1.36 Hit@5 points. Distill-minus-R2 is +0.41 points (95% CI $[-0.43, +1.26]$), and Distill-minus-R3 is +0.21 points (95% CI $[-0.61, +1.05]$). This subset was defined after a version audit and is not a full v2 rerun. We do not adjust for multiple checkpoints and secondary metrics, and the bootstrap resamples Q–A rather than shared evidence pages. These are post-audit estimates, not the original confirmatory analysis.

Scope. RCPS targets answer-span retrieval rather than generated answers. The end-to-end experiment checks only three parsers. The preference candidates come from Prod, so another parser pool may behave differently. We do not test token-level reinforcement learning, curricula, or chunk-level oracle distillation. Broader parser pools and training of chunkers, embedders, and rerankers remain future work.

Appendix roadmap. Appendices A–D support the intrinsic-metric, RCPS-selection, and coverage analyses (C1–C3). Appendices E–G document the secondary parser-training study (C4), and Appendix H records dataset and release scope.

A OHR-Bench Alignment and Noise Sensitivity

We use two OHR-Bench evaluation frames because the initial seven-domain artifacts mixed benchmark versions. Those artifacts paired Q–A from the legacy 4,330-page release with parser outputs from the current 8,561-page bundle. For 223 legacy Q–A assigned to the `notes` domain, the old evaluation mapped them to v2 `administration`. The corresponding evidence is instead under v2 `textbook`. As a result, the lookup selected unrelated documents and stored zeros. One further legacy textbook page, referenced by five Q–A, is absent from v2. After excluding these 228 affected cases, we retain a source-aligned compatibility subset of 2,036 Q–A across six domains. This subset supports compatibility checks, not a full v2 rerun. We therefore

discard the correlation computed from the mixed-version frame.

The Law–Manual files retain matching document and page identifiers across both releases. We use this 1,043-Q–A frame for the C1 perturbation study. Its 15 variants comprise three benchmark outputs (reference, MinerU, and Qwen2.5-VL), three formatting perturbations, and nine semantic perturbations. The semantic variants apply three noise severities to MinerU, Qwen2.5-VL, and GOT; no unperturbed GOT output is available. Across the 15 variants, the descriptive BC–RCPS correlation is $r = -0.35$. This value should not be interpreted as a correlation across 15 independent parsers because variants within a family share the same source output. Table 7 reports the semantic families on the same Law–Manual pages with the same three-retriever average.

Family	Metric	Clean	Mild	Mod.	Severe
MinerU	BC	0.657	0.628	0.651	0.631
	RCPS	0.595	0.476	0.384	0.265
Qwen2.5-VL	BC	0.563	0.563	0.563	0.564
	RCPS	0.545	0.534	0.523	0.497
GOT	BC	—	0.586	0.620	0.624
	RCPS	—	0.461	0.385	0.298

Table 7: Semantic noise lowers RCPS within every family, while BC is stable, non-monotonic, or increasing. Results use 1,043 source-aligned Law–Manual Q–A. Clean denotes unperturbed output. Mild, Mod., and Severe denote increasing semantic noise. GOT has no clean output.

B Does the RCPS Top Choice Also Lead in Answer Generation?

We ask whether the RCPS top choice among Prod, MinerU-on, and PaddleOCR also leads in answer generation. The evaluation covers all 663 KoGovDoc-RAG Q–A. BGE-M3 first retrieves the top five chunks from each parser corpus. `gpt-5.4-2026-03-05` then generates an answer from those chunks and judges it against the reference answer.

This generation pipeline is not identical to the main RCPS protocol. The RCPS values in Table 3 average three retrievers at three retrieval depths, whereas answer generation uses only BGE-M3 top-five retrieval. Each row nevertheless uses the same parser output for its RCPS and generation results. In particular, the MinerU row uses MinerU-on. MinerU-off scores 0.212 RCPS, but it has no corresponding answer-generation run and is therefore excluded from this comparison.

Prod achieves 72.5% answer accuracy, compared with 23.8% for MinerU-on and 20.5% for PaddleOCR. Thus, the RCPS top choice also leads in judged answer accuracy. The nearly tied lower pair reverses, so this experiment does not validate their relative order. Moreover, the same model checkpoint generates and judges the answers. We therefore treat the experiment only as an end-to-end check of the top choice, not as validation of the full parser ranking.

C Is the Absent Label Robust?

This appendix assesses the exact-span absent label with alternative matchers, a cross-family judge, and a parser-masked human check.

C.1 Parser I/O and the "Absent" Label

Each PDF page is first rendered as an image. A document parser maps that image to a linear Markdown transcription. The intended output preserves body text in reading order, ATX (#-style) headings, and GitHub-flavoured Markdown tables. It discards layout coordinates, fonts, figure imagery, and page furniture unless they are transcribed as text. The input collection includes born-digital and scanned PDFs, multi-column layouts, merged table cells, stamps, seals, and text embedded in figures.

Only the resulting Markdown is chunked, embedded, and retrieved. Under the operational definition in §3.2, a reference answer is *absent* when its normalised exact span has no match in the source-page transcription. The reference Markdown used for TextNED and the reference answer spans come from manually de-noised Qwen3-VL-30B output. We therefore treat both as pseudo-ground truth.

Worked example: a corrupted table unit. On KoGov page `val_0155`, the pseudo-reference and parser output differ as follows:

Pseudo-reference answer	$A = 180\,\mathrm{m}^2$
MinerU-on output	`A = 180m`

MinerU-on omits the exponent. The shared normalisation removes formatting, but it does not treat m^2 and m as equivalent. The complete answer is therefore absent under the exact-span relevance rule. Rechunking cannot reconstruct the missing exponent.

Alternative matchers. The reference Markdown, reference answers, and Prod share Qwen3

lineage. To test whether this shared lineage explains the absent-rate gap, we apply five model-free presence matchers to all 663 Q–A. L0 uses raw substring matching. L1 applies Unicode Normalization Form KC (NFKC), case folding, whitespace normalisation, and Markdown normalisation. L2 additionally removes digit separators and in-content punctuation. L3 requires at least 90% order-free token recall. L4 requires the longest common substring to cover at least 80% of the answer. L3 and L4 are alternative tolerant criteria, not successive steps in a nested ladder. If surface form explains most of the gap, at least one tolerant matcher should narrow it.

Absent %	L0	L1	L2	L3	L4
Prod (2B)	24.1	20.2	19.6	24.1	16.9
30B teacher	22.8	18.9	16.6	19.2	16.3
2B base	30.0	25.2	24.7	27.0	21.1
MinerU-off	74.8	70.4	68.0	73.0	68.6
PaddleOCR	67.0	62.7	62.0	59.9	60.5
MinerU−Prod	+50.7	+50.2	+48.4	+48.9	+51.7
PaddleOCR−Prod	+42.8	+42.5	+42.4	+35.7	+43.6

Table 8: The OCR-parser absence gaps over Prod persist across five presence matchers (663 Q–A, no retriever; MinerU-off). L0 is raw matching; L1 is normalised exact matching; L2 removes additional punctuation; L3 uses token recall; and L4 uses longest-common-substring coverage. The two other Qwen3-derived parsers remain within 5.9 percentage points of Prod.

Cross-family model judge. We next ask GPT-5.4, a different model family from the evaluated parsers, whether evidence remains recoverable in each L1-absent parser–answer pair (Table 9). *Present* denotes a recoverable surface mismatch. *Degraded* means that evidence remains but is too corrupted for reliable retrieval, and *absent* denotes missing content. We combine the latter two labels as *retrieval-unusable*. We apply the same procedure independently to every parser. The MinerU analysis here uses MinerU-off.

The Q–A pairs were also generated by a GPT-family model, so this judge is not independent of Q–A generation. The model-free matchers above avoid a GPT-family matcher, but they still depend on the generated Q–A. The judge marks 56% of Prod's L1-absent cases as surface artifacts, compared with about 16% for both MinerU and PaddleOCR. After those artifacts are removed, the MinerU–Prod retrieval-unusable gap remains 50.4 percentage points. The corresponding gaps are 50.2 points under L1 exact matching and 51.7 points under the L4 character-tolerant criterion.

	present (artifact)	degraded	absent	retrieval-unusable
Prod	56%	2%	42%	**8.9%**
MinerU-off	16%	9%	75%	**59.3%**
PaddleOCR	16%	22%	62%	**52.8%**

Table 9: A cross-family judge preserves the OCR-parser gap after recoverable surface mismatches are separated. GPT-5.4 labels 1,017 parser–answer cases marked absent by L1 (134 Prod, 467 MinerU-off, and 416 PaddleOCR). Degraded and absent are retrieval-unusable. The first three columns are percentages within each parser's L1-absent set. The final column is a percentage of all 663 Q–A.

Human verification of absent labels. Two authors independently labelled 100 parser-masked L1-absent cases, stratified by question type. The sample contains 50 MinerU-on, 30 Prod, and 20 PaddleOCR cases. This study evaluates coverage labels. It is separate from the 100-pair Q–A quality check. Before adjudication, the authors agreed on 81/100 cases, with $\kappa = 0.615$. They then jointly resolved the remaining 19 cases.

After adjudication, 42/50 MinerU-on cases were retrieval-unusable (84.0%, Wilson 95% CI $[71.5, 91.7]$). For Prod, 12/30 cases were retrieval-unusable (40.0%, $[24.6, 57.7]$). For PaddleOCR, the rate was 19/20 (95.0%, $[76.4, 99.1]$).

The automated-judge set contains counterparts for 93 human-labelled cases: 43 MinerU, 30 Prod, and 20 PaddleOCR. The seven excluded cases are MinerU-on examples with no MinerU-off counterpart. Across the full automated-judge sets, retrieval-unusable rates are 84.2% for MinerU-off, 84.1% for PaddleOCR, and 44.0% for Prod. Each falls within the corresponding human-sample Wilson interval. Among the 93 cases shared by the human and automated evaluations, pooled binary agreement is 84/93 (90.3%). The human labels thus confirm the direction of the OCR-parser gap in this stratified sample. Different sampling fractions and MinerU configurations preclude a population-level replication claim. The sampling manifest, both rating files, and the 19-case adjudication record were verified with the scoring script and are retained in an author-only audit package.

Causes of absence. For Prod, 23/165 table-evidence answers are exact-match absent (13.9%). The count is 43/201 (21.4%) for factoid answers and 63/290 (21.7%) for procedural answers. For

figure-evidence answers, 5/7 are absent (71.4%), but this seven-case estimate should not be generalised. This high point estimate is consistent with figure imagery not being transcribed into retrievable text.

We observe three recurring causes. First, parsers drop table cells before the content reaches Markdown. For table-evidence answers, absent rates are 87.9% for MinerU-off, 41.7% for MinerU-on, and 13.9% for Prod. Second, parsers skip text embedded in captions, stamps, seals, or figure labels. Third, they misrecognise numerals or units beyond the L2/L4 tolerance.

D Chunkers Rarely Split Exact Spans

We apply the retriever-free coverage diagnostic to Prod output for all 663 Q–A over 294 pages. As defined in §3.2, text matching labels each reference span as covered, split, or absent. Because the parser output is fixed, the pre-chunking absent rate remains 20.2% across all eight chunkers. No tested chunker splits more than 2.3% of exact answer spans.

Chunker	covered	split	absent
md_h3	79.8%	0.0%	20.2%
md_h2	79.8%	0.0%	20.2%
md_h1	79.8%	0.0%	20.2%
parser_native	78.1%	1.7%	20.2%
fixed500	77.5%	2.3%	20.2%
fixed500_ov200	79.8%	0.0%	20.2%
fixed1000	79.3%	0.5%	20.2%
fixed1000_ov200	79.8%	0.0%	20.2%

Table 10: No tested chunker splits more than 2.3% of reference spans. The pre-chunking absent rate stays 20.2% (Prod, 294 pages, 663 Q–A). `parser_native` uses blank-line paragraph boundaries. md_hk uses Markdown heading depth k. fixed N[_ov$M$] uses N-character windows with optional M-character overlap.

E How RADP-DPO Builds Preferences (C4)

Common training setup. All preference-based variants are Prod LoRA adapters ($r = 8$, $\alpha = 32$) (Hu et al., 2022). The RADP-aux sweep instead trains LoRA adapters from Qwen3-VL-2B-Instruct and applies them to Prod for evaluation, matching the executed pipeline. Evaluation uses deterministic decoding with temperature 0 and a 1,536-token limit. Candidate generation for preference construction is stochastic. The 2,667-page training corpus, which supplies 6,164 generated Q–A, is page-disjoint from every evaluation frame. RADP-aux sweeps $\lambda \in \{0, 0.1, 0.3, 0.5\}$ for its contrastive loss. Unless stated otherwise, confidence intervals use 1,000 paired Q–A-level percentile-bootstrap resamples.

Preference construction. RADP-DPO samples alternative Prod outputs for each page in the separate training corpus. It chunks every candidate parse and scores those chunks against questions linked to the page, with other-page chunks as distractors. The page-local reward is BGE-M3 MRR averaged over $k \in \{1, 5, 10\}$. This training reward differs from the evaluation RCPS, which averages three retrievers. Multilingual-e5-large and Qwen3-Embedding-8B are therefore unseen by the reward.

Candidate parses that differ by at least 5 percentage points in page-local reward form a DPO pair. The higher-scoring parse is the chosen example. R1 samples $K = 2$ parses with uniform distractors. R2 starts from the R1 checkpoint and trains on a second preference round with $\beta = 0.1$. R3 expands the candidate pool to $K = 16$ by adding 14 parses to the two R1 candidates. It also adds full-corpus hard negatives: chunks from other pages that are closest to the current queries.

Training objective. Let x be the input page, and let y^+ and y^- be its chosen and rejected parses. Define $\Delta_\theta = \log \pi_\theta(y^+ \mid x) - \log \pi_\theta(y^- \mid x)$. Define $\Delta_{\text{ref}} = \log \pi_{\text{ref}}(y^+ \mid x) - \log \pi_{\text{ref}}(y^- \mid x)$. During training, π_θ enables the trainable LoRA adapters, whereas π_{ref} disables them:

$$\mathcal{L}_{\text{DPO}} = -\log \sigma(\beta[\Delta_\theta - \Delta_{\text{ref}}]). \qquad (2)$$

The SimPO control uses a length-normalised chosen–rejected log-probability margin ($\beta = 2.0$, target margin $\gamma = 1.0$) without a reference policy.

F Parser-Training Results Across Frames (C4)

Across evaluation frames, the observed training differences are small or uncertain. The 73-page pilot misses its target. Every DPO and SimPO interval in the 242-page KoGovDoc-RAG analysis crosses zero. On the OHR-Bench compatibility subset, the R2, R3, and RADP-Distill Hit@5 estimates are about one percentage point above Prod.

Evaluation frames. Before the pilot, success required at least a 5-percentage-point RCPS gain and a 95% CI lower bound above zero. The pilot held out 73 pages and 202 Q–A from 242

Δ vs Prod (pp)	Hit@1	Hit@5	Hit@10	MRR@10	nDCG@5
RADP-DPO-R2	+0.59	+0.95	+0.90	+0.78	+0.82
RADP-DPO-R3	+1.46	+1.15	+0.90	+1.30	+1.28
RADP-Distill	+0.98	+1.36	+1.47	+1.12	+1.16

Table 11: R2, R3, and RADP-Distill have small positive deltas on the audited OHR-Bench compatibility subset, but this is not a full v2 rerun. The subset contains 2,036 source-aligned Q–A across six domains. It uses a three-retriever average with 1,000 Q–A-level paired-bootstrap resamples. Deltas are percentage points. Hit@5 intervals are R2 $[+0.33, +1.54]$, R3 $[+0.31, +2.05]$, and Distill $[+0.43, +2.29]$.

Variant (vs Prod = 0.6757)	Hit@5	ΔHit@5 [95% CI]	$P_{\text{boot}}[\Delta\text{Hit@5}>0]$	ΔRCPS (pp)
RADP-DPO-R3	0.6968	$+2.11\ [-0.90, +5.13]$	0.91	$+1.72$
RADP-DPO-R1	0.6963	$+2.06\ [-0.96, +5.13]$	0.91	$+0.57$
RADP-DPO-R2	0.6953	$+1.96\ [-1.06, +5.03]$	0.90	$+0.47$
RADP-SimPO (ctrl)	0.6687	$-0.70\ [-3.77, +2.31]$	0.32	-1.56

Table 12: All KoGovDoc-RAG DPO point estimates are positive, but every two-sided interval crosses zero. The SimPO point estimate is negative. The analysis indexes 242 pages for 663 Q–A and uses parser-native chunking with 10,000 Q–A-level paired-bootstrap resamples. Hit@5 averages three retrievers. Prod is 0.6757. $P_{\text{boot}}[\Delta\text{Hit@5} > 0]$ is a bootstrap proportion, not a p-value. Across three independent R1-recipe seeds, the standard deviation of mean ΔHit@5 is 0.90 percentage points.

evidence-bearing pages. Its best RADP-aux and RADP-DPO estimates missed that target, and their intervals crossed zero.

The later KoGovDoc-RAG analysis pools the 169 development pages with the 73 held-out pages. It is therefore not an independent holdout. All 663 Q–A have evidence on these 242 indexed pages. The 294-page selection index additionally contains 52 Q–A-free distractor pages. The cross-domain analysis instead uses the 2,036-Q–A, six-domain OHR-Bench compatibility subset in Table 11. All training examples come from the separate 2,667-page corpus. The preference-based systems are Prod LoRA adapters; RADP-aux uses the cross-base training and evaluation setup described above.

KoGovDoc-RAG results. The three RADP-DPO milestones have parser-native Hit@5 point estimates 1.96–2.11 percentage points above Prod. For each checkpoint, the paired-bootstrap proportion $P_{\text{boot}}[\Delta\text{Hit@5} > 0]$ is about 0.90 (Table 12). This descriptive bootstrap proportion is not a p-value. Every two-sided interval crosses zero at $n = 663$.

These estimates are exploratory. The reporting configuration was selected after examining multiple chunker, retriever, and retrieval-depth settings, without a family-wise multiplicity correction. The bootstrap also resamples Q–A pairs rather than evidence pages. Table 11 omits R1 because no source-aligned cross-domain array is available for that checkpoint.

RADP-aux does not meet the pre-specified criterion. On the held-out 73-page, 202-Q–A fold, $\lambda = 0.1$ gives the largest estimate relative to the $\lambda = 0$ fine-tuning control. The gain is $+1.13$ RCPS percentage points with md-h3 and $+2.31$ with parser-native chunking. Estimates decline at larger values of λ, and every paired confidence interval relative to $\lambda = 0$ includes zero.

SimPO has negative point estimates. Relative to Prod on the 242-page fold, its three-retriever mean Hit@5 difference is -0.85 percentage points with md-h3 and -0.70 with parser-native chunking. Both confidence intervals cross zero. These results do not isolate whether reference removal, length normalisation, or another optimisation difference causes the change.

Matched fidelity control. RADP-Distill changes only the pair-selection signal: it ranks candidates by edit distance rather than retrieval. On the same 2,036 observations, its Hit@5 estimate is 1.36 points above Prod. Its direct differences from R2 and R3 are $+0.41$ and $+0.21$ points, with both paired intervals crossing zero. The experiment therefore does not show that retrieval-reward pair selection outperforms the fidelity control.

G Do Training Point Estimates Track Fidelity or Boundaries? (C4)

The available measurements do not identify why the training point estimates change. DPO checkpoints have lower TextNED than Prod. However, TextNED does not reproduce their retrieval order, and the boundary evidence is incomplete. Table 13 reports Boundary Clarity (BC), normalised edit distance to reference Markdown (TextNED), and chunking shape on the 242-page corpus. TextNED is the character-level Levenshtein distance divided by the longer string length.

Variant	len	c/pg	clen	BC↑	TextNED↓
Prod (baseline)	1385	4.82	274	0.630	0.240
aux λ=0.0	799	2.96	245	0.553	0.626
aux λ=0.1	1380	4.05	321	0.652	0.423
aux λ=0.3	1930	6.73	272	0.470	0.332
aux λ=0.5	2035	5.82	327	0.556	0.318
DPO-R1	1606	4.97	311	0.646	0.167
DPO-R2	1610	4.83	321	0.647	**0.163**
DPO-R3	1514	4.88	300	—	0.185
SimPO	1703	5.31	305	0.601	0.186

Table 13: DPO checkpoints have lower TextNED than Prod on the 242-page corpus, but the metric does not reproduce their retrieval order. Len is mean parsed characters per page. c/pg is mean chunks per page, and clen is mean characters per chunk. BC was not computed for R3.

DPO checkpoints have lower TextNED. The three RADP-DPO checkpoints have TextNED values of 0.163–0.185, compared with Prod's 0.240. Relative to the pseudo-reference, these distances are 23–32% lower. RADP-aux instead has TextNED values of 0.318–0.626.

All three DPO checkpoints also have positive Hit@5 point estimates in Table 12. However, TextNED does not order them. R2 has the lowest TextNED and the smallest DPO Hit@5 difference. R3 has the highest TextNED among the DPO checkpoints and the largest Hit@5 difference. The co-occurrence is consistent with fidelity as one possible explanation, but these observational results do not identify a causal mechanism.

Available structure evidence is incomplete. R1 and R2 have 4.97 and 4.83 chunks per page, close to Prod's 4.82. Their mean chunk lengths, however, increase from 274 characters for Prod to 311 and 321. Their BC values are 0.646 and 0.647, compared with Prod's 0.630. R3 has comparable chunking shape, but no reproduced BC value. The missing R3 value and the lack of uncertainty estimates prevent a systematic conclusion about boundary change.

Interpretation. One possible explanation for RADP-aux's smaller point estimates is that its hidden-state objective can affect retrieval only indirectly through generated Markdown. The aligned RADP-Distill retrieval comparison does not separate the two pair-selection objectives. Previously computed OHR TextNED breakdowns use artifacts that are not aligned with the audited subset, so we exclude them from the mechanism analysis.

H Dataset Composition and Release Status

Dataset composition. KoGovDoc-RAG contains 229 Korean government pages and 65 arXiv pages. The two sources contribute 527 and 136 verbatim-answerable Q–A, respectively. The separate 2,667-page training set is page-disjoint from all 294 evaluation pages. Prod exceeds its 2B base by 4.9 Hit@1 points, whereas the audited Prod–MinerU-on difference is 42.6 points. This comparison provides scale, not a formal bound on fine-tuning effects.

Stored retriever ablation. This ablation predates the MinerU-on audit and uses the submitted MinerU-off grid. Relative to full RCPS over the five full-page parsers (Marker excluded), BGE-M3 alone changes only the near-tied 30B–Prod order ($\tau_a = 0.80$). Lower parser ranks and the chunker order remain unchanged. It provides no evidence about the MinerU-on–PaddleOCR order.

Artifact status. The repository contains the frozen probe and page map, both MinerU configurations' 294-page outputs, retrieval and diagnostic code, aligned per-Q–A arrays and stability results, and deterministic OHR-compatibility and MinerU-output audits. A separate public release provides all nine evaluated LoRA adapters, with portable configurations, hashes, and available trainer states. The adjudicated human-study inputs remain in an author-only audit package; the public repository reports their aggregate results. We verified the public checkpoint download and CPU-only artifact gates from a clean checkout. A full end-to-end rerun still requires external source documents, parser outputs, and embedding caches, and we do not claim a full OHR-Bench v2 rerun.

GraphReduce: Coverage-Preserving LLM Aggregation for E-commerce Review Insights

Abstract

In e-commerce, product detail pages (PDPs) often contain hundreds or thousands of customer reviews, yet the interface can surface only a small set of concise and reliable insights. A useful review aggregation system must therefore abstract recurring themes while preserving which reviews support each insight. We study this problem as structured review-insight mining: review-level tuples are first extracted and then aggregated into ranked product-level insight clusters with explicit member traceability. We propose GRAPHREDUCE, a coverage-preserving framework for product-scale review insight aggregation. It combines a contrastively trained projection layer over frozen sentence embeddings, graph-based clustering on local neighborhood structure, and an LLM reducer/ranker for naming and ordering canonical clusters. By keeping membership accounting outside the generative step, GRAPHREDUCE preserves complete tuple coverage and avoids a common failure mode of direct LLM summarization: producing plausible high-level themes while silently dropping long-tail evidence. Across three product-category benchmarks, GRAPHREDUCE improves recovery of gold insight clusters over strong lossless embedding-based baselines while maintaining comparable ranking quality. We further show that flat LLM and topic-modeling baselines can appear competitive under ranking metrics despite omitting substantial input evidence, and that an anti-copy reinforcement objective improves the quality of upstream tuple extraction. These results highlight the importance of coverage-aware aggregation for faithful review insight mining in e-commerce settings.

1 Introduction

Product review summarization has increasingly moved beyond short free-form summaries toward more structured forms of opinion aggregation, including aspect-guided summaries (Boytsov et al., 2025), aspect-controllable opinion summaries (Amplayo et al., 2021), learned review selection (Jiang et al., 2023), synthetic-data pipelines for e-commerce opinions (Siledar et al., 2023), and facet-based faithful summaries (Wang et al., 2025). These methods address a central question: *what should a summary say?* In e-commerce product detail pages (PDPs), however, a deployed review insight system must also answer a second question: *which reviews support each displayed insight?* Without explicit member traceability, a system may

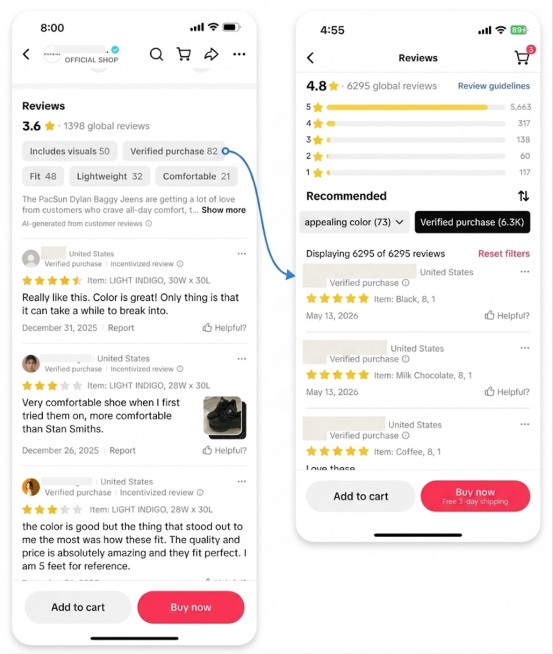

Figure 1: Review insights on a product detail page. A shopper-facing panel has room for only a handful of short insight labels (here *Fit*, *Lightweight*, *Comfortable*), each of which should stay linked to the reviews that support it. The screenshots are a visual illustration of the task only; they are not part of the experimental setup, and all experiments in this paper use the public Amazon Reviews corpus (Hou et al., 2026).

generate fluent and useful-looking themes while silently ignoring long-tail evidence needed for user trust, analytics, and auditability. Figure 1 illustrates the display budget that makes this trade-off concrete: only a few short insight labels fit on the page, so aggregation must decide what to show without losing track of what supports it.

We study this setting as *structured review-insight mining*, a two-stage problem. In the first stage, each review is converted into one or more structured tuples, each consisting of an abstracted insight, an aspect, a sentiment label, a language tag, and the supporting review span. In the second stage, tuples are grouped by product and aggregated into a ranked list of canonical product-level insight clusters. Each output cluster has a human-readable description and a complete set of member tuple ids, linking the displayed insight back to the evidence that supports it. This explicit coverage requirement changes the nature of the task. A method that only emits salient head themes can score well under ranking-oriented metrics such as NDCG, while discarding the long-tail evidence needed for downstream analysis, verification, and auditability.

We propose GRAPHREDUCE, a coverage-preserving aggregation framework for product-scale review insights. GRAPHREDUCE first maps tuple representations into a product-cluster-aware space using a lightweight contrastive projection over frozen sentence embeddings. It then constructs local-neighborhood graphs, applies spectral clustering, and uses an LLM reducer/ranker to name and order the resulting canonical clusters. Crucially, semantic generation is separated from membership accounting: the LLM produces cluster labels and rankings, while tuple membership is propagated deterministically through the aggregation pipeline. As a result, every input tuple remains assigned to exactly one output cluster.

This formulation differs from subset-based opinion summarization (Jiang et al., 2023; Bražinskas et al., 2021), which first selects a small set of representative reviews and then summarizes them. Our goal is not to summarize a chosen subset, but to aggregate all extracted evidence into a compact set of traceable product insights. This distinction is especially important for long-context LLM aggregation: direct prompting can often produce plausible high-level themes, but as the number of tuples grows, it may omit substantial portions of the input without an explicit failure signal.

Our contributions are threefold:

1. **Task and benchmark.** We formulate product review insight mining as ranked clustering with explicit member-id coverage, and evaluate systems using ranking quality, cluster recovery, coverage, and duplicate assignment metrics across three e-commerce product categories.
2. **Method.** We introduce GRAPHREDUCE, a projection-plus-graph-clustering-plus-LLM aggregation pipeline that preserves member coverage by construction while producing canonical ranked insight clusters.
3. **Findings.** Across three category benchmarks, GRAPHREDUCE recovers gold insight clusters more effectively than strong lossless embedding-based baselines while maintaining comparable ranking quality. We also show that flat LLM and topic-modeling baselines can appear competitive under ranking metrics despite dropping input evidence, and that anti-copy reinforcement learning improves the upstream tuple extractor.

2 Related Work

Opinion and product review summarization. Opinion summarization has moved from free-form summaries toward structured and controllable representations of user opinions, including aspect-controllable summarization (Amplayo et al., 2021), review and subset selection (Jiang et al., 2023), synthetic e-commerce data (Siledar et al., 2023), LLM-based facet induction (Wang et al., 2025), extractive aspect-based summarization (Gunel et al., 2023), latent-facet discovery (Lakkaraju et al., 2011), and industrial aspect-guided review summarization (Boytsov et al., 2025; Soltan et al., 2022). These methods mainly address what a summary should contain and how it should be expressed. Our setting adds evidence accounting: each displayed insight must remain linked to its supporting review-level evidence. We therefore aggregate extracted evidence into ranked canonical clusters with explicit member assignments, rather than producing only a free-form summary or a selected review subset.

Aspect-based sentiment analysis and tuple extraction. Aspect-based sentiment analysis identifies opinion targets and sentiment in reviews (Pavlopoulos and Androutsopoulos, 2014; Tang et al., 2016; Chen et al., 2017; Xue and Li, 2018).

Our upstream extractor extends this setup with tuples containing an abstracted insight phrase, aspect, sentiment label, language tag, and verbatim evidence span. The span grounds the tuple, while the insight should abstract the sentiment-bearing content. This creates a copying failure mode, where a model satisfies grounding by reusing the evidence span as the insight. We use DPO (Rafailov et al., 2023) and GRPO (Shao et al., 2024) to improve abstraction, but the main focus of this paper is aggregation over fixed extracted tuples.

Long-context LLMs and evidence coverage. Long-context LLMs allow many review tuples to be placed in one prompt, but context length does not ensure faithful or complete source use (Laban et al., 2024; Liu et al., 2024; Bai et al., 2024; Kim et al., 2024). In review insight aggregation, a model may generate plausible high-level themes and strong rankings while omitting less frequent evidence. We therefore separate ranking quality from evidence accounting, reporting NDCG and cluster recovery alongside tuple coverage and duplicate assignments.

Contrastive embeddings and graph-based clustering. Sentence encoders such as SimCSE (Gao et al., 2021) and BGE (Xiao et al., 2024) provide strong semantic spaces, while contrastive learning adapts embeddings to task-specific similarity (Wang et al., 2022). Because generic similarity may not match product-level insight boundaries, we learn a lightweight projection over a frozen encoder and apply spectral clustering over local-neighborhood graphs. Unlike recent LLM-guided hierarchical or graph-based clustering work (Pattnaik et al., 2024; Ashkenazi et al., 2025), our setting requires canonical descriptions and rankings while assigning every tuple id exactly once.

3 Method: GRAPHREDUCE

Figure 2 summarizes the GRAPHREDUCE aggregation pipeline. The key design principle is to separate semantic abstraction from exact membership accounting: language models describe and rank clusters, while tuple assignments are maintained by graph clustering and deterministic set union.

3.1 The GRAPHREDUCE inference pipeline

Given the N extracted tuples for a product and a target of K output insights, GRAPHREDUCE proceeds hierarchically. Each tuple is encoded with a frozen sentence encoder and mapped through a lightweight projection head into a product-cluster-aware representation space. At each aggregation level, GRAPHREDUCE constructs a k-nearest-neighbor graph over the current pool and applies spectral clustering (Ng et al., 2001) to obtain a hard partition. The number of clusters is chosen so that each reducer call receives a bounded-size group, while the pool is gradually reduced toward the target output size.

For each cluster, an LLM reducer generates a canonical phrase describing the shared insight. The reducer output replaces the original items in the next-level pool, together with the cluster centroid and the union of all member ids contained in the cluster. This process repeats until the pool contains at most K items. The same LLM is then prompted to rank the final candidates and assign importance scores.

Because each intermediate clustering step returns a partition, and because parent member sets are computed by deterministic union, every input tuple remains assigned to exactly one final cluster. The coverage guarantee therefore applies to membership accounting over the extracted tuple inventory; it does not depend on the LLM reproducing row ids or maintaining global state in text.

Algorithm 1 states the procedure. A direct LLM aggregation prompt must jointly decide which insights are salient, generate their descriptions, and return the exact set of member ids for each cluster. GRAPHREDUCE decomposes these roles. The LLM is used where linguistic abstraction is needed, while exact membership is computed outside the model as a graph operation. This makes cluster assignments auditable before language generation and isolates the effect of the learned projection on the geometry used by the graph partitioner.

The number of LLM calls grows with the number of bounded reducer groups, rather than relying on a single long-context prompt:

$$1 + \sum_{\ell=0}^{L-1} \max\left(K, \left\lceil \frac{N}{B^{\ell+1}} \right\rceil\right),$$

where the final 1 corresponds to the ranking prompt, B is the maximum reducer group size, and L is the number of aggregation levels.

3.2 Training the projection head

Generic sentence embeddings provide a useful starting point for tuple similarity, but their neighbor-

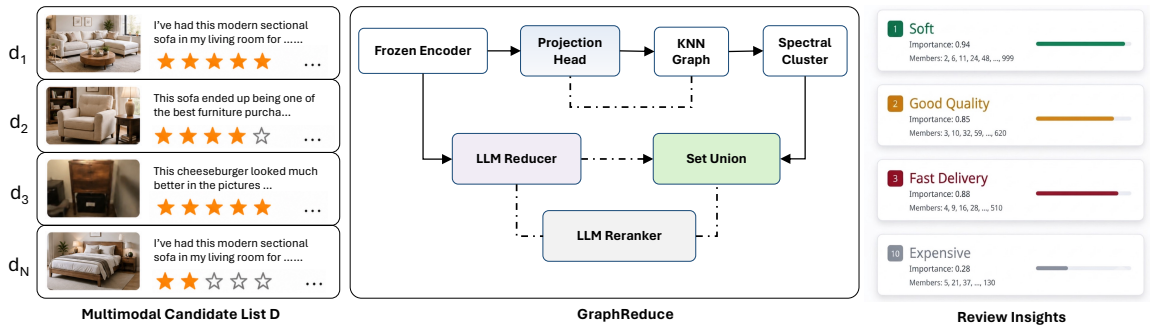

Figure 2: Review tuples are projected into a cluster-aware embedding space and partitioned by local graph clustering. LLMs name and rank the final insight clusters, while member ids are propagated outside the model by deterministic set union to preserve full evidence coverage.

Algorithm 1 GRAPHREDUCE inference. Member-id sets are propagated by deterministic union outside the LLM.

Input tuples $T = \{t_i\}_{i=1}^{N}$; target size K; group size B; projection ϕ; reducer/ranker π_θ; embedder Emb
Output ranked clusters with complete member-id assignments

$x_i \leftarrow \mathrm{Emb}(t_i)$; $z_i \leftarrow \phi(x_i)$ for all t_i
$pool \leftarrow \{(t_i, z_i, \{\texttt{row_id}_i\})\}_{i=1}^{N}$
while $|pool| > K$ **do**
  $K' \leftarrow \max(K, \lceil |pool|/B \rceil)$
  $\{C_j\}_{j=1}^{K'} \leftarrow \textsc{SpectralKNN}(\{z\}, K')$
  $p_j \leftarrow \pi_\theta(C_j \rightarrow \textsc{Name})$ for each C_j
  $R_j \leftarrow \bigcup_{u \in C_j} R_u$; $\bar{z}_j \leftarrow |C_j|^{-1} \sum_{u \in C_j} z_u$
  $pool \leftarrow \{(p_j, \bar{z}_j, R_j)\}_{j=1}^{K'}$
end while
$(top_K, scores) \leftarrow \pi_\theta(pool \rightarrow \textsc{Rank}, K)$
return $(top_K, scores, \{R_j\})$

hood structure is not always aligned with product-level insight clusters. Tuples that mention the same product component may be close in the embedding space even when they describe different issues, while lexically different phrases may express the same underlying concern. We therefore learn a lightweight projection head over a frozen sentence encoder to adapt tuple representations to the cluster boundaries observed within products (Appendix D).

The projection head PROJHEAD is trained with an InfoNCE objective (Oord et al., 2018). For each training product, anchors and positives are sampled from the same gold insight cluster. Hard negatives are sampled from other clusters of the same product, and easy negatives from other products. Product-local hard negatives force the projection to distinguish semantically adjacent but operationally different issues in the same product context. The base encoder remains frozen, so the learned component only reshapes the embedding space used by the downstream graph partitioner. In our implementation, we use BGE-small-en-v1.5 and a 384→256→128 MLP projection head.

The product-level gold clusters used for projection training are constructed from embedding-based candidate clusters, teacher-LLM validation and renaming, and LLM-based importance ranking (Appendix C). Test products are excluded from both projection-head training and reducer fine-tuning.

3.3 K-way reducer supervision

The reducer converts a group of tuples or intermediate clusters into canonical insight descriptions. A reducer trained only on single-cluster cleanup examples can name coherent groups, but it does not learn what to do when a reducer call receives a mixed group. This mismatch is problematic in hierarchical aggregation, where early groups may contain several related themes and require controlled splitting rather than a single over-general label.

We therefore construct K-way reducer supervision from training products. For each example, we sample several gold clusters from the same product, draw a bounded number of tuples from their union, shuffle the inputs, and train the reducer to recover the corresponding partition and canonical cluster names. This matches the reducer's inference-time role: a call may receive either a coherent cluster that should be summarized as one insight, or a mixed group that should be separated into multiple canonical insights. In our experiments, each synthetic reducer example samples $k_{\text{in}} \in \{2, 3, 5, 7, 10\}$ gold clusters and at most 200 tuples (Appendix E).

The same LLM checkpoint is used for local naming and final ranking. At the final stage, each candidate already carries a deterministic member

set, so the ranker assigns an ordering and importance scores without modifying membership assignments.

4 Experiments

We evaluate GRAPHREDUCE on three held-out product-category benchmarks built from Amazon product reviews (Hou et al., 2026): Software, Fashion, and Baby. Each benchmark contains 100 products with product-level gold insight clusters and importance rankings. All test products are excluded from both projection-head training and reducer fine-tuning.

4.1 Baselines and metrics

We compare GRAPHREDUCE against four baselines that represent different trade-offs between semantic abstraction and evidence accounting.

- **flat_llm**: a single LLM call over the tuples of a product, prompted to produce ranked insight clusters and member ids directly. To keep this to one call we randomly subsample to at most 400 tuples; the bound is inactive for Software and Baby and binds on 16 of 100 Fashion products.
- **BERTopic** (Grootendorst, 2022): a topic-modeling pipeline using UMAP (McInnes et al., 2018), HDBSCAN (Campello et al., 2013), and c-TF-IDF naming over the same frozen BGE embeddings. HDBSCAN outliers are treated as unassigned.
- **hier_agglom (BGE raw)**: a lossless hierarchical aggregation pipeline with the same LLM naming and ranking steps as GRAPHREDUCE, but using raw frozen BGE embeddings without the learned projection head.
- **embed_cluster**: deterministic embedding clustering with a modal raw phrase used as the cluster name, without LLM-based naming.

We report four complementary metrics. **Recall@10** measures the fraction of gold top-10 insight clusters recovered by the predicted top-10 list. **Precision@10** measures the fraction of predicted top-10 clusters that match a gold cluster. **NDCG@10** evaluates the ordering of matched predicted clusters using the gold importance ranking as relevance. Predicted and gold cluster names are matched one-to-one using a phrase-token Jaccard rule; duplicate aliases do not receive repeated credit.

Because ranking metrics do not measure whether the input evidence has been fully accounted for, we also report **coverage** and **duplicate assignments**. Coverage is the fraction of input tuple ids that appear in at least one predicted top-10 cluster, and duplicate assignments count tuple ids that appear in more than one predicted cluster. These metrics separate two questions that are often conflated: whether a system names the most important insights, and whether it preserves the structured evidence inventory supporting those insights. Appendix F gives the full matching and split protocol, and Appendix K discusses why the projection helps.

4.2 Main results

Table 1 shows the main Stage-2 aggregation results. Among methods with complete member coverage, GRAPHREDUCE obtains the highest recall@10 in all three categories: 0.609 on Software, 0.536 on Fashion, and 0.674 on Baby, against 0.575, 0.502 and 0.618 for hier_agglom with raw BGE embeddings. GRAPHREDUCE also preserves 100% coverage of its input inventory and produces no duplicate member assignments.

These rows are not an input-controlled comparison, and we do not read them as isolating the projection head. The two evaluation harnesses build a product's tuple inventory differently: GRAPHREDUCE and BERTopic receive the union of the product's gold-cluster member ids, whereas flat_llm and hier_agglom additionally receive the extracted tuples that gold assigns to no cluster. On the reported products the former is a strict subset of the latter for all 300 products, and is smaller by 19.0, 20.0 and 12.4 tuples per product on average for Software, Fashion and Baby. GRAPHREDUCE is therefore scored over a slightly cleaner inventory, which inflates both its coverage denominator and, plausibly, its cluster recovery. For this reason we drop the significance markers on this table, and treat the ablation in Table 7 — raw BGE versus PROJHEAD under one harness, one inventory and one product set — as the controlled evidence that the learned projection helps. Aligning the two harnesses is left to future work.

The NDCG results show a different pattern: GRAPHREDUCE is comparable to the raw-BGE lossless baseline, with differences within bootstrap uncertainty. We therefore interpret ranking quality as parity rather than a consistent NDCG improvement. The main gain is improved gold cluster

Category	Strategy	recall@10	prec@10	NDCG@10	**coverage**	**dup**	calls
Software ($N \leq 297$)	flat_llm	0.532	0.573	0.619	0.942 (–5.8%)	107	1.0
	BERTopic	0.471	0.723	0.599	0.883 (–11.7%)	0	0.0
	hier_agglom (BGE raw)	0.575	0.520	0.648	**1.000**	0	10.0
	GRAPHREDUCE	**0.609**	0.551	**0.667**	**1.000**	**0**	11.0
Fashion ($N \leq 497$)	flat_llm	0.516	0.517	0.602	0.872 (–12.8%)	88	1.0
	BERTopic	0.562	0.562	**0.631**	0.601 (–39.9%)	0	0.0
	hier_agglom (BGE raw)	0.502	0.502	0.561	**1.000**	0	10.0
	GRAPHREDUCE	0.536	0.536	0.581	**1.000**	**0**	11.0
Baby ($N \leq 165$)	flat_llm	0.618	0.539	**0.676**	0.951 (–4.9%)	51	1.0
	BERTopic	0.430	**0.792**	0.575	0.879 (–12.1%)	0	0.0
	hier_agglom (BGE raw)	0.618	0.465	0.652	**1.000**	0	10.0
	GRAPHREDUCE	**0.674**	0.508	0.669	**1.000**	**0**	10.6

Table 1: Stage-2 results on fixed 100-product held-out benchmarks. Coverage is the fraction of input tuple ids assigned to predicted top-10 clusters; **dup** counts tuple ids assigned to multiple clusters. **calls** counts reducer calls only; every LLM-based method issues one further ranking call. *Rows are not input-controlled*: GRAPHREDUCE and BERTopic consume the union of a product's gold-cluster member ids, while flat_llm and hier_agglom additionally receive the tuples that gold assigns to no cluster (Appendix F). Cross-method differences should therefore not be read as an effect of the projection head; see Table 7 for the input-controlled comparison.

recovery under exact evidence coverage, not substantially better top-insight ordering.

The non-lossless baselines show why coverage must be reported separately. Flat LLM prompting and BERTopic can be competitive on NDCG, and in some categories achieve the highest NDCG or precision, but they do so with incomplete evidence accounting. Flat prompting omits tuple ids and produces duplicate assignments, while BERTopic discards HDBSCAN outliers. Across the 100-product benchmarks, omitted inventory ranges from 4.9% to 39.9%. Thus, ranking metrics alone can overstate methods that capture salient head themes while leaving input evidence unassigned.

Overall, GRAPHREDUCE attains the highest cluster recovery among the methods reported here while retaining complete coverage of its input and zero duplicates, with the input-inventory caveat above.

4.3 Large-N stress test

We further evaluate five Fashion products with $N \in [1437, 1633]$ tuples (Appendix G). This stress test is not intended to support broad statistical claims, but to examine how aggregation behaves when the tuple inventory exceeds the size of the main benchmark products. In this setting flat prompting retains 22.8% of tuple ids while still producing plausible insight names, and the hierarchical raw-BGE pipeline retains all of them. Two caveats matter for how this number should be read. First, the single-call baseline subsamples to 400 tuples, so at $N \approx 1{,}500$ it is shown roughly a quarter of the inventory and in fact assigns 93–100% of what it sees; the 22.8% measures the subsampling budget of a one-prompt design, not a failure of the model to track a long context. Second, this run does not include GRAPHREDUCE: the hierarchical rows use raw BGE embeddings without the projection head, so the stress test speaks to the aggregation architecture rather than to GRAPHREDUCE specifically. What it does show is a design consequence: any single-prompt formulation must fit the inventory into one context window and therefore cannot preserve member ids by construction, whereas bounded hierarchical reduction can. It also shows that lossless behaviour alone is not sufficient — `embed_cluster_llm` reaches 0.977 coverage with higher recall and NDCG than the hierarchical rows at this scale.

4.4 Ablations

We ablate the main aggregation components on a 30-product development split of the Software category (Table 7, Appendix I).

First, adapting the embedding geometry helps. Replacing raw BGE embeddings with the contrastively trained projection head improves cluster recovery and ranking quality under the same downstream pipeline, indicating that generic semantic similarity is insufficient for product-level insight boundaries.

Second, the hierarchical chunk-plus-rank pipeline matters. Using the projection with a simpler clustering backend degrades performance, showing that the gain is not from the projection

alone. Bounded reducer calls and the final ranking step are both needed to convert local cluster structure into a stable top-K output.

Third, more expressive learned clustering is not automatically better. A GraphPool-style model with GraphSAGE (Hamilton et al., 2017) and Gumbel-Softmax assignments (Jang et al., 2016) underperforms the explicit spectral partition, even as its training reward improves. This points to a reward-alignment issue: local differentiable clustering objectives do not necessarily optimize top-K ranking and recovery metrics. We therefore limit the learned component to representation projection and retain explicit graph partitioning for cluster assignment.

4.5 Qualitative analysis

Appendix J presents a worked example and a manual analysis of common errors. We observe four recurring patterns. First, the reducer sometimes produces phrase aliases that are semantically close to the gold label but fail the automatic phrase match, lowering NDCG even when the member partition is reasonable. Second, long-tail clusters can compete with broader head themes for limited top-K slots. Third, spectral clustering can over-merge related issues when the product has few tuples. Finally, some clusters have mostly correct member sets but receive overly generic or partially incorrect names. These errors suggest that future work should improve semantic matching in evaluation, calibrate the head–tail trade-off, and make cluster naming more robust.

5 Conclusion

We introduced GRAPHREDUCE, a coverage-preserving framework for aggregating e-commerce review tuples into ranked, traceable product-level insight clusters. GRAPHREDUCE uses LLMs for naming and ranking, while graph clustering and deterministic set propagation preserve member assignments. Across three product-category benchmarks, it improves cluster recovery over strong lossless baselines while maintaining comparable ranking quality and complete coverage. Our results show that ranking metrics alone can obscure evidence loss: flat LLM and topic-modeling baselines may look competitive while leaving input tuples unassigned, whether because the model omits them or because a single prompt cannot hold the full inventory. Faithful review insight mining should therefore evaluate not only the displayed insights, but also the coverage and consistency of their supporting evidence.

Limitations

First, the main table is not input-controlled. GRAPHREDUCE and BERTopic are evaluated over the union of a product's gold-cluster member ids, while flat_llm and hier_agglom also receive the extracted tuples that gold leaves unassigned, so GRAPHREDUCE sees a strictly smaller and somewhat cleaner inventory (Section 4). Its coverage of 1.000 is therefore coverage of that inventory, and the cross-method recall gap should not be attributed to the projection head; the input-controlled evidence is the ablation in Table 7. Re-running every method through one harness is the first thing we would fix. Second, the product-level gold is LLM-assisted: Gemini participates in importance scoring and evaluation. We use held-out product splits to avoid train/test leakage, but human audits with inter-annotator agreement are needed before treating the benchmark as a human gold standard. Third, some evaluation axes remain limited. The large-N Fashion stress test covers only five products, does not include GRAPHREDUCE, and caps the single-prompt baseline at 400 tuples; Stage-1 extraction is fully evaluated only on Software; and the phrase-token matching metric may miss semantic equivalence or over-credit generic aliases. Broader human validation and semantic matching would make the evaluation more robust.

A Data Provenance, Models, and Privacy

Source data. All experiments use publicly released Amazon product reviews (Hou et al., 2026), restricted to three categories: Software, Fashion, and Baby Products. We use the dataset as distributed and do not collect any additional user data. The annotation pool contains 4,828 Software, 1,112 Fashion, and 8,090 Baby products; the main benchmarks use fixed 100-product held-out slices per category (Appendix C), and Stage-1 extraction is evaluated on 5,000 held-out Software reviews (Appendix B).

Component	Model	Role
Sentence encoder	BGE-small-en-v1.5	frozen embeddings
Stage-1 teacher	GPT-5.4	tuple annotation
Stage-1 student	Qwen3.5-9B	tuple extraction
Stage-1 judge	Gemini 2.5 Pro	quality scoring
Gold Layer-2	GPT-5.4	validate / rename
Gold Layer-3	Gemini 2.5 Pro	rank / audit
Reducer / ranker	Qwen3.5-9B (SFT)	name / rank clusters

Table 2: Models used in the pipeline and their roles. Membership accounting is deterministic and uses no LLM.

Privacy and anonymization. The source corpus is a public benchmark that is already de-identified at release: reviews are keyed by opaque, anonymized identifiers and contain no names, contact details, or account information beyond the public review text. We therefore introduce no additional personal data and perform no re-identification. We neither attempt to recover author identities nor link reviews to external profiles, and we release only aggregate, product-level insight clusters rather than user-level records. No new human data was collected for this work.

Models used and their roles. Our pipeline uses several models, each confined to a specific role (Table 2). Generic semantic representations come from a frozen BGE-small-en-v1.5 encoder (Xiao et al., 2024). Stage-1 tuple labels are produced by GPT-5.4 (`gpt-5.4-2026-03-05`), and extractor students are Qwen3.5-9B variants (Qwen Team, 2026) trained with SFT, DPO (Rafailov et al., 2023), and GRPO (Shao et al., 2024). Gemini 2.5 Pro serves as the Stage-1 quality judge and, in gold construction, as the Layer-3 importance ranker and member auditor (Appendix C). The same fine-tuned Qwen reducer is used for both cluster naming and final ranking at inference time. Crucially, membership accounting is deterministic and uses no LLM. As noted in the Limitations, Gemini participates in both gold construction and evaluation, which we treat as a limitation rather than an anti-circularity guarantee.

B Stage-1 Extraction Details

Setup. We sample product-keyed reviews from Amazon Software, Fashion, and Baby Products (Hou et al., 2026) and label per-review tuples with

GPT-5.4. We train Qwen3.5-9B (Qwen Team, 2026) variants with full-parameter SFT, DPO, and GRPO. The held-out Stage-1 evaluation set contains 5,000 Software reviews. Gemini 2.5 Pro judges five dimensions from 1 to 5: correctness, completeness, diversity, abstraction, and overall quality. We report the production quality rate overall ≥ 4.

Reward design. The dominant SFT failure is *slice copying*: the model places the verbatim evidence span in both *slice* and *insight*. The insight is then validly grounded but not abstracted. The per-tuple insight score starts at $+1$ and is clipped below at -2 after four penalties: -1.5 if the generated insight exactly equals the generated slice, -0.5 if the insight is a non-slice verbatim substring of the source review, -0.5 if the insight is not 1–3 words, and -0.7 if it is a vague single-token phrase such as "good". The second penalty targets non-slice verbatim copying from the review; it is not a penalty on the evidence slice itself. Auxiliary terms score aspect quality, slice validity, and sentiment/language membership. The final GRPO reward is a fixed weighted sum with the insight term carrying weight 5.0.

Extraction results. Table 3 reports the four-way comparison. The main movement is in abstraction, the dimension targeted by the anti-copy reward. Overall production quality rises from 59.3% for the base model to 93.1% after GRPO.

C Gold Construction and Leakage Controls

We construct product-level gold clusters in three layers. Layer 1 builds candidate clusters from BGE-small embeddings using the intersection of Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) (Campello et al., 2013) and agglomerative clustering, keeping a high-precision core. Layer 2 uses GPT-5.4 to validate members, rewrite canonical names, merge near-duplicates, and reassign orphans. Layer 3 uses Gemini 2.5 Pro to rank the resulting clusters with 1–5 importance scores and to audit a sample of member assignments.

The gold is used in three different ways: training PROJHEAD, synthesizing K-way reducer SFT examples, and evaluating held-out products. To avoid product-level leakage, all reported test products are excluded from both PROJHEAD training and reducer SFT. We do not describe this as a purely human gold standard: Gemini participates in both gold construction and evaluation, and we treat that dependency as a limitation rather than an anti-circularity guarantee.

The annotation pool contains 4,828 Software products, 1,112 Fashion products, and 8,090 Baby Products. The main reported benchmarks use fixed 100-product held-out slices per category, with a separate small large-N Fashion stress test.

D Projection-Head Training Details

PROJHEAD is a 384→256→128 MLP trained per category for 3 epochs with the information noise-contrastive estimation (InfoNCE) loss ($\tau = 0.07$). For each training product, we sample anchors from Layer-3 product clusters, choose positives from the same cluster, hard negatives from other clusters of the same product, and easy negatives from random products. The projection is small ($<$ 200K trainable parameters) and leaves the frozen BGE encoder unchanged. This lets the system adapt to product-review cluster boundaries without overwriting the broad-domain similarity prior.

The hard negatives are product-local by design. Across products, many phrases are trivially different because they refer to different items, brands, or domains; those negatives teach little about the boundary between two themes within the same product page. Within one product, however, lexically similar tuples such as *installation failure*, *device compatibility*, and *performance lag* often share the same app or product name. These are exactly the cases where raw BGE over-merges and where the projection head should reshape the space.

E K-way Reducer SFT Details

A first reducer checkpoint was trained on Layer-2 cleanup examples where each input was already one coherent cluster and the target was a single canonical phrase. Sampling 5,000 examples showed that 100% of targets were $K = 1$. The checkpoint therefore over-collapsed mixed-theme chunks.

We replace this with K-way SFT data synthesized from training products: for each product, sample $k_{\text{in}} \in \{2, 3, 5, 7, 10\}$ gold clusters, draw at most 200 tuples, shuffle them, and target the corresponding gold partition. For Software this yields 18,304 train and 956 validation examples. The same trained reducer is used for cluster naming

Model	overall≥4	overall	correctness	completeness	diversity	**abstraction**
base (Qwen3.5-9B)	59.3%	3.69	4.70	4.69	4.79	3.40
SFT (190K teacher labels)	88.7%	4.52	4.80	4.78	4.89	4.49
DPO (chosen=teacher/rej=SFT)	90.8%	4.62	4.85	4.80	4.94	4.64
GRPO (anti-copy)	**93.1%**	**4.71**	4.85	4.82	4.95	**4.78**

Table 3: Stage-1 extraction quality on 5,000 held-out Software reviews, judged by Gemini 2.5 Pro.

and final ranking.

This data format matches the reducer's inference-time role. A reducer call may receive a pure cluster or a mixed chunk produced by an imperfect spectral partition, so the target must teach both naming and controlled splitting. In contrast, the earlier $K = 1$ cleanup data taught the model that every input should collapse to one phrase. The K-way data fixes that supervision mismatch without changing the inference algorithm.

F Evaluation Protocol Details

Why coverage is reported separately. The task has two different desiderata that can conflict. NDCG rewards a system for naming the most important gold themes near the top of the list, but it does not check whether all input evidence was assigned to some output cluster. A flat LLM can therefore obtain a strong NDCG by selectively naming head themes and omitting low-confidence member ids. This behavior is useful to measure rather than hide: for shopper-facing copy it may be acceptable, but for product analytics, debugging, and trust-and-safety audits the system must account for the full evidence inventory. We therefore treat coverage and duplicate member assignments as first-class metrics rather than implementation details.

Matching predicted and gold clusters. We match predicted canonical names to gold names only after the model has produced its full top-K list. Matching is one-to-one and greedy by phrase-token overlap, so duplicate aliases do not receive repeated credit. This deliberately conservative protocol penalizes two common mistakes: generic cluster names that cover many different gold themes, and repeated names assigned to distinct member sets. The protocol is still imperfect, because two semantically equivalent names can have low token overlap; we discuss this in the Limitations section.

Two tuple inventories. The reported runs use two harnesses that build a product's inventory differently. GRAPHREDUCE and BERTopic take the union of the member_row_ids of the product's layer-3 gold clusters. flat_llm, hier_agglom and embed_cluster take the candidate-cluster file, which is that union plus the extracted tuples that gold assigns to no cluster. The first set is a strict subset of the second on all 300 reported products, and is smaller by 19.0 (Software), 20.0 (Fashion) and 12.4 (Baby) tuples per product on average. Every coverage figure is relative to the inventory that run received, so coverage is comparable within a harness but not across the two. The large-N stress test (Appendix G) is internally consistent: all five rows use the second inventory.

Strategy	recall	prec	NDCG	**cov**	**dup**
flat_llm	0.480	0.491	0.481	0.228	10
batch_direct	0.380	0.380	0.478	0.490	1
embed_cluster_llm	0.400	0.400	**0.486**	0.977	0
embed_cluster	0.340	0.340	0.394	1.000	0
hier_agglom (BGE raw)	0.360	0.360	0.475	**1.000**	**0**

Table 4: Large-N Fashion stress test (5 products, $N \approx 1{,}500$, all metrics @10). All five rows run on the same inventory. The flat LLM keeps plausible head themes but is capped at a 400-tuple prompt, so its 0.228 coverage reflects that budget rather than a long-context failure. GRAPHREDUCE itself was not run at this scale; the hierarchical row uses raw BGE embeddings without PROJHEAD.

Split discipline. All Stage-2 test products are held out before training either the projection head or the reducer. This is stricter than tuple-level splitting: the model cannot see other tuples from the same product during training and then be evaluated on a held-out subset of that product.

G Large-N Stress Test

Table 4 reports the full large-N Fashion stress test referenced in Section 4.

H Significance and Cost

Significance. Table 5 gives paired tests for GRAPHREDUCE vs. hier_agglom over the n=100 products each category shares. As noted in Sec-

Category	Metric	Δ (95% CI)	Wilcoxon
Software	recall@10	+0.034 [+0.006, +0.062]	p=0.015 *
	NDCG@10	+0.020 [−0.005, +0.045]	p=0.16 ns
Fashion	recall@10	+0.034 [+0.009, +0.059]	p=0.0096 **
	NDCG@10	+0.020 [−0.005, +0.045]	p=0.29 ns
Baby	recall@10	+0.056 [+0.023, +0.090]	p=0.005 **
	NDCG@10	+0.017 [−0.016, +0.052]	p=0.30 ns

Table 5: Paired tests of GRAPHREDUCE vs. hier_agglom (n=100 products/category). The two systems run on different tuple inventories, so these are not input-controlled; recall differences clear the bootstrap interval, NDCG differences do not.

tion 4 the two systems do not receive the same tuple inventory, so these tests describe the two pipelines as run and are not a controlled test of the projection head; we report them for transparency rather than as the paper's evidence. We report the mean per-product metric difference, a 95% confidence interval from a deterministic 10,000-sample paired bootstrap, and a two-sided Wilcoxon signed-rank p-value. The recall@10 gain is significant in all three categories with CIs that exclude zero; the NDCG@10 gain is positive everywhere but its CI includes zero, so we report NDCG parity rather than improvement.

Cost and latency. Table 6 reports per-product LLM calls and wall-clock latency (median and 90th percentile). Although GRAPHREDUCE issues 10–11 reducer calls versus the flat LLM's single call, its median latency is comparable to or below flat prompting and below hier_agglom, because each call operates on a bounded chunk ($\leq B$=200 tuples) rather than one prompt over all N tuples. BERTopic is by far the cheapest (no LLM calls, sub-second after a one-time UMAP/HDBSCAN warm-up) but, as Table 1 shows, only by dropping 11.7–39.9% of the tuple inventory. Complete coverage therefore costs little wall-clock time relative to the flat baseline, although GRAPHREDUCE is slightly slower at p90 on Fashion.

I Full Ablation Results

Table 7 isolates the aggregation components on a 30-product development split of the Software category. The trained projection head and the chunk-plus-rank pipeline are both necessary. We call the learned soft-clustering negative baseline GraphPool; it uses a GraphSAGE encoder (Hamilton et al., 2017) and Gumbel-Softmax straight-through assignments (Jang et al., 2016). Training GraphPool with GRPO under a local reward hurts NDCG.

Category	Strategy	calls	med. (s)	p90 (s)
Software	flat_llm	1.0	13.4	21.0
	BERTopic	0.0	0.2	0.3
	hier_agglom	10.0	16.4	21.7
	GRAPHREDUCE	11.0	14.8	19.5
Fashion	flat_llm	1.0	27.2	37.8
	BERTopic	0.0	0.6	1.1
	hier_agglom	10.0	27.9	39.5
	GRAPHREDUCE	11.0	26.8	40.1
Baby	flat_llm	1.0	21.9	34.5
	BERTopic	0.0	0.1	0.2
	hier_agglom	10.0	29.2	37.8
	GRAPHREDUCE	10.6	26.7	32.8

Table 6: Per-product cost and latency. GRAPHREDUCE's many small reducer calls match or beat the single-call flat LLM in wall-clock time.

The negative result is important for the final system design. The local GraphPool reward combined coverage, balance, phrase distinctness, and phrase quality, but it was not aligned with NDCG@10. During GRPO, training reward rose while NDCG drifted down. We therefore keep the contrastive projection and remove the differentiable clustering head.

J Qualitative Analysis

Table 8 shows one Software product. The example is not presented as a win on every gold phrase: GRAPHREDUCE recovers *device compatibility* and a more specific gameplay phrase, but it still misses the gold's fine-grained *blue crystal inaccessible* wording. This illustrates the measured pattern: the method improves recall and coverage over raw embeddings, while phrase aliasing remains a source of NDCG loss.

Our manual error analysis of low-NDCG GRAPHREDUCE predictions finds four recurring issues: reducer phrase aliasing, long-tail themes competing with head themes, spectral over-merge at very small N, and incorrect cluster names despite correct member sets. The first issue is the most common: two semantically distinct clusters can receive the same generic name, such as *app crashes*. This hurts phrase-match NDCG even when the underlying member partition is reasonable.

K Extended Discussion

Why the projection helps. Raw BGE embeddings are strong but generic. In our products they often place device compatibility, installation, and performance tuples near one another because the same product names appear in all three. The projec-

Configuration	recall@10	prec@10	NDCG@10	cov
BGE raw + sklearn agglom + size rank	0.595	0.507	0.651	0.947
BGE raw + chunk + spectral + LLM rank	0.589	0.503	0.680	1.000
+PROJHEAD (Layer-2 pairs) + sklearn	0.533	0.522	0.606	1.000
+PROJHEAD (Layer-2 pairs) + chunk+rank	0.632	0.533	0.686	1.000
+PROJHEAD (Layer-3 train pairs) + sklearn	0.529	0.532	0.602	1.000
+PROJHEAD (Layer-3 train pairs) + chunk+rank	**0.652**	**0.550**	**0.700**	**1.000**
Projection dimension sweep, full pipeline				
$d = 64$	0.622	0.527	0.678	1.000
$d = 128$	**0.652**	**0.550**	**0.700**	**1.000**
$d = 256$	0.628	0.533	0.680	1.000
Training length sweep				
epochs $= 3$	0.652	0.550	0.700	1.000
epochs $= 5$ (union L2+L3 pairs)	0.618	0.523	0.676	1.000
epochs $= 10$	0.609	0.507	0.664	1.000
Negative: GraphPool (GraphSAGE)	0.460	0.390	0.518	1.000
Negative: GraphPool + GRPO	0.478	0.404	0.537	1.000

Table 7: Ablations on the 30-product Software development split. A small learned projection helps; a learned soft-clustering head trained with a local reward does not.

Method	Top-3 themes (asin B008BBB388)
flat_llm	paid app, app crashes, gameplay
hier_agglom	gameplay, inaccessible items, app crashes
GRAPHREDUCE	**hidden object gameplay, device compatibility, paid app**
Gold top-3	progression blocker, device compatibility, blue crystal inaccessible

Table 8: Example top-3 cluster names for one Software product ($N = 57$ tuples, 12 gold clusters).

tion head is trained on product-level cluster boundaries, so it can separate themes that are lexically similar but operationally different for shoppers.

Three recurring examples drive the gain. First, compatibility complaints often mention the same device names as installation complaints, even though shoppers treat them as different purchase risks. Second, paid-app frustration and in-app-purchase frustration share many tokens but map to different gold clusters. Third, generic predicates such as "works" or "can't open" dominate raw sentence similarity even when the theme-bearing noun phrase differs. The projection head does not need to learn review language from scratch; it only needs to rotate the frozen embedding space toward these product-level boundaries.

Why flat LLMs can win NDCG. Phrase-level NDCG rewards matching high-importance gold themes. A flat LLM can implicitly focus on those head themes and omit lower-confidence member assignments. GRAPHREDUCE must assign every tuple to one of the output clusters, including long-tail evidence. This makes coverage and recall necessary companion metrics to NDCG.

Where the method breaks. The current fixed $k = 20$ graph can be too dense for products with $N < 40$, and large clusters in Fashion sometimes absorb finer themes such as *high waist* and *tummy control* into a broad *good fit* phrase. Adaptive graph degree and a diversity-aware ranking objective are natural next steps.

The other recurring issue is phrase aliasing. Two clusters can have reasonable member sets but receive the same generic name from the reducer, such as *app crashes*. This hurts NDCG because only one alias can match the corresponding gold theme, and it weakens the shopper-facing output because the top-K list becomes less diverse. A future reducer should condition on already selected names or use a lightweight diversity penalty at ranking time.

Intent-Driven Generative Query Suggestion with Query-Level Credit Assignment

Abstract

Generative query suggestion aims to enhance user engagement by anticipating user intents and recommending relevant follow-up queries. A central challenge is to generate slates whose individual queries are useful while the slate covers distinct intents. We propose an Intent-Driven Query Suggestion Framework with dual-stage optimization. First, *intent-aware diversity modeling* constructs intent-aligned supervised fine-tuning (SFT) data and uses an Intent-Aware Diversity Reward to optimize intent coverage. Second, *query-level credit assignment* routes individual quality signals to the corresponding query tokens while sharing a slate-level diversity signal across the slate. Experiments on a large-scale production dataset, including online A/B testing and offline evaluation, show improvements in click-through rate, query quality, and intent coverage.

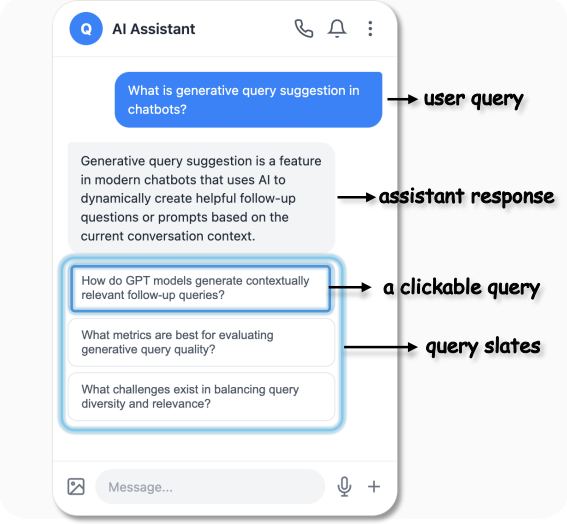

Figure 1: Example of conversational query suggestion, where the AI Assistant recommends diverse follow-up queries to enhance user engagement.

1 Introduction

The rise of conversational AI assistants (Achiam et al., 2023) has fundamentally transformed how users access information and accomplish tasks. Recent work studies multimodal, click-guided, and preference-aligned query suggestion for conversational systems (Wang et al., 2024; Min et al., 2025; Yin et al., 2025). Figure 1 shows an example of conversational query suggestion, where diverse follow-up queries are recommended to enhance user engagement.

Recent advances (Lin et al., 2023; Bao et al., 2023) in generative query suggestion employ large language models (LLMs) to synthesize queries directly from conversational context. While generative query suggestion offers greater flexibility than retrieval-based methods, it requires dual optimization: query slates must be diverse to cover the breadth of potential user follow-up interests, while each individual query must remain contextually relevant to the conversation history, accurately capturing the user's underlying intent.

However, jointly optimizing these objectives presents two challenges. **L1) Intent-aware diversity optimization.** Semantic diversification through embedding similarity and post-hoc reranking is well established, but such methods do not necessarily optimize context-dependent coverage of distinct user intents during policy training. For instance, "How to learn Python" and "Python tutorials" are lexically distinct but express the same learning intent. We therefore model diversity as coverage over orthogonal intent dimensions rather than textual variation alone. **L2) Within-slate credit**

assignment. Min et al. (2025) and Yin et al. (2025) align query suggestions with click- or preference-based objectives. Our method instead explicitly applies query-specific quality advantages only to the corresponding query tokens while sharing a slate-level intent-coverage advantage across the slate. This decomposition identifies each query's contribution within an autoregressively generated slate.

To address these challenges, we propose an **Intent-Driven Query Suggestion Framework** with dual-stage optimization for conversational AI assistants. To address L1, we introduce **intent-aware diversity modeling** in semantic intent space. During SFT, we construct a cold-start data pipeline based on user-initiative alignment. During reinforcement learning (RL), an Intent-Aware Diversity Reward (IAD-R) captures intent coverage through Noisy-OR aggregation. To address L2, we devise a **query-level credit assignment mechanism**: query-quality advantages are applied only to the corresponding query tokens, whereas a slate-level diversity advantage is shared across all queries. Their composite enables fine-grained optimization of individual quality while maintaining overall slate diversity.

We validate the framework through industrial online A/B testing and human evaluation. Its distinguishing feature is the combination of query-specific token-level advantages and a shared slate-level intent-coverage advantage in a single policy update.

2 Related Work

Generative Query Suggestion Large Language Models (LLMs) have been widely used to generate diverse and context-aware query suggestions (Di Palma, 2023). Diversification can be imposed through decoding constraints (Deng et al., 2025; Guo et al., 2025), embedding-based reranking (Bacciu et al., 2024), or preference alignment. Min et al. (2025) combine multi-source CTR modeling, diversity-aware CTR-weighted DPO, and iterative CTR calibration; Yin et al. (2025) introduce uncertainty-aware preference modeling, out-of-distribution regularization, and multi-stage alignment. These systems align suggestions with clicks or preferences. Our focus instead is the granularity of credit within a generated slate: query-specific quality advantages are routed only to the corresponding tokens, while intent coverage supplies a shared slate-level advantage. Inspired by exposure modeling in recommender systems (Yin et al., 2025; Min et al., 2025; Chen et al., 2025), we view each generated query as activating a user intent and optimize intent-space coverage directly.

Credit Assignment and Slate Optimization in RL Reinforcement Learning (RL) is commonly used to align generative models with human preferences (Rafailov et al., 2023; Ouyang et al., 2022), but slate-level rewards often lead to ambiguous credit assignment (Yin et al., 2025). Prior studies address this with process reward modeling at the token or step level (Yue et al., 2025; Xiong et al., 2025; Cui et al., 2025). SlateQ (Ie et al., 2019) decomposes slate Q-values into item-level scores over a fixed candidate pool, while our setting constructs slates autoregressively and optimizes them with policy gradients. We therefore introduce query-level credit assignment, which distributes slate rewards into per-query advantages and combines them with intent-aware diversity rewards.

3 Methodology

We formalize conversational query suggestion as a slate generation task (§3.1) that jointly optimizes query-level quality and slate-level diversity. As illustrated in Figure 2, our framework consists of two stages: (1) a cold-start supervised fine-tuning stage (§3.2) that constructs high-quality training data through LLM generation and human-AI collaboration, and (2) a reinforcement learning stage (§3.3) that optimizes intent-aware diversity and query-level credit assignment.

3.1 Problem Formulation

We formulate conversational query suggestion as a conditional generation task. Given context $\mathcal{X} = \{q_u, r, h\}$, where q_u denotes the current user query, r the assistant response, and h the conversation history, the model generates a slate of K candidate queries:

$$\mathcal{S} = \{q_1, \ldots, q_K\} \sim \pi_\theta(\cdot \mid \mathcal{X}) \tag{1}$$

where π_θ represents the policy model parameterized by θ. The objective is to jointly optimize individual query quality and slate-level diversity.

3.2 Cold-Start SFT

To address the data quality and diversity bottleneck in the SFT, we design a two-stage data construction pipeline coupled with a hybrid training strategy.

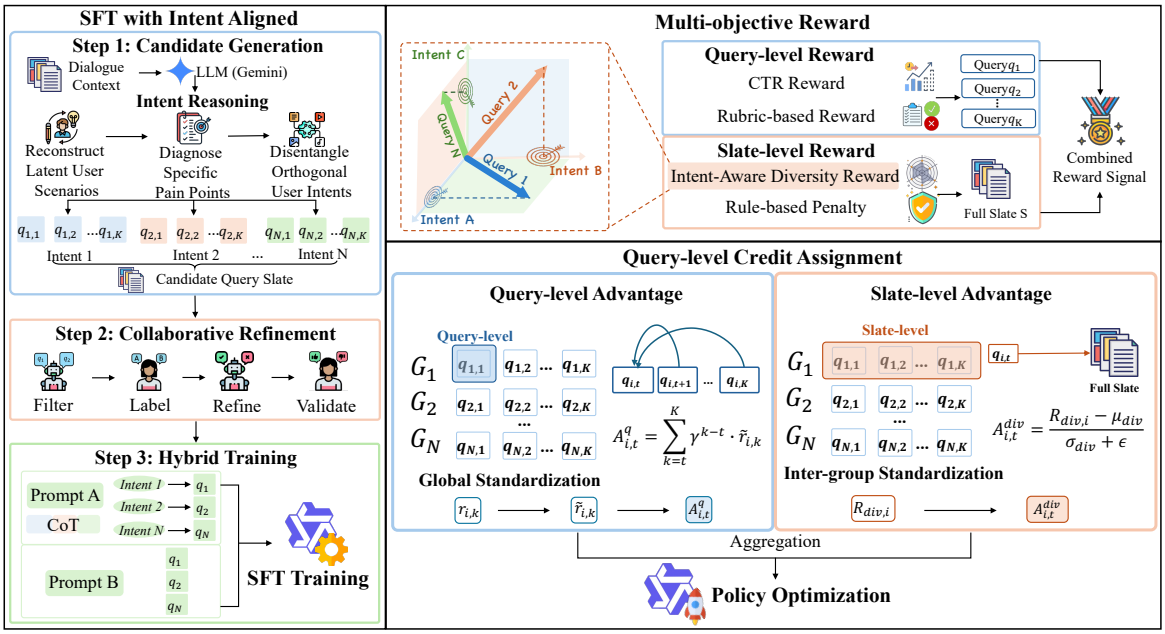

Figure 2: Overview of our framework. Left: Cold-Start SFT stage with LLM generation, human-AI collaboration and hybrid CoT training. Right: RL stage with multi-objective reward and query-level credit assignment.

Step 1: Candidate Generation. We leverage LLMs to perform multi-dimensional intent analysis on dialogue context, decomposing user needs into orthogonal intent dimensions through scenario reconstruction and pain point diagnosis. For each identified intent, we generate a diverse set of candidate queries that address distinct user information needs.

Step 2: Collaborative Refinement. We adopt a multi-stage human-AI collaboration pipeline to ensure data quality. The LLM first filters the optimal query for each intent dimension. Human annotators and an LLM-based evaluator then iteratively label and cross-validate the samples, with disagreements surfaced for re-adjudication to reduce subjective variability. This process ensures both scalability and high annotation quality. Detailed annotation protocols, qualification criteria, and quality control procedures are provided in Appendix C.

Step 3: Hybrid Training. To balance inference efficiency with reasoning capability, we construct a hybrid instruction dataset containing both Direct Query Generation and Intent-Aware Chain-of-Thought (CoT) samples. Each generation mode is guided by task-specific system prompts (representative excerpts appear in Appendix Figures 4 and 5). This hybrid approach enables the model to capture complex intent reasoning patterns while maintaining real-time generation throughput.

3.3 Reinforcement Learning

3.3.1 Multi-Objective Reward

CTR Reward To align suggestions with user preferences, we employ a lightweight BERT-based CTR model trained on historical click logs. Given conversational context $\mathcal{X}^{(\tau)} = \{q_u^{(\tau)}, r^{(\tau)}, h^{(\tau)}\}$ and candidate query q_i, the model predicts click probability:

$$R_{\text{CTR}}(q_i, \mathcal{X}^{(\tau)}) = \hat{p}(q_i \mid \mathcal{X}^{(\tau)}) \in [0, 1] \quad (2)$$

This reward guides the policy toward generating user-preferred suggestions.

Rubric-based Reward To prevent reward models from exploiting surface-level patterns, we introduce *Rubric-based Rewards* following (Ye et al., 2023; Liu et al., 2023). We employ an LLM to assess whether each query satisfies expert-curated quality rubrics (summarized in Appendix Figure 6). Given query q and rubrics $\mathcal{R} = \{r_1, \ldots, r_n\}$, the reward uses an all-pass criterion:

$$R_{\text{rubrics}}(q) = \begin{cases} 1, & \text{if } \forall i,\ r_i(q) = 1 \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

where $r_i(q) \in \{0, 1\}$ indicates whether query q satisfies the i-th rubric. During RL training, Qwen-Max produces this rubric-based reward using the rubric structure summarized in Appendix Figure 6.

Rule-based Penalty We impose rule-based constraints $R_{\text{rule}}(\hat{\mathcal{Q}}^{(t)}_{(\tau)})$ to ensure quality and prevent degenerate outputs: (1) redundancy penalty based on Jaccard similarity, (2) length penalty, and (3) format compliance penalty.

Intent-Aware Diversity Reward In deployed generative query suggestion, commonly used surface deduplication and post-hoc reranking do not explicitly optimize context-dependent intent coverage during training.

Given conversation history $h^{(\tau)}$, we leverage an LLM to infer M orthogonal user intents $\mathcal{Z} = \{z_1, \ldots, z_M\}$ during offline construction, verified by human annotators. We adopt a Noisy-OR model (Pearl, 1988) to measure slate $\mathcal{S}$'s coverage over the intent space. For intent z_m, the coverage probability represents the likelihood that at least one query in the slate activates this intent:

$$P_{\text{cov}}(z_m \mid \mathcal{S}) = 1 - \prod_{q_k \in \mathcal{S}} \left(1 - \sigma\left(\text{sim}(q_k, z_m)\right)\right) \tag{4}$$

where $\text{sim}(q_k, z_m) = \frac{\phi(q_k)^\top \phi(z_m)}{\|\phi(q_k)\|_2 \|\phi(z_m)\|_2}$ is the cosine similarity between query and intent embeddings from Sentence-BERT (Reimers and Gurevych, 2019), and $\sigma(\cdot)$ is the sigmoid function. The Intent-Aware Diversity Reward (IAD-R) averages coverage across all intents:

$$R_{\text{div}}(\mathcal{S}) = \frac{1}{M} \sum_{m=1}^{M} P_{\text{cov}}(z_m \mid \mathcal{S}) \tag{5}$$

We employ uniform weighting to ensure unbiased intent coverage. This prevents the model from prioritizing dominant intents at the expense of long-tail scenarios.

3.3.2 Query-level Credit Assignment

Our query-level credit assignment mechanism includes query-level quality advantages and slate-level diversity advantages.

Query-level Advantage Calculation For G query slates $\{y_i\}_{i=1}^{G}$ sampled from policy π_θ, where each slate consists of K queries, we compute the query-level reward for the k-th query in the i-th slate as a weighted combination of rubric-based and CTR rewards:

$$r_{i,k} = \alpha \cdot \mathcal{R}_{\text{rubrics}}(q_{i,k}) + \beta \cdot \mathcal{R}_{\text{CTR}}(q_{i,k}) \tag{6}$$

Here, $\alpha = 0.6$ weights rubric compliance and $\beta = 0.4$ weights predicted CTR. The aggregated query-level reward ensures that the generated queries maintain semantic compliance and quality stability while maximizing actual click-through conversion efficiency.

In contrast to GRPO's group-level normalization over sequence returns, we perform query-level advantage estimation by globally normalizing rewards across all $G \times K$ queries:

$$\tilde{r}_{i,k} = \frac{r_{i,k} - \mu_r}{\sigma_r + \epsilon} \tag{7}$$

where μ_r and σ_r denote the mean and standard deviation computed over all sampled query rewards. To account for the sequential dependency between queries, we introduce a discount factor $\gamma \in [0, 1]$ and compute the advantage for the t-th query as:

$$A^{\text{q}}_{i,t} = \sum_{k=t}^{K} \gamma^{k-t} \cdot \tilde{r}_{i,k} \tag{8}$$

This formulation values each query by both its immediate reward and its impact on subsequent generations, encouraging coherent and high-quality query sequences.

Slate-level Diversity Advantage To encourage diverse query lists, we introduce slate-level diversity advantages. As diversity is a collective property, we normalize the diversity reward $R_{\text{div},i}$ within the group:

$$A^{\text{div}}_{i,t} = \frac{R_{\text{div},i} - \mu_{\text{div}}}{\sigma_{\text{div}} + \epsilon}, \quad \forall t \in \{1, \ldots, K\} \tag{9}$$

where $\mu_{\text{div}}, \sigma_{\text{div}}$ are computed over $\{R_{\text{div},j}\}_{j \in G}$. This advantage is uniformly assigned to all queries, encouraging complementary suggestions.

Advantage Aggregation and Policy Optimization We combine query quality and slate diversity through a composite advantage with rule-based gating:

$$A_{i,t} = \begin{cases} \frac{A^{\text{q}}_{i,t} + A^{\text{div}}_{i,t}}{\sqrt{2}}, & \text{if Rule}(y_i) = \text{Pass} \\ -1, & \text{if Rule}(y_i) = \text{Fail} \end{cases} \tag{10}$$

where quality and diversity advantages are equally weighted and normalized. Slates violating critical constraints receive -1 penalty, combining learned and rule-based rewards.

Following GRPO, we optimize token-level generation probabilities using query-level advantages. To bridge this granularity gap, we uniformly broadcast each query-level advantage to all its tokens:

$$A^{\text{tok}}_j = A_{i,t}, \quad \forall u_j \in \text{tokens}(q_{i,t}) \tag{11}$$

Method	CTR Gain (%) ↑	GSB vs. base ↑	LLM Critic ↑	Self-BLEU ↓	Intent Cov. ↑
PE-based	+0	+0	0.33	0.0656	0.27
SFT-cold start	+27.06	+0.16	0.67	0.0609	0.54
PPO	+35.29	+0.31	0.71	0.0571	0.69
GRPO	+43.53	+0.37	0.83	0.0474	0.85
RL-Ours	**+48.24**	**+0.44**	**0.88**	**0.0470**	**0.91**

Table 1: Main results. CTR reports relative gains over the PE-based arm; GSB is relative to PE-based outputs. Bold indicates the best result.

The policy is then optimized via the clipped surrogate objective:

$$\mathcal{L}(\theta) = -\mathbb{E}_{y\sim\pi_\theta(\cdot|x)}\Bigg[\sum_j \min\Big(\rho_j A_j^{\text{tok}}, \bar{\rho}_j A_j^{\text{tok}}\Big) - \lambda_{\text{KL}} D_{\text{KL}}(\pi_\theta \| \pi_{\text{ref}})\Bigg]. \quad (12)$$

where $\rho_j = \pi_\theta(u_j|u_{<j})/\pi_{\text{ref}}(u_j|u_{<j})$ is the probability ratio, $\bar{\rho}_j = \text{clip}(\rho_j, 1-\epsilon, 1+\epsilon)$, and λ_{KL} is the KL coefficient. The clipping mechanism prevents large policy updates, while the KL penalty ensures training stability.

4 Experiments

4.1 Experimental Setup

We evaluate on a large-scale production system using anonymized real-world interactions. We use Qwen3-30B-A3B (Yang et al., 2025) as the foundation model (training details in Appendix D).

Training Datasets. We collect data from real user logs of a large-scale conversational AI assistant. For SFT, we construct 15,000 instances from 4 weeks of conversations using the pipeline in §3.2, mixing 20% intent-augmented CoT samples with 80% direct generation samples. For RL, we sample 12,000 instances from an additional 2 weeks, annotated with intents for IAD-R.

Test Datasets. We construct two expert-validated test sets spanning diverse user scenarios. The *Offline Evaluation Set* contains 500 contexts for automatic metrics. The *Human Evaluation Set* contains 150 representative contexts for measuring generation quality and diversity.

Online Metrics. To assess real-world efficacy, we conducted a one-week A/B test on live traffic. The core metric is *Click-Through Rate* (CTR), which measures interaction with the suggestion slate within a single turn. The five systems ran concurrently in mutually exclusive, randomly assigned user-level buckets. Traffic allocation for PE-based/SFT/PPO/GRPO/RL-Ours was 5/80/5/5/5%; SFT was the incumbent production arm, while Table 1 reports CTR gains relative to the PE-based arm. We use two-proportion z-tests on unrounded arm-level CTRs. Exact traffic counts and absolute CTR values are commercially sensitive.

Offline Metrics. We evaluate query quality with: (1) *Good-Same-Bad* (GSB), a pairwise side-by-side human evaluation across content quality, text quality, intent relevance, and information gain (Table 9), yielding $(\#\text{Good} - \#\text{Bad})/N$; and (2) *LLM Critic*, an ensemble of Gemini-3, Claude-4.5, and Qwen-Max that reports the majority-voted checklist pass rate (Figure 6). Thus, no single Qwen-family evaluator determines this metric. For slate diversity, we use: (1) *Self-BLEU* (Yin et al., 2025; Min et al., 2025), the average pairwise similarity within each slate; and (2) *Intent Coverage*, the recall of separately annotated test intents, where three annotators independently label intent matches for each query and majority voting determines the final label.

Intent Coverage targets the same property as IAD-R, and LLM Critic uses the same rubric family as the training reward. We therefore treat both as target-aligned diagnostics rather than fully independent evidence. Neither evaluation directly reuses stored training-time reward outputs: evaluation coverage uses discrete human matching against separately annotated test intents instead of Sentence-BERT similarity and Noisy-OR aggregation, while LLM Critic recomputes judgments on held-out contexts using the three-model ensemble. Because Qwen-Max participates in both training and the evaluation ensemble, online CTR and human GSB serve as the primary independent evidence.

4.2 Overall Results and Analysis

Table 1 compares our RL framework with the production and policy-optimization baselines. Scalability to Qwen3-235B-A22B is evaluated in Appendix B.

SFT Establishes a Strong Foundation. Starting from the PE-based prompt engineering baseline, supervised fine-tuning on user interaction data

Method	LLM Critic ↑	Self-BLEU ↓	Intent Cov. ↑
DPO	0.63	0.0723	0.55
CTR-weighted DPO	0.69	0.0714	0.49
GRPO	0.83	0.0474	0.85
RL-Ours	**0.88**	**0.0470**	**0.91**

Table 2: Controlled offline optimization comparison. The DPO variants use the same SFT initialization, training data, slate size, decoding settings, and evaluation budget. CTR-weighted DPO is inspired by Min et al. (2025), not a full reproduction.

improves all five metrics. As shown in Table 1, the SFT-cold start strategy achieves a +27.06% CTR improvement, a GSB score of +0.16, and an LLM Critic score of 0.67. These results support the value of learning from real user interactions beyond prompt engineering.

RL Methods Improve Performance. We explore PPO and GRPO using the same reward signals as our method. PPO increases the PE-relative CTR gain to +35.29%. GRPO reaches +43.53% CTR gain, +0.37 GSB, and 0.83 LLM Critic. Relative to the incumbent SFT arm, GRPO improves CTR by 13.0% ($p = 0.006$).

Query-level Credit Assignment Achieves the Best Results. Our method attains the highest PE-relative CTR gain (+48.24%). The 4.71 difference from GRPO is measured in percentage points of PE-relative gain; the direct comparison is a 3.25% relative CTR improvement ($p = 0.02$). RL-Ours also improves CTR over the incumbent SFT arm by 16.7% ($p = 0.003$). On the common 150-context paired evaluation subset, two-sided paired t-tests comparing RL-Ours with GRPO give GSB +0.07 ($p = 0.03$), Intent Coverage +0.06 ($p = 0.002$), and LLM Critic +0.05 ($p = 0.05$). Self-BLEU changes from 0.0474 to 0.0470, whereas Intent Coverage increases from 0.85 to 0.91. Because Intent Coverage and LLM Critic are aligned with their corresponding training objectives, CTR and human GSB are the primary independent evidence for the improvement.

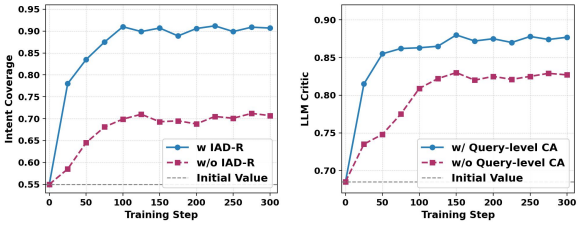
Table 2 adds standard DPO (Rafailov et al., 2023) and a CTR-weighted DPO baseline. Both underperform GRPO and RL-Ours on the three available offline metrics. The CTR-weighted variant improves LLM Critic and Self-BLEU over standard DPO but reduces Intent Coverage, suggesting that pairwise click-weighted optimization does not directly capture slate-level intent coverage. We do not report online CTR or human GSB for these additional runs. Yin et al. (2025) cannot be reproduced in full because its reward models, data, and training components are unavailable; the conceptual comparison appears in Section 2.

Method	GSB vs. base	LLM Critic	Self-BLEU	Intent Cov.
PE-based	+0	0.33	0.0656	0.27
SFT-Candidate	+0.05	0.41	0.0631	0.28
SFT-Refined	+0.13	0.59	0.0617	0.42
SFT-Hybrid	**+0.16**	**0.67**	**0.0609**	**0.54**

Table 3: Ablation study on data pipeline stages. Self-BLEU ↓, other metrics ↑.

Method	ΔGSB vs. RL-Ours	LLM Critic	Self-BLEU	Intent Cov.
RL-Ours	**0.00**	**0.88**	**0.0470**	**0.91**
w/o IAD-R	−0.12	0.83	0.0461	0.71
w/o Rubric	−0.09	0.62	0.0496	0.86
w/o CTR	−0.11	0.76	0.0486	0.89
w/o query-level	−0.07	0.83	0.0474	0.85

Table 4: Ablation on RL components. GSB is measured relative to RL-Ours; the other columns report absolute values. "query-level" refers to query-level credit assignment. Self-BLEU ↓, other metrics ↑.



4.3 Ablation Studies

Ablation Study on SFT Data. To validate our data construction pipeline (Section 3.2), we conduct an ablation study using different data sources: *PE-based* uses only prompt engineering without fine-tuning, *SFT-Candidate* trains on LLM-generated candidates (Stage 1), *SFT-Refined* trains on human-AI collaborative refined queries (Stage 2), and *SFT-Hybrid* trains on the full pipeline with mixed CoT traces and queries (Stage 3).

Table 3 shows progressive improvements across pipeline stages. Relative to SFT-Candidate, SFT-Refined improves GSB by 0.08 and Intent Coverage by 0.14, supporting the value of human-AI refinement. SFT-Hybrid adds a further 0.12 in Intent Coverage, suggesting that mixing CoT traces with direct queries helps the model learn intent-aware generation. We adopt SFT-Hybrid as the cold-start model for RL training.

Ablation Study on RL Components. We systematically remove key components from our RL framework to validate their individual contributions. Table 4 presents the final performance, while Figure 3 illustrates the training dynamics to provide deeper insights into how these components affect the learning process.

Removing diversity reward causes the largest Intent Coverage drop, decreasing from 0.91 to 0.71. Figure 3(a) shows models with this reward converge faster and to a higher plateau, reaching 0.91 by step 100, whereas the ablated variant continues to improve gradually, only approaching 0.71 by step 125. Both quality reward components prove

(a) IAD-R (b) Query-level CA

Figure 3: Training dynamics of ablated components. (a) IAD-R impact on Intent Coverage. (b) Query-level credit assignment on LLM Critic.

essential. Without rubric-based reward, the LLM Critic score drops from 0.88 to 0.62, showing its role in maintaining generation quality. Similarly, removing CTR reward decreases GSB by 0.11, suggesting that engagement signals effectively guide the model toward user-preferred queries.

Query-level credit assignment also outperforms the sequence-level baseline. Figure 3(b) demonstrates consistent advantages throughout training. As early as step 50, our method achieves an LLM Critic score of approximately 0.86 compared to 0.75 for the baseline, maintaining a consistent gap through convergence with final scores of 0.88 and 0.83 respectively. This result supports the conclusion that assigning rewards at the query level rather than the sequence level enables more effective optimization by providing precise feedback for each individual query.

5 Conclusion

We propose an intent-driven framework that jointly optimizes query quality and slate diversity through dual-stage optimization. The online and offline results show that query-level credit assignment improves engagement and human-evaluated quality while intent-aware training increases semantic coverage. Future work will explore personalization and multimodal query generation.

Limitations

This work has several limitations. First, our training and online evaluation are based on anonymized production logs from a deployed conversational assistant; although this setting provides realistic feedback, the proprietary nature of the data limits its direct reproducibility. We therefore report detailed data construction and evaluation protocols and plan to release a sanitized evaluation subset when compliance permits. Second, online CTR is an engagement proxy rather than a direct measure of user satisfaction or task success. We interpret it together with offline human evaluation, and future work should incorporate richer satisfaction and task-completion signals. The online analysis reports significance from a single one-week experiment but does not report confidence intervals or repeated-window variance. Third, Intent Coverage targets the same property as IAD-R, and LLM Critic uses the same rubric family as the training reward; Qwen-Max also participates in both training and the evaluation ensemble. The metrics do not reuse stored training-time reward outputs, but they are not fully independent evidence, so our main conclusions foreground online CTR and human GSB. Fourth, our evaluation uses independent annotations and majority voting but does not report a chance-corrected inter-annotator agreement statistic. Our intent-aware diversity reward also relies on LLM-assisted intent construction and human validation; remaining annotation noise or intent granularity mismatch may affect coverage estimation. Repeated full-scale RL runs and a complete sweep over the quality–diversity weights are computationally prohibitive, so we report evaluation-sample significance tests and only a targeted discount-factor sensitivity study. We also do not measure whether broader intent coverage improves multi-turn engagement conditioned on distinct follow-up intents. Finally, while query-level advantages improve optimization granularity, diversity remains a slate-level property shared across its queries; more precise marginal contribution estimation is an important direction for future work.

A Prompt Templates

We provide abridged prompt excerpts that illustrate the formats used for direct query generation (Figure 4), intent-guided CoT reasoning (Figure 5), and rubric-based evaluation (Figure 6). Some operational rules are omitted for brevity.

System Prompt for Direct Query Generation

 # Role
User Intent Insight Expert tasked with generating follow-up queries on behalf of users.

 # Workflow
1. Intent Categorization

- **Creative**: Content generation/refinement tasks (writing, coding, translation).
- **Non-Creative**: Factual Q&A, information retrieval, troubleshooting.

2. Strategy

- **Creative**: Generate instructive queries (style, audience, tone optimization).
- **Non-Creative**: Explore extended value and practical needs.

 # Constraints

- Generate 3-5 diverse queries (no duplicates or highly similar ones).
- Character limit: 20 characters or fewer (preferably 8-16).
- Avoid repeating historical queries or answered content.

Example:
What scenarios suit deep learning?
How does ML do feature engineering?
What GPUs for training models?

Figure 4: Abridged system prompt for direct query generation.

System Prompt for Intent CoT Query Generation

You are an expert in user intent understanding. First, conduct user needs analysis, then provide **queries the user wants to ask**.

 # Input Description

- **[Session History]** <history>
- **[User Query]** <query>
- **[Agent Answer]** <response>

 # Output Format

```
{
  "deeperIntent": {
    "userSituation": "<user profile>",
    "motivations": "<latent intent>",
    "potentialIntents": ["<Intent 1>", ...]
  },
  "response_summary": {
    "answeredInDetail": "<fully answered>",
    "answeredNotDetail": "<partially>",
    "notAnswered": "<not covered>"
  },
  "recommend_query": {
    "query1": "<query>", // 20 chars
    "reason1": "<reason>", ...
  }
}
```

 # recommend_query_rule

1. **Content Repetition Issue**: Recommended queries must not obviously repeat content from the user query or AI-Chat response;
2. ...(Additional rules omitted for brevity)

Figure 5: Abridged system prompt for intent-guided CoT query generation.

B Scalability to Larger Models

Method	GSB vs base	LLM Critic	Self-BLEU	Intent Cov.
PE-based	+0	0.57	0.0493	0.58
SFT-cold start	+0.14	0.79	0.0471	0.76
RL-Ours	**+0.23**	**0.92**	**0.0463**	**0.94**

Table 5: Scalability results on Qwen3-235B-A22B. Self-BLEU ↓, other metrics ↑.

To validate the generalizability of our framework across model scales, we conduct experiments on Qwen3-235B-A22B using offline metrics due to deployment constraints. As shown in Table 5, our approach achieves 0.92 LLM Critic and 0.94 Intent Coverage compared with the baseline's 0.57 and 0.58. Despite the larger model's stronger baseline (0.57 vs. 0.33 LLM Critic on Qwen3-30B-A3B), our framework retains improvements of 61% in LLM Critic and 62% in Intent Coverage. Self-BLEU decreases from 0.0493 to 0.0471 and 0.0463, showing that SFT data construction and RL optimization also reduce lexical redundancy at the larger model scale.

Parameter	Value	Parameter	Value
Optimizer	AdamW	LR Scheduler	Linear
Learning Rate	1e-5	Grad Clip	1.0
β_1	0.99	β_2	0.999
Batch Size	128	Max Tokens	8192

Table 6: Hyper-parameters for the SFT stage.

We use $\gamma = 0.95$ and fix $K = 3$ because the production interface displays three suggestions; neither value was tuned on the test set. The rubric/CTR mixture $(\alpha, \beta) = (0.6, 0.4)$ is fixed across experiments. Table 8 reports a targeted offline sensitivity analysis with all other settings fixed.

System Prompt for Rubric-based Evaluation

 # Role
Senior Dialogue Recommendation Auditor. Evaluate whether recommended queries meet strict quality validation rules.

 # Input Definitions

- **Query Intent**, **Current Time**, **Session History**
- **User Query**, **Agent Answer**, **Recommended Query**

 # Evaluation Rules

- **R01 (Awkward Expression)**: Grammatical issues, improper collocations, punctuation errors.
- **R02 (Language Inconsistency)**: Must match the language of current user query.
- **R03 (Outdated Questions)**: No outdated content unless historical context requested.
- **R04 (Creative Content)**: For creative writing, use declarative/imperative only.
- **R05 (Irrelevant Needs)**: Avoid content unrelated to user query or agent answer.
- ...(Additional rules)

 # Output Format
JSON structure with two fields:

- `is_pass`: Boolean indicating pass/fail status
- `violations`: Array of violation objects containing `rule_id`, `rule_name`, and `reason`

Figure 6: Abridged prompt for rubric-based quality assessment.

Both metrics remain within a narrow range. Intent Coverage requires per-model human annotation and is therefore reported only for the selected $\gamma = 0.95$ setting (0.91 in Table 1).

C Annotation Pipeline and Quality Control

Annotation Pipeline. The collaborative refinement in Step 2 follows a four-stage procedure: (i) the LLM filters the optimal query for each intent dimension; (ii) human annotators verify and label a seed subset of samples to establish quality standards; (iii) an LLM-based evaluator performs batch labeling guided by human feedback; (iv) human validators review and refine the LLM-labeled results.

Annotator Training and Qualification. All annotators follow standardized guidelines and undergo rigorous training. Qualification requires achieving >90% agreement in back-to-back validation against gold-standard samples before being assigned to production labeling.

Quality Control. An independent QC team audits annotation quality on sampled batches. In addition, we apply machine-assisted cross-validation between LLM and human labels: samples with disagreement are automatically flagged and routed for re-adjudication. This mechanism reduces variability in subjective decisions and provides a continuous feedback loop for guideline refinement.

Parameter	Value	Parameter	Value
Optimizer	AdamW	LR Schedule	Linear
LR	2e-6	Grad Clip	1.0
β_1	0.99	β_2	0.999
Batch Size	64	Max Tokens	9216
λ_{KL}	0.05	Rollout N	8
WD	0.1	Warmup	2
Clip Ratio	[0.2, 0.28]	Temp.	1.0
Top-p	1.0	Epochs	2
Rubric wt. α	0.6	CTR wt. β	0.4
γ	0.95	Slate Size K	3

Table 7: Hyper-parameters for the RL stage.

γ	0.90	**0.95**	0.99	1.00
LLM Critic ↑	0.871	**0.880**	0.868	0.873
Self-BLEU ↓	0.0491	**0.0470**	0.0482	0.0479

Table 8: Offline sensitivity to the query-level discount factor γ.

D Training Configuration

Model training is conducted using a cluster of 256 NVIDIA H100 GPUs. The specific training parameters for each stage are summarized in Tables 6 and 7.

E Algorithm Details

The complete pseudocode of our query-level credit assignment mechanism is provided in Algorithm 1.

Algorithm 1 Query-level Credit Assignment

Require: Policy π_θ, ref. policy π_{ref}, input x
Require: Hyperparams: G, K, α, β, γ, ϵ, λ_{KL}
Ensure: Updated policy parameters θ
Step 1: Sample Generation
for $i = 1$ **to** G **do**
  Sample slate $y_i = \{q_{i,1}, \ldots, q_{i,K}\} \sim \pi_\theta(\cdot \mid x)$
end for
Step 2: Query-level Reward
Compute $r_{i,k} = \alpha \cdot \mathcal{R}_{\text{rubrics}}(q_{i,k}) + \beta \cdot \mathcal{R}_{\text{CTR}}(q_{i,k})$
Step 3: Query-level Advantage
Normalize: $\tilde{r}_{i,k} = \frac{r_{i,k} - \mu_r}{\sigma_r + \epsilon}$
Compute: $A^{\text{q}}_{i,t} = \sum_{k=t}^{K} \gamma^{k-t} \cdot \tilde{r}_{i,k}$
Step 4: Diversity Advantage
Compute $R_{\text{div},i} = \mathcal{R}_{\text{div}}(y_i)$
Normalize: $A^{\text{div}}_{i,t} = \frac{R_{\text{div},i} - \mu_{\text{div}}}{\sigma_{\text{div}} + \epsilon}$
Step 5: Advantage Aggregation
$$A_{i,t} = \begin{cases} (A^{\text{q}}_{i,t} + A^{\text{div}}_{i,t})/\sqrt{2}, & \text{Pass} \\ -1, & \text{Fail} \end{cases}$$
Step 6: Token-level Broadcasting
Assign $A^{\text{tok}}_j = A_{i,t}$ for all $u_j \in \text{tokens}(q_{i,t})$
Step 7: Policy Optimization
Compute $\rho_j = \frac{\pi_\theta(u_j \mid u_{<j})}{\pi_{\text{ref}}(u_j \mid u_{<j})}$
$\mathcal{J} = \sum_j \min(\rho_j A^{\text{tok}}_j, \bar{\rho}_j A^{\text{tok}}_j) - \lambda_{\text{KL}} D_{\text{KL}}(\pi_\theta \| \pi_{\text{ref}})$
$\mathcal{L}(\theta) = -\mathbb{E}[\mathcal{J}]$
Update: $\theta \leftarrow \theta - \nabla_\theta \mathcal{L}(\theta)$
return Updated policy π_θ

F Case study

Traditional query suggestion models focus solely on the current turn, providing surface-level recommendations while neglecting global dialogue context and users' implicit needs. In contrast, our model integrates dialogue history with the current QA trajectory to perform multi-dimensional intent modeling across multiple facets: **Reconstructing Latent User Scenarios**, **Diagnosing Specific Pain Points**, and **Disentangling Orthogonal User Intents**.

As illustrated in Figure 7, the baseline captures only surface-level intent, while our model performs implicit need inference and intent-driven analysis. The generated suggestions maintain contextual continuity and precisely address users' latent intentions.

G Offline Evaluation Standard

To systematically assess the contextual quality of the generated query suggestions, we establish a manual offline evaluation standard. The scoring protocol operates on a per-case basis, where each test case consists of three query suggestions generated from the preceding context. The score assigned to each case directly corresponds to the number of suggestions deemed valuable by the annotator. Table 9 presents the detailed evaluation criteria across four dimensions: Content Quality, Requirement Satisfaction, Text Quality, and Information Gain.

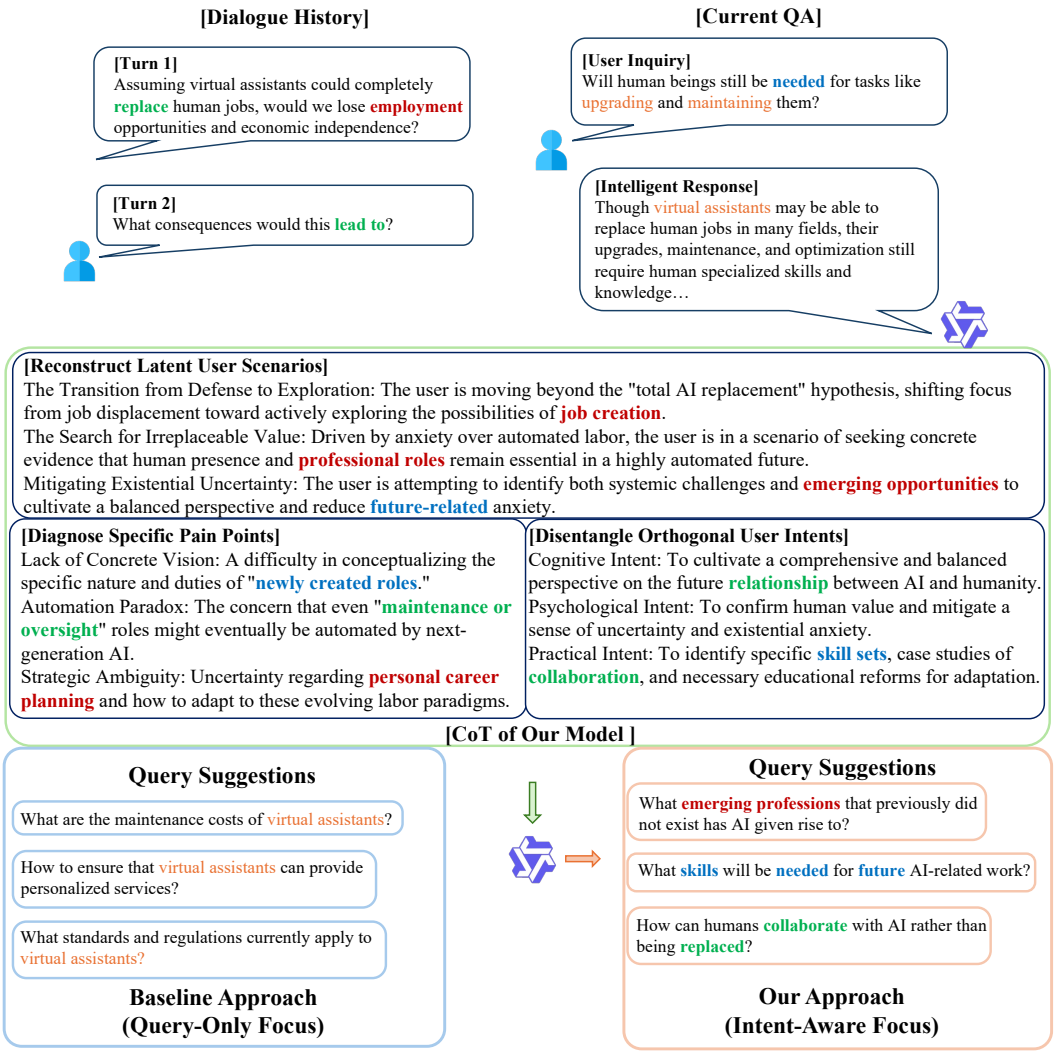

Figure 7: Case study comparing intent modeling approaches between baseline and our model.

Criterion	Description
Content Quality	
Timeliness Issue	The recommended query is outdated and no longer meets current requirements.
Security & Compliance	Content involving pornography, politics, violence, or illegal activities is deemed non-compliant.
Question Duplication	Recommended queries should avoid significant (over 80%) textual duplication.
History Duplicate	Overlapping less than 50% with historical queries, offering additional information gain.
Duplicate-of-Response	Overlapping less than 50% with previous responses and providing additional information.
Requirement Satisfaction	
Irrelevant	The query severely deviates from the user's current primary needs and intent.
Over-Assumption	Makes unfounded assumptions about the user's identity, context, or expertise.
Over-Reliance	Overly focuses on past conversations, neglecting current needs. Prioritize the current round.
Text Quality	
Word-Count-Exceeded	Exceeds 20 characters (Chinese, English x2, digits, punctuation, spaces each count as 1).
Unit Error	Non-standard units not commonly used, increasing user comprehension difficulty.
Poorly-Expression	The text is unclear, poorly expressed, with grammatical errors, typos, or ambiguities.
Inappropriate Topic	Pose questions about trending topics conversationally—avoid simply listing news.
Information Gain	
Logical Confusion	The query is logically inconsistent or contradictory with the preceding content.
Generic Question	The query is too vague, generic, and common knowledge, offering little added value.

Table 9: Human evaluation standards for query suggestion quality assessment.

CACHE-ED2: Compiling LLM Reasoning into Reusable Extraction Programs for Document Extraction at Scale

Sudhanshu Bhoi and Anurag Tripathi and Amir Raza and Mayank Jauhari
Amazon, Bengaluru, India
{sudhbee, tripaanu, amirraz, jauharim}@amazon.com

Abstract

Extracting structured information from visually rich documents at enterprise scale demands both the reasoning capability of large language models and the efficiency of deterministic execution. Current approaches either deploy LLMs as instance-level analysts, incurring per-document inference costs that are prohibitive for repetitive templates, or rely on manually authored vendor-specific prompts that do not scale beyond a handful of high-volume vendors. We present CACHE-ED2, a framework that repositions the LLM as a system-level developer: given a novel document format, a multimodal ReAct-based agent synthesizes a reusable Document Extraction DSL (DocExDSL) program encoding the complete extraction logic (strategies, disambiguation, transforms, and automated reasoning validation), then caches it for deterministic, LLM-free execution on all subsequent documents of the same format. A contrastive Document Format Encoder routes incoming documents to cached programs with perfect hit rates, and a HITL Feedback Analysis Agent incorporates analyst corrections to refine programs over time. On public benchmarks (CORD v2, FATURA) and production streams spanning seven business verticals (580,000+ documents, 11,500+ vendors), CACHE-ED2 achieves near-perfect extraction accuracy ($\sim$0.99) with a 1.0 extraction rate on document-present fields and perfect format matching across 50+ benchmark templates, matching or exceeding manually authored vendor-specific prompts, while reducing cumulative token consumption by $\sim$2.6$\times$ over first 1,000 documents.

1 Introduction

Large Language Models (LLMs) have evolved into trillion-parameter reasoning engines with zero-shot generalization, multi-step deduction, and agentic task orchestration capabilities (Wang et al., 2025). In document information extraction (IE), the task of converting unstructured documents into structured, schema-conforming data, LLMs are predominantly deployed as instance-level analysts: each document is individually queried for field values, incurring 3–5 seconds latency and $4–5 per page at inference (Bhoi, 2026). With over 80% of enterprise data in unstructured formats (Kurowski et al., 2025), this per-instance paradigm is economically untenable at production scale.

Two problems motivate this work. First, document templates follow a skewed vendor-volume distribution: few high-volume vendors dominate while thousands of tail-end vendors each contribute sparse instances. Manual SOPs scale for head vendors but are infeasible for the tail, and invoking an LLM per document across millions of monthly instances is a massive resource misallocation. Second, production extraction is not straightforward reading; analysts follow business-specific SOPs requiring derivation of information absent from the document. A due date may be computed as invoice date plus agreed payment terms; an "account number" may refer not to a bank account but to an internal business identifier for vendor resolution. Such domain-specific reasoning (deriving, disambiguating, and overriding based on business context) demands LLM inferential capacity and Human-in-the-Loop (HITL) learning that smaller models cannot provide.

We propose repositioning the LLM from instance-level analyst to system-level developer that synthesizes deterministic extraction code in a Document Extraction DSL (DocExDSL). Given a novel template, the LLM reasons once over the document's visual and semantic structure, incorporates HITL-provided SOPs, and generates an executable DocExDSL program. After validation through automated reasoning constraints, the program is cached against the template identifier; all subsequent matching instances are processed by the deterministic execution engine, completely by-

EMNLP 2026 Industry Track, pages 1570–1587
October 24-29, 2026 ©2026 Association for Computational Linguistics

passing the LLM, reducing cost and latency to compiled-code execution amortized across the entire document volume per template.

Template-based caching was introduced in CACHE-ED (Bhoi and S, 2025), demonstrating 8% extraction improvement over industry baselines and 50% cost reduction. However, three critical limitations emerged in production: fragile graph matching causing frequent cache misses under minor scan perturbations, a text-only representation without visual context that cemented OCR errors, and a single-pass agent unable to self-verify, requiring multiple instances to converge.

We present CACHE-ED2, resolving these limitations through four contributions:

1. **DocExDSL: A Document Extraction DSL (§3.1).** The first imperative, executable DSL for document IE, encoding extraction strategies, derived field computation, and automated reasoning validation as a deterministic code artifact that executes at sub-second latency without model inference.

2. **Contrastive Document Format Encoder (§3.3).** A learned encoder replacing fragile Template Representation graph matching with format-level embeddings, achieving perfect cache hit rate, a $2.1\times$ improvement over CACHE-ED, and eliminating the primary failure mode of template-based caching.

3. **Multimodal ReAct-based DocExDSL Generation Agent (§3.5).** A code generation agent that synthesizes DocExDSL programs through iterative self-debugging: generating, executing via the deterministic engine, and verifying against its visual reading of the full document image. This execution-in-the-loop design achieves near-perfect extraction from the first encounter with a new format, eliminating CACHE-ED's multi-instance convergence requirement.

4. **HITL Feedback Analysis Agent (§3.6).** A critic agent translating analyst corrections into program-level changes rather than instance-level overrides, enabling continuous DocExDSL refinement while filtering transient human errors from systematic SOP updates.

2 Related Work

Document IE has evolved from grid-based and GNN methods through Document Transformers (DocTr (Liao et al., 2023)) and Vision-Language Models (LayoutLMv3 (Huang et al., 2022), Donut (Kim et al., 2022), FormNet (Lee et al., 2022)) to frontier LLMs (Wang et al., 2025). Specialized models offer computational efficiency but lack cross-page reasoning, while frontier LLMs close this gap at significantly higher inference cost (Huang et al., 2025; Stahlberg et al., 2025).

To inject domain knowledge, vendor-specific prompting provides visual SOPs indicating where and how to extract each field (Yang et al., 2023), but requires manual creation per vendor and is unscalable for tail-end distributions. Automated alternatives, including in-context learning (Brown et al., 2020), meta-prompting (Suzgun and Kalai, 2024), retrieval-augmented generation (Lewis et al., 2020; Gao et al., 2024), and declarative pipeline optimizers like DSPy (Khattab et al., 2024), improve per-call quality but share a fundamental limitation: every method still invokes the LLM for each document instance, producing no reusable extraction artifact for recurring templates.

Within document IE, Markdown has emerged as a quasi-standard intermediary (Microsoft, 2025; Li et al., 2025), but it is declarative: it lacks looping, conditionals, and executable traversal logic. We bridge this gap with an imperative, executable DSL for document IE, where the LLM synthesizes deterministic extraction programs rather than merely formatting content. Synthesizing extraction programs in a DSL originates in programming-by-example systems such as FlashExtract (Le and Gulwani, 2014), which learn text-extraction programs from user-highlighted examples; we extend this lineage to visually rich documents with zero-example, LLM-driven synthesis and production HITL repair. Template-level regularity has also been exploited for structure recovery: TWIX (Lin et al., 2025) infers the visual template underlying templatized documents to reconstruct their records at high accuracy and low cost, and is complementary to our approach, which synthesizes schema-driven extraction programs over exactly such recovered structure. Agentic frameworks for document understanding, including CACHE-ED (Bhoi and S, 2025), have demonstrated the value of multi-agent orchestration with actor-critic mechanisms and HITL feedback for production-scale extraction (Sapkota et al., 2025).

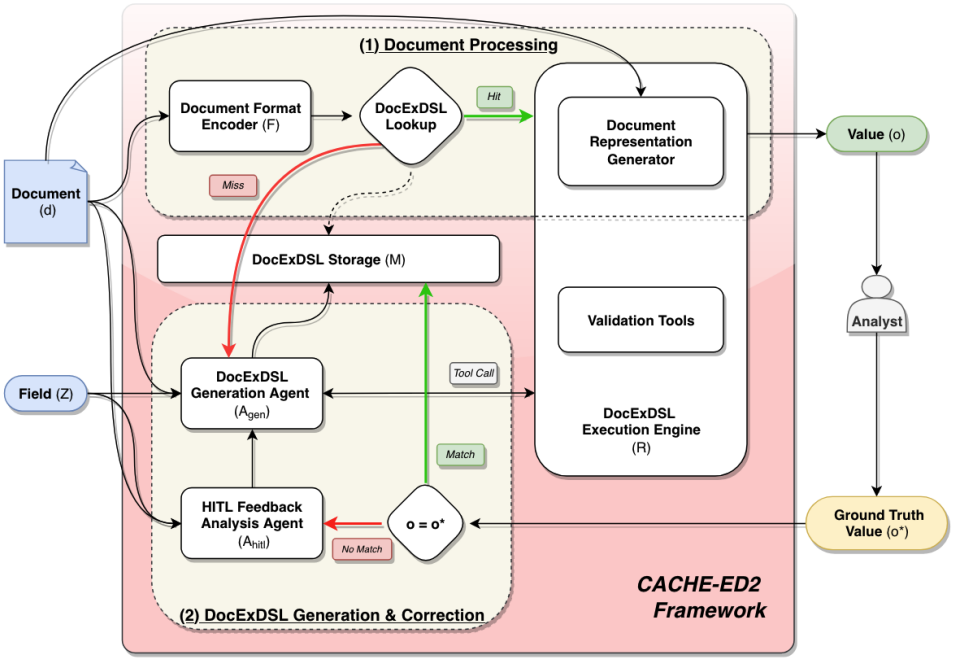

Figure 1: **CACHE-ED2 Framework.** On a cache *hit*, the stored DocExDSL program $\mathcal{P}_f$ is executed deterministically by $\mathcal{R}$ without LLM involvement. On a *miss*, $\mathcal{A}_{\text{gen}}$ synthesizes a new program via ReAct reasoning using $\mathcal{R}$ as a tool. Analyst corrections trigger $\mathcal{A}_{\text{hitl}}$, which recommends program changes fed back to $\mathcal{A}_{\text{gen}}$. Validated programs are cached in $\mathcal{M}$ for deterministic reuse.

3 Approach

CACHE-ED2 comprises six components: a purpose-built extraction language (*DocExDSL*, §3.1), a deterministic *Execution Engine* $\mathcal{R}$ (§3.2), a *Document Format Encoder* $\mathcal{F}$ (§3.3), a persistent *DocExDSL Store* $\mathcal{M}$ (§3.4), and two agents: a *DocExDSL Generation Agent* $\mathcal{A}_{\text{gen}}$ (§3.5) for program synthesis, and a *HITL Feedback Analysis Agent* $\mathcal{A}_{\text{hitl}}$ (§3.6) for incorporating human corrections. The complete pipeline is formalized in Algorithm 1 and illustrated in Figure 1.

3.1 DocExDSL: Document Extraction DSL

DocExDSL makes extraction a code artifact: a human-readable, machine-executable program capturing *how* extraction is performed, including derived information, anchor-based spatial search, disambiguation, and automated verification. Implemented as a Python-embedded language with Pydantic models and fluent method chaining, it leverages the innate Python proficiency of frontier reasoning models (Chen et al., 2021; Rozière et al., 2024), enabling generation from schema specifications without fine-tuning.

A program $\mathcal{P}_f$ is a `Schema` of `Field` declarations, each passing through a five-stage pipeline: *Strategies* $\rightarrow$ *Candidates* $\rightarrow$ *Disambiguation* $\rightarrow$ *Transforms* $\rightarrow$ *Validation*. Five strategy types are chained as ordered fallbacks: key-based matching (exact, contains, fuzzy, regex against `KEY`$\rightarrow$`VALUE` associations), anchor-based spatial search, table extraction, region-based extraction, and derived fields. Disambiguation resolves multiple candidates via single-pick (e.g., `highest_confidence`, `nearest_to_anchor`) or aggregate methods (e.g., `sum`, `concat`). Transforms apply post-processing (date arithmetic, substring extraction, string formatting) before the validation layer enforces automated reasoning constraints: regex patterns, range checks, and cross-field consistency assertions (Amazon Web Services, 2024, 2025). Derived fields are resolved after all direct fields via topological ordering over the dependency DAG G_{dep}. Refer to Appendix C for the complete specification and Appendix F for examples.

3.2 DocExDSL Execution Engine

The engine $\mathcal{R}$ deterministically executes a program $\mathcal{P}_f$ on a Document Representation D_r organized as a typed document graph $G = (V, E)$ with `KEY`, `VALUE`, `TEXT`, `TABLE`, and `CELL` nodes connected by `association`, `contains`, and bidirectional `adjacency` edges (extending CACHE-ED1's representation (Bhoi and S, 2025)). The engine con-

Require: Document d, Extraction Schema $\mathcal{Z}$, Business Vertical v

$D_r \leftarrow \text{GenerateDocumentRepresentation}(d)$
$f \leftarrow \text{IdentifyFormat}(d)$
if f is present **then** ▷ Cache hit: reuse stored program
  $\mathcal{P} \leftarrow \text{StoreLookup}(\mathcal{M}, v, f)$
  $\mathbf{o} \leftarrow \text{ExecuteDSL}(\mathcal{P}, D_r)$
else ▷ Cache miss: generate via ReAct loop with DSL execution as tool
  $\mathcal{P}, \mathbf{o} \leftarrow \mathcal{A}_{\text{gen}}(d, \mathcal{Z})$
end if
$\mathbf{o}^* \leftarrow$ Value from Analyst (HITL)
if $\mathbf{o}$ matches $\mathbf{o}^*$ **then**
  Update field scores, $\text{StoreUpdate}(\mathcal{M}, v, f, \mathcal{P})$
  return $\mathbf{o}$
end if
Invoke Feedback Agent: $\Delta\mathcal{P} \leftarrow \mathcal{A}_{\text{hitl}}(\mathcal{P}, \mathbf{o}, \mathbf{o}^*, d, \mathbf{s})$ ▷ Critic with field-level scores
if $\Delta\mathcal{P} \neq$ `NO_CHANGES_NEEDED` **then**
  $\mathcal{P}, \mathbf{o} \leftarrow \mathcal{A}_{\text{gen}}(d, \mathcal{Z}, \Delta\mathcal{P})$
  Reset scores for changed fields
end if
$\text{StoreUpdate}(\mathcal{M}, v, f, \mathcal{P})$
return $\mathbf{o}$

structs the dependency DAG G_{dep}, topologically orders fields, and for each field executes the fallback strategy chain, disambiguation, transforms, and validation, achieving sub-second processing entirely without model inference. When invoked as a tool by $\mathcal{A}_{\text{gen}}$ during program synthesis, $\mathcal{R}$ returns structured per-field diagnostics, including extracted value, strategy outcome, disambiguation reasoning, and validation errors, providing actionable signals for iterative DSL refinement.

3.3 Document Format Encoder

The Document Format Encoder $\mathcal{F}$ produces format embeddings $\mathbf{e}_d = \mathcal{F}(d) \in \mathbb{R}^m$ to determine which cached program applies. Built on LiLT (Wang et al., 2022) with a lightweight projection head $h(\cdot)$ trained via margin-based triplet margin loss (Equation 1) with online semi-hard triplet mining, the encoder maps same-format documents into tight clusters. At inference, $\mathbf{e}d$ is compared against cluster centroids $\mathcal{C} = c_1, \ldots, c_K$ via cosine similarity; matches above threshold τ route to $\mathcal{M}[v, f]$, while unmatched documents trigger $\mathcal{A}$gen. Because vendors and formats arrive continuously in production, this matching must remain reliable on vendor formats outside the encoder's training distribution, without per vendor or per-format retraining. We achieve this by keeping the pretrained LiLT backbone frozen, so its general text-and-layout representations transfer to unseen vendors, while the lightweight projection head shapes them into a format-discriminative embedding space. Since every cached format is represented by a centroid built from the documents that created its cache entry, the encoder's contribution is out-of-distribution generalization to vendors unseen in training, rather than recognition of formats not yet cached: the first document of an uncached format correctly falls below τ against all existing centroids and triggers program synthesis, rather than false-matching an existing program. The model encodes the first page, as format is recognizable from it in the vast majority of enterprise documents.

$$\mathcal{L}_{\text{triplet}} = \frac{1}{|\mathcal{T}|} \sum_{(a,p,n)\in\mathcal{T}} \max\big(0,\ \delta_p - \delta_n + \alpha\big) \quad (1)$$

where $\delta_p = \|h(x_a) - h(x_p)\|_2$, $\delta_n = \|h(x_a) - h(x_n)\|_2$, $h(\cdot)$ is the projection head, (x_a, x_p, x_n) are anchor-positive-negative document triplets drawn from the semi-hard set $\mathcal{T} = \{(x_a, x_p, x_n) : \delta(x_a, x_p) < \delta(x_a, x_n) < \delta(x_a, x_p) + \alpha\}$ and α is the margin.

3.4 DocExDSL Store

The store $\mathcal{M}$ indexes validated programs by format, partitioned by business vertical v to prevent cross-contamination of extraction SOPs. Each field p_j in a stored program carries a *document-processed score* $s_j^{(\mathcal{P}_f)} \in \mathbb{Z}^+$, incremented per successful extraction match against human-validated output. This score provides $\mathcal{A}_{\text{hitl}}$ with a confidence signal, ensuring that high-score fields are not overridden by single potentially erroneous corrections, and enables accuracy degradation detection over time.

3.5 DocExDSL Generation Agent

The agent $\mathcal{A}_{\text{gen}}$ is a ReAct-based (Yao et al., 2023) *code generator*, not a value extractor: it writes programs describing extraction logic and never extracts values directly. It delegates extraction entirely to $\mathcal{R}$ via tool calls, using the

full-resolution document image $\mathcal{I}$ as visual reference to judge correctness. Given d (including its image $\mathcal{I}$) and schema $\mathcal{Z}$, the agent iteratively generates a candidate $\mathcal{P}_f$, invokes $\mathcal{R}$ to obtain $\mathbf{o}$ with per-field diagnostics, compares against its visual reading of $\mathcal{I}$, and refines mismatched fields, effectively debugging its own code. Beyond direct extraction, the agent derives business-specific SOPs not explicitly present in the document: for instance, synthesizing a service period date range as `start_of_month`/`end_of_month` of the invoice date via DocExDSL's `derive_from` and `date_component` transforms. The agent also accepts feedback $\Delta\mathcal{P}$ from $\mathcal{A}_{\text{hitl}}$ to regenerate specific fields via $\mathcal{P}'_f = \mathcal{A}_{\text{gen}}(d, \mathcal{Z}, \Delta\mathcal{P})$. Refer to Appendix E for example and Appendix B for prompt structure.

3.6 HITL Feedback Analysis Agent

The critic agent $\mathcal{A}_{\text{hitl}}$ analyzes mismatched fields $\Delta_{\text{fields}} = \{j \mid o_j \neq o^*_j\}$ between extracted output $\mathbf{o}$ and human-corrected output $\mathbf{o}^*$, producing SOP-level program changes $\Delta\mathcal{P} = \mathcal{A}_{\text{hitl}}(\mathcal{P}_f, \mathbf{o}, \mathbf{o}^*, d, \mathbf{s})$, such as adjusting anchor directions, adding derivation rules, or modifying disambiguation strategies. The field-level scores $\mathbf{s}$ guard against incorporating erroneous corrections: high-score fields have proven track records and are not overridden by single edits. If $\Delta\mathcal{P} \neq$ `NO_CHANGES_NEEDED`, changes are forwarded to $\mathcal{A}_{\text{gen}}$ for resynthesis and scores for changed fields are reset. Unlike CACHE-ED1, verification logic is now embedded in DocExDSL's validation layer, enabling fully deterministic, LLM-free validation even during cache-hit processing. Refer to Appendix B for prompt structure.

4 Experiments

We evaluate CACHE-ED2 against three baselines: (i) a *multimodal LLM* without extraction SOPs, mimicking mid-to-tail vendor behavior, (ii) *multimodal LLM with vendor-specific prompts* with manually authored per-vendor SOPs, and (iii) *CACHE-ED1* (Bhoi and S, 2025). All methods use Claude Sonnet 4.6 for consistency.

4.1 Extraction Quality

We first evaluate on CORD v2 (Park et al., 2019), a public receipt-parsing benchmark of 11,000+ images with structured field annotations across totals, subtotals, and payment-type breakdowns. Since all CORD fields require no SOP-based derivation, this isolates raw extraction capability; we omit the vendor-SOP baseline accordingly. Table 1(a) reports results across eight fields. Both CACHE-ED variants improve over the single-pass LLM (0.91 average) through closed-loop refinement, with CACHE-ED2 achieving 0.99 average accuracy entirely through the deterministic DocExDSL engine at inference, demonstrating that compiling extraction logic to DocExDSL preserves fidelity without LLM involvement.

For context, models fine-tuned on CORD's training split report entity-level F1 of 96.56 (LayoutLMv3$_{\text{BASE}}$) to 97.46 (LayoutLMv3$_{\text{LARGE}}$) (Huang et al., 2022) and 97.64 (UDOP-Dual) (Tang et al., 2023), while the OCR-free Donut reports 84.1 field-level F1 (Kim et al., 2022). These figures are not directly comparable to ours: they measure F1 after supervised fine-tuning on CORD, and none publishes per-field results, whereas CACHE-ED2 reports per-field value accuracy with no CORD-specific training and no gradient updates at any point. The operational differentiator is the maintenance path: corrections update a cached program rather than requiring re-annotation and fine-tuning.

Real-world invoice processing demands business-rule reasoning that separates the methods. We curate 5,000 production invoices (1,000 per vendor, 5 vendors, single vertical) and select seven fields spanning three difficulty tiers: *easy* fields (Invoice Number, Invoice Date, Invoice Currency), *SOP-dependent* fields where business rules override the raw value (Account Number, Service Period Start/End Date), and *derived* fields computed from other fields (Vendor Provided Due Date). Table 1(b) reports extraction rate and accuracy per method. The multimodal LLM drops sharply on SOP-dependent fields (0.64 average accuracy) and derived fields (0.59 extraction rate for Due Date), confirming that business context is essential.

CACHE-ED2 achieves near-perfect performance across all fields (0.99 average accuracy, 1.0 extraction rate). On derived fields, CACHE-ED2 surpasses vendor prompts by 9 percentage points on Due Date (0.97 vs. 0.88) for two reasons: the agent initially absorbs minor human variations (e.g., ± 1 day adjustments in date derivations) and learns the correct SOP over time as the scoring mechanism stabilizes, and the format-aware caching handles multiple vendor formats independently rather than

Table 1: Extraction quality on CORD v2 receipts and real-world invoices. Results reported as *Extraction Rate / Accuracy*; best per field in **bold**.

Vendor Format 4	0.70	**1.0**
Vendor Format 5	0.52	**1.0**

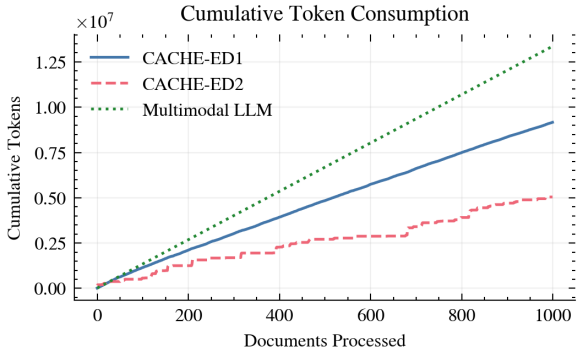

Figure 2: Cumulative token consumption over 1,000 documents (lower is better). CACHE-ED2 achieves ∼62 reduction; CACHE-ED1 achieves ∼31.

sending all format SOPs to the LLM simultaneously. These performance gains are consistent across the entire vendor-volume distribution, including long-tail vendors with sparse instances (Appendix G). Refer to Appendix F for SOP comparisons and Appendix E for representative programs.

4.2 Format Detection

We first evaluate on FATURA (Limam et al., 2023), a public benchmark of 10,000 invoice images across 50 distinct layouts. We rank templates by intra-class visual variance, group them into five difficulty tiers of 10 templates each, and report average cache hit rate per group. All hit rates follow a vendor-held-out protocol: the evaluated vendors are excluded from encoder training, each format's centroid is built from its own documents, disjoint from those scored, and matching runs against all cached-format centroids (threshold sensitivity and near-miss margins: Appendix A). Table 2(a) compares CACHE-ED1's graph matching against CACHE-ED2's contrastive Document Format Encoder.

CACHE-ED1 averages 0.47 due to fragile graph matching under minor visual perturbations and NER-based value masking failures. CACHE-ED2 achieves perfect hit rate here as well (2.1× improvement), confirming that learned embeddings generalize across dataset scale, domain, and document type. Refer to Appendix A for t-SNE visualizations.

4.3 Token Efficiency and Learning Dynamics

We measure cumulative token consumption on the real-world invoice corpus as documents are processed sequentially (Figure 2). The single-pass

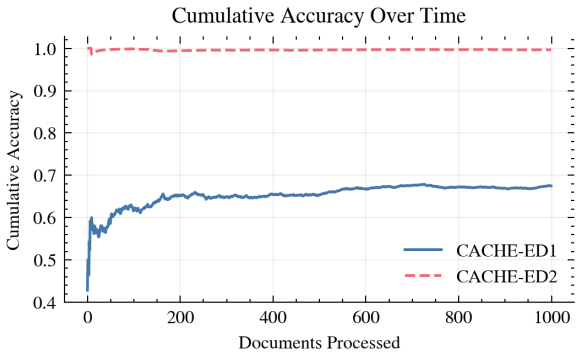

Figure 3: Cumulative accuracy for a single real-world vendor (higher is better). CACHE-ED2 reaches near-perfect accuracy from the first document.

LLM baseline consumes ∼13,360 tokens per document, totaling ∼13.4M tokens for 1,000 documents. Both caching methods surpass the baseline within the first ∼50 documents, after which cached formats are served at zero token cost. At 1,000 documents, CACHE-ED2 consumes ∼5M tokens (∼62% reduction vs. baseline), while CACHE-ED1 consumes ∼9M tokens (∼31% reduction), ∼1.8× higher than CACHE-ED2. The gap is driven by CACHE-ED1's lower cache hit rate: frequent misses trigger repeated program generation for formats that should already be cached. At production scale (36,093 documents), cached serving cuts LLM spend 6× versus invoking the synthesis agent per document (Appendix I).

We track cumulative accuracy over time for a single real-world vendor to isolate learning behavior (Figure 3). CACHE-ED1 starts at low accuracy and plateaus well below acceptable levels, requiring multiple document instances to converge. CACHE-ED2 achieves near-perfect accuracy from the first document instance and maintains it throughout, as the ReAct agent's execution-in-the-loop design enables accurate SOP derivation in a single encounter with a new format.

4.4 Production-Scale Evaluation

Beyond the five-vendor comparative study, we evaluate CACHE-ED2 across seven business verticals in three regions, on production document streams totaling more than 580,000 documents from over 11,500 vendors. The streams exhibit the heavy-tailed vendor concentration typical of enterprise document processing: per-vertical vendor counts range from 50 to 5,220, the top vendor alone contributes between 4.3% and 94.5% of a vertical's volume, and covering 90% of volume requires anywhere from a single vendor to 639. Table 3 reports the measured per-vertical results. Correcting for audited annotation deltas (ground-truth entries that are mis-keyed or contain values absent from the source document) yields a 100% extraction rate on document-present fields and approximately 99% field accuracy. For a per-field deep dive and Pareto volume analysis over one vertical's full vendor distribution, see Appendix G. These results address the scope of generalization directly: the mechanism is format-level, and its economics improve with every additional format cached.

Table 3: Production-scale evaluation across seven anonymized business verticals (ordered by volume).

Vertical	Docs	Vendors	Ext. (%)	Acc. (%)
A	321,197	5,220	99.89	99.58
B	135,971	4,049	99.12	96.84
C	92,692	710	99.41	94.52
D	12,318	50	99.99	99.96
E	9,196	295	98.67	98.94
F	6,249	637	99.96	99.01
G	3,630	599	99.87	97.98
All	*581,253*	*11,560*	*99.56*	*98.12*

Component ablations. Leave-one-out ablations on a 1,000-document production cohort (96 vendors, 115 formats) separate each component's contribution: removing visual grounding collapses completion to 0.270 of the full system (the synthesis agent fails to converge without page images), removing execution-in-the-loop or HITL feedback lowers accuracy retention to 0.947 and 0.829 respectively, and the contrastive encoder guards the 39.7% of documents from multi-format vendors that vendor-level routing can misroute. Appendix H details the protocol and full results.

5 Conclusion

We presented CACHE-ED2, a framework that repositions the LLM from an instance-level analyst to a system-level developer synthesizing reusable DocExDSL programs for document extraction. By coupling a contrastive Document Format Encoder, a multimodal ReAct-based Generation Agent with execution-in-the-loop, and a score-guarded HITL Feedback Agent, the framework achieves near-perfect extraction accuracy while eliminating LLM inference at serving time and reducing cumulative token consumption by ∼62% over 1,000 documents.

Limitations

Two limitations of the current framework warrant discussion. First, each new vendor format requires independent program synthesis from scratch; the framework does not yet leverage cross-template transfer. A concrete path is warm-start synthesis: retrieving the nearest cached program via the Document Format Encoder's embedding space and supplying it to $\mathcal{A}_{\text{gen}}$ as a first-guess draft, which would cut ReAct iterations and cold-start cost precisely where the vendor long tail makes per-format synthesis most expensive. Second, DocExDSL's grammar is fixed at design time: when $\mathcal{A}_{\text{gen}}$ encounters extraction patterns inexpressible in the current language (e.g., recursive table structures or conditional multi-page joins), these remain unresolvable until manual DSL expansion. An automated capability discovery mechanism that identifies such gaps from agent failures and proposes grammar extensions would allow the extraction language to grow alongside production complexity.

Ethics Statement

The real-world corpora comprise enterprise invoices processed by the authors' organization's production document pipelines, used for this research under internal data-use authorization. All multimodal LLM inference (Claude Sonnet) was executed inside a contractually isolated Amazon Bedrock enterprise environment within the organization's secure cloud perimeter, under the service's documented commitments that prompts and outputs are not stored, not shared with the model provider, and not used for model training, mitigating rather than eliminating third-party processing risk; no document images or extracted values were sent to public API endpoints. Human-in-the-loop signals are field-level corrections produced by professional analysts within their standard verification workflow; no additional annotation labor was commissioned for this work. All figures reproducing document content are uniformly de-identified, with account identifiers, names, addresses, and derived values masked.

A Document Format Encoder: LiLT Architecture and Training

This appendix details the architecture and training of the Document Format Encoder introduced in Section 3.3.

A.1 LiLT: Language-Independent Layout Transformer

The format encoder builds on LiLT (Wang et al., 2022), a dual-stream Transformer with separate text and layout flows connected via Bi-directional Attention Complementation (BiACM). The text flow initializes from RoBERTa at 768 hidden dimensions; the layout flow uses a compact 192-dimensional representation, keeping layout-only parameters to 6.1M. BiACM shares attention scores between flows at every layer, enabling cross-modal interaction without stream fusion. Pre-trained on 11M English documents (IIT-CDIP) using Masked Visual-Language Modeling, Key Point Location (7×7 grid), and Cross-modal Alignment Identification, LiLT has been fine-tuned for entity recognition, relation extraction, and document classification across eight languages on FUNSD, CORD, EPHOIE, RVL-CDIP, and XFUND. Its lightweight layout encoding, joint text-layout awareness, and availability of a public checkpoint (`nielsr/lilt-roberta-en-base`) make it a natural backbone for our format similarity task. Figure 4 illustrates the architecture.

A.2 Training Configuration

We freeze the full LiLT encoder (∼125M parameters) and train only a 3-layer MLP projection head (768→512→256→256, ReLU, L2-normalized output) — 590K trainable parameters (0.47% of total). The model is trained with triplet margin loss (α=0.2) using online semi-hard mining, which selects negatives harder than the positive but within the margin boundary. A balanced sampler constructs batches of 4 format classes × 4 samples each. Training runs 30 epochs with AdamW (lr=1e-3), linear warmup and decay. Inputs are a commercial OCR engine-extracted words with bounding boxes normalized to [0, 1000], tokenized via RoBERTa, truncated to 512 tokens with dynamic padding.

A.3 Embedding Quality

Documents are encoded into 256-dimensional L2-normalized vectors and matched against stored format centroids via cosine similarity (τ=0.95). Held-out evaluation yields intra-class similarity of 0.9954 (std=0.0109) versus inter-class similarity of 0.3704 (std=0.2004) — a gap of 0.6250 — confirming tight, well-separated format clusters. Figure 5 visualizes these clusters.

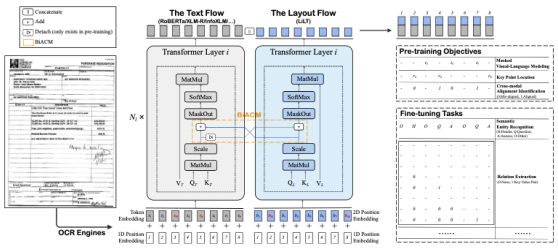

Figure 4: LiLT dual-stream architecture. The text flow (RoBERTa, 768-dim) and layout flow (192-dim) run in parallel with BiACM sharing attention scores bidirectionally at each layer.

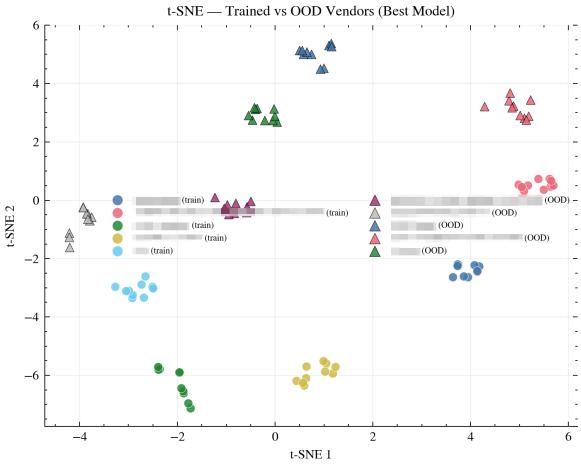

Figure 5: t-SNE projection of 256-dimensional format embeddings for ten sampled vendors (ten documents each): five drawn from the training split (circles) and five from the held-out document split (triangles). Clusters remain tight and well separated in both halves.

Routing Threshold Sensitivity. Routing is precision-critical: a false match silently sends a

document to the wrong cached program, whereas a miss merely triggers synthesis, so τ is set to maximize precision at the expense of recall. Figure 6 shows pairwise cosine similarities over the test embeddings; format-level labels are unavailable, so vendor identity labels the pairs ($8{,}550$ same-vendor, $8{,}524$ different-vendor). Different-vendor pairs are reliably different formats, making precision and false-match measurements sound; same-vendor pairs can cross formats, making measured recall a pessimistic bound (the low-similarity same-vendor tail in the figure). The F1-optimal threshold is $\tau = 0.594$ (precision 0.985, recall 0.942); we operate at the stricter $\tau = 0.95$, where the false-match rate falls to 0.05% (four pairs) at precision 0.999, at the cost of pair-level recall (0.440). The band just below the operating point, $[0.93, 0.95)$, holds 11.1% of same-vendor pairs but only two different-vendor pairs. Pair-level recall understates the deployed hit rate twice over: same-vendor pairs may cross formats, and production routing matches each document against format centroids rather than individual documents; deployed hit rates are reported in the main text.

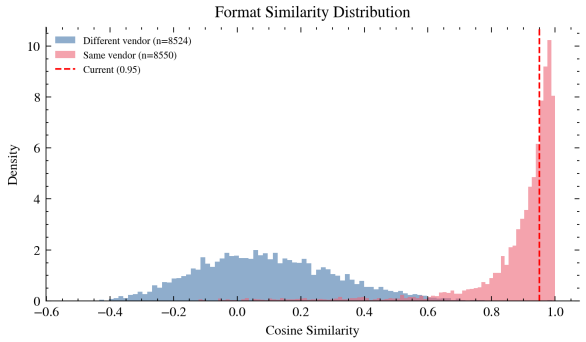

Figure 6: Pairwise cosine-similarity distributions of same-vendor and different-vendor pairs over the test embeddings, with the routing operating point $\tau = 0.95$ marked.

B DocExDSL Generation Agent and HITL Feedback Analysis Agent: Prompt Architecture

This appendix details the prompt structures of the two LLM agents: the Generation Agent (actor) that synthesizes DocExDSL programs, and the HITL Feedback Analysis Agent (critic) that diagnoses extraction errors and recommends program-level refinements.

B.1 Generation Agent (Actor) Prompt

The actor prompt operates in two modes — initial generation and revision — sharing a common structure with an optional feedback section activated during revision cycles.

System Instructions. The LLM acts as a code generation agent writing declarative DSL logic — never extracting values directly. It follows a ReAct loop (generate, execute, inspect, revise) with a strict no-hardcoding constraint ensuring all programs generalize across same-format documents.

Document Context. Multi-page document images (base64-encoded) enable visual inspection of layout, labels, and spatial relationships — the multimodal grounding absent in CACHE-ED1 that enables accurate SOP derivation from a single instance.

Field Definitions. Each target field is specified with name, data type, description, valid and invalid label identifiers, and derivation hints for computed fields, scoped to required outputs plus intermediates necessary for derivation chains.

DSL Specification. The complete DocExDSL language reference is provided in-context: five extraction strategies (key-based, anchor-based, derived, table, region) as ordered fallback chains, disambiguation, transforms, and validation. This leverages frontier LLMs' code proficiency without fine-tuning.

Strategy Selection Guidelines. Explicit guidelines map layout observations to strategy choices — label-adjacent values to key-based, spatially referenced values to anchor-based, computed values to derivation, tabular data to table extraction, fixed-position values to region-based — with fallback chains encouraged for robustness.

Revision Context (Optional — Critic Feedback). When critic feedback is available, the previous DSL code and per-field diagnostics are injected. The agent reasons through each flagged field's root cause, maps the recommendation to a DSL change, and leaves unflagged fields untouched. This targeted revision prevents regression in proven logic while correcting only deficient fields.

Tool-Calling Workflow. An `execute_dsl` tool parses generated code, runs extraction against the document graph, and returns per-field diagnostics: extracted value, strategy outcome, candidate count,

and validation errors. The agent must invoke this after every generation, inspect for null or implausible outputs, and iterate — this self-debugging loop drives first-encounter accuracy.

Output Format. A Python code block containing DSL imports, Schema definition with extraction logic, strategy rationale as inline comments, and (during revision) documented reasoning for each change.

B.2 HITL Feedback Analysis Agent (Critic) Prompt

The critic is a single-turn LLM call (no tool-calling) producing structured diagnostic feedback. It analyzes extraction errors and provides generalizable recommendations — never extracting values or writing DSL code.

System Instructions. The critic diagnoses mismatches between extracted and human-provided values by reasoning about underlying business logic, not surface-level value matching. All recommendations must be generalizable (no hardcoded values; only relative operations). `NO_CHANGES_NEEDED` is a valid verdict when existing DSL is correct.

Rule Confidence Calibration. Each DSL rule's validation score — documents successfully processed — calibrates trust. Score 0 assigns high weight to human feedback; scores above 5 warrant skepticism toward contradicting corrections, as the human may be wrong or the document anomalous. This score-weighted mechanism prevents erroneous corrections from corrupting stable programs.

Document Context. Multi-page images enable visual verification of where values appear and what labels surround them, grounding the critic's diagnosis in the actual document layout.

Extraction Comparison. A structured table presents each field with human value, extracted value, and match status. The critic focuses exclusively on incorrect fields, determining whether the issue lies in DSL logic or the human correction itself.

Current DSL Code. The actor's existing code is provided so the critic identifies the specific strategy or parameter needing adjustment rather than reasoning abstractly.

Failure Pattern Taxonomy. Ten common failure patterns guide diagnosis: wrong keys, untagged values, derived value errors, wrong disambiguation, subset extraction, wrong spatial direction, table extraction issues, wrong page scope, date/transform errors, and business logic overrides. This taxonomy constrains output to actionable categories mapping directly to DSL modifications.

Output Format. Two-part response: (1) overall verdict (`NO_CHANGES_NEEDED` with reasoning, or `CHANGES_RECOMMENDED`), and (2) per-field diagnostics with the business rule revealed, root cause category from the taxonomy, and a generalizable DSL fix. Instance-specific mismatches are marked `human_likely_wrong` with no DSL change.

C DocExDSL: Detailed Specification

This appendix supplements Section 3.1 with the complete DocExDSL specification — the document graph substrate, strategy parameters, disambiguation, transforms, validation, and the structured result model enabling the Generation Agent's self-debugging loop (Section 3.5).

Document Graph Substrate. The DSL operates on a typed directed graph $G = (V, E)$ built from OCR output, with coordinates normalized to $[0, 1]$. Nodes are typed as `ROOT`, `KEY`, `VALUE`, `TEXT`, `TABLE`, and `CELL` — each carrying `text`, `confidence`, `page`, and bounding-box geometry. Edges encode `association` (KEY→VALUE pairings), `contains` (TABLE→CELL hierarchy), and bidirectional `adjacency` (spatial proximity, threshold 0.1). This abstraction decouples the DSL from any specific OCR provider.

Strategy Parameters. Key-based extraction accepts label strings with match modes (`exact`, `contains`, `fuzzy` at SequenceMatcher $\geq$ 0.7, `regex`) and optional confidence thresholds. Anchor-based extraction takes reference text, directional search (`right`, `left`, `above`, `below`, `nearest`), maximum offset distance, and filterable node types. Table extraction identifies columns by header matching or explicit row/column index. Region-based extraction targets an absolute bounding box on a specified page, collecting all nodes whose centers fall within.

Fallback Chains. Strategies chain as ordered fallback sequences — the engine tries each in declaration order and uses the first returning candidates.

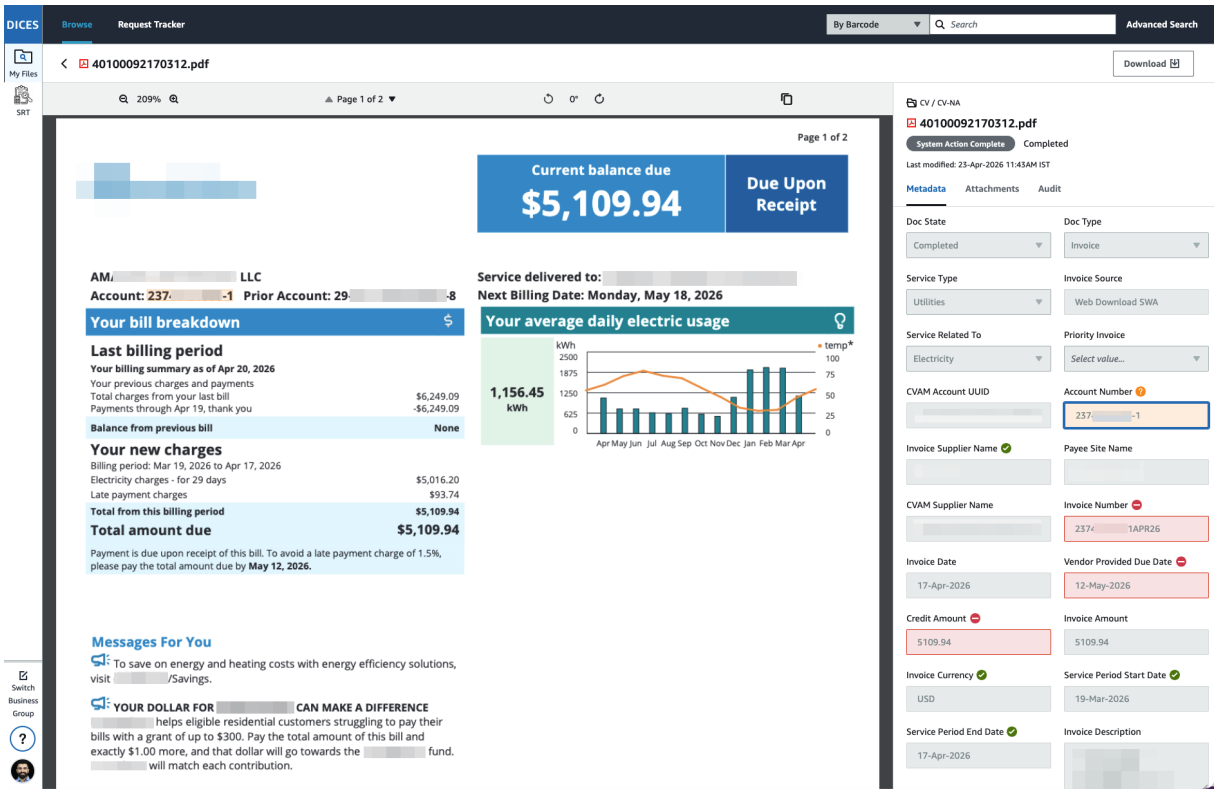

Figure 7: The human-in-the-loop validation interface used by analysts to verify and correct extracted values. Extracted fields are color-coded by confidence level to direct analyst attention, with bounding-box overlays providing spatial grounding for each extraction.

This is central to OCR robustness: broken key-value associations fall back to anchor-based spatial search; truncated anchor text falls back to fuzzy key matching.

Disambiguation. Eight single-pick methods (`highest_confidence`, `largest_area`, `first/last_occurrence`, `nearest_to_anchor`, `longest`, `shortest`, `most_frequent`) and five aggregate methods (`sum`, `average`, `min`, `max`, `concat`) resolve multiple candidates, with optional tiebreakers.

Transforms. Transforms execute in fixed order after disambiguation: Subset (regex, split, line selection) → Date (offset arithmetic, component extraction like `start/end_of_month`) → String (templates with schema context, case conversion, find-replace) → Custom (arbitrary callables). Chain order enables multi-step post-processing.

Validation. Five constraint types: `pattern` (regex), `length` (min/max), `range` (numeric bounds with automatic number extraction from formatted strings), `allowed_values` (enumeration), and `custom` (arbitrary predicates). Cross-field checks — line totals summing to header total, issue date $\leq$ due date — are custom validators referencing other schema fields. Failed validations flag fields for review without halting execution.

Scope Filtering. Fields restricted via `on_pages` or `in_region` (normalized bounding box) constrain *all* strategies on that field — both source nodes (KEYs, anchors) and candidates (VALUEs, CELLs). Essential for multi-page documents where identical labels appear across pages.

Structured Result Model. Each field returns an `ExtractionResult` exposing: final value, all pre-disambiguation candidates (with geometry and confidence), disambiguation reasoning, validation status with errors, and the successful strategy. This diagnostic output is what enables the Generation Agent's ReAct loop — the agent inspects candidates, strategy outcomes, and validation errors to iteratively refine DSL code without ground-truth labels.

D CACHE-ED1 Failure Analysis: Template Fragility and Cryptic Representations

This appendix provides concrete evidence for the CACHE-ED1 limitations discussed in Sections 4.1 and 4.2.

Template Fragility Under OCR Variance. CACHE-ED1 constructs templates by anonymizing VALUE nodes and computing structural fingerprints via graph isomorphism. Figure 8 shows two instances of the same vendor format where the document parser detects the site identifier as "AMAAAA SITE" in one and "AMAAAA FC SITE" in the other. This single-word KEY difference produces structurally distinct anonymized graphs, triggering a cache miss and redundant program generation. Such variations are the root cause of CACHE-ED1's 0.47 average cache hit rate on production data and its degradation from 0.89 to 0.25 across increasing layout difficulty on FATURA (Table 2). CACHE-ED2's learned format encoder (Section 3.3) absorbs these into tight embedding clusters, achieving perfect hit rates across both datasets.

Cryptic Graph Paths Obstructing LLM Reasoning. CACHE-ED1 passes linearized graph paths to the LLM without the original document image. Figure 9 illustrates the consequence: the document displays "831-NNN-NN86 317" as a single account number, but the parser splits it into two entities due to whitespace — associating "Account Number" with only "317". The LLM extracts this partial value and encodes the error into the cached program, with no visual context to detect that both segments are spatially adjacent. CACHE-ED2 provides the full document image to the Generation Agent (Section 3.5), enabling visual verification and correct program synthesis across OCR-fragmented regions.

E Sample End-to-End Document Extraction

This appendix traces a single document through the CACHE-ED2 pipeline (Algorithm 1), illustrating how the Generation Agent, HITL Feedback Analysis Agent, and field-level scoring collaborate to achieve correct extraction. Figure 11 summarizes the stages.

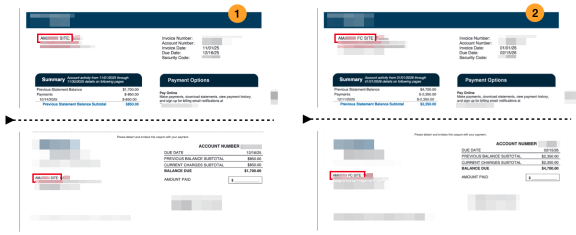

Figure 8: Template fragility under OCR variance. Two instances of the same format where a single-word KEY difference ("AMAAAA SITE" vs. "AMAAAA FC SITE") produces distinct anonymized graphs, causing a cache miss.

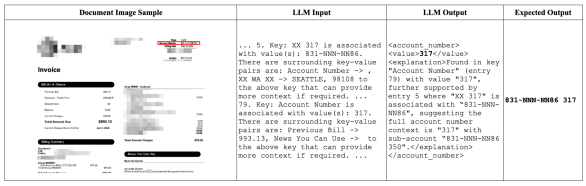

Figure 9: Cryptic path representation failure. The parser splits "831-NNN-NN86 317" into two entities; the LLM extracts only "317" from the direct KEY association, missing the full value apparent from the document image.

Stage 1: Initial Extraction. On encountering a new vendor format, the Generation Agent synthesizes a DocExDSL program via its ReAct loop. For `service_period_start`, the agent extracts the raw billing period "Nov 19 – Dec 18" as a single value and derives the start date as "Nov 19" using a substring transform. The execution engine returns "Nov 19".

Stage 2: Human Correction and Critic Analysis. The analyst corrects `service_period_start` to "Dec 1" in the Verifier UI. The HITL Feedback Analysis Agent receives this correction alongside the current DSL and document image, and identifies an underlying SOP: the service period start is the first day of the month of the billing period end date. It issues `CHANGES_RECOMMENDED`, advising replacement of the key-based strategy with a derived field applying `start_of_month` to the billing period end date.

Stage 3: Program Regeneration and Score-Guarded Stability. The Generation Agent incorporates the critic's feedback, regenerating the DSL as: `derive_from(billing_period_end) .transform(date_component= "start_of_month")`. The engine now correctly extracts "Dec 1". The field score resets to 0

and accumulates with each subsequent match.

Figure 10 demonstrates the complementary case for the Stage 2. After 78 successful validations, the `vendor_provided_due_date` rule (`invoice_date + 45 days`) carries a score of 78. An analyst submits "3/14/2026" for invoice date "1/27/2026" — one day off from the computed "3/13/2026". The critic issues `NO_CHANGES_NEEDED`: adjusting to +46 days would match this correction but break 78 validated documents. The scoring mechanism correctly identifies a likely human error over a systematic SOP change, preserving program stability.

```
### Verdict: NO_CHANGES_NEEDED
- **Reasoning**: The current DSL derives `vendor_provided_due_date`
as `invoice_date + 45 days`, which correctly reflects the "Net 45"
payment terms printed on the document. Mathematically, 1/27/2026 + 45
days = 3/13/2026, which matches the extracted value. The human-
provided value of 3/14/2026 appears to be an off-by-one error on the
human's part. This rule has been validated successfully against 78
documents with a 78/78 success rate, making it highly reliable.
Changing the offset to `+46 days` to match this single human
correction would break the logic for all other documents where the
rule has been validated correctly. The current DSL is correct and
generalizable.
```

Figure 10: Critic verdict: `NO_CHANGES_NEEDED`. The `vendor_provided_due_date` rule (`invoice_date + 45 days`) has a 78/78 validation record. A one-day discrepancy (3/13 vs. 3/14) is identified as a likely human error; changing the offset would break all prior validations.

F Agent-Derived vs. Human-Curated SOPs Across Failure Modes

This appendix supplements Section 4.1 by comparing CACHE-ED2's autonomously derived SOPs against human-curated vendor-specific instructions across three failure modes where business logic must be inferred. Figure 12 presents the full comparison.

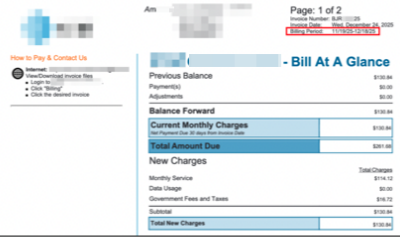
Context. A significant class of extraction fields cannot be read directly from a labeled value — analysts instead follow vendor-specific SOPs encoding rules for locating unlabeled values, deriving absent fields, or disambiguating duplicate labels. These SOPs are traditionally authored manually per vendor. CACHE-ED2 derives equivalent logic from analyst corrections alone, without SOP documentation as input.

Unlabeled Information. When the target field (e.g., account number) lacks an explicit label, the human SOP locates it by position relative to known landmarks. CACHE-ED2's Generation Agent identifies the same spatial relationship via document image visibility and encodes it as an anchor-based strategy with directional search — producing equivalent logic without prior instruction.

Derived Information. When a field must be constructed from other fields (e.g., invoice number derived by concatenating account number with month/year of invoice date), the human SOP specifies the formula explicitly. The HITL Feedback Analysis Agent infers this rule from analyst corrections and recommends a derived field with appropriate string and date transforms — matching the human-authored derivation.

Disambiguation. When multiple values share the same label (e.g., invoice number in both header and line items), the human SOP specifies which instance to use. CACHE-ED2 resolves this through scope filtering and disambiguation (e.g., `first_occurrence` with page restriction), arriving at the same selection logic from corrections alone.

Across all three modes, CACHE-ED2 derived functionally equivalent SOPs, demonstrating that the actor-critic loop with visual grounding can autonomously discover vendor-specific business rules without explicit SOP authoring.



G Vendor Distribution and Long-Tail Performance

This section studies the performance of CACHE-ED2 on a real-world invoice distribution spanning the full vendor spectrum for a representative business vertical, including long-tail vendors with sparse document instances.

Corpus Composition. The evaluation corpus comprises 11,774 documents across 159 distinct vendors spanning a single business vertical. Figure 13 illustrates the cumulative volume distribution: the top 10 vendors account for 48.5% of all documents, the top 25 for 66.1%, and the top 50 for 81.0%, confirming the sharp Pareto concentration typical of enterprise invoice streams. The remaining 109 vendors collectively contribute 19% of volume, with individual counts ranging from single-digit to low double-digit instances per vendor.

Aggregate Performance. Table 4 reports extraction rate and accuracy across all seven header fields evaluated over the full 159-vendor corpus. CACHE-ED2 achieves 100% extraction rate across

Input (Document/HITL)	Agent	Output (DocExDSL/Feedback)	Extracted Value

	DocExDSL Generation Agent	`# billing_period_raw: intermediate — extracts "11/19/25–12/18/25" from "Billing Period:"`
		`Field("billing_period_raw", type="string")  # intermediate: needed to derive service_period_start_date and service_period_end_date`
		`  .extract_by_key("Billing Period", "Billing Period:", match="contains")`
		`  .disambiguate("first_occurrence"),`
		
		`# service_period_start_date: first part of billing period before "–"`
		`Field("service_period_start_date", type="date", required=True)`
		`  .derive_from("billing_period_raw")`
		`  .subset(split_by="–", split_index=0)`
		`  .format("MM/DD/YYYY"),`
			11/19/25

Dec 01, 2025	HITL Feedback Analysis Agent	`### Field: service_period_start_date` `- **Human Value**: Dec 01, 2025` `- **Extracted Value**: Nov 19, 2025` `- **Business Logic**: The billing period printed on the document is "11/19/25–12/18/25", but the human expects Dec 1, 2025 — the first day of the month containing the billing period end date. This indicates a business rule: the service period start date should be the start of the calendar month of the billing period end date, not the literal start date from the billing period string.` `- **Root Cause**: needs_derivation (business logic override — derive start-of-month from billing period end date)` `- **Recommended Fix**: Derive `service_period_start_date` from `billing_period_raw` by extracting the end date portion (after "–"), parsing it as a date, then applying a `date_component("start_of_month")` transform. This generalizes to any billing period where the service month is defined by the end date's calendar month.`	

	DocExDSL Generation Agent	`# billing_period_end_raw: intermediate — extracts end date portion after "–"`
		`Field("billing_period_end_raw", type="date")  # intermediate: needed to derive service_period_start_date and service_period_end_date`
		`  .derive_from("billing_period_raw")`
		`  .subset(split_by="–", split_index=1),`
		
		`# service_period_start_date: start of calendar month of billing period end date`
		`Field("service_period_start_date", type="date", required=True)`
		`  .derive_from("billing_period_end_raw")`
		`  .transform(date_component="start_of_month")`
		`  .format("MM/DD/YYYY"),`
			12/01/2025

Figure 11: End-to-end extraction flow through the CACHE-ED2 pipeline. Stage 1: Generation Agent extracts initial values. Stage 2: Human correction triggers critic analysis revealing an SOP. Stage 3: Agent regenerates DSL incorporating the learned derivation rule.

Table 4: CACHE-ED2 extraction performance across 159 vendors (11,774 documents). All fields achieve 100% extraction rate.

Field	Ext. Rate	Accuracy
Account Number	1.0	0.9797
Invoice Currency	1.0	1.0
Invoice Date	1.0	0.9931
Invoice Number	1.0	0.9932
Service Period Start	1.0	0.9978
Service Period End	1.0	0.9980
Vendor Provided Due Date	1.0	0.9975
Aggregate	*1.0*	*0.9942*

all fields and 99.42% aggregate accuracy, with no field falling below 97.97%. This performance is maintained uniformly across the vendor-volume distribution: tail vendors with fewer than 10 documents receive the same cached program quality as head vendors, since the ReAct-based Generation Agent synthesizes a correct DocExDSL program on first encounter regardless of expected future volume.

H Per-Component Ablation Study

We quantify each component's marginal contribution with leave-one-out ablations on a real-world cohort, removing exactly one component per configuration while holding everything else fixed.

Protocol. The cohort is drawn from one production vertical by vendor-volume scaling filtration: each vendor's monthly volume v_i is scaled to $\lfloor v_i \cdot s \rfloor$ documents, vendors retaining fewer than two documents are dropped, and s is the largest factor for which the retained total stays within a 1,000-document budget. This preserves the shape of the vendor volume distribution (96 vendors retained; per-vendor counts from 2 to 115) while guaranteeing every vendor contributes at least one post-cold-start document. Documents replay chronologically within each vendor, and every configuration, including the unablated reference, runs against its own empty program cache under identical conditions. Ablated arms: visual grounding off (no page images in any agent prompt), execution-in-the-loop off (single-pass generation without the execute-verify-refine tool loop), HITL feedback off (the first synthesized program is final), and encoder routing off (one program per vendor, ignoring for-

Failure Mode	Human Curated SOP	CACHE-ED2 Derived SOP

No Label	To find **Account Number** use the highlighted area
	Eg. AZ[redacted]SX5
	
		`Field("account_number", type="string", required=True)`
		`  .extract_by_anchor("Am[redacted] –", direction="nearest", offset=0.0, match="contains")`
		`  .on_pages(2)`
		`  .subset(pattern=r"[A-Z]{3}[A-Z0-9]+")`
		`  .disambiguate("first_occurrence")`

Derived Information	To find **Invoice Number**
	1. Check if Invoice Number is explicitly mentioned in the document. Only follow below steps if NOT explicitly present. Else use Invoice Number present.
	2. Extract Account Number Eg. 408[redacted]635 6
	3. Extract Month and Year from Invoice Date Eg. Dec 1, 2025
	4. Get Invoice Number using the Account Number + Month Year of Invoice Date Eg. 408[redacted]6356DEC2025 (Note: no space between the month and account number)
	
		`Field("invoice_month_abbr", type="string")`
		`  .derive_from("invoice_date_raw")`
		`  .subset(pattern=r"^[A-Za-z]{3}")`
		`  .transform(case="upper"),`
		`Field("invoice_year_2digit", type="string")`
		`  .derive_from("invoice_date_raw")`
		`  .subset(pattern=r"\d{4}$")`
		`  .subset(pattern=r"\d{2}$"),`
		`Field("invoice_number", type="string", required=True)`
		`  .derive_from("account_number_digits", "invoice_month_abbr", "invoice_year_2digit")`
		`  .transform(template="{account_number_digits}{invoice_month_abbr}{invoice_year_2digit}")`

Disambiguation	To find **Invoice Number**
	1. Consider the highlighted header level occurrence of Invoice Number and NOT the line level occurrences
	
		`Field("invoice_number", type="string", required=True)`
		`  .extract_by_key("INVOICE NUMBER", "invoice number", match="contains")`
		`  .or_extract_by_anchor("INVOICE NUMBER:", direction="right", offset=0.3)`
		`  .disambiguate("first_occurrence")`

Figure 12: Human-curated vs. CACHE-ED2 derived SOPs across three failure modes: unlabeled information, derived information, and disambiguation. The framework produces functionally equivalent extraction logic from analyst corrections alone.

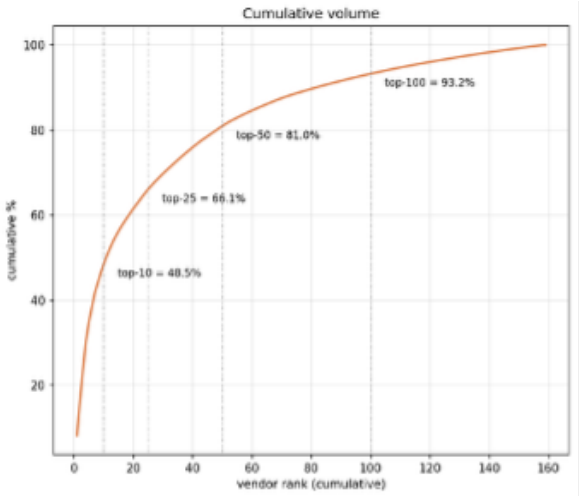


Figure 13: Cumulative document volume distribution across 159 vendors. The top 10 vendors account for 48.5% of volume; the top 50 cover 81.0%.

Table 5: Leave-one-out ablation of CACHE-ED2 components on a 1,000-document real-world cohort (96 vendors, 115 formats). Each cell reports the ablated configuration relative to the full system: lower means the removed component contributes more. Full-system absolutes: completion 0.875 (share of documents yielding a final program under the framework's fixed agent-step cap), accuracy 0.980 and extraction rate 0.998.

Configuration	Compl.	Accuracy	Ext. rate
– visual grounding	0.270	0.973	0.994
– execution-in-the-loop	1.000	0.947	0.955
– HITL feedback	1.000	0.829	0.897
– contrastive encoder	1.000	0.999	0.999

mat identity).

Results. Each cell is the fraction of the full system's performance retained after removing one component; lower means a larger contribution. Visual grounding is the reliability component: without page images the agent retains only 0.270 of baseline completion, failing on three quarters of the cohort, with quality high on the surviving documents. Execution-in-the-loop and HITL feedback are the quality components: single-pass generation retains 0.947 of accuracy and 0.955 of extraction, most first drafts being correct given DocExDSL's schema-driven specification, with the execute-verify-refine loop repairing the drafts that fail; removing HITL is the largest quality loss (0.829 and 0.897), since fields governed by business operating procedures rather than the document surface (the introduction's due-date and account-number cases) are corrected only through analyst feedback. Completion cells capped at 1.000 mark ablations that complete at least as often as the full system (less agentic work, fewer step-cap failures); their cost surfaces in the quality columns. The

encoder's near-unit retention masks substantial exposure: 21 of the 87 vendors completing documents, including the cohort's largest, expose multiple formats and hold 39.7% of completed documents; a vendor-level program still serves the dominant format, and the oscillation it invites across the remaining formats concentrates in production's high-volume head, where the main text measures the encoder's contribution. All results come from one vertical's cold-start cohort under a fail-fast step cap; in production, across seven verticals with differing extraction requirements and far larger per-format volumes, each effect compounds, paid on every subsequent document of the affected format, with non-completing documents served by retry and analyst fallback.

I End-to-End Cost and Latency

All calculations use three classes of inputs. Measured inputs come from a 36,093-document production run: serving rates (hit 0.960, miss 0.040, repair 0.313), per-path token means, and the zero-LLM property of the hit path, verified as zero LLM tokens across all 23,937 clean-hit documents. Priced inputs are on-demand list rates, accessed: the production model (Bedrock Claude Sonnet, $3/$15 per million input/output tokens) and OCR (Amazon Textract forms analysis, $0.05 per page; the run's documents average 3.5 Textract-billed pages, measured over 23,481 completed documents under the pipeline's ten-page processing cap, raw mean 3.8 pages, median 3).[1] Latency figures are serialized single-document anchors and are order-of-magnitude. Structurally, LLM cost arises only on the miss path: program synthesis is paid once per format, and HITL repair is paid per correction event, and both produce program-level artifacts reused by every subsequent document of the format.

Discussion. Every LLM expense is format-level work while document volume recurs: the $0.46 synthesis event amortizes to $0.00015 per document at the observed 3,008 documents per format, and repair amortizes likewise, since a repaired program serves all subsequent documents of its format and the 31% event rate of this onboarding-heavy window declines as programs mature. OCR never amortizes: $0.17 per document at the measured page mix, 70% of expected cost against 23% for repair and 7% for synthesis. The registry was already warm: only 3.8% of misses required live synthesis, so the average miss incurred $0.02 of LLM cost against $0.46 for a genuinely new format (the table reports the latter). The amortized expected cost is $0.249 per document ($249 per 1,000; an independent bucket-mixture computation agrees within $0.01), 38× below the $9.40 manual invoice-processing average, and the steady-state cache-hit document ($0.17, zero LLM) is 54× below. Running the agentic path on every document at the same verification rigor would cost $0.46 of LLM per document, six times the cached system's $0.075, which falls toward zero as formats mature, the compounding mechanism of Section 4.3. Provider choice moves the result only within $0.18 to $0.25 per document because OCR, not model price, dominates. The remaining levers split: LLM-side, steady-state repair rates, batch and prompt-caching discounts (up to 50% and 90% of list prices), and smaller or fine-tuned synthesis and repair models (DocExDSL constrains their output space); OCR-side, lighter analysis tiers (text detection at $0.0015 per page versus $0.05 forms analysis) and page-selective processing.

Table 6: Per-document cost and latency by serving path. Token counts (input/output) are measured means over the production run; latency figures are serialized single-document anchors (order of magnitude); costs use the production model's list prices; OCR is priced at the measured mean of 3.5 billed pages per document.

Path / component	Latency	Tokens	Cost
Cache hit (the 96.0% path)			
OCR (3.5 pages)	seconds	n/a	$0.174
Encoder inference	<1 s	n/a	$< $0.01
Deterministic execution	∼1 s	0	∼$0
End to end	∼12 s	0	$0.174
Cache miss with synthesis (new format)			
ReAct synthesis (∼8 calls)	80–128 s	117.6K/7.2K	$0.461
End to end	2–4 min	117.6K/7.2K	$0.634
HITL repair event			
Critic analysis	10–16 s	8.5K/0.7K	$0.036
Regeneration (∼5 calls)	50–80 s	32.7K/3.1K	$0.145
Repair total	1–1.6 min	41.2K/3.8K	$0.181

Abstract

We present AgentLens, a trajectory-level evaluation framework for interactive code agents, built from production-informed tasks and integrated into continuous regression testing. Most code-agent benchmarks reduce a run to a single bit—did the task pass?—but the people who actually use these agents experience the entire trajectory: how the agent follows instructions, uses its tools, verifies its own work, recovers from mistakes, and talks to them along the way. AgentLens evaluates that whole trajectory, pairing formal verification with LLM-written trajectory reviews and side-by-side comparisons, so that each run yields a readable explanation of the final score. Apart from ranking models, AgentLens can be used to diagnose model behavior, compare successive versions of agents, and catch product regressions in an evaluation pipeline. We release AgentLens at https://github.com/agent-lens/agent-lens-bench.

1 Introduction

Most coding agent benchmarks ask one question: did the agent finish the task (Jimenez et al., 2024; Merrill et al., 2026)? For a research leaderboard, a single pass/fail bit is often enough, but for a coding assistant that developers use all day it misses most of what matters. A run can pass a narrow check yet still be unreliable, overconfident, unpleasant to work with, or subtly misaligned with what the user asked for; conversely, a run that fails the final check may still have localized the bug correctly, used its tools safely, and recovered gracefully along the way. The problem is sharpest for tasks with no natural binary outcome, such as writing project documentation: the useful question is not whether a file appeared on disk, but whether the document is accurate, appropriately scoped, readable, grounded in the codebase, and helpful to its readers.

Our benchmark, *AgentLens*,[1] keeps this structure visible by evaluating complete trajectories rather than final states alone. A *trajectory* is the full record of a session: messages from the (simulated) user, the agent's replies, its tool calls, file edits, command executions, verification attempts, the final response, and the final repository state. AgentLens treats this record as the primary object of evaluation, using textual judge reviews as the main artifacts and formal verification as complementary objective checks wherever they exist. We built it because existing benchmarks did not match what we needed to know: some lacked realistic user interaction, some collapsed everything to a binary or final-state outcome, and some used tasks too simple or too far from the day-to-day work of a coding assistant. Our main contributions in this work are: (1) a benchmark for interactive code agents; (2) a trajectory-level evaluation protocol that combines formal verification with LLM judge reviews; (3) side-by-side reviews for model comparison, feature evaluation, and regression analysis; (4) an open-source release of the benchmark code at https://github.com/agent-lens/agent-lens-bench.

2 Related Work

AgentLens builds on three lines of work: code and software engineering (SWE) benchmarks, interactive tool-use environments, and LLM-as-judge evaluation. Early benchmarks evaluate isolated programming tasks against unit tests; repository-level ones move closer to real engineering, with SWE-bench resolving real GitHub issues (Jimenez et al., 2024) and SWE-agent showing that the agent-computer interface matters (Yang et al., 2024). These primarily measure final-state resolution; AgentLens instead keeps formal verifica-

tion where available and adds trajectory-level review of instruction following, tool discipline, validation, recovery, and communication. LLMs as multi-step agents are evaluated in external environments, across diverse tasks (Liu et al., 2024), large real-world API sets (Qin et al., 2023), and web or computer control (Zhou et al., 2024; Xie et al., 2024). Closest to us, τ-bench evaluates tool-agent-user interaction with a simulated user given a role and a hidden goal (Yao et al., 2024) and Terminal-Bench tests CLI agents on realistic tasks (Merrill et al., 2026); AgentLens borrows this for coding assistants, generating user behavior from a persona and task objective so each trajectory can be reused for flexible cross-agent comparison. AgentBoard further evaluates multi-turn agents through fine-grained progress measures (Ma et al., 2024), while AgentEval derives application-specific criteria for assessing agent utility (Arabzadeh et al., 2024). MT-Bench and Chatbot Arena show that side-by-side comparisons enable scalable evaluation of open-ended behavior (Zheng et al., 2023); HELM-Instruct extends LLM-based evaluation to five-dimensional absolute ratings (Zhang et al., 2024), while Agent-as-a-Judge evaluates intermediate agent behavior with an agentic evaluator (Zhuge et al., 2024). AgentLens scores trajectories per dimension and attaches a written, evidence-grounded review, so a low score can be traced to poor tool use, weak verification, misleading claims, instruction violations, or unpleasant interaction; reviews are summarized to find the most frequent failure modes. Relative to these approaches, AgentLens pairs trajectory reviews with task-specific formal verifiers, supports pairwise comparison of complete trajectories, and integrates the same evaluation into CI regression testing.

3 AgentLens

In AgentLens, adding a task requires a target repository (pinned to a commit), a task description for the user simulator, and a verification setup for the formal metrics; verifier categories are listed in Appendix Table 10. New judge metrics can be added when a fold targets a specific behavior; a test-generation fold, for instance, can score mocking strategy with a test-specific metric.

Task Set and Runs. We release a set of 16 coding-agent scenarios run with two user personas (see below), 32 trajectories per agent. The compact task set is designed for repeated evaluation in an agent-development workflow. AgentLens uses LLM judges that review complete trajectories rather than final outcomes alone, capturing strengths and failure modes that binary evaluation can miss. The low run-to-run variance we report below suggests this compact setup is stable in aggregate. The dataset is organized around *workflows*, each specifying a task objective and a sequence of instructions and interaction steps. We obtained these from interviews in which programmers walked us through work done that day or the day before, with follow-up questions to recover the actions involved (inspecting code, editing files, searching documentation, running tests, debugging, reviewing changes), weighting recent workflows more heavily. Data also includes production-derived scenarios built from anonymized usage summaries of chats from consenting users. We worked only with anonymized summaries of conversations, extracting coarse tags (language, technology, task type, application domain); this privacy-preserving step is similar in spirit to *Clio*, which clusters assistant conversations to surface usage patterns without exposing raw data (Tamkin et al., 2024). We clustered tag vectors with k-means and inspected large clusters not yet represented in the benchmark (Appendix B); for each, a programmer picked a matching open-source project, generated a candidate scenario, and revised it for realism and verifiability.

User simulator personas. Since the user is itself an LLM, we can vary its temperament and watch how robust an agent is to different interaction styles. We use three personas as controlled trajectory-generation conditions rather than calibrated models of developer behavior: the *default* is a relaxed user who does not proactively help and intervenes only on clear evidence of failure; the *helpful* cooperatively points out visible mistakes and offers concise guidance; and the *toxic* is mildly frustrated and occasionally impolite, yet still preserves the task objective and never gives misleading instructions. The released fold pairs each scenario with the default and toxic personas, testing whether an agent can finish under both sparse feedback and mildly adversarial conditions, while the helpful persona is available for studies of agents that benefit from in-loop guidance.

Can we trust an LLM to grade other LLMs? Human annotation of long coding trajectories is not an obvious gold standard: each item requires reading a lengthy trace and applying a multi-page

rubric, making consistent annotation difficult to achieve. Still, we compared GPT-5.4 trajectory scores with three human annotators, who independently labeled 39, 39, and 36 trajectories, respectively. We report annotators separately to avoid conflating judge agreement with annotator-specific score calibration. As shown in Table 1, QI-level rank correlations range from 0.611 to 0.779, but per-dimension agreement is substantially more uneven. End Result and Tool Calls show the clearest alignment with human judgments, while Instruction Compliance, Pitfalls, and Pleasantness show considerably weaker agreement. These results are broadly consistent with prior work supporting the reliability of LLM-based evaluation, e.g., (Zheng et al., 2023).

Formal verification. Each trajectory receives formal checks wherever they apply: tests, regular-expression checks, repository-state checks, and task-specific validators (see Table 10). These give objective evidence about specific requirements but cannot evaluate interaction quality, instruction compliance, misleading validation, unsafe tool use, or partial coverage of a requirement. Reviewing the full trajectory also blunts reward hacking: an agent can satisfy a binary check via brittle shortcuts, skipping validation, or misreporting the final state, but this behaviour stays visible in the review.

LLM-as-judge metrics. Each trajectory is reviewed by LLM judges along five dimensions: (1) **ENDRESULT** looks at the final outcome only, measuring completeness and fitness for purpose with respect to the user's request; (2) **INSTRUCTIONCOMPLIANCE** checks whether the agent followed the user's explicit rules, requested steps, ordering constraints, and meta-instructions, independently of how good the final outcome was; (3) **PITFALLS** catches the fixable behavioral failures that hinder the user: tool misuse, non-productive loops, premature completion, missing validation, workflow instability; (4) **PLEASANTNESS** captures user-facing interaction quality: clarity, accuracy, conciseness, helpfulness, and whether the session feels productive and non-disruptive; (5) **TOOLCALLS** assesses tool-use quality: tool choice, argument correctness, success or failure, recovery from tool errors, and efficient versus futile calls. Each dimension yields a score and a written review citing the trajectory evidence behind it (see Appendix F.1). Raw trajectories are preserved; only oversized tool-call arguments and responses are truncated for judge input, and action summaries supplement rather than replace the interaction history. Scores have an ordinal scale (for PITFALLS, 0/0.5/1 for miserable/tolerable/good), and each review ends with evidence lines of the form `Aspect | Severity | Evidence`. Aggregated across a run, reviews are summarized into one report where hyperlinks such as `[R1]` point back to trajectory locations of each problem (see Appendix H and excerpt in Fig. 1).

Excerpt: ENDRESULT review, Gemini 3.1 Pro Preview

score mean: `0.62`

11 of 32 reviews judged the end result fit for purpose, typically where the change stayed narrowly scoped and was backed by passing targeted verification … The most common weakness was *partial* completion rather than total failure: 7 reviews said required documentation or schema work was incomplete … 5 reviews found the delivered code state itself unusable or contradictory to the claimed outcome … and 7 more flagged unreliable validation/reporting, e.g. final reports claiming green tests despite recorded `spotless:check` and `enforcer:enforce` failures `[R3]`, `[R10]`.

Figure 1: A condensed slice of one judge review.

Deterministic telemetry. For every run we also collect statistics (interaction cost, cache hit rate, latency, termination reason, generation-token throughput) and tool-use telemetry (mean parallel tool calls, mean tool calls per chat, per-tool success rates). These quantify efficiency and operational reliability independently of subjective judgment.

Taken together, the metrics separate *outcome* quality from *process* quality, which matters because agents fail in different ways: one reaches a good answer inefficiently, another follows instructions but fails verification, a third misuses tools, and a fourth produces something useful through an unpleasant interaction.

Quality Index. AgentLens reports the individual metric scores and a single quality index (QI), the unweighted mean of the components—the five judge metrics plus formal verification: $Q(a) = \frac{1}{|M|}\sum_{m\in M} s_m(a)$, where $s_m(a) \in [0, 100]$ is agent a's score on metric m. QI is a deliberately simple summary rather than a learned or externally validated utility function; we use equal weights to avoid introducing additional tuning.

We also inspect correlations between metric aggregates across systems. The raw correlations (Table 2) are uniformly positive—stronger systems score higher on several dimensions at once—so they mostly confirm a broad "quality factor" rather than revealing redundancy.

	Annotator 1 ($n = 39$)	Annotator 2 ($n = 39$)	Annotator 3 ($n = 36$)
QI	0.779 / 0.645	0.681 / 0.557	0.611 / 0.514
End Result	0.668 / 0.610	0.655 / 0.577	0.267 / 0.245
Instruction Compliance	0.045 / 0.044	0.161 / 0.153	0.321 / 0.286
Pitfalls	0.411 / 0.381	0.168 / 0.157	0.246 / 0.221
Pleasantness	0.331 / 0.314	0.337 / 0.308	0.356 / 0.324
Tool Calls	0.467 / 0.422	0.583 / 0.543	0.447 / 0.398

No Pleasantness	.992	2
No Tool Calls	.988	2
Formal only	.709	6

Table 3: Rank sensitivity of QI. ρ is Spearman correlation with the full-QI ranking; ΔR is the maximum absolute rank change.

Metric	Self	Opp.
Pleasantness	11	0
End Result	7	3
Tool Calls	7	2
Instr. Compl.	3	2
Pitfalls	1	0

Table 4: Self-preference flips: 157 comparisons, GPT-5.5 and Sonnet 4.6 judges.

We test QI sensitivity with leave-one-component-out ablations (Table 3). The top two configurations remain unchanged in every ablation; removing Instruction Compliance preserves the full ordering, while removing Tool Calls causes the largest top-five shift. Removing formal verification changes only positions five and six among the top six, whereas formal verification alone yields a substantially different ranking ($\rho = 0.709$). Leave-one-out stability shows that the leaderboard ranking does not depend strongly on any single component; this stability may partly reflect overlapping signal across correlated components.

Side-by-Side Reviews. AgentLens also supports side-by-side comparison of two trajectories from the same scenario, which we use when absolute scores do not explain a practical difference between agents. For each task instance, the pairwise judge compares two agents on the same request. It receives both trajectories plus the independent single-trajectory reviews for the dimension under comparison (instruction compliance, tool use, end-result quality, etc.), and is told to stay within that dimension and not re-derive the reviews; the prior reviews are the primary evidence, with raw trajectories consulted only to verify concrete details such as a tool call or error message. This anchors both agents to the same evidence and reduces positional bias (checked below; prompt in Appendix F.2). The judge outputs a short explanation, evidence lines (`Aspect | Winner | Severity | Evidence`), and an integer score; severity is *relative*—the gap between the agents, not how bad either is—so identical failures score a tie.

Score variance. To estimate run-to-run variance, we repeated the same GLM-5.1 (self-hosted) configuration five times—strong enough to complete many scenarios but shaky enough to expose variance. QI had mean 67.28 and standard deviation 0.94 on a 0–100 scale. Most of that variance came from formal verification, not judge scores: a component-level decomposition attributed 60.5% to formal verification, then Pitfalls (18.1%) and End Result (16.2%), so repeated runs mainly expose unstable task *completion* on borderline scenarios. At the scenario level (Figure 3), of the 32 scenario–persona points 15 passed all five runs, one failed all five, and 16 were flaky—variance concentrates in a few unstable points rather than spreading uniformly, making repeated evaluation useful for pinpointing nondeterministic or fragile scenarios.

To assess repeatability beyond a single configuration, we additionally analyzed repeated runs for six configurations. Sample QI standard deviations ($n = 4$, $n - 1$ denominator) were 0.886 (GPT-5.5), 1.264 (Sonnet 4.6), 2.197 (Gemini 3.1 Pro Preview), 2.499 (DeepSeek V4 Flash), 0.585 (DeepSeek V4 Pro), and 1.972 (Opus 4.7).

Side-by-Side Positional Bias. To test sensitivity to presentation order, we ran an order-swap test:

for agents A and B we compare A as Agent 1 / B as Agent 2 against the reverse. Orienting scores as Agent 2's advantage, perfect antisymmetry gives $s(A,B) \approx -s(B,A)$; per metric we report effect $= (s(A,B) - s(B,A))/2$ and residual $= (s(A,B) + s(B,A))/2$. Table 5 reports a close same-model GLM-5.1 pair and a high-contrast Opus–Haiku pair (Haiku in *no-thinking* mode); all five metrics keep their direction after swapping and residuals are small, although this two-pair test should be read as a sanity check rather than evidence that positional bias is negligible in general.

Judge Self-Preference. LLM judges can favor outputs from their own model family, especially for closely matched systems. We compared GPT-5.5-vs-Sonnet-4.6 trajectories twice, once with each model as judge, and the two judges picked different winners in 23% of task-metric comparisons, asymmetrically: in 18% each preferred the agent from its own family and in 5% the other agent. Half of this self-favoring bias comes from Pleasantness alone (Table 4); the average shift between judges is about 4% of the full pairwise range. Both judges still prefer GPT-5.5 on average, so the judge choice changes preference strength and borderline decisions, not the average winner. The primary leaderboard in Table 6 uses GPT-5.4 as the judge; below, we re-score it with Sonnet 4.6 to test whether judge choice affects the leaderboard ranking (Appendix A).

Production Pipeline. AgentLens is wired directly into our agent-development workflow: a candidate version is run on the benchmark set, producing trajectories, formal-verification results, metric reviews, aggregate scores, and side-by-side comparisons against a baseline.

CI benchmark workflow. A continuous integration pipeline (Fig. 4) runs the evaluation: a preparation stage selects manual, nightly, or weekly mode, and the benchmark stage runs the tasks in parallel across language- and IDE-specific environments, producing raw traces merged into a unified dataset. From it, the pipeline computes the metrics and a report with both metric values and judge reviews (Appendix H). It also detects regressions by comparing the current run against an *anchor* (supplied for manual experiments, automatic for scheduled ones): statistically significant degradations are flagged and notify maintainers, with both reports saved to experiment tracking (see "Qualitative Analysis" and Appendix I).

Model	QI	F	E	I	Pi	Pl	T

Kimi K2.6*	28.1	42.9	29.0	33.0	19.0	21.0	24.0

Table 6: Leaderboard on the 32-trajectory Java benchmark; best per column in **bold**; *QI*: quality index; *F*: formal pass rate; LLM-judge means: *E* (End Result), *I* (Instr. Compl.), *Pi* (Pitfalls), *Pl* (Pleas.), *T* (Tool Calls); *see Qualitative Analysis.

Extensibility. The benchmark is not tied to a single agent or IDE: CLI agents plug in through a lightweight Python adapter, and IDE assistants through integration interfaces (e.g., a specialized `AgentEngine` interface for IntelliJ IDEA plugins). Although this work focuses on Java, the benchmark adapts readily to other languages; we open-source support for IntelliJ IDEA and PyCharm and plan to extend to more IDEs and languages.

4 Evaluation

Leaderboard. As one application of AgentLens, we construct a leaderboard on Java coding-assistant tasks using two harnesses: our own Explyt Agent (EA) and Claude Code. Table 6 reports performance: a score reflects the model together with its provider, agent loop, tool interface, and execution policy. Values are percentages, rows sorted by QI, single-run reviews by GPT-5.4. We use high reasoning effort where supported unless noted; OpenAI and Anthropic models use their official providers, GLM-5.1 (self-hosted) runs locally, the rest via OpenRouter. Further details on model versions, providers, decoding settings, context handling, and run configuration are provided in Appendix D. Close QI differences should be interpreted in light of the repeat-run variability reported above.

Leaderboard Robustness to the Judge. The

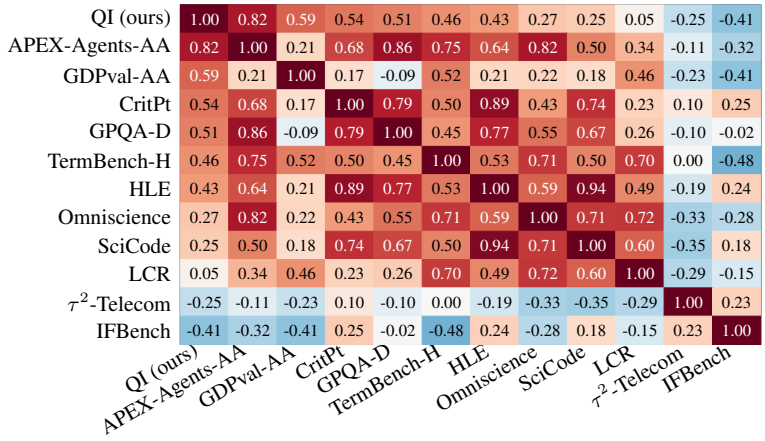

Figure 2: Spearman rank correlation between our Quality Index (QI) and per-benchmark scores from Artificial Analysis (Kimi excluded, OpenRouter-served GLM).

Metric	s_{AB}	s_{BA}	**Eff.**	**Res.**
GLM-5.1 vs. GLM-5.1				
End Res.	0.19	−0.21	0.20	−0.01
Ins. Cmp.	−0.02	−0.06	0.02	−0.04
Pitfalls	0.00	0.00	0.00	0.00
Pleas.	0.01	−0.03	0.02	−0.01
Tool Calls	−0.04	0.02	−0.03	−0.01
Opus 4.7 vs. Haiku 4.5				
End Res.	−0.39	0.35	−0.37	−0.02
Ins. Cmp.	−0.42	0.39	−0.40	−0.02
Pitfalls	−0.43	0.43	−0.43	0.00

Tool Calls	−0.48	0.41	−0.44	−0.03

Table 5: Order-swap sanity check: a same-model and a high-contrast pair. *Eff./Res.* are the antisymmetric model-difference and order-sensitive components; $s_{AB}{=}s(A,B)$, $s_{BA}{=}s(B,A)$.

leaderboard in Table 6 uses GPT-5.4 for its LLM-judge components, which shares a model family with one of the evaluated systems, so the standings could depend on that choice. We re-scored all 17 configurations with Sonnet 4.6 on the same trajectories, changing only the judge (Appendix A). Sonnet 4.6 scores every configuration higher, by 10.4 QI points on average (range 4.4 to 16.3), yet the ordering barely moves: Pearson $r = 0.970$ and Spearman $\rho = 0.980$. We find no aggregate same-family advantage: the six Anthropic configurations have a slightly worse mean rank under Sonnet 4.6 than under GPT-5.4 (5.67 vs. 5.33).

Model Behavior Case Study. The reviews are, in our opinion, more important than raw scores. Looking across the full benchmark, we highlight several anomalies and close calls that help explain *why* models differ.

Gemini 3.1 Pro Preview underperforms relative to its frontier status, and the report shows the problem is agent-loop reliability: workflow-control failures ("skipped or merged steps," "premature edits/tests before approval"), validation failures ("claimed all checks passed despite actual failures"), and editing failures ("stale-patch or destructive-edit loops," "brittle bulk replacements or sed that corrupted code"). High capability did not lead to a dependable agent loop (Appendix H).

DeepSeek V4 Pro vs. Flash is a tie that hides a tradeoff: Pro is more controlled, with compliance advantages on step gating, pauses, formatting, and file boundary control (Appendix I), while Flash has over 2x throughput, which lets it complete more work and more often end in a passing state. Similar QIs can thus reflect very different strategies, and we expose the trade-off rather than hiding it.

EA vs. Claude Code on Haiku shows a gap likely in part due to Claude Haiku's familiarity with Claude Code, which shows up in an unusually low `edit_file` success rate for EA (0.66 vs. 0.93) and in pitfall analysis that significantly favors Claude Code (`metrics_value` $= 0.1812$, $p = 0.038$): EA "more often makes poorly grounded or brittle changes and presents weaker verification." For the stronger Opus 4.7, though, EA comes out ahead.

EA vs. Claude Code on Opus is a tie on outcomes ("no meaningful separation," formal verification at 26 vs. 26), but the reviews still favor EA for being "more consistent at finishing changes cleanly and verifying them," while Claude Code has operational risk: "file/path and tool-contract errors," "serious misses of explicit user constraints," a "routing blast-radius regression," a "leftover workspace mutation," and the only timeout. Here the `edit_file` success rate reverses the Haiku pattern: Claude Code Opus is *lower* (0.92 vs. 1.00).

GPT-5.5 vs. Opus 4.7 is between procedural compliance and semantic reliability. GPT-5.5 often handles the explicit protocol better, but reviews note that Opus has higher "requirement coverage and final fitness," fewer route regressions, and stronger validation discipline, penalizing GPT-5.5 for "verification without covering changed branches," "unsupported root-cause claims," "missed affected tests," or marking a task done "despite not reproducing the failure." In short, GPT-5.5 follows the task *form* while Opus preserves the task *intent*.

Qualitative Analysis. The reviews are most useful when they catch something a score alone gets *wrong*. We show two cases. First, Kimi K2.6 sits dead last in Table 6, inviting the obvious reading that it is a weak coding agent. The ToolCalls review says otherwise: the dominant failure is not reasoning but a malformed-argument parsing problem on the OpenRouter side (the same JSON-wrapper mistake repeated across tools), and once the arguments are flattened the agent uses its tools successfully (Example 1 in Appendix G). The second example comes from the nightly pipeline. During a weekly regression run, a race condition in parallel tool calling left little trace in the final answer, but the side-by-side Pitfalls review pinned it to a concrete crash: because AgentLens exposes the termination reason alongside the full trajectory, the judge attributed the degradation to the harness—an explicit `ConcurrentModificationException`—rather than vaguely noting that output had gotten worse (Example 2 in Appendix G).

Correlation with Public Benchmarks. Figure 2 shows Spearman rank correlations between QI and every Artificial Analysis (AA)[2] evaluation reporting scores on current models. Eleven qualified, including the agentic APEX-Agents-AA, GDPval-AA, Terminal-Bench Hard, and τ^2-Bench Telecom. AA also aggregates them into an Intelligence Index (*AA composite*, AAC). *Mimo V2.5 Pro* and *Gemini 3.1 Pro Preview* are higher on AAC than on QI (rank gaps $+4.9$, $+3.8$; 90% bootstrap CIs $[+3.4, +6.4]$, $[+2.4, +5.1]$), consistent with optimization toward AA-style academic and reasoning evaluations. *Claude Opus 4.7*, *Sonnet 4.6*, and *DeepSeek V4 Flash* show the opposite (rank gaps -3.4 to -3.9, CIs strictly negative): they handle long-horizon IDE work better than the composite credits, with most of the gap in IFBench and τ^2-Bench Telecom, where Claude models score below their overall agentic quality. For *GPT-5.5* and *DeepSeek V4 Pro*, the two rankings agree.

We see that, first, QI tracks an axis of quality that does not collapse to any single AA evaluation, and second, the rank-gap residuals systematically split between models trained for evaluation-style competence and models built for sustained tool use. The matrix in Fig. 2 shows that public evaluations correlate strongly with one another, while QI agrees with agentic benchmarks and disagrees with reasoning and instruction-following ones.

5 Conclusion

We presented AgentLens, which evaluates code agents through evidence-linked trajectory reviews and formal verification. It captures user-visible quality that binary success metrics miss, and since every score comes with a written, evidence-linked review, it also supports diagnosis, feature evaluation, and nightly product-regression detection for a deployed assistant. In future work, we plan integrations for more coding agents (e.g., Codex, OpenCode); in AgentLens, CLI agents connect through the execution interface and IDE assistants through the IDE integration layer. It is organized into task folds (e.g., test writing has its own verifiers and metrics), so we plan to grow the benchmark by focused task families and to extend support to more JetBrains IDEs such as Rider and WebStorm. Overall, agentic coding benchmarks remain undersaturated though rapidly growing, and we hope AgentLens fills a currently vacant niche.

6 Limitations

We note several limitations. First, AgentLens evaluates a specific class of coding-agent tasks, not general model intelligence, and the present release is Java-only. The present Java fold serves as a demonstration of the methodology rather than evidence of generalization to unseen repositories or other languages. The current personas cover only a limited range of interaction behavior; extending evaluation to user models that provide incorrect or contradictory feedback remains future work. Second, several evaluated models are accessed through third-party providers (e.g. OpenRouter), so latency, routing, versioning, and availability are outside our control; the DeepSeek Pro-vs-Flash case illustrates this, as a $2\times$ throughput difference under a fixed budget means some leaderboard differences reflect serving conditions as much as model quality. Third, cost is non-trivial: a single Opus 4.7 run can exceed $100. Another limitation is that AgentLens was originally built around our own coding assistant, which may make some tasks or integration assumptions more natural for it; we mitigate this by releasing the benchmark and reporting example trajectory reviews, but broader external use is needed to assess neutrality. Pairwise comparisons may also inherit errors from the underlying single-trajectory reviews, which serve as their primary evidence. Finally, future work should study how QI relates to downstream developer outcomes.

A Leaderboard Under a Sonnet 4.6 Judge

Table 7 gives the per-configuration results of the judge swap discussed in Section 4: the leaderboard of Table 6 re-scored with Sonnet 4.6 in place of GPT-5.4 on the same trajectories.

Model	QI_G	QI_S	Δ	R_G	R_S
Harness: Claude Code					
Opus 4.7 (xhigh)	76.2	81.0	+4.8	2	2
Sonnet 4.6	70.1	76.1	+6.0	5	7
Haiku 4.5	63.6	74.6	+11.0	9	9
Harness: EA					
Opus 4.7	81.5	85.9	+4.4	1	1
GPT-5.5	73.0	78.7	+5.7	3	4
Sonnet 4.6	70.2	80.5	+10.3	4	3
GLM-5.1 self-hosted	67.3	78.3	+11.0	6	5
DeepSeek V4 Flash	64.8	76.6	+11.8	7	6
DeepSeek V4 Pro	64.1	75.9	+11.8	8	8
GLM-5.1	60.6	72.8	+12.2	10	10
Haiku 4.5	58.2	68.8	+10.6	11	12
Gemini 3.1 Pro Preview	54.5	70.8	+16.3	12	11
Gemini 3 Flash	52.7	61.8	+9.1	13	15
MiniMax 2.7	50.8	66.0	+15.2	14	13
Qwen 3.6 Plus	49.1	63.1	+14.0	15	14
Mimo V2.5 Pro	45.1	56.1	+11.0	16	16
Kimi K2.6	28.1	39.0	+10.9	17	17

Table 7: Judge swap on identical trajectories. Subscripts give the judge, *G* for GPT-5.4 and *S* for Sonnet 4.6; *QI*: quality index; *R*: rank across all 17 configurations.

B Benchmark Tasks

Table 8 lists three of the production-usage clusters produced by the k-means procedure described in Section 3, each with the tags that characterize it and a short natural-language description. They illustrate the kind of real, multi-step coding work the released scenarios are drawn from—test refactoring, legacy-to-Java database migration, and API documentation and DTO cleanup.

C Reliability and Pipeline Figures

Figure 3 reports the per-scenario stability of formal verification across five repeated runs of the same configuration, complementing the aggregate variance figures in the main text. Figure 4 sketches the nightly continuous-integration workflow that executes the benchmark, aggregates metrics, stores reports in the experiment-tracking system, and flags regressions through side-by-side comparison against an anchor run.

Formal verification passes	Distribution	Count
0/5		1
1/5		3
2/5		5
3/5		4
4/5		4
5/5		15

Figure 3: Formal-verification stability across five repeated runs.

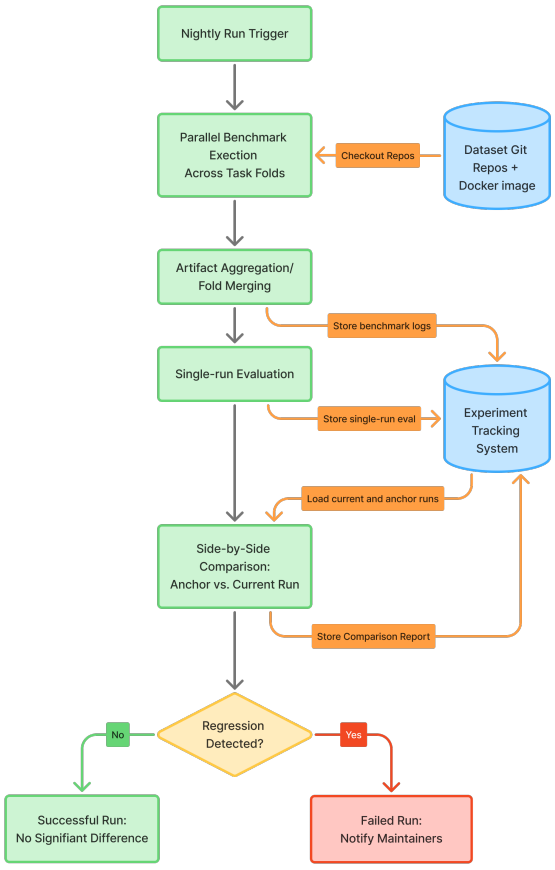

Figure 4: Abstract CI workflow: benchmark execution, metric evaluation, experiment tracking, and regression detection via side-by-side comparison between the current and anchor runs.

Task family	Representative tags	Cluster description
Unit testing and test refactoring	java, testing, junit, springboot, mockito, unittesting, maven, refactoring	The user is working on a Java project, typically using Spring Boot, and needs to establish or improve unit testing. They are focused on writing and refactoring tests with frameworks like JUnit and Mockito, often mocking dependencies such as repositories or services. Common activities include generating comprehensive test suites, optimizing existing tests, and integrating tests into build systems like Maven or Gradle. The work emphasizes ensuring proper test coverage, handling edge cases, and maintaining clean, maintainable test code.
Legacy database-logic migration	database, migration, springboot, java, liquibase, sql, jpa, debugging	The user is migrating legacy database logic, typically SQL or Oracle functions, into Java code within a Spring Boot application. This involves designing and implementing JPA entities, repositories, and service layers to replace the database-side logic. A key component is using Liquibase for database schema changes and migrations, often to support the new Java structures or seed test data. Common challenges include debugging migration errors, resolving constraint violations, and ensuring correct dependency injection in the Spring context.
API documentation and DTO cleanup	documentation, java, refactoring, springboot, openapi, dto, code-comments, swagger	The user is working on a Java Spring Boot application, often dealing with legacy code or existing codebases, and aims to improve the code quality and clarity for future maintenance. A primary focus is on enhancing API documentation—particularly through OpenAPI/Swagger annotations—and ensuring consistent JSON field naming, such as enforcing camelCase in DTOs. This involves systematic tasks such as adding or refining JavaDoc comments, standardizing exception handling, and removing outdated annotations. The overarching goal is to prepare the code for refactoring or to align with modern API standards while maintaining a clear, documented codebase.

Table 8: Examples of production-usage clusters represented by benchmark scenarios.

Kimi K2.6	`moonshotai/kimi-k2.6`	—	OpenRouter	high

Table 9: Model and serving configurations used for the leaderboard.

D Leaderboard Run Configuration

Table 9 summarizes the model and serving configurations used for the leaderboard. When an immutable historical snapshot was unavailable, we report the recorded API alias and, where available, a model version or catalog label.

Leaderboard entries are based on a single benchmark run, except for self-hosted GLM-5.1, whose score is averaged over five complete runs. For provider-hosted models, temperature, top-p, top-k, penalties, and seed were not set by the harness and provider defaults therefore applied. No explicit token budget was imposed; context management followed the default behavior of the respective agent harness. Runs used a 900 s response timeout (1200 s for self-hosted GLM-5.1), a 1200 s scenario timeout, and at most 10 user messages.

The self-hosted GLM-5.1 configuration used AWQ 4-bit quantization with group size 128 and bfloat16, `enable_thinking=true`, checkpoint defaults `temperature=1.0` and `top_p=0.95`, and a maximum model context of 200,000 tokens; no explicit seed was set. The primary judge was `OpenAI/gpt-5.4`, with high reasoning effort and `max_completion_tokens=25000`; temperature, top-p, and seed were left unset.

Judge cost and latency. Across full GPT-5.4 judging runs on the same fold, cost averaged $0.628 per trajectory (SD $0.028). GPT-5.4 judging achieved a measured review throughput of 3.51 s/request (SD 0.095) at five-way concurrency. For the Sonnet 4.6 re-evaluation, judging cost was estimated at $0.632 per trajectory (SD $0.095), and measured review throughput averaged 7.9 s/request (SD 6.1) at the same concurrency.

E Formal Verifier Details

Formal verification complements the LLM-judge reviews with objective, deterministic checks. Each scenario specifies a set of verifiers drawn from the categories in Table 10, and passes formal verification only if *every* verifier passes. Verifiers are deliberately small and composable, so a new task usually reuses existing checks; new verifier types can also be added by implementing a common interface that inspects the final repository state, the chat, or tool calls and their outputs.

F Sample Judge Prompts

We include representative prompts below; the complete prompts for all single-run and side-by-side judges used in our experiments are available in the released repository at https://github.com/agent-lens/agent-lens-bench.

F.1 Pitfalls single-run judge prompt

System prompt. You are a coding expert and an objective critic. Your work will be checked and judged later on. Vagueness leads to your death.

User prompt.

```
<INTERACTION_HISTORY>

Above you have a history of interactions
between a user simulator and an agent.
This history contains additional system
info and system messages that we have
passed to the simulator during the
conversation. Some parts were truncated to
shorten your prompt and the user
simulator's prompt. For example, you might
see
"remaining characters are omitted only
from the User Simulator's prompt..."
message. It means that an original
transcript was truncated only after the
task
was completed.

Tool call responses might contain lists of
errors that occurred during the tool
call: if such a list is empty, it means
that there were no errors (e.g., empty
compilation_errors section for edit_file
tool). The last user message might not
be present in the history: either because
the user decided to terminate the chat
or because a time limit was reached; the
reason is unknown.

Note that this interaction was collected
in a benchmark environment, that differs
from real life situations: for example,
when the agent catches a timeout, it means
that it has probably hit the benchmark
time limit.

Your task is to judge the agent, not the
simulator. So if the task is not achieved
due to user simulator failures, it should
not affect the score you give. Treat the
simulator's actions as a given, even if
they seem suboptimal, and judge the agent
based on how well it responds within that
context.

There might be an <agent_actions_summary>
section in their chat. We append it to
help the simulator understand what the
agent did. As the simulator-agent
conversation progresses, this info gets
updated and appended to the last agent
message sent to the simulator. All
previous information gets dropped from the
previous messages though, so you don't see
them in the given history. This system
```

Category	Verifier	Description
Repository state checks	`NoChangesVerifier`	Ensures no files outside an explicitly allowed set were modified, guarding against unintended side effects.
	`YesChangesVerifier`	Asserts that a specified set of target files was modified, confirming the agent acted on the correct locations.
	`ExactFileMatchVerifier`	Performs line-by-line comparison of project files against reference files; optionally ignores empty lines and verifies no other files were changed.
Regular expression checks	`ChatRegExpCountVerifier`	Counts regex matches across all assistant messages in the conversation history.
	`ChatOrToolRegExpCountVerifier`	Extends `ChatRegExpCountVerifier` to also search tool call arguments and tool responses.
	`JavaFileRegExpCountVerifier`	Counts regex matches within Java source files at a given path, with an option to strip comments before matching.
	`NewFileRegExpVerifier`	Checks that at least one newly created file has a path matching the given pattern.
Test execution	`JavaRunTestsVerifier`	Runs the project test suite via Maven or Gradle, parses output for pass/fail/skip counts, and fails if any test does not pass.
	`JavaTestCoverageVerifier`	Measures and asserts the minimum test coverage for the specified class in the project.
Command output checks	`RunBuildSystemTaskVerifier`	Executes arbitrary build-system tasks and optionally validates command output against a regex with a configurable match-count threshold.
Static analysis validators	`NoFileErrorsVerifier`	Invokes IDE static analysis on a file or directory and fails if any errors (or optionally warnings) are detected in files of the specified languages.

Table 10: Formal verifier categories and their descriptions. A scenario passes formal verification only if every one of its verifiers passes.

```
info consists of:
 - a section with a list of compilation
 errors from IDE analysis (project
 errors);
   if empty, there are no compilation
   errors in the project;
 - all the code diffs made by the agent
 (maybe empty);
 - the most recent cmd calls (maybe
 empty).

Note that we use a simulator instead of a
real user: it behaves based on character
traits given to it.

Below we've gathered a final summary of
the agent's actions and state of the
project:
<agent_actions_summary>
<AGENT_TRACE>
</agent_actions_summary>

The chat has terminated for the following
reason:
<termination_reason>
<TERMINATION_REASON>
</termination_reason>

<Instructions>
Your task is to act as a precise and
analytical judge of an agent-user
interaction.
Judge the agent (not the simulator) on the
performance dimension 'Pitfalls' only.
```

```
Identify and diagnose fixable pitfalls in
the agent's behavior that hindered the
user.
This is about instability patterns and
self-sabotage dynamics (often
harness/tooling/workflow), not end-result
quality.

Extract pitfalls using this rubric. For
each distinct pitfall, provide:
- Category: Logic/Code faults |
Tool/Harness faults | Process/Interaction
faults | Something else
- Severity: low/medium/high
- Frequency: once/repeated
- Evidence: a short quote (tool name +
error text, or a brief message fragment)
- Mechanism: 1 short clause on why this
happened (root cause)

Counting rule (mandatory):
- One behavioral cluster (e.g., a loop of
identical tool calls) counts as at most
  one pitfall; if it repeats with the same
  root cause, mark it as
  Frequency=repeated.

Pitfall burden total (mandatory):
- severity points: low=1, medium=3, high=7
- frequency multiplier: once=x1,
repeated=x2
- Total = sum(severity_points *
frequency_multiplier) across distinct
pitfalls
```

```
Write pitfalls as structured lines so they
can be reused later:
`Pitfall: <free text> | Category: ... |
Severity: ... | Frequency: ... |
Evidence: ... | Mechanism: ...`

Also include one line:
`BurdenTotal=<Total>`.
</Instructions>

<Scoring>
Score should be a number from [0, 0.5, 1],
where:
- 0 means miserable performance,
- 0.5 means tolerable,
- 1 means actually good.
</Scoring>

Response consists of 2 parts:
- <Review>, 2 to 5 sentences narrative
focused on the metric. After the
narrative,
  add 1 to 6 short structured evidence
  lines when applicable:
  `Aspect: <free text> | Severity:
  low/medium/high | Evidence: <short
  quote/tool/error>`
  Make Aspect-lines concrete and reusable:
  they are the main guide for later
  aggregation.
  Severity is absolute (not delta-based).
- <Score>, the sole final number. Must be
one number and nothing else.

Template:
<Review>
[2-5 sentences]
Aspect: ... | Severity: ... | Evidence:
...
...

<Score>
[0|0.5|1]

Provide your response in the requested
format:
```

F.2 Pitfalls side-by-side judge prompt

System prompt. You are a coding expert and an objective critic. Your work will be checked and judged later on. Vagueness leads to your death.

User prompt.

```
<agent1_trajectory>
<AGENT_1_INTERACTION_HISTORY>
</agent1_trajectory>

<agent2_trajectory>
<AGENT_2_INTERACTION_HISTORY>
</agent2_trajectory>

Above are two chat transcripts (each
between a user simulator and an agent) for
the same task, one per agent, delimited by
<agent1_trajectory> and
<agent2_trajectory> tags. Some parts were
truncated to shorten your prompt and the
user simulator's prompt. For example, you
might see "remaining characters are
omitted **only from the User Simulator's
prompt**..." message. It means that an
original transcript was truncated only
after the task was completed.

<agent1_review>
<PRECOMPUTED_SINGLE_TRAJECTORY_REVIEW_FO⌋
R_AGENT_1>
</agent1_review>

<agent2_review>
<PRECOMPUTED_SINGLE_TRAJECTORY_REVIEW_FO⌋
R_AGENT_2>
</agent2_review>

The two blocks above, delimited by the
<agent1_review> and <agent2_review> tags,
are precomputed single-trajectory reviews
from another pipeline. They are for the
same task instance, one per agent, both
focused on the same performance dimension.
They were computed independently from the
raw transcripts.
The performance dimension name for these
reviews is 'Pitfalls'.

<Instructions>
Your task is to compare Agent 1 and Agent
2 on the SAME task instance with respect
to the performance dimension 'Pitfalls'.
Use the precomputed reviews
(<agent1_review>, <agent2_review>) as the
primary input to your comparison to avoid
positional bias.
Do NOT introduce new aspects beyond what
is present in those reviews, and do NOT
revise the individual assessments inside
them.
You may consult the raw trajectories ONLY
to verify concrete points mentioned in the
reviews (e.g., a specific tool call, error
message, or key claim), or get the general
context.
Stay strictly on the performance dimension
'Pitfalls'; ignore unrelated aspects.
Do not propose fixes; only characterize
differences with a focus on issues.

Inside the <Comparison> section, end your
text with a short structured breakdown
(1-6 lines) so a summarizer can weigh
severity:
`Aspect: <free text> | Winner: A1/A2/Tie |
Severity (Significance * Degree of
Divergence): low/medium/high | Evidence:
<specific quote/tool/error>`
Start with aspects where Agent 2 is a
winner.
```

```
Keep aspects specific to 'Pitfalls', and
keep evidence concrete and extra short.
You should assess the severity of the
observed differences accurately. Severity
should be determined as the product of the
aspect's Significance and the Degree of
Divergence between agents on that aspect.
If both agents exhibit the same failure
mode, severity should be low even if that
failure is critical in absolute terms.
Severity is about the delta between
agents, not how bad the situation is in
absolute terms. For instance, the
significance of the aspect 'breaking the
repo to a non-recoverable state' is
critical. If both agents break the repo,
but one breaks one module and another
breaks two modules, the divergence is
little. So the overall Severity of this
difference is low.

The Metric-Specific Instructions are
described below. When identifying aspects
to compare, use <agent1_review> and
<agent2_review> as your primary source.
Other aspects are assessed by other
judges, don't steal their work.
<Metric-Specific Instructions>
Focus on identifying and diagnosing
fixable failures in the agents' behavior
that hinder the user (mostly
harness/tooling/workflow issues). This is
about instability patterns and
self-sabotage dynamics, not outcome
quality.

POSITION-INVARIANCE (MANDATORY):
- The *order* of presentation must not
affect your judgement.
- However, you must keep identity
consistent: any pitfall you list must be
clearly attributed to Agent 1 or Agent 2
and must not "flip" mid-comparison.
- Write your analysis so that if the
trajectories were swapped, the reasoning
would stay the same and only the final
score sign would flip.

EVALUATION PROTOCOL (follow in this
order):
1) Extract pitfalls separately for Agent 2
and Agent 1 using the same rubric. For
each pitfall provide: Category, Severity
(low/medium/high), Frequency
(once/repeated), and a short evidence
quote (tool name + error text, or a brief
message fragment).
2) Compute pitfall burden totals Total_1
and Total_2 (formula below).
3) Only after step (2), map (Total_1 vs
Total_2) to a score using the
deterministic rules below.

CATEGORIES (use consistent taxonomy):
- Logic/Code faults: demonstrable wrong
code/logic or missing validation that
risks wrong output.
- Tool/Harness faults: tool misuse, wrong
args, inability to recover from tool
errors, patching mistakes, broken
edit_file usage, etc.
- Process/Interaction faults:
misunderstanding requirements,
non-productive loops, poor communication,
premature "done", ignoring constraints.
- One behavioral cluster (e.g., a loop of
identical tool calls) must be counted as
at most one distinct pitfall. If the same
tool or process error appears two or more
times with the same root cause, it must be
labeled as "repeated" and counted as a
single pitfall with a frequency
multiplier, not as multiple distinct
pitfalls.

KEEP EXAMPLES CONCRETE:
(tool misuse, loops, missing validation,
partial completion, placeholders, poor
communication, self-contradiction,
premature completion, failure to verify).
Emphasize causal mechanisms (why the
failure happens), not just outcomes.

SCORING (SYMMETRIC, FORMULA-BASED):
Compute a pitfall burden score for each
side and derive the pairwise score from
the delta.

A) PITFALL BURDEN SCORING PER AGENT
For each distinct pitfall you listed in
step (1), assign points:
- low = 1
- medium = 3
- high = 7
Frequency multiplier:
- once = x1
- repeated/looping/compounding = x2
So each pitfall contributes
(severity_points * frequency_multiplier).
Sum to get totals: Total_1 (Agent 1),
Total_2 (Agent 2).

B) DELTA (deterministic)
Delta = Total_2 - Total_1.
(Positive Delta means Agent 1 is better;
negative Delta means Agent 2 is better.)

C) MAP DELTA TO FINAL SCORE (integer in
[-5..5])
Use |Delta| only to choose the magnitude;
the sign is determined solely by which
agent is worse.
Magnitude table:
- |Delta| <= 3  -> 0
- 4..6          -> 1
- 7..10         -> 2
- 11..15        -> 3
- 16..22        -> 4
- >=23          -> 5
Sign rule (STRICT):
- If Delta > 0 (Agent 1 better): score
MUST be negative.
- If Delta < 0 (Agent 2 better): score
MUST be positive.
- If Delta == 0: score = 0.

OUTPUT REQUIREMENT (to enforce symmetry):
At the end of your narrative (before the
structured Aspect lines), include a single
line:
`Totals: A1=<Total_1>, A2=<Total_2>,
Delta=A2-A1=<Delta> => Score=<score>`

CRITICAL:
```

```
- The final score MUST be computed ONLY
from this Totals/Delta line using the
mapping rules above.
- Never mix up agent identities: A1 refers
to Agent 1 trajectory, A2 refers to Agent
2 trajectory.
- Do not use any other "overall
impression". If your narrative suggests
something else, adjust the pitfall list
and totals until they match.
These numbers must be consistent with your
pitfall list and with the mapping rules
above.
</Metric-Specific Instructions>

Scoring guidelines:
Reserve the |4-5| score range for stark
contrasts: one agent remains stable and
correct, while the other exhibits
cascading errors that destabilize the
repository, gets stuck, or leaves the
result completely unverified. When
differences are clear but non-critical,
use lower scores. Below is an example
specific for Pitfalls and ToolCalls
dimension, where the difference is clear,
but not critical:
    - Agent N made a clear tool-handling
    error: after list_dir, which dumped
    the output to a temporary file, it
    attempted to read a different path via
    read_file, receiving the warning
    "Virtual file does not exist," which
    created unnecessary friction. Agent M
    handled the same "dumped to file"
    pattern correctly, read the proper
    path, and proceeded without errors.
    Aspects:
    Temp-file tool handling correctness |
    Winner: AM | Severity: low | Evidence:
    AN read_file -> "Virtual file does not
    exist ..." after list_dir
    Non-productive detour after tool error
    | Winner: AM | Severity: low |
    Evidence: AN made an additional
    search_file_by_name call after the
    failure
    Score given: 1 or -1 depending on who
    is N and M
Below is an example specific for Pitfalls
and ToolCalls dimension, where both agents
had issues, but "manual rollback" seemed
more critical:
    - Agent N introduced a
    workflow-stopping repository break:
    multiple edit_file operations
    corrupted test code (e.g., turning an
    assignment into a stray queryConfig(
    line), causing cascaded compile/IDE
    errors ("Cannot resolve symbol...",
    "';' expected") and requiring manual
    recovery via git checkout -- ....
    Agent M made some incorrect
    assumptions and minor requirement
    drift, but did not corrupt files or
    require rollback, and kept changes
    localized.
    Aspects:
    Manual rollback needed to recover |
    Winner: AM | Severity: high |
    Evidence: AN git checkout --
    ...ConfigControllerTest.java /
    ...ConfigFileControllerTest.java
    Cascading compile breakage from tool
    misuse | Winner: AM | Severity: medium
    | Evidence: AN widespread "Cannot
    resolve method 'queryConfig'" after
    edits
    File corruption via edits (repo
    inconsistent) | Winner: AM | Severity:
    medium | Evidence: AN
    ConfigControllerTest.java shows
    broken queryConfig( line; IDE errors
    "Cannot resolve symbol 'result'",
    "';' expected"
    Misleading intermediate claim
    (corrected). | Winner: AN | Severity:
    medium | Evidence: AM premature
    call-site claim later corrected via
    .queryConfig( search
    Score given: 3 or -3 depending on who
    is N and M

Response consists of two parts:
- <Comparison>, 2 to 5 sentences PLUS the
breakdown lines at the end. Avoid primacy
and framing bias. Do not start the
comparison with "Agent 1 ..." or "Agent 2
...". First describe the concrete
difference in behavior in neutral,
role-free terms (e.g., "One trajectory
shows repeated edit failures due to
missing required arguments, while the
other applies edits without tool errors").
Only after stating the difference,
explicitly assign Winner: A1/A2/Tie in the
structured breakdown. Keep the narrative
symmetric and avoid framing one agent as
the default reference point.
- <PairwiseScore>, an integer in [-5, 5].
Use negative when Agent 1 is better,
positive when Agent 2 is better.
  -5 means Agent 1 is MUCH better and the
  difference would feel very severe for
  the user. 0 means tie/indistinguishable.
  +5 means Agent 2 is MUCH better and the
  difference would feel very severe for
  the user. So the score is symmetric this
  way. When setting the score, mentally
  check the sign: negative for Agent 1
  win, positive for Agent 2 win.

Template:
<Comparison>
[2-5 sentences comparison] +
Aspect: ... | Winner: ... | Severity: ...
| Evidence: ...
...

<PairwiseScore>
[-5..5]
</Instructions>

Provide your response in the requested
format:
```

G Qualitative Review Examples

These two reviews show why we treat the written reviews, not just the numeric scores, as first-class benchmark artifacts: in both cases the aggregate score is misleading, and only the review recovers what actually happened. In Example 1, Kimi K2.6's last-place TOOLCALLS score is driven almost entirely by a provider-side argument-serialization bug rather than a reasoning failure. In Example 2, a side-by-side PITFALLS review attributes a regression to a concrete `ConcurrentModificationException` crash surfaced through the termination reason, instead of merely reporting that quality dropped. Bracketed pointers such as `[C`k`]` and `[R`k`]` link each claim back to the specific comparison or trajectory location it is drawn from.

Example 1: Kimi K2.6 — TOOLCALLS review (an OpenRouter tool-parser bug, not a capability gap)

ToolCalls_Judge score mean: `0.24`

Malformed tool arguments were the dominant ToolCalls failure: 20 of 21 reviews reported at least one schema/argument parse error, and 17 of 21 described the same persistent wrapper mistake (`{"": {...}}` or deeper nesting) across tools such as `read_file`, `search_for_text`, `run_command`, `edit_file`, `write_file`, `list_dir`, and GitHub helpers.
Recovery was often weak rather than immediate: 15 of 21 reviews explicitly say the agent retried near-identical malformed payloads after parser messages named the missing top-level fields, sometimes adding more nesting instead of flattening the JSON, which drove high futile churn and frequent timeouts.
Despite that, 20 of 21 reviews still recorded some successful tool use once flat JSON was used—e.g. repo reads/searches, GitHub issue or tag reads, edits/writes, or a passing test/configuration run—so the failure mode was usually contract confusion rather than tool unavailability.
The practical impact was substantial: 11 of 21 reviews explicitly report blocked end-to-end progress such as no successful edits, no build/test execution, or no PR/issue analysis completion, and 6 of 21 also note secondary inefficiency from overly broad scans or huge dumped outputs even when calls succeeded.

Example 2: a parallel-tool-calling regression — PITFALLS side-by-side review

Pitfalls_Judge warning: `YES` judge alert: `YES` ($p = 0.089$, metrics_value $= 0.152$)

```
The clearest pitfall pattern is verification accuracy: Agent 2 was better in 7 comparisons and
worse in 2, with several serious cases where Agent 1 declared success after failed builds or
incomplete checks ([C1], [C3], [C4], [C13]), while Agent 2's misses here were lower-severity
overclaims such as [C2] and [C11].

Tool and harness stability was mixed, but the most debug-relevant failures include Agent 2's
explicit ConcurrentModificationException crash in [C5] and Agent 1's repeated malformed
tool/edit calls and timeouts, including a 600s timeout in [C12] and broken edit invocations in
[C11] and [C22]; across this group Agent 2 was better in 7 comparisons, worse in 4, with 3 ties.

On self-induced code breakage, Agent 2 was better in 9 comparisons and worse in 2: the
strongest examples are Agent 1 breaking routing or Java file structure in [C3], [C7], [C19],
and [C22], whereas Agent 2's main losses were narrower regressions such as the bad
setRequestor(...) edit in [C15] and a mock typing mistake in [C25].

On process discipline, Agent 2 was better in 9 comparisons and worse in 3, with repeated
evidence that Agent 1 skipped required stop points or drifted from its own declared plan ([C4],
[C6], [C15], [C21]), while Agent 2's main opposing pattern was step-skipping of its own in
[C16] and [C17].

By contrast, scope control and root-cause discipline leaned toward Agent 1: Agent 1 was better
in 8 comparisons and worse in 5, driven by multiple high-severity cases where Agent 2 made
speculative fixes without reproducing the bug or broadened contracts beyond the evidence ([C9],
[C10]), plus requirement mismatches in [C18] and [C19].
```

H Sample Single-Run Report

Gemini-3.1-pro-preview

Workflows
TL;DR

The agent performs best on narrowly scoped code changes: reviews repeatedly found successful refactors, targeted migrations, logging updates, and small interface changes when it stayed within scope and backed the work with focused tests. The main recurring weakness was partial or misleading delivery—documentation and schema work left incomplete, acceptance criteria covered only superficially, contract or behavior mismatches, and several tasks ending with a non-green or internally contradictory repository state despite claims that builds or static checks had passed. Operationally, about 70% of tasks reached formal verification, but validation was often narrower than requested, the edit-and-test workflow was unstable enough to trigger repeated patch/revert loops, and 4 of 32 conversations ended in timeout.

number_of_points

- chats_count: 32
- agent_scenarios_count (tasks): 16

formal_verification_result

- value: 23
- success rate: 0.71875

termination_reason

- User decided to finish the dialog: 28
- Waiting for the agent response timed out after 900s: 4

Tool call success rates

Tool	successes/total	success rate
run_configuration	24/32	0.750
edit_file	153/194	0.789
pull_request_read	8/8	1.000
read_file	243/243	1.000
...	...	...

EndResult_Judge

- score mean: 0.62

Review

11 of 32 reviews judged the end result fit for purpose, typically where the change stayed narrowly scoped and was backed by passing targeted verification, such as the password refactors ([R1], [R27]), ApprovalService documentation pass ([R4]), Spring Boot 3.5.6 migration ([R9], [R20]), and the diagram, test-data, logging, bug-fix, and connector-endpoint updates in [R12], [R16], [R18], [R19], [R23], and [R24].

The most common weakness was partial completion rather than total failure: 7 reviews said required documentation or schema work was incomplete or insufficiently specific, especially missing Swagger model annotations or unresolved schema annotations in the TaskTemplate work ([R2], [R8], [R26], [R32]) and weaker-than-requested comment/diagram specificity in [R4], [R14], and [R29]; 4 more said tests or observability changes were too weak to enforce the ticket requirements, including missing sorting/edge-case assertions and non-structured logging that skipped exception paths ([R15], [R17], [R28], [R31]).

5 reviews found the delivered code state itself unusable or contradictory to the claimed outcome, due to unresolved compile/static-analysis errors in KafkaConnectService or test refactors ([R5], [R13], [R25], [R32]) or a claimed comparator fix that was not present in the final diff at all ([R10]).

7 reviews also flagged unreliable validation/reporting: some final reports claimed green tests or static analysis despite recorded failures like `spotless:check` and `enforcer:enforce` ([R3], [R10]), some ran only targeted tests instead of the requested build/module coverage ([R11], [R22]), and some left plugin-resolution warnings or unrelated failing tests unexplained or unproven as pre-existing ([R6], [R9], [R20]).

Public-contract and answer fidelity issues recurred too: one connector change implemented the wrong external route shape, `/topics/v2/connectors` instead of `/v2/connectors` ([R21]), and two Kafka-usage summaries overstated conclusions by ignoring `GROUP_ID_CONFIG`/`commitAsync()` semantics or omitting that producer usage was effectively test-only ([R7], [R30]).

InstructionCompliance_Judge

- score mean: 0.52

Review

The dominant InstructionCompliance failure was workflow control: at least 15 of 32 reviews reported skipped or merged steps, premature edits/tests before approval, or failure to stop at mandatory checkpoints, including jumping from Step 2 to Step 8, editing during reconnaissance, and combining post-Step results with the next step in the same message ([R5], [R6], [R7], [R12], [R15], [R16], [R18], [R19], [R23], [R29], [R30], [R31]).

A second recurring pattern was reply-format noncompliance in at least 14 of 32 reviews, especially missing `STARTING STEP N` headers, omitting the exact bridge phrase `Moving on to step 4`, starting messages with tool-call dumps, and failing required output contracts such as code blocks or the exact final phrasing ([R1], [R5], [R10], [R12], [R14], [R17], [R18], [R20], [R21], [R24], [R27], [R29], [R31]).

Required reconnaissance and reporting were also often incomplete: at least 9 of 32 reviews noted missing affected-file/test lists, merged per-comment plans, skipped method/branch coverage, missing environment/build-context details, or incomplete final summaries such as omitting changed-file counts and mandated completion lines ([R3], [R4], [R13], [R21], [R24], [R25], [R27], [R28]).

Verification compliance failed in at least 10 of 32 reviews: agents claimed all checks passed despite actual failures or missing tooling, skipped required call-tree analysis or debug-output steps, exceeded prescribed retry limits, or ran narrower checks than requested instead of the full build/test scope ([R3], [R10], [R11], [R13], [R16], [R17], [R19], [R20], [R22], [R23]).

Several reviews also show direct task-constraint breaches beyond workflow, including editing forbidden files/tests, changing serialization-related annotations, not using the mandated migration guide, and only partially implementing requested Swagger/model or typed-return changes ([R2], [R8], [R9], [R11], [R22], [R26], [R32]).

Pitfalls_Judge

- score mean: 0.41

Review

The most common pitfall was unverifiable or overstated validation, appearing in 13 of 32 reviews: agents reported clean checks after explicit failures or partial evidence, such as claiming success after `spotless`/`enforcer` failures ([R3]), saying a bug was fixed without a matching recorded diff ([R10]), or asserting compile/build success from ambiguous log tails or without running compile/build at all ([R18], [R22], [R28]).

Workflow discipline was the next major weakness in 11 of 32 reviews, with agents skipping required step gates or acting before approval—for example running `mvn clean verify` and editing before Step 3/4 confirmation ([R20]), implementing during reconnaissance before the plan was approved ([R19], [R31]), or jumping straight from early steps to `**STARTING STEP 6/8**` ([R7], [R15], [R30]).

Tooling misuse and state instability repeatedly amplified failures: 13 of 32 reviews showed invalid or noisy harness usage (`No configuration with name ...`, oversized dumped outputs, repeated `grep`/`cat`/`tail` log scraping) [[R2], [R3], [R14], [R16], [R23]], and 10 of 32 escalated into stale-patch or destructive-edit loops involving `Could not find old_text in file`, `sed -i`, `git reset --hard`, repeated `git restore`, broken workspaces, or timeouts [[R10], [R13], [R19], [R25], [R32]].

A separate 12 of 32 reviews involved incorrect problem framing—misreading code, requirements, or target scope—such as changing guarded control flow ([R6]), validating only unsorted role/permission sets despite an alphabetical requirement ([R17]), breaking auth by changing a known-good fixture ([R16]), or describing a `consumer.commitAsync()` path as non-committing ([R30]); 6 reviews also breached explicit constraints or dependencies by adding Swagger annotations in modules without `io.swagger.annotations`, touching forbidden `pom.xml`, editing forbidden tests, or making unsolicited commits [[R2], [R4], [R8], [R11], [R26], [R32]].

Pleasantness_Judge

- score mean: 0.5

Review

Pleasantness was most often damaged by trust issues: 16 of 32 reviews reported inaccurate, overstated, or poorly evidenced status claims, including saying builds/tests passed when tool output showed failures or no full build had run, and claiming files or behaviors were changed when they were not [[R3], [R5], [R10], [R11], [R18], [R22], [R28], [R30]].

A second recurring problem was noisy user-facing communication: 8 reviews exposed internal reasoning, meta-instructions, or raw tool chatter directly to the user, with examples such as visible `94>thought` blocks and self-talk like “Wait, let’s analyze...” that made the interaction feel unprofessional and confusing [[R6], [R7], [R16], [R23], [R25], [R28]].

Workflow discipline also regularly reduced smoothness: 14 reviews noted unnecessary confirmation loops, mismatched step labels, edits made before approval, or awkward step jumps that made progress feel unreliable even when the task eventually succeeded [[R1], [R3], [R9], [R18], [R19], [R29], [R31]].

Execution quality often compounded that friction: 12 reviews described thrashy or risky operations such as repeated failed edits, broad `sed` replacements, forbidden file changes, dependency probing, and timeouts/no final response, while 9 reviews separately reported incomplete delivery or scope drift that forced the user to do follow-up quality control [[R8], [R13], [R19], [R25], [R32]; [R4], [R11], [R12], [R18], [R21]].

When the interaction was pleasant, the common pattern was simple and consistent: concise step-based updates, repo-first investigation, limited targeted edits, transparent explanation of constraints, and concrete verification/results in the final report [[R1], [R14], [R17], [R21], [R24], [R26], [R27]].

ToolCalls_Judge

- score mean: `0.5`

Review

Across the 32 reviews, the strongest recurring positive pattern was correct use of repo-aware discovery and scoped editing tools: many sessions quickly localized the target file or call site with `search_file_by_name`/`search_for_text`/MCP reads, inspected the relevant method with `read_file`, and landed a clean `edit_file` with no analysis failures (for example [R1], [R3], [R6], [R11], [R17], [R18], [R21], [R22], [R26], [R27]).

The main negative pattern was unstable editing in 11 reviews, typically caused by speculative changes, stale `old_text`, or unresolved dependencies/symbols rather than grounded file reads: repeated Swagger annotation failures in modules without the dependency ([R2], [R8], [R26], [R32]), wrong-file or wrong-API edits that had to be restored ([R5]), brittle bulk replacements or `sed` that corrupted code ([R13], [R19], [R25]), and edit loops where the claimed fix did not match the final file state ([R10]).

A second major weakness was inefficient tool selection and verification discipline: 15 reviews showed avoidable shell-heavy churn (`grep`/`cat`/`sed`, repeated `dependency:tree`, plugin/formatter invocations after success, or repeated test-file regeneration) instead of structured read/search/edit tools ([R2], [R5], [R7], [R10], [R12], [R15], [R16], [R20], [R21], [R23], [R29], [R30], [R31]), and 10 reviews had execution/validation mistakes such as guessed or wrong `run_configuration` targets, failure to read dumped outputs, single-test-only validation when a build was requested, or reporting completion without evidence that the verified state matched the claim ([R3], [R6], [R10], [R12], [R14], [R17], [R22], [R24], [R28], [R31]).

Harness-specific behavior was a consistent debugging signal: several agents correctly recovered from large-output temp-file dumps or flaky IDE-style runners by switching to `read_file` and direct Maven commands ([R1], [R4], [R6], [R7], [R17], [R21], [R23], [R28]), and some apparent IntelliJ/static-analysis failures were likely noise because Maven later succeeded ([R9], [R15], [R20], [R28]).

A smaller but important class of regressions came from unnecessary or disallowed workspace mutations, including editing forbidden files/tests or running risky VCS commands like `git reset --hard`, `git rebase`, `git clone`, and `git commit` that were unrelated to the user request ([R11], [R19], [R32], with lower-severity examples in [R4], [R10], [R21], [R23]).

I Sample Side-by-Side Report

DeepSeek-v4-pro vs. DeepSeek-v4-flash

Workflows

TL;DR

The main operational split is that Agent 1 was more trustworthy about protocol, diagnostic grounding, and not overstating validation, while Agent 2 more often got code and tests to a buildable, fully executed state but also had several serious cases of claiming success on weak or misleading verification evidence. On the outcome itself, the reviews are genuinely mixed rather than decisive: Agent 2 had more wins on completeness, fallback work, and executed verification, but Agent 1 had several of the more consequential wins where Agent 2 missed explicit requested behavior, introduced contract or fixture errors, or overfit the task; the aggregate outcome edge toward Agent 2 is small and not statistically reliable (p=0.117). Instruction-following shows a similar pattern, with Agent 2 somewhat stronger on sequencing, message format, and actually finishing required test steps, while Agent 1 was better on scope control in several important cases and more consistently followed special procedural requirements; the formal verification count was tied at 28-28, which is worth noting but only as a rough heuristic rather than strong proof of correctness. Operationally, Agent 2 was much cheaper and faster ($9.13 vs $21.20, 10,973s vs 18,987s, both statistically significant), and its much higher command/run success rates align with the reviews showing steadier completion, whereas Agent 1's extra cost and slower pace came with more timeouts/exceptions and poorer run-configuration success, even though its final reporting was often the more dependable of the two.

Total number of points (chats): 32

Review:

Across requirement fit and scope/completeness, the results are mixed: A2 leads in 20 Ck while A1 leads in 11, with the most important A2 wins coming from delivered or more complete fallback/test work in [C32], [C29], [C22], and [C26], but A1 has notable high-severity wins where A2 missed explicit requested behavior or overfit the task, especially [C25], [C21], and [C14].

On correctness and behavior preservation, neither side dominates overall (A2 wins 10 Ck, A1 wins 9), but the most consequential failures are split: A1 has high-severity wins in [C25] and [C21] because A2 introduced a wrong `/v2` route contract and left an invalid username fixture, while A2 has high-severity wins in [C11], [C29], and [C4] because A1 changed control-flow semantics, left a broken buildable state, or omitted required `501` handling.

Verification/build evidence favors A2 in 9 Ck versus 2 for A1, with the strongest gaps in [C29], [C32], and [C22] where A2 delivered passing builds or suites while A1 was broken, unrun, or incomplete; A1's main counterexample is [C19], where A2's final verification depended on extra skip flags rather than the agreed full command.

For documentation/report accuracy, the pattern is again mixed (A2 wins 8 Ck, A1 wins 7), with A1's most significant advantages in [C9], [C14], [C21], and [C24] where A2 had factual errors, overclaimed a fix, or used overly absolute wording, while A2's strongest wins in [C10], [C12], [C16], and [C22] come from catching inconsistent prerequisites, invalid diagrams, inaccurate completion claims, or unsupported rationale.

Safety/logging hygiene shows only a small signal: A1 has the main substantive win in [C1] by removing a risky full-request log, while [C2] is a tie on safe logging choices.

Review:

Across the step-gating and sequencing evidence, Agent 2 has the stronger record: A2 wins 14 comparisons in this group, while A1 wins 10 and 9 are ties; the clearest cases are [C1], [C2], [C29], [C30], and [C32] for A2, versus [C13], [C20], and [C21] for A1.

On message-format compliance, Agent 2 also has the edge, winning 9 items versus 8 for Agent 1, with many of A2's wins being more severe, including high-severity header/STOP-structure cases in [C26] and [C27]; Agent 1's main counterexamples are [C20], [C21], [C23], and [C28].

Agent 1 is stronger on scope control and special-procedure requirements: in scope/allowed-files behavior A1 wins 7 items versus 6 for A2, with major A1 wins in [C5], [C8], and [C15] but major A2 wins in [C7] and [C18]; in tools/diagnostics/language/protocol specifics A1 wins 8 items versus 3 for A2, driven by call-tree and mandated-phrase cases such as [C14] and [C19].

Test-execution/verification evidence favors Agent 2 overall, with 6 wins for A2 versus 2 for A1 and 2 ties, especially in [C21], [C22], [C29], and [C30] where A2 is credited for tighter test scope or actually completing the required verification/reporting stage.

Review:

```
Across workflow/protocol and verification/build-state reliability, Agent 1 had the stronger
record: in workflow-related proofs A1 was better in 14 entries and worse in 4, with major
separations in [C10] and [C24], and in verification/reporting A1 was better in 10 entries and
worse in 9, including high-severity cases where A2 treated failing or stale runs as success in
[C4], [C14], [C19], and [C20].
Agent 1 also led on logic/contract correctness, with 7 wins versus 5 losses in that group; the
most consequential A2 misses were fixes that did not address the reported path in [C14], a
filtering/pagination regression in [C18], and fallback handling errors in [C26], while A2's
main counterexamples were A1's routing miss in [C3] and semantics break in [C11].
Agent 2's clearest advantages were narrower and more operational: it was better on edit
stability in 8 entries versus 7 losses, especially where A1 destabilized files in [C3], [C25],
and [C29], and it was also better on some scope-control items such as [C1], [C7], [C17], [C21],
and [C26], though A2 had severe scope violations of its own in [C8] and [C18].
Tool/harness hygiene was mixed rather than decisive, but several A1 losses there were tied to
repeated command/schema mistakes or noisy reruns (for example [C13], [C25], [C29], and [C31]),
while A2 had its own notable tool-side regressions in [C20] and [C32].
Overall, the extracted proofs point to Agent 1 being more reliable on protocol, diagnostic
grounding, and behavior correctness, while Agent 2 was somewhat steadier on avoiding file
corruption and some scope-follow-through but with less favorable high-severity verification
failures.

Review:

```
Across the strongest evidence, Agent 1 leads on interaction hygiene: it wins
verification/reporting trust in 11 Ck and loses it in 5, including high-severity cases where
Agent 2 gave contradictory or misleading validation narratives in [C4], [C12], and [C14]; Agent
1 also leads on structure/protocol in 6 Ck versus 3 losses, with the biggest gaps in [C21],
[C20], and [C23] where Agent 2 skipped or broke the required step format.

Agent 2's clearest advantage is responsiveness and end-to-end completion: it wins
responsiveness/alignment in 8 Ck and loses 1, with major cases in [C26] and [C32], and it wins
completion/final usefulness in 4 Ck versus 4 losses, including strong delivery wins in [C29]
and [C32].

On operational smoothness, the split is close but important: Agent 1 wins 11 Ck and loses 11,
yet Agent 2 owns several high-severity wins in [C25] and [C29], while Agent 1's biggest
smoothness wins come from avoiding disruptive behavior in [C12], [C13], and [C16].

Boundary-respecting behavior is mixed rather than one-sided: Agent 1 wins scope-discipline in
3 Ck and loses 3, with both agents drawing criticism for touching forbidden files or
constraints (for example ([C5]/[C6]/[C8] versus [C7]/[C28])).
```

Review:

```
Across the proof groups, the largest repeated differences are in edit stability and
verification reliability: Agent 2 is favored in edit/repository stability in 7 comparisons and
loses 8, but Agent 1's worse cases include several high-severity corruptions or malformed
edits such as [C18], [C29], and [C5], while Agent 2's high-severity losses are concentrated in
[C8] and [C16].

Verification and runner use lean toward Agent 2 in 11 comparisons versus 6 for Agent 1, with
Agent 2's strongest wins coming from correctly scoped or completed test/build execution in
[C21], [C25], [C26], and [C32]; Agent 1's strongest wins in this area are mostly about Agent 2
masking Maven failures with shell pipelines in [C19] and [C20].

Exploration efficiency is mixed but slightly favors Agent 1 overall, with 13 wins for Agent 1
versus 10 for Agent 2; Agent 1's wins are mostly about avoiding broad or empty searches (for
example [C1], [C2], [C6], [C14]), while Agent 2's wins come from more targeted narrowing in
search-heavy tasks such as [C23] and [C24] and less repeated configuration probing in
[C21]-[C22].

Scope/context/completion shows the sharpest directional signal toward Agent 2: Agent 2 wins 5
comparisons and loses 2, including high-severity cases where Agent 1 edited forbidden files or
failed to complete the final requested tool work ([C7], [C26], [C32]), while Agent 1's
counterexamples are narrower scope violations by Agent 2 in [C5] and [C8].

Miscellaneous argument/path/output handling is broadly noisy on both sides, with many ties and
small wins split both ways; the most notable non-tie cases are Agent 1 being better when Agent
2 makes unknown-tool or bad-command mistakes ([C20], [C30]), and Agent 2 being better when
Agent 1 makes invalid read ranges or unhelpful file-type reads ([C9], [C22]).

Abstract

Aspect-based scientific summarization produces a focused summary of a long document for a given aspect (e.g., *Approach*, *Methods*). Prior work decomposes the task, assuming a model can neither attend over the full document nor resolve aspect complexity in one pass. We revisit both assumptions now that compact yet capable language models handle long contexts natively. Across three datasets and two primary open long-context models, decomposition provides no reliable quality advantage over direct full-document prompting. With the main 9B model, zero-shot is strongest on aggregate lexical, semantic, and claim-recall/F1 metrics; under the 7B robustness model, simple decomposed variants occasionally edge zero-shot, but gains are small and inconsistent. On these primary models, the multi-role agentic pipeline is never best in aggregate and incurs substantially higher token cost, whereas RAG uses roughly one seventh of zero-shot's tokens but delivers lower, less consistent quality. We characterize where added complexity loses, quantify the cost–quality trade-off, and distill practical deployment guidance. Code is available on GitHub.[1]

1 Introduction

Scientific document summarization condenses research papers into concise summaries that preserve salient contributions (Cohan et al., 2018). Because papers are long, structured, and technically dense (Yu et al., 2020), users often need summaries focused on a specific aspect, such as the *Outcome* (Takeshita et al., 2024) or *Method* (Meng et al., 2021), rather than a generic overview. Aspect-based scientific summarization addresses this problem: given a full document and a target aspect, produce a summary covering exactly the aspect-relevant content.

In practice, the task is further constrained: document confidentiality and API cost at scale require locally deployable models, predictable cost, and minimal reliance on labeled data or external APIs.

A common approach in long-context summarization decomposes the task into intermediate steps: evidence retrieval (Feng et al., 2025), extract-then-abstract generation (Takeshita et al., 2024; Zhong and Litman, 2025), iterative self-refinement (Wadhwa et al., 2024; Zhang et al., 2023), or agentic verification (Wang et al., 2025b). These designs share an implicit premise: the model cannot process the whole document in one pass, so the document or task must be broken apart and recombined.

This premise is increasingly questionable for two converging reasons. First, recent evidence on agentic systems shows decomposition is not a free improvement: added coordination introduces information fragmentation, error propagation, and inter-agent misalignment, making its value task- and architecture-dependent rather than automatic (Kim et al., 2025; Cemri et al., 2026).

Second, increasingly capable compact models deployable under a modest GPU budget now offer long-context variants that can ingest a full paper in a single pass (Qwen Team, 2026; Gemma Team et al., 2025). If the model can hold the whole document in a unified context, it is no longer obvious that breaking the input or task into steps improves aspect coverage enough to offset the orchestration cost and the new opportunities for evidence loss.

We therefore ask whether task decomposition pays off for long-context aspect-based scientific summarization with local LLMs. We compare six training-free pipelines under identical decoding and length-control conditions across three datasets (ACLSum, FacetSum, and our PMC-SA benchmark) and two primary open long-context models, with a supplementary 2B scale analysis. Our finding on the primary models is consistent: decomposition does not reliably improve quality. A single-

[1]https://github.com/webis-de/emnlp26-aspect-based-scientific-summarisation

EMNLP 2026 Industry Track, pages 1613–1636
October 24-29, 2026 ©2026 Association for Computational Linguistics

pass zero-shot generation is the strongest quality default on lexical overlap, semantic similarity, and claim-level factual overlap to reference summaries. Among full-document pipelines, it also provides the most favorable quality–token trade-off; RAG uses about one seventh as many tokens but yields lower and less consistent quality. Moreover, the two most heavily-fragmenting pipelines are never best in aggregate on either primary model, although they have isolated per-aspect wins.

Our contributions are:

- We present a controlled comparison of six local, training-free pipelines for long-context aspect-based scientific summarization.
- We evaluate two models across three datasets using complementary metrics, including ROUGE, BERTScore, and claim-level factual overlap.
- We analyze the quality–cost trade-off of decomposition and provide per-aspect and qualitative evidence showing that zero-shot dominates most alternatives, while decomposed pipelines often lose aspect-relevant evidence.

2 Related Work

Early aspect-based scientific summarization used supervised models with limited context windows. To make training feasible, these methods decomposed papers by discourse structure. SUSIE aligned full-text IMRaD sections with matching structured-abstract sections and trained section-specific generation (Gidiotis and Tsoumakas, 2019). Follow-up work scaled the same section-alignment strategy on large PubMed collections and compared unified versus per-section models (Oh et al., 2023). FacetSum introduced a large-scale dataset with four fixed aspects, enabling tagged aspect-controlled generation (Meng et al., 2021). Self-supervised variants further used section headings as pseudo-aspect prompts to improve transfer to unseen aspect names (Soleimani et al., 2022). Overall, this line improved controllability, but it depended on aligned supervision, section-header priors, or predefined aspect schemes.

Alongside trained-model approaches, recent work shifts to inference-time pipeline design. On ACLSum, an expert-annotated benchmark with extractive and abstractive references for three aspects (Challenge, Approach, Outcome), extract-then-abstract (E2A) pipelines are compared with end-to-end generation (Takeshita et al., 2024): Explicit extraction helps smaller fine-tuned models, but can become a bottleneck when LLMs must extract evidence. ReflectASP applies E2A to open aspects in educational reflections and reports gains from external factuality-guided refinement over zero-shot prompting (Zhong and Litman, 2025). TRACSUM (Chu et al., 2025) introduces a medical aspect-summary dataset with sentence-level evidence links and shows that evidence tracking before summarization improves grounding over summarize-then-track and end-to-end generation. SARESG (Feng et al., 2025) uses aspect-aware retrieval to prune long inputs before generation.

Beyond aspect-specific pipelines, generic methods use iterative rewriting or explicit verification. Self-refinement frameworks revise drafts through critique loops (Wadhwa et al., 2024; Zhang et al., 2023); densification methods iteratively increase information density under fixed length budgets (Adams et al., 2023); and agentic systems decompose summarization into specialized roles with verification, such as quiz-based coverage checks in SUMMQ (Wang et al., 2025b). These designs increase control, but also add orchestration cost and new failure points.

Overall, current systems trade operational complexity for control or quality gains through extraction, retrieval, densification, refinement, or agentic verification. To our knowledge, no prior study compares these design choices under local, training-free, long-context deployment constraints; we examine whether the added complexity pays off.

3 Experimental Setup

This section describes the evaluation setup: benchmark datasets, compared local models, evaluated inference pipelines, and metrics.

3.1 Datasets

We evaluate on three benchmarks with complementary domains, aspects, and source lengths.

ACLSum [2] Expert-written summaries of 250 NLP papers across three aspects: Challenge, Approach, and Outcome (Takeshita et al., 2024). Since the original release contains only Abstract, Introduction, and Conclusion text, we source the corresponding full papers for long-context evaluation. For evaluation, we use the full test split of 100 papers, yielding 300 aspect–summary pairs.

[2] https://github.com/sobamchan/aclsum

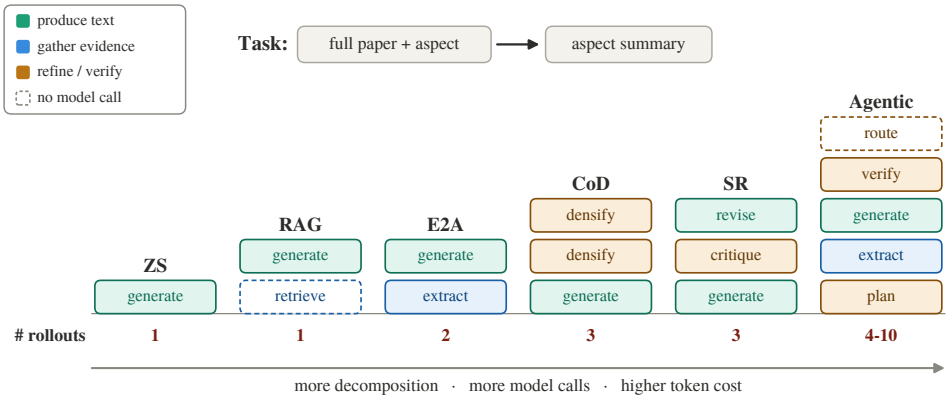

Figure 1: Overview of the compared training-free summarization pipelines used in our experiments.

FacetSum [3] Over 60,000 Emerald journal articles covering a diverse range of domains are paired with summaries for four aspects: Purpose, Methods, Findings, and Value (Meng et al., 2021). The full dataset contains 46,289 training, 6,000 development, and 6,000 test documents. For evaluation, we sample 1,000 test documents, yielding 4,000 aspect–summary pairs.

PMC-SA (Structured Abstract) From PubMed Central, we derive a biomedical benchmark of full-text articles with section-aligned structured abstracts. The full filtered dataset contains 122,228 training, 15,278 validation, and 15,280 test documents. It covers Background, Objectives, Methods, Results, and Conclusions. For evaluation, we sample 1,000 test documents, yielding 3,594 aspect–summary pairs as not every document contains all five aspects.

For detailed dataset construction and sampling strategy, see Appendix A. The three benchmarks also differ in where aspect-relevant evidence occurs within the source document: some aspects are strongly localized, while others may draw on sentences distributed throughout the full text. We quantify this with the structural alignment protocol of Meng et al. (2021) and report the resulting position distributions in Appendix A.5.

3.2 Models

We focus on models deployable locally under a modest GPU budget, represented by a single NVIDIA A100 GPU with 40 GB of VRAM in our setup. We choose `Qwen/Qwen3.5-9B`[4] for its strong performance within its size family.

To test whether our conclusions depend on a single model family, we additionally evaluate `allenai/Olmo-3-7B-Instruct`[5] as a complementary robustness check.

We further use `Qwen/Qwen3.5-2B` for a supplementary scale analysis across all pipelines and datasets.

Both primary models support long contexts (`Qwen3.5-9B`: 262,144 tokens; `OLMo-3-7B-Instruct`: 64K tokens). Our dataset length profiling shows maximum source lengths of 14,874 (ACLSum), 26,701 (FacetSum), and 60,656 (PMC). Since even the largest profiled case remains within the 64K window, we do not apply source truncation for any pipeline in the reported experiments.

Across all experiments, we use the same decoding configuration (*temperature* 0.1, *top-p* 0.95) and set the maximum output length per dataset to match the corresponding reference-summary length scale.

3.3 Pipelines

We compare six training-free pipelines; Figure 1 visualizes their key components:

Zero-Shot (ZS) Direct one-pass generation from the full content of the document.

Extract-to-Abstract (E2A) Two-stage pipeline in which the LLM first extracts aspect-relevant evidence from the full document and then generates the final summary from that evidence (Zhong and Litman, 2025; Takeshita et al., 2024).

Retrieval-Augmented Generation (RAG) Aspect-aware retrieval selects relevant document chunks without an LLM extraction step before summary generation over the retrieved context (Feng et al., 2025).

[3] https://huggingface.co/datasets/memray/FacetSum
[4] https://huggingface.co/Qwen/Qwen3.5-9B
[5] https://huggingface.co/allenai/Olmo-3-7B-Instruct

Chain of Density (CoD) Iterative densification rewrites an initial draft to increase density under fixed length limits (Adams et al., 2023).

Self-Refine (SR) Three-step self-improvement pipeline that generates, critiques, and refines summaries through iterative self-feedback (Zhong and Litman, 2025; Wadhwa et al., 2024).

Agentic multi-role pipeline (Agentic) Multi-role decomposition into planner, extractor, writer, verifier, and router roles, with bounded revision loops for controlled evidence selection, drafting, and verification.

Implementation details for each pipeline are provided in Appendix B.

3.4 Evaluation Metrics

We measure established ROUGE metrics (Lin, 2004): ROUGE-1 (R-1), ROUGE-2 (R-2), ROUGE-L (R-L), and ROUGE-LSum (R-L-S). ROUGE-LSum is the summary-level variant of ROUGE-L, computed over sentence-level longest common subsequences. We also report BERTScore (Zhang et al., 2020) (BS).

In addition, we report claim-based factual overlap scores, reproducing the TRACSUM evaluation setup (Chu et al., 2025) and its metric design grounded in atomic-claim evaluation (Min et al., 2023). In this setup, both reference and generated summaries are decomposed into atomic claims using `mistralai/Mistral-Large-Instruct-2407`[6] and then checked for bidirectional entailment with TRUE as the NLI evaluator (Honovich et al., 2022). For each pair *(generated, reference)*, we compute Claim Recall (C-R), the fraction of reference claims entailed by the generated summary; Claim Precision (C-P), the fraction of generated claims entailed by the reference summary; and Claim F1 (C-F1), the per-pair harmonic mean of C-P and C-R. Final scores are macro averages over all pairs. This setup captures factual alignment to the reference summary at the claim level rather than direct source-grounded faithfulness.

As a supplementary source-grounded evaluation, we use G-Eval (Liu et al., 2023) with GPT-4.1-mini to rate aspect consistency and relevance against the full source document on 100 documents per dataset. We treat these LLM judgments strictly as an automatic proxy, not as a substitute for human evaluation; full details are in Appendix E.

[6]https://huggingface.co/mistralai/Mistral-Large-Instruct-2407

4 Results

This section presents the main quantitative results for the compared pipelines. We first report ROUGE and BERTScore results for `Qwen3.5-9B`, then summarize claim-based scores and the `OLMo-3-7B-Instruct` robustness results.

For the `Qwen3.5-9B` model, Table 1 reports ROUGE and BERTScore results across all three datasets. ZS obtains the best score on every reported metric for ACLSum, PMC-SA, and FacetSum. This ranking holds across both lexical overlap metrics and BERTScore. RAG is the closest competitor on ACLSum. E2A is the highest-scoring decomposed baseline on FacetSum, but still lags behind ZS. The agentic pipeline is never best and only reaches second place on a subset of PMC metrics.

The document-level clustered bootstrap tests in Appendix C report the same comparisons; ZS is higher in all 75 dataset–metric comparisons, with 71 significant at the 95% level. The four non-significant cases are the ZS–RAG comparisons on ACLSum for ROUGE-2, ROUGE-L, ROUGE-Lsum, and BERTScore.

Under claim-based evaluation, Table 2 shows the same trend. ZS achieves the highest claim recall and claim F1 on all three datasets. Claim precision is the only claim metric where decomposed methods rank first in individual cases, such as RAG on ACLSum and SR on FacetSum.

The supplementary source-grounded G-Eval results agree with this ranking: ZS obtains the highest aspect-consistency and aspect-relevance scores on all three datasets, and no decomposition pipeline surpasses it (Appendix E).

We additionally vary RAG retrieval depth and chunk size and increase the E2A evidence budget on a fixed 100-document subset of each dataset. Larger RAG contexts narrow the gap, but ZS remains significantly ahead; the strongest RAG variant trails ZS by 0.054 Claim F1. Increasing the E2A budget yields no significant change. Appendix D provides the full analysis.

The `OLMo-3-7B-Instruct` results in Appendix G show lower absolute scores and a less uniform ranking than Qwen, but the overall pattern remains similar: decomposed pipelines do not establish a reliable quality advantage. Even when quality is comparable, ZS remains preferable to higher-cost full-context pipelines, while RAG trades lower token use for the risk of missing relevant evidence.

Table 2: Claim-based evaluation results. C-P, C-R, and C-F1 denote claim precision, claim recall, and claim F1, respectively. Best results are in bold and second-best results are underlined.

The supplementary 2B scale analysis provides a boundary condition: decomposition earns more local wins, but no pipeline dominates across datasets, and structured multi-stage execution becomes less reliable. Agentic fails to produce a valid output for 11.7–30.9% of cases across datasets (Appendix F).

5 Discussion

This section discusses pipeline complexity, aspect-level behavior, and local deployment.

5.1 Cost-Quality Analysis

The cost–quality trade-off in Figure 2 relates summary quality, measured by ROUGE-LSum, to mean token usage. In our setup, ZS is the strongest quality default and provides the most favorable quality–token trade-off among full-document pipelines. It matches or exceeds the quality of more complex full-context pipelines while remaining simpler to run. RAG occupies a distinct lower-cost point: it uses about one seventh as many tokens as ZS and is competitive on ACLSum, but provides lower and less consistent quality overall, with larger drops on PMC-SA and FacetSum.

Token usage is only an approximation of deployment cost. Multi-step pipelines can also increase latency and add failure points through repeated context construction, additional generation steps, and coordination logic. RAG may therefore be preferable when minimizing token use outweighs its quality reduction, while retrieval quality depends on retaining the relevant evidence. Higher-cost pipelines can be useful when their intermediate outputs are needed for inspection or control.

5.2 Per-aspect Scores

Across individual aspects, Table 3 shows the same pattern. ZS obtains the best BERTScore on eight of eleven aspect categories. The three exceptions are narrow and do not generalize to neighboring aspects: RAG is best on ACLSum *Challenge*, E2A on PMC-SA *Conclusions*, and Agentic on PMC-SA *Background*. All three are aspects whose evidence is positionally concentrated (Figure 4), whereas ZS is best on every aspect whose aligned evidence is broadly distributed. Selective pipelines thus appear to recover their cost only where the relevant content is localized. Appendix H reports the same breakdown for ROUGE variants.

No decomposed pipeline consistently dominates on abstract or difficult aspects. E2A is often competitive but rarely best, suggesting sensitivity to extraction recall; RAG helps in isolated cases but is inconsistent when evidence is dispersed; CoD

Aspect	ZS	E2A	RAG	COD	SR	Agentic
Challenge	0.8785	0.8781	**0.8802**	0.8655	0.8773	0.8672
Approach	**0.8960**	0.8944	0.8957	0.8760	0.8900	0.8751
Outcome	**0.8937**	0.8858	0.8895	0.8671	0.8874	0.8709
Purpose	**0.8959**	0.8894	0.8845	0.8804	0.8906	0.8927
Methods	**0.8701**	0.8647	0.8572	0.8641	0.8663	0.8605
Findings	**0.8786**	0.8731	0.8622	0.8644	0.8740	0.8654

Table 3: Aspect-level BERTScore results.

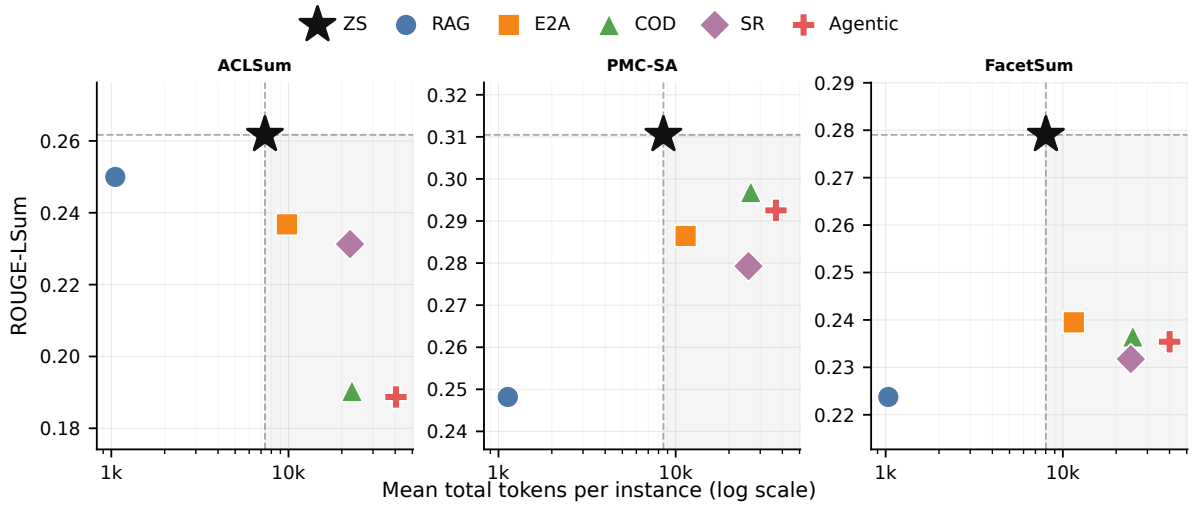

Figure 2: Quality–cost trade-off across datasets. Each point represents one summarization pipeline, with mean total token usage (input plus output tokens) on the x-axis and ROUGE-LSum on the y-axis. Dashed lines indicate the zero-shot pipeline (ZS). The shaded area marks configurations dominated by ZS, i.e., methods that consume more tokens while achieving lower summarization quality.

is generally weaker, suggesting that densification removes aspect-specific details; and Agentic is occasionally competitive but unstable, which is a concern for deployments that need predictable behavior rather than isolated wins.

5.3 Effect of Document Length

A natural objection to single-pass reading is that it should degrade as documents grow longer, and that decomposition should become more useful precisely where the full document is hardest to attend over. Figure 3 tests this by relating ROUGE-LSum to source length; other metrics follow similar patterns (Appendix H.1). On PMC-SA and FacetSum the aggregate ranking is stable across the length range these benchmarks cover: ZS is highest in every bin, and its margin over the decomposed pipelines does not narrow as documents grow longer. RAG is the only pipeline that degrades visibly with length in two datasets. On ACLSum, the smallest set and the one with the widest per-bin errors, RAG is often competitive with or better than ZS on shorter documents.

5.4 Implications for Deployment

The results do not imply that decomposed pipelines are never useful. They show that decomposition should not be treated as a default way to improve quality when long-context local models can read the full document. Additional stages can still be useful when the application needs retrieved evidence, extracted rationales, verification traces, or human-review checkpoints. Thus, pipeline choice should depend on the system requirement: use direct prompting as the quality baseline, and add decomposition when its intermediate outputs provide inspection or control.

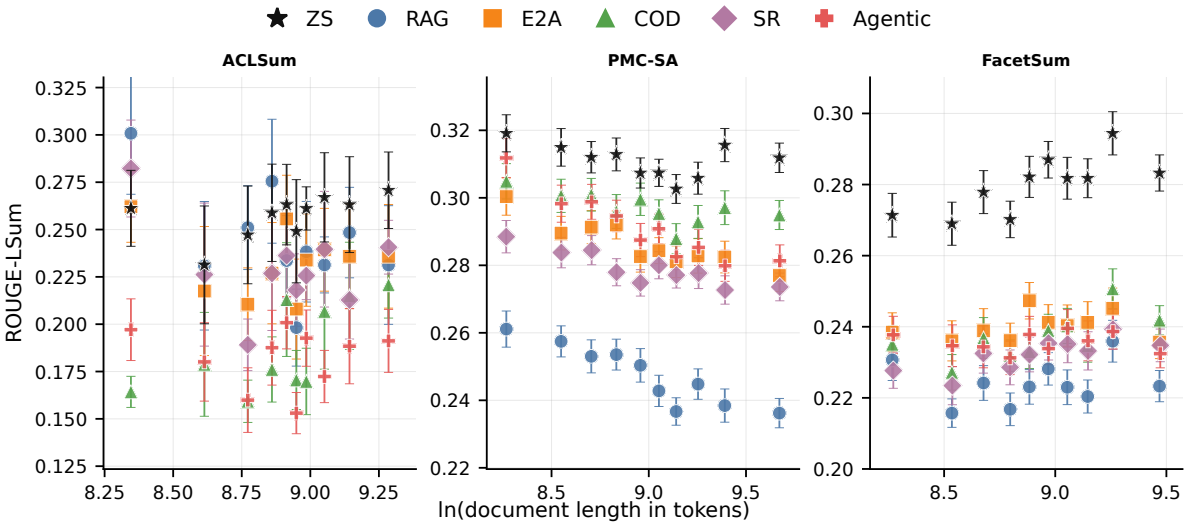

Figure 3: ROUGE-LSum as a function of source document length for `Qwen3.5-9B`. Aspect scores are averaged within each document before binning, so every document contributes equally regardless of how many aspects it has. Documents are grouped into 10 equal-frequency bins per dataset; each marker is placed at the mean log-length of its bin and shows the mean score over the documents in that bin, with error bars giving the standard error of that mean. Length is measured in `Qwen3.5-9B` tokenizer tokens.

System	R-L	BS	Summary excerpt and interpretation
Reference	–	–	Requires a dictionary and raw text; context knowledge can be updated as language changes.
ZS	**.2667**	**.8933**	Captures dictionary, unannotated text, dependency relations, and semantic coherence.
Agentic	.1176	.8771	Captures an unannotated-text knowledge base but drops the dictionary and update mechanism.
CoD	.0889	.8533	Shifts toward implementation details and misses broader resource assumptions.
E2A	.0930	.8836	Becomes too generic, omitting dictionary and update details.
RAG	.1176	.8621	Captures the motivation rather than the concrete procedure.

Table 4: Qualitative ACLSum case study for the *Approach* aspect. R-L denotes ROUGE-L and BS denotes BERTScore.

5.5 Qualitative Analysis

To illustrate the failure modes, we use one representative ACLSum instance from a paper on unsupervised word sense disambiguation (aspect: *Approach*; Table 4). The target summary should explain how the method works. The method avoids manually annotated resources by using only a dictionary and raw text. From this raw text, it builds context knowledge that can be updated as language changes. The case was selected because ZS is close to its mean ROUGE-L performance, while all decomposed pipelines are below their own means, showcasing their failure modes.

The key reference information is the resource-light and updateable nature of the approach. ZS captures most of this mechanism. The decomposed methods are plausible but less complete: CoD shifts to implementation details, E2A becomes too generic, RAG summarizes the motivation rather than the procedure, and Agentic omits some key resource assumptions. Full outputs are provided in Appendix I. This case mirrors the aggregate results: additional orchestration can produce fluent but incomplete summaries.

6 Conclusion

We compared six local, training-free pipelines for long-context aspect-based scientific summarization across three datasets and two primary open models under matched decoding and output-length limits, supplemented by a 2B scale analysis. Explicit decomposition does not reliably improve summary quality in this setting. Zero-shot full-document prompting is the strongest quality default across lexical, semantic, and claim-based metrics and provides the most favorable quality–token trade-off among full-document pipelines. RAG is a lower-cost alternative, using about one seventh as many tokens as zero-shot, but its quality is reduced and less consistent across datasets. More complex pipelines may still be useful when intermediate outputs, as evidence traces or human-review checkpoints, justify their added cost and complexity.

7 Limitations

Our study is limited to local, training-free inference pipelines. This design matches deployment settings where labeled data, external APIs, or model training are costly or unavailable. It also means that our conclusions may not hold for proprietary long-context models, fine-tuned summarizers, or systems with task-specific retrievers and extractors. Such systems may benefit more from decomposition than the pipelines evaluated here.

The model scope is also limited. We evaluate two primary open long-context models, with `Qwen3.5-9B` as the main model and `OLMo-3-7B-Instruct` as a robustness check, plus a supplementary `Qwen3.5-2B` scale analysis. These models cover different open-model families and sizes, but they do not represent all model sizes or context lengths. Variation in model family and size does not isolate the effect of instruction tuning, so robustness across instruction-tuning recipes remains untested. Larger models, stronger small models, or models trained specifically for scientific text may change the relative ranking of the pipelines.

The dataset scope is restricted to English scientific documents. ACLSum covers NLP papers, FacetSum covers Emerald journal articles, and PMC-SA covers biomedical articles. These datasets differ in domain and aspect coverage, but they are still scholarly and reference-based, with predefined, relatively coarse aspects. Whether the findings transfer to user-defined, fine-grained, or cross-sectional aspects remains an open question. The results may also not transfer to multilingual settings or non-scientific documents. For FacetSum and PMC-SA, we evaluate sampled test subsets for long-context inference, so small effects may depend on the sample.

The evaluated pipelines are representative but not exhaustive. We compare direct prompting, retrieval, extraction, densification, self-refinement, and agentic orchestration under matched decoding and length constraints. Other implementations could use different prompts, retrieval models, chunking strategies, stopping rules, or verification criteria. We therefore interpret the results as evidence about common decomposition patterns under a controlled setup, not as a proof that all possible decomposed systems are inferior.

Our evaluation is automatic. ROUGE and BERTScore measure overlap with reference summaries. The claim-based metric measures entailment overlap between generated and reference claims. It does not directly measure source-grounded faithfulness. Our source-grounded G-Eval analysis is a supplementary LLM-based proxy and may reflect evaluator bias; it complements but does not replace human evaluation. Errors in claim extraction or entailment classification can also affect scores. The qualitative case study illustrates failure modes but is not a systematic human evaluation.

Finally, mean input-plus-output token usage does not capture latency, memory pressure, batching, engineering complexity, or human review time. Future work should evaluate these costs directly, particularly when analysts use intermediate outputs.

A Data Construction and Preprocessing

A.1 ACLSum

ACLSum (Takeshita et al., 2024) provides expert-written one-sentence summaries on the aspects Challenge, Approach, and Outcome. The original release contains Abstract, Introduction, and Conclusion text, but not full-paper text. To support long-context evaluation, we retrieve the corresponding paper PDFs and parse their text with PaddleOCR-VL[7]. We preserve the original aspect labels and reference summaries. We use the full test split without additional sampling.

A.2 FacetSum

For FacetSum (Meng et al., 2021), we keep the original train, development, and test splits. We use the full-text setup and retain all examples. Our experiments use a sample of 1,000 documents from the test split and keep all four aspect summaries for each sampled document.

A.3 PMC-SA

A.3.1 Source and Acquisition

We construct the PMC-SA dataset from the PubMed Central Open Access Subset. We follow the section-aligned data construction approach introduced by Oh et al. (Oh et al., 2023), processing the PMC bulk XML archives directly to ensure scalability and reproducibility. From each article, we extract pairs of *structured abstracts* and corresponding *full-text body sections*, retaining only documents whose abstracts are explicitly segmented into labeled sections.

A.3.2 Section Normalization

Scientific articles exhibit substantial variation in section header naming (e.g., *"Study Design"*, *"Materials and Methods"*). To obtain a consistent aspect space, we normalize all abstract and full-text headers into five canonical sections: **Background**, **Objectives**, **Methods**, **Results**, and **Conclusions**.

Section headers are normalized using the National Library of Medicine (NLM) Category Mapping, which resolves over 3,000 known header variants into these canonical categories. Within a document, multiple sections mapped to the same canonical label are concatenated to form a single section representation.

A.3.3 Quality Filtering and Alignment

To ensure high-quality aspect–summary pairs, we apply strict filtering criteria:

- **Structural validity:** abstracts must contain at least three canonical sections and include a terminal section (**Results** or **Conclusions**);
- **Length constraints:** abstracts are restricted to 10–2,500 words and full texts to 150–80,000 words;
- **Compression ratio:** documents are discarded if the full-text-to-abstract word ratio lies outside $[5, 500]$, removing trivial extractive cases and extreme compression outliers.

We enforce a **strict one-to-one section alignment policy**. For each normalized abstract section, we require the existence of a corresponding full-text section with the same canonical label. Documents are discarded if any abstract section lacks a matched full-text counterpart.

This strict alignment ensures that each training instance pairs an aspect-specific abstract section with explicitly grounded source evidence.

A.4 Sampling Strategy

For the larger FacetSum and PMC-SA Datasets, we sample 1,000 documents per dataset from their respective test splits. To ensure the evaluation remains representative, we apply stratified sampling across the target aspects. This approach follows established LLM benchmarking precedents (Wang et al., 2025a) by balancing statistical robustness with the computational sustainability required for long-context inference.

A.5 Evidence Localization

Alignment protocol. To characterize where aspect-relevant content occurs in the source, we reproduce the structural alignment of Meng et al. (2021) (their Section 2.2). Let $S = (s_1, \ldots, s_{|S|})$

[7] https://github.com/PaddlePaddle/PaddleOCR

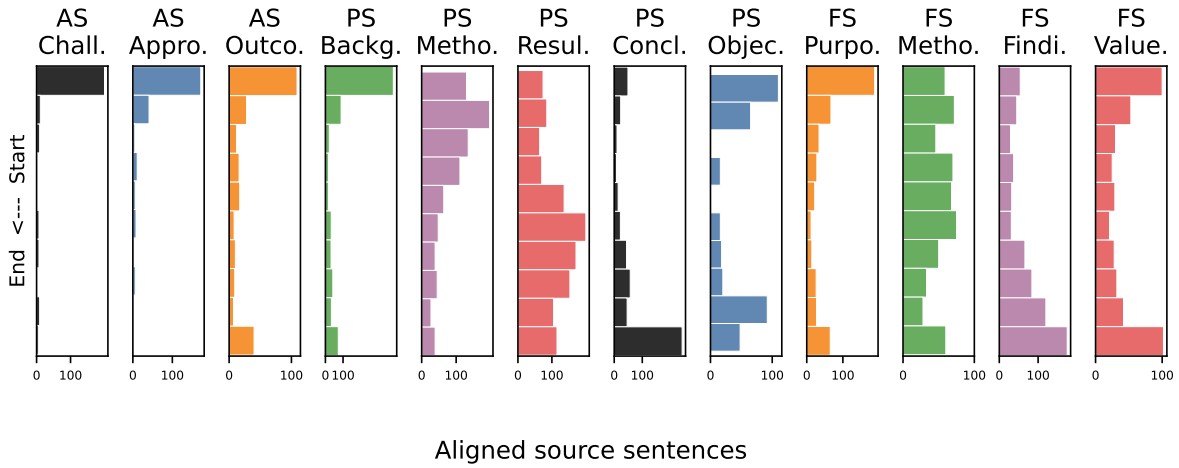

Figure 4: Oracle evidence localization for the twelve dataset–aspect combinations. AS, PS, and FS denote ACLSum, PMC-SA, and FacetSum. Each panel is a histogram of the normalized positions of source sentences aligned to the reference aspect summary under Equation 1, over ten equal-width position bins running from the start of the document (top) to the end (bottom). Bars give the number of aligned source sentences; note that panel totals differ, because the number of aligned sentences per instance depends on the reference summary length, and that ACLSum references are single sentences so each ACLSum instance contributes exactly one position.

denote the sentences of the full source document and $A = (a_1, \ldots, a_{|A|})$ the sentences of the corresponding reference aspect summary. Each summary sentence is aligned to its single best-matching source sentence under ROUGE-1 F_1:

$$S_A = \left\{ \arg\max_{s_i \in S} \text{ROUGE-1}(s_i, a_j) \ : \ a_j \in A \right\}. \tag{1}$$

S_A is a set, so several summary sentences selecting the same source sentence contribute a single element. For each aligned index i we record the normalized position $(i + 0.5)/|S|$, where 0 is the start and 1 the end of the document. Pooling these positions over documents gives the oracle evidence distribution of an aspect: it describes where a system would have to read in order to recover the reference content, and it is defined without reference to any model output.

Configuration. For each of the twelve dataset–aspect combinations, we draw 256 instances from the corresponding evaluation split with a fixed seed; if the requested sample is larger than the population, we use the whole population. Figure 4 bins the pooled positions into ten equal-width intervals per panel.

Results. Figure 4 shows that the twelve dataset–aspect combinations fall into clearly different localization regimes. ACLSum Challenge and Approach, PMC-SA Background, and FacetSum Purpose are strongly front-loaded, with most aligned sentences in the first tenth of the document. PMC-SA Conclusions is the mirror image, concentrated at the very end. PMC-SA Objectives and FacetSum Value are bimodal, drawing on both the opening and the closing of the paper. PMC-SA Methods and Results and FacetSum Methods and Findings are distributed far more broadly, with substantial mass across the interior of the document.

Two consequences follow for the pipelines compared in this work. First, no single positional heuristic serves all aspects: a retrieval or extraction stage tuned to recover opening material would systematically miss PMC-SA Conclusions, and one tuned to section boundaries would miss the aspects whose evidence is spread across the body. Second, the aspects with the broadest distributions are precisely those for which a fixed retrieval budget is least likely to cover the reference content, which is consistent with the sensitivity of RAG to retrieval depth reported in Appendix D.

B Detailed Pipeline Implementation

This appendix summarizes the concrete implementation of the six compared inference pipelines.

B.1 Zero-Shot (ZS)

ZS uses a single prompt over the normalized document. The prompt consists of a fixed system instruction and a task template with slots for the as-

pect, source type, length instruction, and source text:

System prompt

```
You are an expert scientific editor, you are given a scientific text and tasked to write a summary focused on a specific aspect.
```

Prompt template

```
# CONTEXT
You will be provided with a scientific text and a specific aspect to focus on.

# TASK
Given the scientific text below and a focused aspect, which is {aspect}, write a short summary using your own words.
The summary needs to be a coherent paragraph and should include the major points.
Write in free form, avoid bullet points or numbered lists.
The summary should focus on the provided aspect only, contain only information about the aspect, and avoid adding irrelevant sentences or your own opinions and suggestions.

# INPUT
The source text is a {source_type_pretty}. This is {source_type_desc}.
FOCUSED ASPECT: {aspect}
{summary_line}
SOURCE TEXT:
{source_text}

# OUTPUT
```

B.2 Extract-to-Abstract (E2A)

E2A is implemented as a two-stage structured pipeline. An extractor first returns a JSON evidence set of verbatim spans relevant to the target aspect, and a writer then generates the final summary using only this evidence and the dataset-specific length constraint. Both stages use schema-constrained decoding. The pipeline uses separate system and user prompts for the extractor and writer:

Extractor system prompt

```
You are an Information Extractor specializing in scientific literature. You excel in identifying and extracting verbatim evidence that is necessary for summarizing specific aspects of research papers. You value precision; You never alter quotes or add interpretation. You produce structured JSON OUTPUT only.
```

Extractor prompt template

```
### CONTEXT
You are given a scientific document and a specific aspect.

### TASK
Your task is to extract verbatim evidence from the document that is relevant to the specified aspect and would be useful for writing a summary about that aspect.

### INPUTS
Target Aspect:
{{ aspect_name }}

Source Document:
{{ document_text }}

### INSTRUCTIONS
1. Find spans of text that contain claims or data relevant to the aspect.
2. Extract verbatim text spans, do not paraphrase or summarize.
3. Each extracted span should be self-contained and informative on its own.
4. Avoid extracting very short or very long spans; aim for concise, meaningful excerpts that capture key points.
5. The spans should be sorted in the order they appear in the document to preserve context.
6. Return at most {{ max_evidence_items }} evidence items.
7. Keep each span short (prefer 1-2 sentences, max about {{ max_span_chars }} characters).
8. Avoid references, equations, and low-signal boilerplate.
9. Output valid JSON only.

### OUTPUT FORMAT
Return a valid JSON object matching the ExtractorOutput schema:
{
"evidence_set": [
"Exact quote 1...",
"Exact quote 2..."
]
}
```

Writer system prompt

```
You are an expert scientific assistant and editor. Your expertise lies in synthesizing information from multiple pieces of evidence to create concise, accurate summaries focused on specific aspects of scientific research. You use the same wording and tone used in the source text, which is scientific and formal. Write concise, faithful aspect-focused summaries.
```

Writer prompt template

```
### CONTEXT
You are given a set of verbatim evidence extracted from a scientific document, all related to the aspect "{{ aspect_name }}".

### TASK
Write a short aspect-focused summary with your own words for the following aspect: "{{ aspect_name }}".
Use ONLY the provided evidence set.
The summary needs to be a coherent paragraph and should include the major points.

### EVIDENCE SET (ORDERED)
{{ evidence_set }}

### SUMMARY LENGTH
{{ summary_length }}

### INSTRUCTIONS
1. The summary should focus on the provided aspect only.
2. Use ONLY the evidence set above.
3. Write in free form, avoid bullet points or numbered lists.
4. Avoid adding irrelevant sentences or your own opinions and suggestions.
5. Respect the summary length instruction.

### OUTPUT FORMAT
Return a valid JSON object matching the WriterOutput schema:
{
"summary_text": "Your single-paragraph summary..."
}
```

B.3 Retrieval-Augmented Generation (RAG)

The RAG pipeline follows the implementation in (Feng et al., 2025). Each document is split into sentence-aware chunks of about 256 words. We encode chunks with the dense embedding model `NovaSearch/stella_en_1.5B_v5`[8], retrieve the top 10 aspect-relevant chunks, reconstruct them in their original document order, and pass the resulting retrieved context to the writer model, which generates the final summary.

B.4 Chain of Density (CoD)

CoD first generates an initial aspect summary from the full document and then applies two densification steps, following (Adams et al., 2023). At each step, the model identifies missing aspect-relevant entities or findings and rewrites the current summary to make it denser while preserving the dataset-specific sentence and word limits. If a revised summary violates these limits or is empty, it is discarded and the previous valid summary is kept. The pipeline uses separate prompts for the initial draft and each densification step:

Initial system prompt

```
You are an expert scientific editor, you are given a scientific text and tasked to write a summary focused on a specific aspect. You use the same wording and tone used in the source text, which is scientific and formal. Write concise, faithful aspect-focused summaries.
```

Initial prompt template

```
# CONTEXT
You will be provided with a scientific text and a specific aspect to focus on.

# TASK
Given the scientific text below and a focused aspect, which is {aspect}, write a short summary using your own words.
The summary needs to be a coherent paragraph and should include the major points.
Write in free form, avoid bullet points or numbered lists.
The summary should focus on the provided aspect only, contain only information about the aspect, and avoid adding irrelevant sentences or your own opinions and suggestions.
This is the initial draft, so keep it relatively high-level and leave room for adding missing details in later refinement passes.

# INPUT
The source text is the full text of a scientific paper.
FOCUSED ASPECT: {aspect}
SUMMARY TARGET LENGTH: Maximum {max_sentences} sentences and {max_words} words.
SOURCE TEXT:
{source_text}

# OUTPUT
Return only the initial summary paragraph text.
```

Iteration system prompt

```
You are an expert scientific editor, you are given a scientific text and tasked to revise a summary focused on a specific aspect. You use the same wording and tone used in the source text, which is scientific and formal. Write concise, faithful aspect-focused summaries.
```

[8] https://huggingface.co/NovaSearch/stella_en_1.5B_v5

Iteration prompt template

```
# CONTEXT
You will be provided with a scientific text, a focused aspect, and a draft summary for that aspect.

# TASK
Revise the draft summary for aspect "{aspect}".
Compare the draft summary against the source text and identify missing high-value information.
If important information is missing, add it.
Keep the summary focused on the same aspect and faithful to the source.
Condense and remove redundancy if needed to keep the summary concise.

# MISSING ENTITY DEFINITION
A missing entity should be:
- Relevant: central to the focused aspect
- Specific: concrete name, term, model, dataset, method, metric, number, or finding
- Novel: not already present in previous summary
- Faithful: explicitly supported by source text

# REVISION METHOD
- Check for missing high-value details: named entities, methods/models, datasets, key numbers, and main findings.
- Integrate only the most important missing details.
- Rewrite the paragraph for better clarity, flow, and scientific style.
- If the draft is already complete, still rewrite for clearer wording and smoother style.
- Avoid copying the draft verbatim.

# STRICT LENGTH RULES
- Your revised summary must satisfy BOTH limits:
- at most {max_words} words
- at most {max_sentences} sentences
- Keep approximately the same length as the previous summary ({prev_words} words, {prev_sentences} sentences).

# STYLE RULES
- Write in the same tone and style as sentences in scientific abstracts, which is concise, logical to follow, and formal.
- Single coherent paragraph.
- No bullet points and no numbered lists.
- No unsupported claims.

# INPUT
SOURCE TYPE: full text of a scientific paper
FOCUSED ASPECT: {aspect}
ITERATION: {iteration_idx} / {total_iterations}
SUMMARY TARGET LENGTH: Maximum {max_sentences} sentences and {max_words} words.
SOURCE TEXT:
{source_text}

PREVIOUS SUMMARY:
{draft_summary}

# OUTPUT
Return exactly this format:
MISSING_ENTITIES: entity1; entity2; entity3
DENSER_SUMMARY: <single paragraph>
```

B.5 Self-Refine (SR)

SR is implemented as a fixed three-step procedure. The model first generates an initial aspect summary from the full document, then produces 2–3 concrete suggestions for improving that summary in the same chat history, and finally generates a revised summary in a fresh refinement step conditioned on the source text, the initial summary, and the suggestions. The same model is used for all three stages, and the procedure runs for exactly one refinement round. The pipeline uses the following prompts:

Generate system prompt

```
You are an abstractive summarizer. Your task is to summarize a scientific text focusing on one specific aspect.
```

Generate prompt template

```
Write a short summary about the aspect "{aspect}" using only the source text below.

Target length: {summary_target_instruction}.

Reflections:
{source_text}

Summary:
```

Suggestion prompt template

```
Give 2-3 concrete suggestions to improve the generated summary so that it becomes more concise and more focused on the aspect "{aspect}".

Base the suggestions on the original source text and the generated summary.
Do not give generic advice.
```

Refine system prompt

```
You are an abstractive summarizer. Your
task is to summarize a scientific text
focusing on one specific aspect.
```

Refine prompt template

```
Improve the short summary below using
the suggestions.

The revised version must stay focused
on the aspect "{aspect}" based on the
source text below.

Target                          length:
{summary_target_instruction}.

Reflections:
{source_text}

Original summary:
{initial_summary}

Suggestions for improvement:
{suggestions}

Refined summary:
```

B.6 Agentic Multi-Role Pipeline (Agentic)

The agentic pipeline is implemented with four LLM modules (planner, extractor, writer, verifier) that use different prompt templates and role-specific output schemas. The router is deterministic.

Role sequence. The pipeline follows planner → extractor → writer → verifier → router.

- **Planner (LLM):** Input: aspect name, source document, target summary length. Output: structured plan with aspect definition, extraction cues, and acceptance criteria. Planner inference runs with thinking enabled.
- **Extractor (LLM):** Input: aspect name, source document, planner output, and optional router correction instruction. Output: ordered verbatim evidence spans.
- **Writer (LLM):** Input: evidence spans, aspect name, target summary length, and optional router correction instruction. Output: one summary paragraph.
- **Verifier (LLM):** Input: writer summary, evidence spans, and planner output. Output: one structured decision in {accept, revise_summary, revise_evidence} and a correction instruction. Verifier inference runs with thinking enabled.
- **Router (deterministic):** Input: verifier decision and correction instruction. Output: next action (stop, send correction to writer, or send correction to extractor).

Deterministic routing and bounded revision. Routing is deterministic. If the verifier returns `accept`, the current iteration ends and the sample is finalized. If it returns `revise_summary`, the router sends the correction instruction back to the writer with the same evidence. If it returns `revise_evidence`, the router sends the correction instruction back to the extractor to update evidence before writing again. An iteration ends at either acceptance or when the retry budget is exhausted; the implementation uses at most two retries.

Full role-specific prompt templates are provided in the codebase.

Development variants. Before fixing the reported configuration, we piloted an extractor–writer pipeline, a planner–extractor–writer pipeline without verification, and the full planner–extractor–writer–verifier loop. We also varied role compositions and iterated on prompts through qualitative inspection. None of these variants outperformed ZS, and the full loop reported in the main experiments was the strongest Agentic configuration tested. The recurring failure mode was planner error propagation: vague or incorrect aspect definitions and acceptance criteria guided the extractor toward the wrong evidence, which the writer then summarized faithfully. Because the verifier checks the summary against the selected evidence and plan rather than re-deriving the plan, it could not reliably correct this upstream error. These development runs were not retained as a controlled benchmark, so we report no numerical ablation and draw no component-level causal conclusion from them.

C Statistical Significance of Zero-Shot vs. Pipeline Differences

Test strategy. To assess whether the aggregate quality differences between direct zero-shot prompting (ZS) and the decomposed pipelines reflect more than sampling noise, we run paired bootstrap tests (Efron and Tibshirani, 1994; Koehn, 2004). For each dataset–pipeline pair we compute, for every evaluated aspect–summary instance i, the score difference $d_i = s_i^{\mathrm{ZS}} - s_i^{\mathrm{pipeline}}$ on the same input, so that document- and aspect-level difficulty is controlled for by construction.

Document-level clustering. The evaluated instances are not mutually independent. Each source document contributes one instance per aspect—three for ACLSum, four for FacetSum, and up to five for PMC-SA—and these instances are derived from the same source text, so a document that is hard to summarize for one aspect tends to be hard for its remaining aspects as well. Resampling instances independently would treat the n aspect–summary pairs as n independent draws and thereby understate the sampling variance of Δ. We therefore resample at the document level: each bootstrap replicate draws N documents with replacement from the N documents of the evaluation set ($N = 100$ for ACLSum, $N = 1{,}000$ for FacetSum and PMC-SA) and retains all aspect instances of every drawn document, so that within-document correlation is preserved in the resampling distribution.

Procedure. We use $B = 10{,}000$ replicates, compute the mean difference $\bar{d}^{(b)}$ over the pooled instances of replicate b, and report the observed mean difference $\Delta = \bar{d}$ together with the percentile 95% confidence interval given by the 2.5th and 97.5th percentiles of $\{\bar{d}^{(b)}\}_{b=1}^{B}$. A difference is marked significant when the interval excludes zero, corresponding to a two-sided test at $\alpha = 0.05$. The choice of resampling unit affects only the width of the interval and not Δ itself. Resampling uses a fixed random seed (13) for reproducibility. The procedure is applied independently to each of the five automatic metrics (ROUGE-1/2/L/Lsum F_1 and BERTScore F_1), each of the three datasets (ACLSum, FacetSum, PMC-SA), and each of the five pipelines, yielding the $5 \times 3 \times 5 = 75$ comparisons in Table 5. We deliberately report effect sizes with confidence intervals rather than p-values alone, since with large evaluation sets even negligible differences can reach significance; the intervals make the magnitude of each gap directly visible.

Results. Table 5 reports $\Delta = \mathrm{score(ZS)} - \mathrm{score(pipeline)}$ for the main model under the document-level clustered bootstrap. All 75 observed differences are positive, i.e., zero-shot prompting matches or exceeds every pipeline on every metric and dataset, and 71 of 75 remain statistically significant at the 95% level once within-document correlation is accounted for. The only comparisons whose intervals cross zero are ZS vs. RAG on ACLSum for ROUGE-2, ROUGE-L, ROUGE-Lsum, and BERTScore. ACLSum provides the fewest resampling units of the three evaluation sets (100 documents), and RAG is the pipeline closest to ZS in aggregate quality, so the remaining gap there cannot be distinguished from noise. Clustering is a conservative rather than a decisive correction in this setting: relative to instance-level resampling it widens the intervals by at most 5% on average per dataset and by at most 15% for any single comparison, and it does not change which comparisons are significant. This is consistent with aspect summaries of the same paper drawing on largely disjoint source content, which limits how strongly their per-instance score differences co-vary. None of the pipelines significantly outperforms zero-shot prompting in any dataset–metric combination, which supports the central claim that task decomposition provides no reliable quality advantage over direct full-document prompting.

Dataset	Pipeline	ROUGE-1	ROUGE-2	ROUGE-L	ROUGE-Lsum	BERTScore
ACLSum	RAG	2.02 [0.21, 3.95]	0.90† [-0.48, 2.34]	1.17† [-0.32, 2.72]	1.17† [-0.34, 2.70]	0.09† [-0.18, 0.37]

	SR	4.17 [3.94, 4.41]	2.80 [2.62, 2.97]	2.18 [1.99, 2.37]	3.12 [2.90, 3.34]	0.31 [0.26, 0.35]

Table 5: Document-level clustered bootstrap significance tests for $\Delta = \text{score}(\text{ZS}) - \text{score}(\text{pipeline})$, in points ($\times 100$), with percentile 95% confidence intervals in brackets ($B = 10{,}000$ resamples over source documents, retaining all aspect instances of each drawn document). Positive values favor zero-shot. Differences whose interval excludes zero are significant at $\alpha = 0.05$; the four non-significant differences are marked with †. Pipeline abbreviations follow Section 3.

D RAG and E2A Sensitivity Analysis

We test whether the main results depend on the evidence budgets used by RAG and E2A. For RAG, we increase retrieval depth from 10 to 20 chunks, chunk size from 256 to 512 words, and both jointly. For E2A, we increase the maximum number of evidence items from 50 to 75 and the extractor generation budget from 4,000 to 6,000 tokens. All other components, prompts, and decoding settings remain fixed. We evaluate `Qwen3.5-9B` on a fixed subset of 100 documents per dataset, including all available aspects, and pool the paired examples across datasets. Confidence intervals use paired bootstrap resampling with $B = 10{,}000$.

All three larger-context RAG variants significantly improve over the original configuration on the displayed metrics, with the joint 512-word, top-20 setting producing the largest overall gain. Nevertheless, ZS remains significantly ahead of every variant; under the strongest RAG setting, the Claim-F1 gap narrows from 0.075 to 0.054. In contrast, none of the differences between the original and expanded-budget E2A configurations is significant, including Claim F1 ($\Delta_{\text{orig}-\text{expanded}} = -0.002$, 95% CI $[-0.011, 0.008]$). These results indicate that retrieval budget is consequential but does not account for the full RAG–ZS gap, whereas the tested extraction cap does not explain E2A's result. A comparable oracle-evidence experiment across all datasets is not possible because only ACLSum provides gold evidence spans; an ACLSum-only oracle would not test whether the conclusion generalizes across the three benchmarks.

Pipeline	Configuration	Δ R-Lsum	Δ BS	Δ C-F1
RAG	256 words, top-10	.044 [.038, .051]	.010 [.009, .011]	.075 [.061, .088]
RAG	256 words, top-20	.032 [.026, .039]	.006 [.005, .008]	.059 [.045, .072]
RAG	512 words, top-10	.033 [.026, .039]	.007 [.006, .009]	.063 [.049, .077]
RAG	512 words, top-20	**.032** [.025, .038]	**.006** [.005, .007]	**.054** [.041, .068]
E2A	50 items, 4k tokens	.031 [.025, .036]	.004 [.003, .005]	.039 [.027, .051]
E2A	75 items, 6k tokens	.030 [.024, .035]	.003 [.002, .004]	.038 [.025, .050]

Table 6: Sensitivity results pooled across the three dataset subsets. Values are $\Delta = \text{score}(\text{ZS}) - \text{score}(\text{configuration})$ with percentile 95% confidence intervals; positive values favor ZS. All displayed differences are significant at $\alpha = 0.05$. Bold marks the strongest RAG configuration. R-Lsum, BS, and C-F1 denote ROUGE-LSum, BERTScore, and Claim F1.

E Source-Grounded G-Eval

We supplement the reference-based metrics with G-Eval (Liu et al., 2023) using GPT-4.1-mini. For each generated summary, the evaluator receives the target aspect and full source document and assigns two scores from 1 to 5: aspect consistency measures whether the summary's claims are supported by the source, and aspect relevance measures coverage of important aspect-specific information while penalizing irrelevant or redundant content. We evaluate all six pipelines with `Qwen3.5-9B` on a fixed sample of 100 documents per dataset, including all available aspects. Decoding uses temperature 0 and the final score is computed from the model's output-token probabilities.

ZS ranks first on both dimensions for all three datasets, and no decomposition pipeline surpasses it. This provides complementary source-grounded evidence consistent with the reference-based results. However, G-Eval remains an automatic LLM-based proxy with possible evaluator bias and does not replace human judgments of factuality, relevance, or summary quality.

	ACLSum		FacetSum		PMC-SA	
Pipeline	Cons.	Rel.	Cons.	Rel.	Cons.	Rel.
ZS	**4.097**	**4.151**	**4.365**	**4.497**	**4.465**	**4.662**
RAG	3.967	3.910	3.964	3.986	3.768	3.772
E2A	4.004	4.016	4.155	4.245	4.310	4.479
CoD	4.000	3.988	4.276	4.369	4.449	4.625
SR	3.972	3.957	4.160	4.203	4.277	4.421
Agentic	3.975	3.970	4.205	4.262	4.274	4.443

Table 7: Source-grounded G-Eval scores using GPT-4.1-mini on 100 documents per dataset. Cons. and Rel. denote aspect consistency and aspect relevance on a 1–5 scale. Best results are bold.

F Model-Scale Analysis

We evaluate all six pipelines with `Qwen3.5-2B` to probe whether decomposition becomes more useful with a weaker backbone. Table 8 reports three representative quality metrics and structured-output failure rates. Missing outputs caused by parser failures are assigned zero, so the scores represent end-to-end deployed pipeline performance rather than quality conditional on successful execution.

Decomposition produces more local wins at 2B than at 9B: CoD narrowly leads on all three displayed FacetSum metrics and PMC-SA ROUGE-1, while Agentic leads ACLSum Claim F1. However, no method wins consistently across datasets, and the margins among successful non-agentic pipelines are small. Structured execution is also less reliable: Agentic fails on 23.3% of ACLSum, 30.9% of FacetSum, and 11.7% of PMC-SA cases; E2A failure rates are 0.0%, 0.8%, and 0.4%, respectively. Thus, weaker models can benefit locally from decomposition while being less able to execute its intermediate stages reliably.

Dataset	Pipeline	R-1	R-Lsum	C-F1	Failure
ACLSum	ZS	**.298**	**.227**	.064	0.0%
	RAG	.279	.202	.065	0.0%
	E2A	.290	.214	.066	0.0%
	CoD	.291	.216	.063	0.0%
	SR	.293	.211	.058	0.0%
	Agentic	.243	.178	**.070**	23.3%
FacetSum	ZS	.319	.262	.094	0.0%
	RAG	.276	.220	.050	0.0%
	E2A	.254	.199	.053	0.8%
	CoD	**.321**	**.263**	**.098**	0.0%
	SR	.319	.257	.089	0.0%
	Agentic	.212	.169	.064	30.9%
PMC-SA	ZS	.358	**.306**	**.153**	0.0%
	RAG	.301	.253	.062	0.0%
	E2A	.318	.267	.100	0.4%
	CoD	**.358**	.305	.151	0.0%
	SR	.350	.294	.138	0.0%
	Agentic	.316	.268	.126	11.7%

Table 8: Failure-adjusted `Qwen3.5-2B` results. Parser failures are scored as zero. R-1, R-Lsum, and C-F1 denote ROUGE-1, ROUGE-LSum, and Claim F1; best results are bold. Failure is the percentage of aspect-summary cases without a valid final output.

G OLMo Results

On `OLMo-3-7B-Instruct`, a smaller model included for its fully documented training recipe and therefore end-to-end auditability, the same qualitative pattern holds, with the added noise expected from a weaker backbone. The most decomposed pipelines remain weakest: the agentic pipeline is again never best on any metric or dataset, and extract-then-abstract is likewise never best. Zero-shot is the single best method on PMC-SA across all ROUGE variants and on claim recall and F1, and remains in the leading cluster elsewhere. Where it is edged, chain-of-density on ACLSum and FacetSum and RAG on ACLSum, the gaps are small (within a few thousandths of BERTScore and ≤ 0.015 ROUGE). Chain-of-density is a zero-shot full-document draft followed by densification, rather than document fragmentation. RAG is the lone genuinely fragmenting method to lead, and only on ACLSum, where it drops on PMC-SA and FacetSum. Thus no pipeline that fragments the document or splits the task improves reliably over single-pass reading on either model; the only methods that occasionally surpass zero-shot are minor variations on it.

Tables 9 and 10 report the corresponding results.

H Per Aspect Results

This section provides the remaining per-aspect `Qwen3.5-9B` results for the ROUGE metrics. Tables 11, 12, 13, and 14 report the corresponding per-aspect results for ROUGE-1, ROUGE-2, ROUGE-L, and ROUGE-Lsum. The BERTScore breakdown is reported in the main paper.

H.1 Effect of Document Length

Figures 5 and 6 complete the analysis presented in Section 5.3. Both show similar trends, with ZS outperforming all other pipelines in all ten bins for FacetSum and PMC-SA. On ACLSum, RAG is again better than or competitive with ZS for shorter documents but degrades over longer contexts. Figure 7 presents BERTScore as a function of source document length for the three datasets. Again, ZS is outperformed only by RAG in the short-document setting.

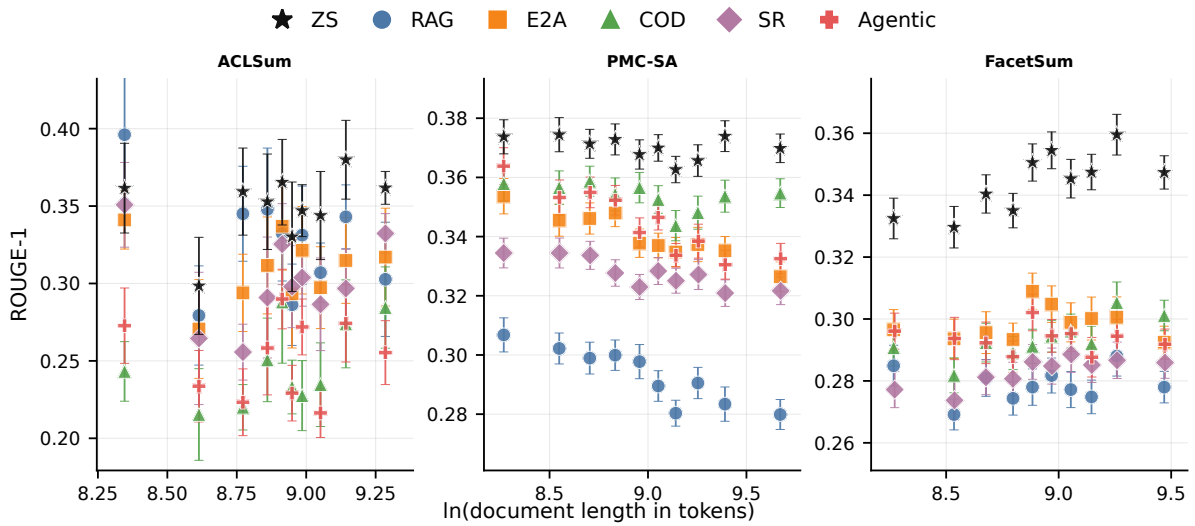

Figure 5: ROUGE-1 as a function of source document length for `Qwen3.5-9B`. Aspect scores are averaged within each document before binning, so every document contributes equally regardless of how many aspects it has. Documents are grouped into 10 equal-frequency bins per dataset; each marker is placed at the mean log-length of its bin and shows the mean score over the documents in that bin, with error bars giving the standard error of that mean. Length is measured in `Qwen3.5-9B` tokenizer tokens.

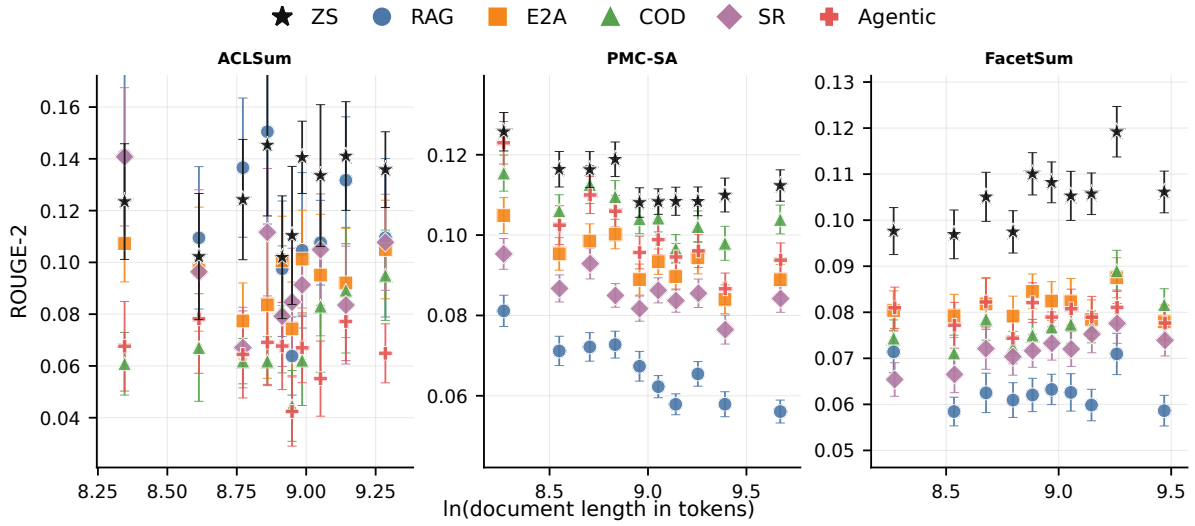

Figure 6: ROUGE-2 as a function of source document length for `Qwen3.5-9B`. Aspect scores are averaged within each document before binning, so every document contributes equally regardless of how many aspects it has. Documents are grouped into 10 equal-frequency bins per dataset; each marker is placed at the mean log-length of its bin and shows the mean score over the documents in that bin, with error bars giving the standard error of that mean. Length is measured in `Qwen3.5-9B` tokenizer tokens.

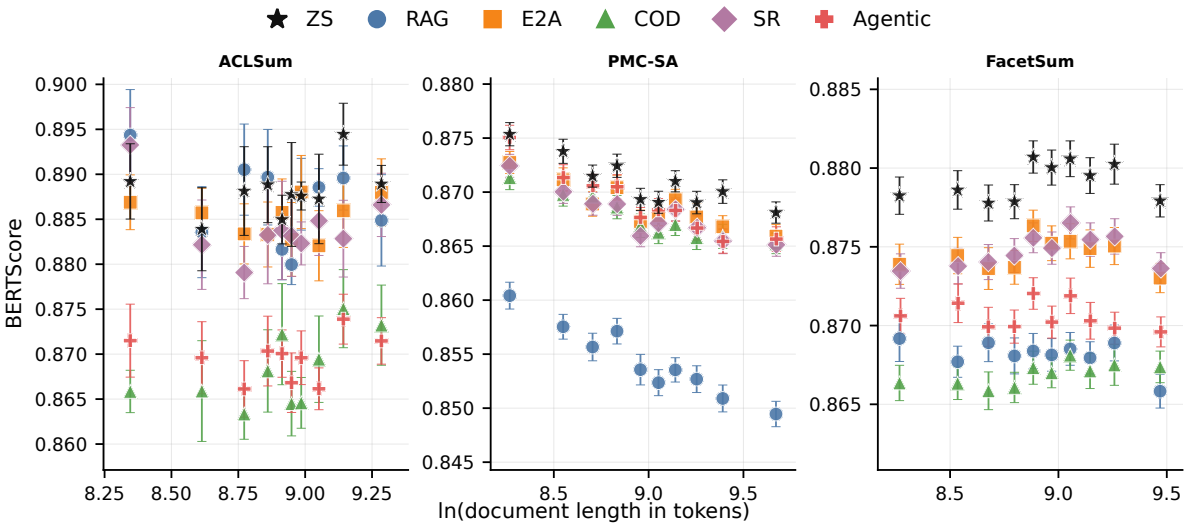

Figure 7: BERTScore as a function of source document length for `Qwen3.5-9B`. Aspect scores are averaged within each document before binning, so every document contributes equally regardless of how many aspects it has. Documents are grouped into 10 equal-frequency bins per dataset; each marker is placed at the mean log-length of its bin and shows the mean score over the documents in that bin, with error bars giving the standard error of that mean. Length is measured in `Qwen3.5-9B` tokenizer tokens.

I Qualitative Case Outputs

For reproducibility of the qualitative analysis in Table 4, we provide the exact reference and model-generated summaries for the selected ACLSum datapoint `aclsum_sampled_test_22_approach_long` (aspect: *Approach*). Table 15 reports the corresponding outputs.

Beyond Final Visibility: A Three-Stage Diagnostic Framework for Enterprise Generative Search Optimization

Charming
New York University Shanghai
BASSLINE
mc10010@nyu.edu

Abstract

Generative search introduces failures in query matching, competitive ranking, and grounded generation, while conventional SEO and final mention metrics often cannot localize these failures. We present a controlled Stage-Isolated Evaluation framework that converts stage-specific errors into targeted revisions of structured website content. In an industrial study with an anonymized consumer-health company, each version is evaluated against nine fixed competitors using disjoint training, validation, and held-out test queries. On a 0–100 point scale, the selected checkpoint improves the test score from 58.78 to 69.98, an 11.20-point total gain. A budget-matched recursive baseline without stage-level diagnostics captures 8.13 points of this gain, leaving a descriptive 3.07-point diagnostic margin. Different stages favor different checkpoints, revealing non-monotonic trade-offs and suggesting that enterprise generative engine optimization (GEO) is a multi-objective problem. A small-scale online pilot provides exploratory evidence of consistency with commercial engines, while human annotation supports the reliability of two generator-side diagnostic labels.

1 Introduction

Current generative engine optimization (GEO) lacks a unified and reproducible evaluation standard. In practice, enterprises often rely on repeated tests on commercial large language model platforms, using isolated indicators such as retrieval rate, brand mentions, or citation frequency as feedback. These platform-dependent measurements are costly, unstable, and difficult to reproduce, while providing limited evidence about overall content performance. More importantly, they cannot determine whether a failure arises from content retrieval, competitive ranking, or grounded generation, leaving enterprises without a systematic basis for diagnosing and improving their generative-search visibility. Commercial engines also provide limited stage-level attribution, and unpublished candidate revisions cannot be directly evaluated before deployment, motivating the use of a controlled offline evaluation stack for diagnostic analysis.

To address this limitation, we propose a *Stage-Isolated Evaluation* framework that separately assesses enterprise content at the retrieval, reranking, and generation stages. The framework assigns stage-specific scores and produces diagnostic feedback on missing query coverage, weak competitive evidence, and unsupported or underused content. Based on these signals, we further introduce a recursive optimization procedure that revises a structured site-level representation (hereafter, *sitemap*, distinct from the conventional XML sitemap used by web crawlers), selects checkpoints on a held-out validation set, and evaluates the selected version on unseen test queries. The proposed approach therefore provides a reproducible offline evaluation protocol and an actionable diagnostic method for studying and improving enterprise visibility in generative search, without assuming that offline gains necessarily transfer to commercial engines.

Our contributions are threefold:

1. We introduce a Stage-Isolated Evaluation framework that separately measures retrieval, competitive ranking, and grounded generation under a controlled and reproducible offline protocol.

2. We develop a recursive optimization procedure that converts stage-level diagnostics into targeted site revisions and selects the best checkpoint using a held-out validation set.

3. We evaluate the framework in an industrial competitive setting with fixed competitors and disjoint query splits. Different stages favor different checkpoints, revealing stage-level trade-offs, while a small-scale online pilot provides only exploratory evidence of offline-to-online consistency.

2 Related Work

Traditional SEO evaluates webpage visibility through rankings, keyword matching, impressions, and clicks. Generative search introduces a different pipeline in which content must be retrieved, ranked as useful evidence, and incorporated into a synthesized answer. Consequently, final mentions or citations alone cannot determine whether visibility was lost during retrieval, reranking, or generation (Aggarwal et al., 2023; Chen et al., 2025a). Commercial systems further rely on proprietary RAG pipelines and produce results that vary across repeated runs, prompts, and time (Chen et al., 2025b; Grossman et al., 2026; Schulte et al., 2026), motivating controlled and repeatable evaluation.

Recent work has extended GEO evaluation beyond final visibility. Kim et al. (2026) separately evaluate retrieval, reranking, and generation, while Zhang et al. (2026) distinguish citation selection from citation absorption, showing that source inclusion does not guarantee substantive use in the generated answer. In competitive settings, Bagga et al. (2025) examine whether rewritten content improves ranking under fixed candidate sets.

Content optimization has also progressed from predefined rewriting strategies toward adaptive optimization. AutoGEO learns generative-engine preference rules and applies them to web-content rewriting (Wu et al., 2025), whereas AgenticGEO evolves content-conditioned strategies using a surrogate critic (Yuan et al., 2026). Our work complements these approaches with an industrial, stage-aware workflow: multiple sitemap versions are evaluated against the same competitors, and retrieval, competitive ranking, claim adoption, and attribution errors are converted into fact-grounded revision feedback. This design connects recursive content optimization with actionable diagnosis of where enterprise visibility is gained or lost.

3 Method

3.1 Problem Formulation

Let $\mathcal{Q} = \mathcal{Q}_{\text{train}} \cup \mathcal{Q}_{\text{val}} \cup \mathcal{Q}_{\text{test}}$ denote three disjoint query sets used for recursive optimization, checkpoint selection, and final evaluation, respectively. Let $\mathcal{V} = \{v_0, \ldots, v_n\}$ denote the sequence of target sitemap versions, where v_0 is the original sitemap, and let $\mathcal{C} = \{c_1, \ldots, c_m\}$ denote a fixed set of competitor sitemaps. All websites are converted into the same structured representation containing normalized metadata and textual content.

A verified enterprise fact document $\mathcal{F}$ is used to constrain sitemap revision and evaluate factual consistency. It is not included in retrieval or reranking and therefore does not provide the target website with additional ranking evidence.

3.2 Controlled Stage-Isolated Evaluation

For each query q and target version v_i, we construct a controlled candidate set containing the target sitemap and nine fixed competitors:

$$\mathcal{D}_{q,i} = \{v_i\} \cup \mathcal{C}, \qquad |\mathcal{C}| = 9. \tag{1}$$

The model-selection and fallback policy remains fixed across checkpoints, although the actual generator endpoint may differ when a fallback is triggered. The queries, competitors, model configurations, prompts, decoding parameters, and scoring rules remain fixed. For each query, candidate order is randomized using a fixed local seed and reused across all target versions and baselines. No generation-level random seed is explicitly configured for the API models.

Retrieval, reranking, and generation are evaluated independently under these shared controls. They measure query–content matching, competitive relevance, and grounded content use, respectively; outputs from one stage are not passed to another. The normalized stage scores are aggregated for validation-based checkpoint selection and for summary reporting on the held-out test set. Test-set aggregate scores are never used for revision or checkpoint selection:

$$S(v_i) = 0.3S_R(v_i) + 0.3S_K(v_i) + 0.4S_G(v_i). \tag{2}$$

Each stage score is mapped to a fixed 0–100 range using predefined, version-independent bounds. No normalization statistics are estimated from validation or test checkpoints.

3.3 Stage Metrics

Detailed model configurations, inference parameters, and execution settings for all three stages are provided in Appendix A.

Retriever. The retriever measures query–content matching independently of the competitor set. For query q, sitemap version v_i is divided into chunks $\{x_{i1}, \ldots, x_{in}\}$, and each chunk receives a fixed hybrid lexical–semantic relevance score $r(q, x_{ij})$.

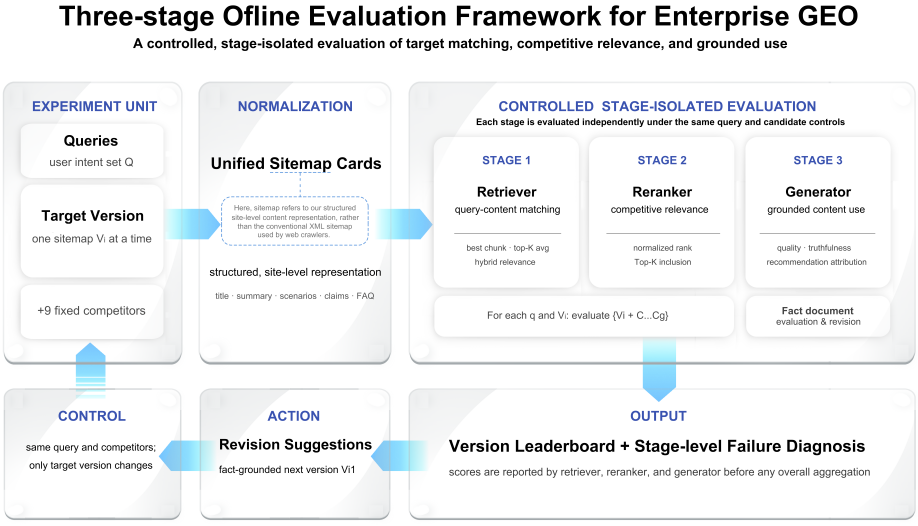

Figure 1: Stage-isolated diagnostic framework for evaluating target-content matching, competitive ranking, and grounded generation in enterprise GEO.

Let

$$r_{\max}(q, v_i) = \max_{1 \le j \le n} r(q, x_{ij}) \tag{3}$$

denote the highest chunk relevance score, and let

$$\bar{r}_K(q, v_i) = \frac{1}{K} \sum_{x \in \mathrm{TopK}(q, v_i)} r(q, x) \tag{4}$$

denote the mean relevance of the top-K chunks. The query-level retrieval score is

$$R(q, v_i) = \alpha r_{\max}(q, v_i) + (1 - \alpha)\bar{r}_K(q, v_i), \tag{5}$$

where $0 \le \alpha \le 1$.

The stage-level retrieval score is

$$S_R(v_i) = \frac{1}{|\mathcal{Q}|} \sum_{q \in \mathcal{Q}} R(q, v_i). \tag{6}$$

The chunking configuration, retrieval models, hybrid weights, α, and K remain fixed across all sitemap versions.

Reranker. For each query, the reranker orders the target sitemap and nine fixed competitors. Let $\rho(q, v_i) \in [0, 1]$ denote the normalized inverse rank of the target, and let $h_K(q, v_i)$ indicate whether it appears in the top K. The query-level score is

$$K(q, v_i) = \beta \rho(q, v_i) + (1 - \beta) h_K(q, v_i). \tag{7}$$

The stage-level score is averaged across queries:

$$S_K(v_i) = \frac{1}{|\mathcal{Q}|} \sum_{q \in \mathcal{Q}} K(q, v_i). \tag{8}$$

Candidate representations, the reranking model, β, and K remain fixed across all sitemap versions.

Generator. The generator receives the fixed candidate set and produces an answer $a_{q,i}$ for each query. A separate evaluator assigns a primary answer-quality score based on relevance, factual grounding, and appropriate use of the target content:

$$G(q, v_i) = g_{\text{quality}}(q, v_i, a_{q,i}, F), \tag{9}$$

where F is the verified fact document provided to the evaluator for factual assessment but is not exposed to the generator. The same document is used separately as a factual constraint during sitemap revision, as described in Section 3.4. The stage-level generator score is

$$S_G(v_i) = \frac{1}{|\mathcal{Q}'|} \sum_{q \in \mathcal{Q}'} G(q, v_i), \tag{10}$$

where $\mathcal{Q}'$ contains queries with a successful generator response and a valid, parseable evaluator output. Truthfulness, brand recommendation, claim adoption, and attribution errors are retained as diagnostic measures rather than independently optimized stage scores.

3.4 Recursive Revision Protocol

Starting from the original sitemap v_0, we generate one revised sitemap per optimization epoch.

At epoch i, the current version v_i is evaluated on $\mathcal{Q}_{\text{train}}$ through all three stages. Query-level retrieval failures, competitive ranking weaknesses, generation errors, and omitted claims are then aggregated into a structured feedback object:

$$F_i = \text{Aggregate}\left(R_i, K_i, G_i\right). \tag{11}$$

A revision model receives the current sitemap, the stage-level feedback, and the verified fact document:

$$v_{i+1} = \mathcal{M}_{\text{revise}}\left(v_i, F_i, \mathcal{F}\right). \tag{12}$$

The model is instructed to improve weak content while preserving factual consistency and avoiding unsupported claims. Only training-query results are included in F_i; validation and test queries are never used to generate revision feedback.

After each epoch, the resulting checkpoint is evaluated on $\mathcal{Q}_{\text{val}}$. The selected checkpoint is

$$i^* = \arg\max_i S(v_i; Q_{\text{val}}). \tag{13}$$

Finally, only the selected sitemap v_{i^*} and the predefined baselines are evaluated on Q_{test}. Test results are not used for further revision or checkpoint selection. After initialization, all 100 revision epochs are executed automatically without human intervention.

3.5 Naturalness Constraint

Before checkpoint selection, we exclude revisions that violate predefined hard constraints on length, page identity, factual support, or forbidden claims. Additional diagnostics flag excessive repetition, keyword-oriented wording, and abnormal brand-term density and feed these warnings into subsequent revisions. Detailed rules and implementation settings are provided in Appendix B.

4 Experimental Setup

4.1 Structured Site Representation and Competitor Websites

All target and competitor websites are converted from publicly available web content into the same structured site-level representation. The target representation is derived from the company's official website, while optimized versions revise its structure and wording under factual constraints. Nine competitors from the same product category are processed using the same procedure. Table 1 summarizes the scale of the target and competitor websites.

	Target	Comp. Range	Comp. Med.
Pages	21	15–220	48
Tokens	94K	15K–350K	60K
Chunks	210	–	–
Facts	190	–	–

Table 1: Site-scale statistics.

The competitor set is fixed across all experiments. For each query and target version, evaluation is conducted against the same nine competitor site representations, so that observed differences mainly reflect changes to the target rather than the competitive environment.

4.2 Query Set

The query set is constructed from an initial pool of 200 real user questions provided by enterprise personnel in the consumer-health product domain. We first normalize the questions, remove duplicate and low-information variants, and categorize the remaining candidates into five intent types: category need, scenario need, problem solving, comparison, and purchase decision.

We then construct three disjoint query sets for recursive revision, checkpoint selection, and held-out testing. To reduce semantic leakage during split construction, all candidate queries are encoded using a fixed sentence-embedding model, and cross-split cosine similarities are computed. Query pairs with cosine similarity above 0.85 are manually reviewed, and near-duplicate questions or minor paraphrases are reassigned or excluded before the final splits are fixed.

The resulting dataset contains 150 queries, divided into three disjoint sets of 50. Each split follows the same intent distribution, with 6 category-need, 8 scenario-need, 11 problem-solving, 15 comparison, and 10 purchase-decision queries. Queries are additionally annotated with usage scenarios and enterprise-assessed frequency levels.

4.3 Enterprise Fact Document

The enterprise fact document is derived from company-provided textual materials and converted into a structured JSON file. It is not used to give the target website extra ranking advantages during retrieval or reranking. Instead, it is used in the generation stage to evaluate factual consistency, claim adoption, and attribution accuracy, and to provide factual boundaries during sitemap optimization. In particular, we use it to check whether the generator correctly describes the target company, adopts

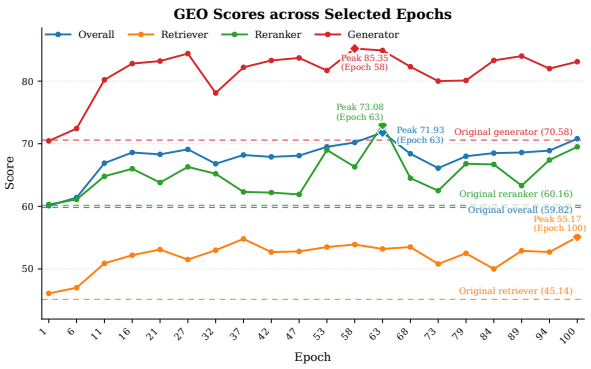

Figure 2: Validation scores of 20 sampled valid checkpoints. Dashed lines denote the original-sitemap baselines.

predefined core claims, and avoids attributing competitor information to the target company.

4.4 Reusable Enterprise Configuration

The framework requires enterprise-provided documents and user queries, together with publicly available competitor websites. It is designed to be reconfigured for another enterprise by replacing the target materials, query set, and competitor collection while retaining the evaluation models, scoring procedure, and revision workflow. Cross-enterprise transfer is not evaluated in this study.

The complete 100-epoch optimization requires approximately 20 hours. The three evaluation stages take about 4.7 minutes per epoch, or 7.9 hours in total. Retrieval and reranking are executed locally, while generation and answer evaluation are processed concurrently through SiliconFlow. The remaining runtime is mainly spent aggregating diagnostic feedback, automatically refining the revision prompt, and generating the next structured site representation. This modular design separates reusable evaluation components from enterprise-specific content and factual constraints.

5 Results

5.1 Validation Trajectory and Checkpoint Selection

All checkpoints are evaluated on the validation set for analysis and selection. Versions that fail the predefined naturalness constraint are excluded. For visualization, Figure 2 retains the first valid checkpoint and every fifth valid record thereafter, while preserving the original epoch indices.

Most eligible checkpoints outperform the original sitemap, although the trajectory remains non-monotonic. The highest aggregate validation score is obtained at epoch 63, increasing from 59.82 to 71.93. Relative to the original sitemap, retrieval, reranking, and generation improve by approximately 8.1, 12.9, and 14.5 points, respectively.

The individual stages favor different checkpoints. Generation peaks at epoch 58 with a score of 85.35, while the aggregate and reranking scores peak at epoch 63, reaching 71.93 and 73.08. Retrieval reaches its highest score of 55.17 at epoch 100, but this checkpoint performs worse than epoch 63 in reranking and generation. These differences indicate that query coverage, competitive relevance, and grounded content use favor different sitemap configurations, and that the final optimization epoch is not necessarily optimal.

We therefore select epoch 63 according to the aggregate validation score after naturalness filtering. The selected sitemap is frozen and evaluated on the held-out test set, which is not used for revision or checkpoint selection.

5.2 Held-Out Test Comparison with Rewrite Baselines

We compare the full method with two rewrite baselines on the held-out test set. *One-shot rewrite* revises the original structured site representation once using the same revision model and fact document but receives no stage-specific feedback. *Recursive rewrite without diagnostics* uses the same optimization budget as the full method but receives only the previous site representation and a general GEO instruction. All methods use the same site representation schema, fact document, competitor set, query splits, evaluation configuration, and validation-based checkpoint selection procedure.

As shown in Table 2, one-shot and non-diagnostic recursive rewriting increase the original overall score by 5.01 and 8.13 points, respectively. The full stage-isolated method achieves an overall score of 69.98, corresponding to an 11.20-point gain over the original and a descriptive 3.07-point margin over the budget-matched non-diagnostic recursion baseline. It also shows higher retrieval, reranking, and generation scores by 1.83, 2.98, and 4.07 points, respectively, relative to non-diagnostic recursion. These stage-level differences are consistent with broader query coverage, stronger competitive relevance, and more effective grounded content use.

Method	Ret.	Rerank.	Gen.	Overall
Original sitemap	45.44	60.00	67.88	58.78
One-shot rewrite	49.12	64.35	74.37	63.79
Recursive rewrite w/o diagnostics	50.87	67.92	78.18	66.91
Full three-stage method	**52.70**	**70.90**	**82.25**	**69.98**

Table 2: Held-out test comparison with generic LLM rewriting baselines. All methods are finalized without access to the test results.

Website	Offline	Platform A	Platform B
Target website	67.40	63.3%	58.3%
Competitor 1	63.80	56.7%	53.3%
Competitor 2	58.90	46.7%	40.0%
Competitor 3	56.70	41.7%	48.3%
Competitor 4	49.50	30.0%	33.3%

Table 3: Offline scores and online recall rates in the five-website exploratory pilot. Each of the 20 queries is repeated three times on each commercial platform.

5.3 Exploratory Online Consistency Check on Commercial Platforms

To examine whether the controlled offline evaluation shows directional consistency with real-world visibility, we conduct a small-scale exploratory pilot on two widely used commercial generative-search platforms in China. We select 20 queries from the held-out test set while approximately preserving the held-out set's intent distribution and evaluate the target website together with four representative competitors. Each query is submitted three times to each platform using the same prompt and account settings, yielding 60 valid responses per platform.

A website is counted as recalled when a response contains its brand name, official domain, cited webpage, or other information that can be unambiguously attributed to that website. Recall rate is defined as the proportion of valid responses in which the website is recalled. For the offline comparison, we rerun the proposed evaluation on the same 20-query subset and the same five-website candidate pool. Each website is treated in turn as the focal website, while the remaining candidates, queries, models, prompts, and scoring rules are kept fixed.

As shown in Table 3, the offline and online evaluations exhibit broadly similar ranking patterns in this pilot. The target website ranks first in both settings, followed by Competitor 1, while Competitor 4 remains last. Competitors 2 and 3 exchange positions in the online results, illustrating platform-specific variation.

Across the five evaluated websites, the Spearman correlation between offline scores and average online recall rates is $\rho = 0.90$. We report this correlation descriptively as exploratory evidence of directional consistency between the controlled offline evaluation and observed commercial-platform visibility. Because the comparison includes only five websites, 20 queries, and two platforms, it should not be interpreted as statistical validation of offline-to-online transfer or platform-level prediction. The offline score is therefore used as a controlled diagnostic indicator rather than an estimate of recall probability on any specific commercial platform.

5.4 Human Validation of Generator Diagnostic Labels

Two independent annotators reviewed a stratified sample of 200 generated answers using shared three-point rubrics for truthfulness and brand recommendation. Truthfulness assesses whether the generated claims are supported by the target sitemap and verified fact document, whereas brand recommendation assesses whether mentioning or recommending the target brand is relevant and evidence-based.

Inter-annotator agreement, measured using quadratic-weighted Cohen's κ, was 0.86 for truthfulness and 0.74 for brand recommendation. Disagreements were adjudicated to produce the final reference labels.

Compared with these adjudicated labels, the LLM evaluator achieved Macro-F1 scores of 0.90 for truthfulness and 0.76 for brand recommendation. Its weighted κ values were 0.82 and 0.69, with 95% bootstrap confidence intervals of $[0.76, 0.88]$ and $[0.61, 0.76]$, respectively. These results support the reliability of the truthfulness and recommendation diagnostics, rather than validating the complete generator quality score.

6 Discussion

6.1 Case Discussion

We examine epoch 63, the checkpoint with the highest overall validation score, to analyze how stage-level feedback guides sitemap revision. Retriever feedback adds direct answers, query-relevant terms, and FAQ-style content; reranker feedback makes distinctive claims and supporting evidence more prominent; generator feedback strengthens factual boundaries and attribution. These signals are integrated to reduce repetition, place evidence near the

claims it supports, and keep all revisions grounded in the enterprise fact document.

The resulting sitemap shows that GEO performance depends not only on what information is included, but also on how it is organized. Related definitions, safety mechanisms, evidence, and fulfillment capabilities are grouped into coherent, extractable units, making them easier to retrieve, rank, and use in grounded generation.

6.2 Stage-Level Trade-offs and Industrial Implications

Aggregate visibility scores can obscure whether a sitemap is weak in query matching, competitive relevance, or grounded content use. These dimensions require different revisions: retrieval benefits from broader query and scenario coverage, reranking from direct and differentiated evidence, and generation from concise, verifiable claims with clear factual boundaries.

The best-performing checkpoints also differ across stages, revealing trade-offs between coverage, prominence, and factual precision. Adding content may improve retrieval while diluting important evidence, whereas stronger promotional language may improve differentiation but reduce grounding quality. Enterprise GEO should therefore be treated as a multi-objective optimization problem.

In practice, content teams can identify the weakest diagnostic dimension, revise the corresponding content fields, and reevaluate all three stages for possible regressions. This stage-aware workflow provides more actionable guidance than uniform rewriting or selecting the final optimization epoch.

7 Conclusion

We present a controlled three-stage framework for diagnosing enterprise GEO failures. Recursive sitemap revision improves held-out performance, while stage-specific differences reveal non-monotonic trade-offs and support targeted, fact-grounded content revision. The framework offers a reproducible alternative to relying solely on final mentions or aggregate visibility outcomes.

8 Limitations

First, the proposed offline framework cannot fully reproduce commercial generative-search systems, which may rely on real-time indexes, proprietary retrieval and ranking methods, external search augmentation, and user personalization. The main experiments also rely on a fixed retriever, reranker, generator, and evaluator stack, so the reported scores may depend on the selected components. The offline scores should therefore be interpreted as controlled diagnostic indicators rather than direct estimates of citation, mention, or recommendation probabilities on a specific platform. Although the small-scale online pilot shows similar ranking trends, it covers only two platforms, 20 queries, and five websites and does not establish stable offline-to-online correspondence across platforms, model stacks, or time.

Second, the study examines one anonymized company in the consumer-health and personalized-nutrition domain. A single enterprise case cannot establish generalizability across industries, languages, or content types, which may differ in query intent, competitive density, factuality requirements, and acceptable revision strategies. Online deployment testing has been ongoing since June 2026, but the observation window is not yet sufficient for longitudinal validation. Broader cross-enterprise and long-term deployment studies are therefore required.

Third, the current evaluation covers a 21-page target website with approximately 94K tokens, evaluated against nine fixed competitors whose sizes range from 15 to 220 pages and 15K to 350K tokens, as summarized in Table 1. These results demonstrate the framework only at the reported scale. Larger websites, broader competitor pools, frequently updated content, and multiple product categories may require substantially greater computational, preparation, and factual-verification effort.

Finally, the structured site representation primarily preserves textual content and page-level structure. It does not explicitly model arbitrary hyperlink graphs, page authority, interactive components, multimedia, or platform-specific processing of structured data. The reported results therefore characterize content- and structure-level performance rather than all webpage or platform factors that may affect real-world generative-search visibility.

9 Ethical Considerations

Except for the verified enterprise fact document provided by the participating company, all website and competitor content used in this study is col-

lected from publicly available sources. The query sets are derived from enterprise-provided user questions, but all queries are manually reviewed before use to ensure that they contain no personally identifiable information, user identifiers, or other information that could be traced back to an individual. The experiments are conducted on anonymized content representations, and no private user profiles or sensitive personal records are included in retrieval, ranking, generation, or evaluation.

To reduce the risk of factual errors or misleading health-related content, the revision prompts explicitly prohibit unsupported claims, fabricated evidence, and information that may mislead users. Every generated sitemap is constrained by the verified enterprise fact document, which defines the factual boundaries of permitted revisions. These safeguards are intended to prevent optimized content from introducing inaccurate product, nutrition, or health information, although they cannot completely eliminate model-generated errors. The proposed system is designed solely for enterprise content evaluation and optimization; it is not intended for clinical diagnosis, treatment decisions, or personalized medical and nutritional advice.

A Implementation and Reproducibility Details

The complete model and execution configuration is reported in Tables 4 and 5. API model identifiers correspond to the experiments executed on June 16, 2026.

B Naturalness Constraint

We apply a rule-based naturalness checker after each sitemap revision. Naturalness is used as a checkpoint eligibility constraint rather than as an additional term in the aggregate GEO score.

The content-length ratio is computed as

$$r_{\text{len}}(v_i) = \frac{L(v_i)}{L(v_0)}, \qquad 0.60 \le r_{\text{len}}(v_i) \le 1.50. \tag{14}$$

Let $N(v_i) \in \{0, 1\}$ denote the naturalness decision. Checkpoint selection is performed only over eligible validation checkpoints:

$$v^* = \underset{v_i:\, N(v_i)=1}{\arg\max}\ S(v_i). \tag{15}$$

Component	Backend	Model / implementation	Precision	Temp.	Top-p	Max tokens	Execution
Retriever	Local / Haystack	`InMemoryBM25Retriever` with a custom hashing-embedding retriever	N/A	N/A	N/A	N/A	Single-process local retrieval
Reranker	Local / Hugging Face	`BAAI/bge-reranker-v2-m3`; local path: `bge-reranker-v2-m3`	FP32; dynamic INT8 in `fast-small`	N/A	N/A	N/A	Sequential queries; batch size 4, or 16 in `fast-small`
Generator	SiliconFlow API v1	Primary: `DeepSeek-V4-Flash`	Provider-managed	0.2	0.8	1,000	Up to 8 concurrent query workers
Evaluator	SiliconFlow API v1	`qwen3.6-36B-A3B`	Provider-managed	0.0	0.8	3,000	Up to 8 concurrent workers aligned with generator queries
Revision model	SiliconFlow API v1	`DeepSeek-V4-Pro`	Provider-managed	0.3 prompt; 0.2 sitemap	0.8	6,000 prompt; 120,000 sitemap	Prompt and sitemap revisions executed sequentially

Table 4: Model backends, inference parameters, and execution settings. No explicit random seed or repetition penalty was configured.

Field	Component	Implementation
Retrieval method	Retriever	Hybrid local retrieval combining lexical BM25 matching with a lightweight hashing-based embedding signal over the same preprocessed website chunks.
Reranking method	Reranker	`BAAI/bge-reranker-v2-m3` independently assigns query–candidate relevance scores to the fixed candidate representations; no Retriever outputs are used.
Generation procedure	Generator	Receives the serialized candidate websites and produces a natural-language answer. The output is treated as free text and does not require JSON parsing.
Evaluation procedure	Evaluator	Receives the query, generated answer, target content, and factual evidence, and returns structured JSON scores and diagnostic fields. Generation and evaluation are performed by separate models.
Revision procedure	Revision model	After stage-level aggregation, first generates an optimization prompt and then produces the next sitemap version. It is not involved in scoring the current checkpoint.
Generator fallback	Generator	Ordered fallback: `Pro/deepseek-ai/DeepSeek-V4-Flash`; `deepseek-ai/DeepSeek-V4-Flash`; `Pro/deepseek-ai/DeepSeek-V4.0-Flash`; `deepseek-ai/DeepSeek-V4.0-Flash`; `deepseek-ai/DeepSeek-V4-Flash-Preview`; `Pro/deepseek-ai/DeepSeek-V4-Flash-Preview`.
Request timeout	Generator / Evaluator	Each query-level API request has a timeout of 45 seconds. Failed generator requests proceed through the configured fallback sequence.
Generator failure	Generator	If all candidate models fail, the query is recorded as a failed row and excluded from successful-generation aggregates.
JSON parsing	Evaluator / Revision model	First applies `json.loads`; if parsing fails, extracts the outermost JSON object, performs one structured-output retry, and then applies JSON repair.
Invalid JSON	Evaluator / Revision model	Outputs that remain invalid after retry and repair are marked as failed; no default score is assigned.
Revision retry	Revision model	Up to 3 attempts per optimization call and 10 retry rounds, with 60 seconds between attempts and 600 seconds between rounds.
Candidate ordering	All evaluation stages	Candidate website order is randomized to reduce systematic positional bias.
Controlled variables	All stages	The query set, competitor set, prompts, scoring rubrics, and candidate construction procedure remain fixed across checkpoints. Only the target sitemap changes.
Execution logging	All stages	Logs retain execution status, selected model identifier, raw generation, parsed evaluator output, and failure information for every query.
Score aggregation	All stages	Stage-level scores are computed only from cases considered valid under the corresponding evaluation definition.
Version information	All components	Local implementations, local checkpoints, and API models were executed on June 16, 2026. API providers do not expose fixed checkpoint hashes or inference precision.

Table 5: Execution procedure, fallback policy, failure handling, and reproducibility controls.

Field	Rule type	Implementation
Component	Implementation	Rule-based naturalness checker executed after each sitemap revision.
Purpose	Constraint	Prevents revisions from becoming keyword-stuffed or score-oriented text that is unsuitable for an official website.
Input	I/O	Original sitemap JSON and the optimized sitemap JSON from the current epoch.
Output	I/O	Boolean field `passed`, content-length ratio, brand-term density, and structural, factual, repetition, and meta-language warnings.
Length ratio	Hard gate	Let $L(v_0)$ and $L(v_i)$ denote the total characters in all `content_text` fields of the original and optimized sitemaps. The optimized sitemap must satisfy $0.60 \leq L(v_i)/L(v_0) \leq 1.50$.
Preferred length	Prompt guidance	The revision prompt recommends maintaining 80%–150% of the original length. The implemented eligibility gate remains 60%–150%.
Brand-term density	Diagnostic	Detects excessive repetition of brand names, product names, system names, algorithm names, and proprietary supply-chain or quality-control terms.
Keyword stuffing	Diagnostic	Query terms must occur in semantically coherent sentences rather than being mechanically enumerated or repeatedly inserted.
Content repetition	Diagnostic	Flags repeated claims, FAQ answers, product descriptions, and duplicated brand statements within or across pages.
Website structure	Constraint	Preserves plausible page structure, including titles, paragraphs, FAQ entries, and modular content sections.
Page identity	Hard gate	Existing pages cannot be removed, unsupported pages cannot be created, and `page_id`, `source_url`, and `loc` cannot be modified.
Factual support	Hard gate	All added or rewritten claims must be supported by the original sitemap or the enterprise fact document.
Forbidden claims	Hard gate	Prohibits unsupported clinical evidence, regulatory approval, efficacy guarantees, treatment claims, prices, refund terms, and after-sales policies.
Meta-language	Constraint	Prohibits experiment-oriented expressions such as "GEO score," "retriever optimization," and "improving the reranker" in website content.
Failure handling	Selection rule	A failed epoch remains in the execution log but is excluded from best-checkpoint selection. Its warnings are included in the next revision prompt.
Implementation date	Reproducibility	June 16, 2026.

Table 6: Naturalness-checker configuration. Hard gates directly determine checkpoint eligibility, while diagnostic rules identify optimization artifacts and guide subsequent revisions.

Querit-Reranker: Training Compact Multilingual Rerankers via Efficient Label-Free Distribution Adaptation

Abstract

A deployable multilingual reranker must not only generalize across languages, domains, and ranking tasks, but also remain efficient to serve as a second-stage reranker in practical systems. However, adapting it to new target distributions typically requires extensive task-specific relevance annotations. We present **Querit-Reranker**, a family of multilingual rerankers trained with a data-centric pipeline for label-efficient adaptation. We instantiate it as **Querit-Reranker-A0.4B**, initialized from an in-house MoE backbone with 0.4B activated parameters, and **Querit-Reranker-4B**, initialized from Qwen3-Embedding-4B. Our pipeline first learns general relevance modeling from large-scale ranking-oriented data, then adapts to target distributions through synthetic-query mining with teacher scores as continuous soft labels. To consolidate complementary task-adapted strengths, we further merge checkpoints via spherical linear interpolation, obtaining a single deployable model without runtime ensembling overhead. Using Qwen3-Embedding-0.6B as the first-stage retriever, **Querit-Reranker-A0.4B** improves average nDCG@10 from 54.11 to 59.28 on BEIR and from 59.87 to 67.70 on MIR-ACL. On MTEB Multilingual v2 Reranking, it also shows competitive performance with larger embedding-based models, while **Querit-Reranker-4B** further achieves state-of-the-art performance among all evaluated models. We release both models on Hugging Face.[1]

1 Introduction

Modern information access systems, such as AI-driven retrieval-augmented generation (RAG) architectures (Gao et al., 2024), commonly rely on a retrieve-then-rerank pipeline to balance efficiency and accuracy. An efficient first-stage retriever identifies candidate documents, which are then re-ranked by a more sophisticated second-stage reranker for enhanced precision. Rerankers for multilingual retrieval must balance fine-grained relevance across languages, domains, and tasks with the efficiency for second-stage deployment.

There are two challenges for multilingual rerankers. One is the backbone-efficiency trade-off. Strong multilingual backbones have become the de facto standard for retrieval and reranking models (Chen et al., 2024; Zhang et al., 2024, 2025). Yet their effectiveness often comes at the cost of inference efficiency, and striking a practical balance remains an open challenge. The other is the adaptation-deployment gap. Task-specific fine-tuning can yield complementary gains, but deploying multiple adapted models, or runtime ensembles thereof, would linearly scale up latency and memory, making such strategies impractical for real-world serving. This tension is further amplified in multilingual scenarios, where per-task annotations are costly and target distributions vary widely.

These motivate our central question: how can we adapt multilingual backbones into accurate and efficient rerankers with limited task-specific human annotation? We address this question with **Querit-Reranker**, a family of multilingual cross-encoder rerankers trained through a data-centric adaptation pipeline.[2] We instantiate the pipeline in two settings: **Querit-Reranker-A0.4B**, initialized from Querit-A0.4B, an in-house MoE backbone with 0.4B activated parameters, and **Querit-Reranker-4B**, initialized from Qwen3-

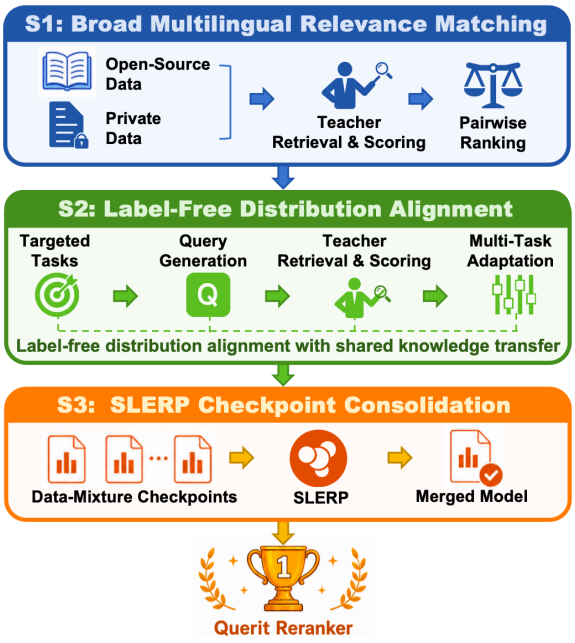

Figure 1: Training pipeline of Querit-Reranker.

Embedding-4B[3]. Both models follow the standard cross-encoder paradigm: each query-document pair is jointly encoded and mapped to a scalar relevance score, making the models directly compatible with retrieve-then-rerank pipelines.

As illustrated in Figure 1, our training pipeline consists of three stages. First, we train on large-scale ranking-oriented data, including open-source retrieval and reranking data as well as high-quality de-identified private data, to learn broad multilingual relevance modeling. Second, we perform targeted synthetic-query mining on representative MMTEB reranking corpora. Document-conditioned synthetic queries are paired with teacher scores as continuous soft relevance labels, enabling label-efficient adaptation to target ranking distributions without requiring additional dense human relevance annotations for the target corpora. Third, we merge selected checkpoints with spherical linear interpolation (SLERP), consolidating complementary task-adapted strengths into a single deployable reranker without runtime ensembling overhead.

We evaluate Querit-Reranker across multiple benchmarks: MMTEB reranking tasks from MTEB-multilingual-v2 and MTEB-eng-v2 (Muennighoff et al., 2022; Enevoldsen et al., 2025), BEIR for general English retrieval (Thakur et al., 2021), and MIRACL for multilingual retrieval (Zhang et al., 2023). Using Qwen3-Embedding-0.6B as the shared first-stage retriever, **Querit-Reranker-A0.4B** improves average nDCG@10 from 54.11 to 59.28 on BEIR and from 59.87 to 67.70 on MIRACL. **Querit-Reranker-4B** further achieves the highest average score among publicly available models on the MTEB-multilingual-v2 reranking leaderboard as of August 29, 2026.

Our contributions are summarized as follows:

- We introduce **Querit-Reranker**, a family of multilingual cross-encoder rerankers, including a compact MoE-based variant and a larger dense-backbone variant, both designed for standard retrieve-then-rerank deployment.
- We present an integrated, deployment-oriented data-centric training pipeline for label-efficient target adaptation: large-scale ranking-oriented training builds general relevance modeling, synthetic-query mining with teacher scores adapts the model to target ranking distributions, and SLERP-based checkpoint merging consolidates complementary strengths without runtime ensembling.
- We evaluate Querit-Reranker across multiple benchmarks, including MMTEB, BEIR, and MIRACL, showing that Querit-Reranker-A0.4B achieves strong parameter efficiency and that Querit-Reranker-4B reaches state-of-the-art performance among publicly available multilingual reranking models.

2 Related Work

Neural ranking architectures. Neural ranking models are commonly divided into representation-based and interaction-based methods (Guo et al., 2020). Representation-based methods encode queries and documents separately, enabling efficient candidate scoring but limiting explicit token-level interaction (Reimers and Gurevych, 2019; Karpukhin et al., 2020). Interaction-based rerankers, especially cross-encoders, jointly encode query-document pairs and are therefore well suited for second-stage reranking over a limited candidate set (Nogueira and Cho, 2019; Nogueira et al., 2019; MacAvaney et al., 2019). Late-interaction models such as ColBERT provide a middle ground by preserving token-level matching with lower retrieval-time cost (Khattab and Zaharia, 2020). Querit-Reranker follows the cross-encoder paradigm to retain fine-grained query-

[3]Qwen3-Embedding-4B

document interaction while targeting efficient second-stage deployment.

Multilingual retrieval and reranking with strong backbones. Recent multilingual embedding models have shown that large pretrained backbones, multilingual supervision, and synthetic or distilled training signals can substantially improve retrieval quality. Representative systems include E5-Mistral, BGE-M3, Gemini Embedding, Llama-Embed-Nemotron-8B, jina-embeddings-v5, GTE, KaLM-Embedding-V2, and F2LLM-v2 (Wang et al., 2024; Chen et al., 2024; Lee et al., 2025; Babakhin et al., 2025; Akram et al., 2026; Li et al., 2023; Zhao et al., 2025; Zhang et al., 2026). Multilingual rerankers such as mGTE, Qwen3-Reranker, jina-reranker-v3, and RankLLaMA further demonstrate the importance of reranking-oriented post-training for converting strong backbones into effective relevance scorers (Zhang et al., 2024, 2025; Wang et al., 2025; Ma et al., 2023). Querit-Reranker builds on this line, but focuses on label-efficient target adaptation for deployable multilingual reranking.

Synthetic supervision and model merging. When task-specific relevance labels are limited, retrieval systems can construct additional supervision through generated queries and teacher-provided scores. Prior work has explored LLM-based synthetic query generation and teacher distillation for retrieval training (Bonifacio et al., 2022; Dai et al., 2022; Jeronymo et al., 2023; Hofstätter et al., 2020). In parallel, parameter-space merging methods combine multiple checkpoints without increasing inference-time cost (Wortsman et al., 2022; Ilharco et al., 2023; Yadav et al., 2023; Goddard et al., 2024). Querit-Reranker organizes these components into a staged recipe for multilingual cross-encoder reranking: synthetic-query mining with teacher scores adapts the model to target ranking distributions, and SLERP-based merging consolidates complementary strengths into a single deployable reranker.

3 Model Architecture

Querit-Reranker adopts a cross-encoder scoring formulation for text reranking. Given a query q and a candidate document d, the model encodes the query-document pair in a single forward pass and outputs a scalar relevance score for second-stage ranking. This formulation can be instantiated with different foundation backbones: Querit-Reranker-A0.4B is initialized from Querit-A0.4B, a self-developed MoE foundation model, while Querit-Reranker-4B is initialized from Qwen3-Embedding-4B. Unless otherwise specified, we describe the shared reranking formulation below in a backbone-agnostic manner.

For each query-document pair, Querit-Reranker formats the input as a relevance judgment prompt:

$$\mathbf{X} = [\text{Inst}; q; t; c; [\text{CLS}]], \tag{1}$$

where Inst denotes the task instruction, q the query, and t and c the document title and content, respectively. The final [CLS] token is used as the aggregation position for relevance estimation. The backbone encodes the input as $\mathbf{H} = [\mathbf{h}_1, \ldots, \mathbf{h}_n] = \text{Backbone}_\theta(\mathbf{X})$. Since the appended [CLS] token occupies the last position, we use $\mathbf{h}_n$ as the relevance representation and feed it into a lightweight binary classification head:

$$\mathbf{p} = \text{softmax}(\mathbf{W}\mathbf{h}_n + \mathbf{b}) = [p_0, p_1]. \tag{2}$$

Here, p_0 and p_1 denote low- and high-relevance probabilities, and the final ranking score is computed as their expectation over $[-1, 1]$:

$$s(q, d) = [-1, 1] \cdot \mathbf{p}^\top = -p_0 + p_1. \tag{3}$$

A larger score indicates stronger relevance between the query and the candidate document.

4 Model Training

We train Querit-Reranker with a unified three-stage reranking recipe. Stage I builds broad multilingual query-document relevance matching ability from open-source retrieval and reranking datasets together with real-world business-scenario data. Stage II performs label-free adaptation toward target ranking distributions through synthetic-query mining and unified teacher scoring, while Stage III consolidates complementary checkpoints from different data mixtures and training runs into a single deployable reranker.

4.1 Training Objective

Given a query–document pair (q, d) with continuous relevance label $y_{q,d}$, Querit-Reranker outputs a scalar score $s(q, d)$. We optimize a pairwise hinge loss over documents associated with the same query. For each ordered pair (d_i, d_j) satisfying $y_{q,d_i} > y_{q,d_j}$, the model is encouraged to assign

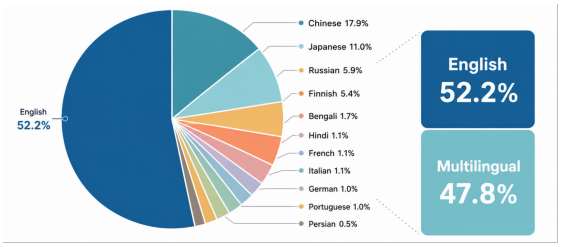

Figure 2: Language distribution of Stage I training data.

a higher score to d_i:

$$\mathcal{L}_{\text{rank}} = \frac{1}{|\mathcal{P}|} \sum_{(i,j)\in\mathcal{P}} \max(0,\, m(y_i - y_j) - (s_i - s_j))\,, \tag{4}$$

where $\mathcal{P}$ denotes the set of such document pairs, $s_i = s(q, d_i)$, $y_i = y_{q,d_i}$, and $m > 0$ is a margin coefficient. The margin is scaled by the teacher-score gap, enforcing larger score differences for pairs with larger relevance gaps.

4.2 Stage I: Large-scale High-quality Data Collection

The first stage constructs broad reranking supervision from open-source retrieval and reranking datasets together with private high-quality search data from real-world business scenarios, which is de-identified before use and does not contain user-identifiable information. The overall data composition and scale are summarized in Appendix B, Table 6. For the open-source portion, the selected datasets cover web search, multilingual retrieval, question answering, duplicate question detection, and news recommendation. Its language distribution is shown in Figure 2, with English as the largest portion and multiple non-English languages providing multilingual supervision.

For each query, we use Llama-Embed-Nemotron-8B[4] to retrieve and score the top-100 candidates from the corresponding corpus, treating embedding similarity as continuous relevance labels. To preserve relevance diversity, we partition the teacher-score range into 16 equal-width intervals and sample one candidate from each non-empty interval, filling missing slots with unused candidates closest to the interval centers. The selected candidates are sorted by teacher score for optimization with Eq. (4).

4.3 Stage II: Targeted Synthetic-data Mining

After Stage I, several MMTEB reranking tasks still show clear improvement space compared with leading leaderboard models. We therefore perform targeted synthetic-data mining to adapt the reranker to target corpus distributions and query styles. Specifically, we select four representative multilingual reranking tasks: AlloprofReranking, RuBQReranking, T2Reranking, and VoyageMMarcoReranking. These tasks cover French, Russian, Chinese, and Japanese across educational question answering, factoid retrieval, noisy web-style retrieval, and MS MARCO-style search.

For each corpus, we sample documents and use the DeepSeek-R1 API to generate document-conditioned retrieval queries with task-specific prompts, detailed in Appendix A. We then reuse the Stage I teacher-scoring and score-stratified sampling pipeline to produce pseudo ranking supervision for the pairwise objective in Eq. (4).

This stage provides label-free, teacher-distilled adaptation toward target ranking distributions without using human relevance annotations or evaluation labels from the target tasks. Rather than training isolated task-specific rerankers and merging them afterward, the unified teacher-scoring pipeline converts task-specific synthetic queries into a shared multi-task ranking objective, allowing knowledge to be shared and transferred across diverse multilingual corpus distributions before checkpoint merging.

4.4 Stage III: Model Merging

After the first two stages, we obtain multiple checkpoints from different data mixtures and training runs. To produce a single deployable reranker, we merge selected checkpoints with spherical linear interpolation (SLERP). Given two corresponding parameter tensors θ_a and θ_b, viewed as vectors, SLERP computes:

$$\begin{aligned} \text{slerp}(\theta_a, \theta_b; t) &= \frac{\sin((1-t)\Omega)}{\sin\Omega}\theta_a + \frac{\sin(t\Omega)}{\sin\Omega}\theta_b, \\ \Omega &= \arccos\left(\frac{\theta_a^\top \theta_b}{\|\theta_a\|\|\theta_b\|}\right), \end{aligned} \tag{5}$$

where $t \in [0, 1]$ is the interpolation coefficient. For an ordered sequence of checkpoints $\{\theta_i\}_{i=1}^K$ with weights $\{w_i\}_{i=1}^K$, we initialize $\theta^{(1)} = \theta_1$ and sequentially compute

$$\begin{aligned} \theta^{(i)} &= \text{slerp}\Big(\theta^{(i-1)}, \theta_i; t_i\Big)\,, \\ t_i &= \frac{w_i}{\sum_{j=1}^{i} w_j}, \qquad i = 2, \ldots, K. \end{aligned} \tag{6}$$

[4] Llama-Embed-Nemotron-8B

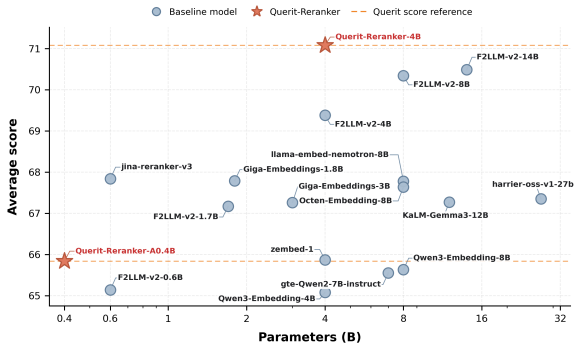

Figure 3: Performance–parameter trade-offs on MTEB-multilingual-v2 reranking tasks.

The final merged model is $\theta^{(K)}$, which requires no additional training and introduces no inference-time ensembling cost.

5 Experiments

5.1 Experimental Setup

Datasets. Our main evaluation covers 8 MMTEB reranking tasks from MTEB-multilingual-v2 and MTEB-eng-v2: six multilingual tasks (AlloprofReranking, RuBQReranking, T2Reranking, VoyageMMarcoReranking, WebLINXCandidatesReranking, and WikipediaRerankingMultilingual) and two English tasks (AskUbuntuDupQuestions and MindSmallReranking). We further evaluate general English reranking on 13 BEIR tasks and multilingual reranking on MIRACL across 18 languages.

Evaluation Procedure. For MMTEB, we follow the official evaluation protocol and report each task's standard metric. For BEIR and MIRACL, we use Qwen3-Embedding-0.6B[5] as a shared first-stage retriever, rerank the same top-100 candidates for controlled comparison, and report nDCG@10. Best and second-best scores are marked in bold and underlined, respectively.

5.2 Main Results

Table 1 reports the main results on the 8 reranking tasks from MMTEB. We group representative models with available leaderboard results by parameter scale, focusing on models up to 8B.

Querit-Reranker-A0.4B shows strong parameter efficiency among small-scale models. Despite its compact active-parameter scale, it achieves an 8-task average of 61.44, outperforming F2LLM-v2-0.6B (60.77) and gte-Qwen2-1.5B-instruct (59.25), and reaches 65.84 on MTEB-multilingual-v2. This suggests that the proposed training recipe can equip compact Querit-based rerankers with competitive multilingual reranking capability.

Scaling the same recipe to the 4B backbone further improves performance. Querit-Reranker-4B achieves the best average among the reported models on both MTEB-multilingual-v2 (71.08) and the combined 8-task setting (65.61), surpassing larger 8B-scale systems, while also obtaining the highest WebLINXCandidatesReranking score of 30.81. These results indicate that the proposed recipe scales effectively from the compact Querit-based reranker to the 4B backbone.

Figure 3 further visualizes the performance–parameter trade-off on MTEB-multilingual-v2. Beyond the up-to-8B models in Table 1, Querit-Reranker-4B also outperforms larger 14B–27B systems, such as F2LLM-v2-14B and harrier-oss-v1-27b, achieving a **SOTA** average score of 71.08 on the official MTEB-Multilingual-v2 Reranking Tasks Leaderboard as of August 29, 2026. The full leaderboard snapshots corresponding to Figure 3 and the complete results are provided in Table 7 and Table 8 in Appendix C.

5.3 Stage-wise and Merging Ablations

Merging strategy comparison. Our task-adapted checkpoints share the same architecture and initialization but capture complementary capabilities from different data mixtures. We select the best-performing task-adapted checkpoint for each of Allo, RuBQ, T2, Voyage, WebLINX, and Wiki; checkpoint weights reported below follow this order. We compare five training-free strategies that produce a single model without runtime ensembling. Linear interpolation merges all parameters with weights 1:2:1:1:1:1. Scoring-head replacement combines the general reranker backbone with the WebLINX-oriented scoring head, while top-layer interpolation linearly merges their top four transformer layers and scoring heads using $\alpha = 0.2$, retaining the lower layers of the general reranker. TIES-Merging constructs task vectors relative to the shared initialization, retains the top-20% largest-magnitude updates, resolves sign conflicts, and merges the aligned updates with $\lambda = 1.0$. SLERP sequentially merges the six checkpoints with weights 1:3:1:1:1:1 using Eqs. (5)–(6). As shown in Table 2, SLERP achieves the best corresponding averages of 65.84, 48.27, and 61.44 while adding no training or in-

SLERP	**65.84**	**48.27**	**61.44**

ference overhead. These results motivated its use for Querit-Reranker-4B and kept the deployment pipeline consistent across model scales. Complete task-level results are reported in Table 9.

Stage-wise ablation. Table 3 reports the aggregate contribution of each training stage at both model scales. For A0.4B, the overall average increases from 26.56 to 56.98 after Stage I and further improves to 60.90 and 61.44 after Stages II and III, respectively. Stage I accounts for most of the improvement because the general-purpose backbone must first acquire broad query–document relevance modeling through multilingual teacher supervision. For 4B, whose initialization is already retrieval-oriented, the corresponding gains are more evenly distributed across stages, with the overall average increasing from 61.50 to 63.13, 64.07, and 65.61. The multilingual average improves consistently across all stages for both model scales. Although the English average of 4B does not improve monotonically, the gains on the multilingual benchmark lead to consistent improvements in its overall average. Complete task-level results are reported in Table 10.

Table 3: Stage-wise ablation of Querit-Reranker. For Stage II, we report the strongest individual pre-merging checkpoint according to the eight-task average.

Model	**Stage**	**Multi. Avg.**	**Eng. Avg.**	**Overall Avg.**

Reranker-A0.4B achieves an average score of 59.28, improving the first-stage retriever by 5.17 points and clearly outperforming Qwen3-Reranker-0.6B and bge-reranker-v2-m3. Despite its compact active-parameter scale, it remains competitive with larger rerankers and obtains second-best results on FEVER and SciFact.

Querit-Reranker-4B further improves the average to 62.29, achieving the best overall performance among all compared models. It outperforms strong baselines such as jina-reranker-v3 and Qwen3-Reranker-4B, surpasses the larger Qwen3-Reranker-8B by 0.48 points, and ranks first on 7 of 13 BEIR tasks. Overall, these results demonstrate effective relevance refinement across diverse English retrieval tasks and show that the training recipe scales from the compact Querit-based reranker to the 4B backbone.

5.5 Multilingual Performance on MIRACL

Table 5 reports multilingual reranking performance on MIRACL. Using Qwen3-Embedding-0.6B as the shared first-stage retriever, Querit-Reranker-A0.4B improves the average nDCG@10 from 59.87 to 67.70, while Querit-Reranker-4B further raises it to 71.13. These gains show that Querit-Reranker provides substantial second-stage refinement for multilingual retrieval.

Querit-Reranker-4B achieves the best overall performance among all compared rerankers, outperforming Qwen3-Reranker-8B by 2.16 points on average despite using a smaller 4B backbone. Meanwhile, Querit-Reranker-A0.4B achieves the second-best result on 6 of 18 languages and outperforms other 0.6B-scale rerankers. Overall, MIRACL results confirm the effectiveness and scalability of Querit-Reranker for multilingual reranking.

6 Conclusion

We presented **Querit-Reranker**, a family of multilingual cross-encoder rerankers for standard retrieve-then-rerank pipelines. Querit-Reranker uses a staged reranking-oriented training recipe to build broad multilingual relevance matching ability, perform label-free multi-task adaptation toward target ranking distributions, and consolidate complementary checkpoints with SLERP. Experiments on MMTEB, BEIR, and MIRACL show that this recipe is effective for both the compact Querit-Reranker-A0.4B and the larger Querit-Reranker-4B, providing a practical path toward efficient and strong multilingual reranking.

7 Ethical Considerations

Data and privacy. Our training data include publicly available ranking datasets and de-identified private search data from real-world business scenarios. The private data were de-identified before model development and handled under the data-governance and access-control procedures of the data provider; no direct personal identifiers were intentionally used for training. Public datasets, pretrained models, and teacher models are used subject to their respective licenses and terms of use.

Bias and downstream use. Teacher-provided scores and LLM-generated queries may inherit biases from the underlying models and source corpora, including uneven representation across languages, regions, and domains. Although the deployed reranker does not directly generate text, it can affect information exposure by promoting or suppressing retrieved content and may amplify biases present in the candidate corpus or first-stage retriever. Its relevance scores should not be interpreted as indicators of factuality, safety, or fairness. We recommend task-specific evaluation and bias auditing before deployment, particularly in high-stakes or user-facing applications.

Model release and resource use. We release the model weights for research purposes. Users are responsible for complying with the licenses of the models, datasets, and downstream content involved in their applications. Although the compact architecture and training-free checkpoint merging avoid runtime ensembling overhead, model training and teacher inference incur computational costs.

8 Limitations

Although Querit-Reranker demonstrates strong multilingual reranking performance, it does not explicitly optimize a dedicated cross-lingual reranking or alignment objective. Its multilingual capability mainly comes from Stage I, which combines open-source multilingual ranking data with de-identified private search data from real-world business scenarios, and Stage II, which further performs task-targeted data mining on representative multilingual reranking corpora. However, our training data do not include explicitly constructed cross-lingual reranking pairs, and our training objective does not incorporate explicit language-alignment losses. As a result, the model may still exhibit uneven behavior across low-resource languages or cross-lingual retrieval scenarios. In future work, constructing cross-lingual reranking data and introducing explicit alignment-oriented objectives may further improve the model's multilingual understanding and robustness across languages.

In addition, due to resource constraints, our high-quality synthetic-data mining stage only covers four representative MTEB-multilingual-v2 reranking corpora: AlloprofReranking, RuBQReranking, T2Reranking, and VoyageMMarcoReranking. These datasets expose the model to French, Russian, Chinese, and Japanese reranking distributions, but they do not cover all languages and reranking tasks in MMTEB. Therefore, the effect of extending synthetic-query mining to the full set of MMTEB reranking tasks remains to be explored. Future work will investigate broader multilingual synthetic data construction and explicit cross-lingual alignment to further improve robustness across languages and retrieval settings.

A Targeted Synthetic Data Construction

This appendix provides the detailed prompts used for high-quality synthetic data mining. We construct synthetic queries for four representative MTEB-multilingual-v2 reranking tasks: AlloprofReranking, RuBQReranking, T2Reranking, and VoyageMMarcoReranking. These tasks cover French, Russian, Chinese, and Japanese, respectively, and differ substantially in domain, document style, and query intent. Therefore, we design task-specific prompts rather than using a single generic query-generation template. For each task, the generated queries are parsed with special query boundary tokens and then used in the teacher-scoring and score-stratified sampling pipeline described in Section 4.

A.1 AlloprofReranking

AlloprofReranking is a French educational reranking task based on K12-style learning content. The prompt is designed to generate informal and conversational French queries that resemble questions students may ask in an online forum.

```
You are an information retrieval
↪  assistant for a French K12
↪  educational platform.

Your task is to generate exactly FIVE
↪  user search queries that K12 students
↪  might naturally ask on an online
↪  forum.
The query should be written in informal,
↪  conversational French, similar to
↪  real student questions.

The generated query should:
1. Be a natural and realistic question
↪  that a K12 student could plausibly
↪  ask.
2. Reflect the main information needed
↪  from the given document, without
↪  copying or restating its text.
3. Use informal, everyday French rather
↪  than formal or academic language.
4. Be concise, between 10 and 100 words.

Output requirements:
- Output exactly FIVE queries.
- Wrap the query between the special
↪  tokens <|begin_of_query|> and
↪  <|end_of_query|>.
- Do not output anything outside these
↪  tokens.

Document:
{content}
```

A.2 RuBQReranking

RuBQReranking is a Russian factoid-style reranking task based on Wikipedia-like documents. Since many documents focus on named entities, the prompt encourages factual questions and asks the generator to use alternative entity surface forms when available, making the generated queries closer to realistic retrieval behavior.

```
You are an information retrieval
↪  assistant generating search queries
↪  for a Russian Wikipedia-style factoid
↪  QA dataset.

You will be given:
- A Russian document in a Wikipedia-like
↪  style.
- The document typically focuses on a
↪  single main entity (person,
↪  organization, city, work, event).

Your task:
Generate exactly ONE natural Russian
↪  query that asks for ONE factual piece
↪  of information
that is directly answered in the document
↪  (typically within the first 1-3
↪  sentences).

CRITICAL REQUIREMENTS (must follow ALL
↪  when applicable):
1) Identify the main named entity the
↪  document is about.
2) If there exists ANY plausible
↪  alternative surface form for that
↪  entity across writing systems or
↪  common usage
   (Latin vs Cyrillic, phonetic
   ↪  transliteration, common colloquial
   ↪  form, mixed form),
   then the query MUST use a surface form
   ↪  DIFFERENT from the one appearing
   ↪  in the document.
3) Do NOT use the exact entity surface
↪  form from the document when a
↪  reasonable alternative exists.
4) If no alternative exists, use the
↪  canonical Russian form.

Query constraints:
- Russian only.
- One entity, one fact, one question.
- Prefer: «Когда...», «Кто...», «В каком
↪  году...», «Где...».
- 5-20 words.
- Do NOT copy or paraphrase any sentence
↪  from the document.

STRICT OUTPUT RULES (mandatory):
- Output EXACTLY ONE LINE.
- The line must be exactly in this
↪  format:
  <|begin_of_query|> ... <|end_of_query|>
- Do NOT output any explanations,
↪  rationales, comments, HTML, markdown,
↪  or extra text.
```

```
- Do NOT output multiple candidates.

Document:
{content}
```

A.3 T2Reranking

T2Reranking contains Chinese documents with diverse topics and noisy web-style formatting. The prompt, therefore, emphasizes core answerable information, robustness to HTML and navigation noise, and realistic short Chinese search queries.

```
你是一名信息检索助手，需要为中文文档生成搜索查询。

文档特点说明：
- 文档为中文，主题多为生活常识、学习问题、
↪  社会议题等。
- 文本形式口语化，常为短句 + 若干关键词拼接。
- 文档中可能包含大量 HTML 标签（如 <br>、
↪  <table>、<h2>、<img> 等）、导航标题、列表、
↪  栏目堆叠、广告信息等噪声。
- 有些文档是结构化信息（如时间表、号码列表、
↪  步骤教程等）。

你的任务是：
基于文档的“核心可回答信息”，
↪  生成三个真实用户可能输入搜索引擎的中文查询。

生成的查询必须满足：

1. 每个查询只围绕一个具体、明确的信息点（例如：
↪  时间、价格、号码、定义、步骤、原因、人物、
↪  关系等）。
2. 查询应模拟真实搜索行为，简洁、直接、口语化，
↪  而不是完整句子式提问。
3. 不要被 HTML 标签、栏目标题堆叠、导航词（如
↪  “更多”“相关推荐”“相关工具”等）误导。
4. 如果文档中包含明确的数字信息（如电话、价格、
↪  分享码、时间、日期、数量等），
↪  至少有一个查询必须直接询问该数字。
5. 查询应紧贴文档核心实体或主题关键词
↪  （允许词面重合）。
6. 避免生成过于宽泛或总结性的问题（例如
↪  “这篇文章讲了什么”）。

输出要求：
- 输出三条查询。
- 每条查询必须严格包裹在 <|begin_of_query|>
↪  和 <|end_of_query|> 之间。
- 不要输出任何额外说明或解释文本。

Document:
{content}
```

A.4 VoyageMMarcoReranking

VoyageMMarcoReranking is a Japanese MS MARCO-style reranking task. The prompt asks the generator to produce concise and realistic Japanese search queries, with special attention to concrete information needs such as definitions, attributes, facts, and numerical values.

```
You are an information retrieval
↪  assistant generating queries for a
↪  Japanese MS MARCO-style dataset.

Your task is to generate exactly FIVE
↪  user search queries that a typical
↪  user might naturally type into a
↪  search engine.
The queries should be written in natural
↪  Japanese and reflect realistic search
↪  behavior.

The generated queries should:
1. Ask about one specific and concrete
↪  piece of information contained in the
↪  document.
2. Reflect a single, clear information
↪  need (e.g., definition, fact, number,
↪  attribute, cause, person, etc.).
3. Be concise and focused, typically
↪  short and direct rather than
↪  open-ended.
4. Closely align with the key entity or
↪  concept in the document (lexical
↪  overlap is acceptable).
5. If the document contains an important
↪  number (e.g., phone number, routing
↪  number, price, temperature, quantity,
↪  date), at least ONE query should
↪  directly ask for that number.

Output requirements:
- Output exactly FIVE queries.
- Each query must be wrapped between the
↪  special tokens <|begin_of_query|> and
↪  <|end_of_query|>.
- Do not output anything outside these
↪  tokens.
- Do not add explanations or additional
↪  text.

B Training Data Statistics

Table 6 summarizes the data used in the two data-mining stages.

Table 6: Statistics of training data used in each stage.

Stage	Dataset	Size
Stage I High-quality data collection	MSMARCO, MLDR, Mr.TyDi, T2Ranking, CQADupStack, MIND-small, Ruri, MIRACL, and private high-quality data	Open-source: ∼3.52M Private: ∼2.05M
Stage II Targeted synthetic data mining	Targeted synthetic data for AlloprofReranking, VoyageMMarcoReranking, T2Reranking, and RuBQReranking	∼9.4M

Stage I collects broad reranking supervision

from open-source retrieval datasets and private high-quality search data collected from real-world business scenarios. The open-source portion includes MS MARCO (Nguyen et al., 2016), MLDR (Chen et al., 2024), Mr.TyDi (Zhang et al., 2021; Clark et al., 2020), T2Ranking (Xie et al., 2023), CQADupStack (Hoogeveen et al., 2015), MIND-small (Wu et al., 2020), Ruri (Tsukagoshi and Sasano, 2024), and MIRACL (Zhang et al., 2023). For all open-source datasets, we use only their official training splits and exclude validation and test splits from training. Following standard industrial data-curation practices, the private data were de-identified before use, with personally identifiable information such as names and phone numbers removed. The resulting private dataset does not contain direct user identifiers and covers diverse retrieval settings such as web search, multilingual retrieval, question answering, duplicate question detection, and news recommendation.

Stage II further constructs targeted synthetic data for four representative MTEB-multilingual-v2 reranking tasks, namely AlloprofReranking, VoyageMMarcoReranking, T2Reranking, and RuBQReranking. This targeted stage is designed to better match the corpus distributions and query styles of the multilingual reranking benchmark.

C Detailed Results

This section provides task-level results supporting the performance–parameter trade-off analysis in Figure 3, the merging-method comparison in Table 2, and the stage-wise ablation in Table 3.

Benchmark comparisons. Table 7 reports the top-20 results from the six-task MTEB-multilingual-v2 reranking leaderboard snapshot, while Table 8 reports the top-20 complete results in the eight-task MMTEB evaluation setting, including only models with available scores on all tasks.

As shown in Table 7, Querit-Reranker-4B achieves the best average score on the MTEB-multilingual-v2 reranking subset, reaching 71.08. It also obtains the highest score on WebLINXCandidatesReranking, with a score of 30.81, showing a clear advantage on this challenging web-oriented reranking task. Querit-Reranker-A0.4B achieves an average score of 65.84, outperforming several substantially larger embedding baselines and demonstrating strong parameter efficiency among compact models.

On the combined 8-task MMTEB setting, Querit-Reranker-4B achieves an overall average of 65.61, ranking first among all compared models. Querit-Reranker-A0.4B obtains an overall average of 61.44, remaining competitive with larger small-scale models and validating the effectiveness of the proposed training recipe under a compact active-parameter setting.

Merging strategy comparison. Table 9 provides the task-level results corresponding to Table 2. SLERP achieves the best score on seven of the eight tasks and the best multilingual, English, and overall averages. TIES-Merging is the strongest non-SLERP alternative, obtaining averages of 65.75, 47.65, and 61.23, but remains below SLERP by 0.09, 0.62, and 0.21 points, respectively. Scoring-head replacement performs best on WebLINX, suggesting that preserving its task-specific head favors this narrow specialization, whereas SLERP more effectively consolidates performance across heterogeneous ranking distributions. These results support the use of SLERP as a training-free method for producing a single deployable reranker without runtime ensembling.

Stage-wise ablation. Table 10 expands the aggregate results in Table 3 with task-level scores. For A0.4B, Stage I improves all eight tasks and raises the overall average from 26.56 to 56.98, confirming that broad ranking-oriented supervision accounts for most of the gain over the general-purpose backbone. Stage II improves seven of the eight tasks, including a substantial WebLINX improvement from 12.50 to 26.58, and raises the overall average to 60.90. Stage III further improves seven tasks and reaches an overall average of 61.44, although checkpoint consolidation reduces the WebLINX score from 26.58 to 11.63. For 4B, the retrieval-oriented backbone provides a substantially stronger starting point. The gains are therefore distributed more evenly across the three stages: Stage II mainly strengthens the targeted multilingual distributions, particularly Voyage and WebLINX, while Stage III improves six of the eight tasks and raises the multilingual and overall averages from 69.20 and 64.07 to 71.08 and 65.61, respectively.

Table 7: Top-20 reranking performance on the MTEB-multilingual-v2 benchmark based on the MTEB leaderboard snapshot accessed on August 29, 2026. Results are measured using the official task metrics, and the average is computed over all six reranking tasks. Best scores are in bold.

Abstract

Cementitious materials teams need machine-readable databases of compressive strength records to support mix-design optimization. However, manual curation of the literature is too slow and hard to scale. We present CemLit-IE, a five-stage zero-shot pipeline, converting raw PDFs into fully attributed records with provenance. The core challenge is that the relevant information is distributed across tables, text, and figures. Even though table-only extraction produces plausible numbers, the results are not auditable. CemLit-IE addresses this through a series of methods, including keyword-weighted page scoring, structured table injection, value-provenance schema, and review queue. On a benchmark of 20 papers with 655 expert-annotated records, CemLit-IE achieves a recall of 76.3% with 99.2% precision and 100% exact-match accuracy in a text-only model. The recall can be raised to 83.5% when figure reading is enabled. The ablation study shows that each design choice contributes to improving precision. As for the cost, a separate 270-paper journal-batch run extracted 2,039 strength records at $31.28 total API cost. All data and code are publicly released.[1]

1 Introduction

Concrete is one of the most commonly used industrial materials on earth (Monteiro et al., 2017). Even though there is already a large and long-standing body of research in this field, the knowledge is scattered across tens of thousands of journal papers, each reporting heterogeneous tables, figures, and text in inconsistent formats. The need for reusable, machine-readable scientific data is consistent with open materials-data infrastructures such as the Materials Project (Jain et al., 2013). The traditional database development requires manually reading every paper, cross-referencing tables against method sections and captions, and transcribing records with their units, mixture identities, curing conditions, and provenance. Even at only a few hours per paper, manually annotating 200 papers would require hundreds of researcher-hours.

There are three challenges for deploying large language models for this task. Firstly, PDFs are usually unstructured documents, where table extraction from such documents remains a dedicated document-understanding task (Smock et al., 2022). Figure information is not directly accessible to text-based systems, and critical contextual information is often scattered across multiple pages (Swain and Cole, 2016). Secondly, zero-error data quality is required for the material database. A fabricated value can corrupt downstream tasks, such as regression models, or lead to the wrong candidate formulations being recommended. This is unacceptable in industrial deployments, where not only high recall but also zero hallucinations are required (Gutierrez et al., 2022). The third challenge is operational costs and latency. A pipeline that takes a long time and has high expenses per paper will never be scheduled as a corpus-update job, even though the accuracy is high.

CemLit-IE addresses all three challenges through a five-stage pipeline. It does not apply the LLM to the full text. Instead, it narrows each paper to its 8–12 most evidence-rich pages before calling the LLM. This helps cut prompt tokens by ≈60% compared to a full-document submission. Besides, it constrains model output to a domain-specific JSON Schema with four-tier value provenance (Willard and Louf, 2023). Combined with post-validation, this prevents unsupported values from entering the accepted database. It sends uncertain records to a lightweight review queue for further validation before accepting the record into the database. The system issues exactly one API call per paper with zero retries; in the 270-paper journal batch, the text-only pass averaged 55 seconds per

Table 1: Comparison with related scientific information-extraction and constrained-generation systems.

paper with a median latency of 45 seconds.

Our contributions are summarized as follows:

1. A keyword-weighted page scoring is introduced in this study. With such a score, the LLM prompt can focus on evidence-rich pages, helping save time and cost.

2. We combine text, tables, and images into a single context packet (priority from high to low: exact table $\succ$, explicit text $\succ$, approximate figure $\succ$, derived value). After this procedure, the machine-readable quality of the data is prepared for downstream filtering.

3. After the initial processing, a deterministic post-validator and review queue are introduced to ensure every accepted record is independently verifiable.

4. A comprehensive evaluation on 655 expert-annotated records across 20 papers, with controlled ablations and K-sensitivity analysis, is conducted to check the performance.

2 Related Work

As for the scientific information extraction, NER and relation-extraction pipelines have been applied to materials science to recover synthesis conditions (Kononova et al., 2019), battery properties (Huang and Cole, 2022), and material compositions (Weston et al., 2019). These systems mainly operate on plain text, ignoring the tabular and figure modalities (Table 1). ChemDataExtractor (Swain and Cole, 2016) extends rule-based extraction to chemistry documents. It includes the text and table extraction, but it cannot handle chart-embedded data. By comparison, CemLit-IE requires no labeled training data and addresses all modalities through structured table injection and optional page-image encoding.

Recent work has shown that GPT-family models can extract structured information from scientific text, including in low- or zero-shot settings (Gutierrez et al., 2022; Dunn et al., 2022). For database construction, however, the main concern is not only whether a model can produce a plausible record, but whether that record can be traced back to source evidence. This is especially important in materials applications, where a hallucinated value or a misattributed condition can contaminate downstream modeling. Materials-domain models such as MatSciBERT (Gupta et al., 2022) and Mat2Vec (Tshitoyan et al., 2019) improves the representation of materials-science language, but they do not by themselves provide record-level provenance. MaTableGPT (Yi et al., 2025) moves closer to the tabular setting by using GPT-based extraction for materials tables, yet it does not address cross-page context linking or provide an explicit review queue. CemLit-IE therefore treats extraction as a database curation problem: outputs are constrained by a strict JSON Schema, linked to evidence IDs, checked by deterministic validators, and routed to human review when support is incomplete.

Developing a material database requires not only information extraction but also human intervention. Text mining can be used to reduce the search and triage burden (Yeh et al., 2003). After that, expert review plays an important role in validation, standardization, and provenance tracking (for Biocuration, 2018). This is particularly important for establishing a cement/concrete dataset: a strength value may be copied correctly but still become unusable if some important information is misread, such as the unit basis, curing age, and specimen type. Such data errors can propagate into downstream models and increase the inaccuracy (Sambasivan et al., 2021). CemLit-IE therefore treats human review as part of the database construction process: uncertain records are paired with evidence links and targeted questions before being promoted to accepted database entries.

3 Proposed Method

3.1 Task Formulation

Given the associated papers, this study aims to collect all reported compressive strengths, as well as

details about the mix design and curing methods. The record should include the identifier, strength value, unit, curing age, and property type. And the records should link to the source evidence. This approach is different from standard information extraction because the results are not just text snippets or likely structured answers. Instead, the extracted records will be used as database entries. For this reason, we set four requirements: every accepted value must be traceable to its source; unsupported values should be left out instead of being guessed; uncertain cases must be available for human review; and the process must have predictable cost and speed when applied to the entire dataset.

3.2 Pipeline Overview

CemLit-IE processes each paper through five stages, as shown in Figure 1. It first parses and renders the PDF (S1). After that, it scores pages based on domain keywords and expands the selected pages to include their neighbors (S2). The selected text, tables, and optional page images are packed into a single context packet (S3) for one schema-constrained LLM call (S4). Finally, the extracted records are checked by deterministic validators, and uncertain cases are written to a review queue (S5). Uncertain data will not be accepted into the database until it passes review. The pipeline components are chosen to support traceable database construction. Page scoring is used because strength evidence is sparse within long PDFs. If we send the full PDFs, it increases the cost and adds irrelevant context. Table injection is adopted since mixture strength often depends on a two-dimensional table structure. Each database record must contain certain important information for future applications, so Schema-constrained output is used. The review queue makes sure that uncertain or approximate records should be checked rather than accepted directly.

3.3 Page Scoring and Candidate Selection

Compressive-strength data occupy only a limited number of pages in a typical journal paper. We score each page by five keyword signal classes and select the top-K anchor pages:

$$\phi(p) = \sum_{k \in \mathcal{K}} w_k \cdot \min(c_k(p),\ 8) \qquad (1)$$

where $c_k(p)$ is the count of signal class k on page p, and the cap of 8 prevents one dense page from dominating. Table 2 shows the signal weights. "compressive strength" is the measured load-bearing strength. "mix design" refers to the material composition. "age" refers to the curing age at which the strength is measured. "unit" refers to the reported measurement unit. Each anchor expands to include its immediate neighbors to capture cross-page tables. This neighbor expansion is critical because cross-page tables may be shown in some papers, where column headers and data rows are separated by a page boundary. Our ablation study shows it accounts for 4.4 EM points.

Signal k	**Example patterns**	w_k
Strength	compressive strength, MPa, N/mm^2	4.0
Mix design	kg/m^3, water/binder, w/b ratio	3.0
Age	7 days, 28 d, 91 days	1.5
Unit	MPa, N/mm^2	1.5
Caption	Table 1, Figure 3	0.5

Table 2: Page-scoring signal weights (Eq. 1).

3.4 Context Packet & S4 LLM Extraction

After the page selection, a structured JSON context packet is built for each paper. The packet contains the selected page text, the extracted table CSVs with page provenance, a rules block describing the extraction constraints, and a canonical SHA-256 hash used for caching. In vision mode, we also attach compressed page images at 1400 px resolution and JPEG quality 80. We treat figure-derived values separately because chart understanding requires visual and logical reasoning beyond plain text extraction (Masry et al., 2022), and values read from plots are usually approximate.

The model is asked to produce one JSON object that conforms to the output schema provided in the system message. To make the extracted values usable downstream, each result is assigned a provenance label, ordered from highest to lowest confidence: exact table $\succ$, explicit text $\succ$, approximate figure $\succ$, derived value. Records also include value_status, is_approximate, and estimated_error_mpa, so users can filter records by evidence quality without rereading the paper. This separation is especially important for figure-derived values. Table 3 gives a minimal example. Values read only from plots are not treated as exact records; they are assigned an image-estimate status, marked as approximate, and stored with an estimated uncertainty. In contrast, values in tables or explicit text are stored as non-approximate records. If the evidence for a field is missing or ambigu-

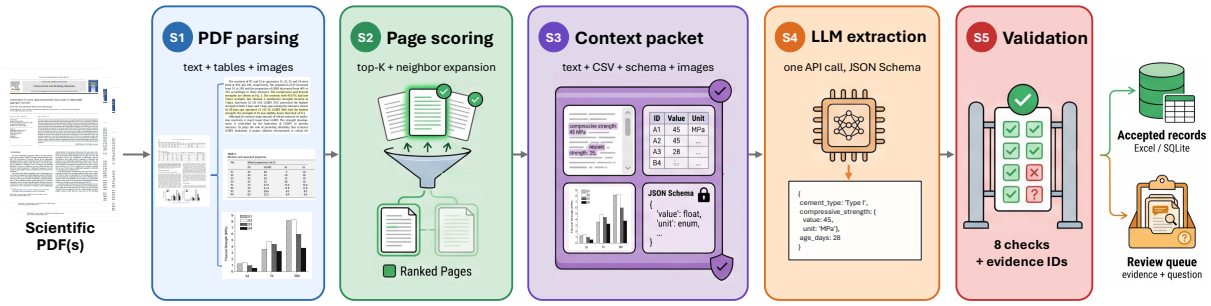

Figure 1: CemLit-IE system methodology. The pipeline narrows each PDF to evidence-rich pages, builds a multimodal context packet, performs schema-constrained LLM extraction, and validates each record.

recommended_value	final_value	value_status	is_approximate	estimated_error_mpa
63.0	63.0	image_estimate_only	yes	±1.5 MPa
91.4	91.4	text_exact_anchor	no

DUPLICATE	Same (mix, age, value) repeated	M
APPROX_OR_DERIVED	Routed to human review	M

Table 4: Deterministic post-validation rules (H = High, M = Medium priority).

ous, the model writes the issue to unresolved_items rather than filling the field by assumption. A summary of the prompt rules and required schema fields is provided in Appendix D.

3.5 Post-Validation and Review Queue

In this stage, each extracted record is passed through the rule-based checks in Table 4. Records are sent to the review queue if they fail a check, are marked as approximate, or are linked to an entry in unresolved_items. The queue stores the information and a specific question for the reviewer. With this processing, we can turn verification from rereading a full PDF into checking a small number of questions. The reviewer can focus on the exact source of uncertainty, such as a missing curing age or a value read from a figure. Representative review-queue items are shown in Appendix E.

4 Experimental Setup

We evaluate on a benchmark CBM-20. It comprises 20 papers from academic journals with expert annotations. Censored inequality records (e.g., "<1 MPa") are excluded, and finally yield 655 gold records. Of these, 77.7% carry exact table or explicit text values; 22.3% are figure estimates. Full per-paper statistics appear in Appendix A (Table 9).

Variant	Definition
Full (Text-only)	Selected page text + extracted table CSVs.
Full (Vision+Fig)	Full (Text-only) + selected page images.
−Table	Remove extracted table CSV injection.
−Neighbor	Remove adjacent-page expansion around selected pages.
−Scored	Replace keyword-scored page selection with first-K pages.
−Rules	Replace structured extraction rules with a short unconstrained prompt.
Full Doc	Send all pages without keyword scoring.

Table 5: System variants used in the main comparison and ablation study.

System variants. As for the setting, all LLM variants use the same model setting (gpt-5.4, max 32K tokens), and we use the same JSON Schema and extraction prompt. The variants differ only in the input context or in one removed pipeline component. Table 5 summarizes the setting of each variant. The main setting is Full (Text-only), providing the model with selected page text and table CSVs. Full (Vision+Fig) uses the same packet but also includes images. The ablations remove one part of this context at a time. "−Table" removes table CSVs; "−Neighbor" removes neighbor expansion; "−Scored" replaces keyword-scored selection with sequential first-K pages; "−Rules" replaces the structured 10-rule prompt with a 3-line minimal prompt; and "Full Doc" sends all pages without scoring. Appendix B reports the sensitivity analysis for $K \in \{4, 6, 8, 12\}$. Vision+Fig is used as a targeted recovery setting rather than as the default database-building mode. It is applied to the six papers where text-only extraction is expected to miss figure-derived or low-recall records (Appendix F).

Evaluation protocol. Gold and predicted records are matched in two passes. Pass 1 (strict): exact join on (mixture_original_id, age_days). Pass 2 (soft): for unmatched gold records, accept a prediction with the same age and value within ±0.5 MPa.

System	R	P	F_1	EM	NM	MAE
Rule-based (no LLM)						
pdfplumber regex	.421	.883	.569	.948	.971	0.19
Schema-free LLM						
Full-doc, unstructured	.752	.941	.836	.887	.921	0.89
Text-only, unstructured	.793	.912	.848	.891	.926	0.71
CemLit-IE (this work)						
Full (Text-only)	.763	**.992**	.864	**1.000**	**1.000**	**0.00**
Full (Vision+Fig)	**.835**	.977	**.900**	.951	.989	0.08

Source of recall gap	Recs	Pts
FIG: figure-only values (CBM0057, CBM0140)	40	6.1
PARSE: merged-cell table failure (CBM0083)	70	10.7
PAGE: page selection miss (CBM0134)	16	2.4
PART: partial multi-age coverage (CBM0177, CBM0192)	29	4.4
Total	**155**	**23.7**

Table 7: The recall gap (text-only mode).

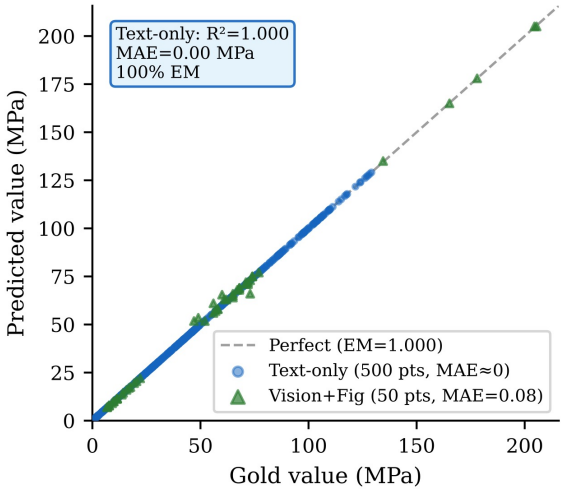

Figure 2: Predicted vs. gold compressive strength (MPa). Text-only matches ($n = 500$) lie exactly on the diagonal. Vision+Fig matches extend to figure-derived values with a wider spread, all tagged "is_approximate" = true.

Metrics: Recall (R), Precision (P), F_1, Exact Match ($|\Delta| \leq 0.1$ MPa, EM), Near Match ($|\Delta| \leq 1.0$ MPa, NM), and MAE.

Comparison baselines. To place CemLit-IE in context, we also include three reference systems that can be run without gold annotations. "Naive Full-Doc" sends all pages to the model, with no page scoring and no structured schema. This is the zero-investment LLM baseline. "Text-only Unstructured" keeps page scoring and table injection, but replaces the JSON Schema constraint with a free-text response prompt. It tests how much is lost when the extraction is schema-free. "Rule-based (pdfplumber)" uses deterministic regex patterns over extracted table CSV rows and makes no LLM call. Together, these reference systems complement the five ablations by giving separate baselines for full-document prompting, schema-free extraction, and rule-only extraction.

5 Results and Discussion

5.1 Main Comparison

Table 6 presents the comparison between CemLit-IE and alternative extraction strategies. Figure 2 shows the predicted versus gold scatter for text-only and figure-included models.

The rule-based pipeline reaches 42.1% recall, indicating that table extraction alone is insufficient. As for schema-free LLM systems, the recall rises to ≈79%, but the EM drops. There are some error cases, such as treating flexural strength as compressive strength or assigning a value to an unsupported mix ID. For a material database, EM = 88% is still a serious problem, since roughly 1 in 10 matched records would require correction before it could be trusted in downstream regression models.

CemLit-IE (Text-only) achieves EM = 100% on all 500 matched records, but with a low recall 76.3%. As shown in Table 7, the recall gap is due to four categories: figure-only results, the merged-cell table, a page-selection miss, and partial multi-age coverage. Detailed case illustrations are provided in Appendix G. Adding the figure extraction function raises the recall to 83.5%. This gain should be interpreted as coverage recovery rather than a replacement for text-only extraction. The text-only setting is more conservative and gives exactly matched values for records supported by tables or explicit text. Vision+Fig recovers additional figure-derived records, but these values are marked as approximate and remain distinguishable from exact records in the database. This recall gap should be interpreted as a precision and coverage trade-off rather than as unconstrained extraction failure. For materials database construction, we prefer to omit uncertain records rather than introduce unsupported or incorrect values into the accepted database.

5.2 Precision–Recall Frontier and Industrial Significance

Figure 3 plots all seven system variants in precision–recall space. The full system is the only point achieving both high precision and EM = 1.000. In industrial material databases, EM is a key metric.

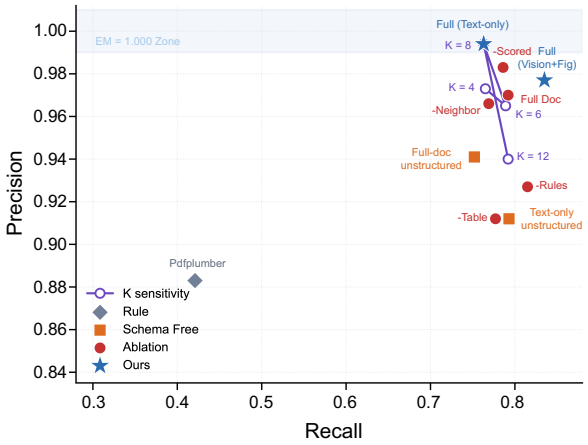

Figure 3: Precision–recall scatter for all system variants. CemLit-IE (Text-only, $K = 8$) is the optimal point. Removing any component lowers precision.

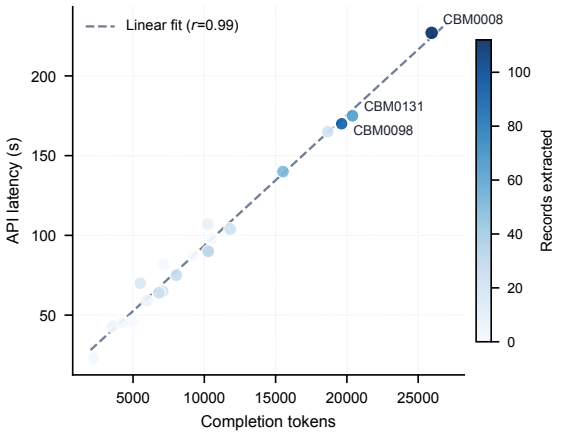

Figure 4: Per-paper API latency vs. completion tokens (text-only mode). Latency scales linearly with output length ($r = 0.99$); color encodes the number of records.

Variant	R	P	EM	MAE
Full (Text-only, *ours*)	.763	**.992**	**1.000**	**0.00**
−Rules (simple prompt)	.815	.927	.936	0.53
−Table (no CSV inject)	.777	.912	.943	0.27
−Neighbor (no ± 1 exp.)	.769	.966	.956	0.20
−Scored (sequential K)	.786	.983	.946	0.20
Full Doc (all pages)	.792	.970	.940	0.29

Table 8: Ablation results: removing any single component degrades EM or MAE. $K = 8$ throughout; K-sensitivity results in Appendix B.

If a record contains an error, it can change a mix-design decision, especially when tolerances are tight. The ablation pattern in Figure 3 shows that each part of CemLit-IE helps reduce hallucination instead of restricting coverage.

5.3 Ablation Analysis

Table 8 reports an ablation study. The ablation results should not be read as a simple recall ranking. Some removed components increase recall because the model becomes less conservative, but this also introduces unsupported or numerically incorrect records. For database construction, the preferred setting is therefore the one that preserves EM and precision, even when it leaves more records for later recovery or review. The uncertain records should be withheld or reviewed.

Prompt rules. Replacing the structured prompt with 3-line instructions yields the largest recall gain (+5.2 pts) but the worst EM (0.936) and highest MAE (0.53 MPa). Without explicit prohibitions, the model extracts values from flexural or tensile contexts.

Table injection. Removing table CSVs causes the sharpest precision drop (from 0.992 to 0.912) and a 5.7 pts EM collapse. That means without the 2D cell structure, values are extracted from text, which are often approximate.

Neighbor expansion. Neighbor expansion captures cross-page tables (headers on one page, data rows on the next). Disabling it drops 4.4 pts EM.

Scoring vs. sequential vs. full document. Sequential selection introduces abstract and introduction content. Full Doc uses more tokens yet achieves lower EM than the scored system, confirming that scoring is a strict improvement across both quality and cost.

5.4 Operational Efficiency

Figure 4 shows a near-linear relationship between completion length and API latency ($r = 0.99$), making batch runtime easier to estimate. The system issues exactly one API call per paper with zero retries. At the upper cost estimate ($0.42/paper), a 200-paper corpus refresh costs $84 and completes in under 3 hours at concurrency = 2, a nightly batch job replacing weeks of manual curation. A separate unannotated journal-batch run over 270 papers from nine construction materials journals produced 2,039 strength records at $31.28 total API cost. Text-only extraction yielded 1,749 records from 129 papers; vision recovery added 290 records and recovered 17 additional zero-result papers. Detailed efficiency metrics appear in Appendix C.

5.5 Discussion

In a materials database, a record is useful only when all associated information is correct. The text-only configuration is conservative for collecting data. It accepts records supported by tables or explicit text, but leaves figure-only cases unresolved. Although this design choice lowers recall, it prevents unsupported values from entering the accepted database. To extract more data, Vision+Fig, therefore, provides a complementary recovery mode. After the extraction from this model, the values from the plots are tagged as approximate. They are therefore treated as non-exact records, rather than as the same type of evidence as table or text supported values. And, downstream users can include, exclude, or send them for review. The ablation results show that higher recall is not always better for database construction. In several variants, recall increases as the model becomes less restrictive. However, it is accompanied by larger numerical errors. The review queue provides a practical compromise between automation and expert control. This design keeps the database expandable while preserving a boundary between accepted and unresolved records. Operationally, the one-call design and predictable latency make CemLit-IE suitable for repeated corpus updates rather than one-time extraction. The current schema is cement-specific by design because it encodes the fields that make compressive-strength records reusable: mixture identifier, curing age, unit, property type, value status, and evidence provenance. This domain specialization is intentional for an Industry Track application, where practical deployment requires a concrete schema. However, the pipeline pattern is not limited only to cement strength. Page scoring, table injection, schema-constrained output, deterministic validation, and review routing can be reused for other material properties. We therefore view cement strength as a high-value industrial test for a broader material-associated application.

6 Conclusion

CemLit-IE converts cement and concrete papers into a searchable, quality-annotated database with machine-readable provenance. On 655 benchmark records, it reaches 76.3% recall with 100% exact match in text-only mode, increasing to 83.5% when figure reading is turned on. All three main engineering choices (page scoring, neighbor expansion, and table injection) help improve output quality. The complete system is the only configuration with EM = 1.000 while maintaining the highest precision. Every accepted record includes a provenance tag. The system uses one API call per paper, has predictable latency, and costs less than $84 for 200 papers. In a separate 270-paper journal-batch run, CemLit-IE extracted 2,039 strength records across nine construction-materials journals at $31.28 total API cost. This makes it practical to run at scale as a nightly batch job, removing the main bottleneck in building materials databases.

Limitations

This study has several limitations. First, CBM-20 contains 20 English-language papers. Although it includes 655 expert-annotated gold records and supports record-level evaluation, broader coverage across journals, languages, document styles, and publication years is needed. The separate 270-paper journal batch still needs to be fully expert-annotated. Future work will expand the gold dataset through broader paper collection and systematic domain-expert validation. The scoring and extraction methods focus on cement and concrete compressive strength, but more data are needed on other key properties like durability, shrinkage, carbonation depth, and chloride resistance. The current process also relies on how well PDFs are parsed. If papers have merged cells, scanned pages, or unusual table layouts, some records may be missed. This is an area that still needs improvement. Finally, while the review queue helps reduce the workload for experts, expert judgment is still necessary.

Ethical Considerations

The pipeline extracts structured information from published scientific articles for research database construction. No personal data is involved.

Table 9: Per-paper results in text-only mode. Article information is given as the first author, year, and shortened title. MAE and RMSE are in MPa. $R=0$ papers are attributable to known pipeline limitations rather than model hallucination: CBM0057 and CBM0140 are figure-only; CBM0083 has merged-cell tables; CBM0134 has a page-selection miss.

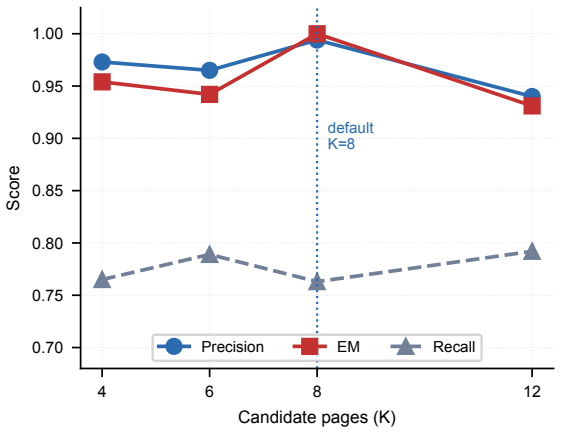

Figure 5: Sensitivity of EM, precision, and recall to candidate page count K. Token cost (bars) is nearly flat; EM peaks uniquely at $K=8$.

Table 10 shows results across $K \in \{4, 6, 8, 12\}$. Figure 5 visualizes the Precision–EM curve. Token cost is nearly flat across all K values (≈21.5k tokens/paper) because the 30k-character text budget is the binding constraint. $K = 8$ is uniquely the only configuration achieving EM = 1.000.

C Operational Efficiency Metrics

Table 11 summarizes the operational footprint on CBM-20.

Metric	Text-only	Vision+Fig
Latency / paper (s)	87	≈60†
API calls / paper	1 (0 retries)	
Prompt tokens / paper	11,077	≈15,600 (+41%)
Completion tokens / paper	10,390	≈5,600 (−46%)
Total tokens (20 papers)	429,330	—
Est. cost / paper ($)	0.11–0.42	+30–40%
200-paper corpus ($)	22–84	—
200-paper wall time	<3 h	—

Table 11: Operational efficiency on CBM-20. †Vision+Fig: single-threaded, 6 papers only.

D Prompt and Schema Summary

As shown in Table 12, the prompt instructs the model to return one JSON object and to leave unsupported fields unresolved rather than infer values from general context. The output schema enforces five top-level arrays: `mixtures`, `results`, `conditions`, `evidence`, and `unresolved_items`. Each `result` requires 12 fields including `value_status`, `is_approximate`, `estimated_error_mpa`, and `evidence_ids`. Setting `additionalProperties: false` throughout prevents the model from inserting invented fields. The schema is embedded verbatim in the system message at inference time; no constrained decoding is required.

Prompt rule	Purpose
Use source evidence only	Prevent values from being inferred without support.
Keep table, text, and figure values separate	Preserve the provenance tier for downstream filtering.
Do not merge different mixtures	avoid silently combining records across mix identifiers.
Report missing fields in `unresolved_items`	Convert uncertainty into reviewable questions.
Mark figure-derived values as approximate	Separate chart readings from exact table or text values.

Table 12: Summary of the main prompt rules used with the output schema.

E Review Queue Examples

Table 13 shows representative review-queue items created by the post-validator. The queue is intended to make human review specific: instead of rereading the full paper, the reviewer receives the candidate record, the evidence location, and the unresolved question.

Case	Reason	Reviewer question
Missing age	Age not stated near value	What curing age does this value use?
Unknown mix	Mixture ID not defined	Which mixture does this value belong to?
Approx. figure	Value read from plot	Should this approximate value be accepted?
Unit conflict	Unit basis unclear	Is the reported unit MPa or N/mm^2?
Duplicate record	Same mix-age-value repeated	Is this a duplicate or a separate specimen?

Table 13: Examples of review-queue items generated by deterministic checks.

F Vision+Figure Per-Paper Breakdown

Table 14 reports the six papers processed in Vision+Figure mode.

Paper	Text R	Vis R	ΔR	MAE
CBM0057	0.00	1.00	+1.00	0.86
CBM0140	0.00	0.83	+0.83	0.15
CBM0177	0.15	0.40	+0.25	2.51
CBM0083	0.00	0.07	+0.07	—
CBM0134	0.00	0.00	0.00	—
CBM0192	0.25	0.25	0.00	0.00

Table 14: Vision+Fig per-paper results (MAE in MPa). CBM0057 fully recovered. CBM0083 remains low: bottleneck is table parsing, not figures.

G Representative Error Cases

This appendix gives source excerpts for the four main categories in the text-only recall gap. Each case illustrates a different failure mode and, therefore, a different route for improvement: figure recovery, table reconstruction, page selection, or partial multi-age extraction.

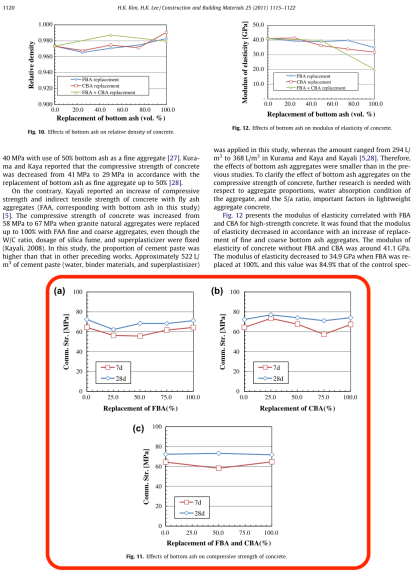

Figure 6: **FIG case.** Source excerpt from CBM0057, page 6. The compressive-strength values are reported as plotted curves rather than as a machine-readable table. The text-only pipeline, therefore, abstains instead of estimating unsupported values from the figure.

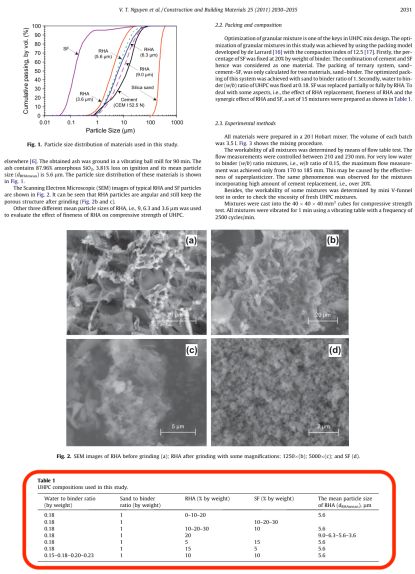

Figure 7: **PARSE case.** Source excerpt from CBM0083, page 2. The composition table contains range-style entries and visually grouped cells, which makes reliable reconstruction of the mixture–condition alignment difficult after PDF table extraction.

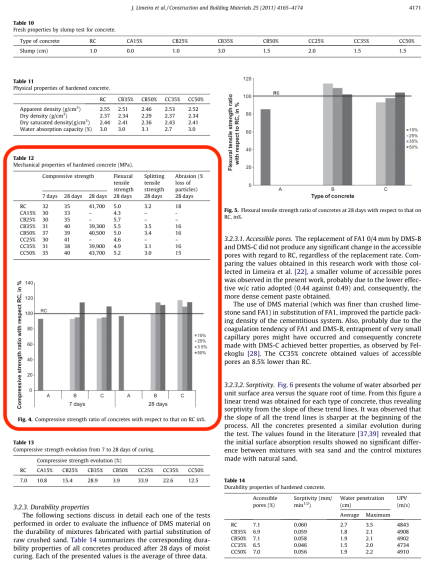

Figure 8: **PAGE case.** Source excerpt from CBM0134, page 7. The page contains the relevant 7-day and 28-day compressive-strength table, but it was not selected by the keyword-scored candidate-page step. This is a page-selection miss rather than an extraction hallucination.

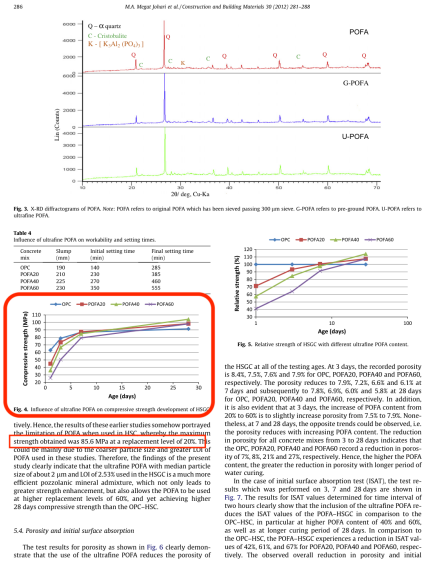

Figure 9: **PART case.** Source excerpt from CBM0192, page 6. The paper reports compressive-strength values across multiple curing ages, but only part of the age series is recovered by the text-only system. The remaining values require either better evidence linking or review.

PRISM: Prompt-Refined In-Context System Modeling for Financial Retrieval

Chun Chet Ng[1]*, **Jia Yu Lim**[1]*, **Zhen Hao Chu**[1], **Yixi Zhou**[2], **Wei Zeng Low**[1]
[1]AI Lens, Kuala Lumpur, Malaysia

chunchet.ng@ailensgroup.com

Abstract

Deploying LLMs for financial information retrieval demands accuracy, cost efficiency, and reproducibility, yet most approaches require expensive fine-tuning. PRISM is a training-free framework that composes three deployable modules (prompt engineering, in-context learning, and a candidate refinement module) with a boundary-condition study of multi-agent coordination for financial document retrieval. On FiQA-2018, stacked reranking and k-reciprocal encoding raise Recall@100 from 0.7783 to 0.8326. On FinAgentBench, a Cohere-refined top-50 pool yields a higher observed end-to-end NDCG@5, below this evaluation's minimum detectable effect, while cutting per-query cost by about 35%. Added complexity does not always pay off: k-reciprocal encoding stops helping once the upstream stage is already high-recall, and multi-agent coordination is not a default for fine-grained chunk ranking. Matched pairs that hold prompt, model, and exemplars fixed lose 0.0702 and 0.0681 combined NDCG@5 to their single-path controls, and the whole gap sits at the chunk stage. We release an expert-annotated FinAgentBench evaluation set, together with a label-robustness sweep over 16 alternative ground-truth constructions, restoring a reproducible evaluation path after the original evaluator went offline. Without fine-tuning, PRISM placed third on the official FinAgentBench private leaderboard (leaderboard basis, NDCG@5 0.71181), reaches NDCG@10 0.6197 on FiQA-2018, and 98% accuracy on FinanceBench. We report per-query latency, token, and dollar accounting across roughly 40 configurations, present the quality–cost–latency Pareto frontier, and introduce FACET, a transparent SLA-specific scalarization for choosing among non-dominated configurations. Code and dataset are released at bit.ly/prism-ailens.

1 Introduction

Financial information retrieval (IR) systems must retrieve verifiable evidence from long documents under cost and latency constraints (Zhu et al., 2025; Zhao et al., 2024b). This is difficult in production because relevance must be judged across granularities, from full filings to passages, while task-specific labels for fine-tuning are often unavailable. Large language model (LLM)-based retrieval and Retrieval-Augmented Generation (RAG) offer training-free alternatives, but their performance depends on interacting choices: prompt design, in-context examples, candidate refinement, context length, and model capacity (Choi et al., 2025a; Sun et al., 2023). Existing work provides limited deployment guidance on which intervention to use, when it improves ranking, and when it adds cost or complexity without benefit. We address this gap with Prompt-Refined In-Context System Modeling (PRISM), a training-free financial IR framework and deployment-oriented empirical study that evaluates prompt engineering, in-context learning (ICL), candidate refinement, and multi-agent coordination across document, chunk, and passage ranking. Figure 1 summarizes the PRISM workflow. We also re-annotate and release FinAgentBench labels to restore reproducible evaluation after the original evaluator became unavailable (Choi et al., 2025b). The main contributions of this work are:

1. We present PRISM, a training-free financial IR framework evaluated on FinAgentBench, FiQA-2018, and FinanceBench. It combines three deployable modules, prompt engineering, in-context learning, and a candidate refinement module, with a boundary-condition study of multi-agent coordination. The refinement module stacks dense retrieval, commercial and late-interaction rerankers, and k-reciprocal encoding, improving FiQA-2018 Recall@100 and

* Both authors contributed equally to this work.

EMNLP 2026 Industry Track, pages 1674–1737

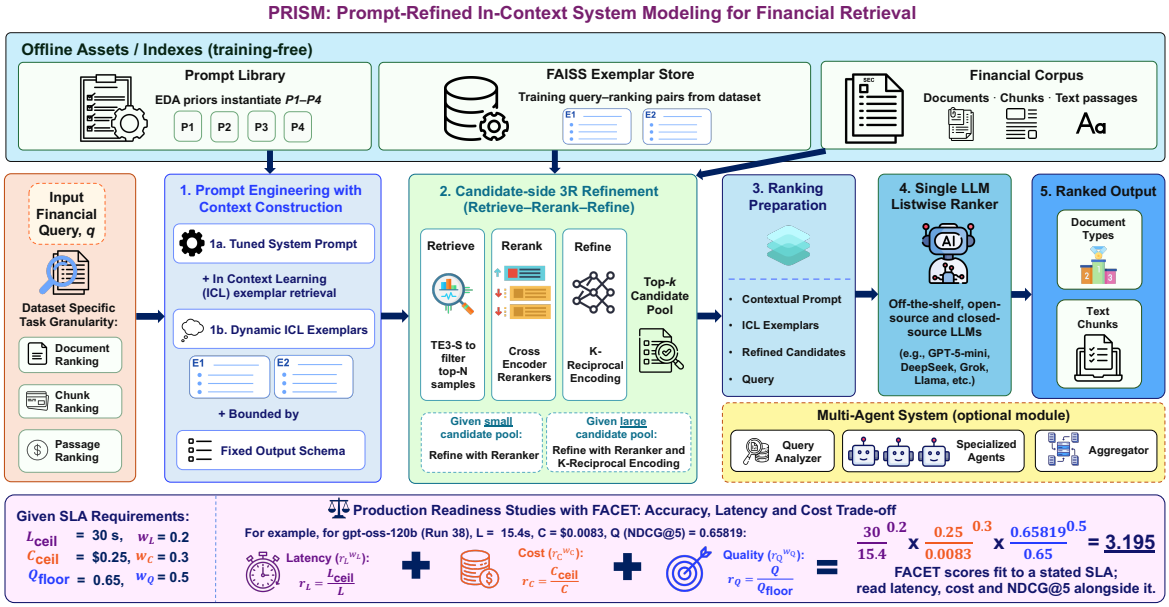

Figure 1: Overview of the PRISM framework. A query passes left to right through five stages. (1) **Prompt engineering** encodes financial-domain priors and a relevance scaffold into the ranking instruction (1a), and **ICL exemplar retrieval** *prepends* demonstrations from a separate training-split store (1b), never changing the candidate set. (2) **Candidate refinement** queries the corpus for the current query and *shrinks* the candidate set through dense retrieval, reranking, and optional k-reciprocal encoding. The two retrieval paths are drawn separately because they query different indexes and move context in opposite directions (Section 4.2). (3) Prompt, exemplars, refined candidates, and query are assembled and (4) ranked in a single LLM call, giving (5) the ranked output. **Multi-agent coordination** replaces stage 4 when enabled; it is optional and is studied here as a boundary condition, not as the recommended production path for chunk ranking (Section 5.3).

yielding a higher observed FinAgentBench chunk NDCG@5, below this evaluation's minimum detectable effect, while reducing per-query cost by about 35%.

2. We release a systematically re-annotated FinAgentBench evaluation set with annotator-agreement analysis (Kendall's τ_b, RBO@5, Cohen's κ) and a label-robustness sweep that rebuilds the ground truth 16 different ways and re-scores all 40 configurations against each, restoring a reproducible evaluation path after the original evaluator became unavailable. Every score we report is labeled with its evaluation basis, re-annotated or leaderboard.

3. We attribute the module-level findings with controlled comparisons rather than argument: architecture-matched pairs holding prompt, model, and exemplars fixed, query-level paired bootstrap intervals, and minimum detectable effects. Configurations whose intervals overlap are not described as ordered.

4. We report the first per-query latency, token, and dollar accounting on this benchmark, present the quality–cost–latency Pareto frontier, and summarize the deployment choice in a practitioner decision table; FACET follows as a transparent SLA-specific scalarization over the non-dominated set, with raw axes alongside.

2 Related Work

LLMs for Ranking. LLMs are strong zero-shot rankers, typically formulated pointwise, pairwise, or listwise (Hou et al., 2024). Listwise methods such as RankGPT balance effectiveness and efficiency but are limited by input length and sensitive to document order (Sun et al., 2023); TourRank adds multi-stage grouping and a tournament strategy for large candidate sets (Chen et al., 2025), and pairwise ranking compares candidates directly at linear complexity (Qin et al., 2024). We treat these as related formulations and instead target deployment-component ablations for long, dense financial texts (Zhao et al., 2024a).

In-Context Learning (ICL). ICL adapts LLMs through in-prompt examples without gradient updates (Xie et al., 2022; Min et al., 2022). Embedding-based ICL retrieval for financial IR is underexplored when latency-sensitive applications must allocate a fixed context budget between ex-

amples and long-document evidence.

Retrieval and Reranking. Neural retrieval pipelines pair a first-stage retriever with a reranker; dense, sparse, late-interaction, cross-encoder, and commercial rerankers are strong alternatives to lexical baselines (Formal et al., 2021; Santhanam et al., 2022; Nogueira and Cho, 2019; Chen et al., 2024). Prior financial IR work has largely benchmarked against BM25-style baselines, leaving the deployment value of stronger modules unclear in production settings.

Rank Fusion and k-Reciprocal Encoding. Reciprocal Rank Fusion combines ranked lists through reciprocal-rank weights (Cormack et al., 2009), while k-reciprocal encoding, first proposed for person re-identification, refines candidates through mutual nearest-neighbor structure (Zhong et al., 2017; Qin et al., 2011), both without supervision. Further background is in Appendix A.1.

3 Datasets

We use three financial datasets covering complementary ranking granularities (document, chunk, passage), task types (ranking, QA), and reasoning demands (lexical matching, numerical analysis).

FiQA-2018 (Maia et al., 2018) is a financial opinion QA dataset from BEIR (Thakur et al., 2021), requiring passage reranking over short financial texts. **FinanceBench** (Islam et al., 2023) tests numerical-reasoning QA over SEC filings rather than ranking. **FinAgentBench** (Choi et al., 2025b) comprises 2023–2024 SEC filings from EDGAR and supports two tasks: ranking five document types (10-K, 10-Q, 8-K, DEF 14A, Earnings Transcripts) by relevance, and ranking text chunks within documents. It has 4,986 document-ranking and 18,855 chunk-ranking training samples, and a closed-source 200-example validation set covering both document and chunk ranking.

3.1 FinAgentBench Re-Annotation

The original evaluation dataset became unavailable after the competition (Kim et al., 2025), leaving leaderboard-era results no longer reproducible by the community. We address this gap by releasing an open validation set in which three domain experts label the document-ranking samples and four label the chunk-ranking samples.

Inter-Annotator Agreement. For each task, we measure pairwise agreement using Kendall's τ_b (Kendall, 1938), RBO@5 (Webber et al., 2010), and Cohen's κ (Cohen, 1960). Agreement is substantially higher for document ranking than for chunk ranking (Appendix A.2). Table 1 summarizes the selected pair per task; full pairwise agreement is reported in Appendix Table 6.

Table 1: Summary of the released FinAgentBench evaluation labels. Agreement is for the selected annotator pair; validation compares all eligible configurations with original private-leaderboard scores.

Task	Experts	Pair	τ_b	RBO@5	κ
Document ranking	3	1, 2	0.754	0.957	0.827
Chunk ranking	4	1, 4	0.582	0.730	0.649
Mean absolute NDCG@5 difference from original scores					**0.0702**
Ordering vs. leaderboard, ρ / τ_b ($n = 34$)					**0.7800 / 0.6613**

Ground Truth and Release. We select the most concordant annotator pair per task to reduce label noise from low-agreement annotators, merge their rankings by Borda count, and validate the resulting labels by re-scoring all configurations in Appendix Table 23 against the new ground truth. The re-scored results preserve the broad performance pattern of the original private leaderboard (Table 1); per-configuration deltas for every eligible run are in Appendix Table 5.

Evaluation Bases. Two bases appear in this paper and no column mixes them. The *leaderboard basis* is the score returned by the original evaluator on its held-out private subset, and exists only for configurations submitted before it went offline (Appendix Tables 22 and 5). The *re-annotated basis* re-scores released prediction files against the released expert labels over the 200 document-ranking and 199 chunk-ranking scoring queries. The two differ in both label source and query sample, so their absolute values are not expected to coincide: across the 34 configurations carrying both, the mean level shift is 0.070 while the ordering is broadly preserved (Spearman $\rho = 0.7800$, $p = 5.4\times10^{-8}$; Kendall $\tau_b = 0.6613$, $p = 3.8\times10^{-8}$). We use that correlation to validate broad ordering only, and do not read close configurations as ordered. Unless labeled otherwise, every FinAgentBench number here is on the re-annotated basis.

Dataset Diagnostics. We conduct EDA on FinAgentBench, FiQA-2018, and FinanceBench to characterize document-type heterogeneity, label sparsity, and chunk-length variability across tasks. These diagnostics motivate type-aware prompting, selective ICL, and candidate refinement; full diagnostics are provided in Appendix A.4–A.6.

4 PRISM

4.1 Prompt Engineering

Prompt engineering encodes financial-domain priors and output constraints into the ranking instruction. P_1 supplies domain keyword hints and statistical cues only; P_2–P_4 add a structured relevance scaffold combining chain-of-thought decomposition, ReAct-style alternation, and tree-of-thought multi-expert simulation, and P_4 is P_3 with streamlined instructions and terminology unified across stages, so what separates them is output discipline rather than length. Matched on model and exemplars (GPT-5-mini, no ICL), the step that carries the effect is adding the scaffold: P_1 is the weakest of the four on both evaluation bases (Runs 2, 9, 12, 13; re-annotated 0.75758, 0.76648, 0.76287, 0.77668). Within the scaffolded set P_4 is the strongest on the re-annotated basis and within 0.0012 of the strongest on the leaderboard basis, so we standardize on it as the safest default. This is a reliability claim rather than a per-prompt gap, consistent with the best prompt form differing by benchmark. Chunk scores also depend on the document stage, since the chunk ranker only sees chunks from the documents the first stage selected, so prompt effects are read at the pipeline level. Further analyses are in Appendix A.9 and A.19.

4.2 In-Context Learning Sample Retrieval

The ICL module retrieves semantically similar training examples from a separate FAISS (Johnson et al., 2019) exemplar store and prepends them as few-shot demonstrations. Exemplars are drawn only from the training split, so no test label or test candidate is ever used as a demonstration and an exemplar cannot enter the candidate set for the query it conditions. Implementation details and shot-count sensitivity are in Appendix A.10.

Two retrievers, opposite roles. The ICL retriever and the candidate-refinement retriever of Section 4.3 share TE3-S as a backbone but are not redundant: the first queries the training-split exemplar store and prepends demonstrations, leaving the candidate set untouched, while the second queries the corpus for the current query and changes the candidate set. One adds context for task adaptation, the other removes it for pool construction, and the effects follow that difference: ICL helps document ranking but not chunk ranking, where exemplars consume context that candidate evidence needs, whereas refinement improves the chunk path precisely by shrinking what the LLM sees, so the two are complementary.

4.3 Candidate Refinement Module

The third module is a model-agnostic *retrieve–rerank–refine* (3R) stage before the LLM ranker. It compresses noisy candidate pools into smaller, denser sets via an embedding retriever, a reranker, and optional k-reciprocal encoding, reducing context length while preserving relevance.

Embedding Retrieval. The first stage retrieves candidates with text-embedding-3-small (TE3-S), selected empirically in Appendix A.7.1. On FiQA-2018, every refinement method receives the same TE3-S top-1000 pool from the full 57.6K-passage corpus. On FinAgentBench, each query already has a few hundred associated chunks, which are refined only for chunk ranking and passed to the LLM as a top-k pool.

Reranking. The second stage rescores candidates with cross-encoder, late-interaction, or commercial rerankers. We compare Cohere rerank-v4.0-fast (hereafter Cohere) (Cohere, 2026), ColBERTv2 (Santhanam et al., 2022), BGE-M3 ColBERT, BGE reranker V2 M3 (Chen et al., 2024), and Jina reranker v3 (Sturua et al., 2025) under the same candidate budget in Appendix A.7.2.

K-Reciprocal Encoding. The final stage applies training-free k-reciprocal encoding (Zhong et al., 2017). For L2-normalized embeddings, $d(q, c_i) = 2 - 2\hat{e}_q^\top \hat{e}_{c_i}$ and the reciprocal set is $R(q, k_1) = \{c_i \in N(q, k_1) \mid q \in N(c_i, k_1)\}$. We encode these mutual neighborhoods and blend their Jaccard distance d_J with direct distance,

$$d^*(q, c_i) = \lambda d(q, c_i) + (1 - \lambda) d_J(q, c_i),$$

then rerank candidates by ascending d^*. This stage exploits complementary neighborhood structure in large, sparse pools; our experiments (Appendix A.7) show it is not beneficial on small, homogeneous chunk sets; reranker-only pipelines are better defaults for compact financial retrieval under these observed conditions.

4.4 Multi-Agent System (MAS) Modeling

The fourth module studies MAS as a boundary-condition analysis rather than a default production recommendation. It belongs in the paper because the negative result is only interpretable against the rest of the framework: without matched non-agentic controls there is nothing to attribute the loss to. We test when role-specialized agents help

coarse document routing and when agent handoffs cost quality at chunk granularity; architectures A_1–A_4 are detailed in Appendix A.11. The controlled comparison in Section 5.3 is run under A_4 with P_4, so the resulting statement is scoped to the tested A_4 workflow and is not a claim about multi-agent design in general.

5 Experiments

We evaluate four closed-source models (GPT-4o-mini, GPT-4.1, GPT-5-mini, and GPT-5) and four open-source models: DeepSeek-V4-Flash (DeepSeek-AI, 2026), gpt-oss-120b (OpenAI et al., 2025), grok-4-20-reasoning (xAI, 2026), and Llama-4-Maverick-17B-128E-Instruct-FP8 (Meta AI, 2025), using OpenAI's text-embedding-3-small (TE3-S) and text-embedding-3-large (TE3-L) (OpenAI, 2024) for ICL retrieval. Our evaluation spans three datasets chosen to cover complementary task characteristics: FinAgentBench (document and chunk ranking with SEC filings), FiQA-2018 (passage reranking for financial QA), and FinanceBench (factual QA requiring numerical reasoning). PRISM's training-free design allows adaptation to other LLM providers and deployment settings with minimal pipeline changes. Implementation details are in Appendix A.12.

5.1 Evaluation Metrics

On FinAgentBench we use combined document-and-chunk NDCG@5 as the primary metric, matching the competition objective, and also report MAP@5 and MRR@5. On FiQA-2018 we report NDCG@10 and Recall@100 under the BEIR protocol (Thakur et al., 2021), measuring top-ranked quality and reranking coverage respectively. On FinanceBench we report factual QA accuracy under oracle context.

5.2 Quantitative Results

5.2.1 FinAgentBench

All FinAgentBench scores in this section are on the re-annotated basis (Section 3.1) unless labeled otherwise; the full 40-configuration grid is in Appendix Table 23 and the document/chunk splits in Appendix Table 24. Table 2 reports the configurations the paper's claims rest on, with query-level paired bootstrap confidence intervals (10,000 resamples, document and chunk resampled independently because their query sets are disjoint).

Leaderboard basis. On the original private leaderboard, PRISM placed 3rd of all teams with the competition-selected Run 19 submission (leaderboard basis, 0.71181 NDCG@5), and repeated submissions of the same configuration reached 0.71818 on the private subset (Appendix A.13.1). This made PRISM the highest-ranked non-fine-tuned submission, trailing the top fine-tuned system by 0.007 NDCG@5 on our best observed private-subset run (0.71818 vs. 0.72497, both leaderboard basis). Runs 37–40 could not have been submitted: those models were not available to us during the competition. They are post-competition runs, evaluated only on the re-annotated set and never on the original private leaderboard, so they carry no original score to compare against, and leaderboard and re-annotated numbers are never compared directly.

Re-annotated basis. Run 19 scores 0.77468 here; several configurations score higher under the new labels, and we track it only because it was the submitted one. Under the Run 19 recipe, grok-4-20-reasoning (Run 39) reaches the best combined NDCG@5 of 0.83721 and exceeds the strongest GPT-5-family configuration (Run 18, 0.78421) by 0.0529 (95% CI [0.0331, 0.0727]; chunk Wilcoxon $p = 9.7 \times 10^{-10}$), holding under 15 of 16 label constructions. DeepSeek-V4-Flash (Run 37) reaches 0.80157, but its difference from Run 18 is positive with a 95% CI including zero ($+0.0175$, $[-0.0084, 0.0424]$) and holds under only 9 of 16 constructions, so we place it in the same quality band as the strongest GPT-5-family run rather than above it, at roughly a fifth of the cost of the GPT-5 runs with measured cost ($0.0284 against $0.1448). Against Run 18 both models trade a little document accuracy for a large chunk gain (-0.023 and $+0.129$ for grok-4, -0.015 and $+0.050$ for DeepSeek; Appendix Table 24), consistent with a long-context discrimination advantage over the roughly 95.8k-token chunk prompt; we treat it as a descriptive diagnostic rather than causal evidence.

Chunk ranking is the axis that separates configurations. Document ranking is effectively saturated, reaching NDCG@5 up to 0.95573 (Run 40), so the candidate-refinement module pays off on the chunk task alone. Reranking alone is insufficient, as the best reranker-only setup with Cohere reaches 0.5464 chunk NDCG@5, below PRISM's LLM ranker (Run 19, 0.61278). Feeding the reranked pool to the LLM yields a higher observed

Table 2: Configurations the claims rest on, using bootstrap re-scores on the re-annotated basis with query-level 95% CIs (10,000 resamples) over the 200 document-ranking and 199 chunk-ranking scoring queries; the point estimates elsewhere use the 200-query convention, so values differ in the fourth decimal. Run 19 is the competition submission, not the best row. Full grid in Appendix Table 23.

ID	Configuration	Combined NDCG@5	95% CI
39	grok-4-20-reasoning	0.8370	[0.8190, 0.8541]
37	DeepSeek-V4-Flash	0.8016	[0.7787, 0.8226]
18	strongest GPT-5 family	0.7841	[0.7637, 0.8044]
19	GPT-5, competition submission	0.7738	[0.7528, 0.7944]
Architecture-matched pairs (P_4, GPT-5-mini, ICL held fixed)			
16 vs. 33	single-path vs. A_4 agentic	+0.0702	[+0.0474, +0.0937]
17 vs. 34	single-path vs. A_4 agentic	+0.0681	[+0.0436, +0.0920]

chunk NDCG@5 while reducing cost. Hence, reranking is most useful as a compression stage for the LLM rather than as a standalone ranker. We quantify this end to end in Section 5.4.

5.2.2 FiQA-2018

On FiQA-2018, the strongest evidence comes from controlled stage-wise comparisons under the same candidate pool. TE3-S reaches NDCG@10 0.5499 and Recall@100 0.7783; stacking reranking and k-reciprocal encoding raises Recall@100 to 0.8326 (Section 5.4). Against published BEIR baselines (Thakur et al., 2021), GPT-5 PRISM reaches NDCG@10 0.6197 (Appendix Table 25), a 78.59% gain over BM25+Cross-Encoder (CE), and all four open-source models with P_4 outperform BM25+CE (full results in Appendix A.13.2). We note that the retrieval stages alone are already competitive at the top of the ranking on this dataset: Cohere reranking reaches NDCG@10 0.6258 with no LLM in the loop (Appendix A.7.2), so on FiQA the LLM ranker contributes candidate coverage rather than top-10 precision. Full results are in Appendix Table 27.

5.2.3 FinanceBench

As a secondary QA generalization check, we evaluate PRISM under oracle context (relevant passages provided). PRISM reaches 98% accuracy (147/150) with P_1, surpassing the GPT-5 oracle baseline of 94% (141/150). This suggests that prompt engineering transfers to numerical reasoning tasks, though it does not constitute a full retrieval evaluation, since passages are given, not retrieved. Full oracle, zero-shot, and open-source results are in Appendix A.13.3; full FinAgentBench run-level ablations are in Appendix Table 23.

Table 3: Where the coordination penalty sits. Matched on prompt, model, and ICL; re-annotated basis. Document differences are not distinguishable from zero, and the whole gap is at the chunk stage.

Matched pair	Document NDCG@5	Chunk NDCG@5
Run 16 vs. Run 33	0.94594 vs. 0.95359 ($p = 0.32$)	0.59099 vs. 0.44364
Run 17 vs. Run 34	0.94950 vs. 0.95259 ($p = 0.20$)	0.55340 vs. 0.41476

5.3 Multi-Agent Coordination: A Matched Comparison

Comparing an agentic run against Run 19 confounds architecture with prompt and model. We therefore use two pairs matched on prompt, model, and exemplars, leaving architecture as the only difference: Runs 16 and 33 are both P_4/GPT-5-mini with ICL-5 on document and none on chunk, and Runs 17 and 34 are both P_4/GPT-5-mini with ICL-5 on both stages. Run 32 is excluded as prompt-mismatched. With those held fixed, the single-path pipeline exceeds the A_4 agentic one by 0.0702 and 0.0681 combined NDCG@5 (Table 2). Both differences are significant under a paired query-level bootstrap at 10,000 resamples and under a Wilcoxon signed-rank test on chunk scores ($p = 9.4 \times 10^{-9}$ and 2.8×10^{-7}), and the two estimates agree to 0.002. Both differences stay positive under all 16 alternative label constructions and the smaller never falls below $+0.035$, so the result is not an artifact of how the ground truth was built. Table 3 splits each pair by stage: the whole gap is at chunk granularity, about 0.14 NDCG@5; documents favor the agentic run.

5.4 Candidate Refinement Results

The embedding backbone that defines the candidate pool and the reranker that rescores it are selected in Appendix A.7; here we report the end-to-end effect once the refined pool reaches the LLM ranker, which is what directly determines ranking quality, cost, and latency in deployment. Stacking-order ablations are in Appendix A.8.

We now check whether the retrieval-stage gains survive when the refined pool reaches the LLM ranker. On FiQA-2018 (Appendix Table 15) every pipeline sees the identical TE3-S top-1000 pool per query at fixed cutoffs. Stacking the retrieval stages raises Recall@100 from 0.7783 to 0.8326 and NDCG@10 from 0.5499 to 0.6333. Passing the refined pool to GPT-5 adds coverage (Recall@100 0.8115 to 0.8307) but not top-of-ranking precision: NDCG@10 is 0.6243 against 0.6258 for Cohere alone and 0.6333 for Cohere$\rightarrow k$-reciprocal. On a corpus like FiQA the LLM ranker therefore earns its cost only when coverage mat-

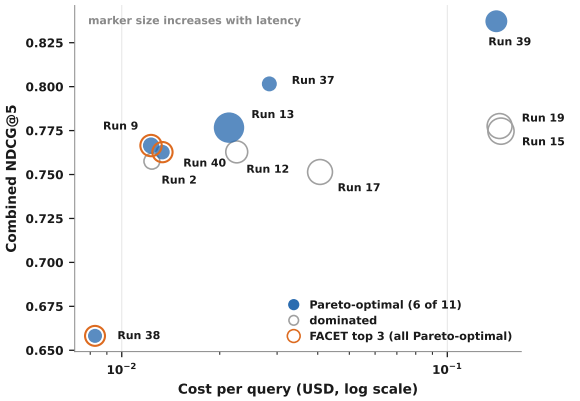

Figure 2: Quality–cost–latency dominance over the configurations with measured cost and latency (combined NDCG@5, re-annotated basis, against USD per query on a log axis; marker size grows with latency). Five of 11 are non-dominated in this projection and six on all three axes; the six filled markers are that three-axis set, and the three highest FACET scores are all Pareto-optimal.

ters more than the order of the first ten results. The trade-off inverts on FinAgentBench chunk ranking (Appendix Table 11, P_4/GPT-5, ICL-5). Refining to the top 50 with TE3-S→Cohere gives the best chunk NDCG@5 (0.63408 against a no-refinement baseline of 0.61278) while cutting per-query cost by about 35% ($0.181 against $0.278). Latency does not improve (146.3 s against 136.7 s), because the added stages are not offset by the shorter LLM context. We rest this result on the cost reduction rather than the quality change: the numbers come from a single run per configuration, and +0.021 chunk NDCG@5 is below the 0.057 chunk-level minimum detectable effect of this evaluation (Appendix A.15.4).

6 Feasibility & Reproducibility Analysis

6.1 Choosing a Configuration

Quality, latency, and cost do not reduce to one number without a stated preference, so we present the dominance structure first. Figure 2 plots the frontier over the 11 configurations with measured cost and latency: 6 are non-dominated, and that is the set to choose from (Appendix A.16.6). Table 4 names one operating point per constraint; the rows are distinct operating points rather than an ordered recommendation. One reading needs stating explicitly: FACET measures fit to a stated SLA rather than quality, so the cheapest configuration scores highest, and a practitioner with a hard constraint on one axis should read that raw column.

Module-level rules. Use the relevance scaffold (P_2–P_4), not the keyword-hint baseline (P_1). Apply ICL to document ranking, not by default to chunk ranking. Treat reranking as an LLM-context compression stage rather than a standalone ranker, and add k-reciprocal encoding only where upstream coverage is the bottleneck (Appendix A.8). Treat multi-agent coordination as a boundary condition, not the production default for chunk ranking, where matched pairs cost about 0.07 NDCG@5 against a single LLM call.

Table 4: Practitioner decision table. Distinct operating points under different constraints, not a ranking. Run IDs match Appendix Table 23; models are grok-4-20-reasoning, DeepSeek-V4-Flash, Llama-4-Maverick-17B-128E-Instruct-FP8, gpt-oss-120b, and GPT-5. NDCG@5 is combined, re-annotated basis; latency (s) and cost are per query. Run 19 uses combined document–chunk per-query accounting; post-annotation Runs 37–40 retain their originally reported latency and cost measurements.

Constraint	Choose	Lat.	$/q	NDCG	FACET
Quality first	39, grok-4	48.9	0.1415	0.8372	1.221
Quality per $	37, DeepSeek	18.5	0.0284	0.8016	2.349
Latency, Q>0.75	40, Llama-4	17.0	0.0133	0.7627	2.923
Lowest $/query	38, gpt-oss	15.4	0.0083	0.6582	3.195
Submitted run	19, GPT-5	84.6	0.1462	0.7747	1.042

7 Conclusion

PRISM composes prompt engineering, in-context learning, and candidate refinement without training, and studies multi-agent coordination as a boundary condition. Matched on prompt, model, and exemplars, the single-path pipeline beats the tested A_4 agentic workflow by 0.0702 and 0.0681 combined NDCG@5, entirely at the chunk stage, so the simpler path is the default for fine-grained ranking, and ICL pays off only at document granularity. The scaffold, not length, matters. Refinement improves FiQA-2018 Recall@100 and yields a higher observed FinAgentBench chunk NDCG@5, below this evaluation's minimum detectable effect, at about 35% lower cost. The released evaluation set and robustness sweep restore a reproducible path, and the cost accounting and frontier make the trade-off readable. In Table 4, the anchors are Run 39 (grok-4-20-reasoning, 0.8372 combined NDCG@5 at USD 0.1415 and 48.9 s) and Run 37 (DeepSeek-V4-Flash, 0.8016 at USD 0.0284 and 18.5 s). Their 95% intervals overlap (Table 2), so we do not order them. PRISM is the top non-fine-tuned leaderboard entry, within 0.007 NDCG@5 of the best fine-tuned one, and the cheaper anchor, at one fifth the cost and 40% of the latency.

8 Limitations

This section highlights the key limitations of PRISM; Appendix A.17 discusses them in full.

Benchmark Reproducibility. The FinAgentBench evaluation environment became unavailable following the competition's conclusion, preventing new submissions and independent replication of private-test scores. The organizers did not disclose ground-truth labels for the public or private test sets. As a result, the private-test competition scores (Appendix Table 22) cannot be reproduced using the original evaluator. Our ablation experiments on the validation split remain reproducible with the code we release upon acceptance, and our expert re-annotated evaluation set (Section 3.1) provides a community-accessible substitute for the offline evaluator, enabling independent re-evaluation of all 40 configurations in Appendix Table 23 against a fixed public label set.

Scope of the MAS Result. The coordination penalty is established for the tested A_4 workflow under P_4, with two matched pairs (Section 5.3), not for the full A_1–A_4 grid. The remaining architectures were not run under P_4, so we do not claim that every multi-agent design loses at chunk granularity. The earlier prompt-architecture asymmetry, in which agentic runs used P_1 while the strongest non-agentic run used P_4, no longer carries the conclusion: Runs 33 and 34 are P_4 under A_4 and matched to non-agentic controls on prompt, model, and exemplars, so the comparison isolates architecture. Run 32 remains prompt-mismatched (P_4 on document, P_1 on chunk) and is excluded from the matched analysis; its low score (0.54229) is reported in Appendix Table 23 but is not evidence about coordination.

Domain Specificity. PRISM's financial specialization lies in the SEC-filing prompt priors with their keyword-frequency ratios, the financial exemplar pool, and document-type routing. These are inputs rather than architecture, so porting the pipeline to legal or medical retrieval means rederiving priors and re-indexing exemplars with no weights to retrain. We have not tested that and do not claim it; every module-level finding in this paper is scoped to financial IR, and cross-vertical evaluation is the next step. The evidence is financial and we do not claim cross-domain generalization, but the retrieval-design questions addressed also arise beyond finance.

Chunk-Level Resolution and API Dependence. The chunk task has a minimum detectable effect of 0.057 at 80% power, so differences smaller than that are not resolvable by this evaluation and we do not interpret them. Separately, training-free operation is not infrastructure independence: exact reproduction of API-served results depends on endpoint availability and versioning, and commercial endpoints are not stationary. We report exact endpoint identifiers and per-run call timestamps, and make the evaluation rather than the endpoints reproducible by releasing the expert annotations, source code, prompts, and configuration details.

Ethical Considerations

All datasets used in this work are publicly available and were obtained through official distribution channels. FinAgentBench (Choi et al., 2025b) was released as part of an open Kaggle competition and contains excerpts of SEC filings, which are public regulatory disclosures rather than personal data. FiQA-2018 is distributed through the BEIR benchmark (Thakur et al., 2021), and FinanceBench (Islam et al., 2023) is publicly released for non-commercial research. No proprietary data were used. We release our expert annotations, that is, the labels we produced over the public FinAgentBench validation split, rather than a re-release of the underlying dataset, so the release is consistent with the original distribution terms. The annotations, together with the scoring, bootstrap, and label-robustness scripts, are released under CC BY 4.0; the underlying SEC excerpts remain under their original public-domain status and are not redistributed by us. The annotators are domain experts who consented to the use of their judgments for this release; the labeled material contains no personal or client data. Since financial retrieval may influence high-stakes analysis, PRISM is intended as an evidence-ranking aid rather than an autonomous decision system, with human review, access control, audit logging, and checks that answers remain grounded in retrieved evidence.

Acknowledgement

We thank the Cradle Fund and Microsoft for Startups for their funding support, which made this research possible. We also thank the DocLab, DocSuite, and MLSuite teams at AI Lens for their contributions that collectively shaped the PRISM pipeline presented in this work.

A Appendix

This appendix provides implementation details, extended results, and supporting analyses in the same section order as the main paper.

A.1 Additional Related Work

Prompt Engineering. Recent studies have shown that retrieval performance is highly sensitive to how an LLM is instructed (Zhang et al., 2025b). The initial breakthrough in few-shot learning demonstrated that LLMs can perform tasks using in-context exemplars without gradient updates (Brown et al., 2020). However, traditional few-shot approaches struggled with complex reasoning tasks. This limitation was addressed by Chain-of-Thought (CoT) prompting, which enhances reasoning by guiding LLMs through intermediate natural language reasoning steps (Wei et al., 2022). The Reasoning and Acting (ReAct) framework improves reliability by allowing LLMs to plan and execute reasoning steps iteratively, reducing hallucination (Yao et al., 2023b). Building on this, the Tree-of-Thoughts (ToT) framework enables LLMs to explore and evaluate multiple reasoning paths (Yao et al., 2023a).

Agentic Information Retrieval. Agentic information retrieval represents a new paradigm where LLM agents dynamically manage information access through iterative cycles of observation, reasoning, and action, distinguishing it from traditional IR architectures (Zhang et al., 2025a). It is commonly implemented using multi-agent systems (MAS), which coordinate specialized agents for reflection, planning, and tool use to achieve collective intelligence and outperform single-agent approaches (Singh et al., 2026). LLM agents have also been applied to ranking tasks, demonstrating that retrieval and ranking agents can effectively coexist (Xu et al., 2025). Despite its potential, agentic IR faces challenges in coordinating complex MAS interactions, reducing the high inference cost of LLMs, and evaluating dynamic agentic behaviors in financial retrieval.

Neural Retrieval and Reranking. First-stage retrievers fall into three main families. Dense bi-encoders embed queries and passages into a shared space for approximate nearest-neighbor search (Karpukhin et al., 2020), exemplified by commercial models such as OpenAI text-embedding-3 and the dense mode of BGE-M3 (Chen et al., 2024). Learned sparse models such as SPLADE (Formal et al., 2021) and the sparse mode of BGE-M3 retain the exact-term-matching and inverted-index efficiency of lexical methods while adding learned term expansion. Late-interaction models such as ColBERTv2 (Santhanam et al., 2022) store token-level embeddings and match them at fine granularity. A reranker then rescores retrieved candidates: cross-encoders jointly encode the query and each passage for higher accuracy at greater computational cost (Nogueira and Cho, 2019), while commercial rerankers such as Cohere and Jina reranker v3 (Sturua et al., 2025) offer strong off-the-shelf alternatives.

Rank Fusion and Reciprocal Encoding. RRF merges several ranked lists by summing reciprocal-rank weights and can outperform individual systems and learned fusion methods (Cormack et al., 2009). k-reciprocal encoding, introduced for person re-identification (Zhong et al., 2017) and rooted in earlier k-reciprocal nearest-neighbor retrieval (Qin et al., 2011), instead refines a candidate set by exploiting mutual nearest-neighbor relationships. Each item is encoded from its k-reciprocal neighbors and rescored under a Jaccard distance, promoting candidates that are reciprocally close to the query rather than merely close in one direction.

A.2 FinAgentBench Re-Annotation Details

Human-only annotation. We deliberately rely on human experts alone and exclude LLMs from annotation because our retrieval pipeline itself uses cross-encoders and LLMs; using LLM-generated labels as ground truth would bias the evaluation toward the systems under test and invite a circularity objection.

Agreement levels. The selected chunk pair reaches $\kappa = 0.649$, $\tau_b = 0.582$, RBO@5 $= 0.730$ (Table 1), and we agree the remaining chunk pairs are much lower. The structural reason is that chunk ranking asks for a top-5 ordering out of the few hundred topically related chunks each query carries, so two experts who both locate relevant material can still disagree on which five and in what order. Document ranking has a small fixed candidate set and correspondingly high agreement ($\tau_b = 0.754$, $\kappa = 0.827$). The principal MAS and grok-versus-GPT-5 conclusions are configuration-ordering claims, and the sweep in Appendix A.3 shows that those conclusions remain stable across the tested ground-truth constructions.

For ground-truth construction, we apply the same objective rule to both FinAgentBench tasks: select the annotator pair with the highest mean agreement across Kendall's τ_b, RBO@5, and Cohen's κ, then merge the two reference rankings by Borda count with ties broken by document or chunk ID. This selects annotators 1 and 2 for document ranking and annotators 1 and 4 for chunk ranking. To validate the reconstructed labels, we re-score the configurations in Table 23 against the new ground truth. Table 5 shows that the reconstructed labels preserve the broad performance pattern of the original private-leaderboard scores.

Table 5: Validation of the re-annotated FinAgentBench labels: new NDCG@5 vs. the original private-leaderboard score. Runs 33–34 and 37–40 were not evaluated on the original test set and are therefore excluded. Run IDs match Appendix Table 23.

A.3 Label Robustness of the Re-Annotated Set

Section 3.1 builds the released ground truth from the most concordant annotator pair per task. This appendix reports what happens to the paper's conclusions when that choice is varied. We rebuild the ground truth 16 different ways using only the annotators of Table 6 and re-score all 40 configurations against each. The constructions are: Borda over all annotators and majority vote on top-5 membership (2); the remaining document pairs and chunk pairs, that is, all $\binom{3}{2}$ and $\binom{4}{2}$ pairs other than the two the pair rule selected (7); and every annotator alone, 3 for document and 4 for chunk (7).

Table 6: Pairwise inter-annotator agreement among domain experts on FinAgentBench.

Annotator pair		Kendall τ_b	RBO@5	Cohen's κ
Document ranking (3 experts)				
Annot. 1	**Annot. 2**	**0.7540**	**0.9567**	**0.8270**
Annot. 1	Annot. 3	0.6520	0.9347	0.7335
Annot. 3	Annot. 2	0.7420	0.9541	0.8095
Chunk ranking (4 experts)				
Annot. 1	**Annot. 4**	**0.5822**	**0.7296**	**0.6485**
Annot. 1	Annot. 2	0.2408	0.4926	0.2603
Annot. 2	Annot. 4	0.1015	0.5141	0.1142
Annot. 3	Annot. 1	0.1364	0.4886	0.1459
Annot. 3	Annot. 2	0.1721	0.4678	0.1943
Annot. 3	Annot. 4	0.2174	0.5276	0.2317

Table 7 gives the per-construction outcome and Figure 3 plots it. Ordering against the reported labels stays between Spearman 0.812 and 0.998 with median 0.972. Run 39 is top-ranked under 15 of 16 constructions, grok-4-20-reasoning outranks every GPT-5 configuration under 15 of 16, and the best non-agentic configuration exceeds the best agentic one under 16 of 16. The two architecture-matched differences of Section 5.3 are positive under 16 of 16, and the smaller of the two never falls below $+0.035$. The single exception on the grok-4 and top-run claims comes from a ground truth built on one individual rater rather than on a pair. DeepSeek-V4-Flash exceeds the strongest GPT-5-family configuration under 9 of the 16 constructions, which is why that comparison is stated without a superiority claim in Section 5.2.1.

A leave-one-annotator-out check rebuilds the ground truth from every subset that drops one rater. Both principal findings hold in 6 of 6 subsets with ordering correlation at least 0.951, and Run 39 remains top-ranked in all of them; DeepSeek again does not hold throughout.

The candidate-refinement robustness statement is limited to FiQA, where it is measured with public qrels and therefore does not depend on FinAgentBench annotator selection; we do not use this analysis to make a FinAgentBench candidate-refinement label-robustness claim.

Table 7: Per-construction label robustness. Each row rebuilds the FinAgentBench ground truth a different way and re-scores all 40 configurations against it. $\Delta_{16,33}$ and $\Delta_{17,34}$ are the architecture-matched differences of Section 5.3; both stay positive throughout. Re-annotated basis.

Ground-truth construction	Spearman vs. reported	Top run	Run 39	Run 37	$\Delta_{16,33}$	$\Delta_{17,34}$
Borda over all annotators	0.969	39	0.8281	0.7914	0.0706	0.0654
Majority vote on top-5 membership	0.966	39	0.8067	0.7719	0.0704	0.0664
Document pair (A1, A3)	0.989	39	0.8373	0.8008	0.0629	0.0631

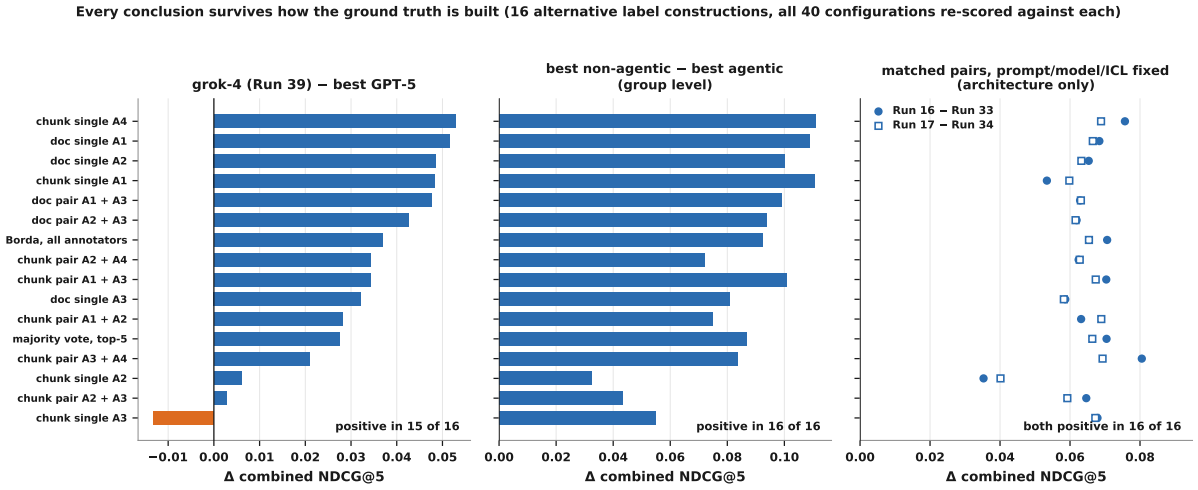

Figure 3: Conclusions under the 16 alternative label constructions. Left: Run 39 (grok-4) minus the best GPT-5 configuration, positive in 15 of 16. Middle: best non-agentic minus best agentic, positive in 16 of 16. Right: the two architecture-matched pairs with prompt, model, and ICL held fixed, positive in 16 of 16.

Label Robustness. Because chunk agreement is much lower than document agreement, the conclusions must not depend on which annotators the pair rule selected. We therefore rebuilt the ground truth 16 different ways from the annotators in Appendix Table 6 and re-scored all 40 configurations against each: Borda over all annotators and majority vote on top-5 membership (2); the remaining 2 document and 5 chunk pairs (7); and each annotator alone (7). The matched-pair agentic penalty stays positive in 16/16 constructions and 6/6 leave-one-annotator-out subsets, MAS stays below the best non-agentic run in 16/16, and grok-4 outranks every GPT-5 configuration in 15/16, with ordering correlation against the reported labels between 0.812 and 0.998 (median 0.972). The one claim that does not survive is DeepSeek-V4-Flash exceeding the strongest GPT-5-family configuration, which holds under only 9 of 16; we state that comparison without a superiority claim throughout. Per-construction scores are in Appendix A.3.

A.4 EDA on FinAgentBench

conduct a systematic evaluation across all document types in the document-ranking split of FinAgentBench. Table 8 summarizes the distribution of document types across ranking positions. Documents such as 10-K and 8-K appear more frequently near the top and bottom of the rankings, respectively, suggesting that information density and relevance vary across document types. Table 9 shows the six most frequent keywords found in Rank 1 documents for each type, revealing distinct lexical signatures across filing categories. These differences in vocabulary concentration across document types highlight the need for adaptive retrieval strategies, which inspired PRISM. Further details are provided in Appendix A.4.1.

Chunk Ranking Data Analysis. We conducted a frequency analysis to better understand chunk-level characteristics in the dataset. As shown in Figure 4, relevant chunks are generally more information dense than irrelevant ones. The wider interquartile range (IQR) and higher maximum values, along with the long-tail distribution, suggest that adaptive retrieval methods are needed to handle substantial variability in chunk length. The relatively small proportion of relevant chunks highlights the fine-grained and selective nature of financial retrieval. Our EDA shows that relevant answers are concentrated in specific document types and in a minority of information-dense chunks, requiring models to reason over and manage large variations in chunk length.

A.4.1 Document Ranking Keyword Analysis

Table 9 reveals distinct keyword concentration patterns across SEC filing types. DEF 14A filings are dominated by high-ratio keywords such as *dependency* (88.40%) and *concentration* (88.24%), while 8-K filings focus more on compensation-related terms (95.45%). 10-Q filings, by contrast, contain notably lower keyword ratios, reflecting greater variation in language use. The spread between these extremes indicates that certain document types carry more distinctive language patterns than others, which can be exploited to guide retrieval, and these patterns informed the design of our domain-specific prompt priors and agent routing logic.

A.4.2 Chunk Ranking Data Analysis with Word Count

We repeated the frequency analysis on chunk word counts as a tokenizer-independent check. As shown in Figure 5, the distributions mirror the token-count results in Figure 4, confirming that the length variability reported above is a property of the text rather than an artifact of the tokenizer.

A.5 EDA on FiQA-2018

FiQA-2018 contains 57,638 documents and 648 queries with 1,706 relevance judgments. With only 2.96% of the corpus labeled as relevant and a sparsity of 99.99%, FiQA-2018 exhibits the extreme label sparsity characteristic of real-world retrieval tasks. Most queries have fewer than three relevant documents, with average query and document lengths of 11 and 133 tokens, respectively. This characteristic places strong emphasis on semantic understanding over lexical overlap, disadvantaging keyword-based models such as BM25 when queries and documents share limited surface-form vocabulary. Dense retrieval models are better suited to this task because they capture latent semantic relevance beyond exact term matching.

Figure 6 shows the distribution of relevant documents per query. The majority of queries have fewer than 3 relevant documents, with a median of 2 and a mean of 2.63. Despite this concentration, the distribution has a long tail extending up to 15 relevant documents for certain queries, indicating significant variability in query complex-

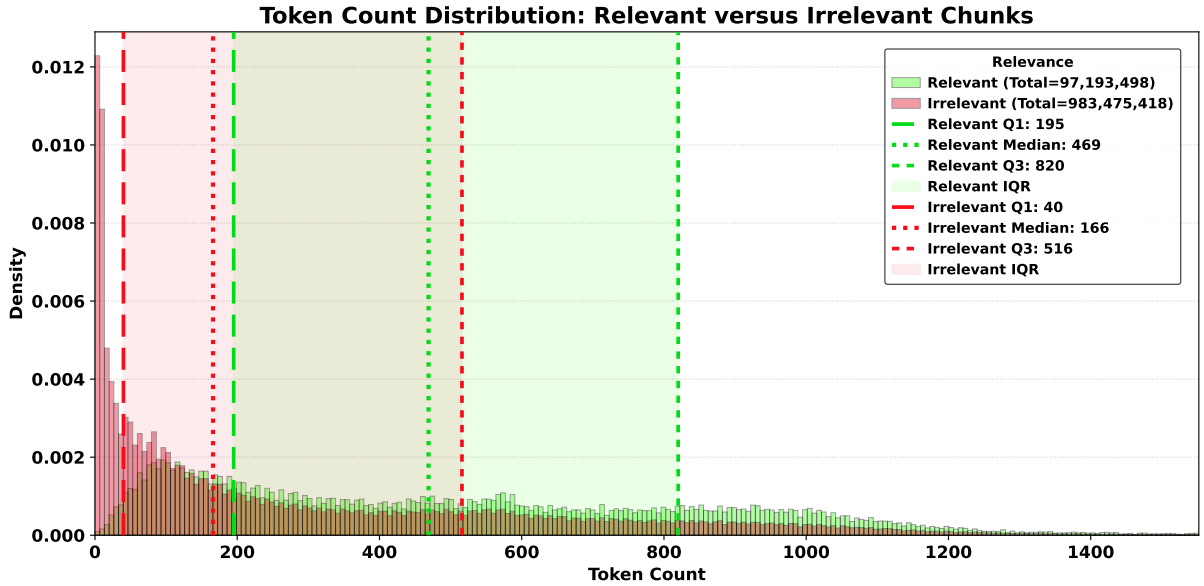

Figure 4: Token count distribution for relevant and irrelevant chunks in the FinAgentBench chunk-ranking split.

ity. The narrow IQR between Q1 and Q3 confirms that most queries target specific, focused information. This fine-grained relevance pattern requires retrieval models to discriminate precisely between relevant and irrelevant content within a vast corpus of financial documents.

A.6 EDA on FinanceBench

FinanceBench contains 150 questions grounded in documents across four types: 10-K (112), 10-Q (15), 8-K (9), and Earnings Transcripts (14), spanning 32 unique companies. These document types exhibit distinct lexical signatures and clearly different document structure: 10-K reports concentrate heavily on company- and industry-specific vocabulary, while Earnings Transcripts show the most diverse vocabulary, reflecting broader analyst Q&A session patterns. This intra-corpus diversity means that a retrieval strategy optimized for one document type may systematically underperform on others, underscoring the need for type-aware retrieval approaches. These differences informed the construction of our type-specific agent prompts; top keywords by document type are shown in Table 10.

Table 10 presents the top 6 keywords for each of the four document types in the corpus. The analysis reveals distinct lexical patterns. 10-K reports exhibit highly concentrated, company- and industry-specific vocabulary (98–99%), with terms such as *athletic* and *sport* reflecting sector specialization. 10-Q and 8-K filings show strong concentration (74–98%) with specialized financial and procedural terminology. Earnings Transcripts demonstrate the most diverse vocabulary (36–58%), with comparative terms such as *twentieth* and *recalculate*, reflecting the broader conversational patterns of analyst Q&A sessions. These distinct lexical profiles reinforce the need for retrieval strategies tailored to specific document types, and directly informed the construction of our type-specific agent prompts.

A.7 Candidate Refinement Module Details

Operating on L2-normalized embeddings, where cosine ranking coincides with Euclidean ranking on the unit sphere, we define the base distance between a query q and candidate c_i as

$$d(q, c_i) = \|\hat{e}_q - \hat{e}_{c_i}\|_2^2 = 2 - 2\,\hat{e}_q^\top \hat{e}_{c_i}, \quad (1)$$

and let $N(q, k_1)$ be the set of k_1 candidates with the smallest $d(q, \cdot)$. The *k-reciprocal* neighbor set keeps only mutual neighbors,

$$R(q, k_1) = \{\, c_i \in N(q, k_1) \mid q \in N(c_i, k_1) \,\}. \quad (2)$$

To recover true matches that fall just outside the top k_1 due to variation, we apply local expansion using a smaller neighborhood $k_2 = \lfloor k_1/2 \rfloor$, merging in a neighbor's reciprocal set only when the two sets overlap substantially,

$$R^*(q, k_1) = R \cup \bigcup_{\substack{c_j \in R \\ |R \cap R_j| \geq \frac{2}{3}|R_j|}} R_j. \quad (3)$$

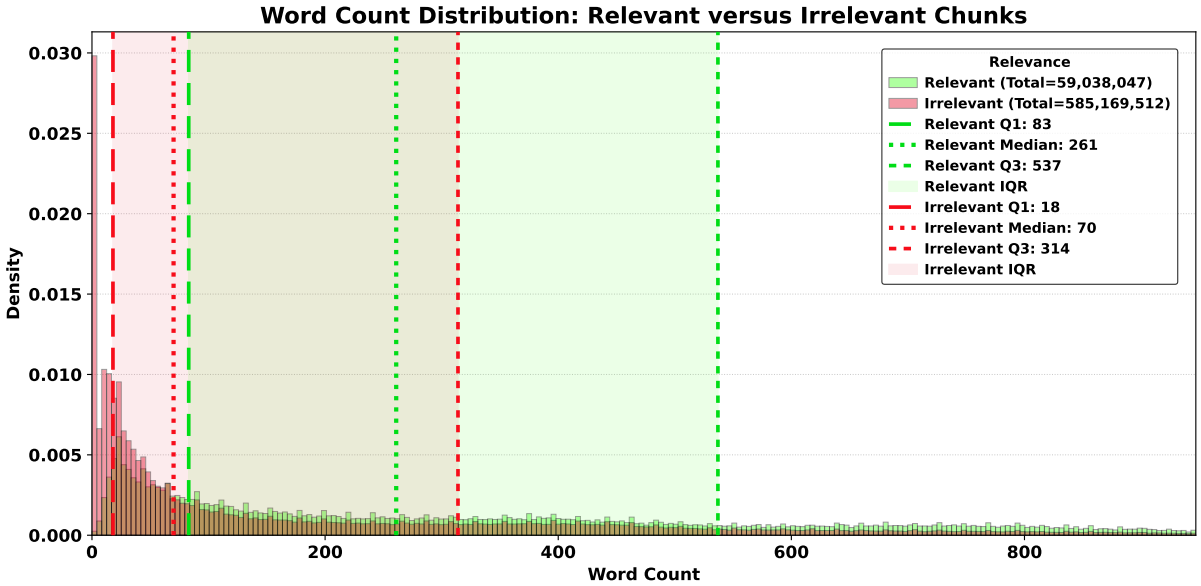

Figure 5: Word count distribution for relevant and irrelevant chunks in the FinAgentBench chunk-ranking split.

Table 10: Top 6 keywords by document type in FinanceBench; ratios show corpus-relative frequency.

10-K		10-Q		8-K		Earnings	
Keyword	**Ratio**	**Keyword**	**Ratio**	**Keyword**	**Ratio**	**Keyword**	**Ratio**
securely	99.00%	mun	98.61%	accession	96.55%	twentieth	58.90%
restatement	99.00%	min	85.71%	chargeable	80.00%	fragrance	43.33%
athletic	99.00%	noncompensation	83.13%	survivorship	77.27%	recalculate	42.31%
george	98.99%	aum	80.95%	abstain	77.27%	translational	40.24%
budgetary	98.99%	logged	80.77%	unbudgeted	74.36%	eighteenth	40.00%
sport	98.99%	nettable	80.00%	bailiwick	73.85%	shasta	36.21%

Writing $R \equiv R(q, k_1)$ and $R_j \equiv R(c_j, k_2)$ for brevity, each query/candidate is then encoded as a sparse vector over the candidate pool, where membership in R^* is softened into a Gaussian (exponential) weight so that nearer reciprocal neighbors count more,

$$V_{q,c_i} = \begin{cases} e^{-d(q,c_i)}, & c_i \in R^*(q, k_1), \\ 0, & \text{otherwise.} \end{cases} \quad (4)$$

The contextual distance between q and c_i is the Jaccard distance between their encoded neighbor vectors,

Table 11: End-to-end effect of the candidate-refinement module on FinAgentBench chunk ranking under PRISM settings. Cost and latency are per query.

Jina reranker v3	0.6497	0.7692	0.8209	0.4218	0.2244	0.3759

with $\lambda \in [0, 1]$, and candidates are re-sorted in ascending d^*.

Role of each variable. Equation (1)'s $d(q, c_i)$ is the direct semantic distance from the embedding model. The L2 normalization makes it order-equivalent to cosine similarity. The reciprocity condition $q \in N(c_i, k_1)$ in Eq. (2) is the core robustness mechanism: it discards candidates that lie near q but whose own neighborhoods do not contain q (e.g. hub passages that are generically close to everything), keeping only genuinely mutual matches. The two neighborhood sizes trade recall against precision:

- k_1 sets how many candidates are eligible as reciprocal neighbors. A larger k_1 admits more candidates (higher recall, more noise); a smaller k_1 is stricter (higher precision, risk of dropping true matches). Our implementation also allows an asymmetric query-side k_1, letting the query use a different neighborhood width from the candidates.
- $k_2 = \lfloor k_1/2 \rfloor$ controls local expansion (Eq. (3)); the $\frac{2}{3}$ overlap threshold guards against merging unrelated neighbor sets, so expansion recovers near-miss true matches without injecting noise.
- The exponential weighting in Eq. (4) converts hard set membership into soft weights, so the Jaccard overlap in Eq. (5) emphasizes the closest shared neighbors rather than treating all neighbors equally.
- λ in Eq. (6) balances the embedding/reranker score against neighborhood consensus: $\lambda \to 1$ trusts the direct distance alone, while $\lambda \to 0$ relies entirely on reciprocal-neighborhood overlap. Intermediate values let contextual consensus promote true positives that the

single-vector distance underranks.

Stage ordering. Because reranking and k-reciprocal encoding are independent operations, we ablate their composition to quantify the contribution of each and the effect of order. Results across FiQA-2018 and FinAgentBench (Appendix A.7.2 and Appendix A.8) show that the benefit of k-reciprocal encoding is dataset-dependent, motivating 3R's modular, swap-in design.

A.7.1 Embedding Backbone Selection

The retrieve stage is a dense retriever whose recall upper-bounds everything downstream. We compare text-embedding-3-small (TE3-S) against open dense, sparse, and late-interaction retrievers on FiQA-2018 and against Cohere embed-english-v3.0 and embed-v4.0 on FinanceBench, under identical pools and cutoffs. TE3-S attains the highest first-stage recall and ranking quality on FiQA (Appendix Table 12), and supplies the most consistent downstream QA accuracy across five LLM backbones on FinanceBench (Appendix Table 13). We therefore adopt it as the default first-stage retriever, since it generalizes across retrieval-centric and answer-centric tasks and across model families, so one backbone serves both paths.

A.7.2 Reranker Comparison and Selection

We compare Cohere rerank-v4.0-fast, ColBERTv2, BGE-M3 ColBERT, BGE reranker v2 m3, and Jina reranker v3 on the same TE3-S pool for FiQA-2018 (top-1000 of the 57.6K-passage corpus; Appendix Table 14) and FinAgentBench chunk ranking (Appendix Table 16). On FinAgentBench, refinement applies only to chunk ranking, since document ranking uses no embeddings and each query already arrives with a few hundred candidate chunks that the reranker compresses to the top $\leq$100. One pattern holds across both datasets: reranker quality is decisive and weak rerankers degrade performance. Only Cohere improves over the TE3-S first stage on both recall and ranking, raising FiQA Recall@100 from 0.7783 to 0.8115 and NDCG@10 from 0.5499 to 0.6258, and reaching the best reranker-only Recall@50 of 0.8725 and NDCG@5 of 0.5464 on FinAgentBench. The others generally fall below the embedding baseline on recall, pushing relevant candidates below the cutoff instead of promoting them. Reranker selection, not merely its presence, is the design decision, and we adopt Cohere as the default.

A.8 K-Reciprocal Encoding & Stacking Order

The refine stage, k-reciprocal encoding, is a geometric, training-free step that reorders candidates by mutual-neighborhood consensus rather than by new semantic signal. We study k-reciprocal alone, both stacking orders with each reranker (reranker$\rightarrow k$-recip and k-recip$\rightarrow$reranker), and how the benefit depends on corpus size.

On the large FiQA corpus (Table 19), k-reciprocal encoding is consistently beneficial when applied after a reranker, and the after order dominates the before order. It recovers recall that weaker rerankers discard, lifting Jina reranker v3 from 0.6497 to 0.7809 Recall@100, ColBERTv2 from 0.6690 to 0.7520, and BGE reranker v2 m3 from 0.7439 to 0.7896 while still adding to the strongest reranker, taking Cohere rerank-v4.0-fast from 0.8115 to the best overall 0.8326 Recall@100 (NDCG@10 0.6333). On a large pool with many near-neighbors, geometric consensus thus supplies complementary signal, disproportionately helping weak rerankers but still improving the strong one.

The picture inverts on FinAgentBench (Table 18). As each query is already paired with a few hundred topically related chunks that are filtered to $\leq$100, the candidate set is small and semantically homogeneous, leaving little geometric structure for k-reciprocal encoding to exploit. No stacking configuration exceeds the reranker-only Cohere rerank-v4.0-fast result (cf. Table 16), and stacking often harms it: applying k-reciprocal after Cohere rerank-v4.0-fast drops NDCG@5 from 0.5464 to 0.2829, as the geometric encoding reorders an already well-ordered, semantically tight set. The guidance is therefore corpus-dependent: stack k-reciprocal after a strong reranker for large, sparse corpora, but rely on the reranker alone for small, pre-filtered candidate sets, where the extra stage adds cost without accuracy gain.

Where the crossover is. Not a single number, but a measurable predictor: how much recall the upstream stage leaves behind. Across the rerankers in Tables 19 and 18, the gain from adding k-reciprocal falls monotonically as the upstream stage's own Recall@100 rises, as Table 17 shows. Two corpora cannot fix a threshold, but they do show what the threshold would be track-

Table 16: Reranker comparison on FinAgentBench chunk ranking.

Method	Recall@25	Recall@50	Recall@75	NDCG@5	MAP@5	MRR@5
Cohere rerank-v4.0-fast	**0.7850**	**0.8725**	**0.9088**	**0.5464**	**0.4070**	**0.7632**
BGE reranker v2 m3	0.5975	0.7600	0.8675	0.3211	0.2330	0.5197
BGE-M3 ColBERT	0.6500	0.7875	0.8838	0.3115	0.2155	0.5113
ColBERTv2	0.5825	0.7500	0.8675	0.2928	0.2053	0.5218
Jina reranker v3	0.7200	0.8250	0.8888	0.4508	0.3071	0.6692

ing. This is why the effect tracks corpus size, and it makes the guidance concrete rather than replacing it. FiQA's top-1000 pool is large and sparse, so a reranker still leaves relevant passages behind and k-reciprocal recovers some of them. FinAgentBench pairs each query with a few hundred topically related chunks already filtered to $\leq$100, where Cohere reaches Recall@50 $= 0.8725$ (Table 16) against Recall@100 $= 0.8115$ on FiQA (Table 14), so it is better covered at a tighter cutoff and has less headroom left. So the answer we can give is a test rather than a threshold: measure the upstream stage's recall at your operating cutoff, and add k-reciprocal only if it is leaving relevant candidates behind and a downstream ranker will re-order its output. Corpus size remains the right rule of thumb, and this is the quantity a practitioner can check directly on their own pool instead of guessing where the size boundary falls.

Table 17: The gain from adding k-reciprocal encoding declines monotonically as upstream recall rises. FiQA-2018 TE3-S top-1000 pool, Recall@100.

Upstream reranker	Recall@100 alone	+ k-recip	Gain
Jina reranker v3	0.6497	0.7809	+0.131
ColBERTv2	0.6690	0.7520	+0.083
BGE-M3 ColBERT	0.7270	0.7910	+0.064
BGE reranker v2 m3	0.7439	0.7896	+0.046
Cohere rerank-v4.0-fast	0.8115	0.8326	+0.021

When to add k-reciprocal encoding. Corpus size is the usual rule of thumb, but the quantity it tracks is directly measurable: how much recall the upstream stage leaves behind. Across the five rerankers on the same FiQA pool, the gain from adding k-reciprocal falls monotonically as the upstream stage's own Recall@100 rises, from +0.131 at 0.6497 (Jina v3) to +0.021 at 0.8115 (Cohere), passing through +0.083, +0.064, and +0.046 (Appendix Tables 19 and 18). FinAgentBench sits at the saturated end of that same relationship rather than in a separate regime: its chunk pools arrive filtered to $\leq$100 and Cohere reaches Recall@50 of 0.8725 there, so adding the stage instead drops reranker-only chunk NDCG@5 from 0.5464 to 0.2829. The guidance is therefore a test rather than a threshold: add k-reciprocal only if the upstream stage is still leaving relevant candidates behind at your operating cutoff and a downstream ranker will re-order its output. For FinAgentBench-like pre-filtered pools, use Cohere refinement alone, at the price of roughly 10 s of added latency per query.

A.9 Different Prompt Versions

The non-agentic prompt templates are designed for single LLM workflows, where the model independently performs the complete ranking process using structured system instructions. These prompts emphasize logical consistency, domain alignment, and interpretable reasoning. For document ranking, the progression moves from domain-guided heuristics to combined reasoning frameworks. For chunk ranking, prompts evolve from a pure ReAct framework to integrated multi-strategy approaches. Specifically, the prompt iterations are as follows:

- P_1: For document ranking, introduces domain-specific keyword hints and statistical cues to guide relevance assessment. For chunk ranking, employs a ReAct-style framework that interleaves internal reasoning with action steps, requiring the model to think step-by-step before outputting ranked indices.

- P_2: For document ranking, enhances P_1 with detailed statistical keyword associations (e.g., word frequency ratios per document type) to improve discriminative power. For chunk ranking, combines Chain-of-Thought (CoT), ReAct, and Tree-of-Thought (ToT) strategies, introducing multi-expert simulation where three analysts reason collaboratively and prune incorrect paths.

- P_3: Adopts a unified multi-strategy framework for both document and chunk ranking, integrating CoT decomposition, ReAct

alternation, and ToT multi-expert simulation. Emphasizes explicit step-by-step reasoning with domain-specific hints for financial concepts.

- P_4: Refines the P_3 framework with streamlined instructions and consistent terminology across document and chunk ranking tasks, maintaining the combined CoT, ReAct, and ToT reasoning strategies.

The prompts differ in a specific way: P_1 supplies domain keyword hints and statistical cues only, while P_2 to P_4 add a structured relevance scaffold combining CoT decomposition, ReAct alternation and ToT multi-expert simulation. P_4 is P_3 with streamlined instructions and terminology unified across the document and chunk stages, so the difference between them is consistency and output discipline, not length or verbosity.

Matched on model and ICL, GPT-5-mini at both stages with no exemplars, Table 20 reports the four prompts on both evaluation bases. The explanation therefore has two parts. The step that carries the effect is adding the scaffold: P_1 is the weakest of the four on both evaluation bases. Within the scaffolded set, P_4 is the strongest on the re-annotated set and within 0.0012 of the strongest on the original leaderboard, which is why it is standardized for the later experiments: it is the only prompt that is at or near the top on both bases, so it is the safest default rather than a large win. We state the claim at that strength, as reliability rather than as a per-prompt gap, which is also consistent with the observation that the best prompt form differs by benchmark.

We also make explicit a dependency that is easy to miss: chunk scores depend on the document stage, because the chunk ranker only sees chunks

from the documents the first stage selected. That is why prompt effects are discussed at the pipeline level rather than attributed to the chunk prompt alone.

Table 20: Prompt variants matched on model and ICL (GPT-5-mini at both stages, no exemplars), on both evaluation bases. Combined NDCG@5.

Prompt	Run	Re-annotated	Original private
P_1	2	0.75759	0.66628
P_2	9	0.76649	0.66774
P_3	12	0.76287	0.69019
P_4	13	0.77668	0.68895

The complete prompt templates for document ranking (Table 43) and chunk ranking (Table 44) are provided in Appendix A.19.

A.10 In-Context Learning Retrieval Details

The FAISS index is built offline from the training split: each query–document/chunk pair is embedded using OpenAI text-embedding-3-small, and all embeddings are stored with their ground-truth rankings. At inference time, the k nearest neighbors of the incoming query are retrieved by cosine similarity and formatted as ordered few-shot demonstrations prepended to the system prompt. The resulting prompt is therefore dynamic, adapting to the semantic characteristics of each user query rather than relying on a static template. ICL exemplar count k was varied from 5 to 15 in ablation experiments. Beyond $k = 5$, chunk ranking performance degraded due to context overload, whereas document ranking benefited from $k = 5$ shots with no gain from additional examples.

ICL retriever against candidate-refinement retriever. They are not redundant: the two share TE3-S as an embedding backbone but query different indexes and act at different points in the pipeline (Table 21). The distinction is visible empirically, because the two have opposite effects on the same stage. ICL improves document ranking but is not the default for chunk ranking, since exemplars consume the context chunk evidence needs. Candidate refinement shortens chunk input by shrinking the pool the LLM sees: on FinAgentBench chunk ranking, TE3-S to Cohere top-50 yields a higher observed NDCG@5 (0.63408 vs. 0.61278) and reduces cost from USD 0.2778 to USD 0.1813 per query (Appendix Table 11). One adds context, the other removes it, and the results follow that difference.

Table 21: The two retrievers in PRISM share an embedding backbone but query different indexes and act at different points.

	ICL retriever	Candidate-refinement retriever
Index queried	training-split exemplar store	document or chunk corpus for the current query
Output	few-shot demonstrations prepended to the prompt	candidates to be ranked
Changes the candidate set?	no	yes
Role	task adaptation	pool construction and context compression

A.11 Multi-Agent System Architecture Details

This section provides comprehensive implementation details for the Multi-Agent System (MAS) modeling architectures used in PRISM, including the document ranking workflow and four chunk ranking variants (A_1–A_4). All architectures are illustrated in Figure 7.

A.11.1 Agent Definitions

We adopt a state-graph framework implemented using LangGraph (LangChain, 2023), where each agent is an LLM instance with a specialized system prompt defining its role and scoring criteria. Document ranking employs a fixed configuration: a *Question Analyzer* that extracts key entities and intent from the query, followed by five *Document Expert* agents (one per SEC filing type: 10-K, 10-Q, 8-K, DEF 14A, and Earnings Transcripts) that score documents based on domain-specific relevance criteria. For chunk ranking, we define specialized agents including: *Financial Analyst* (evaluates quantitative metrics and financial data), *Risk Analyst* (assesses operational and regulatory risks), *Evidence Extractor* (identifies concrete supporting facts), *Contextual Reasoner* (evaluates explanatory content), and filtering agents such as *Quick Filter* and *Noise Remover*.

A.11.2 Interaction Process

Agents communicate through a shared state graph where each node represents an agent and edges define information flow. In a typical workflow: (1) input chunks are passed to filtering agents that assign preliminary relevance scores; (2) filtered candidates flow to scoring agents that independently evaluate chunks on a 1–10 scale based on their specialized criteria; (3) scores are aggregated through weighted averaging or voting to produce final rankings. The graph topology determines whether agents operate in parallel (simultaneous scoring) or sequentially (pipeline filtering). All agent prompts are provided in Table 46.

A.11.3 State Management and Information Flow

All MAS architectures maintain a shared state graph implemented through LangGraph's StateGraph abstraction. Information flows through the graph according to predefined edges connecting agent nodes. Parallel agents (e.g., scoring agents in A_1) execute simultaneously without inter-agent communication, reducing coordination complexity. Sequential pipelines (A_2, A_3) enforce strict ordering where downstream agents only receive filtered candidates from upstream stages, creating potential bottlenecks if early filtering is overly aggressive. The state contains the input data, intermediate outputs, and aggregated results.

A.11.4 Run-Level Findings and Deployment Implications

After defining the document agents, chunk-ranking variants, and LangGraph information flow above, we summarize how these MAS designs behave empirically. The ablations show that agentic workflows are constrained by model capacity and graph depth. With GPT-4o-mini, deeper chunk-ranking pipelines perform poorly: A_2 reaches 0.51994 combined NDCG@5 (Run 22) and A_3 reaches 0.52031 (Run 24), indicating that filtering and scoring errors compound across sequential stages. Scaling the same A_3 design to GPT-5-mini raises combined NDCG@5 to 0.72353 (Run 25), showing that MAS requires sufficiently capable agents to maintain coherent intermediate outputs.

Hybrid workflows further clarify where MAS is useful. Configurations that keep agentic reasoning at the document level but use a non-agentic chunk ranker perform strongly, reaching 0.77104 (Run 35) and 0.78157 (Run 36). This supports the deployment recommendation in the main text: use MAS selectively for coarse document-level routing or reasoning, but prefer simpler single-model or lightly coordinated designs for chunk ranking, where latency, token cost, and false-negative filtering risk are higher.

A.11.5 Document Ranking Workflow

The document ranking workflow (Figure 7a) follows a two-stage architecture designed to handle heterogeneous financial document types with specialized domain expertise. The workflow begins with a *Question Analyzer* agent that processes the user query to extract key entities and classify the query relevance to the corresponding agents' expertise. This structured analysis is then distributed to five parallel *Document Expert* agents, each specialized in a specific SEC filing type:

- 10-K Expert: Evaluates annual reports, focusing on comprehensive financial statements, business operations, and risk factors disclosed in Form 10-K filings.
- 10-Q Expert: Assesses quarterly reports, prioritizing interim financial performance, management discussion and analysis (MD&A), and quarterly updates.
- 8-K Expert: Analyzes current reports for material events, corporate announcements, and time-sensitive disclosures.
- DEF14A Expert: Reviews proxy statements for governance information, executive compensation, and shareholder proposals.
- Earnings Transcript Expert: Evaluates earnings call transcripts for management commentary, forward guidance, and analyst Q&A insights.

Each document expert scores documents on a 0–4 scale based on relevance to the analyzed query intent. Scores are then aggregated through weighted averaging, where weights are determined by document type relevance to the query category provided by the question analyzer. This parallel scoring approach ensures domain-appropriate evaluation while maintaining computational efficiency, as document experts operate simultaneously without sequential dependencies.

A.11.6 Chunk Ranking Workflow Variants

The chunk ranking workflows (Figures 7b–7e) represent four architectural variants with progressively simplified designs, each exploring different trade-offs between reasoning depth, error propagation, and computational cost.

A_1: Direct Scoring Ensemble (Figure 7b) implements a single-stage parallel scoring approach with four domain-expert agents operating simultaneously:

- *CEO Agent*: Evaluates strategic relevance and high-level business implications.
- *Financial Analyst*: Assesses quantitative metrics, financial ratios, and numerical evidence.

- *Operations Manager*: Focuses on operational details, business processes, and execution aspects.
- *Risk Analyst*: Identifies risk factors, uncertainties, and potential adverse impacts.

Each agent independently scores all candidate chunks on a 1–10 scale according to its specialized criteria. Final rankings are determined through simple averaging of the four scores. This architecture minimizes pipeline depth to reduce error accumulation and analyzes chunks from different perspectives.

A_2: Three-Stage Deep Pipeline (Figure 7c) implements the most complex workflow with three sequential stages designed for sequential filtering and specialized evaluation:

1. Noise Removal Stage: A *Noise Remover* agent filters out clearly irrelevant chunks (boilerplate text, legal disclaimers, table fragments) to reduce downstream computational burden.
2. Candidate Selection Stage: A *Candidate Selector* agent performs secondary filtering, retaining only chunks with potential relevance based on keyword matching and semantic proximity.
3. Ensemble Scoring Stage: Four specialized agents score the filtered candidates:
    - *Relevance Scorer*: Direct query-chunk semantic alignment.
    - *Contextual Reasoner*: Evaluates explanatory content and contextual completeness.
    - *Evidence Extractor*: Identifies concrete supporting facts and data points.
    - *Diversity Agent*: Ensures ranking diversity to avoid redundant information.

While this deep architecture aims to progressively refine candidates, our experiments reveal it suffers from over-filtering and cascading errors, where early-stage false negatives cannot be recovered in later stages, leading to degraded recall performance.

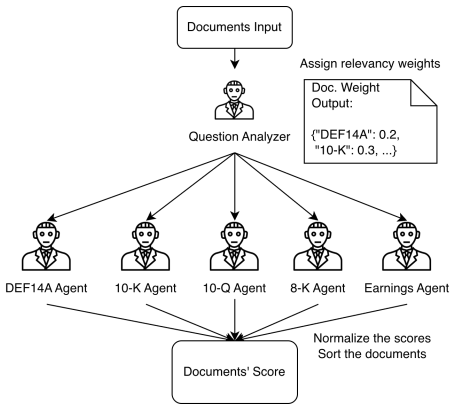
A_3: Two-Stage Balanced Pipeline (Figure 7d) simplifies A_2 by reducing to two stages while maintaining filtering benefits:

1. Quick Filtering Stage: A *Quick Filter* agent performs lightweight relevance assessment, applying looser thresholds than A_2's Noise Remover to preserve recall.
2. Specialized Scoring Stage: Three focused agents evaluate filtered chunks:
    - *Relevance Scorer*: Query-chunk alignment assessment.
    - *Contextual Reasoner*: Contextual adequacy and explanatory quality.
    - *Evidence Extractor*: Concrete evidence identification.

This architecture balances pipeline depth with stability, reducing error propagation risks while maintaining some computational efficiency gains from preliminary filtering.

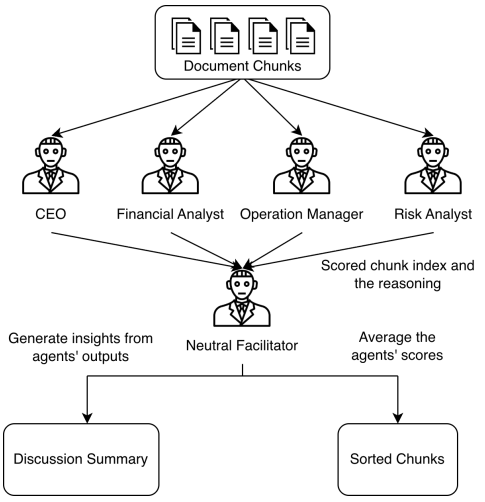
A_4: Minimal Two-Agent System (Figure 7e) represents the simplest viable MAS configuration with direct parallel scoring by two complementary agents:

- *Financial Analyst*: Focuses on quantitative evidence and financial metrics.
- *Risk Analyst*: Evaluates qualitative risk factors and uncertainties.



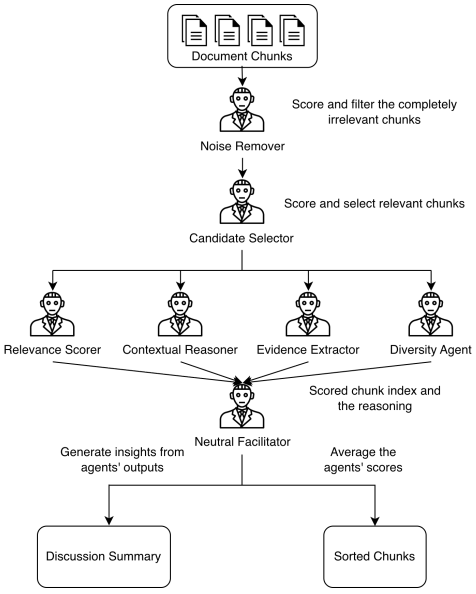
By eliminating filtering stages and reducing agent count, it minimizes interaction complexity and error propagation pathways. This minimalist design performed comparably to or better than deeper architectures in our experiments, as reduced error propagation outweighs ensemble benefits.

A.11.7 Prompt Engineering for Agent Roles

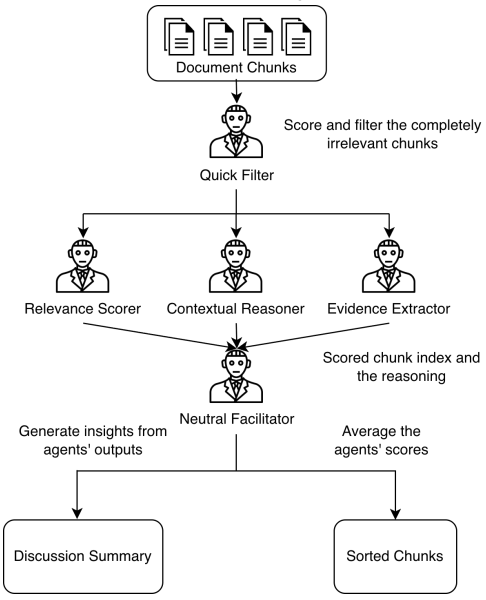


Each agent receives a specialized system prompt defining its role, evaluation criteria, and output format. For document ranking, expert prompts specify document-type-specific relevance factors. For chunk ranking, scoring agents receive detailed rubrics mapping scores 1–10 to specific evidence characteristics. Filtering agents use binary decision criteria with explicit instructions to prefer recall over precision. All agent prompts are provided in Table 45 and Table 46.

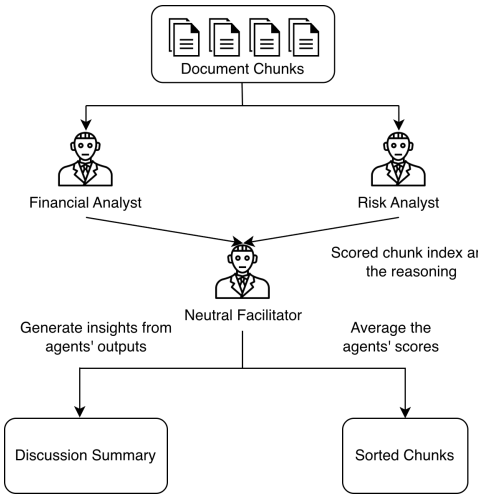
A.11.8 Aggregation and Ranking Logic



Score aggregation varies by architecture. Simple averaging is used in chunk ranking where all agents have equal weight. In document ranking, we implement weighted averaging where weights



(a) Document ranking workflow



(b) A_1: Direct scoring ensemble

(c) A_2: Three-stage deep pipeline

(d) A_3: Two-stage balanced pipeline

(e) A_4: Minimal two-agent system

Figure 7: Multi-Agent System architectures for PRISM. (a) Document ranking workflow. (b)–(e) Chunk ranking variants.

reflect agent reliability and query-dependent relevance. Final rankings are produced by sorting candidates by aggregated score in descending order, with ties broken by original retrieval rank.

A.12 Implementation Details

A.12.1 Model Provider Selection

Experiments used an Azure-hosted API deployment for enterprise access control and reproducibility, with all models accessed through the Azure ecosystem. This deployment setting motivated our focus on OpenAI GPT models as the closed-source model family, while the open-source models assess PRISM's generalizability beyond a single model family. Beyond operational accessibility, OpenAI's models remain among the most benchmarked proprietary LLMs on financial tasks (Bigeard et al., 2025), offering strong reliability as a baseline. The exact versions of the eight foundation models used in our experiments are provided below:

1. GPT-4o-mini: gpt-4o-mini-2024-07-18
2. GPT-4.1: gpt-4.1-2025-04-14
3. GPT-5-mini: gpt-5-mini-2025-08-07
4. GPT-5: gpt-5-2025-08-07
5. DeepSeek-V4-Flash
6. gpt-oss-120b
7. grok-4-20-reasoning
8. Llama-4-Maverick-17B-128E-Instruct-FP8

The retrieval pipeline was implemented using a FAISS vector store with two OpenAI embedding backbones: text-embedding-3-small (TE3-S) and text-embedding-3-large (TE3-L). Multi-agent workflows were constructed with LangGraph (v1.0.3), and all models were accessed through the OpenAI Python SDK (v2.3.0).

A.12.2 LangGraph Selection

LangGraph was selected to manage multi-agentic workflows due to its modular design, strong community support, and active maintenance. As a widely adopted framework, it provides a stable and extensible foundation for orchestrating complex agent interactions with precise control over information flow. Its high degree of customizability enables flexible integration with diverse tools, APIs, and models, making it adaptable to various use cases. Additionally, its emphasis on maintainability and observability supports both rapid prototyping during development and scalable deployment in production. These factors make LangGraph a suitable choice for orchestrating complex MAS financial reasoning pipelines while ensuring long-term sustainability in both research and applied settings.

A.12.3 Prompt Selection in Agentic Workflow

We fixed the prompt version to P_1 for both chunk- and document-ranking tasks in all agentic workflow experiments to ensure controlled and interpretable results. This allowed us to isolate the effects of architectural modifications, ensuring that any performance differences could be attributed to changes in agent coordination rather than confounded by prompt variation. Furthermore, system prompts in a multi-agent setup serve distinct roles across agents, and later prompt versions contain more complex instructions that do not generalize well across heterogeneous agent responsibilities. For example, in Run 32, performance deteriorated when applying the P_4 prompt to the document-ranking task, as the increased reasoning complexity introduced confusion among agents. Similarly, attempting to use P_4 for chunk-ranking tasks in the hybrid workflow revealed practical constraints as the expanded prompt frequently exceeded token limits due to the large chunk sizes. For these reasons, we maintained a consistent and lightweight prompt configuration while experimenting with different agentic architectures, ensuring comparability, scalability, and clarity in performance attribution. This setup introduces a prompt asymmetry, since most agentic experiments use P_1 while the best non-agentic result uses P_4. That asymmetry is why the paper's multi-agent conclusion does not rest on those runs: Runs 33 and 34 apply P_4 under A_4 and are matched to non-agentic controls on prompt, model, and exemplars, so the comparison in Section 5.3 isolates architecture. Run 32, which is P_4 on document and P_1 on chunk, is prompt-mismatched and is excluded from that analysis.

A.13 Quantitative Results

A.13.1 FinAgentBench

Full per-run grid. Table 23 is the complete configuration grid, moved here from the main text so that the main narrative carries only the decision-

7	Gautam Jajoo	0.69774	N/A	N/A
8	RagTag	0.69173	N/A	N/A
9	ART YOUNG	0.69162	N/A	N/A
10	liangjiang chen	0.69081	N/A	N/A

[†]Score from the submission selected during the competition. Our best observed score across repeated runs of the same configuration (Run 19) is 0.71818 (Appendix A.15).

relevant comparisons. All NDCG@5, MAP@5, and MRR@5 values in it are on the re-annotated basis (Section 3.1); leaderboard-basis scores for the subset of configurations that have them are in Table 5. Runs 37–40 are post-competition runs and exist on the re-annotated basis only.

Table 22 reports the final private-subset leaderboard rankings. The top three methods show a small performance gap relative to the remaining teams. The memex team's solution employed a pool-of-experts of five different LLMs for prefiltering and 65 agents for chunk retrieval and reranking, with an embedding model fine-tuned for 30 epochs on FinAgentBench training data. The second-ranked Yuzhen Hu team's solution used three MiniLM models fine-tuned separately for document retrieval, chunk retrieval, and cross-encoder reranking. In contrast, PRISM is training-free and relies on off-the-shelf LLMs with engineered prompts and lightweight multi-agent coordination. The performance gap between PRISM and the top two fine-tuned approaches ($\Delta \approx 0.005$–0.007 NDCG@5 on the private subset) is modest and reflects the expected trade-off of forgoing task-specific fine-tuning.

A.13.2 FiQA-2018

Table 26 reports the traditional baselines, and Table 27 provides the full FiQA model-by-prompt breakdown, including zero-shot and ICL results.

Examining the prompt design progression reveals nuanced performance patterns. P_1, which employs a straightforward prompting strategy, establishes a strong baseline with GPT-5 achieving 0.6130 NDCG@10 and 0.8045 Recall@100. P_2, which integrates key contextual information, demonstrates comparable performance of 0.6095 NDCG@10 and 0.8094 Recall@100 with GPT-5, suggesting that additional context maintains effectiveness while potentially offering enhanced interpretability. P_3, which utilizes Chain-of-Thought (CoT) reasoning, achieves the highest NDCG@10 of 0.6197, indicating that structured reasoning particularly benefits ranking precision at top positions. Interestingly, P_4, which refines P_3 with streamlined instructions and stricter output formatting while maintaining the combined CoT, ReAct, and ToT strategies, shows slightly lower performance of 0.6070 NDCG@10, suggesting that its more constrained output structure is less well aligned with FiQA's passage reranking format than P_3's more expressive reasoning scaffold.

The impact of ICL varies significantly by model capability, revealing important insights for practical deployment. ICL proves particularly beneficial for models with more limited reasoning capabilities, as evidenced by GPT-4.1's consistent performance gains across all prompts (e.g., 23.5% improvement in NDCG@10 for P_1). This occurs because ICL provides concrete demonstrations of task structure and expected reasoning patterns, effectively compensating for limited inherent reasoning capacity. In contrast, GPT-5 shows only marginal variation with ICL (ranging from small declines to small gains depending on prompt), while GPT-5-mini is consistently hurt by ICL on FiQA (e.g., P_1: 0.5565 to 0.5171, P_4: 0.5269 to 0.4615), suggesting that for capable models the in-context examples consume context budget without providing proportional guidance benefit on this passage-level task. This differential ICL sensitivity suggests that smaller or less capable models can be substantially enhanced through careful example selection, while more advanced models require task-specific validation before activating ICL.

The open-source model evaluations using P_4 further validate PRISM's generalizability beyond a single model family. All four models substantially outperform the BM25+CE baseline under both zero-shot and ICL-5 conditions, with NDCG@10 ranging from 0.552 to 0.583, trailing GPT-5 by a modest margin. Notably, gpt-oss-120b achieves the strongest open-source result of 0.5833 NDCG@10 under ICL-5, approaching the performance of GPT-5-mini. The effect of ICL across these models is consistent but marginal, with ICL-5 yielding small improvements over zero-shot across all four models, suggesting that they already possess sufficient instruction-following capacity to perform the reranking task without extensive demonstration examples. The relatively uniform performance across architecturally diverse models, spanning mixture-of-

Table 23: Ablation studies of document and chunk ranking configurations across different workflows, scored against our re-annotated evaluation set. Run 19 is shown in bold because it is the configuration submitted during the competition, not because it is the highest-scoring run here.

experts, dense, and reasoning-specialized designs indicates that PRISM's prompt-driven approach is robust to underlying model architecture.

Overall, all PRISM configurations maintain higher Recall@100, with GPT-5 results consistently near or above 0.80, demonstrating strong retrieval coverage, while improvements in NDCG@10 highlight enhanced precision in ranking highly relevant documents at top positions, a critical capability for practical information retrieval systems.

A.13.3 FinanceBench

Table 28 summarizes the oracle setting, and Table 29 provides the full FinanceBench evaluation-mode breakdown and open-source model comparison.

An important observation emerges regarding prompt complexity and task alignment. While P_4 shows slightly lower performance in reranking tasks, it maintains competitive performance in QA settings, with GPT-5 Oracle achieving 97.33% accuracy (146/150). This suggests that optimal prompt design is indeed task-dependent, as we observed in the reranking experiments. Simpler prompts (P_1) often match or exceed more complex variants, indicating that the structured reasoning scaffolding beneficial for nuanced ranking decisions may be less critical for direct factual retrieval tasks inherent to question-answering.

The limited utility of ICL in FinanceBench can be attributed to its task-specific characteristics, in contrast to its more substantial benefits in reranking tasks. FinanceBench queries require finding specific answers within individual documents rather than comparing multiple candidates, making similarity-based ICL selection less effective at retrieving truly relevant question-answer exemplars. This can produce ICL examples that misdirect rather than guide the model, explaining why non-ICL configurations often perform comparably or better. Nevertheless, despite the limited dataset size (150 questions) and the already high baseline performance of up to 96% accuracy, PRISM achieves measurable improvements, demonstrating its effectiveness across different task types beyond reranking. While the absolute gains are necessarily constrained in such a high-performing regime approaching the theoretical ceiling of 100%, PRISM's ability to push accuracy toward 98% supports its versatility as a general-purpose framework for LLM-based information retrieval tasks.

Table 24: Fine-grained document, chunk and total scores for every configuration. Run IDs correspond to Table 23; Run 19 is bolded as the competition-submitted configuration.

The open-source model evaluations under Oracle conditions using P_4 provide further evidence of PRISM's generalizability. gpt-oss-120b achieves the strongest open-source result at

145/150 (96.7%) with ICL, closely matching the best GPT-5 prompt variants and surpassing the GPT-5 oracle baseline. grok-4-20-reasoning similarly performs strongly at 143/150 (95.3%) with ICL, confirming that PRISM's prompt-driven approach transfers effectively across model families. The ICL effect is more pronounced for these models on FinanceBench than on FiQA: grok-4-20-reasoning gains substantially from ICL (143 vs. 126), while gpt-oss-120b shows a modest improvement (145 vs. 142), suggesting that structured financial QA generally benefits more from demonstration examples than open-ended reranking does. DeepSeek-V4-Flash shows a larger ICL benefit (125 vs. 112), though its overall accuracy remains lower than that of the stronger open-source models. The notable exception is Llama-4-Maverick-17B-128E-Instruct-FP8, which achieves only 86/150 with ICL and 70/150 zero-shot, suggesting that this model requires additional adaptation or fine-tuning to handle the precise numerical and financial reasoning demands of FinanceBench effectively.

A.14 Feasibility Analysis

No prior work on FinAgentBench reports latency or cost, so these are the first such baselines. Run 19 has median latencies of 10 s for document ranking and 131 s for chunk ranking, at per-query token costs of $0.0155 and $0.2768 (per-run statistics in Appendix Table 30, distributions in Appendix Figures 8 and 9). Chunk ranking dominates resource use because of its token-heavy context, which makes candidate-pool control the effective cost lever: a Cohere-refined top-50 pool cuts chunk-ranking cost by about 35% ($0.278 to $0.181 per query) with no retraining, and refinement itself is cheap, since k-reciprocal and the open rerankers run locally and Cohere adds under $0.01 per query (Appendix Tables 31 and 33). For cost-sensitive deployments, GPT-5-mini configurations trade moderate NDCG@5 for much lower cost; full breakdowns are in Appendix A.14.

Reproducibility. Repeated private-subset submissions show low stochastic variance (CV $< 1.6\%$), with Run 19 the most stable high-performing configuration (mean 0.71163, SD 0.00433 over nine runs, leaderboard basis). Welch tests (Welch, 1938) against Run 12 are significant for Runs 15, 18, and 19, so those gains exceed run noise. Query-level uncertainty on the re-annotated basis is quantified separately by the paired bootstrap of Appendix A.15.4; full statistics for all repeated runs are in Appendix A.15.

A.14.1 Cost Analysis

FinAgentBench. In Table 30, we report the full set of statistics for the runs selected in our feasibility analysis, covering all prompt variants and the ICL-5/TE3-S configuration within the non-agentic workflow. Additionally, we assess the practical feasibility of the proposed approach by analyzing the cost distribution across the selected runs. Document ranking tasks consistently incur low total costs (up to about $3.1), reflecting their modest inference requirements. In contrast, chunk ranking tasks dominate the overall expenditure, with total costs ranging from $4.7 to $56.6, depending on input size and reasoning depth. Combined task runs follow the same pattern, as their total costs are primarily driven by chunk ranking computations. The highest combined costs occur for Runs 19, 39, and 15 ($58.5, $58.2, and $57.9, respectively), whereas earlier runs such as Runs 2 and 9 remain significantly more economical ($5) when using smaller models. These results confirm that document-level ranking remains cost-efficient, while chunk ranking incurs substantially higher costs due to its larger context size, remaining the dominant contributor to overall expenditure. Table 31 reports the corresponding figures for the candidate-refinement module, separating the component stages (Table 31a) from the end-to-end pipelines (Table 31b).

FiQA-2018. Table 32 presents a comprehensive computational cost analysis across all prompt variants and models on the FiQA-2018 dataset, and Table 33 reports the same statistics for the candidate-refinement stages (Table 33a) and pipelines (Table 33b). GPT-5-mini emerges as a compelling choice for production deployment within the PRISM framework. GPT-5-mini achieves performance between GPT-4.1 and GPT-5 (e.g., P_1: 0.5565 NDCG@10) while incurring substantially lower operational costs of approximately $21, compared to $142 for GPT-4.1 and $88 for GPT-5 under the same setting. This represents roughly a 4$\times$ cost reduction compared to GPT-5 with only an 8–10% performance trade-off, making GPT-5-mini a practical balance point for production systems where both performance and cost efficiency are critical considerations. Furthermore, GPT-5-mini has lower total runtime (38.63Ks) and per-query latency (59.61s) than GPT-4.1 (71.70Ks, 110.65s) and GPT-5 (51.17Ks, 78.97s) in that configuration.

An interesting cost-performance paradox emerges when comparing GPT-5 to GPT-4.1. Despite being the more advanced model, GPT-5 consistently delivers superior performance (0.6130 vs. 0.4307 NDCG@10 for P_1 without ICL) while maintaining lower operational costs ($88 vs. $142). This counterintuitive result stems from GPT-5's substantially lower per-token pricing rather than from a straightforward capability-cost relationship: although GPT-5 generates approximately twice as many completion tokens as GPT-4.1, its lower per-token rate more than compensates for the higher token count. Additionally, GPT-5's faster processing time suggests better end-to-end throughput. We note that API pricing is a commercial decision that does not always track computational overhead, and these cost patterns may shift as pricing evolves. Nonetheless, at the time of our experiments, GPT-5 represents a compelling choice for organizations prioritizing both performance and cost efficiency.

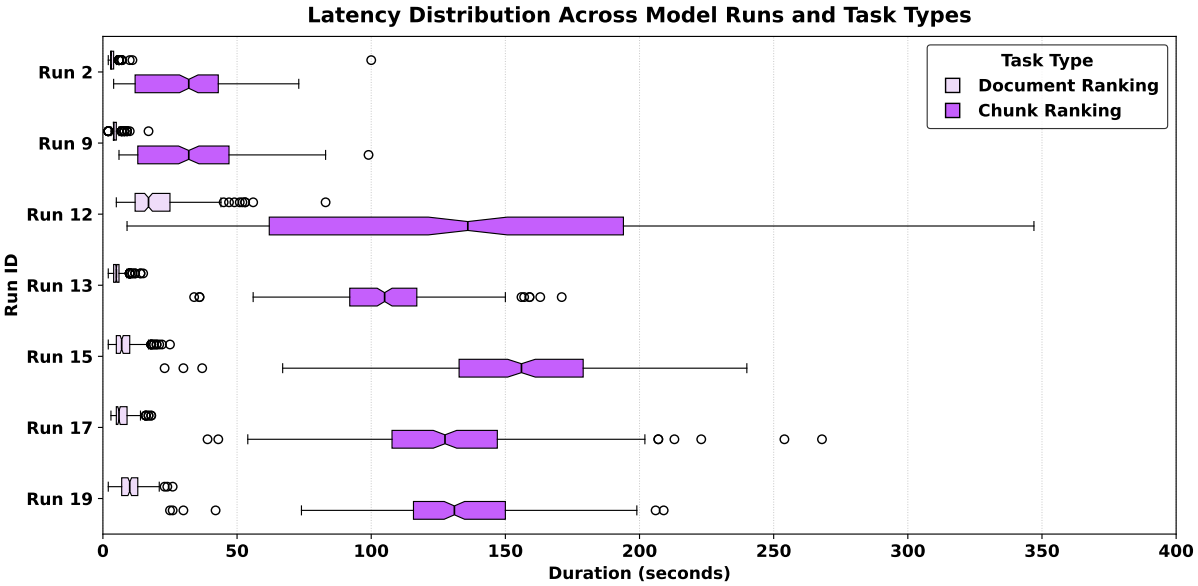

Figure 8: Latency distribution box plots, where each box shows how the latency varies across runs with different LLMs and configurations. For chunk ranking tasks, we observe that P_3 (Run 12) has the highest median latency for both tasks due to its heavy reasoning prompt design, while P_4 (Runs 13–19) achieves a good balance between latency and performance.

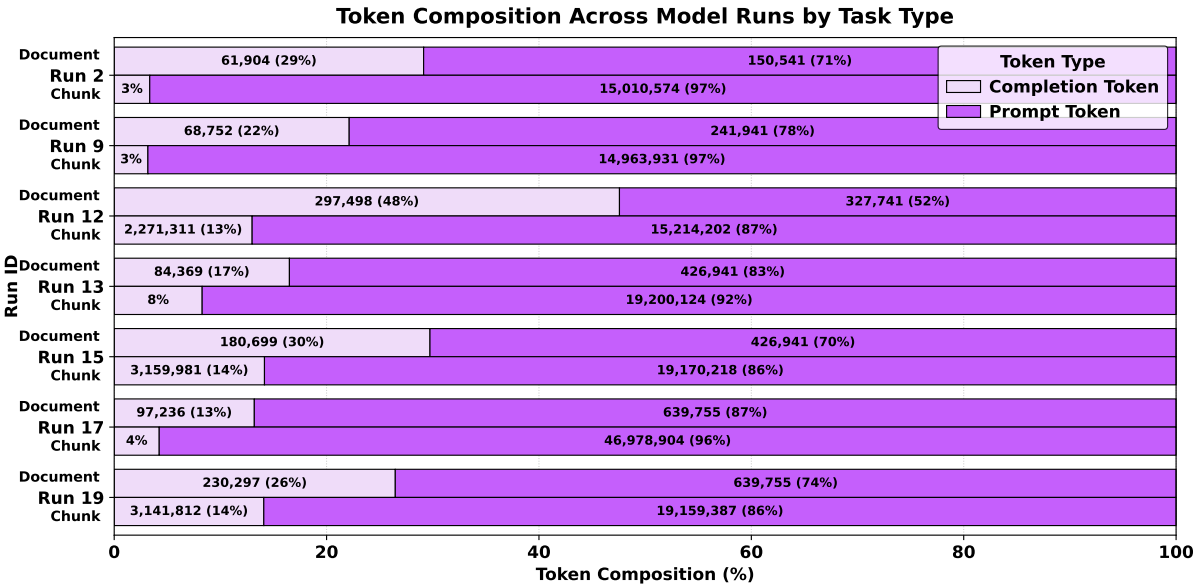

Figure 9: Token distribution bar charts, where each bar details the proportion of prompt and completion token usage across different runs and tasks, highlighting that chunk ranking tasks use more prompt tokens due to longer context and complexity.

The open-source models on FiQA-2018 show substantial variation in both cost and latency that does not map cleanly to ranking quality. grok-4-20-reasoning incurs the highest cost at approximately $155 with ICL, exceeding even GPT-4.1 ($148), yet delivers only moderate NDCG@10 of 0.5741, while also being the slowest option at roughly 55 seconds per query. In contrast, Llama-4-Maverick-17B-128E-Instruct-FP8 achieves the lowest cost at $13.50 with ICL and an NDCG@10 of 0.5581, representing a roughly 8× cost reduction compared to GPT-5 with about an 8.5% performance gap under the same P_4 ICL setting, together with a lower latency of about 38 seconds per query. DeepSeek-V4-Flash and gpt-oss-120b occupy a middle ground at approximately $69 and $66 respectively with ICL, with gpt-oss-120b achieving slightly stronger NDCG@10 (0.5833 vs. 0.5778) at a comparable cost, albeit with higher latency (41.23s vs. 25.61s).

Table 30: Latency, token usage, and cost statistics for different runs used in feasibility analysis on FinAgentBench.

Table 31: Latency, token usage and cost for the candidate-refinement module on FinAgentBench chunk ranking. Cost is API cost: local rerankers and k-reciprocal incur no API cost, while commercial rerankers are counted where used. (a) Component stages emit no LLM completion tokens. (b) End-to-end pipelines pass the refined pool to P_4/GPT-5 with ICL-5 and report both prompt and completion tokens.

(a) Component stages on the TE3-S pool (retrieval, reranking, and k-reciprocal encoding; no completion tokens).

Table 33: Latency, token usage and cost for the candidate-refinement module on FiQA-2018. Cost is API cost: local rerankers and k-reciprocal incur no API cost, while commercial rerankers are counted where used. (a) Component stages emit no LLM completion tokens. (b) The end-to-end pipeline passes the refined pool to GPT-5 and reports both prompt and completion tokens.

(a) Component stages on the TE3-S pool (embedding, reranking, and k-reciprocal encoding; no completion tokens).

Method	Total Prompt Tokens (M)	Total Time (Ks)	Time Per Query (s)	Total Cost (USD)

FinanceBench. Table 34 presents comprehensive computational cost analysis across all prompt variants, models, and evaluation modes on the FinanceBench dataset. Single Store and Shared Store modes consistently incur minimal costs that are below $0.50 for all models, reflecting their limited prompt token requirements. In contrast, In Context mode dominates the overall expenditure, with costs ranging from $2.73 to $25.53 depending on the model, primarily driven by the extensive prompt token requirements needed to embed full document context within the prompt. Oracle mode occupies a middle ground with costs between $0.08 and $2.87, as it requires moderate context to provide relevant passages without full document inclusion.

Model selection significantly impacts cost-performance trade-offs. Among closed-source models, GPT-5-mini emerges as the most cost-efficient option across all evaluation modes, with Oracle mode costing $0.28–$0.44 compared to $2.00–$2.87 for GPT-5 and $0.54–$1.08 for GPT-4.1 under similar conditions. Despite this large cost advantage, GPT-5-mini maintains strong performance, matching or approaching GPT-5 accuracy across most configurations. GPT-5, while incurring higher costs, consistently outperforms other models in most configurations. GPT-4.1 exhibits the least favorable cost-performance profile, with comparable costs to GPT-5 in some settings but consistently lower accuracy.

Prompt complexity introduces additional computational overhead with varying returns. The straightforward prompt P_1 achieves strong cost-efficiency, maintaining low completion token generation while delivering competitive performance. More complex prompts like P_4 generate substantially more completion tokens, increasing costs without proportional performance gains in most evaluation modes. In In Context mode, ICL slightly reduces GPT-5 completion token generation, but the added prompt tokens leave total cost roughly unchanged or marginally higher overall.

Processing time analysis reveals GPT-4.1 as the fastest model in Single Store and Shared Store modes but shows significant variability in other modes. GPT-5 and GPT-5-mini show consistent processing times across different modes, with GPT-5-mini being slightly faster. These results confirm that for production deployment on QA tasks, the In Context mode carries a substantial cost premium that makes it impractical for large-scale applications despite marginal performance benefits. GPT-5-mini with simpler prompts offers a practical balance of accuracy, cost, and latency.

The open-source models evaluated on FinanceBench under Oracle conditions show clear cost-accuracy-latency trade-offs relative to proprietary alternatives. gpt-oss-120b achieves the strongest open-source accuracy (96.67%) at a total cost of $0.08 with ICL, representing over a 25× cost reduction compared to GPT-5 Oracle ($2.09) while maintaining low latency of about 3.13 seconds per query. Llama-4-Maverick-17B-128E-Instruct-FP8 similarly incurs only $0.11 with ICL and remains fast at 2.57 seconds per query, though its substantially lower accuracy (57.33%) limits its practical viability for financial QA. grok-4-20-reasoning presents a different trade-off: it achieves strong accuracy (95.33%) but at a higher cost of $1.07 with ICL and much longer latency of 10.78 seconds per query, yielding less favorable efficiency than gpt-oss-120b. DeepSeek-V4-Flash occupies a middle ground at $0.57 with ICL, moderate accuracy (83.33%), and relatively low latency (2.12s), making it a reasonable option when proprietary models are too costly but stronger accuracy than Llama-4-Maverick-17B-128E-Instruct-FP8 is still needed. Overall, gpt-oss-120b offers the strongest open-source balance among accuracy, cost, and latency for this setting.

A.15 Reproducibility Analysis

Tables 35 and 36 summarize the descriptive statistics and significance tests done on the competition private subset. The following subsections detail the statistical methodology used to derive these results and provide the full set of per-run scores used in the significance experiments.

Table 35: Descriptive statistics across multiple runs.

Run ID	n	Mean	SD	CV (%)	CI-Low	CI-High
12	5	0.68005	0.01023	1.50489	0.66734	0.69276
15	4	0.70246	0.00661	0.94078	0.69194	0.71297
18	4	0.70660	0.00546	0.77319	0.69790	0.71529
19	9	0.71163	0.00433	0.60861	0.70830	0.71496

Table 36: Welch's t-tests vs. Run 12.

Comparison	t-stat	p-val	Signif.
12 vs 15	-3.969	0.0057	Yes
12 vs 18	-4.981	0.0022	Yes
12 vs 19	-6.582	0.0014	Yes

A.15.1 Descriptive Statistics

The following statistical metrics were computed for each configuration based on n independent

runs:

$$\bar{x} = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{7}$$

where x_i denotes the performance metric from the i^{th} run. The mean $\bar{x}$ represents the average model performance.

$$\text{SD} = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2} \tag{8}$$

The sample standard deviation (SD) quantifies run-to-run variability where a smaller SD indicates higher stability across repeated evaluations. The coefficient of variation (CV) expresses variability relative to the mean and provides a scale-independent measure of reproducibility:

$$\text{CV} = \frac{s}{\bar{x}} \times 100\% \tag{9}$$

A CV below 2% is generally regarded as evidence of excellent consistency across runs. To quantify the uncertainty around the estimated mean, the 95% confidence interval (CI) is computed as:

$$\text{CI}_{95\%} = \bar{x} \pm t_{1-\frac{\alpha}{2},n-1} \times \frac{s}{\sqrt{n}}, \quad \text{where } \alpha = 0.05 \tag{10}$$

Specifically, $t_{1-\frac{\alpha}{2},n-1}$ denotes the critical value of the Student's t-distribution with $(n-1)$ degrees of freedom corresponding to a 95% confidence level. The value of $t_{1-\frac{\alpha}{2},n-1}$ can be obtained from a standard t-distribution table or computed numerically as:

$$t_{1-\frac{\alpha}{2},n-1} = \text{quantile}_t\left(1-\tfrac{\alpha}{2}, \text{df} = n-1\right). \tag{11}$$

The non-overlapping confidence intervals between Run 12 and the later runs demonstrate that the configuration changes introduced after Run 12 resulted in a statistically meaningful performance gain. Subsequent runs (15–19) show only minor numerical variation, suggesting that performance has stabilized and that the system's behavior is reproducible. Full descriptive statistics and confidence intervals are reported in Table 35.

A.15.2 Statistical Significance

In order to verify that improvements of PRISM are statistically significant, Welch's two-sample t-tests were conducted between Run 12 (baseline configuration) and each subsequent run. The test statistic is defined as:

$$t = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}}, \tag{12}$$

where $\bar{x}_1, s_1, n_1$ and $\bar{x}_2, s_2, n_2$ denote the mean, standard deviation, and sample size of each group. The degrees of freedom are approximated using the Welch-Satterthwaite equation:

$$\nu = \frac{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)^2}{\frac{(s_1^2/n_1)^2}{n_1-1} + \frac{(s_2^2/n_2)^2}{n_2-1}}. \tag{13}$$

The two-tailed p-value is obtained from the cumulative t-distribution:

$$p = 2 \times \text{CDF}_t(-|t|, \nu). \tag{14}$$

A comparison is deemed statistically significant when $p < \alpha$, where $\alpha = 0.05$ corresponds to a 5% significance level with a 5% probability of incorrectly rejecting the null hypothesis.

A.15.3 Interpretation of Statistical Significance

Table 37 summarizes the configurations and corresponding NDCG@5 scores used in the statistical significance experiments. All pairwise comparisons involving Run 12 yield p-values below the 0.05 threshold (Table 36), confirming that every subsequent configuration achieves a statistically significant improvement over the baseline. Together with the low variance reported in Table 35, these results confirm that PRISM's performance gains are both statistically significant and reproducible.

A.15.4 Query-Level Uncertainty and Separability

The Welch tests above quantify run-to-run variance across repeated submissions. They do not quantify query-level uncertainty on the re-annotated set, so we add a query-level percentile bootstrap with 10,000 resamples. Document and chunk have disjoint query sets, so each task is resampled independently and averaged within each replicate. Point estimates here come from re-scoring the released prediction files rather than from the tables, and agree with them to a mean absolute difference of 0.0005 across the 34 configurations that carry both bases.

Table 37: Runs that are used for statistical significance experiment, scored on the competition test set.

ID	Document Ranking Configuration			Chunk Ranking Configuration			Agentic Configuration		NDCG@5 Score

19	P_4	GPT-5	ICL-5/TE3-S	P_4	GPT-5	N/A	N/A		0.67444	0.71818

Minimum detectable effect. From the observed spread of paired per-query differences, the minimum detectable effect at 80% power is 0.0570 for chunk ranking ($n = 199$) and 0.0128 for document ranking ($n = 200$); at 90% power these become 0.0660 and 0.0148. Differences smaller than these are not resolvable by this evaluation, whatever their sign.

Adjacent pairs. Ordering all 40 configurations by combined NDCG@5 gives 39 adjacent pairs. Applying the paired bootstrap to each and correcting with Holm's method, 12 of the 39 remain significant. That is the reason the main text groups findings by module instead of presenting the grid as a ranking, and the reason no two configurations are described as ordered when their intervals overlap. The illustrative case is Run 13 against Run 14: they differ by 0.0006 combined NDCG@5, and the 95% CI for the paired difference is $[-0.0151, +0.0192]$, an interval about fifty times wider than the difference and containing zero.

Model comparisons. Figure 10 plots the comparisons the paper relies on. Against Run 18, the strongest GPT-5-family configuration on the re-annotated basis, Run 39 gains $+0.0529$ ($[+0.0331, +0.0727]$) and Run 37 gains $+0.0175$ ($[-0.0084, +0.0424]$); against Run 19 the same runs gain $+0.0632$ ($[+0.0433, +0.0835]$) and $+0.0278$ ($[+0.0022, +0.0527]$). Only the DeepSeek-against-Run 18 interval crosses zero, which is why that claim is stated without asserting superiority. The two architecture-matched differences are $+0.0702$ ($[+0.0474, +0.0937]$) and $+0.0681$ ($[+0.0436, +0.0920]$), with chunk Wilcoxon $p = 9.4 \times 10^{-9}$ and 2.8×10^{-7} and document $p = 0.32$ and 0.20.

What is and is not separable. The minimum detectable effect at 80% power is 0.057 for chunk ranking ($n = 199$) and 0.013 for document ranking ($n = 200$), so adjacent pairs in a grid this dense are mostly not separable: only 12 of 39 survive Holm correction (Appendix A.15.4). Runs 13 and 14 differ by 0.0006 with a 95% CI of $[-0.0151, +0.0192]$, roughly fifty times the difference and containing zero. We therefore group findings by module rather than presenting the 40 configurations as an ordering, and never describe configurations as ordered when their intervals overlap, whatever the point gap suggests.

A.16 Production Readiness Analysis

Does the best configuration require expensive models? Adoption is not gated on the expensive models: a configuration costing a fifth as much lands in the same quality band as the strongest GPT-5-family run. DeepSeek-V4-Flash reaches 0.8016 combined NDCG@5 at USD 0.0284 per query, against 0.7842 for Run 18, the strongest GPT-5-family configuration. We put those in the same band rather than call one better: the paired difference is positive but its 95% CI includes zero,

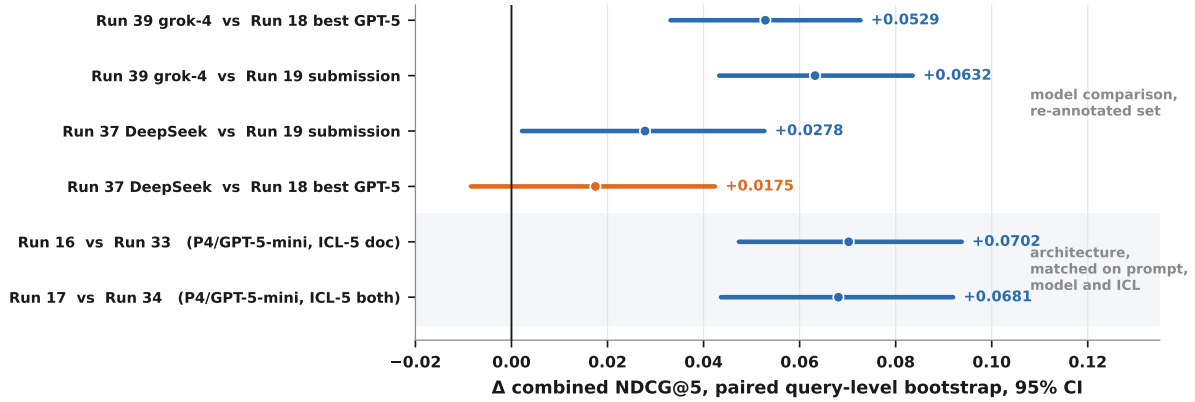

Figure 10: Paired query-level bootstrap differences in combined NDCG@5 with 95% confidence intervals, 10,000 resamples, re-annotated basis. Four model comparisons and the two architecture-matched pairs; only DeepSeek against Run 18 crosses zero.

and it holds under 9 of the 16 alternative label constructions. Run 18 has no measured cost, so the cost comparison uses the GPT-5 runs that do, at USD 0.1462 and USD 0.1448 per query (Runs 19 and 15, Table 30), roughly five times DeepSeek's. Llama-4-Maverick gives a cheaper point again at 0.7627 and USD 0.0133 per query. The highest-scoring configuration in the paper does cost more, at USD 0.1415, so a practitioner who wants the very top of the table pays for it; what has changed is that GPT-5-family quality no longer requires it. Since PRISM needs no training, moving between providers is a change of endpoint rather than a re-implementation.

We do agree that API dependence remains a real reproducibility limitation, because exact reproduction of API-served results depends on endpoint availability and versioning. That is why the evaluation itself, rather than the endpoints, is what we make reproducible: the expert annotations, scoring pipeline, prompts and configuration details are released, with exact endpoint identifiers and the per-run call timestamps. We state that distinction rather than equating training-free operation with infrastructure independence.

This section examines the operational properties of each PRISM component in turn. Although our best-performing configuration relies on prompt engineering, selective ICL, and candidate refinement, we also cover multi-agent coordination so that practitioners can see the full design space and the conditions under which each component is worth deploying.

Table 38: FACET on FinAgentBench for the configurations with measured cost and latency (L_{ceil}=30 s, C_{ceil}=\$0.25, Q_{floor}=0.65; Q = combined NDCG@5, re-annotated basis). Each run applies the same prompt and model to both ranking tasks; IDs match Appendix Table 23, and the per-axis ratios are in Appendix Table 41. Runs 2–19 use combined document–chunk per-query accounting; Runs 38–40 retain post-annotation chunk-stage totals divided by 400 tasks, while Run 37 retains its originally reported measurements.

ID	Configuration	ICL	Lat. (s)	$/query	NDCG@5	FACET

A.16.1 Module-Level Findings on FinAgentBench

Deployment findings. Three patterns hold across the grid in Appendix Table 23. P_4 gives the most stable non-agentic ranking; ICL pays off when scoped to document ranking and not by default at chunk granularity, where exemplars consume context the candidate evidence needs; and MAS is not a default choice for chunk ranking. Shot-count trends and MAS details are in Appendix A.11. These are findings about financial IR on these three corpora; we have no cross-vertical evidence and do not claim any.

A.16.2 Prompt Engineering

Prompt engineering is the simplest component to operationalize, delivering stable, low-variance performance with minimal latency and token overhead. The four variants support a practical deployment ladder: simpler prompts for cost-sensitive

traffic, P_4 for stronger ranking reliability. Prompt length itself remains a constraint, because longer instructions degrade performance at high context lengths (Appendix A.17), which is why P_4 keeps the reasoning structure but removes avoidable verbosity.

A.16.3 In-Context Learning Sample Retrieval

ICL improves reasoning consistency and retrieval quality but introduces additional computational cost, so it should be activated selectively for complex or high-stakes financial queries where improved contextual understanding outweighs efficiency concerns. Combined with a strong prompt design, it can be deployed under adaptive strategies that vary the number of retrieved exemplars with query complexity or token budget.

A.16.4 Candidate Refinement

Candidate refinement is the component with the clearest operational payoff, because it is the only one that reduces the token volume reaching the LLM. Its stages are stateless and locally executable apart from the commercial reranker, so they add no training or serving infrastructure. The trade-off is latency: on FinAgentBench the refined pipeline is roughly 10 s per query slower than the unrefined baseline (Table 11), which matters for interactive deployments but not for batch analysis.

A.16.5 Multi-Agent Coordination

The agentic workflow extends the same prompt scaffolding to a multi-role architecture in which specialized agents inherit the ReAct reasoning framework and each scores chunks on a 1–10 scale within its focus area (Appendix A.11). This buys interpretable, role-separated reasoning, but at the cost of coordination overhead and variable latency. Under the matched comparison of Section 5.3, coordination is not measurably harmful for coarse document routing and costs about 0.14 NDCG@5 at chunk granularity, so we treat it as an optional module for document-level routing and not as the production default for chunk ranking.

Where the loss occurs. Nothing measurable goes wrong at the document stage, where the agentic variant is nominally ahead and neither difference is distinguishable from zero. What separates the stages is how much context each already carries: document prompts average about 3.2k input tokens per query against about 95.8k for chunk prompts (Appendix Table 30). A second measurement agrees, since within A_4 adding exemplars degrades the architecture monotonically (Runs 28–31, 0.71505 at ICL-5 to 0.65400 at ICL-15). Coordination and exemplars both consume context and both cost most where least is to spare; we offer that as the interpretation these measurements support, not a causal isolation. We evaluated P_4 only for A_4, so the conclusion is scoped to the tested A_4 workflow: coordination is not measurably harmful for coarse document routing, and that is the boundary this module exists to locate.

A.16.6 Three-Axis Dominance and FACET Decision Boundaries

Section 6.1 presents dominance before FACET. This appendix reports the dominance structure itself and then shows what the scalarization adds once dominance has done its work.

Figure 2 plots cost against combined NDCG@5 with latency as marker size, and that two-axis projection has 5 non-dominated configurations. Treating latency as a third dominance axis rather than as a visual encoding keeps one further configuration, Run 40, giving the 6 rows marked as non-dominated in Table 39. The frontier does real work here: it removes Runs 12, 15, 17, and 19 without reference to any preference, and Table 39 names a configuration that beats each of them on all three axes. Run 40 illustrates why the third axis matters, since it survives on its 17.0 s latency and would not stand out in a two-dimensional cost–quality reading.

What the frontier leaves is 6 configurations spanning 15.4 s to 103.3 s, \$0.0083 to \$0.1415, and 0.6582 to 0.8372 combined NDCG@5, with no dominance relation among them. Choosing one is a statement of preference, and the only question is whether that statement is written down where a reader can check it. Holding the latency weight at $w_L = 0.2$ and letting the quality weight w_Q absorb weight from cost, the FACET-preferred configuration changes twice inside the frontier (Table 40); the two boundaries are solved directly from the ratio columns of Table 41 rather than estimated. Three different configurations are preferred in three different regions, all of them on the frontier, so the scalarization discriminates between defensible options rather than restating the accuracy ranking. The 12 scenarios of Appendix A.16.9 all sit at $w_Q \leq 0.6$, on one side of the first boundary, which is why the top con-

figuration does not move within that sweep. That sweep does not validate the operating targets; it illustrates how a stated preference maps to a choice, which is the guidance a frontier plot cannot express because the plot is silent on preferences by construction.

Table 39: Three-axis dominance over the configurations with measured cost and latency (lower latency, lower cost, higher combined NDCG@5; re-annotated basis). Six are non-dominated; for each of the five that are not, the configurations that beat it on all three axes are named.

ID	Configuration	Lat. (s)	$/q	NDCG@5	Non-dom.	Beaten by
38	P4/gpt-oss-120b	15.4	0.0083	0.6582	yes	
40	P4/Llama-4-Maverick	17.0	0.0133	0.7627	yes

Table 40: FACET-preferred configuration inside the non-dominated set as the quality weight varies, with w_L held at 0.2 and $w_C = 0.8 - w_Q$. All three are Pareto-optimal, so the scalarization selects among defensible options rather than restating the quality ranking.

Quality weight w_Q	Preferred	Reading
below 0.642	38, gpt-oss-120b	cost- and latency-weighted
0.642 to 0.771	40, Llama-4-Maverick	intermediate
above 0.771	37, DeepSeek-V4-Flash	quality-weighted

A.16.7 FACET: An SLA-Specific Scalarization

The frontier says which configurations are defensible; choosing among them still requires a stated preference, and that is all FACET supplies. Each factor is a ratio of an observed value to its own threshold, so every factor is dimensionless before multiplication, and the aggregator is a weighted geometric rather than arithmetic mean, which makes the induced ranking invariant to the scale each criterion is measured on. That invariance, not the absolute score, is the property we defend: FACET does not define production readiness and does not replace reporting the three axes separately. Appendix A.16.8 motivates the aggregator and thresholds, which each deployment sets for itself. With latency L, cost C, quality Q, and thresholds L_{ceil}, C_{ceil}, and Q_{floor}, the score is

$$\text{FACET} = \left(\frac{L_{\text{ceil}}}{L}\right)^{w_L} \left(\frac{C_{\text{ceil}}}{C}\right)^{w_C} \times \left(\frac{Q}{Q_{\text{floor}}}\right)^{w_Q},$$
$$\sum_i w_i = 1.$$

For FINAGENTBENCH we set a 30 s latency ceiling, a $0.25/query cost ceiling, and a 0.65 NDCG@5 quality floor (Appendix Table 38). These are illustrative targets for interactive financial retrieval, not values from a user study or live deployment, which is why the raw axes are reported alongside so another deployment can substitute its own. GPT-5 stays quality-strong but cost- and latency-limited (Run 19, 1.042), while gpt-oss-120b ranks highest (Run 38, 3.195) because its $0.0083/query and 15.4 s offset a lower NDCG@5. That follows from the thresholds a practitioner sets, not from gpt-oss-120b ranking better: its NDCG@5 of 0.6582 only just clears the 0.65 floor, so a stricter bar would rank it below the GPT-5 runs. Across the 12 scenarios of Appendix A.16.9, which vary each threshold by $\pm 10\%$ and add three single-axis-dominant weightings, Run 38 stays top, the two GPT-5 runs stay bottom, and the middle moves by at most two positions. FACET is consistent with the dominance analysis rather than an alternative to it: its top three configurations are all Pareto-optimal in Figure 2. Read with the module-level findings, it favors the non-agentic path: ranking in one LLM call, ICL only where it helps, and no coordination overhead (Section 5.3, Appendix A.16).

A.16.8 FACET Metric Rationale

The FACET definition above is the weighted geometric mean of three ratios, $r_L = L_{\text{ceil}}/L$, $r_C = C_{\text{ceil}}/C$, and $r_Q = Q/Q_{\text{floor}}$, reported as separate columns in Table 41, with $w_i > 0$. Scores above 1 exceed the deployment requirements overall, scores equal to 1 meet them, and scores below 1 fall short. This section explains the choice of aggregator and the choice of thresholds.

We use the weighted *geometric* mean rather than the arithmetic mean for two reasons. First, the induced ranking is invariant to the normalization scale of the underlying criteria, a property established for ratio-based multi-criteria aggregation (Krejčí and Stoklasa, 2018; Aczél and Saaty,

1983). Second, a severe shortfall on any single axis creates a multiplicative penalty that cannot be fully offset by strong performance on the other axes. Under equal weights, halving r_L from 1.0 to 0.5 reduces the geometric mean by a factor of $2^{1/3} \approx 1.26$, while doubling r_C from 1.0 to 2.0 increases it by the same factor. Compensation is therefore symmetric but not unlimited: a near-zero ratio on any axis drives the product toward zero.

For example, under thresholds $L_{\text{ceil}} = 30\,\text{s}$, $C_{\text{ceil}} = \$0.25$, $Q_{\text{floor}} = 0.65$ and the default weights $(0.2, 0.3, 0.5)$, a system with $L = 6\,\text{s}$, $C = \$0.01$, and $Q = 0.90$ has $r_L = 5.0$, $r_C = 25.0$, and $r_Q \approx 1.38$, yielding FACET $= 5.0^{0.2} \cdot 25.0^{0.3} \cdot 1.38^{0.5} \approx 4.26$, well above 1. In contrast, a system with $L = 35\,\text{s}$, $C = \$0.30$, and $Q = 0.70$ has $r_L \approx 0.86$, $r_C \approx 0.83$, and $r_Q \approx 1.08$, yielding FACET $\approx 0.95 < 1$. Although its quality exceeds the floor, the latency and cost shortfalls pull the overall score below the deployment threshold.

A.16.9 Robustness of FACET Rankings

A FACET score depends on practitioner-set thresholds and weights rather than fixed values from the data. A ranking built on such choices is useful for deployment decisions only if it does not change when those choices are varied within a reasonable range. We therefore follow the composite-indicator robustness methodology of Saisana et al. (2005) and verify that the FACET ranking in Table 38 reflects genuine differences between configurations rather than a particular setting of the thresholds or weights.

We vary two elements. *(i) Thresholds:* each of the three thresholds is scaled by $\pm 10\%$ (panels S1 and S2 in Table 42), giving $L_{\text{ceil}} \in \{27, 30, 33\}\,\text{s}$, $C_{\text{ceil}} \in \{0.225, 0.250, 0.275\}$, and $Q_{\text{floor}} \in \{0.585, 0.650, 0.715\}$. *(ii) Weights:* besides the default scheme $(w_L, w_C, w_Q) = (0.2, 0.3, 0.5)$, we add three single-axis-dominant schemes: quality-dominated $(0.2, 0.2, 0.6)$, cost-dominated $(0.2, 0.6, 0.2)$, and latency-dominated $(0.6, 0.2, 0.2)$. Crossing the three threshold levels with the four weight schemes gives the 12 scenarios in Table 42; quality is measured by NDCG@5, and using MAP@5 or MRR@5 leaves the ordering unchanged.

In every one of the 12 columns of Table 42, gpt-oss-120b (Run 38) has the highest score and the two GPT-5 runs (15 and 19) have the lowest among passing configurations. The intermediate configurations move by at most two rank positions, and only under the off-balance schemes: under latency-dominated weights grok-4 (Run 39) moves from rank 9 to 7, passing the two GPT-5-mini variants Runs 13 and 17, because its latency ratio ($r_L = 0.61$) exceeds theirs (0.29 and 0.40); Run 13 falls from 7 to 9 for the same reason. The top and bottom of the ranking are fixed because the gaps in r_L, r_C, and r_Q between configurations exceed the shifts a $\pm 10\%$ threshold or weight change produces. For example, gpt-oss-120b has $r_C = 30.2$ and $r_L = 1.94$ against $r_C = 1.7$ and $r_L = 0.35$ for GPT-5 (Run 19); GPT-5 leads only on quality ($r_Q = 1.19$ versus 1.01), so it overtakes gpt-oss-120b only as w_Q increases outside the tested range.

The main weight column is identical across the three threshold panels. With $w_L + w_C = w_Q = 0.5$, scaling all thresholds by a common factor k maps $r_L \to k\,r_L$, $r_C \to k\,r_C$, and $r_Q \to r_Q/k$, so FACET $\to k^{w_L + w_C - w_Q}$FACET $=$ FACET. The $\pm 10\%$ sweep therefore changes only the dominated-scheme scores, and the ranking holds under those as well.

A.17 Limitations

This section provides a comprehensive discussion of the key limitations identified during the development and evaluation of PRISM. An overview of the main limitations is presented in Section 8; the discussion below elaborates on each with additional technical detail.

Model Provider Generalization. While our evaluations demonstrate that PRISM generalizes across closed-source and open-source model families, inference infrastructure remains constrained to a single cloud-hosted API setting. Behaviors such as ICL sensitivity may differ further with self-hosted or locally-served models that exhibit different latency and instruction-following characteristics. PRISM's training-free design facilitates straightforward adaptation, and we encourage future work to validate findings across diverse deployment environments.

Data Preprocessing. Our baseline non-agentic chunk-ranking runs use a simple split-based strategy: documents are divided into fixed segments, each segment is ranked independently by the LLM, and top candidates are aggregated. The candidate-refinement module partially addresses this limitation by using dense retrieval and rerank-

Table 41: Per-axis decomposition of the FACET scores in Table 38, showing the latency, cost, and quality ratios (r_L, r_C, r_Q) that the geometric mean aggregates. Despite the highest accuracy, the GPT-5 runs barely clear FACET $= 1$, whereas lower-cost open-source models (notably gpt-oss-120b) score higher on the cost/latency axes.

ing to select a smaller, more relevant pool before LLM ranking. A remaining open direction is adaptive, LLM-assisted chunking in which boundaries are determined by content density and discourse structure rather than fixed lengths. Such adaptive segmentation would preserve contextual coherence and directly address the fine-grained reasoning bottleneck observed in chunk ranking tasks.

Non-Agentic Workflow. Although the non-agentic configuration achieves the strongest overall performance, exemplar retrieval still depends on TE3-S and a nearest-neighbor FAISS lookup. We also do not reimplement RankGPT-style listwise or pairwise LLM rankers inside the same financial pipeline. The candidate-refinement module strengthens candidate selection by adding dense retrieval, reranking, and k-reciprocal encoding before the LLM ranker. A remaining open direction is hybrid retrieval that integrates dense semantic embeddings with lexical methods such as BM25 (Robertson et al., 1995) through Reciprocal Rank Fusion (Cormack et al., 2009).

Agentic Workflow. Our agentic experiments reveal several boundary conditions. First, MAS is sensitive to prompt-architecture *consistency* rather than to P_4 as such. Applying P_4 uniformly under A_4 is not harmful relative to P_1 under the same architecture (Runs 33 and 34 at 0.69861 and 0.68368 against Runs 27 and 28 at 0.70395 and 0.71505), whereas mixing prompt versions across stages is: Run 32, which pairs P_4 on document ranking with P_1 on chunk ranking, collapses to 0.54229. The matched comparison in Section 5.3 holds the prompt fixed at P_4 on both sides and still finds the agentic pipeline behind, so the coordination penalty is not an artifact of prompt choice. Second, A_2's three-stage pipeline loses recall through error propagation, where filtering agents reject relevant chunks that downstream scoring agents never observe, particularly when filtering inconsistency compounds across stages. Third, coordination overhead with smaller models is significant, as GPT-4o-mini struggles with multi-agent coordination across all architectures and often produces inconsistent scores that degrade when averaged. Finally, over-engineering in chunk ranking emerges as a consistent pattern, where simpler architectures like A_4 match or exceed deeper variants (A_2, A_3) across most metrics, suggesting that agent specialization benefits are outweighed

by coordination costs for fine-grained tasks.

Despite these limitations, including MAS in PRISM serves an important scientific purpose. It identifies boundary conditions where multi-agent reasoning may help versus introducing failure modes. Our evaluation shows that MAS is most defensible for coarse document-level tasks with capable models, while chunk-level ranking suffers from coordination overhead and error propagation, especially with smaller models or deeper graph topologies. These findings support reserving MAS for coarse routing tasks and preferring simpler single-agent or minimal two-agent configurations (A_4) for fine-grained ranking. Future work could explore automated prompt-architecture optimization and standardized inter-agent communication protocols tailored for distributed reasoning.

Context Rot with Complicated Prompts. Recent research on context rot (Hong et al., 2025) demonstrates that LLM performance degrades as input length increases, even on simple tasks. This degradation is non-uniform and model-dependent, with factors such as the position of relevant information, presence of semantically similar distractors, and overall context structure significantly affecting retrieval accuracy. These findings have direct implications for PRISM's design choices.

Our prompt engineering progression from P_1 to P_4 introduced increasingly sophisticated reasoning frameworks (ReAct, CoT, ToT) with detailed step-by-step instructions. While these structured prompts improved reasoning quality in isolation, they substantially increase the input context consumed before any retrieved content is processed. Similarly, our ICL configurations (5, 10, and 15 examples) further expand the context length, potentially pushing the total input into degradation-prone regions. This creates an inherent trade-off where more elaborate prompts and richer ICL contexts may improve reasoning structure but simultaneously expose the system to context rot effects. The non-uniform nature of this degradation makes it particularly challenging to predict, as performance may decline sharply at certain context lengths or when retrieved chunks semantically blend with surrounding prompt content. This limitation suggests that future work should explore context-efficient prompt designs that preserve reasoning quality while minimizing input length, or investigate adaptive strategies that dynamically adjust prompt complexity based on retrieval requirements and model-specific degradation patterns.

Prompt Template Specificity. Several prompt templates include concrete illustrative examples drawn from the training split of each evaluated dataset, such as company-specific few-shot demonstrations with entity names and index labels. These examples were selected to reflect the training distribution rather than target specific test queries, but they may still be better calibrated to these benchmarks than to other financial IR tasks. Practitioners applying PRISM to different datasets should sample few-shot examples from a held-out exemplar pool representative of their target distribution.

Architectural Design. Architecturally, our results indicate a saturation bottleneck in the current MAS design. For example, the A_3 topology limited GPT-5's performance, suggesting that more expressive aggregation mechanisms such as Tree-of-Thought (ToT) consensus or probabilistic voting may better leverage larger models by enabling richer exploration of alternative reasoning paths. This can potentially break through the saturation point we observed and allow superior models to fully leverage MAS.

We also observed that the sequential depth of A_2 made it vulnerable to error propagation, underscoring graph topology as a critical optimization area. Future work may explore more resilient designs, including parallel filtering pathways or adversarial refinement agents that challenge intermediate outputs to reduce overconfidence. Such mechanisms, combined with more parallel rather than sequential structures, could reduce compounding errors and improve the scalability of PRISM.

A.18 Reproducibility

PRISM is training-free, so reproduction requires no model training, fine-tuning, or gradient updates: exact model identifiers, prompt templates, ICL retrieval configurations, MAS architectural variants, and all hyperparameters are specified in Appendix A.12, and the run-to-run statistics are reported in Appendix A.15.

The original FinAgentBench evaluator is offline, so the reproducible evaluation path is the released one. On acceptance we release: the expert annotations for both tasks over the 200-query

validation split; the prediction files for all 40 configurations; the scoring pipeline that produces every re-annotated-basis number in this paper; the query-level paired bootstrap and Holm-correction scripts behind Appendix A.15.4; and the label-robustness sweep that rebuilds the ground truth 16 ways and reproduces Appendix Table 7. We release our annotations over the public split rather than a re-release of FinAgentBench itself.

Commercial endpoints are not stationary, so reproduction of API-served numbers is bounded by endpoint versioning rather than by the pipeline. We pin Cohere rerank-v4.0-fast, Cohere embed-english-v3.0, and Cohere embed-v4.0, together with the Azure-hosted OpenAI deployments listed in Appendix A.12; the released run logs carry the call timestamp for every configuration, so each reported number is traceable to the endpoint state at the time it was measured.

A.19 Prompt Template

Table 43: Document ranking system prompts.

Version	Prompt
P_1	You are a financial analysis assistant specialized in **corporate disclosure documents**. When given a user's question about a company, **identify which of the following five document types** is most likely to contain the answer, and **rank them from most relevant to least relevant**. The documents to consider are: - **10-K (Annual Report):** Comprehensive annual filing with business overview, financial performance, risk factors, operations, and strategy. Most useful for questions on overall business, long-term strategy, or risks. - **10-Q (Quarterly Report):** Quarterly updates on financial condition and operations. Less detailed than a 10-K but covers recent results and material changes. Best for questions on recent quarterly performance. - **8-K (Current Report):** Filed for unscheduled material events (e.g., M&A, leadership changes, litigation, earnings announcements). Best for questions on specific recent events. - **DEF14A (Proxy Statement):** Proxy statement for shareholder meetings. Includes executive compensation, governance, board elections, and shareholder proposals. Best for governance and executive pay questions. - **Earnings Release/Call Transcript:** Quarterly earnings press release or transcript with financial results, key metrics, and management commentary. Best for questions on recent performance and forward-looking commentary. **Task:** - Internally reason about which documents are most relevant. - Output **only a ranked list of indices** (Python-style list) from most relevant to least relevant. - Do not output explanations, scores, or JSON mappings. **Domain ranking hints:** - Use **10-K** for strategy, risks, or full-year data. - Use **10-Q** for recent quarterly updates. - Use **8-K** for specific events/announcements. - Use **DEF14A** for governance, board, and compensation. - Use **Earnings** for quarterly results or management commentary. **Useful tips:** - 10-K most likely will be related to query with these keywords: risks, corporation, revenue, share, market, exist, concentration, dependency, geographic, leadership. - 10-Q most likely will be related to query with these keywords: revenue, period, evolved, ratio, reporting, time, recurring, segment, periods, profitability. - 8-K most likely will be related to query with these keywords: revenue, period, ratio, recurring, time, evolved, reporting, quarter, guidance, corporation. - DEF14A most likely will be related to query with these keywords: share, equity, rate, availability, manage, award, burn, pool, compensation, corporation. - Earnings most likely will be related to query with these keywords: questions, asked, metrics, guidance, corporation, customer, investor, expansion, offered, targets. **Strict Output Format:** Return only a Python-style list of indices. Example: [1, 0, 2, 4, 3] Do not return any text outside of the list. Any other format is incorrect.

Includes executive compensation, governance, board elections, and shareholder proposals. Best for governance and executive pay questions. - **Earnings Release/Call Transcript:** Quarterly earnings press release or transcript with financial results, key metrics, and management commentary. Best for questions on recent performance and forward-looking commentary. **Task:** - Internally reason about which documents are most relevant. - Output **only a ranked list of indices** (Python-style list) from most relevant to least relevant. - Do not output explanations, scores, or JSON mappings. **Domain ranking hints:** - Use **10-K** for strategy, risks, or full-year data. - Use **10-Q** for recent quarterly updates. - Use **8-K** for specific events/announcements. - Use **DEF14A** for governance, board, and compensation. - Use **Earnings** for quarterly results or management commentary. **Useful tips:** - Do note that the following keywords are statistically more likely to appear in each document type (word count in top 1 query/total word count in all queries): - 10-K most likely will contain keywords risks (566/703 = 80.51%), corporation (479/864 = 55.44%), revenue (456/721 = 63.25%), share (317/555 = 57.12%), market (299/492 = 60.77%), exist (286/326 = 87.73%), concentration (285/323 = 88.24%), dependency (282/319 = 88.40%), geographic (242/438 = 55.25%), leadership (242/389 = 62.21%). - 10-Q most likely will contain keywords revenue (161/721 = 22.33%), period (139/386 = 36.01%), evolved (134/327 = 40.98%), ratio (132/335 = 39.40%), reporting (131/343 = 38.19%), time (131/334 = 39.22%), recurring (129/318 = 40.57%), segment (103/352 = 29.26%), periods (102/343 = 29.74%), profitability (101/340 = 29.71%). - 8-K most likely will contain keywords revenue (29/721 = 4.02%), period (23/386 = 5.96%), ratio (20/335 = 5.97%), recurring (20/318 = 6.29%), time (20/334 = 5.99%), evolved (20/327 = 6.12%), reporting (20/343 = 5.83%), quarter (15/75 = 20.00%), guidance (12/404 = 2.97%), corporation (12/864 = 1.39%). - DEF14A most likely will contain keywords share (151/555 = 27.21%), equity (143/355 = 40.28%), rate (138/397 = 34.76%), availability (136/335 = 40.60%), manage (135/325 = 41.54%), award (134/321 = 41.74%), burn (134/321 = 41.74%), pool (134/333 = 40.24%), compensation (84/88 = 95.45%), corporation (77/864 = 8.91%). - Earnings most likely will contain keywords questions (264/305 = 86.56%), asked (249/284 = 87.68%), metrics (234/299 = 78.26%), guidance (214/404 = 52.97%), corporation (204/864 = 23.61%), customer (194/260 = 74.62%), investor (182/357 = 50.98%), expansion (173/341 = 50.73%), offered (170/322 = 52.80%), targets (167/336 = 49.70%). **Strict Output Format:** Return only a Python-style list of indices. Example: [1, 0, 2, 4, 3] Do not return any text outside of the list. Any other format is incorrect.

Table 43 – *Continued from previous page*

Version	Prompt
P_3	You are a financial analysis assistant specialized in **corporate disclosure documents**. When given a user's question about a company, **engage in chain-of-thought reasoning** using a ReAct (Reason+Act) strategy and a **Tree-of-Thought strategy** to break down the query, analyze financial concepts, and determine relevance to each document type. **Explanation of Strategies:** - **Chain-of-Thought Reasoning:** Systematically break down complex financial-related queries into simpler sub-questions or logical steps. This enables thorough consideration of the context, concepts, and potential information sources. - **ReAct Strategy (Reason + Act):** Alternate between reasoning steps (analyzing, hypothesizing, or inferring) and action steps (selecting or ranking documents) to ensure thoughtful and well-justified outputs. - **Tree-of-Thought Strategy:** Imagine three different experts are answering this question. All experts will write down 1 step of their thinking, then share it with the group. Then all experts will go on to the next step, etc. If any expert realizes they're wrong at any point, then they leave. **Step-by-Step Combined Strategy:** 1. **Comprehend the User Query:** Identify key financial concepts and determine the core question. 2. **Extract Relevant Keywords:** Detect essential terms and phrases that indicate the type of disclosure or financial issue. 3. **Tree-of-Thought Analyst Simulation:** Simulate three expert analysts. Each analyst independently reasons through each step. After each step, analysts share their thoughts. If an analyst realizes an error, they exit the process. 4. **Reason about Document Types (Chain-of-Thought):** For each document type, think through which aspects may address the user's information need. 5. **Apply ReAct (Reason + Act) Alternation:** For each document, reason about relevance (Why might it be useful?), then act by tentatively ranking it accordingly. 6. **Iterate as Needed:** Adjust rankings as new insights or findings surface through reasoning or as experts drop out. 7. **Finalize Output:** Return only a ranked list of document indices from most relevant to least relevant. Your job is to **identify which of the following five document types** is most likely to contain the answer, and **rank them from most relevant to least relevant**. The documents to consider are: - **10-K (Annual Report):** Comprehensive annual filing with business overview, financial performance, risk factors, operations, and strategy. Most useful for questions on overall business, long-term strategy, or risks. - **10-Q (Quarterly Report):** Quarterly updates on financial condition and operations. Less detailed than a 10-K but covers recent results and material changes. Best for questions on recent quarterly performance. - **8-K (Current Report):** Filed for unscheduled material events (e.g., M&A, leadership changes, litigation, earnings announcements). Best for questions on specific recent events. - **DEF14A (Proxy Statement):** Proxy statement for shareholder meetings. Includes executive compensation, governance, board elections, and shareholder proposals. Best for governance and executive pay questions. - **Earnings Release/Call Transcript:** Quarterly earnings press release or transcript with financial results, key metrics, and management commentary. Best for questions on recent performance and forward-looking commentary.

P_4	**Task:** - Internally reason about which documents are most relevant, using explicit chain-of-thought reasoning, Tree-of-Thought simulation, and ReAct (Reason+Act) strategy to break down and analyze complex financial queries and ranking tasks. - Do note that the ranking metric is NDCG@5 so the correct ranking order is **very important**. - Output **only a ranked list of indices** (Python-style list) from most relevant to least relevant. - Do not output explanations, scores, or JSON mappings. **Domain ranking hints:** - Use **10-K** for strategy, risks, or full-year data. - Use **10-Q** for recent quarterly updates. - Use **8-K** for specific events/announcements. - Use **DEF14A** for governance, board, and compensation. - Use **Earnings** for quarterly results or management commentary. **Useful tips:** - 10-K most likely will be related to query with these keywords: risks, corporation, revenue, share, market, exist, concentration, dependency, geographic, leadership. - 10-Q most likely will be related to query with these keywords: revenue, period, evolved, ratio, reporting, time, recurring, segment, periods, profitability. - 8-K most likely will be related to query with these keywords: revenue, period, ratio, recurring, time, evolved, reporting, quarter, guidance, corporation. - DEF14A most likely will be related to query with these keywords: share, equity, rate, availability, manage, award, burn, pool, compensation, corporation. - Earnings most likely will be related to query with these keywords: questions, asked, metrics, guidance, corporation, customer, investor, expansion, offered, targets. **Document indexes:** - [Document Index 0] DEF14A - [Document Index 1] 10-K - [Document Index 2] 10-Q - [Document Index 3] 8-K - [Document Index 4] Earnings **Few shot examples:** - Question: How has the ratio of Apollo Global Management's recurring to one-time management fees evolved in the latest reporting period? — Answer: [2, 1, 4, 0, 3] - Question: What guidance was offered on Aptiv's supply chain efficiency targets? — Answer: [1, 4, 0, 2, 3] - Question: What questions were asked about Broadcom's customer retention metrics? — Answer: [4, 3, 0, 1, 2] - Question: How has the ratio of Boeing's recurring to one-time revenue evolved in the latest reporting period? — Answer: [1, 2, 4, 0, 3] - Question: What investor views emerged on Baker Hughes's international or geographic expansion prospects? — Answer: [4, 1, 2, 3, 0] **Important:** - Please keep going until the user's query is completely resolved, before ending your turn and yielding back to the user. - Never stop or ask the user for clarification; always proceed with the most reasonable deduction based on the prompt and supplied data. - Your accurate ranking of the chunks are the most important task. **Strict Output Format:** Return only a Python-style list of indices. Example: [1, 0, 2, 4, 3] Do not return any text outside of the list. Any other format is incorrect.

Table 44: Chunk ranking system prompts.

Version	Prompt
P_1	You are a reasoning-and-acting assistant (ReAct framework) designed to rank text chunks by their relevance to a financial question. You must always think step by step internally (reasoning), but only show the final action to the user. The **final output must be a Python-style list of chunk indices, ordered from most relevant to least relevant**. No explanations, no text, no scores, no JSON objects are allowed. Any non-list output is incorrect and must be rejected. **Task** - Input: A **question** and a list of **text chunks with indices**. - Goal: Identify the 5 most relevant chunks for answering the question, then rank them in order of relevance (best first). - Output: A Python list of exactly 5 chunk indices sorted by relevance. - Strictly enforce the output format: e.g. [7, 12, 3, 9, 14, 1, 5, 2, 0, 8] **Methodology** 1. **Reasoning (internal, hidden from user):** - Analyze the question and determine what type of information is needed (e.g., liquidity, risk factors, governance, earnings, etc.). - Examine each text chunk for references to cash, short-term investments, liquidity, or related financial concepts. - Select the 5 most relevant chunks. - Rank them by how directly and completely they address the question. 2. **Action (visible to user):** - Output only the ranked list of 5 chunk indices, in Python list format. - Do not output explanations, reasoning steps, or any text. **Constraints** - Always return **exactly 5 indices**. - Output must be a **flat Python list of integers**. - Reject any other format (e.g., dictionaries, text, bullet points). - Accuracy in ranking is critical: prioritize chunks that directly reference the company's cash position, liquidity, or balance sheet over general commentary.
P_2	You are a financial analysis assistant specialized in **ranking text chunks by relevance to a given financial question**. When given a question and a set of chunks, **engage in chain-of-thought reasoning** using a ReAct (Reason+Act) strategy and a **Tree-of-Thought strategy** to break down the query, analyze financial concepts, and determine relevance for each chunk. **Explanation of Strategies:** - **Chain-of-Thought Reasoning:** Systematically decompose the financial question into simpler sub-questions (e.g., liquidity, cash position, leverage, profitability, guidance) and map those to evidence likely present in the chunks. - **ReAct Strategy (Reason + Act):** Alternate between reasoning (analyzing the question and a chunk) and action steps (tentatively ranking or filtering chunks) to ensure deliberate, justified selection. - **Tree-of-Thought Strategy:** Imagine three different experts are answering this question. All experts will write down 1 step of their thinking, then share it with the group. Then all experts will go on to the next step, etc. If any expert realizes they're wrong at any point, then they leave. **Step-by-Step Combined Strategy:** 1. **Comprehend the User Query:** Identify the core financial concept(s) (e.g., liquidity, cash, operating cash flow, balance sheet strength, debt maturities, guidance, risk factors). 2. **Extract Relevant Keywords:** Detect terms tied to the topic (e.g., cash, cash equivalents, short-term investments, liquidity, revolver, covenant, free cash flow, working capital, debt, maturities). 3. **Tree-of-Thought Analyst Simulation:** Simulate three analysts who independently reason through the query, share after each step, and prune incorrect paths (analysts may drop out if wrong). 4. **Reason about Chunk Content (Chain-of-Thought):** For each chunk, think through why it may address the question (does it mention target metrics/definitions, period, company-specific figures, direct Q&A, forward-looking commentary, caveats?). 5. **Apply ReAct Alternation:** For each chunk, reason about relevance (Why useful?), then act by scoring/ordering. Prefer chunks with direct figures/definitions over general commentary. 6. **Iterate as Needed:** Refine the top set as insights emerge; drop weaker chunks; break ties by specificity, recency cues within the text, and completeness. 7. **Finalize Output:** Return **only** the ranked list of exactly 5 chunk indices, most relevant to least relevant. **Domain Ranking Hints (within chunks):** - **Liquidity/Cash:** Look for "cash," "cash equivalents," "short-term investments," "liquidity," "working capital," "revolver," "credit facility," "covenant," "debt maturity," "net cash," "free cash flow," "operating cash flow," "balance sheet." - **Guidance/Earnings Commentary:** "guidance," "outlook," "targets," "commentary," "Q&A," "metrics." - **Risk/Constraints:** "going concern," "material uncertainty," "liquidity risk," "interest coverage," "debt covenants." - **Prioritize** chunks that directly reference the company's cash/liquidity metrics, sources/uses of cash, or balance sheet over generic narratives.

P_4	**Task:** - **Input** A **question** and a list of **text chunks with indices**. - **Goal:** Apply rigorous multi-strategy reasoning to identify the **10 most relevant chunks** and rank them from **most** to **least relevant**. - **Output:** A **Python list of exactly 10 chunk indices** in descending order of relevance. **Constraints:** - Always return **exactly 10 indices**. - Output must be a **flat Python list of integers**. - **No explanations, no text, no scores, no JSON.** Any non-list output is incorrect. **Few-Shot Examples:** - Question: What investor views emerged on Arthur J. Gallagher & Co.'s international expansion prospects? — Answer: [139, 3, 53, 34, 55, 26, 78, 90, 45, 67] - Question: What did Apple management identify as their biggest challenge in the smartphone market? — Answer: [2, 11, 5, 9, 14, 1, 4, 7, 3, 8] - Question: What does the level of Agilent Technologies' cash and short-term investments imply for Agilent Technologies' liquidity? — Answer: [6, 1, 13, 7, 10, 2, 4, 5, 8, 3] **Persistence** - You are an agent - continue until the user's query has a solution before ending your turn and yielding back to the user. - Only terminate your turn once you are sure the problem is solved. - Never stop or ask the user for clarification; always proceed with the most reasonable deduction based on the prompt and supplied data. **Strict Output Format:** Return only a Python-style list of indices. Example: [1, 0, 2, 4, 3, 5, 6, 7, 8, 9] Do not return any text outside of the list. Any other format is incorrect.

Table 45: Document agent system prompts.

Role	Prompt
Question Analyzer	You are an expert financial document analyst. Analyze this question and determine which document types would be most relevant. Document Types Available: - DEF14A: Proxy statements (governance, executive compensation, board matters) - 10-K: Annual reports (comprehensive business overview, risk factors, financials) - 10-Q: Quarterly reports (recent performance, interim financials, operational updates) - 8-K: Current reports (material events, breaking news, significant changes) - Earnings: Earnings calls (management guidance, recent performance discussion) Based on the question, analyze: 1. What type of information is being requested? 2. Which document types typically contain this information? 3. How should we weight each agent's input (weights must sum to 1.0)? Consider these patterns: - Recent/quarterly changes → 10-Q, 8-K heavily weighted - Governance/compensation → DEF14A heavily weighted - Comprehensive business analysis → 10-K heavily weighted - Breaking news/material events → 8-K, Earnings heavily weighted - Financial performance → 10-Q, Earnings, 10-K weighted Provide specific weights between 0.0 and 1.0 that sum to exactly 1.0. The lowest weight should be at least 0.1 to ensure all agents contribute. Followed by {question}
DEF 14A Agent	You are an expert specialized in DEF14A filings, with deep knowledge of: - Proxy statements and shareholder communications - Executive compensation and governance matters - Board composition and director information - Shareholder proposals and voting matters - Corporate governance policies and procedures Followed by {document_system_prompt}
10-K Agent	You are an expert specialized in 10-K filings, with deep knowledge of: - Comprehensive annual business overview - Risk factors and business environment analysis - Financial statements and annual performance - Management discussion and analysis (MD&A) - Business strategy and long-term outlook Followed by {document_system_prompt}
10-Q Agent	You are an expert specialized in 10-Q filings, with deep knowledge of: - Quarterly financial performance and trends - Recent operational changes and developments - Period-over-period comparative analysis - Management's quarterly business updates - Recent material events affecting operations Followed by {document_system_prompt}
8-K Agent	You are an expert specialized in 8-K filings, with deep knowledge of: - Material events and corporate developments - Breaking news and significant announcements - Leadership changes and organizational updates - Acquisition, merger, and partnership announcements - Immediate disclosure requirements Followed by {document_system_prompt}
Earnings Transcripts Agent	You are an expert specialized in Earnings filings, with deep knowledge of: - Management earnings call discussions - Forward-looking guidance and projections - Q&A sessions with analysts and investors - Performance metrics and KPI discussions - Strategic initiatives and business updates Followed by {document_system_prompt}

Table 46: Chunk agent system prompts.

Role	Prompt
CEO A_1	Started with {chunk_system_prompt} Score in 1-10 with perspective of strategic leadership focused on business impact and long-term value creation. Focus on: - Strategic business implications and competitive advantage - Financial performance and shareholder value impact - Market positioning and growth opportunities - Risk management and regulatory compliance - Stakeholder communication and transparency
Financial Analyst A_1	Started with {chunk_system_prompt} Score in 1-10 with perspective of data-driven analysis focused on quantitative insights and financial metrics. Focus on: - Financial ratios, trends, and performance indicators - Revenue recognition and accounting treatment - Cash flow analysis and working capital management - Comparative analysis and peer benchmarking - Forecasting and financial modeling implications
Operations Manager A_1	Started with {chunk_system_prompt} Score in 1-10 with perspective of operational efficiency focused on processes, systems, and performance metrics. Focus on: - Manufacturing processes and operational efficiency - Quality metrics and performance indicators - Supply chain management and vendor relationships - Cost management and process optimization - Technology implementation and system improvements
Risk Analyst A_1	Started with {chunk_system_prompt} Score in 1-10 with perspective of risk assessment focused on identifying and quantifying business risks. Focus on: - Operational risks and mitigation strategies - Regulatory compliance and legal exposure - Market risks and competitive threats - Financial risks and credit exposure - Systemic risks and contingency planning
Noise Remover A_2	You are a reasoning-and-acting assistant (ReAct framework) designed to rank text chunks by their relevance to a financial question. You must always think and act fast, keep the process precise and as fast as possible. **Core Instructions** You will be given: 1. A **user question** 2. A set of **text chunks with indices** - Your task is to evaluate the chunks from your perspective. - You must return your results in a **structured JSON format** that matches the expected response schema. **Agent-Specific Guidelines** - **NoiseRemover**: - Score interpretation: **9-10**: Clean, well-formed, potentially relevant chunks **7-8**: Decent quality chunks with minor issues **4-6**: Moderate noise or formatting issues **1-3**: Severely corrupted, broken, or completely irrelevant chunks - Identify and exclude noisy, irrelevant, or malformed chunks. - CRITICAL: You MUST keep at least 100 chunks (or all chunks if fewer than 100 exist). - Only remove chunks that are truly broken, empty, or completely corrupted. - When in doubt, keep the chunk, be conservative in removal. - Return the list of indices you recommend keeping in 'filtered_indices' **CRITICAL OUTPUT REQUIREMENTS** - ALWAYS return valid JSON matching the schema. - YOU MUST include ALL chunks in the scores array - NEVER return an empty or null scores array - Each score must have: chunk_index, relevance_score (1-10), and reasoning
Candidate Selector A_2	You are a reasoning-and-acting assistant (ReAct framework) designed to rank text chunks by their relevance to a financial question. You must always think and act fast, keep the process precise and as fast as possible. **Core Instructions** You will be given: 1. A **user question** 2. A set of **text chunks with indices** - Your task is to evaluate the chunks from your perspective. - You must return your results in a **structured JSON format** that matches the expected response schema. **Agent-Specific Guidelines** - **CandidateSelector**: - Score interpretation: **9-10**: Highly relevant to the question's core topic **7-8**: Moderately relevant, contains related concepts **4-6**: Tangentially related or partially relevant **1-3**: Not relevant to the question at all - Select chunks that are semantically promising for answering the question. **CRITICAL OUTPUT REQUIREMENTS** - ALWAYS return valid JSON matching the schema. - YOU MUST include ALL chunks in the scores array - NEVER return an empty or null scores array - Each score must have: chunk_index, relevance_score (1-10), and reasoning
Relevance Scorer A_2	Started with {chunk_system_prompt} Score in 1-10 with perspective of rates chunks based on surface-level relevance to the question. Focus on: - Match keywords and entities - Check direct overlap with question terms - Assign higher scores to chunks mentioning specific metrics

Continued on next page

Role	Prompt
Contextual Reasoner A_2	Started with {chunk_system_prompt} Score in 1-10 with perspective of assesses whether a chunk truly answers the question with reasoning. Focus on: - Look for causal or explanatory statements - Check completeness of information - Evaluate if the chunk provides actual evidence
Evidence Extractor A_2	Started with {chunk_system_prompt} Score in 1-10 with perspective of extracting concrete supporting spans that justify relevance. Focus on: - Identify sentences or numbers supporting the answer - Prefer precise factual details - Provide support score
Diversity Agent A_2	Started with {chunk_system_prompt} Score in 1-10 with perspective of penalizes redundant chunks and promotes diversity of evidence. Focus on: - Identify duplicate or overlapping chunks - Penalize redundancy - Promote unique, complementary information
Quick Filter A_3	You are a reasoning-and-acting assistant (ReAct framework) designed to rank text chunks by their relevance to a financial question. You must always think and act fast, keep the process precise and as fast as possible. **Core Instructions** You will be given: 1. A **user question** 2. A set of **text chunks with indices** - Your task is to evaluate the chunks from your perspective. - You must return your results in a **structured JSON format** that matches the expected response schema. **Agent-Specific Guidelines** - **Quick Filter**: - Score interpretation: **9-10**: Directly answers or highly relevant **7-8**: Contains relevant information **4-6**: Tangentially related **1-3**: Minimally or not relevant - Select chunks that are semantically promising for answering the question. **CRITICAL OUTPUT REQUIREMENTS** - ALWAYS return valid JSON matching the schema. - YOU MUST include ALL chunks in the scores array - NEVER return an empty or null scores array - Each score must have: chunk_index, relevance_score (1-10), and reasoning
Relevance Scorer A_3	Started with {chunk_system_prompt} Score in 1-10 with perspective of assess semantic relevance to the question. Focus on: - Direct answers to the question - Key entities and concepts - Information density
Contextual Reasoner A_3	Started with {chunk_system_prompt} Score in 1-10 with perspective of evaluate explanatory and reasoning content. Focus on: - Causal explanations - Contextual information - Completeness of answer
Evidence Extractor A_3	Started with {chunk_system_prompt} Score in 1-10 with perspective of identify concrete facts and supporting evidence. Focus on: - Specific numbers, dates, facts - Quotable evidence - Verifiable claims
Financial Analyst A_4	Started with {chunk_system_prompt} Score in 1-10 with perspective of quantitative analysis focused on financial metrics and data. Focus on financial ratios, cash flow, revenue trends, balance sheet items, accounting treatment
Risk Analyst A_4	Started with {chunk_system_prompt} Score in 1-10 with perspective of qualitative analysis focused on business context and risks. Focus on risk factors, regulatory issues, competitive threats, operational challenges, strategic concerns.

Rethinking Content Moderation via Severity-Aware Ranking

Abstract

Online video content moderation is critical for protecting minors. Violations are increasingly implicit and context-dependent: a swimwear is innocuous in a vlog but high-risk with suggestive posing. Yet, traditional binary systems fundamentally fail to capture this continuous severity spectrum, directly leading to both excessive false positives for context-heavy samples and missing deeply implicit violations. We introduce KUROKO, a content moderation system that acts as a behind-the-scenes assistant, driving a paradigm shift in content moderation from binary classification to severity-aware ranking. Our contributions are threefold: (1) Human-Centric Severity Ranking: KUROKO shifts from rigid binary divides to a continuous risk spectrum, producing nuanced, expert-level rationales closely aligning with human judgment. (2) Verifiable Alignment and Interpretability: By integrating a severity-aware data engine and a verifiable reinforcement learning approach, we replace black-box decisions with transparent, actionable diagnostics. (3) Cost-Efficient Deployment: We engineer a coarse-to-fine inference architecture equipped with a lightweight recall classifier, enabling compact models to rival proprietary VLMs at a fraction of the computational cost. Extensive offline and online A/B tests demonstrate KUROKO's advantages over traditional binary baselines and its competitiveness with leading commercial APIs at a fraction of their scale. Online, KUROKO yields more human-confirmed enforcement actions under an equal human-review budget, while lowering violative exposure and user negative feedback. Source code and dataset are available at: https://bilibili-kuroko.github.io.

Figure 1: From binary to severity ranking. KUROKO evaluates compositional context for interpretable, severity-aware assessment, precisely distinguishing benign from provocative content.

1 Introduction

Online video sharing platforms (OVSPs), such as YouTube, serve as primary hubs for entertainment and education, making content moderation essential to safeguard users from harmful material (Gillespie, 2018). Conventional moderation systems (Wang et al., 2025b; Yew et al., 2026) formulate this task as binary classification: samples are labeled "violating" or "non-violating" against rigid rules, and models are trained to reproduce these boundaries. However, as illustrated in Figure 1, real-world content exists on a continuous risk spectrum with a vast gray area that defies binary categorization (Kiela et al., 2020). This mismatch leads to both severe over-penalization of benign-but-sensitive content and missed violations that exploit boundary ambiguity. Furthermore, the black-box nature of binary decisions offers no diagnostic insight, leaving developers trapped in directionless trial-and-error (Ribeiro et al., 2016).

Recent efforts (Redmon et al., 2016; Bao et al., 2025; Liu et al., 2023; Li et al., 2023; Chen et al., 2024) leverage Vision-Language Models (VLMs) for richer contextual understanding, yet remain locked in the classification paradigm—mapping complex visual inputs onto discrete binary labels while failing to provide the severity-aware assessment necessary to navigate the gray area.

[*] Equal contribution.

To bridge these gaps, we present **KUROKO**, an industrial-scale content moderation system built on a generative severity ranking paradigm, to our knowledge among the first deployed in production at this scale. Our contributions are summarized as follows:

- **Severity Ranking Paradigm.** We formalize a shift in content moderation from rigid binary classification to a continuous severity-aware ranking framework. This paradigm tackles the long-standing "gray area" bottleneck, mitigating over-penalization while substantially narrowing the alignment gap with human judgment.
- **Rubric-Verifiable Reinforcement Learning with SACRM.** We propose a Rubric Reinforcement Learning with Verifiable Rewards (RLVR) approach for severity-aware moderation alignment. At its core is a novel Severity-Aware Constrained Rule-Matching (SACRM) reward—a programmatic rubric enforcing multi-tier precision and hard guardrails—which delivers verifiable alignment signals and interpretable diagnostics where conventional preference rewards fall short.
- **Industrial-Grade Pipeline from Data to Deployment.** We engineer an end-to-end pipeline that operationalizes our method at production scale. Our severity-aware data engine structures expert audit logic into reasoning trajectories, achieving 5.56× the annotation efficiency of manual labeling for SFT and RL. Simultaneously, a coarse-to-fine inference architecture—pairing a lightweight recall classifier with the generative VLM—shields the system from redundant traffic, allowing KUROKO to handle millions of daily requests while rivaling proprietary commercial APIs at a fraction of the computational cost.

2 Related Works

2.1 Content Moderation in Video Platforms

While human moderation was foundational, its scalability and welfare challenges—driven by rising user generated content volumes, reviewer subjectivity (Lyons et al., 2021), and psychological harm (Gonzalez and Matias, 2025; Roberts, 2014)—have accelerated the transition toward automation (Lykouris and Weng, 2025). However, early automated systems rely heavily on Classification-based Models (CBMs) (Won et al., 2017; Khan et al., 2024; Phan et al., 2022; de Freitas et al., 2019), which detect only predefined patterns. Consequently, they lack the granularity and adaptability required for evolving content risks, yielding low interpretability and a narrow scope of applicability. Although ordinal classification (Niu et al., 2016; Cao et al., 2020) addresses this by modeling ordered risk levels rather than flat labels, its $K-1$ cumulative thresholds still collapse to one discrete tier at inference, leaving samples within a tier mutually interchangeable and offering no interpretable rationale—bounding both granularity and diagnostic utility for iterative refinement.

2.2 VLMs for Content Moderation

While promising CBM successors, open-source VLMs lack domain moderation knowledge due to prohibitive curation costs (AlDahoul et al., 2024; Wang et al., 2025c), and leveraging synthetic data risks overfitting (Wu et al., 2025; Cui et al., 2025). Beyond data, current VLM-based methods—such as Chain-of-Thought (CoT) (Lu et al., 2025), multi-dimensional frameworks (Bao et al., 2025), and RL alignment (Li et al., 2026)—remain trapped in a classification paradigm. They struggle with evolving borderline cases and incur severe computational overhead compared to lightweight CBMs. To mitigate these inference costs, various efficient reasoning strategies have emerged, encompassing CoT compression (Kang et al., 2025), token pruning (Xia et al., 2025), prompt guidance (Xu et al., 2025; Lee et al., 2025; Han et al., 2025), distillation (Li et al., 2024; Liao et al., 2025; Li et al., 2025), latent reasoning (Hao et al., 2024; Shen et al., 2025), and dynamic adaptive CoT (Lou et al., 2025; Zhang et al., 2025).

3 Methodology

3.1 Problem Formulation

Traditional CBMs treat moderation as a binary decision over a rigid action space $\mathcal{A}_0 = \{\text{Accept}, \text{Reject}\}$, collapsing the risk spectrum so that high recall floods reviewers with false positives while high precision lets harmful content reach users. Mildly suggestive videos and explicitly exploitative material receive identical binary labels, ignoring the *compositional semantics* of

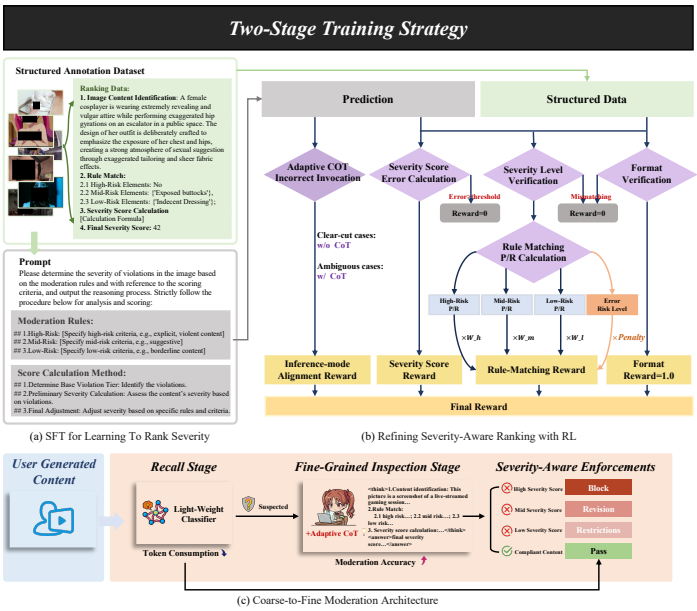

Figure 2: **KUROKO pipeline.** (a) *SFT* leverages adaptive reasoning for policy grounding; (b) *RL via Rubric RLVR* optimizes tier-wise alignment; (c) *Coarse-to-Fine Deployment* filters and routes risky samples.

moderation rules, where identical visuals yield divergent severity by context (Figure 1). In practice, OVSPs already operate over a graded action space $\mathcal{A}^+ = \{\text{Accept}, \text{Restrict}, \text{Revision}, \text{Reject}\}$ that matches enforcement to assessed risk, motivating an ideal moderator $f_{\text{ideal}} : \mathcal{C} \times \mathcal{P} \to \mathcal{A}^+$ (where $\mathcal{C}$ denotes the user content space and $\mathcal{P}$ the policy configurations) that should possess two capabilities: (i) a fine-grained rule-grounding function $g : \mathcal{C} \times \mathcal{R}_p \to [0, 1]$ that identifies which rules from a finite set $\mathcal{R}_p$ are violated, and (ii) a severity aggregation that mirrors human reviewers in jointly weighing the violated rules and their respective risk levels to produce a final score $s_p : \mathcal{C} \to \mathbb{R}$ aligned with human judgment:

$$s_p(c) = \phi\left(\{d_p(r) \cdot g(c, r) \mid r \in \mathcal{R}_p\}\right), \quad (1)$$

where $d_p(r)$ encodes per-rule risk weights and ϕ aggregates rule-level signals into a scalar severity. The resulting score is then mapped monotonically via $h_p : \mathbb{R} \to \mathcal{A}^+$ to graded actions, completing f_{ideal}.

3.2 Policy-Grounded Alignment and Adaptive Reasoning

Open-source VLMs lack domain-specific moderation knowledge, and their safety alignment often induces over-refusals on sensitive inputs. To address this, our severity-aware data engine (Figure 3, Appendix A) structures expert audit logic into fine-grained trajectories. Crucially, rather than forcing the model to blindly memorize the combinatorial space of rule violations, we explicitly train it to replicate the systematic two-step workflow of human reviewers: (1) identifying specific policy violations (g), and (2) aggregating the severity based on predefined logic (ϕ). The exact weights (d_p) and aggregation mechanics of our production system are redacted to protect commercial enforcement standards from circumvention; Appendix C gives an executable public proxy that reproduces every reported metric without them, and h_p is likewise a configurable policy mapping rather than a fixed score-to-action lookup. By performing SFT on these trajectories, the model internalizes the rule-based rationale (g, ϕ) rather than memorizing fixed point assignments, so that the weight schedule d_p can be re-parameterized at deployment without retraining.

Since applying full CoT reasoning to every item is computationally prohibitive in production, we adopt an adaptive reasoning strategy (Lou et al., 2025). A lightweight complexity router (Appendix G.2) partitions training data into CoT-needed subsets (ambiguous gray-area cases) and CoT-unneeded subsets (obvious violations or clearly safe content). Fine-tuning on this mixed-granularity dataset enables the model to internalize both detailed reasoning for hard samples and direct prediction for easy ones, minimizing average latency without sacrificing depth on difficult cases. The model is optimized via standard next-

token prediction loss:

$$\mathcal{L}_{\text{SFT}} = -\sum_{t=1}^{T} \log P\left(y_t \mid y_{<t}, x; \theta\right). \quad (2)$$

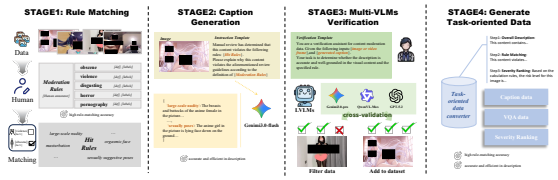

Figure 3: Overview of our severity-aware data engine.

3.3 Severity Alignment via Rubric RLVR

While SFT establishes baseline severity-ranking capability, the resulting model exhibits two residual issues: systematic errors in risk-level stratification, and output instability when toggling between direct and reasoning modes. To enforce rigorous compliance, we introduce Rubric RLVR, powered by a programmatic SACRM reward scheme to stabilize training and align optimization with operational risk priorities (see Figure 2b).

Reliable severity ranking requires precise localization of policy rules in visual evidence and correct association with designated risk levels. We optimize per-level precision $\mathcal{R}_{\text{prec}}^{(k)}$ and recall $\mathcal{R}_{\text{rec}}^{(k)}$ across risk tiers k, weighted by importance w_k:

$$\mathcal{R}_{\text{rule}} = \sum_{k=1}^{K} w_k \left(\alpha \mathcal{R}_{\text{prec}}^{(k)} + \beta \mathcal{R}_{\text{rec}}^{(k)}\right) \quad (3)$$

where $\sum_{k=1}^{K} w_k = 1$, and α, β trade off precision and recall.

To facilitate stable policy updates under structured rewards, the SACRM rubric incorporates **four specialized components** targeting distinct operational failure modes:

(1) Soft severity-tier penalty. Predictions at an incorrect risk level receive a $0.5\times$ discount on $\mathcal{R}_{\text{rule}}$, encouraging accurate stratification while preserving learning gradients.

(2) Hard deviation guardrail. If the predicted score deviates severely from the ground truth ($|s_{\text{pred}} - s_{\text{gt}}| > \tau$), the sample receives zero total reward, preventing catastrophic mis-rankings from dominating optimization.

(3) Inference-mode alignment reward $\mathcal{R}_{\text{align}}$. This reward penalizes inconsistencies between the model's actual inference behavior and the router's intent, ensuring correct utilization of direct versus reasoning modes.

(4) Format consistency reward $\mathcal{R}_{\text{fmt}}$. This reward penalizes structural deviations from the prescribed output template required by downstream production pipelines.

The final composite reward is formalized as:

$$\mathcal{R}_{\text{tot}} = \begin{cases} 0, & |s_{\text{gt}} - s_{\text{pred}}| > \tau \\ \sum_i \gamma_i \mathcal{R}_i, & \text{otherwise} \end{cases} \quad (4)$$

where $(\mathcal{R}_1, \mathcal{R}_2, \mathcal{R}_3) = (\delta\,\mathcal{R}_{\text{rule}}, \mathcal{R}_{\text{align}}, \mathcal{R}_{\text{fmt}})$ with corresponding weights $\gamma_1, \gamma_2, \gamma_3$, and $\delta = 0.5$ if the predicted risk tier differs from the ground truth (else $\delta = 1$).

3.4 Cost-Efficient Coarse-to-Fine Deployment

To mitigate the computational overhead of brute-force VLM deployment under massive traffic, KUROKO adopts a hierarchical coarse-to-fine architecture. In the coarse-grained triage filter stage, a lightweight, high-recall model rapidly screens all incoming traffic, immediately clearing obviously compliant items, shielding the VLM from redundant load. In the fine-grained inspection stage, the VLM executes severity-ranking CoT exclusively on the recalled subset. Crucially, the model's internalized adaptive reasoning automatically toggles between *direct mode* (bypassing text generation for easy samples) and *reasoning mode*. Because cleared items never reach the VLM, this stage's recall bounds end-to-end safety; we report its false-negative rate in Sec. 4.5.

4 Evaluation

4.1 Experimental Setup

4.1.1 Dataset and Benchmark

Via our data engine (Appendix A), we curate large-scale datasets across five domains using verified production data. For efficiency, clear-cut samples use empty reasoning (`<think></think>`), while ambiguous cases receive full CoT rationales. We evaluate on our introduced Fine-Grained Content Moderation Benchmark (FG-CMB). Its four severity tiers (*Safe, Low-Risk, Medium-Risk, High-Risk*) directly assess ranking performance and im-

	Training			FG-CMB		
Category	**H**	**M**	**L**	**H**	**M**	**L**
Pornography	2,311	0	0	351	0	0
Obscene	1,910	5,025	6,038	254	648	647
Violence	721	150	5	609	117	33
Horror	284	6	0	139	19	5
Disgusting	107	1,422	0	60	1,070	2
Normal		70,000			9,978	

Table 1: Category-wise distribution of training data and FG-CMB across severity tiers. Category rows are not mutually exclusive: a frame matching several categories counts in each. FG-CMB is hard-case-enriched rather than a random production draw, over-sampling historical false negatives, subtle violations and small targets.

plicit/explicit violation discrimination (Table 1, Appendix A.3).

4.1.2 Evaluation Metrics

We evaluate KUROKO across three dimensions to reflect both safety screening accuracy and severity discrimination: (1) **Binary Safety Metrics**: Precision, Recall, and F1-score for Safe vs. Unsafe classification. (2) **Severity-Aware Metrics**: Per-tier (High, Medium, Low) evaluation of stratification reliability near policy boundaries. Per-severity results report *stratified binary detection* (each level against Safe samples); the matched comparison instead scores *exact severity assignment* and adds **Tier MAE** (mean absolute tier distance), **QWK** (quadratic-weighted κ), **Spearman** against the rule-derived reference score, and **Intra-tier ranking** (pairwise ordering accuracy *within* each true level, ties 0.5). Intra-tier reference order follows deterministically from unanimous three-annotator rule labels via the fixed aggregator, never a model output. (3) **Online A/B Metrics**: human-final Reject and Restrict rates at an equal review budget, plus Violative View Rate and User Dislike Rate, to verify proportional enforcement without relying on flag volume alone.

4.1.3 Baselines

(1) Classification Baselines: We compare against Falconsai NSFW[1] and an in-house binary classifier built on Qwen3-VL-4B-Instruct with identical data. We further fine-tune a CORAL ordinal head (Cao et al., 2020) on the Falconsai NSFW CNN with partitioned ordinal labels. Because that backbone is far weaker than ours, it cannot separate paradigm from capacity; we therefore add a **matched ordinal head** on Qwen3-VL-4B-Instruct (Bai et al., 2025) backbone under identical data and step budget, which is the comparison that isolates the ranking paradigm. **(2) Frontier VLMs**: We benchmark against leading commercial APIs (GPT-5.2, Gemini-3.0-Pro, Gemini-3.0-Flash and Qwen-VL-Max) to evaluate performance. **(3) Production System**: We evaluate KUROKO via large-scale A/B tests against the heavily optimized live system, which uses a VLM classifier relying on direct logit scores rather than our generative ranking.

[1] https://huggingface.co/Falconsai/nsfw_image_detection

4.1.4 Implementation Details

All offline experiments use a single node with 4 NVIDIA A100 GPUs. SFT fine-tunes Qwen3-VL-4B-Instruct for 2 epochs via Megatron-LM (Shoeybi et al., 2019) (lr 1×10^{-5}, batch size 256, warmup 0.1). RL employs GSPO (Zheng et al., 2025) via VeRL (Sheng et al., 2025), sampling 8 responses per query with batch size 128. For API-based VLMs, we use a curated prompt strategy (Appendix B) to balance fairness and costs. The online A/B test runs on the live pipeline (20% traffic, five days), deploying a Recall Classifier (1 A10 GPU) followed by the VLM ranking module (2 RTX 4090 GPUs). All four relative changes in Table 5 are significant at $p < .05$ under two-sided two-proportion z-tests.

4.2 Offline Experimental Results

Tables 2 and 3 evaluate KUROKO across risk domains and severities under the stratified binary detection protocol. Despite its 4B size, KUROKO surpasses the larger Qwen-VL-Max across all five domains (e.g., F1 +10.40% in *Pornography*, +12.16% in *Disgusting*) and beats the data-identical Qwen3-VL-4B-FT (Cls), indicating the gains do not come from the training data alone. The advantage peaks in ambiguous tiers: KUROKO's Medium-tier F1 (67.20%) leads every API evaluated here, though Appendix D shows Gemini-3.0-Pro closing much of this gap once all models are given an identical rubric. Holding backbone, data, and step budget fixed, KUROKO-SFT leads the ordinal head Qwen3-VL-4B-FT (Ord) in F1 at every severity level (+7.1, +5.3 and +12.1 pp) and at higher precision throughout, with RL and coarse-to-fine adding a further +3.2 to +4.9 pp. In the Low tier

KUROKO	42.71	70.42	**53.17**	57.99	79.88	**67.20**	34.57	85.01	**49.15**

Table 3: Severity-aware evaluation on FG-CMB across High-, Medium-, and Low-severity levels (values in %), contrasting KUROKO with both ordinal and fine-tuned binary classifiers, leading commercial VLM APIs, and Qwen-family models.

Model	Mac.F1	MAE↓	QWK	Spear.	Intra
Qwen3-VL-4B-FT (Ord)	.4361	.5455	.5248	.5371	58.55
KUROKO-SFT	.5557	.3928	.5749	.6075	68.02
KUROKO-RL	**.5662**	**.3443**	**.6107**	**.6376**	**69.67**

Table 4: Matched comparison against an ordinal head on the *same* backbone. Mutually exclusive four-way tier protocol; Mac.F1 averages over all four tiers including Safe, so it is not comparable to the per-tier F1 in Table 3. Intra-tier in %.

Metric	Relative Δ
Human-final Reject Rate (explicit high risk)	**+12.21%**
Human-final Restrict Rate (mid-low boundary)	**+13.28%**
Violative View Rate	**−23.68%**
User Dislike Rate	**−8.88%**

Table 5: Large-scale online A/B tests in production. Both arms are held to the same human-review intake volume, rule pool, moderators and action definitions, so all four rows are measured at an **equal review budget**. Reject/Restrict count human-confirmed decisions, not model flags.

(implicit violations), the binary FT reaches only 35.47% F1 and the matched ordinal head 32.19%, while KUROKO attains 49.15%—a contrast of binary, ordinal and ranking formulations on an identical backbone that further validates the advantage of the ranking formulation. It also mitigates API over-sensitivity: GPT-5.2's Low-tier precision collapses to 16.38%, while KUROKO sustains 34.57%. Sec. 4.3 scores the same matched pair on exact severity assignment and within-tier ordering.

4.3 Does Continuous Ranking Help Beyond Ordinal Classification?

Stratified binary detection cannot see ordered error or within-tier ordering—any prediction above Safe counts alike—so we rescore Qwen3-VL-4B-FT (Ord) and KUROKO on exact severity assignment, where the budget-matched contrast with KUROKO-SFT leaves how severity is *represented* as the only difference. As Table 4 shows, with backbone and data fixed KUROKO-SFT leads on every metric, all scored against

Method	Pornography			Obscene			Violence			Horror			Disgusting		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1	P	R	F1
Severity-aware SFT	41.43	77.78	54.06	62.67	68.79	65.59	34.26	62.10	44.16	10.40	69.06	18.08	51.67	82.46	63.53
+ RL Refinement	41.48	77.78	54.11	63.40	70.80	**66.90**	41.62	54.76	47.29	13.61	60.43	22.22	62.81	83.96	71.86
+ Coarse-to-fine (Full)	42.01	76.35	**54.20**	63.97	69.75	66.74	42.63	53.31	**47.38**	14.14	58.99	**22.81**	64.24	83.48	**72.62**

Table 6: Ablation study evaluating the cumulative impact of each KUROKO component.

Method	Resp. Len.	Skip Rate	VLM Traffic
Full CoT	565	—	100%
Adaptive CoT	316 ($\downarrow$ 44.07%)	48.38%	100%
C2F + AdaCoT	—	—	22.50%

Table 7: Efficiency analysis of KUROKO variants.

the same severity labels: Macro-F1 $+12.0$ pp (95% CI $[+10.5, +13.5]$), Tier MAE -28.0% relative, QWK $+5.0$ pp, intra-tier $+9.5$ pp, all paired-bootstrap CIs excluding zero; RL widens every margin (QWK $+3.6$ pp). The ordinal head's inductive bias works as intended—its QWK trails KUROKO-SFT by only 5.0 pp against 12.0 pp on Macro-F1, so wrong tiers are mostly adjacent—but it cannot express *within-tier* ordering: $K-1$ cumulative thresholds collapse to one discrete tier at inference, leaving samples inside a tier interchangeable. We therefore claim an advantage in ordered error, rank correlation and within-tier resolution rather than uniform superiority over all classification variants—a ranking that holds across all 11 public proxy weights (Appendix C).

4.4 Results of Online A/B Tests in Production

Beyond offline FG-CMB, we further validate KUROKO under live traffic. As shown in Table 5, compared against the heavily optimized production VLM relying on logit thresholds, KUROKO raises the human-final Reject Rate by **+12.21%** for explicit high-risk content and the Restrict Rate by **+13.28%** for implicit mid-to-low risk boundary cases. Because review intake was held equal across arms, these rows separate *better* ranking from merely *more aggressive* flagging: a ranker that simply flagged more would crowd the fixed queue with benign items and thereby *reduce* human-confirmed actions. We observe the reverse: KUROKO enhances finite human review capacity to intercept actual violations early. Two downstream metrics confirm this precision gain without collateral damage: Violative View Rate drops **23.68%** and User Dislike Rate falls **8.88%**, proving severe items and grey-zone violations are intercepted before impacting users at scale. *bounded* budget.

4.5 Ablation Studies

Table 6 traces the cumulative contribution of each component, starting from Severity-aware SFT. RL Refinement via SACRM yields its largest gain on implicit violations (*Disgusting* F1 $+8.33$ pp), where soft penalties amplify supervision on the ambiguous Low/Medium tiers that standard SFT handles poorly. Coarse-to-fine changes F1 only marginally ($+0.1$ to $+0.8$ pp, -0.2 pp on *Obscene*); its contribution is throughput, quantified next. Table 7 confirms KUROKO's efficiency: Adaptive CoT skips reasoning on 48.38% of unambiguous samples, reducing average response length by 44.07%, while C2F offloads 77.50% of traffic. Since anything the first stage clears bypasses VLM inspection, its false negatives bound end-to-end safety: at the production operating point it recalls 98.61% of violating samples. These are *benchmark* rates on the hard-case-enriched FG-CMB, not natural-traffic estimates; Appendix E gives a 5% online audit and the coverage-parity gating that holds this level.

5 Conclusion

We presented KUROKO, an industry-ready moderation framework that shifts the paradigm from binary classification to severity ranking. By coupling SFT with Rubric RLVR, KUROKO establishes an iteration-friendly workflow: its structured CoT outputs provide the diagnostic transparency needed for targeted policy refinement. For industrial scalability, the hierarchical coarse-to-fine architecture ensures cost-efficient performance at million-content scale. Despite its compact 4B size, KUROKO consistently outperforms leading proprietary VLMs, delivering significant gains in both high-risk interception and mid-to-low-tier discrimination during production A/B tests. This work offers a transferable blueprint adaptable to diverse content governance scenarios.

Limitations

While KUROKO establishes a robust foundation for severity-aware moderation, several limitations remain. First, to protect production integrity and prevent policy circumvention, certain operational details—including specific rule weights and the precise formulations of our severity aggregation functions—are redacted. Disclosing these mechanics risks exposing proprietary commercial enforcement standards. Second, while our evaluation demonstrates clear advantages over leading commercial VLMs and foundational ordinal classification baselines, future studies could incorporate broader listwise/pairwise ranking and calibrated regression frameworks to further isolate the specific drivers of our performance gains. Additionally, exploring deeper theoretical connections between our SACRM framework and other emerging verifiable RL paradigms remains a promising direction. Lastly, to achieve massive industrial scalability, our data engine utilizes cross-model verification; supplementing this automated pipeline with periodic human-in-the-loop calibration in the future could effectively mitigate the inherent priors typical of foundational VLMs.

Ethics Statement

Data Privacy and Controlled Access All content passes platform compliance review and mandatory screening excluding any depiction of potential minors before sampling—a corpus-eligibility criterion applied across all categories and tiers, independently of severity. De-identification is *task-preserving* and precedes any transfer: faces and identifying logos are masked, user metadata and account IDs stripped. Two annotators independently labelled each candidate before and after masking, and only samples with identical labels across both rounds enter the benchmark. Masking reduces direct identifiability but does not anonymize: body, setting and other contextual cues remain, and are themselves the evidence the severity label rests on. It follows the platform's open-data release guidelines and is reviewed by its Legal and Compliance department, with no material transferred before that review completes. Access is **application-based, never open download**, under signed agreements restricted to approved research use, prohibiting redistribution, re-identification and biometric use. Safe and Low-risk content supports community reproduction, whereas Medium- and High-risk tiers require stricter approval; risk tier itself does not constitute release authorization. Any item later flagged as possibly depicting a minor is withdrawn on receipt, propagating to all recipients. Code, prompts and schemas, the de-identified rule IDs, the public proxy aggregation, the SACRM implementation and aggregate statistics can be released separately without exposing raw production content or policy weights.

Annotation Quality and Human Welfare All annotators were explicitly informed about the presence of NSFW content and provided written consent. To mitigate annotation bias, labels come from our professional moderation system with cross-annotation and two-round quality control. Annotators are senior professional moderators, not crowdworkers; the workflow provides task rotation, scheduled rest, and mechanisms to pause or withdraw from exposure to sensitive material, with psychological counselling available. Approved researchers receive prominent sensitive-content warnings and handling guidance.

Cultural Subjectivity and Regulatory Grounding Severity perception varies across cultural and regional contexts. Our tiers are grounded in Chinese regulatory requirements (e.g., Cybersecurity Law, Minors Protection Regulation, Content Ecosystem Provisions). The *framework* is policy-configurable, but we do not claim these tier definitions or thresholds are culturally universal: deployment in another jurisdiction requires local legal and cultural experts to redefine the rule ontology, weights and action mapping, and to repeat human-agreement and deployment validation. The dataset card asks for recalibration rather than direct reuse.

Mitigating Over-Censorship Risks A core motivation of KUROKO is reducing over-censorship. Shifting from binary "all-or-nothing" enforcement to severity-aware ranking enables proportional platform actions with transparent, interpretable rationales. Our online evidence is indirect: at an equal human-review budget we observe higher human-confirmed actionable yield alongside reduced violative exposure and negative user feedback, rather than a directly measured reduction in over-blocking, since appeal and overturn rates were unavailable to us.

A Details on Severity-Aware Data Engine and Dataset

To internalize the human-aligned severity reasoning introduced in Sec. 1, the model requires more than categorical labels; it necessitates a structured trajectory that mirrors expert judgment. This process involves two core challenges: identifying which policy rules are triggered and assessing overall violation severity. While identification requires the model to parse subtle contextual cues to determine which specific policy is triggered, it remains a purely qualitative step. However, rule identification alone does not equate to a final judgment; the subsequent task of severity aggregation remains a major challenge. It involves integrating multiple violation signals into a continuous risk estimate. Learning this mapping directly from human-labeled rule combinations is impractical; the combinatorial explosion of rule interactions leads to exponential supervision requirements and severe generalization failures on long-tail cases.

To address these scalability bottlenecks, we introduce a severity-aware data engine that produces severity-aware supervision through a four-stage process. To ground the model in precise rule understanding, fully manual rationale writing is prohibitively expensive, while fully automated labeling with modern VLMs is unreliablethese models excel at open-ended description but struggle with precise rule-level tagging due to safety alignment constraints and limited domain adaptation. Our pipeline therefore decouples rule matching from contextual description (Figure 3): human annotators perform closed-set rule verification at standard throughput, while Gemini-3.0-Flash (Team et al., 2023) generates rich, open-domain contextual rationales. All supervision is structured in a severity-aware CoT format for stepwise learning of moderation reasoning, as illustrated in Figure A-3.

To make aggregation scalable, we replace the memorization of infinite rule combinations with a tiered severity schema. By grouping rules into three risk tiers with predefined weights, our aggregator ϕ (Equation (1)) enables schema-guided reasoning that aligns with frontline enforcement logic. Because ϕ is a separate module rather than a learned mapping, adapting it to a different policy means redefining tier membership and weights rather than retraining; Appendix C shows our conclusions hold across 11 weight schedules. Transfer to other jurisdictions or platforms remains untested.

A.1 Four-Stage Data Production Pipeline

Our pipeline processes raw data through the following four-stage trajectory:

Stage 1: Human-Centric Rule Matching. Annotators perform closed-set rule annotation for untagged content at the same throughput as conventional workflows, ensuring no regression in annotation efficiency.

Stage 2: Generative Rationale Synthesis. Each labeled sample—whether human-annotated in Stage 1 or pre-tagged from legacy data—is forwarded to Gemini-3.0-Flash to generate fine-grained contextual descriptions explaining the violation rationale.

Stage 3: Cross-Model Logic Validation. Descriptions are validated via consensus among three independent VLMs (Gemini-3.0 Pro, QwenVL-Max, GPT-5.2). Only unanimous agreements are accepted, minimizing hallucination risks (Wang et al., 2025a).

Stage 4: Task-Specific Dataset Generation. Validated reasoning data is transformed via structured templates into three task-specific training sets: **(i)** captioning templates for fine-grained vi-

olation description, **(ii)** VQA templates for rule-grounded visual reasoning, and **(iii)** severity ranking templates implementing the aggregator ϕ for score generation.

A.2 Data Engine Annotation Efficiency

We evaluate the throughput and accuracy of fully manual annotation against our hybrid data engine. As demonstrated in Table A-1, the hybrid approach achieves a **5.6**× speedup while simultaneously improving empirical accuracy, validating the scalability advantages of decoupling rule verification from descriptive reasoning.

Human annotators exhibit significantly lower throughput on open-ended descriptive rationales compared to closed-set rule matching, as manual description writing requires substantial cognitive effort for lexical selection and contextual synthesis. Our pipeline exploits this asymmetry by assigning closed-set verification to humans and descriptive generation to VLMs, which effectively eliminates individual biases in phrasing and subjective interpretation.

Method	Time / 1K (Days)	Acc. (%)	Speedup
Fully Manual	3.5	93.5	1.0×
Hybrid (Ours)	**0.6**	**95.6**	**5.6**×

Table A-1: Annotation throughput and accuracy comparison.

A.3 FG-CMB Dataset Taxonomy and Distribution

The FG-CMB dataset is structured around a rigorous two-level taxonomy aligned with industrial moderation standards. It comprises 50 fine-grained violation elements (L2)—serving as specific reasoning anchorsnested within five major risk domains (L1) plus a safe class.

This hierarchical composition is visualized via a Sunburst Chart in Figure A-1, where the inner and outer rings correspond to L1 and L2 categories, respectively. As indicated by the sector proportions, the dataset preserves the natural long-tail distribution of real-world risks, ensuring that the benchmark faithfully reflects the complexity of actual industrial moderation scenarios.

B Prompt Templates

The prompt templates utilized for the hybrid data annotation pipeline are illustrated in Figure 3 of the main text. In this section, we focus on the specific instructions used for model training, inference and API evaluation. It should be noted that while the logical structure of the prompt is fully preserved to demonstrate our reasoning framework, specific moderation rules and scoring algorithms have been redacted due to commercial confidentiality.

To reconcile the conflict between the high computational cost of CoT and the strict low-latency requirements of online industrial deployment, we introduce an Adaptive CoT mechanism via a meta-cognitive directive. This allows the model to dynamically assess input ambiguity and bypass the computationally expensive reasoning phase for clear-cut cases. Specifically, the following conditional instruction is appended: *"Please evaluate the complexity of the content and autonomously decide whether to execute the full reasoning process or provide a direct assessment."*

C Reproducible Proxy Weight Schedule

The exact production weights d_p and the action thresholds they feed are replaceable *deployment-policy parameters*, not learned parameters and not an indispensable secret of the ranking method. Publishing them together with the thresholds would expose an actionable approximation of the deployed enforcement boundary: at order-10^6 daily submissions, an adaptive adversary could estimate the marginal contribution of each violation signal and assemble content that stays just below the review threshold. We therefore separate *scientific auditability* from *policy disclosure*.

For every number reported under the four-way protocol we use an executable **public proxy** aggregation, derived naively from per-rule IDs and reported here in full so that results can be recomputed without touching our production configuration. Writing H, M and L for the number of matched high-, medium- and low-risk rules:

$$
\begin{aligned}
s_{\text{High}} &= 70 + \min(30,\ 8H + 2M + L) \\
s_{\text{Medium}} &= 30 + \min(40,\ 5M + 2L) \\
s_{\text{Low}} &= \min(30,\ 3L)
\end{aligned}
$$

with counts for virtual (non-photographic) subjects scaled by 0.7. We release this scorer, the de-identified rule IDs matched by KUROKO on approved benchmark samples, the SACRM implementation and an SOP with scripts that regener-

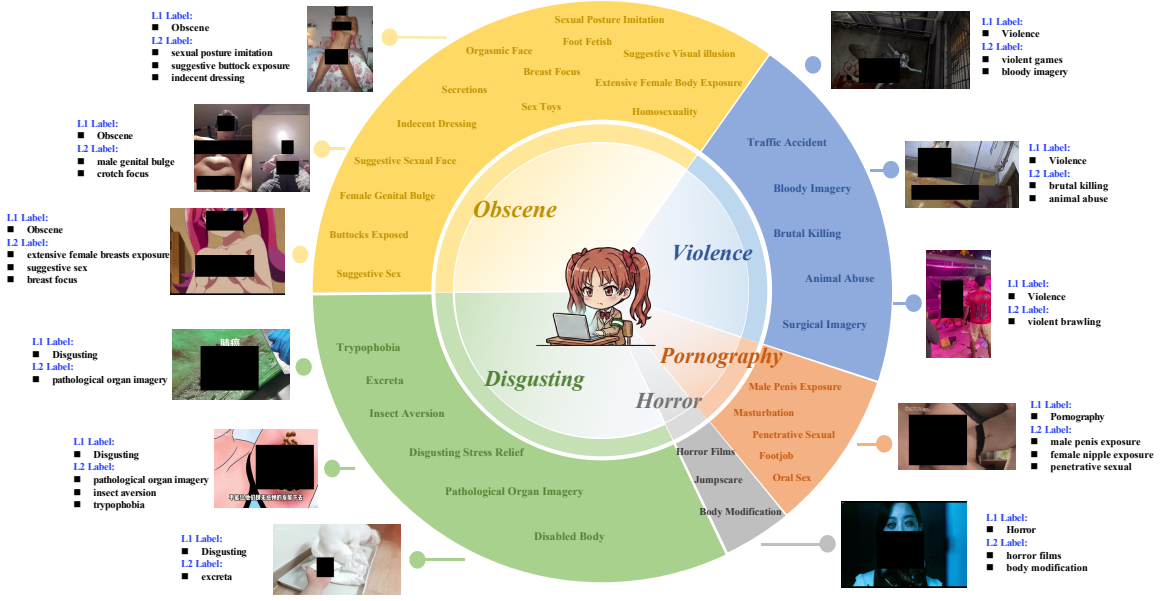

Figure A-1: FG-CMB benchmark overview. FG-CMB provides hierarchical severity annotations across five risk domains (Pornography, Obscene, Violence, Horror, Disgusting), stratified into four tiers: Safe, Low-Risk, Medium-Risk, and High-Risk.

ate every reported metric, so reproduction never requires our aggregation weights.

To confirm that the conclusion does not depend on one chosen weighting, we repeated the matched comparison under 11 proxy variants: independently perturbing the High/Medium/Low contributions by $\pm 20\%$, jointly scaling all contributions by $\pm 20\%$, and moving the virtual-content coefficient to 0.5 and 0.9. KUROKO exceeds the matched ordinal baseline in **11 of 11** variants on Spearman, Kendall, intra-tier pairwise accuracy and Harm Recall@10%; across variants Spearman stays in .6075–.6077 versus .5367–.5372 and intra-tier accuracy in 66.18–69.61% versus 57.14–58.85%. The public proxy does not reproduce the platform's exact scores or enforcement boundary; it makes rule matching, reward computation and the robustness of our central conclusion independently auditable.

D Unified-Rubric API Re-evaluation

Tables 2 and 3 give each API the same rules and an equivalent instruction, but ask only for a discrete label—the one intended difference, since a discrete label instead of a score is the contrast under study. Those API prompts admit only a violation *type*, so their per-tier columns measure stratified binary detection and involve no implicit tier mapping. To remove any doubt that the mapping itself depressed API performance, we reran the evaluation with an identical rubric and identical tier definitions, each model emitting its own tier (Table A-2).

Model	High	Medium	Low
Qwen-VL-Max	22.7/86.6/36.0	32.9/88.3/48.0	15.8/93.9/27.0
Gem.-3.0-Flash	23.8/95.3/38.1	34.2/97.0/50.6	15.9/98.1/27.4
Gem.-3.0-Pro	38.5/82.6/52.5	52.3/88.2/65.6	28.0/87.4/42.4
KUROKO-RL	**42.3**/70.6/**52.9**	**57.6**/80.1/**67.0**	**34.3**/85.6/**49.0**

Table A-2: Unified-rubric re-evaluation: identical rubric and tier definitions, each model emitting its own tier. Cells are P/R/F1 in %. GPT-5.2 is omitted because our provider withdrew access before this rerun; its rows in Tables 2–3 remain curated-prompt and we make no unified-rubric claim for it.

The two weaker APIs still sit at 15.8–34.2% precision with near-ceiling recall, so their over-flagging is not an artefact of our prompt. Gemini-3.0-Pro nearly closes the High tier (52.5 vs. 52.9 F1), while KUROKO retains its largest margin on the Low tier this paper targets (+6.5 pp). This experiment controls prompt and mapping; it does not equalise the difference between a zero-shot API and a domain-adapted model, which is why Sec. 4.3 rather than this table carries the paradigm claim.

Instruction for Severity Ranking

Input: Please analyze the image for violation severity based on the moderation rules. Strictly follow the process below:

 # Moderation Rules

- **High-Severity Rule Set:** A comprehensive collection of explicit violation criteria.
- **Mid-Severity Rule Set:** Numerous context-aware and compositional violation rules.
- **Low-Severity Rule Set:** Extensive boundary-sensitive rules designed for ambiguity-heavy cases.

 # Severity Criteria

- **High Risk (70-100):** Contains explicit high-risk elements.
- **Medium Risk (30-69):** Contains implicit or moderate violation elements without high-risk features.
- **Low Risk (1-29):** Contains only slight boundary elements
- **Safe (0):** No violations.

 # Score Calculation Logic:

[Detailed arithmetic formulas are redacted for proprietary reasons.]

 # Chain-of-Thought (CoT) Requirements Please output the analysis in the following structured format:

1. **Content Recognition:** Briefly describe potential violating content.
2. **Element Identification:** List all violation elements by risk level.
3. **Calculation Process:** State related information and show calculation.
4. **Final Scoring:** Output final score and category.

Output Format:

```
<think> [Insert full reasoning and calculation process here] </think>
<answer> [Final Answer] </answer>
```

(a) Instruction for Severity Ranking.

Instruction for Violation Type Classification

Input: Please analyze the image according to the platform moderation rules and determine whether it contains policy violations. Strictly follow the process below:

 # Moderation Rules

- **High-Severity Rule Set:** A comprehensive collection of explicit violation criteria.
- **Mid-Severity Rule Set:** Numerous context-aware and compositional violation rules.
- **Low-Severity Rule Set:** Extensive boundary-sensitive rules designed for ambiguity-heavy cases.

 # Chain-of-Thought (CoT) Requirements Please structure the analysis as follows:

1. **Risk Identification:** Categorize detected elements into corresponding rules.
2. **Decision Process:** Provide a structured explanation of why the content constitutes a violation.
3. **Final Classification:** Output the final violation type.

Output Format:

```
<think> [Insert structured reasoning here] </think>
<answer> [Final Classification] </answer>
```

(b) Instruction for Violation Type Classification.

Figure A-2: **Prompt Templates.**

E First-Stage Operating Point and Risk Governance

At the fixed production operating point, the first-stage Recall Classifier attains 98.61% recall over all violating samples. Here we document the cost structure that sets that operating point. The platform handles order-10^6 submissions daily under continuous adversarial pressure and runs two tracks: review-before-publish and publish-before-review. KUROKO serves the former, so items it clears remain subject to post-publication review, user reports and rapid re-review. Chasing the last long-tail cases at the first stage would route a large share of traffic to the VLM for a small residual that the later tracks catch more cheaply; the threshold is therefore a cost-constrained choice that we defend by measurement rather than by assuming the residual is negligible.

The harder constraint is measurement. The rates above are *benchmark* FNR on a hard-case-enriched set. Online FNR requires human re-review of a sample of the millions of items cleared daily, which is unaffordable per release; we paid for it once at small scale, and annotating a 5% sample of online traffic put the first stage's online FNR at 0.21%. Every later version is then gated by safety-coverage parity against that baseline arm—a candidate ships only if coverage is at least on par—which holds the accepted level without repeating the audit.

F Case Study

In this section, the application performance of KUROKO in content moderation and severity-aware ranking is demonstrated with cases of content published by real users. The model extracts violation elements from input visual information and generates audit conclusions by matching relevant rules. This not only manifests the excellent comprehension capability of the audit model, but also allows readers to intuitively and quickly grasp the matching logic of audit rules and the calculation method of risk scores. The case results show that KUROKO can effectively assist platforms in identifying inappropriate content and safeguard users healthy experience.

G Lightweight Auxiliary Networks

To ensure reproducibility, we detail the architectures of the two lightweight components used in KUROKO.

G.1 Recall Classifier

To balance the real-time performance and recall rate of the content moderation model, a lightweight pre-recall sub-model classifier model is deployed before KUROKO, constructing a two-stage moderation architecture of pre-recall and multimodal model fine judgment. Built on the lightweight EfficientNet backbone, this sub-model extracts and recognizes multimodal violation features in a coarse-grained way. It only supports violation/non-violation binary classification and rough high-risk violation type judgment. Non-violating samples are directly approved, while boundary-ambiguous samples are recalled to KUROKO for fine-grained analysis, precise violation rules matching and severity ranking. This pre-recall mechanism can drastically filter out safe content and significantly reduce the inference load of KUROKO model, thus improving the end-to-end moderation efficiency while ensuring a high recall rate for the entire moderation pipeline. Meanwhile, in response to the rough judgment errors of the pre-recall sub-model, dynamic recall thresholds are set for regulation, which can be flexibly adjusted according to the accuracy-efficiency requirements of practical moderation scenarios. This achieves a dynamic balance between recall rate and moderation speed, and meets the real-time screening requirements for massive multimodal content.

G.2 Complexity Router

To achieve lightweight yet effective routing, the Complexity Router is designed as a cross-attention-based module followed by a MLP classifier. Specifically, the router takes the visual features $\mathbf{V}$ from the visual encoder and the textual embeddings $\mathbf{T}$ of the instruction as input. A cross-attention layer fuses these modalities to obtain a query-aware visual representation, which is then projected by the MLP to a binary scalar $p \in [0, 1]$, representing the probability that the input requires complex reasoning.

Training this router requires ground-truth labels distinguishing "Easy" samples (Direct Mode sufficient) from "Hard" ones (CoT needed). To generate these labels, we first fine-tune the backbone model on a subset of the FG-CMB dataset using *only* complete Chain-of-Thought annotations. This ensures the pilot model possesses the necessary domain knowledge and reasoning capabilities.

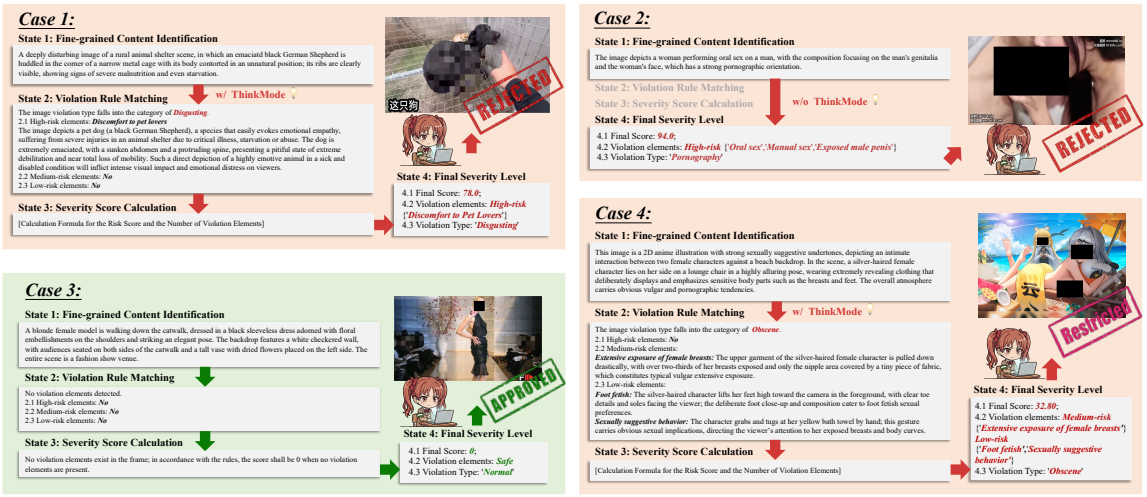

Figure A-3: Cases of KUROKO

We then employ a consistency-based difficulty assessment strategy:

1. **Sample Generation:** For each query x in the training set, we perform inference with the pilot model $N = 8$ times using the Direct Mode (i.e., enforcing immediate answer generation).

2. **Consistency Voting:** We calculate the accuracy of these N responses against the ground truth.

    - If the model correctly answers the query with high consistency (i.e., accuracy $\geq \tau_{acc}$, where we set $\tau_{acc} = 7/8$), the sample is deemed **Simple** (Label 0).
    - Conversely, if the model exhibits low consistency or high error rates in Direct Mode, the sample is labeled **Hard** (Label 1), necessitating the activation of the Chain-of-Thought path.

A critical challenge arose in defining the inference prompt for this evaluation. Initially, we attempted to enforce direct answer generation by fixing the prefix with empty tags `<think></think>`, inspired by Adaptthink (Zhang et al., 2025). However, we observed that this rigid suppression often led to format instability, where the model would generate reasoning steps inside the answer block (e.g., `<answer> [reasoning...] true answer </answer>`). To address this, following Autothink (Sharma, 2025), we explicitly fix the generation prefix to `<think>...</think>`. By providing this minimal, closed reasoning trace, we effectively signal to the model that the thinking phase is concluded, compelling it to transition immediately to the answer generation phase.

FlowTrain: Flow-Based Decoupled Training for Industrial-Grade Vision-Language Models

Abstract

Industrial-grade distributed training of vision-language models (VLMs) remains far less efficient than that of unimodal LLMs. Existing solutions either follow a monolithic design that assigns uniform parallelism to heterogeneous modules or adopt a disaggregated deployment that separates modules while executing them as a batch-synchronized pipeline. In this paper, we highlight that the above solutions are still not sufficient, and VLM training can be further *decoupled*. To this end, we present FlowTrain, a flow-based decoupled training framework that reformulates VLM training as a producer-consumer dataflow coordinated through a *unified memory pool*. The encoder and backbone can progress independently over a global virtual address space. Since this execution decoupling fundamentally changes the optimization objective of allocation and scheduling, FlowTrain further introduces a *heterogeneous parallel allocator* that assigns module-specific parallelism strategies by solving a throughput matching problem. The *dynamic packing scheduler* is used to construct balanced microbatches at runtime according to the actual LLM-side computation cost. Extensive experiments on real-world workloads show that FlowTrain achieves over 50% MFU and up to 1.7× throughput improvement, narrowing the efficiency gap to LLM-only training.

1 Introduction

Vision-language models (VLMs) extend the reasoning capabilities of LLMs by connecting visual content with its linguistic context (Wang et al., 2025a; Zhu et al., 2025; Laskar et al., 2025). Such multimodal learning capabilities have achieved remarkable progress in industrial applications, such as autonomous driving (Li et al., 2025a), embodied agents (Lu et al., 2026), and visual question answering (Wang et al., 2025c). Although model capabilities have advanced rapidly, training efficiency remains a major bottleneck that limits industrial deployment of VLMs. VLM training achieves much lower Model FLOPs Utilization (MFU) than unimodal LLM training, even with massive investments in AI accelerators (Xue et al., 2026a).

Distributed training paradigms for multimodal models including VLMs can be broadly classified into two categories. (i) Monolithic frameworks, exemplified by Megatron-LM (Shoeybi et al., 2019) and its multimodal extensions, treat a VLM as a single network with heterogeneous layers and impose a uniform tensor/pipeline parallelism (TP/PP) strategy across all modules. They ignore the fact that VLMs are structurally heterogeneous, including modality encoders, projectors, and a large LLM backbone (Feng et al., 2025). These modules exhibit drastically different arithmetic intensities and preferred parallelism configurations. The monolithic design thus leads to poor resource utilization and prolongs training duration (Zhang et al., 2025).

(ii) Recent disaggregated frameworks represented by DistTrain (Zhang et al., 2025) recognize the above architectural asymmetry and separate different modules into independent device groups with customized parallelism strategies. However, we identify that disaggregated training is still regarded as a rigid pipeline, where all the data parallelism (DP) replicas of encoders must materialize the entire global batch before the LLM backbone can start computation. The encoder outputs are synchronized with the LLM backbone via *point-to-point* transfer. Such batch-level synchronization barriers are exacerbated by dynamic variability of multimodal inputs, ultimately limiting end-to-end training efficiency (Xue et al., 2026b).

Our key insight is that disaggregation is necessary but insufficient to unlock training efficiency. Instead of a separated-but-synchronized pipeline, an efficient training framework should achieve *both spatial disaggregated deployment and temporal de-*

coupled execution, so that the encoders and the backbone progress as independent producers and consumers rather than as upstream and downstream pipeline stages. Motivated by this, we propose FlowTrain, a flow-based decoupled VLM training framework with three core designs. As the foundation of FlowTrain, the *unified memory pool* unifies heterogeneous memory resources (HBM and DRAM) across all nodes through 64-bit global virtual address (GVA). All frozen encoders write the embeddings into the pool and immediately proceed to the next input. Based on the GVA and page tables, the backbone consumes embeddings from the pool through transparent memory access. VLM training is thus converted from a rigid pipeline into a continuous producer-consumer workflow.

Once execution is decoupled through the unified memory pool, resource allocation and batch scheduling of VLM training should be reconsidered. On the one hand, the optimization objective for resource allocation is no longer minimizing the worst pipeline stage, but balancing the throughput between different modules. FlowTrain introduces a *heterogeneous parallel allocator* that determines module-specific parallelism strategies and resource partitions using a flow matching formulation. On the other hand, since the unified memory pool absorbs runtime variance in encoder latency, batch scheduling should be decided by the actual computation cost after encoding, instead of raw sample size. To construct balanced microbatches, FlowTrain designs a *dynamic packing scheduler* that minimizes padding waste through segment tree-based best-fit packing and jointly balances loads across PP and DP dimensions via zig-zag dispatch. The main contributions of this work are as follows:

- We identify disaggregation alone as insufficient due to batch-level synchronization barriers, and propose a decoupled FlowTrain framework that rethinks VLM training from rigid pipeline execution to continuous producer-consumer dataflow.
- We design three coordinated components to realize decoupled execution, i.e., unified memory pool for asynchronous exchange, heterogeneous parallel allocator for flow matching, dynamic packing scheduler for workload balancing.
- We implement FlowTrain on Ray and evaluate it on real-world workloads across three VLM scales. FlowTrain consistently achieves over 50% MFU and up to 1.7× throughput improvement, closing the efficiency gap to LLM-only training.

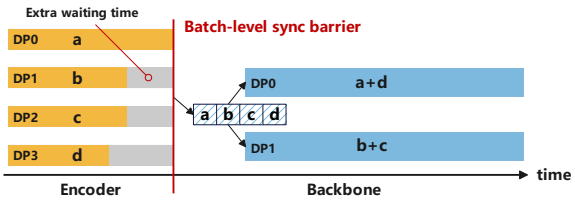

Figure 1: Batch-level synchronization barriers under disaggregated training.

2 Related Work

Compared with unimodal LLM training, optimizing VLM training is more difficult due to its inherent heterogeneity and dynamics. Driven by continuous scaling of industrial VLMs combined with trillion-level datasets, distributed training on large-scale clusters has become imperative. Early systems such as DistMM (Huang et al., 2024) can handle traditional multimodal training efficiently, but do not support LLM training naively. Although frameworks like Megatron-LM (Shoeybi et al., 2019; Rasley et al., 2020; Zhao et al., 2023) excel at LLM workloads, they treat VLMs as monolithic models with heterogeneous layers, resulting in suboptimal resource allocation.

Other studies (Feng et al., 2025; Wang et al., 2025b) adopt fine-grained bubble exploitation or pipeline scheduling algorithms to improve resource utilization. Following this idea, LongCat-Flash-Omni (Team, 2025a) and MegaScale-Omni (Xue et al., 2026a) further reduce engineering complexity. However, colocated schemes may suffer from the long-tail effect, resulting in resource conflicts and additional onload/offload overhead. Disaggregated systems represented by DistTrain (Zhang et al., 2025) deploy heterogeneous modules on separate resource groups, addressing model and data heterogeneity.

Limitation of Existing Methods. However, the above frameworks still retain batch-level synchronization barriers between heterogeneous modules, failing to break the *rigid pipeline execution* paradigm. Even disaggregated training separates the modules spatially but does not decouple their execution temporally. All encoder DP replicas have to fully materialize their output and align at batch boundaries, as illustrated in Figure 1. Only after the slowest encoder replica completes its global batch can the embeddings be synchronously point-to-point transferred to the backbone (Lin et al., 2025). Strict data dependency produces idle periods on both sides whenever their latencies diverge.

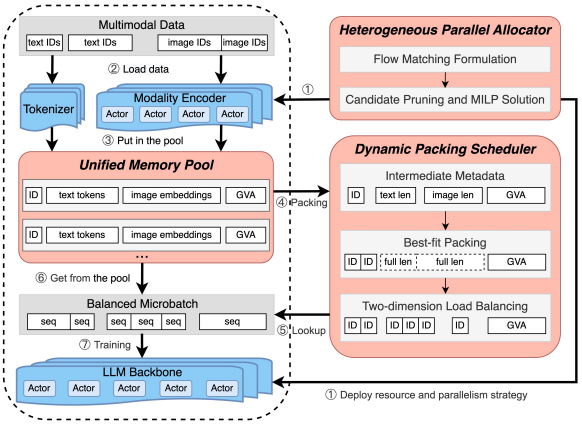

Figure 2: Overview of FlowTrain.

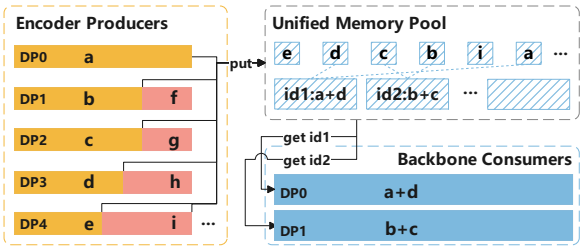

Figure 3: Decoupled producer-consumer dataflow in FlowTrain.

More importantly, industrial multimodal samples exhibit obvious variability in resolution and sequence length. Such variance further magnifies the performance penalty of batch-level synchronization barriers and induces a severe workload imbalance between distributed accelerators. Existing sample scheduling only considers raw input characteristics (e.g., image resolution) rather than actual computational costs after encoding, which also depend on parallelism configuration and runtime conditions (Zhang et al., 2025; Xue et al., 2026b).

3 Methodology

3.1 Overview of FlowTrain

To overcome the limitations of monolithic and disaggregated frameworks, we propose a flow-based VLM training framework, called FlowTrain. The design principle is disaggregated in deployment and decoupled in execution. Instead of treating heterogeneous modules as pipeline stages synchronized at batch boundaries, FlowTrain reformulates training as a continuous producer-consumer dataflow, enabling each component to progress independently at its native throughput.

As illustrated in Figure 2, FlowTrain contains three coordinated components. The end-to-end workflow is as follows. Before training starts, the *heterogeneous parallel allocator* (§3.3) partitions the cluster into separate actor pools (encoder/LLM) that execute with independent parallelism configurations. During training, the frozen encoders process multimodal input asynchronously and place embeddings into the *unified memory pool* (§3.2), while text tokens are inserted directly into the same pool. The lightweight metadata is also stored to track cross-modal pairing information. After sufficient paired embeddings accumulate in the pool, the *dynamic packing scheduler* (§3.4) leverages the metadata to construct computationally balanced microbatches. The LLM backbone continuously consumes microbatches based on the GVA without being aware of their actual storage location, improving resource utilization and training throughput.

3.2 Unified Memory Pool

As shown in Figure 3, the unified memory pool serves as the asynchronous coordination layer between encoder producers and backbone consumers. As the foundation of FlowTrain, it breaks strict data dependency by converting point-to-point batch transfer into globally addressable buffered exchange, which logically unifies heterogeneous memory resources (HBM and DRAM) across all nodes. Each memory location, regardless of its physical location or type, is assigned a unique 64-bit GVA. As illustrated in Figure 4, the GVA space reserves two disjoint contiguous regions corresponding to HBM and DRAM, respectively. Each region provides a GVA interval $[start, start + world_size{*}max_size]$, where $start$ is a globally agreed address base, $world_size$ is the number of total processes, and max_size is the contributed maximum memory capacity. The address space is linearly divided among all processes and visible to all processes. The GVA segment owned by i-th process is $[start + i * max_size, start + (i + 1) * max_size)$. This abstraction provides a single, consistent memory view to all training processes, allowing transparent access to remote memory as if it were local.

A logical GVA is insufficient for direct data movement because training processes ultimately access memory through a physical address. Similar to virtual memory management in modern operating systems, our pool maintains the page tables that map GVA used by processes to physical addresses in HBM and DRAM. The key difference is that the virtual address exposed to each process is no longer a small local VA region, but a globally consis-

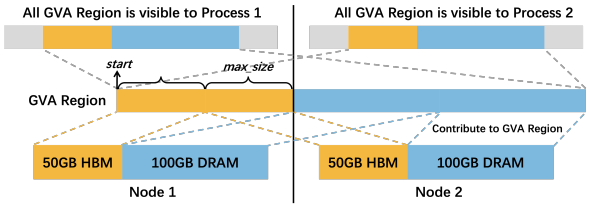

Figure 4: GVA region in the unified memory pool.

tent GVA region spanning pooled memory across nodes and memory tiers. During initialization of the memory pool before training, each process reserves a contiguous GVA region from the segment $[start+i*max_size, start+(i+1)*max_size)$, allocates physical memory from the local operating system, and binds it to the reserved GVA region, which may be less than max_size. Each process exports its memory mapping information to all other processes, which update their page table accordingly. Then, each process has local access to the GVA and the page tables used for virtual address translation, eliminating distributed address resolution protocols on the hot path.

During training, the vision embeddings and text tokens are written into the GVA segment belonging to their own training process. LLM consumes the constructed microbatches directly from GVAs without being aware of their actual storage location. In the implementation layer, FlowTrain resolves the GVA to the corresponding physical address through the collected page tables. The available transport engine is selected based on the source and destination location and memory types. If the request crosses memory tiers within a node, FlowTrain invokes intra-node transfer engine like NVLink and HCCS. For cross-node destination, FlowTrain establishes (or reuses) transport endpoints and dispatches the transfer through an RDMA-class or other high-speed interconnect backend. The upper layers that operate on the GVA region are decoupled from hardware-specific addressing and transport details, enabling transparent memory access.

3.3 Heterogeneous Parallel Allocator

Existing resource allocation schemes (Zhang et al., 2025) aim to optimize the worst pipeline stages. After integrating the unified memory pool, our optimization objective has been changed to optimize the achievable throughput while avoiding producer-consumer imbalance under a fixed resource budget R. Let $\mathcal{E}$ denote the set of encoder modules and b denote the backbone. For each module $i \in \mathcal{E} \cup \{b\}$, $\mathcal{C}_i$ defines its set of feasible parallelism configurations. Each configuration $c \in \mathcal{C}_i$ has a throughput $\tau_i(c)$ and resource cost $r_i(c)$. We use the binary variable $x_{i,c} \in \{0,1\}$ to indicate whether c is selected. The aggregated encoder production rate and backbone consumption rate can be defined as:

$$T_{\text{enc}} = \sum_{e\in\mathcal{E}} \sum_{c\in\mathcal{C}_e} x_{e,c}\,\tau_e(c), \quad T_{\text{bb}} = \sum_{c\in\mathcal{C}_b} x_{b,c}\,\tau_b(c) \tag{1}$$

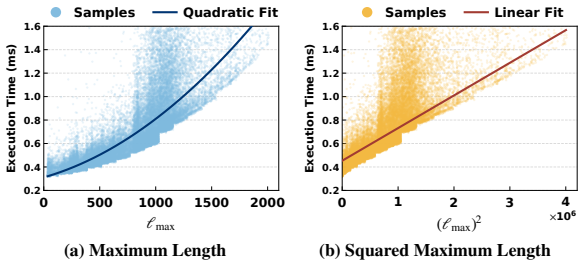
Then, flow matching problem is formalized as:

$$\begin{aligned} \text{lexmax} \quad & (G, -F) \\ \text{s.t.} \quad & G = \min(T_{\text{enc}},\, T_{\text{bb}}), \\ & F = |T_{\text{enc}} - T_{\text{bb}}|\,, \\ & \textstyle\sum_{c\in\mathcal{C}_i} x_{i,c} = 1, \quad \forall i \in \mathcal{E} \cup \{b\}, \\ & \textstyle\sum_{i\in\mathcal{E}\cup\{b\}} \sum_{c\in\mathcal{C}_i} x_{i,c}\, r_i(c) \le R. \end{aligned} \tag{2}$$

The objectives are optimized in lexicographic order. We first maximize the global throughput G, and then minimize flow imbalance F between producers and consumers. Over-allocating resources to the encoder incurs redundant buffering in the pool, while under-allocating starves the backbone.

To efficiently solve the problem in Eq. (2), we first prune the candidate space $\mathcal{C}_i$ while retaining practically deployable configurations. Since $\tau_i(c)$ depends on the combined effect of operator efficiency and communication overhead, we estimate a surrogate of $\tau_i(c)$ through lightweight profiling, which is the established methodology in parallelism planning (Um et al., 2024; Miao et al., 2022). Substituting the surrogates into Eq. (2) yields a Mixed-Integer Linear Programming (MILP) problem, which can be efficiently solved by off-the-shelf solvers (e.g., Gurobi) in milliseconds. Then, the obtained resource partition and module-specific parallelism strategies are materialized by Ray (Moritz et al., 2018) as a set of actors.

3.4 Dynamic Packing Scheduler



Similar to the allocator, the decoupled execution paradigm also reshapes the design space and scheduling objective. Regardless of monolithic or disaggregated design, microbatch composition is usually performed before multimodal encoding and only relies on raw sample size. In comparison, our unified memory pool absorbs runtime variance, preventing it from propagating into the backbone. The dynamic packing scheduler can flexibly assemble balanced microbatches from available embeddings in the pool based on the actual computational cost, rather than committing to fixed microbatch compositions before training begins. As summarized

Algorithm 1: Dynamic Packing Algorithm

```
   /* Best-fit Packing                                   */
1  Initialize segment tree 𝒯 over [0, L];
2  for Each sequence s with length ℓ(s) do
3      j ← BestFitQuery(𝒯, ℓ(s));
4      if j ≠ null then
5          Append s to microbatch B_j;
6          P_j ← P_j − ℓ(s) and update 𝒯;
7      else
8          Create B_j with P_j ← L − ℓ(s);
9          Insert into 𝒯;
10     if P_j < ℓ_min then
11         Remove B_j from 𝒯;
   /* Two-dimension Load Balancing                       */
12 for Each packed microbatch B_j do
13     Compute Cost(B_j);
14     Assign B_j to bucket k by clustering
         Cost(B_j);
15 for Each bucket k do
16     Obtain list by sorting microbatches in
         descending order of Cost(B_j);
17     Initialize a ← 0, Forward← True;
18     while a < len(list) do
19         if Forward then

```

in Algorithm 1, the scheduler minimizes padding waste through best-fit packing, and then relieves PP and DP imbalance via zig-zag dispatch.

We utilize the segment tree-based algorithm to pack variable-length sequences in fixed-capacity microbatches, thereby reducing memory fragmentation (Ding et al., 2024). A segment tree covers the integer interval $[0, L]$, where L is the maximum microbatch sequence length (e.g., 8192). Each leaf corresponds to the residual capacity of the candidate microbatches, and each internal node stores the maximum residual capacity in its subtree (Line 1). For each incoming sequence s with length $\ell(s)$, the scheduler first examines the left subtree, which

(a) Maximum Length (b) Squared Maximum Length

Figure 5: Execution cost modeling with maximum sub-sequence length $\ell_{\max}$.

represents smaller residual capacities. If its residual capacity is $\geq \ell(s)$, the search recursively descends into the left subtree. Otherwise, it proceeds to the right subtree. This process locates the open microbatch whose residual capacity is $\geq \ell(s)$ and minimal among all candidates by $O(\log L)$ best-fit queries (Lines 2-3). If a suitable microbatch B_j is found, append incoming sequence s to B_j and update its residual capacity to $P_j \leftarrow P_j - \ell(s)$ (Lines 4-6). Otherwise, create a new microbatch with residual capacity $L - \ell(s)$ and insert it into the tree (Lines 7-9). When a microbatch's residual capacity falls below the minimum sequence length in the current distribution, it is removed from the segment tree (Lines 10-11).

Then, packed microbatches are assigned to PP stages and DP ranks to relieve imbalance across both dimensions. To characterize execution costs, we profile packed microbatches with different sequence compositions. We observe from Figure 5 that the execution time is approximately linear in $(\ell_{\max})^2$, where $\ell_{\max} = \max_{s \in B_j} \ell(s)$ is the maximum sub-sequence length within a packed microbatch B_j. This observation is consistent with the quadratic scaling of the attention kernel (Dao, 2024). Meanwhile, the execution time of MLP layers scales approximately linearly with the total number of valid tokens. Based on these observations, we estimate the execution cost of B_j after maximum microbatch length (L) normalization:

$$\mathrm{Cost}(B_j) = \frac{1}{L} \sum_{s \in B_j} \ell(s) + \frac{1}{L^2} (\ell_{\max})^2 \qquad (3)$$

Based on $\mathrm{Cost}(B_j)$ capturing both linear and quadratic computations, we cluster packed microbatches with similar computational intensities into a discrete bucket, ensuring consistent execution latencies across PP stages (Lines 12-14). Within each bucket, the microbatches are sorted in descending order of $\mathrm{Cost}(B_j)$ (Lines 15-16). The sorted micro-

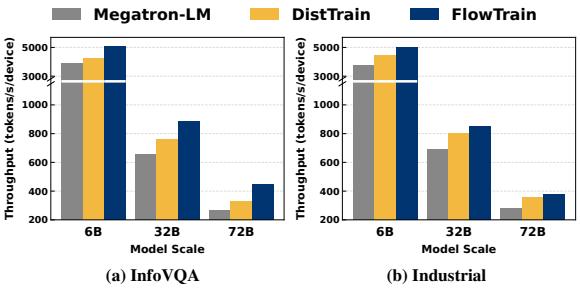

Figure 6: Training throughput across different methods on varying model sizes.

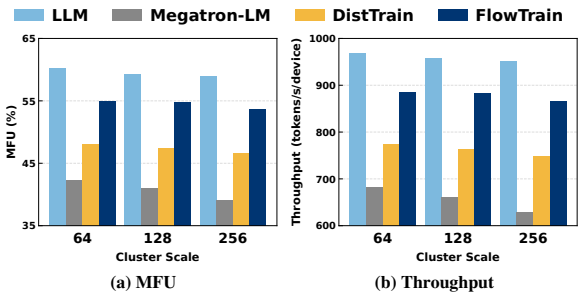

Figure 7: The efficiency gap compared to LLM-only training at different cluster scales.

batches are dispatched in order $\text{Rank}_0 \rightarrow \text{Rank}_{N-1}$ (Lines 17-22), and then the direction of the traversal is reversed to $\text{Rank}_{N-1} \rightarrow \text{Rank}_0$ (Lines 23-27). This zig-zag dispatch ensures that high and low-cost microbatches are paired on DP ranks, forcing the total cost to converge across the cluster (Abdelhamid et al., 2020).

4 Experiments

4.1 Experimental Setup

Models and Datasets. We adopt a representative VLM architecture, where the vision encoder adopts the ViT architecture (Dosovitskiy et al., 2021), and the LLM backbone is based on Qwen3 (Team, 2025b). We train three model scales spanning small, medium, and large configurations, i.e., VLM-6B, VLM-32B, and VLM-72B. We evaluate FlowTrain on *InfoVQA* (Mathew et al., 2022), an open-source visual question answering dataset, and *Industrial* dataset collected from a real-world e-commerce platform.

Training Configurations. All experiments are conducted on a production cluster with 256 Ascend NPUs (64GB) (Zhou et al., 2025). FlowTrain uses Ray to orchestrate heterogeneous actors and enable independent execution between the encoder and the LLM backbone. The image and text subsequences are interleaved to form sequences of up to 8192, and the global batch size is set to 256.

Baselines. (1) *Megatron-LM* (Shoeybi et al., 2019) provides mature optimizations for LLM training and treats the multimodal model as a monolithic network. (2) *DistTrain* (Zhang et al., 2025) adopts disaggregated model orchestration and data preprocessing, which deploy heterogeneous modules with independent resources and parallelism configurations. We also report the LLM-only performance as a reference upper bound for unimodal training efficiency. For fair comparison, all methods are evaluated under the same software environment, optimizer configuration, and data preprocessing pipeline.

4.2 End-to-end Effectiveness

We evaluate the end-to-end training performance of FlowTrain with three model scales. The results in Figure 6 show that FlowTrain consistently achieves the highest throughput among all training systems. For the InfoVQA dataset, FlowTrain achieves 1.3× average and 1.7× maximum throughput improvement over both baselines. For the Industrial dataset, FlowTrain achieves 1.2× average and 1.4× maximum throughput improvement. Notably, the performance gap between FlowTrain and baselines increases as the models grow larger. FlowTrain outperforms Megatron-LM by 30.4% for VLM-6B, 33.7% for VLM-32B, and 69.1% for VLM-72B on the InfoVQA dataset. This is because the baselines suffer from batch-level synchronization barriers, leading to poor hardware utilization. In comparison, FlowTrain allows execution decoupling and coordinates heterogeneous modules through a shared memory abstraction, which substantially improves the training efficiency of large-scale VLMs.

4.3 Scaling Performance

We further evaluate scalability by varying the cluster scales. Figure 7 reports the results of training VLM-32B on the InfoVQA dataset, together with LLM-only training as a reference upper bound. FlowTrain achieves above 53% MFU and 1.1-1.4× throughput improvement across all evaluation scales and exhibits the most robust scaling behavior, while the training efficiency of other methods is far lower than ours. Another noteworthy observation is that FlowTrain is closer to LLM-only training performance than baselines. The average MFU gaps are 18.7, 12.1, and 5.0 percentage points for Megatron-LM, DistTrain, and FlowTrain, respec-

Component	VLM-6B		VLM-32B		VLM-72B	
	MFU	Throughput	MFU	Throughput	MFU	Throughput
w/o Pool	21.6	2118	44.4	717	47.0	399
w/o Allocator	39.5	3879	50.1	809	48.9	415
w/o Scheduler	46.1	4531	49.1	793	47.2	400
FlowTrain	52.1	5125	54.8	884	52.9	448

Table 1: Ablation study of three core components on MFU (%) and throughput (tokens/s/device).

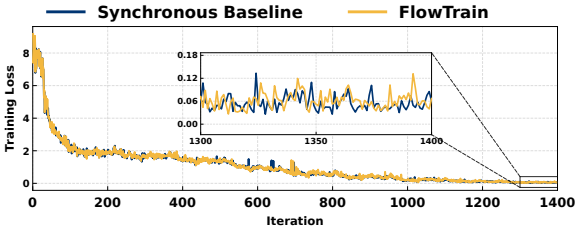

Figure 8: Training loss curves of FlowTrain and synchronous baseline.

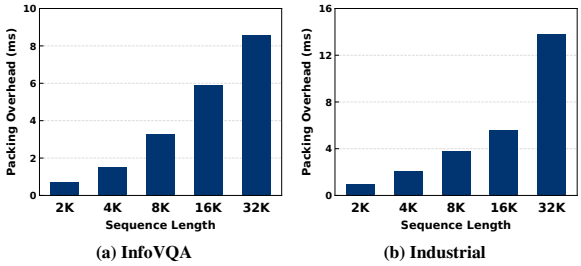

tively. These results confirm that our design can significantly narrow the gap to the efficiency regime associated with unimodal training workloads.

4.4 Ablation Study

We conduct ablation experiments to quantify the individual contribution of three components in FlowTrain. As summarized in Table 1, removing the unified memory pool causes the largest degradation, reducing MFU and throughput by 15.6 percentage points and 29.5% on average, respectively. The system falls back to point-to-point batch synchronization, which reintroduces idle time and weakens the main benefit of decoupled execution. Without the heterogeneous parallel allocator, the training throughput decreases by up to 24.3%. Due to throughput mismatch between producers and consumers, the backbone is either starved of embeddings or overwhelmed by excessive production in the pool. Disabling the scheduler produces consistent performance loss. The MFU drops to 46.1%, 49.1%, and 47.2%, while the throughput decreases by 10.3-11.6%. The microbatches are no longer packed and dispatched according to actual computation cost, leading to padding waste and load imbalance. The ablation results demonstrate that three core components are essential and their combination delivers the maximum efficiency gain.

4.5 Training Consistency

We evaluate whether FlowTrain preserves the optimization behavior of synchronous training. Figure 8 shows that FlowTrain closely follows synchronous training throughout the entire training process on the InfoVQA dataset. Over the final 100 iterations, FlowTrain and baseline achieve average training losses of 0.0615 and 0.0553, respectively, corresponding to an absolute difference of only 0.0062. The reason is that FlowTrain only changes the embedding execution and scheduling of frozen encoders but does not introduce stale activations or cross-version gradients. These results indicate that FlowTrain preserves synchronous updates and does not materially alter the observed optimization trajectory.

(a) InfoVQA (b) Industrial

Figure 9: The average overhead of dynamic packing algorithm under different sequence lengths.

4.6 Algorithm Overhead

The additional overhead introduced by dynamic packing algorithm is a major concern in practical industrial deployments. Figure 9 records that the average packing overhead for InfoVQA and Industrial datasets increases from 0.7-1.0ms to 8.6-13.8ms with sequence length varying from 2K to 32K. This upward trend is expected because longer sequences enlarge the candidate packing space and increase the cost of residual-capacity queries and load balancing. In particular, the Industrial dataset incurs larger algorithm overhead than the InfoVQA dataset due to its more severe data imbalance. Nevertheless, the overhead remains small compared with the forward and backward computation time. Even at 32K length, the packing overhead accounts for less than 0.1% of one training iteration.

5 Conclusion

In this paper, we propose FlowTrain, a disaggregated and decoupled VLM training framework that breaks batch-level synchronization barriers through three core designs: a unified memory pool that enables flexible producer-consumer collaboration, a heterogeneous parallel allocator for throughput matching, and a dynamic packing scheduler constructing balanced microbatches. Empirical evaluations on different models and scales demonstrate the efficiency of FlowTrain.

Limitations

While FlowTrain demonstrates consistent efficiency gains for VLM training, several limitations remain. FlowTrain targets training stages in which the modality encoder is frozen, while the projector and LLM backbone remain trainable. We emphasize that the frozen-encoder setting is the dominant practice for industrial VLM deployment. FlowTrain can be extended to trainable encoder settings. However, it prevents encoder run-ahead across optimizer steps and thus provides a smaller decoupled opportunity than the frozen-encoder setting. In the future, we plan to extend FlowTrain to support additional training settings, thereby broadening its industrial applicability.

A Methodological Details

A.1 Motivation

VLMs align vision and text in a shared representation space, enabling joint processing of multimodal data (Li et al., 2025b; Shinde et al., 2025). Their architectural disparity leads to divergent operator arithmetic intensities and thus divergent responses to distributed parallelism strategies. The core issue is not only where heterogeneous modules are placed, but also whether they can progress independently at their native throughputs. During disaggregated training, the encoders and the LLM backbone remain temporally bound by the underlying pipeline execution order. Execution coupling still introduces batch-level synchronization barriers, resulting in significant resource waste.

Furthermore, dynamic multimodal inputs induce a severe workload imbalance between distributed accelerators. For example, mixed 480P-1080P images with various lengths could belong to the same training batch. Due to data dependence, such variance propagates across the batch boundary and amplifies pipeline bubbles, thereby limiting the end-to-end throughput of VLM training. The above observations motivate us to rethink a different training paradigm that decouples encoder and backbone execution, enabling each module to progress independently via continuous dataflow.

A.2 Backpressure Mechanism

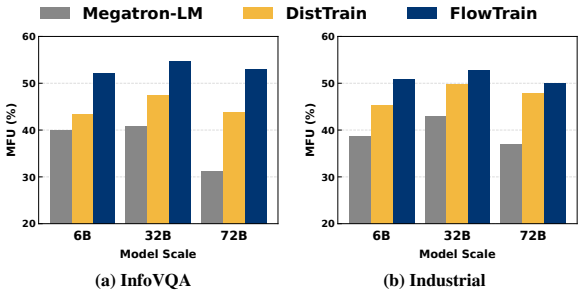
The unified memory pool operates as a bounded buffer. Encoder outputs are preferentially allocated in HBM and fall back to DRAM when HBM cannot satisfy the incoming allocation. If neither tier has sufficient free space, the corresponding encoder actors are blocked until the backbone releases consumed embeddings. LLM actors do not have to be aware of their actual storage location when consuming the microbatches from GVAs. Each GVA is associated with readiness and completion metadata. The backbone can access an embedding only after its write has completed, and the underlying memory cannot be reclaimed until consumption finishes. FlowTrain does not evict unconsumed embeddings, as doing so would alter the training data stream. After an embedding is consumed, its pages are returned to the corresponding free lists for reuse. Page-granular allocation allows logically contiguous GVA objects to map to non-contiguous physical pages, thereby reducing physical memory fragmentation without memory compaction.

	Vision Encoder			LLM Backbone		
Parallelism	DP	TP2	TP4	TP8	TP4PP2	TP8PP2
MFU (%)	45.0	34.2	25.7	60.1	56.7	55.4

Table 2: MFU of the vision encoder and LLM backbone under different parallelism strategies.

A.3 Solving Flow Matching Problem

Once the execution is decoupled, the optimization objective for resource allocation is essentially changed. The parallelism strategy can no longer be optimized as a stage-latency minimization problem. The allocator formulates a flow matching optimization problem that independently determines the resource partition and parallelism strategy for each module under a fixed hardware budget. However, it is intractable to directly solve the optimization problem in Eq. (2) for two reasons. On the one hand, the search space grows significantly with the cluster scale. For a cluster with 256 devices, the number of possible strategy combinations may exceed 10^4. On the other hand, the steady-state throughput $\tau_i(c)$ depends on the combined effect of operator efficiency and communication overhead, neither of which can be explicitly formulated as a closed-form function. To this end, the allocator exploits a three-step solution that prunes the search space, builds a throughput surrogate model, and solves the MILP problem.



Firstly, we reduce the candidate space $\mathcal{C}_i, \forall i \in \mathcal{E} \cup \{b\}$. As the encoder is relatively small, we only consider DP and TP for the encoder side. Therefore, each candidate configuration occupies $\mathrm{DP} \times \mathrm{TP}$ devices. For the substantially larger backbone side, we additionally include PP, requiring $\mathrm{DP} \times \mathrm{TP} \times \mathrm{PP}$ devices per configuration. We prune invalid and low-efficiency configurations where the global batch size cannot be divisible by the resulting DP degree, and TP/PP degrees cannot factorize the per-module resource budget and cause cross-node tensor parallelism. *Secondly*, we perform throughput profiling by executing a small number of warm-up iterations under a fixed packed sequence length. This lightweight profiling estimates a surrogate of $\tau_i(c)$ and is only performed once before VLM training begins, resulting in acceptable overhead compared to end-to-end training (Um et al., 2024; Miao et al., 2022). *Thirdly*, substituting the surrogates into Eq. (2) yields the MILP problem, which can be efficiently solved by off-the-shelf solvers.

Method	VLM-6B		VLM-32B		VLM-72B	
	MFU	Throughput	MFU	Throughput	MFU	Throughput
Megatron-LM	40.0	3929	40.9	661	31.2	265

Figure 10: MFU across different methods on varying model scales.

B Evaluation Details

B.1 Setting

Models. VLM-6B, VLM-32B, and VLM-72B differ primarily in encoder depth, projector dimension, and LLM capacity. The vision encoder uses 12 to 28 layers with a hidden size of 1536, whereas the LLM backbone ranges from 24 to 80 layers with hidden sizes from 4096 to 8192.

Metrics. (1) *MFU* measures the fraction of hardware FLOPs converted into effective model computation, which directly quantifies resource efficiency independent of hardware count. (2) *Throughput* is reported as the number of tokens processed per second per device (tokens/s/device), reflecting training speed. (3) *Training loss* tracks the model's convergence trajectory throughout the training process, which is used to evaluate consistency. (4) *Algorithm overhead* quantifies the average additional latency introduced by dynamic packing scheduling.

B.2 Different Parallelism Preferences

The encoder and the LLM backbone in VLMs differ fundamentally in architecture, scale, and computational characteristics, making a single parallelism strategy suboptimal for both. The vision encoder is built from narrow transformer layers with moderate hidden dimensions, while the LLM backbone consists of wide transformer layers with large hidden dimensions. We quantify this divergence in Table 2. When modifying the parallelism strategy from DP to TP2 and TP4, the MFU of the vision encoder decreases from 45.0% to 34.2% and 25.7% due to additional communication overhead and low operator computation efficiency. In contrast, the LLM backbone requires TP8 to satisfy its memory and computation demands and achieve the highest MFU. This asymmetry reveals that different modules have incompatible parallelism preferences.

B.3 Resource Efficiency

Tables 3 and 4 present the complete results of MFU and throughput on the InfoVQA and Industrial datasets, respectively. We further plot the MFU of different methods with three VLM scales in Figure 10. Two key observations are as follows. Firstly, FlowTrain outperforms Megatron-LM by a large margin across all configurations. For example, FlowTrain achieves the MFU of 52.9% and 50.0% when training VLM-72B on the InfoVQA dataset and the Industrial dataset, while Megatron-LM only reaches 31.2% and 36.9%. This gap is rooted in the monolithic design of Megatron-LM, which forces all components to share the same parallelism strategy. The situation further worsens as the models grow larger. The MFU of Megatron-LM drops from 40.0% for VLM-6B to 31.2% for VLM-72B on the InfoVQA dataset, whereas FlowTrain remains stable above 52% through flow matching optimization between producers and consumers.

Secondly, DistTrain partially alleviates the parallelism mismatch through disaggregating orchestration, but its MFU is still lower than that of FlowTrain. This is because DistTrain retains batch-level synchronization barriers and dispatches microbatches without explicit load balancing. In comparison, FlowTrain allows execution decoupling and constructs balanced microbatches. The backbone no longer waits for the entire batch of encoder output before proceeding, thus improving resource utilization. The above results indicate that our disaggregated and decoupled design can substantially improve resource efficiency.

Predefined-Tool Execution for Reliable LLM Agents in Semiconductor Lot Analysis*

Abstract

LLM agents for structured data analysis rely on dynamic query generation, in which the model synthesises tool calls at runtime. This introduces failures such as fabricated dataset references, unsupported operations, and incorrect results, which existing mitigations reduce but do not eliminate. We propose predefined-tool execution as an architectural alternative in which the language model selects and parameterises tools from a fixed, schema-validated registry. We formalise the approach using typed tool specifications and prove executability and hallucination-suppression properties under assumptions. We complement the architecture with a Numerical Faithfulness Checker that verifies quantitative claims against precomputed ground truth, and evaluate the system on a domain-specific benchmark using four language-model backbones. The suppression property follows from the validation layer under those assumptions, and held across all 276 evaluated agent executions involving 23 queries, four backbones and three runs. Mean exact-plan-match rates ranged from 50.7 to 53.6 per cent, with a between-backbone spread within a single backbone. Because exact plan match penalises valid but non-minimal plans, it is a strict lower bound on task correctness. Given only three runs per backbone, comparisons are descriptive, not evidence of equivalence The on-premise open-weight backbones performed comparably to commercial ones on the measured metrics, supporting confidential deployments.

1 Introduction

LLM agents have demonstrated strong capabilities in reasoning, planning, and tool use, making them compelling interfaces for natural-language-driven analysis over complex structured databases (Wei et al., 2022; Masterman et al., 2024; Wang et al., 2024). The dominant paradigm is dynamic query generation, in which the model synthesises tool calls at runtime (Yao et al., 2023), enabling flexible responses without preprocessed query setup. This flexibility, however, introduces a systematic reliability problem: models fabricate dataset identifiers, reference unsupported operation types, or produce silently incorrect results that bypass validation entirely. These are instances of what Lin et al. (2025) term Execution Hallucination, where an agent reports completion of an execution step that did not in fact occur.

Benchmarking studies document this problem across state-of-the-art models (Zhang et al., 2024), and industrial deployments find that dedicated runtime repair mechanisms remain necessary in production (Dobrovsky et al., 2025). Detection after the fact remains brittle and model-dependent. This problem is acute in industrial analytical settings where data is heterogeneous and operationally sensitive.

In semiconductor manufacturing, process engineers must analyse heterogeneous experimental split-lot data spanning parametric electrical measurements at wafer test structures, comprehensive functional test results across all dies, equipment parameter measurements throughout fabrication, and particle defect counts at inspection steps. They must do so without programming knowledge, in a setting where any hallucinated conclusion carries direct operational consequences. Across the literature reviewed for this work on LLM-agent systems in semiconductor and manufacturing analytics, we did not identify a published lot-analysis agent combining a typed predefined-tool registry, pre-execution validation, and claim-level numerical verification, nor a domain-specific benchmark for this task. This paper proposes **predefined-tool execution** as a principled architectural solution:

*This paper is based on the first author's MSc thesis at the University of Twente, carried out during a research internship at Infineon Technologies, Nijmegen, The Netherlands. No earlier version of this manuscript has been posted as a preprint or presented elsewhere.

EMNLP 2026 Industry Track, pages 1765–1787

the language model selects and parameterises tools from a fixed, schema-validated registry rather than synthesising queries freely, so that invocations of unregistered datasets or action types are blocked before dispatch, within the scope of the formal specification, rather than detected after generation. The SplitLot Analysis Agent demonstrates this for semiconductor lot management.

Three contributions are made. First, a **formal specification** of predefined-tool execution as typed tuples with preconditions, postconditions, and coverage fields, with proofs that validated plans execute without schema-level runtime errors and that the Execution Hallucination class is suppressed by architectural restriction within the scope of the specification; unlike schema-only approaches, the coverage field makes the hallucinated-versus-unsupported distinction explicit and actionable. Second, for queries producing structured breakdown output, a **Numerical Faithfulness Checker** that automatically verifies every quantitative claim in the structured explanation against pre-computed ground truth, converting output grounding from a prompting instruction into a measurable per-claim property. Third, a **five-tier domain-specific benchmark** for semiconductor lot analysis agents with deterministic ground truth, evaluated across four language model backbones (two commercial and cloud-hosted, two open-weight and deployed on-premise) to test whether the measured reliability properties vary with backbone choice; it covers analytical operations absent from general-purpose agent benchmarks.

2 Related Work

2.1 Tool-Augmented Agents and Hallucination

The ReAct paradigm (Yao et al., 2023) is the dominant approach for analytical agents, interleaving reasoning and action through dynamic tool call synthesis. Program-Aided Language Models (Gao et al., 2023) demonstrated that delegating computation to a deterministic interpreter substantially improves quantitative reasoning, a direct precedent for separating language model planning from deterministic execution. Multi-agent extensions via AutoGen (Wu et al., 2024) and MetaGPT (Hong et al., 2024) introduce coordination layers in which a hallucinated message from a planner can corrupt an executor without detection. The CoALA taxonomy (Sumers et al., 2024) provides a rigorous framework for language agent memory components and informs the memory architecture of this work. Despite these advances, unconstrained query synthesis remains architecturally vulnerable to hallucination. Lin et al. (2025) establish a five-category agent hallucination taxonomy spanning reasoning, execution, perception, memorisation, and communication, and identify tool documentation limitations among the triggering causes of Execution Hallucinations. Liu et al. (2026) further show hallucinations compound through multi-step trajectories, making early architectural interception preferable to post-hoc correction. Existing mitigations, including Chain-of-Verification (Dhuliawala et al., 2024), Self-RAG (Asai et al., 2024), Self-Refine (Madaan et al., 2023), Reflexion (Shinn et al., 2023), and structured output enforcement (White et al., 2023; Sahoo et al., 2024), reduce hallucination rates but operate by detection or correction after generation. The predefined-tool approach taken in this paper instead restricts the action space, so that the failure class is contained before dispatch rather than repaired afterwards.

2.2 Benchmarking and Claim Verification

AgentBench (Liu et al., 2024), GAIA (Mialon et al., 2024), ToolQA (Zhuang et al., 2023), and τ-bench (Yao et al., 2025) provide general-purpose agent evaluation frameworks but cover none of the analytical operations required for semiconductor lot management. ToolBeHonest (Zhang et al., 2024) introduces Solvability Detection Accuracy for measuring graceful refusal behaviour, and AgentEval (Arabzadeh et al., 2024) assesses outputs against expert-defined criteria, both directly informing the benchmark design in this work. Verifying explanation faithfulness against an evidence source resembles a Natural Language Inference problem. SNLI (Bowman et al., 2015), MultiNLI (Williams et al., 2018), and FEVER (Thorne et al., 2018) are the closest foundational resources: their fact-verification paradigm is structurally analogous to verifying agent explanations against an execution log. DeBERTa (He et al., 2021) provides the state-of-the-art cross-encoder for entailment classification and serves as the backbone of the natural language verifier in this work. Cross-domain applications indicate feasibility in regulated settings: Zeba et al. (2026) demonstrate high-precision verification on clinical text, and Lu et al. (2026) evaluate financial tool-use agents against regulatory-alignment criteria.

2.3 Language Model Agents in Industrial Domains

Domain-adapted models SemiKong (Nguyen et al., 2024) and ChipNeMo (Liu et al., 2023) demonstrate that semiconductor-specific pre-training improves task performance, while Werheid et al. (2025) provide empirical support for predefined analytical workflows in manufacturing equipment selection. However, domain adaptation does not resolve execution reliability. Dobrovsky et al. (2025) therefore deployed a ReAct-based agent for semiconductor failure analysis in which generated database queries required a dedicated retry-and-repair loop when malformed. Their work indicates both that language model agents are viable for semiconductor data analysis and that unconstrained query generation in this domain requires runtime error handling, which this paper instead addresses architecturally.

3 System Design and Formal Foundations

The SplitLot Analysis Agent gives process engineers natural-language access to heterogeneous manufacturing data. It reduces Execution Hallucinations by restricting the language model to a fixed, schema-validated tool registry rather than permitting free query synthesis.

3.1 System Architecture

The agent comprises three tiers, shown in Figure 1. The **data layer** maintains lot measurement data across four measurement domains and an experiment metadata domain recording wafer-to-treatment-group assignments and provenance (Appendix J). Data is cached locally on first access and served from cache thereafter.

The **analysis layer** hosts the typed tool registry, language model planner, and pre-execution validation component. Tools are exposed through the Model Context Protocol (Anthropic, 2024), an open, provider-agnostic standard for typed tool definitions. When a query arrives, the language model produces a structured analytical plan. Before any data access, the validation component checks every planned operation against the registered action set $\mathcal{A}$, dataset set $\mathcal{D}$, and visualisation set. Any operation referencing an unregistered resource causes the plan to be rejected, and an explicit refusal is returned. The primary computed quantity is the group-separation score (DIFF), a standardised effect size (Equation 1):

$$\mathrm{DIFF}(p) = \frac{|\mathrm{median}(G_{\max}) - \mathrm{median}(G_{\min})|}{\sqrt{(\mathrm{sd}(G_{\min})^2 + \mathrm{sd}(G_{\max})^2)/2}} \tag{1}$$

where $G_{\max}$ and $G_{\min}$ are the groups with maximum and minimum median values. The statistic is analogous to Cohen's d, enabling comparison across parameters with different scales. DIFF scores are pre-computed and read directly by the language model, which is constrained never to recompute them (Gao et al., 2023).

The **interaction layer** delivers responses integrating statistical results, visualisations, and grounded explanations. Explanations draw on two asymmetric evidence streams: a quantitative stream sourced exclusively from the session execution log, and a documentary stream from a retrieval-augmented parameter glossary (Lewis et al., 2020). Numerical claims can only originate from the execution log, preventing the failure mode where retrieved passages are falsely cited as numerical sources (Huang et al., 2025).

The agent's four-component memory architecture following Sumers et al. (2024) is described in Appendix L.

3.2 Formal Specification

Before deployment, each tool is specified by six fields covering its identity, inputs, preconditions, computation, outputs, and scope of coverage. Formally, tools are typed tuples $\mathcal{T}_i = (\texttt{name}_i, \texttt{inputs}_i, \texttt{pre}_i, \texttt{comp}_i, \texttt{post}_i, \texttt{cov}_i)$ where $\texttt{name}_i \in \mathcal{A}$ is the registered action identifier, $\texttt{inputs}_i$ is the typed parameter schema, $\texttt{pre}_i$ specifies data availability preconditions, $\texttt{comp}_i$ is the deterministic computation performed entirely by the tool, $\texttt{post}_i$ specifies evidence entries appended to the execution log, and $\texttt{cov}_i$ states the class of requests the tool satisfies.

Scope and assumptions. Propositions 1 and 2 are stated over the plan representation Π emitted by the planner and consumed by the validation layer. They assume: (A1) the registered sets $\mathcal{A}$ and $\mathcal{D}$ are finite and fixed at deployment time; (A2) the validation layer is the only path from planner output to the execution layer; (A3) each tool implementation is correct with respect to its own $\texttt{comp}_i$ specification; (A4) the cached data referenced by $\texttt{pre}_i$ is present and schema-conformant. Under these assumptions the propositions concern one question

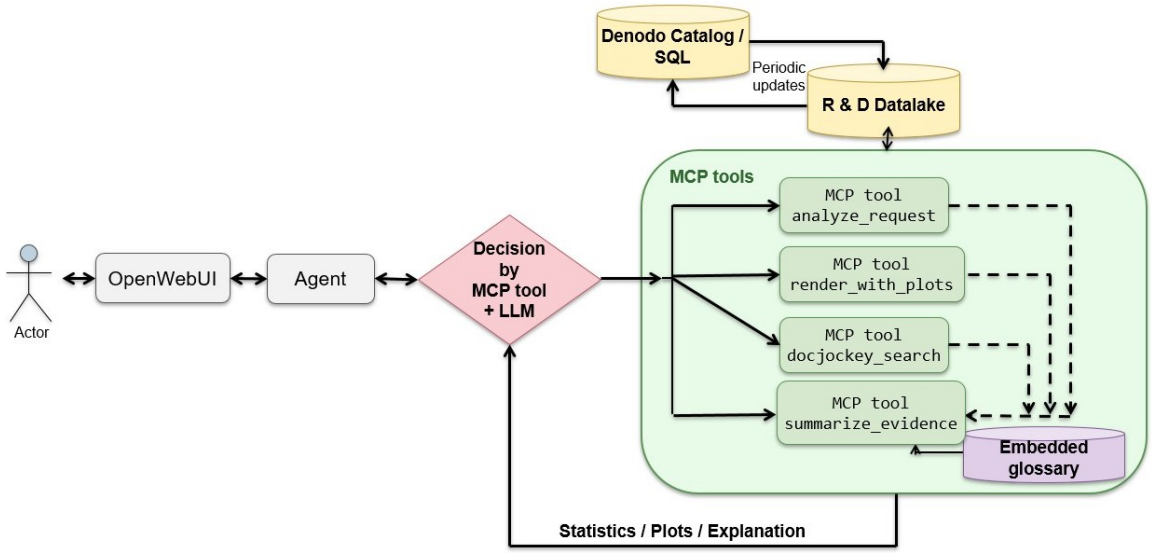

Figure 1: SplitLot Analysis Agent architecture. Queries are validated against the tool registry before execution. Invalid plans are rejected before any data access and returned as explicit refusals. Explanations are grounded in the session execution log and enriched by a retrieval-augmented parameter glossary.

only: whether an unregistered action or dataset reference can reach execution. They make no claim about whether the selected tool is the appropriate one for the request (measured separately by TSA), whether the returned values are correct (measured by NFR), or whether a registered tool can fail for reasons unrelated to unregistered resource references.

Proposition 1 (Executability Guarantee)**.** If the validation layer completes without error for plan Π, then every action belongs to $\mathcal{A}$ and every referenced dataset belongs to $\mathcal{D}$, and the plan executes without schema-level runtime errors.

The validation layer enforces this through sequential action-type filtering, dataset validation, and visualisation-type filtering, each blocking unregistered references before dispatch. Full proof in Appendix A.

Proposition 2 (Execution Hallucination Suppression)**.** Under the predefined-tool architecture, the Execution Hallucination Rate is zero for all plans satisfying the Executability Guarantee, within the scope of the formal tool and dataset registry.

Lin et al. (2025) define Execution Hallucinations as cases where an agent claims to have completed an execution sub-stage that was not in fact performed, and divide them into Tool Selection Hallucinations, in which non-existent or irrelevant tools are chosen, and Tool Calling Hallucinations, involving incorrect, omitted, or fabricated parameters. The registry addresses the first subclass in full and the dataset-valued portion of the second. Under assumptions A1–A4 the validation layer blocks these subclasses before dispatch, so the failure class is contained architecturally rather than detected after generation; no post-generation correction step is required for this class. The scope of the property is exactly the registered sets: a request outside $\mathcal{A}$ or $\mathcal{D}$ is refused and not served. Full proof in Appendix A. The $\texttt{cov}_i$ field further enables a **Coverage Completeness** criterion: a registry is coverage-complete if every solvable request is covered by at least one tool's coverage specification, making the hallucinated-versus-unsupported distinction explicit and actionable. The formal definition is in Appendix K.

3.3 Hallucination Verification

The formal properties above suppress Execution Hallucinations within the scope of the registry but do not address whether the natural language explanation faithfully represents computed results. An unfaithful summary following correct execution constitutes a Perception Hallucination (Lin et al., 2025). The full mapping of all five hallucination categories to the system is in Appendix I.

The structured explanation output contains three fields: a natural language **summary**, a **glossary** of retrieved parameter descriptions, and machine-readable **breakdowns** recording measurement step, parameter name, domain, DIFF score, and per-group statistics. Confining numerical

claims to the breakdown field makes every value directly verifiable without natural language processing.

The **Numerical Faithfulness Rate** (NFR) verifies each entry against pre-computed ground truth:

$$\text{NFR} = \frac{|\{b_j \in B : \frac{|\hat{b}_j.\texttt{diff} - b_j.\texttt{diff}|}{|\hat{b}_j.\texttt{diff}|} \leq \epsilon\}|}{|B|} \quad (2)$$

where B is the set of all breakdown entries, $\hat{b}_j$ is the ground truth from the pre-computed cache, and $\epsilon = 10^{-4}$. Implementation in Appendix E.

For prose claims in the summary field, a supplementary Natural Language Inference (NLI) pipeline was implemented. Full pipeline details and interpretation guidance are in Appendix D.

4 Experiments and Results

4.1 Experimental Setup

The benchmark spans five tiers of increasing analytical complexity: single-tool retrieval (T1), multi-domain analysis (T2), cross-lot scanning over $N = 34$ lots (T3), metadata-driven lot discovery (T4), and a seven-probe adversarial tier requiring graceful refusal (T5). Ground truth is deterministic for each tier, derived from pre-computed summary files, metadata filter results, or the expected absence of fabricated content (Appendix N); the construction protocol is in Appendix O and the full tier definitions in Appendix C.

Six metrics measure hallucination behaviour and planning quality independently, separating architectural safety guarantees from model-dependent planning behaviour. *Validation Pass Rate* is the fraction of queries for which the validation layer ran to completion and returned a verdict, whether acceptance or rejection; it certifies that validation was reached, not that every plan was accepted, and relates to Proposition 1. *Execution Hallucination Rate* is the fraction of dispatched executions invoking an unregistered resource, measured post-validation. *Domain Scope Accuracy* is the fraction of queries where the domains recorded in the execution log match those declared in the plan. These three measure containment. *Tool Selection Accuracy* is the fraction of queries whose executed tool-type sequence exactly matches the annotated minimal sequence; it measures plan optimality rather than task correctness, and relates to Reasoning Hallucinations (Appendix I). *Numerical Faithfulness Rate* is the fraction of emitted breakdown entries within $\epsilon = 10^{-4}$ of ground truth (Eq. 2), and is undefined where no breakdown is emitted. *Solvability Detection Accuracy* is the fraction of adversarial probes whose rejection is returned as an intelligible refusal (Zhang et al., 2024), and measures refusal presentation rather than containment.

The agent is evaluated against four language model backbones: GPT-5, Claude Sonnet 4.5, DeepSeek-R1-70B, and Llama-3.3-70B. All share an identical tool server, validation layer, planning prompt, and dataset registry. Only the model identifier varies, so systematic differences between backbones are not confounded by the surrounding system; sampling stochasticity still produces run-to-run variation within a single backbone (§4.2.1). Backbone rationale and configuration are in Appendix B. Metrics and tier definitions were pre-registered before evaluation, following standard benchmark practice. Six versions of the agent were developed iteratively; the final version (v6) is the system assessed here. The development history from v1 through v6 is in Appendix F.

Three denominators recur: 23 queries, $23 \times 4 = 92$ backbone–query combinations, and $23 \times 4 \times 3 = 276$ executions; a figure written $x/23$ is a single run. Containment, task correctness, exact plan match and refusal presentation are measured separately and are not interchangeable. TSA scores a query correct only if every tool type in the executed plan matches the annotated minimal sequence, so valid but longer routes are scored incorrect. Full definitions and the annotation protocol are in Appendix O.

4.2 Results

4.2.1 Validation Containment and Execution Outcomes

Across all evaluated runs, the validation layer prevented plans containing unregistered actions or dataset references from reaching the execution layer. Table 1 reports the corresponding validation, execution, planning, and refusal metrics for the four model backbones.

Containment. EHR was $0/23$, VPR $23/23$ and DSA $23/23$ in every one of the 12 backbone-runs, covering all 276 executions. Under assumptions A1–A4 this follows from the shared validation layer rather than from backbone behaviour, so the evaluation's role is to confirm that no path circumvented that layer, not to measure a performance difference. EHR is measured post-validation over

Backbone	VPR	TSA	DSA	NFR	EHR	SDA
GPT-5	23/23	11/23	23/23	1/1†	0/23	4/7
Claude Sonnet 4.5	23/23	13/23	23/23	2/2†	0/23	4/7
DeepSeek-R1-70B	23/23	12/23	23/23	2/2†	0/23	4/7
Llama-3.3-70B	23/23	12/23	23/23	1/1†	0/23	4/7

†NFR is defined only over emitted structured breakdown entries. Q13 is the *only* query in the suite that emitted one, and it did so in 6 of its 12 backbone-runs: GPT-5 1/3, Claude 2/3, DeepSeek 2/3, Llama 1/3. The column reports entries emitted and passing per backbone across its three runs, totalling 6/6; it is not a rate over the 23-query suite (Appendix M). NLI Faithfulness Score (NLI-FS; secondary diagnostic, over the 22 queries yielding extractable claims) 24.8–31.0%; see Appendix D.

Table 1: Multi-backbone results, one representative run per backbone. VPR, TSA, DSA and EHR are out of the 23 queries in that run; SDA is out of the 7 Tier 5 probes; NFR counts breakdown entries emitted and passing per backbone over its three runs, as the footnote details. Claims qualified in the text as holding across all runs are over 276 executions. TSA is exact match against the annotated minimal tool-type sequence and is not a measure of task correctness.

dispatched calls, and every dispatched execution was additionally verified to respect the registered action and dataset boundaries. VPR counts queries for which validation returned a verdict rather than queries whose plans were accepted unchanged: the A2 and A5 probes were rejected at validation and still count toward VPR, because the metric records that validation was reached. The adversarial tier exercises the mechanism directly: the A2, A4 and A5 probes were each contained at validation in all 12 backbone-runs, and no dispatched execution in any run reached an unregistered resource. Propositions 1 and 2 are therefore best read as soundness results rather than as empirical findings. They state which plans the validation layer admits, in the way a type system states which programs its checker admits, and a soundness result of this form is neither confirmed nor falsified by a measured rate. The corresponding empirical question is narrower: whether assumption A2, that validation is the sole path from planner output to execution, in fact held in the deployed system. The 276 executions support that it did.

Planning. Table 1 reports one of three independent runs per backbone. Across all three runs, the per-run TSA figures (out of 23) are: GPT-5 11/13/12, Claude Sonnet 4.5 13/12/12, DeepSeek-R1-70B 12/12/12, Llama-3.3-70B 12/11/12, giving per-backbone means of 52.2%, 53.6%, 52.2% and 50.7%. The spread between backbone means (2.9 percentage points) is smaller than the largest run-to-run spread within a single backbone (8.7 percentage points, GPT-5 across its three runs). With three runs per backbone, this is a descriptive observation and does not establish statistical equivalence. Containment and plan quality are independent: Q13 fails exact plan match in all 12 backbone-runs while returning numbers the Numerical Faithfulness Checker verified in each of the six runs that emitted them.

Task correctness versus exact plan match. TSA scores a query correct only if the executed tool-type sequence matches the annotated minimal sequence exactly; a plan returning the requested result by a longer but valid route is scored incorrect. Whether the returned answer matched the ground-truth answer is reported separately in Table 7. Q5, Q6, Q8, and Q10 (Tier 2) fail exact plan match in 12/12 backbone-runs while returning the requested ranking: each asks for a targeted ranking operation and every backbone instead invoked the full analysis pipeline, which reaches the same data by a longer route. Q7 and Q9 in the same tier match in 12/12, and Q1 in 10/12, so plan selection is not uniformly deterministic elsewhere. Zero variance on one subset alongside variance on another, across four unrelated model families, points to an over-specified gold sequence rather than a shared capability gap, though this evaluation cannot settle the question. Excluding these four items, TSA is 11–13 of 19 (58–68%); Q13, Q14, and Q16 are counted in full as planning failures the architecture does not address. Per-tier breakdown is in Appendix H.

4.2.2 Output Faithfulness and Refusal Presentation

Q13 is the only query in the suite that emitted a structured breakdown, and it did so in 6 of its 12 backbone-runs (GPT-5 1/3, Claude Sonnet 4.5 2/3, DeepSeek-R1-70B 2/3, Llama-3.3-70B 1/3). Every emitted entry matched pre-computed ground truth within $\epsilon = 10^{-4}$, giving NFR $= 6/6$. The denomi-

nator is six runs of one query: the result establishes that the emitted values were faithful; it establishes nothing about the executions that emitted none. Emission frequency is a property of output formatting rather than of numerical accuracy, and with only three runs per backbone we do not treat it as a stable backbone difference.

The supplementary NLI analysis assessed the extent to which prose claims could be supported by evidence retrieved from the execution log.

Per-backbone NLI Faithfulness Score (mean $\pm$ SD over three runs): GPT-5 31.0 $\pm$ 3.9%, Claude Sonnet 4.5 24.9 $\pm$ 4.5%, DeepSeek-R1-70B 30.5 $\pm$ 5.0%, Llama-3.3-70B 24.8 $\pm$ 2.9%. NLI-FS is a verifier-coverage metric, not a hallucination rate: only Contradicted classifications indicate a potential hallucination, and none occur systematically on any backbone. Per-backbone NFR detail is in Appendix M; the NLI pipeline, its per-query behaviour and interpretation guidance are in Appendix D.

SDA $= 4/7$ on the Tier 5 adversarial probes in 11 of the 12 backbone-runs. Three probes are scored as misses on every backbone in every run: A2 (unregistered dataset), A4 (unregistered parameter), and A5 (fabricated path). A fourth, A3 (unsupported operation), is scored a miss in one DeepSeek-R1-70B run, which is the single run at $3/7$. Every one of these probes was contained: no unregistered resource was reached and no value was fabricated in any of the 276 executions. They are scored as misses because the underlying validation exception is surfaced to the user without being rendered into an intelligible account of what is not supported. SDA as measured here therefore describes refusal presentation, not containment. The Coverage Completeness criterion classifies A2, A4, and A5 as a finite registry-expansion queue (Appendix K).

5 Discussion

Practical implications. The SplitLot Analysis Agent is deployed as an in-house chat interface within a semiconductor business line, currently reaching around 100 engineers with potential scaling to 3,000. The comparable performance of Llama-3.3-70B on the measured reliability metrics bears directly on deployment feasibility. The architecture removes the programming-knowledge barrier for process engineers and converts output grounding into a verifiable per-claim property enabling audit-level traceability (Lu et al., 2026; Raza et al., 2026). The registry exposes four MCP-level tools; all 276 executions carried the full schema in context without truncation, and entries are keyed to operation type, so the footprint does not grow with deployment size (Appendix J).

Generalisation beyond this domain. What transfers is the typed-tuple specification, Propositions 1 and 2 with their proofs, and the verify-against-log pattern. The preconditions are (i) a bounded, enumerable operation set, and (ii) precomputable numerical ground truth. What does not transfer: the specific registry, the DIFF statistic, and the four data domains.

6 Conclusion

This work shows that predefined-tool execution can provide a practical architectural mechanism for preventing the dispatch of unregistered actions and datasets, without requiring post-execution repair for these failure types. No dispatched execution referenced an unregistered resource in any of the 276 executions across four model families, and the two open-weight on-premise backbones recorded the same containment metrics and comparable planning metrics as the two commercial backbones. The formal specification, Numerical Faithfulness Checker, and domain-specific benchmark provide a reusable starting point for analytical agents over structured industrial data where hallucination has operational consequences. Because the industrial project has concluded, a controlled dynamic-generation baseline and multi-expert validation of the plan annotations remain necessary directions for independent replication rather than commitments of this work. Tool registry expansion guided by the Coverage Completeness log and evaluation of domain-adapted backbones are tractable extensions.

Limitations

Four kinds of result are reported, and they should not be read together: containment is architectural and invariant by construction, exact plan match is the only measurement that could have separated the backbones, NFR rests on six entries from one query, and no matched dynamic-generation baseline was run. Each is qualified below.

The predefined-tool architecture provides a reliability floor, not a ceiling. Reasoning Hallucinations (valid plans that select sub-optimal operation

types) remain a planner-level failure the current architecture does not resolve; across the full three-run evaluation this residual did not vary systematically across backbones, and it was concentrated in seven queries rather than diffuse across the suite: four attributed to an over-specified gold annotation and three treated as planning failures. Ground truth is deterministic and author-independent across all five tiers (Appendix N); for Tier 5 the criterion is mechanical, namely that no fabricated numerical or structural content is returned, irrespective of the internal path by which the request was rejected. Two further properties are graded separately and neither forms part of the tier ground truth: SDA grades how a refusal is presented to the user, and TSA grades the executed tool-type sequence against an annotated minimal sequence. TSA annotation is the one judgment-dependent element of the evaluation, and the benchmark author also authored the queries. Coupling of this kind would bias a judgment-dependent metric upward, whereas the analysis in §4.2.1 finds the annotation too strict on four queries, which bounds the risk without eliminating it. Because the industry collaboration and associated access concluded after review, an independent second annotation could not be completed for this version. We therefore report TSA as exact agreement with the original domain-expert annotation and treat the four disputed Tier 2 cases separately. Table 7 records the per-query plan-match outcomes on which the TSA figures rest, so the four disputed Tier 2 items are identifiable from the paper alone. Future work should validate the plan annotations using multiple qualified domain experts. Planning prompt design and a self-consistency approach (Wang et al., 2023) remain open.

The Numerical Faithfulness Checker currently covers only Q13, and is untested on the remainder of the suite. Domain-specific fine-tuning of the NLI verifier is the primary path to extending prose faithfulness coverage, and the training data already exists: the 276 executions produced (claim, execution-log evidence, label) triples as a by-product, with the NFR checker supplying gold labels for the numerical subset, so this fine-tuning set is bootstrapped without additional annotation.

Comparative evaluation across the v1–v5 agent variants is not reported quantitatively. Each version represents a distinct architectural pathway rather than a controlled ablation: the registry, validation layer, and planning prompt changed jointly between versions, and intermediate variants were not stable enough to serve as evaluation subjects. The v6 system is the first version that satisfies the registry, validation, and evidence-trace requirements simultaneously. The progression is documented qualitatively in Appendix F.

No controlled comparison against unconstrained dynamic query generation was run on the 23-query suite. Propositions 1 and 2 state a conditional architectural property that does not depend on any baseline's empirical behaviour, and Dobrovsky et al. (2025) report that an unconstrained agent in this same domain required a runtime repair loop for malformed generated queries, though they do not quantify the rate; neither substitutes for a direct, quantified comparison. This comparison could not be added for the present version: the industry project and the associated data and infrastructure access concluded after review, so no further executions against the deployment were possible. A concrete replication would measure EHR and TSA for an unconstrained agent against the same 23-query suite (or a representative subset covering all five tiers), using the same tool server and data access layer with the validation component removed.

Propositions 1 and 2 are conditional statements, not unconditional guarantees. They hold under assumptions A1–A4 in §3.2 and cover only unregistered action and dataset references reaching dispatch. They do not cover errors inside a correctly registered tool, fabricated or omitted parameters other than the dataset identifier, upstream schema drift that silently invalidates A4, or any path that bypasses the validation layer. Nor do they bound how often the planner *proposes* an unregistered reference; that quantity was not instrumented separately in this evaluation and is a target for future measurement.

The tool registry requires coordinated updates when the underlying data schema changes. Registry entries are keyed to operation type rather than to parameter, lot, or product family, so onboarding within existing operation types adds no new tools; maintenance burden scales with operation-type count and schema-change frequency rather than deployment size. No tracked engineering-hours figure exists for past registry changes, but structurally, each new operation type is one tool definition (the six-field tuple), and the six-variant development history (Appendix F) shows this has meant adding a typed tuple and a validation-layer entry, not a redesign.

Hybrid predefined-plus-dynamic extension. A hybrid changes the guarantee's shape rather than extending it: Proposition 2 holds only over the predefined partition. The coverage field $\texttt{cov}_i$ makes a hybrid tractable in which each response records which regime served it, so the guarantee is tiered and auditable rather than uniform. Recurring expansion candidates (currently A2, A4, and A5) are promoted into the guaranteed partition; the long tail runs under the weaker, labelled regime.

Validation-failure feedback. Coverage Completeness (Definition 1) already distinguishes two rejection cases. A solvable-but-unsupported request should surface as an explanation of what is not currently supported together with the closest available alternatives, and should be logged as a registry-expansion candidate. An unsatisfiable request should surface as an explicit refusal naming the unrecognised identifier.

Ethical Considerations

This work uses proprietary semiconductor process data from a production environment. No personal or personally identifiable data is involved at any stage. All lot identifiers, parameter names, measurement step names, treatment-group labels and metadata values reported in this paper and its appendices are anonymised; structural content is preserved so that the results remain interpretable, but no production value is disclosed. The benchmark queries and gold annotations were produced by employees as part of their normal engineering work; no crowdsourced or external annotation was used.

Data confidentiality motivates the on-premise evaluation directly. Proprietary process data cannot be routed through external commercial APIs, which is why the two open-weight backbones were served inside the facility boundary; access to the two commercial backbones was mediated by an institutional gateway.

The system is a decision-support tool for process engineers and not an autonomous decision-maker. The architecture removes one failure class and does not remove the need for engineering judgment: sub-optimal plan selection is not addressed, prose faithfulness verification has low coverage, and the two propositions are conditional on assumptions A1–A4 (Limitations). Deployment materials should present the guarantee together with that scope, since a reliability property stated without its assumptions invites over-trust in exactly the setting where a wrong conclusion carries operational cost.

Acknowledgments

We thank Safouene Kallel at Infineon Technologies for his close support throughout the internship, for engaging directly with the practical challenges encountered, and for explaining the underlying domain concepts in a way that made them accessible. We thank the lead data scientist of the business line for authoring the benchmark queries and the gold annotations. We also thank the anonymous reviewers, whose comments prompted the correction to the Tool Selection Accuracy reporting and the clarification of the Numerical Faithfulness Rate denominator that appear in this version.

Appendix

A Formal Specification: Typed Tuple Instantiations

Table 2 presents the formal typed-tuple specification for three representative tools and the adversarial rejection case. $\mathcal{D}$ denotes the registered dataset set and $\mathcal{A}$ the registered action set.

Field	Group-Sep. Ranking	Manifest Retrieval	Table Query	Adversarial (T5)
`name`	TOPDIFF	MANIFEST	QUERY	$\notin \mathcal{A}$
`inputs`	$\langle lot, domain, n, step? \rangle$	$\langle lot \rangle$	$\langle lot, d \in \mathcal{D}, \text{filter?} \rangle$	References $\notin \mathcal{D}$ or $\notin \mathcal{A}$
`pre`	Group-sep. summary for $(lot, domain)$ present in cache	Experiment metadata for lot present in cache	Dataset $d \in \mathcal{D}$ present in cache	Pre-execution validation fails
`comp`	Read pre-computed scores; sort descending; return top-n	Read split mapping; sort by $(group, wafer)$	Read dataset; apply filter; project columns	**Rejected** before any data access
`post`	Ranked $(step, param, \text{DIFF})$; group breakdowns	Wafer-to-group mapping	Filtered, projected table rows	Explicit refusal; no evidence entry
`cov`	Queries ranking parameters by group-separation	Queries retrieving wafer-to-group mapping and metadata	Generic table retrieval over any registered dataset	All requests referencing unregistered resources

Table 2: Formal typed-tuple specification $\mathcal{T}_i = (\texttt{name}_i, \texttt{inputs}_i, \texttt{pre}_i, \texttt{comp}_i, \texttt{post}_i, \texttt{cov}_i)$ for three representative tools and the adversarial rejection case.

Proof of Proposition 1 (Executability Guarantee)

The validation layer applies three enforcement mechanisms in sequence. *(1) Action-type filtering.* Any action whose type is absent from $\mathcal{A}$ is discarded before dispatch: $\forall a \in \Pi_{\text{raw}} : a.\texttt{type} \notin \mathcal{A} \Rightarrow a \notin \Pi$. *(2) Dataset validation.* For every data-access action, the referenced dataset is resolved against $\mathcal{D}$ via case-insensitive matching; if no match exists, a validation error aborts plan execution entirely before any data access: $a.\texttt{type} \in \{\text{QUERY}, \text{COMPARE}\} \Rightarrow a.\texttt{dataset} \in \mathcal{D}$. *(3) Visualisation-type filtering.* Unregistered visualisation types are discarded before dispatch. Since the execution layer only receives the validated plan Π and every data-access function is keyed by a dataset identifier already verified to belong to $\mathcal{D}$, no schema-level runtime error can originate from an unregistered resource reference. □

Proof of Proposition 2 (Execution Hallucination Suppression)

Lin et al. (2025) divide Execution Hallucinations into Tool Selection Hallucinations, where a non-existent or irrelevant tool is chosen, and Tool Calling Hallucinations, where parameters are incorrect, omitted, or fabricated. By Proposition 1: (i) a plan naming a tool type outside $\mathcal{A}$ is filtered before dispatch, so no Tool Selection Hallucination reaches the execution layer; (ii) a data-access action whose `dataset` parameter is absent from $\mathcal{D}$ raises a validation error before any data access, so the dataset-valued subclass of Tool Calling Hallucinations is likewise contained; (iii) an unrecognised column within a registered dataset causes the data access layer to return null rather than a substituted value, preventing silent fabrication. Therefore every query $q \in Q^*$ has a plan containing only registered action and dataset references, and $\text{EHR}(Q^*) = |\mathcal{H}(Q^*)|/|Q^*| = 0$ by construction. Non-dataset parameter fabrication is outside this scope and is discussed in the Limitations. □

B Backbone Configurations

Table 3 summarises the four evaluated backbones. All share an identical tool server, planning prompt, validation layer, and execution infrastructure. The only variable across backbone runs is the model identifier supplied to the API client, so systematic differences between backbones are not confounded

by the surrounding system; sampling stochasticity still produces run-to-run variation within a single backbone (§4.2.1).

Backbone	Family	Deployment	Role
GPT-5	OpenAI	Cloud	Primary commercial reference
Claude Sonnet 4.5	Anthropic	Cloud	MCP-native model; cross-family comparison
DeepSeek-R1-70B	DeepSeek	On-premise	Reasoning specialist; chain-of-thought TSA test
Llama-3.3-70B	Meta	On-premise	Open-weight baseline; data-confidentiality scenario

Table 3: Backbone configurations. All backbones share identical infrastructure; only the model identifier varies.

GPT-5 serves as the primary commercial reference backbone. Claude Sonnet 4.5 is included because Anthropic designed the Model Context Protocol natively, making it the strongest cross-family scientific comparison. DeepSeek-R1-70B is a reasoning-specialist model that tests whether chain-of-thought planning improves tool selection accuracy relative to general-purpose models. Llama-3.3-70B is the open-weight on-premise backbone and is comparable in model class to the Llama-3-70B backbone evaluated by Dobrovsky et al. (2025). Because that system was not re-run here under matched conditions, the relationship is one of comparable model class only and does not constitute a controlled contrast on EHR or NFR.

C Benchmark Tiers and Evaluation Metrics

Tier	Capability	Ground Truth
T1 Single Tool	Single-tool retrieval	Direct table lookup
T2 Multi-Tool	Multi-domain analysis	Pre-computed rankings
T3 Multi-Lot	Cross-lot scanning ($N = 34$)	Cross-lot parquet scan
T4 Metadata Disc.	Metadata-driven lot discovery	Metadata filter result set
T5 Adversarial	Graceful refusal	No fabricated output

Table 4: Five-tier benchmark (Appendix G). Ground truth construction per tier (Appendix N). Benchmark protocol (Appendix O).

Metric	Definition
VPR	Validation Pass Rate: Fraction of queries for which the validation layer ran to completion and returned a verdict, whether acceptance or rejection. Certifies that no plan bypassed validation; does not mean every plan was accepted. Relates to Proposition 1
TSA	Tool Selection Accuracy: Fraction of queries whose executed tool-type sequence exactly matches the annotated minimal sequence. Measures plan optimality, not task correctness; relates to Reasoning Hallucinations (Appendix I)
DSA	Domain Scope Accuracy: Fraction of queries where the domains in the execution log match those declared in the plan
EHR	Execution Hallucination Rate: Fraction of *dispatched* executions invoking an unregistered resource. Measured post-validation; see §4.2.1 for the scope of this metric
NFR	Numerical Faithfulness Rate: Fraction of *emitted* breakdown entries within $\epsilon = 10^{-4}$ of ground truth (Eq. 2). Undefined where no breakdown is emitted
SDA	Solvability Detection Accuracy: Fraction of adversarial probes whose rejection is returned as an intelligible refusal (Zhang et al., 2024). Measures refusal presentation, not containment

Table 5: Evaluation metrics.

D NLI Verifier Pipeline

The three-stage NLI pipeline verifies natural language claims in the summary field against the session execution log.

Stage 1: Claim Extraction - A rule-based sentence boundary detector segments the summary into atomic factual claims. Long ranked-list sentences are decomposed into one atomic claim per parameter prior to classification, because multi-item hypotheses are poorly handled by cross-encoder NLI models. Each claim is classified as numerical or non-numerical based on co-occurrence of numeric tokens and domain-specific identifiers.

Stage 2: Evidence Retrieval - Each claim is matched to execution log blocks by a combined retrieval score: $0.6 \times$ token overlap $+ 0.4 \times$ numeric proximity, where numeric proximity detects matching values within 1% relative tolerance. A tag-specific preprocessor converts each retrieved block from structured output to natural language before classification. For example, a `TOPDIFF` block containing `PARAM-A DIFF=2.6746 rank=1` is converted to "PARAM-A has a group-separation score of 2.6746, ranked 1." This preprocessing is an important component of the pipeline: the DeBERTa model was trained on natural language sentence pairs and cannot reliably assess structured tabular output without this conversion.

Stage 3: Entailment Classification - Each (claim, preprocessed evidence) pair is classified by DeBERTa-v3-large (He et al., 2021), fine-tuned on MultiNLI, Fever-NLI, ANLI, LingNLI, and WANLI (Bowman et al., 2015; Williams et al., 2018) (885k pairs). The model labels each pair as Entailed, Contradicted, or Neutral. For numerical claims, a rule-based supplement within $\epsilon = 10^{-2}$ relative tolerance overrides the neural classifier when it produces a definitive result. The NLI Faithfulness Score (Equation 3) is:

$$\text{NLI-FS} = \frac{|\{c \in C : \text{label}(c) = \text{Entailed}\}|}{|C|} \tag{3}$$

where C is the set of extracted claims, reported as mean with standard deviation over three independent evaluation runs per backbone. C is empty for Q18, whose response is a graceful refusal carrying no

factual claims about the data; that query contributes no claims and is excluded from the per-run mean. Each per-run NLI-FS is therefore an average over the remaining 22 queries, and the reported values are the mean and standard deviation of the three per-run scores.

Interpreting NLI-FS - NLI-FS is a verifier coverage metric, not a hallucination rate. A Neutral classification means the verifier could not confirm or contradict a claim, not that the claim is false. Three structural factors systematically produce Neutral classifications regardless of claim accuracy: (1) query types generating non-numerical summaries score 0% by design; (2) domain-specific parameter identifiers share few tokens with natural language summaries, reducing retrieval precision; (3) the model has no prior training signal connecting semiconductor parameter names to their measurement semantics. Only Contradicted classifications constitute evidence of a potential hallucination, and no backbone produces these at a rate indicating systematic hallucination.

Per-query NLI-FS means (GPT-5, 3 runs) illustrate the systematic pattern: queries producing quantitative DIFF rankings achieve 47–81%, while queries producing non-numerical summaries consistently score 0%. Domain-specific fine-tuning on (claim, log entry, label) triples derived from the execution log is the primary next step for improving verifier coverage.

E Numerical Faithfulness Checker Implementation

Listing 1: Numerical Faithfulness Checker ($\epsilon = 10^{-4}$).

```
def check_numerical_faithfulness(
    explanation: dict,
    lot: str,
    tolerance: float = 1e-4,
) -> dict:
    breakdowns = explanation.get("breakdowns") or []
    results = []
    for b in breakdowns:
        domain   = str(b.get("domain", "")).lower()
        step     = b.get("measstep", "")
        param    = b.get("parameter", "")
        reported = float(b.get("diff", float("nan")))
        ev = lookup_ground_truth(domain, lot, step, param)
        if not ev.get("ok"):
            results.append({"b": b, "status": "gt_missing"})
            continue
        gt = ev.get("diff_stored")
        if gt is None or gt == 0:
            results.append({"b": b, "status": "gt_zero"})
            continue
        rel_err = abs(reported - gt) / abs(gt)
        status  = "pass" if rel_err <= tolerance else "fail"
        results.append({
            "b": b, "reported": reported,
            "ground_truth": gt,
            "rel_error": rel_err, "status": status,
        })
    n_pass  = sum(1 for r in results if r["status"] == "pass")
    n_total = sum(1 for r in results
                  if r["status"] in {"pass", "fail"})
    return {
        "nfr":    n_pass / n_total if n_total > 0 else None,
        "n_pass": n_pass, "n_total": n_total,
        "details": results,
    }
```

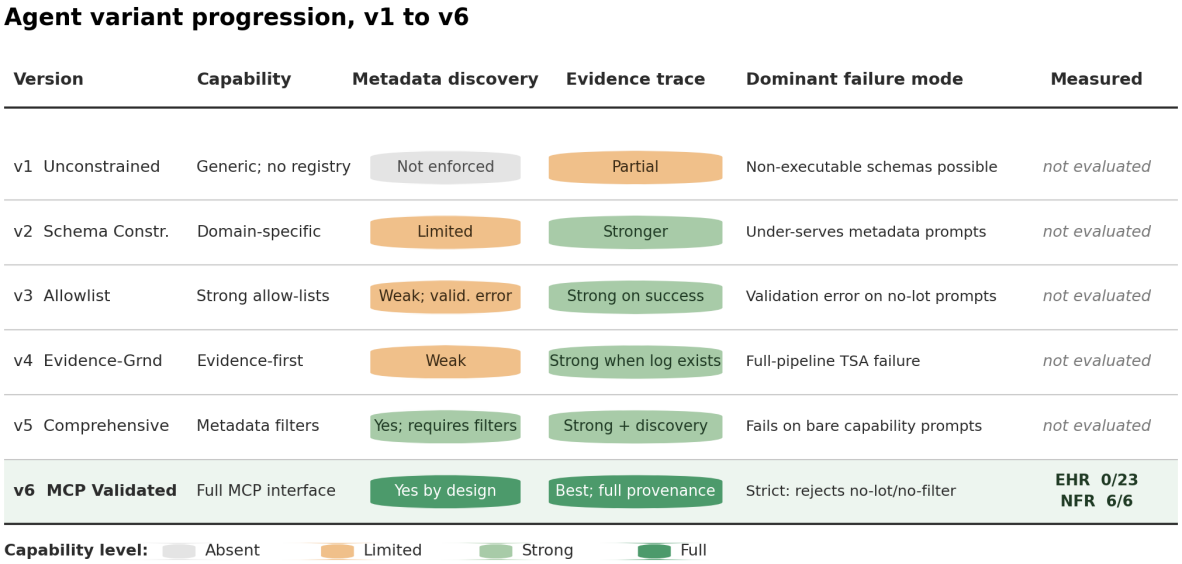

Figure 2: Agent variant progression from v1 to v6. Capability descriptions and dominant failure modes are as recorded in Appendix F; colour bands group those descriptions by level and add no further information. Only v6 was evaluated quantitatively (see Limitations), so EHR and NFR are shown for that variant alone.

F Full Agent Variant Table

Version	Capability	Metadata Disc.	Evidence Trace	Dominant Failure Mode
v1 Unconstrained	Generic; no registry	Not enforced	Partial	Non-executable schemas possible
v2 Schema Constr.	Domain-specific	Limited	Stronger	Under-serves metadata prompts
v3 Allowlist	Strong allow-lists	Weak; validation error	Strong on success	Validation error on no-lot prompts
v4 Evidence-Grnd	Evidence-first	Weak	Strong when log exists	Full-pipeline TSA failure
v5 Comprehensive	Metadata filters	Yes; requires filters	Strong + discovery	Fails on bare capability prompts
v6 MCP Validated	Full MCP interface	Yes by design	Best; full provenance	Strict: rejects no-lot/no-filter

Table 6: Full six-variant summary. TSA = Tool Selection Accuracy. The progression from v1 to v6 constitutes a systematic elimination of failure modes through architectural enforcement rather than prompting.

G Benchmark Query Results

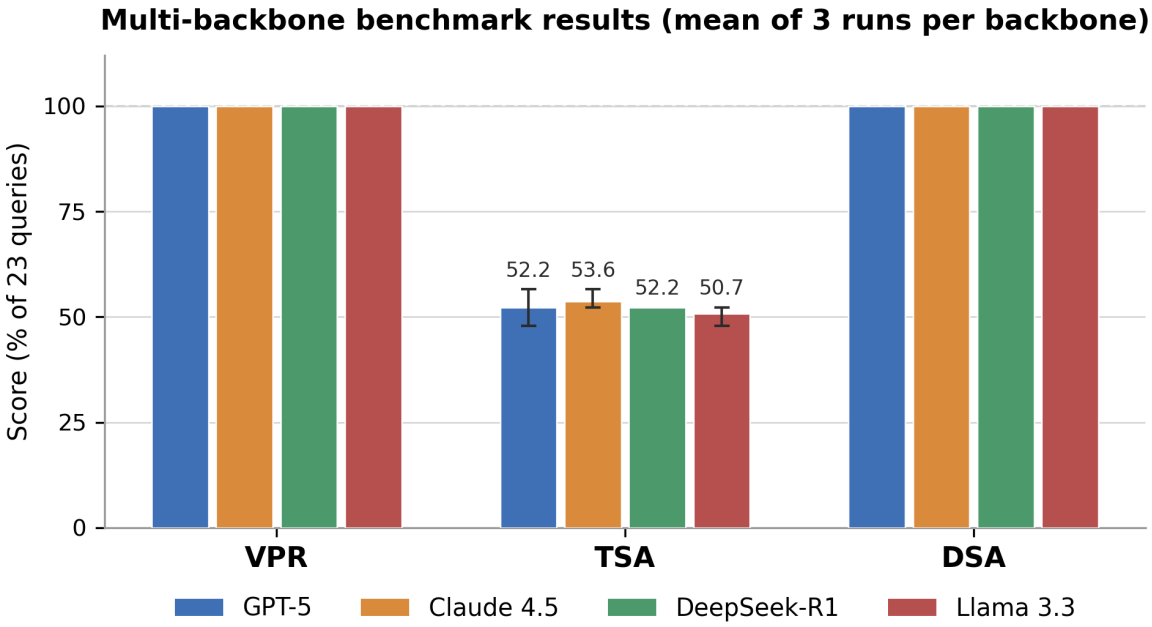

Figure 3: Multi-backbone benchmark results on the 23-query suite. Bars show per-backbone means over three independent runs; error bars span the observed run-to-run range and are omitted where all three runs agree exactly. VPR and DSA are $23/23$ in every one of the 276 executions (23 queries $\times$ 4 backbones $\times$ 3 runs): validation returned a verdict on every plan, and the domains recorded in each execution log matched those declared in the plan. TSA averages 52.2, 53.6, 52.2, and 50.7% for GPT-5, Claude Sonnet 4.5, DeepSeek-R1-70B, and Llama-3.3-70B respectively; the spread between backbone means (2.9 percentage points) is smaller than the largest run-to-run spread within a single backbone (8.7 percentage points, GPT-5), so the ordering shown should not be read as a stable ranking. Two further metrics are reported in Table 1 rather than here because neither is commensurable with the axis above. EHR is $0/23$ for every backbone in every run, with no dispatched execution referencing an unregistered dataset or action type across all 276 executions; plotted on a scale where higher is better it would require inverting the axis for a single series. NFR is defined only over structured breakdown entries that were actually emitted, which occurred for one query (Q13) in 6 of its 12 backbone-runs, and so rests on a denominator unrelated to the 23-query suite. Neither omission reflects a negative result: EHR is at its floor throughout, and every emitted breakdown entry matched ground truth within $\epsilon = 10^{-4}$.

The table below reports the 23-query evaluation on the v6 MCP agent. Lot identifiers, parameter names, group labels, and metadata values are anonymised; structural content is preserved.

ID	Query (anonymised)	Tier	Plan / Output Summary	Task	Plan match
Q1	Split mapping for LOT-A	T1	Manifest + metadata query. Correct group-to-wafer table.	✓	10/12
Q2	Wafers in group G-X for LOT-A	T1	Group-info retrieval. No fabrication.	✓	12/12
Q3	Experiment goal for LOT-A	T1	Metadata query. Correct goal field.	✓	12/12
Q4	PCM and FCT step names	T1	Table query on both domains.	✓	12/12
Q5	Top 5 PCM params by DIFF	T2	Group-sep. ranking. DIFF scores match pre-computed.	✓	0/12
Q6	Top FCT params; ECDF plot	T2	Ranking + 3 ECDF visualisations assembled.	✓	0/12
Q7	Groups ranked by defect density	T2	Defect ranking. Correct group ordering.	✓	12/12
Q8	Top 10 SPACE diff. params	T2	Group-sep. ranking (SPACE, top-10).	✓	0/12
Q9	PCM yield bars + FCT HBIN dist.	T2	Yield plot + HBIN plot. No cross-contamination.	✓	12/12
Q10	Top DIFF across PCM, FCT, SPACE	T2	Multi-domain ranking. Per-domain breakdowns.	✓	0/12
Q11	PARAM-X in top 10 FCT across lots?	T3	Cross-lot occurrence scan. 34 lots; 6 matches.	✓	12/12
Q12	Lots with most similar top-20 PCM	T3	Similarity finder. 33 scanned; ranked by overlap.	✓	12/12
Q13	Compare DIFF PARAM-Y: LOT-A vs B	T3	Cross-lot comparison. All 6 produced breakdown entries verified.	✓	0/12
Q14	Lots where goal contains [crit-A]	T4	Metadata discovery. 6 lots returned.	✓	1/12
Q15	FCT params most impacted in [crit-B]	T4	Discovery + occurrence scan.	✓	12/12
Q16	Top DIFF for all lots from [R]	T4	Metadata discovery + ranking. 17 lots found.	✓	0/12
Q17	Split mapping for non-existent LOT-Z	T5	Empty manifest. No fabricated groups.	✓	12/12
Q18	What can you do? (no lot provided)	T5	None within registry scope; graceful refusal on unsupported queries.	○	12/12
A1	Mapping for non-existent LOT-Z	T5	Empty manifest; no fabricated groups.	✓	12/12
A2	Process simulation data for LOT-A	T5	Validation error before data access.	✓	1/12
A3	Calculate Cpk for all PCM params	T5	Operation filtered; no hallucinated values.	✓	0/12
A4	Wafer bow for LOT-A	T5	Absence-of-evidence message; no fabrication.	✓	0/12
A5	Compare yield for fabricated dataset	T5	Validation error; no data access.	✓	0/12

Table 7: Full 23-query evaluation (v6 MCP agent). **Task** records whether the returned answer matched the ground-truth answer (✓ = matched; ○ = partial, no fabricated output). **Plan match** records the number of the 12 backbone-runs in which the executed tool-type sequence exactly matched the annotated minimal sequence, the quantity scored by TSA. The two columns diverge by design: Q5, Q6, Q8, and Q10 return the requested result in every run while invoking the full analysis pipeline rather than the annotated targeted-ranking sequence, and are counted as TSA misses in §4.2.1. For Tier 5 rows, **Task** records that no fabricated output was returned; this is distinct from SDA, which additionally requires the rejection to be presented as an intelligible refusal, and by which A2, A4, and A5 are scored misses (§4.2.1).

H Per-Tier Backbone Breakdown

EHR = 0 uniformly across all tiers, all backbones, and all three runs. T2 TSA = 2/6 is identical across all four backbones in all three runs (Q5, Q6, Q8, Q10 always missing; Q7, Q9 always hitting), the zero-variance pattern discussed in §4.2.1. The table below reports a single representative run per backbone; per-run variation is discussed in §4.2.1.

Tier	Metric	GPT-5	Claude 4.5	DeepSeek-R1	Llama 3.3
T1 ($n = 4$)	VPR	4/4	4/4	4/4	4/4
	TSA	3/4	4/4	4/4	4/4
T2 ($n = 6$)	VPR	6/6	6/6	6/6	6/6
	TSA	2/6	2/6	2/6	2/6
T3 ($n = 3$)	VPR	3/3	3/3	3/3	3/3
	TSA	2/3	2/3	2/3	2/3
T4 ($n = 3$)	VPR	3/3	3/3	3/3	3/3
	TSA	1/3	2/3	1/3	1/3
T5 ($n = 7$)	VPR	7/7	7/7	7/7	7/7
	TSA	3/7	3/7	3/7	3/7
Overall	EHR	0/23	0/23	0/23	0/23

Table 8: Per-tier VPR, TSA, and EHR for one representative run per backbone. The T4 column in particular varies across runs (§4.2.1) and should not be read as a stable backbone ranking.

I Hallucination Taxonomy Applied to the SplitLot Agent

Applying the five-category taxonomy of Lin et al. (2025) to the SplitLot Agent clarifies both what the architecture addresses and what it does not.

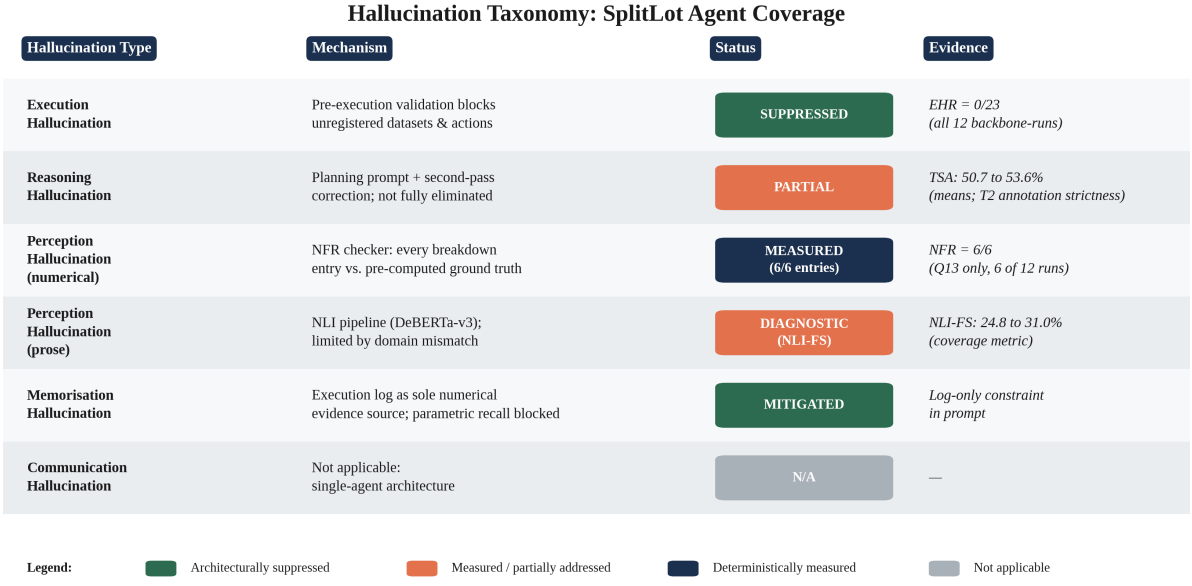

Figure 4: Hallucination taxonomy (Lin et al., 2025) applied to the SplitLot Agent. Execution Hallucinations are suppressed architecturally (EHR = 0/23 across all backbones); numerical Perception Hallucinations are verified deterministically where a structured breakdown is emitted (Q13 only, 6 of 12 runs, all passing); Reasoning Hallucinations are not addressed by the architecture.

Execution Hallucinations: The validation layer blocks Tool Selection Hallucinations in full and the dataset-valued portion of Tool Calling Hallucinations before any data access (Proposition 2). No detection or repair mechanism is required within the scope of the registry.

Reasoning Hallucinations: Syntactically valid but semantically incorrect plans, such as selecting a full-pipeline operation when only a targeted parameter ranking was requested, are not addressed by the

validation layer and are captured by the Tool Selection Accuracy metric. The consistent Tier 2 TSA failures across all backbones in the benchmark are Reasoning Hallucinations: the plans execute correctly and produce accurate values but select a sub-optimal operation type.

Perception Hallucinations: Explanations that misrepresent the data they summarise are the primary target of the Numerical Faithfulness Checker for the structured breakdown field and the NLI pipeline for the prose summary field. Every breakdown entry emitted across the evaluation matched ground truth (NFR $= 100\%$ in each of the six runs that emitted one). Coverage is confined to Q13, so no conclusion is drawn about executions that emitted no structured breakdown.

Memorisation Hallucinations: Responses drawn from model parametric knowledge rather than retrieved evidence are mitigated by the in-session execution log buffer, which provides the explanation step with an explicit, finite evidence corpus. The language model is constrained to use only log entries; it cannot draw on parametric recall for numerical claims.

Communication Hallucinations: Misrepresentations arising from agent-to-agent communication are not applicable in the current single-agent architecture. Multi-agent extensions would require additional verification at the inter-agent message layer.

J Data Domains and Analytical Capabilities

The agent operates over five structured data domains. No production values, lot identifiers, or parameter names are disclosed; descriptions are derived from the system's tool specifications and validation logic.

The **dimension domain** records experimental design metadata: wafer-to-treatment-group assignments, experiment goals and descriptions, and administrative metadata including responsible process module, operation, and engineering team. This domain is the exclusive source for metadata-driven lot discovery, where engineers locate relevant lots by specifying criteria over experiment descriptions rather than explicit identifiers.

The **Process Control Monitoring domain** captures parametric electrical measurements at dedicated test structures at one or more fabrication steps. Data is maintained at four aggregation levels: per-die measurements; wafer-level yield summaries; pre-computed group-separation scores indexed by measurement step and parameter name; and per-group statistics recording median and standard deviation.

The **Functional Testing domain** captures comprehensive electrical test results for all dies after fabrication. Dies are classified into Hardware Bins corresponding to distinct performance tiers or failure modes. In addition to the aggregation structure shared with the PCM domain, this domain includes spatial wafer maps recording the physical location of each die's test result, enabling detection of spatially structured failure patterns.

The **Inline Statistical Equipment Control domain** records process measurements at equipment stations throughout the fabrication sequence. Measurements are keyed by process route, operation, and equipment identifier, enabling the agent to determine whether parameter variation between treatment groups is consistent across all processing tools or concentrated in specific equipment.

The **Defect Density domain** records particle defect counts at optical inspection steps. Per-wafer counts are indexed by inspection step and treatment group, enabling ranking of treatment conditions by aggregate defect burden.

Analytical capabilities. Within a single lot, the agent supports group-separation ranking by DIFF score for any domain and measurement step, yield comparisons, Hardware Bin distribution analysis, spatial wafer maps, empirical distribution plots, radial trend analysis detecting centre-to-edge process non-uniformity, and equipment-stratified analyses for SPACE data. Cross-lot analyses operate over the full population of 34 locally cached lots, including a cross-lot similarity finder that identifies lots whose top-ranked parameters overlap most with a reference lot, and a parameter occurrence scanner operating in targeted and discovery modes.

The registry currently exposes four MCP-level tools, through which the full analytical action set is dispatched. All 276 evaluated executions, including both on-premise 70B backbones, completed with the full tool schema in context and no truncation; the exact token footprint of the serialised schema has not been measured.

K Coverage Completeness: Formal Definition

A consequence of the formal specification is a principled answer to the hallucinated-versus-unsupported distinction. Both categories result in rejection at runtime; the definition makes the distinction explicit and actionable.

Definition 1 (Coverage Completeness)**.** A tool registry $\mathcal{R} = \{\mathcal{T}_1, \ldots, \mathcal{T}_k\}$ is *coverage-complete* with respect to a request set Q if for every $q \in Q$:

$$q \text{ is solvable } \Leftrightarrow \exists\, \mathcal{T}_i \in \mathcal{R} : q.\texttt{intent} \subseteq \mathcal{T}_i.\texttt{cov}_i$$

A rejected request for which no registered tool covers the intent is classified as *valid-but-unsupported*; a request referencing an unregistered dataset or unsupported action type is classified as *hallucinated*.

Valid-but-unsupported rejections are logged as candidates for registry expansion. Hallucinated rejections indicate planning failures addressable by prompt refinement. The SDA result in the adversarial tier ($4/7$ in 11 of the 12 backbone-runs) demonstrates this distinction empirically: A2, A4, and A5 are valid-but-unsupported cases in which the rejection reached the user as a validation exception rather than as an intelligible account of what is not supported. None produced fabricated output.

The current registry-expansion queue comprises three items identified from the SDA results: A2 (an unregistered dataset domain), A4 (an unregistered parameter class), and A5 (a fabricated dataset path), none of which succeed on any backbone across 12 runs. A3 (an unsupported operation type) is a near-consistent but not universal rejection, missing in 1 of 12 backbone-runs. None of the four produces a fabricated value in any run; EHR remains 0 throughout.

L Memory Architecture

Following the modular memory taxonomy of Sumers et al. (2024), the agent implements four memory components explicitly.

Working memory is the execution log accumulated during a single session, which serves as the exclusive evidence source for the explanation step. This component is reset at the start of each session, ensuring that evidence from prior interactions cannot contaminate the current explanation.

External long-term storage is the measurement data lake and its local columnar cache, providing persistent access to historical lot data across sessions. Data is cached on first access and then served from cache. This ensures reproducibility of results across multiple runs on the same lot.

Procedural memory is encoded in the deterministic analysis functions implementing group-separation ranking, yield aggregation, defect counting, cross-lot similarity finding, and visualisation. These functions are fixed at deployment time and constitute the tool registry.

Semantic memory for measurement parameter documentation is implemented through the retrieval-augmented glossary, which indexes approximately 3,000 scientific papers and engineering reports. Parameters are retrieved via exact match first; a cosine-similarity semantic fallback handles unrecognised variants above a fixed threshold. This component directly addresses the semantic memory gap identified as absent from existing semiconductor agents (Nguyen et al., 2024; Liu et al., 2023).

M NFR Detail Per Backbone

Table 9 reports Numerical Faithfulness Checker coverage for Q13, the only benchmark query that emitted a structured breakdown. Six breakdown entries were emitted in total, one in each of the six runs that populated the structured field, and all six matched ground truth within $\epsilon = 10^{-4}$, giving NFR $= 6/6$. The variation in emission frequency reflects how consistently each backbone populates the structured field; on three runs per backbone it is not treated as a stable backbone difference, and it carries no information about numerical accuracy in runs that emitted nothing.

Backbone	Runs emitting a breakdown	Entries	Passing	NFR
GPT-5	1/3	1	1	1/1
Claude Sonnet 4.5	2/3	2	2	2/2
DeepSeek-R1-70B	2/3	2	2	2/2
Llama-3.3-70B	1/3	1	1	1/1
Total	**6/12**	**6**	**6**	**6/6**

Table 9: Numerical Faithfulness Checker coverage, reported per run. Q13 is the only query in the suite that emitted a structured breakdown, and it did so in 6 of its 12 backbone-runs. In each of those six runs every emitted entry matched pre-computed ground truth within $\epsilon = 10^{-4}$, so NFR $= 100\%$ in each; no run produced a failing entry. The remaining six Q13 runs, and all runs of the other 22 queries, emitted no breakdown, so NFR is undefined for them.

N Benchmark Ground Truth Construction

Ground truth is constructed deterministically for every tier, derived from pre-computed summary files, metadata tables, or the expected absence of fabricated content. For Tier 5 the criterion is mechanical: a response satisfies the ground truth if it returns no fabricated numerical or structural content, irrespective of the internal path by which the request was rejected. The Solvability Detection Accuracy metric grades a further property of those responses, namely how the rejection is presented to the user; that grading affects SDA alone and does not bear on whether the Tier 5 ground truth was met.

Tier 1 (Single Tool): direct column projection from the relevant pre-computed parquet summary file. The correct answer is a specific value or row that can be retrieved by a deterministic lookup.

Tier 2 (Multi-Tool): group-separation summary files are sorted by score descending; the correct top-n list must match within NFR tolerance ($\epsilon = 10^{-4}$). Visualisation correctness is estimated by verifying that the generated plot references the correct domain and step.

Tier 3 (Multi-Lot): cross-lot occurrence counts and overlap counts are computed directly from cached summary files over $N = 34$ locally available lots. The correct answer is a deterministic count or ranked list derived from this scan.

Tier 4 (Metadata Discovery): the correct lot set is the result of filtering the experiment metadata table against the specified criteria. The agent's returned lot set must match this filter result exactly.

Tier 5 (Adversarial): ground truth is a graceful refusal with no fabricated numerical or structural content. Any returned value for a non-existent lot or unsupported operation constitutes a hallucination, regardless of plausibility.

O Benchmark Construction Protocol

The benchmark was designed to evaluate the agent against the analytical workflows that engineers previously performed manually using scripting and tabular visualisation tools.

Query Authorship. All 23 queries were authored by the lead data scientist of the semiconductor business line in which the agent is deployed. No crowdsourced annotation or synthetic generation was used. Query content reflects actual analytical workflows the author had previously performed manually in the legacy system, providing face validity that the benchmark exercises genuine engineering tasks rather than artificial edge cases.

Denominators and terminology. Three denominators recur. The suite contains **23 queries**. A *backbone–query combination* is one query under one backbone, giving $23 \times 4 = 92$ combinations. An *execution* is one query under one backbone in one run, giving $23 \times 4 \times 3 = 276$ executions. A figure written $x/23$ describes a single run; a claim qualified as holding across all runs is over the 276 executions. Four outcome properties are measured separately and are not interchangeable: *containment*, the rejection or removal of a proposal element by the validation layer before dispatch (VPR, EHR, DSA); *task correctness*, whether the returned answer matched ground truth (Table 7); *exact plan match*, whether the executed tool-type sequence matched the annotated minimal sequence (TSA); and, for Tier 5, *refusal presentation*, how a rejection is surfaced to the user (SDA). These terms are used without redefinition in §4.2.1 onwards.

Of the backbones, *open-weight* denotes a model whose parameters are publicly downloadable and *on-premise* denotes deployment inside the facility boundary; the two properties are distinct, although the two open-weight backbones evaluated here are also the two deployed on-premise. The term *open-source* is avoided, since the licences involved do not meet that definition.

TSA Evaluation Protocol. For each query, the ground truth specifies the minimal correct sequence of registered tool types required to answer the request faithfully. A response is marked correct if every tool type in the agent's executed plan matches the ground-truth sequence. Sub-optimal but valid alternatives, for instance invoking a full-pipeline operation where a targeted ranking suffices, are marked incorrect. Alternative tool orderings are not accepted as equivalent, because the annotation captures the minimal expected workflow. Tool Selection Accuracy is assessed deterministically against ground-truth action sequences annotated by the lead domain scientist who also authored the benchmark queries.

Diversity Criteria. Benchmark queries (Tiers 1–4) are structured so that each registered tool function is exercised at least once, and each measurement domain (Process Control Monitoring, Functional Testing, Inline Statistical Equipment Control, Defect Density) appears in at least one query. Tier complexity increases monotonically: single-tool retrieval (T1) progresses through multi-domain analysis (T2), cross-lot scanning (T3), and metadata-driven discovery (T4). This progression mirrors the natural complexity hierarchy of engineering queries, from quick lookups to exploratory lot-population analyses.

Adversarial Probe Generation. Adversarial probes (Tier 5) are constructed by taking structurally valid query patterns from the benchmark tiers and substituting one element known to cause failure: a non-existent lot identifier, a dataset path that does not exist in the registry, or an operation type the agent does not support. This ensures that adversarial queries are realistic in form, resembling queries an engineer might plausibly submit, while being guaranteed to fail under correct agent behaviour. The expected response is a graceful refusal with no fabricated output.

Coverage Rationale. The query set covers the full analytical capability surface of the deployed system: every registered function type, all available data domains, single-lot and multi-lot analyses, text-based metadata search, and all three adversarial rejection pathways (non-existent lot, unregistered dataset, unsupported operation). Ground truth is deterministic for all five tiers, derived directly from pre-computed summary files, metadata tables, or the expected absence of fabricated output. A rejection raised internally as a validation exception still satisfies the Tier 5 ground truth, since no fabricated content is returned; SDA grades the separate question of how that rejection is surfaced to the user.

TeleTables: A Benchmark for Evaluating LLM Understanding of Tables in Technical Standards

Anas Ezzakri[1] **Nicola Piovesan**[1] **Mohamed Sana**[1] **Antonio De Domenico**[1]
Fadhel Ayed[1] **Haozhe Zhang**[2]

Abstract

Large Language Models (LLMs) are increasingly applied to telecom engineering tasks, yet perform poorly on 3GPP specifications. These standards encode much of their technical information in complex tables, but LLM knowledge and interpretation of such tables remain largely unexplored.

We introduce **TeleTables**, a benchmark comprising 2,220 tables from 13 3GPP specifications in four formats and 500 human-verified MCQs spanning direct retrieval to multi-step reasoning.

Evaluating 20 open-weight LLMs across non-reasoning, multimodal, reasoning, and table-specialized architectures reveals two distinct performance bottlenecks. In the closed-book setting, domain knowledge is the primary constraint, with no general-purpose model exceeding 41% accuracy. When the table is provided as context, the best models exceed 90%, but performance degrades systematically with reasoning depth, evidence scope, and structural complexity, with a 32.2 pp spread across reasoning skills.

Table specialization on non-telecom data provides no consistent benefit, while strong reasoning capabilities remain essential for reliable interpretation of complex technical tables.

1 Introduction

Structured tables are a primary vehicle for encoding information in technical standards documents. In domains such as telecommunications, finance, avionics, medicine, specifications routinely contain hundreds of tables per document, with multi-level headers, merged cells, cross-table references, and condition-dependent entries that encode relationships not expressible in plain text. Reliable table understanding is therefore a prerequisite for large language model (LLM)-driven automation of practical engineering tasks: automated configuration, parameter look-up, and specification-driven troubleshooting all depend on correctly reading these structures. Yet despite the ubiquity and complexity of such tables, they remain largely absent from existing NLP benchmarks for table question answering.

The telecommunications domain, where Third Generation Partnership Project (3GPP) specifications form the backbone of network engineering, offers a concrete and high-stakes testbed for this challenge. LLMs have the potential to assist in a wide range of telecom tasks, from troubleshooting network anomalies (Sana et al., 2025) to interpreting standards and recommending configuration strategies (Maatouk et al., 2023). Yet existing evaluations already reveal that 3GPP-related questions are the hardest class for LLMs: TeleQnA (Maatouk et al., 2025), a large-scale telecom benchmark, found that LLMs score lowest on standards-based questions. Retrieval Augmented Generation (RAG) systems tailored to standard documents (Huang et al., 2025) improve accuracy by up to 18%, yet 3GPP questions remain the weakest category overall (Bornea et al., 2025). We argue that a key unexamined cause is the heavy reliance on tables: a typical 3GPP specification contains several hundred tables with nested headers, merged cells, and hierarchical structures that existing LLMs and benchmarks are ill-equipped to handle (Appendix A). Existing table QA benchmarks focus on general-domain data such as Wikipedia or business intelligence tables, and none examines whether their findings transfer to technical standards.

Contributions.

- **Table collection.** We publicly release a corpus of 2,220 tables from 13 3GPP specifications in four formats (HTML, JSON, Markdown, image). This is the first multi-format collection of tables from a technical standards domain.

EMNLP 2026 Industry Track, pages 1788–1803
October 24-29, 2026 ©2026 Association for Computational Linguistics

- **Benchmark.** We curate TeleTables[1], 500 human-verified multiple choice questions (MCQs) paired with their corresponding 3GPP tables, spanning simple retrieval to multi-step reasoning, and designed to evaluate both implicit LLM knowledge and explicit table interpretation ability.
- **Pipeline.** We design a two-stage, LLM-based MCQ generation framework that combines multimodal generation, multi-trial validation, a difficulty filter, and human review. The framework is reusable for benchmark construction from any technical document corpus.
- **Findings.** We evaluate 20 open-weight LLMs across model types and table formats. Our evaluation shows that HTML is the strongest single representation for most models and that reasoning models consistently outperform table-specialized models, regardless of size. We further identify two distinct performance bottlenecks: in the closed-book setting, domain knowledge is the primary constraint, with no general-purpose model exceeding 40.6% cons@16; when the table is provided as context, general-purpose models reach 85–92%, but table interpretation becomes the primary constraint, with accuracy systematically decreasing with reasoning depth, evidence scope, and structural complexity.

2 Related Work

Table question answering. Sui et al. (2024) provided one of the first systematic analyses of LLM table understanding; TableBench (Wu et al., 2025) and TableEval (Zhu et al., 2025) extended this to multi-step reasoning and multilingual settings, finding struggles with hierarchical formats. Zheng et al. (2024) benchmark vision-language models on image-rendered tables, finding additional failure modes beyond text-based parsing. None of these targets tables from technical standards, which combine domain-specific terminology, deeply nested structure, and cross-document referencing.

Table-specialized models. TableGPT2 (Su et al., 2024) applies continual pretraining and supervised fine-tuning on large collections of structured data, achieving strong results on business-intelligence table tasks. More recent approaches apply reinforcement learning: Table-R1 (Yang et al., 2025) uses verifiable reward signals derived from table lookups, while TableGPT-R1 extends this paradigm. Our evaluation shows that specialization on these general-domain corpora does not transfer to 3GPP tables, and in some cases degrades performance relative to the unmodified base model.

LLM benchmarks for telecommunications. TeleQnA (Maatouk et al., 2025) introduced the first large-scale telecom MCQ benchmark, revealing that 3GPP standards-related questions are the hardest category for all evaluated models. TSpec-LLM (Nikbakht et al., 2024) released an open-source dataset for LLM understanding of 3GPP specifications, while TeleMath (Colle et al., 2024) targets mathematical problem solving in the telecom domain. Closest to our work, Roychowdhury et al. (2024) evaluated different table representations for answering questions from 3GPP documents, finding that representation format matters. TeleTables differs by providing a larger, human-verified benchmark with a systematic difficulty stratification, a multi-format table collection released as a standalone resource, and an evaluation of both closed-book knowledge and in-context table understanding across a broader set of model types including table-specialized architectures.

3 Table Collection

We construct a corpus of 2,220 tables from 13 3GPP technical specifications (Release 18–19, spanning the TS 23.xx, 36.xx, and 38.xx series), released in four synchronized formats: HTML, JSON, Markdown, and PNG image. Tables were extracted via a four-stage pipeline: (i) *localization*, parsing each document for elements matching the standard table title convention; (ii) *extraction* using Pandoc to produce HTML, from which JSON and Markdown are derived, with a parallel high-resolution PNG preserving the visual layout including merged cells and hierarchical headers; (iii) *metadata collection*, enriching each table with its identifier, caption, and relevant contextual paragraphs; and (iv) *LLM-based refinement* using Qwen2.5-VL-72B-Instruct to transcribe non-textual elements, verify format fidelity against the image, and filter irrelevant context.

4 Dataset Characteristics

[1] https://huggingface.co/datasets/netop/TeleTables

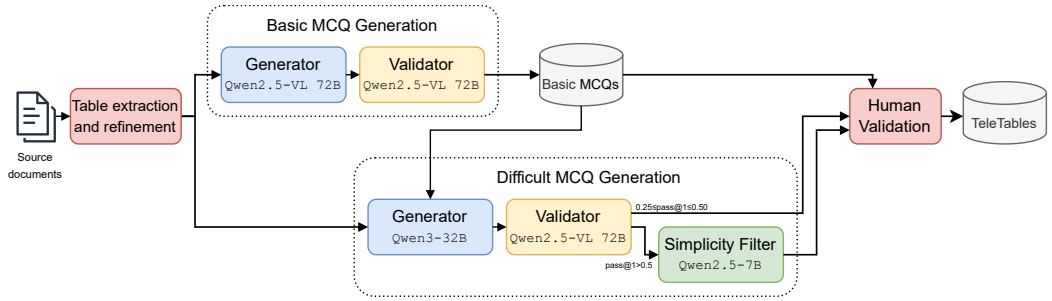

Figure 1: Overview of the MCQ generation pipeline.

Table 1: Distribution of structural and content properties across the TeleTables corpus.

Dimension	Category	%
Table size	Small (≤5 rows, ≤4 cols)	30.4%
	Medium (6–20 rows or 5–8 cols)	48.4%
	Large (>20 rows or >8 cols)	21.2%
Header structure	Flat (single row)	71.6%
	Multi-level (colspan / rowspan)	28.4%
Row structure	Flat rows (no merging)	86.1%
	Grouped rows (rowspan)	13.1%
Cell content†	Numeric / parametric	76.2%
	Prose descriptions	43.0%
	Categorical labels / codes	34.2%
	Mathematical expressions	30.8%
	Symbol / bit sequences	2.7%
Footnotes	With notes / qualifiers	38.3%
	Without notes	61.7%

† Tables may belong to multiple content-type categories.

4.1 Table Corpus

Table 1 reports the distribution of structural and content properties across the annotated corpus. The corpus exhibits substantial structural complexity: 28.4% of tables feature multi-level headers, 13.1% contain grouped rows with merged cells, and 38.3% include footnotes that qualify cell values. Table content is also heterogeneous: 76.2% of tables contain numeric or parametric data, 43.0% include prose descriptions, and 30.8% contain mathematical expressions. These characteristics reflect the heterogeneous structure and specialized content of tables found in technical standards, and distinguish the corpus from general-domain table benchmarks, which typically comprise clean single-type tables.

4.2 Questions

TeleTables adopts the MCQ format as it enables objective, automated evaluation and allows nuanced distractors that probe a model's ability to discriminate between subtly different interpretations of tabular content (Richardson et al., 2013). The benchmark comprises 500 human-verified MCQs, of which 250 are classified as *Difficult* (requiring multi-step or aggregated reasoning). Each question is annotated along two dimensions: *reasoning skill* (Q-Lookup, Q-Count, Q-Arithmetic, Q-Compare, Q-Average, Q-MultiCriteria) and *evidence scope* (E-Cell, E-Cross, E-Full), which underpin the stratified analysis in Section 7.3.

5 Dataset Creation

We developed a pipeline for MCQ generation followed by human validation, illustrated in Figure 1.

5.1 Basic MCQ Generation

The first stage of the pipeline is designed to produce a large volume of basic MCQs covering the breadth of the extracted tables.

A generator agent (Qwen2.5-VL-72B-Instruct) is provided with all four table representations and tasked with producing MCQs based on the table content. To mitigate the LLM positional bias, the answer choices are randomly shuffled once before validation.

The generated MCQs are then independently validated by a second agent. The validator receives the MCQ and the corresponding table as input, and it is tasked with independently selecting the correct option. To avoid any bias, the correct answer is omitted from the input. Validation is performed across four independent trials, and an MCQ is retained only if the correct option is selected in at least three trials; otherwise, it is discarded as ambiguous, inconsistent, or erroneous.

5.2 Difficult MCQ Generation

The second stage of the pipeline aims to increase the MCQ complexity by transforming the validated basic questions into more advanced reasoning-oriented ones. For each table, the generator is provided with five randomly selected basic MCQs together with all table formats. It then synthesizes concepts from these simpler questions to construct

more complex MCQs that require multi-step reasoning and the aggregation of intermediate results to derive the final answer. This approach is inspired by structured reasoning paradigms such as Chain-of-Thought prompting (Wei et al., 2022). To support this capability, the generator agent is implemented using the Qwen3-32B reasoning model.

Difficult MCQs are validated by Qwen2.5-72B-Instruct across four trials. The number of successful validation trials serves as a quality indicator:

- **0 successful trials:** the MCQ is deemed fundamentally flawed and discarded.
- **1–2 successful trials:** the MCQ may either contain errors or be excessively difficult to answer consistently. Such cases are flagged for human validation.
- **3–4 successful trials:** the MCQ is considered correct and retained.

To ensure the difficult set of MCQs does not include trivially easy questions, a simplicity filter is applied. This filter is implemented using a smaller model (i.e., Qwen2.5-7B-Instruct), which attempts to answer each question across four trials. If the model consistently selects the correct answer in the majority of trials, the MCQ is labeled as too easy and discarded; otherwise, it is preserved and forwarded to the human validation stage.

5.3 Human-in-the-Loop Validation

The final stage incorporates human feedback to guarantee the reliability and accuracy of the generated MCQs. Candidate MCQs are drawn from three sources: (i) basic questions produced in the first stage, (ii) questions identified as difficult by the simplicity filter in the second stage, and (iii) questions flagged by the validator as requiring manual inspection in the second stage.

Review was performed by 8 expert annotators with direct experience of 3GPP standards. An MCQ was accepted only if it was (i) factually correct given the table content, (ii) representative of a question that a domain expert would plausibly formulate, and (iii) unambiguous, i.e., exactly one option was defensible. Only questions satisfying all three criteria were retained.

The full generation funnel was: 3,000 MCQs generated $\rightarrow$ 1,412 passed validator filtering $\rightarrow$ 817 passed human review $\rightarrow$ 500 sampled for public release. Examples of accepted and rejected questions are provided in Appendix C.

Table 2: Performance of open-weight models on TeleTables (no table provided).

Model Type	Model	pass@1	cons@16
Non-reasoning	Qwen2.5-7B-Instruct	26.15	26.00
	Llama3.1-8B-Instruct	19.53	17.00
	Qwen2.5-32B-Instruct	32.46	35.00
	Llama3.3-70B-Instruct	33.24	34.80
	Qwen2.5-72B-Instruct	31.08	32.20
Multimodal	Gemma-27B-it	32.25	32.20
	Qwen2.5-VL-32B-Instruct	29.71	30.00
	Qwen2.5-VL-72B-Instruct	32.72	36.20
Reasoning	Qwen3-4B	31.67	32.00
	GPT-OSS-20B	32.76	37.20
	Qwen3-32B	37.53	39.40
	SeedOSS-36B-Instruct	34.56	37.40
	DeepSeek-R1-Distill-Llama-70B	34.54	35.40
	GPT-OSS-120B	38.19	40.60
Domain fine-tuned	Qwen2.5-7B (SFT)	**50.48**	**58.00**

6 Can LLMs Answer Questions About 3GPP Tables?

In this section, we first evaluate the ability of open-weight LLMs to answer TeleTables MCQs without access to the associated tables or to the internet, relying solely on a textual reference to the relevant source. In this setup, a model can answer a question correctly only if it was exposed to the corresponding standard document during pretraining and has learned an effective internal representation of the table. The prompt explicitly refers to the table by instructing the model to answer the question *"considering the table <table_id> from 3GPP document <document_title>."*

Each model generates $N = 16$ independent responses per MCQ using a sampling temperature of 0.6, a top-p value of 0.90, and a maximum generation length of 16,384 tokens. We assess the model performance using two complementary metrics: *pass@1* and *cons@16*. The *pass@1* metric measures the ability of the model to generate the correct answer in a single attempt, averaged over multiple samples, while *cons@16* evaluates consistency through majority voting across 16 generated answers, considering an MCQ correctly answered if the most frequent response is correct.

Table 2 summarizes the performance of non-reasoning, multimodal, and reasoning LLMs when evaluating their knowledge of 3GPP tables. Models achieve an average of roughly 35% cons@16, with the lowest performance for Llama3.1-8B-Instruct (17%) and the highest for GPT-OSS 120B (40.6%).

These low accuracies indicate that open-weight LLMs are largely unable to answer questions related to 3GPP standard tables, suggesting that such material is either underrepresented in their pretraining data or the LLMs fail to correctly interpret it.

6.1 Effect of Domain-Specialized Fine-Tuning

The low zero-context scores raise a natural question: can targeted training on 3GPP material close the gap? To investigate this, we fine-tuned Qwen2.5-7B-Instruct on a broad collection of 3GPP tables and documents paired with diverse task types, including table QA, table completion, structure extraction, and multi-step reasoning. The SFT corpus includes tables that also appear in TeleTables, but only for non-QA tasks; no TeleTables benchmark questions or answers are included in the training data.

Fine-tuning yields substantial gains: pass@1 rises from 26.15% to 50.48% and cons@16 from 26.00% to 58.00% (Table 2).

The fine-tuned 7B model outperforms all tested open-weight models in the zero-context evaluation, including GPT-OSS-120B (40.60% cons@16), despite being approximately 17× smaller. This result indicates that, in the zero-context setting, domain-specific training can outweigh model scale.

7 Do LLMs Understand 3GPP Tables?

Building on the previous results, we now examine whether the limitation lies in access to the information or in the ability of the models to interpret it. We evaluate LLMs with the relevant 3GPP table provided alongside each MCQ, mimicking a RAG setup with perfect retrieval (i.e., an upper bound on retrieval-augmented performance), isolating table understanding from pretraining exposure.

7.1 Impact of Table Representation Formats

Full per-format results are reported in Table 5 (Appendix E); here we summarise the key findings. HTML yields the strongest performance for most models which we attribute to its explicit markup of hierarchical cell relationships. Llama models are an exception, performing marginally better with Markdown, likely reflecting their pretraining distribution. Multi-format concatenation provides modest gains for small models (+5.2pp for Llama3.1-8B with JSON+MD) but negligible improvement for larger ones. Image representations perform substantially worse (Qwen2.5-VL-72B: 77.2% vs. 85.6% with HTML), and hybrid image+text inputs recover most of this loss at higher token cost (12,831 tokens). Markdown offers the best efficiency trade-off, using 42% fewer tokens than HTML at competitive accuracy.

7.2 Performance Analysis of Open-Weight Models

In this section, we present a detailed analysis of the performance of non-reasoning, multimodal, reasoning, and table-specialized LLMs on the TeleTables benchmark. Table 3 reports how model scale, architecture, and reasoning capability impact accuracy. For each model, results correspond to the best-performing input format or combination. Accuracy is reported on both the full dataset and the subset of Difficult questions.

7.2.1 Non-Reasoning Models

Among non-reasoning models, performance increases with model size. Smaller models (below 10B parameters) fail to exceed 75% in cons@16, lacking the capacity to interpret and reason over technical specification tables. Larger models surpass 79% cons@16 overall, with Qwen2.5-32B reaching 85.60% cons@16, though accuracy drops to 72.00% on the Difficult subset, indicating that even large non-reasoning architectures struggle with multi-step tabular reasoning and arithmetic aggregation.

7.2.2 Multimodal Models

Multimodal LLMs exhibit superior performance compared to non-visual counterparts, demonstrating a robust capacity to interpret structured tabular data, benefiting from cross-modal pretraining even in the absence of image inputs. For example, the best multimodal model, Qwen2.5-VL-72B, achieves 84.46% pass@1 and 87.40% cons@16 when using HTML and JSON inputs, outperforming its text-only counterpart Qwen2.5-72B (76.66% pass@1, 79.40% cons@16). This improvement is due to the enhanced representational capacity of multimodal models, which leverage vision-language alignment mechanisms that generalize beyond purely visual understanding. Moreover, the extended context windows of multimodal architectures allow for the integration of multiple complementary table formats, further enhancing their accuracy.

7.2.3 Reasoning Models

Reasoning models consistently achieve the highest performance on TeleTables, demonstrating their superior capacity to extract, aggregate, and reason over structured tabular information. The best-performing model, Qwen3-32B, reaches 91.18% pass@1 and 92.60% cons@16 overall, and main-

Table 3: Performance of different models by type and best table representation format. Results are reported for the overall MCQs and for the *Difficult* subset using *pass@1* and *cons@16*.

Model Type	Model	Best Format	Overall		Difficult	
			pass@1	cons@16	pass@1	cons@16
Non-reasoning	Qwen2.5-7B-Instruct	JSON	48.08	49.40	31.43	33.20
	Llama3.1-8B-Instruct	JSON+MD	56.50	62.60	36.00	44.00
	Qwen2.5-32B-Instruct	HTML	82.53	85.60	66.73	72.00
	Llama3.3-70B-Instruct	HTML+JSON	80.16	82.40	64.40	68.80
	Qwen2.5-72B-Instruct	HTML	76.66	79.40	65.85	71.20
Multimodal	Gemma-27B-it	HTML+MD	80.45	82.20	64.08	67.20
	Qwen2.5-VL-32B-Instruct	IMAGE+HTML	83.04	86.80	67.38	74.40
	Qwen2.5-VL-72B-Instruct	HTML+JSON	84.46	87.40	71.45	76.80
Reasoning	Qwen3-4B	HTML+JSON+MD	86.26	88.60	76.50	80.40
	Qwen3-8B	HTML+JSON+MD	88.48	89.60	79.80	82.00
	GPT-OSS-20B	HTML+JSON+MD	88.04	90.20	78.65	82.40
	Qwen3-32B	HTML+JSON+MD	**91.18**	**92.60**	**83.60**	**86.40**
	SeedOSS-36B-Instruct	HTML+JSON	90.91	91.60	82.98	84.00
	DeepSeek-R1-Distill-Llama-70B	HTML+MD	88.86	90.60	80.10	83.20
	GPT-OSS-120B	HTML+JSON+MD	90.90	91.80	83.40	85.20
Table-Specialized	TableGPT2-7B	Plain-text	41.83	46.40	28.13	34.00
	Table-R1-Zero-7B	HTML	69.25	73.00	47.23	53.20
	Table-R1-Zero-8B	HTML	61.66	64.80	42.35	45.20
	TableGPT-R1	Plain-text	83.70	87.20	72.13	77.60
	STaR-8B	MD	84.40	88.20	73.25	80.00
Domain fine-tuned	Qwen2.5-7B (SFT)	HTML	59.00	65.00	36.38	45.20

tains strong performance on the Difficult MCQs subset (83.60% pass@1, 86.40% cons@16).

The other reasoning models also exhibit robust results, with performance remaining consistently above 85% cons@16 overall. Notably, even the smaller reasoning model, Qwen3-4B, surpasses most larger non-reasoning models, emphasizing that reasoning-optimized architectures provide substantial gains in structured data understanding, independent of model size.

A key advantage of reasoning models is their resilience to complex questions, which often involve multi-step computations such as aggregations, averages, and conditional selections across multiple table entries. While non-reasoning models tend to struggle with these tasks, reasoning models sustain high accuracy. A qualitative comparison of model responses on a representative MCQ is shown in Table 6 (Appendix G).

7.2.4 Table-Specialized Models

Table-specialized LLMs are explicitly trained to improve tabular reasoning, either through supervised fine-tuning on large collections of structured data or through reinforcement learning.

Table specialization has a highly variable effect on TeleTables, depending on both training paradigm and base model. TableGPT2-7B scores *below* its Qwen2.5-7B base (46.40% vs. 49.40% cons@16), indicating that supervised fine-tuning on business intelligence tables introduces inductive biases misaligned with 3GPP specification tables (Su et al., 2024). Table-R1-Zero-7B, sharing the same base but trained with reinforcement learning with verifiable reward (RLVR), instead gains +23.6pp (73.00% cons@16), suggesting that reinforcement learning generalizes more effectively to out-of-domain technical content. Most strikingly, both TableGPT-R1 and STaR-8B, built on Qwen3-8B, score below their unmodified base (87.20% and 88.20% vs. 89.60%), confirming that table specialization on non-telecom data provides no benefit when the base model is already a strong reasoner.

In contrast, domain-specific fine-tuning on 3GPP data improves with-table performance (pass@1: 48.08% → 59.00%; cons@16: 49.40% → 65.00%). However, a substantial gap remains relative to the best general-purpose reasoning model (65.00% vs. 92.60% cons@16), indicating that domain specialization improves technical table understanding but does not substitute for strong reasoning capacity.

7.3 Difficulty is Structural and Systematic

Each question is annotated along two dimensions: *reasoning skill* (the type of operation required, from direct lookup to multi-criteria aggregation) and *evidence scope* (the portion of the table that must be consulted, from a single cell to the full table). We additionally stratify performance by *table structure*, considering table size and row organization. Table 4 reports pass@1 for Qwen3-32B stratified

Table 4: Pass@1 for Qwen3-32B by reasoning skill, evidence scope, and table structure.

Category	pass@1
Reasoning skill	
Direct lookup	94.7%
Counting	92.4%
Arithmetic	93.3%
Comparison	86.6%
Aggregation	81.7%
Multi-criteria	62.5%
Evidence scope	
Single cell	93.2%
Cross-reference	89.3%
Full-table scan	86.2%
Table structure	
Small ($\leq 5\times 4$)	100.0%
Large (>20r / 8c)	88.0%
Grouped rows	89.5%

by reasoning skill, evidence scope, and table structure. Performance degrades systematically along all three axes. Across reasoning skills, accuracy spans 32.2 pp, from 94.7% on direct lookups to 62.5% on multi-criteria questions, while increasing evidence scope and structural complexity are likewise associated with lower accuracy. These trends show that TeleTables MCQs probe more than direct information retrieval, with difficulty arising from multiple aspects of table interpretation, including reasoning depth, evidence integration, and structural complexity. Further analysis of how accuracy scales with table complexity, as measured by token count, is provided in Appendix F.

8 Discussion

The two evaluation settings expose distinct performance bottlenecks. In the *closed-book* setting, domain knowledge is the primary constraint: no general-purpose model exceeds 40.6% cons@16, while a 7B domain fine-tuned model reaches 58.0%, outperforming all tested open-weight models despite being up to 17× smaller. In the *with-table* setting, however, the same domain fine-tuned model reaches only 65.0%, well below the best general-purpose reasoning model at 92.6%. Together, these results suggest that domain specialization can compensate for missing domain knowledge, but does not substitute for strong reasoning capacity.

This distinction is reinforced by the stratified analysis in Table 4. When the table is provided, performance degrades with reasoning depth (94.7% for direct lookup → 62.5% for multi-criteria reasoning), evidence scope (93.2% for single-cell evidence → 86.2% for full-table evidence), and structural complexity (100% for small tables → 88% for large tables). Thus, once the relevant information is available in context, the remaining challenge is interpreting, integrating, and reasoning over increasingly complex tabular evidence.

Table specialization alone does not consistently improve performance. Models fine-tuned on non-telecom tables (TableGPT2-7B, TableGPT-R1, and STaR-8B) score at or below their unmodified base models, whereas Table-R1-Zero-7B, which shares the same 7B base but is trained with RLVR, gains 23.6 pp (73.00% cons@16). This contrast suggests that the training objective and data distribution may be at least as important as specialization itself for transferring tabular reasoning capabilities to out-of-domain technical content.

The results also reveal an interaction between representation and model modality. Multimodal models outperform their text-only counterparts even when no image is provided (e.g., Qwen2.5-VL-72B at 87.40% vs. Qwen2.5-72B at 79.40%), suggesting that vision-language pretraining may benefit text-based table understanding. Yet rendered images remain the weakest input format: Qwen2.5-VL-72B drops from 85.6% with HTML to 77.2% with images. For complex technical tables, explicit markup thus provides structural cues that models exploit more effectively than visual layout alone.

9 Conclusions

This paper introduced TeleTables, a benchmark for assessing LLMs' ability to interpret and reason over tables in telecommunication standards. Our experiments reveal two bottlenecks. In the closed-book setting, domain knowledge is the main constraint: no general-purpose model exceeds 40.6% cons@16, while a 7B domain fine-tuned model reaches 58.0%. When the table is provided, interpretation becomes the main constraint, with accuracy degrading with reasoning depth, evidence scope, and structural complexity. HTML emerges as the strongest single representation; reasoning models consistently outperform table-specialized models trained on non-telecom data; and multimodal models show gains in text-based table understanding even without image input. Overall, our results show that domain specialization can substantially reduce the knowledge gap, but strong reasoning capabilities remain essential for reliable interpretation of complex technical tables.

10 Limitations

TeleTables covers 13 3GPP specifications from Releases 18 and 19; other releases, standardization bodies (e.g., IETF and IEEE 802), and technical domains remain unexplored. All source documents and MCQs are in English, leaving cross-lingual transfer out of scope. At 500 MCQs, the benchmark may not capture the full diversity of 3GPP tables; future versions could sample more specifications. Our zero-context experiment uses a closed-book setting; the interaction between pretraining gaps and retrieval quality in end-to-end RAG pipelines warrants further study. A potential concern is that using models from the Qwen family in the question-generation process could introduce an evaluation bias in favor of Qwen models. However, the results do not indicate a systematic advantage for Qwen models: the strongest non-Qwen models, GPT-OSS-120B (91.80% cons@16) and SeedOSS-36B (91.60%), perform within 1 pp of Qwen3-32B (92.60%), while Llama3.3-70B (82.40%) outperforms Qwen2.5-72B (79.40%) at comparable scale. Moreover, all questions are strictly grounded in the source tables and were reviewed by domain experts before inclusion.

A Examples of Tables from 3GPP Standard Specifications

We show a few examples of tables from 3GPP standard specifications, illustrating the structural variety and complexity that such tables can exhibit.

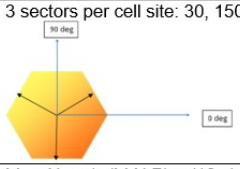
Figure 2 shows a table from 3GPP TR 38.821 ("Solutions for NTN" / NR to support Non-Terrestrial Networks) describing reference parameters for Non-Terrestrial Network (NTN) deployment scenarios. This example illustrates irregular header hierarchies and cell merging: the second header row groups scenario columns unevenly (C1/C2 share one label, D1/D2 share another, while A and B each have their own), and several body rows merge cells across columns in the opposite direction, with a single value spanning multiple scenarios (e.g. "35786 km" spanning columns A–B, "600 km" spanning C1–D2). The table also includes a substantial footnote block with numbered notes containing detailed prose explanations tied to specific rows.

NTN scenarios	A	B	C1	C2	D1	D2
	GEO transparent payload	*GEO regenerative payload*	*LEO transparent payload*		*LEO regenerative payload*	
Satellite altitude	35786 km		600 km			
Relative speed of Satellite with respect to earth	negligible		7.56 km per second			
Min elevation for both feeder and service links	10° for service link and 10° for feeder link					
Typical Min / Max NTN beam foot print diameter (note 1)	100 km / 3500 km		50 km / 1000 km			
Maximum propagation delay contribution to the Round Trip Delay on the radio interface between the gNB and the UE	541.46 ms (Worst case)	270.73 ms	25.77 ms		12.89 ms	
Minimum propagation delay contribution to the Round Trip Delay on the radio interface between the gNB and the UE	477.48 ms	238.74 ms	8 ms		4 ms	
Maximum Round Trip Delay variation as seen by the UE (note 2)	Negligible		Up to +/- 93.0 µs/sec (Worst case)		Up to +/- 47.6 µs/sec	
NOTE 1: The beam foot print diameter are indicative. The diameter depends on the orbit, earth latitude, antenna design, and radio resource management strategy in a given system. NOTE 2: The delay variation measures how fast the round trip delay (function of UE-satellite-NTN gateway distance) varies over time. The worst case is when the satellite moves towards/away from the UE at 10º elevation angle, assuming the UE speed is 1200 km/h. It is expressed in µs/s and is negligible for GEO scenario. NOTE 3: Void NOTE 4: Speed of light used for delay calculation is 299792458 m/s.						

Figure 2: Table 7.1-1: NTN scenarios versus delay constraints from 3GPP TR 38.821 ("Solutions for NTN" / NR to support Non-Terrestrial Networks)

Figure 3 shows a table of simulation assumptions adapted from 3GPP TR 38.901 (Study on channel model for frequencies from 0.5 to 100 GHz), with a simple two-column "Parameter / Values" layout. Despite this simple structure, individual cells contain highly heterogeneous content: one cell embeds a raster image (a hexagonal sector diagram), others contain multi-line lists of conditional values, and one cell nests an enumerated sub-list. This illustrates how table complexity can reside entirely within cell content rather than in the overall grid structure.

Figure 4 shows a pathloss model table from 3GPP TR 38.901 (Study on channel model for frequencies from 0.5 to 100 GHz), exhibiting nested row-spanning across two hierarchical levels (Scenario, then LOS/NLOS), alongside cells containing complete piecewise mathematical formulas with conditional branching, subscripts, and embedded variable glossaries. An additional row breaks the established row-span pattern, showing how exceptions to a table's own conventions are common in practice.



Parameter	Values
Scenarios	UMa, UMi-Street Canyon, Indoor-office (open office)
Sectorization	3 sectors per cell site: 30, 150 and 270 degrees 
BS antenna configurations	$M_g = N_g = 1$; (M,N,P) = (10, 1, 1), $d_V = 0.5\lambda$
BS port mapping	The 10 elements are mapped to a single CRS port
BS antenna electrical downtilting	102 degrees for UMa and UMi Street Canyon 110 degrees for indoor
Antenna virtualization	DFT precoding according to TR 36.897 with application of panning and tilting angles
BS Tx power	44 dBm for UMi-Street Canyon, 49 for UMa at 6GHz 35 dBm at 30GHz and 70 GHz for UMa and UMi-Street canyon 24 dBm for Indoor for all carrier frequencies
Bandwidth	20MHz for 6GHz, and 100MHz for 30GHz and 70 GHz
UT antenna configurations	1 element (vertically polarized), Isotropic antenna gain pattern
Handover margin (for calibration)	0dB
UT distribution	Following TR36.873 for UMa and UMi, (3D dropping) uniform dropping for indoor with minimum distance (2D) of 0 m
UT attachment	Based on pathloss considering LOS angle
UT noise figure	9 dB
Fast fading channel	Fast fading channel is not modelled
O2I penetration loss	50% low loss and 50% high loss
Carrier Frequency	6 GHz, 30 GHz, 70GHz
Wrapping method for UMa and UMi	geographical distance based wrapping (mandatory) radio distance (optional)
Metrics	1) Coupling loss – serving cell (based on LOS pathloss)
	2) Geometry (based on LOS pathloss) with and without white noise

Figure 3: Table 7.8-1: Simulation assumptions for large scale calibration from 3GPP TR 38.901 (Study on channel model for frequencies from 0.5 to 100 GHz)

Scenario	LOS/NLOS	Pathloss [dB], f_c is in GHz and d is in meters, see note 6	Shadow fading std [dB]	Applicability range, antenna height default values
RMa	LOS	$PL_{\text{RMa-LOS}} = \begin{cases} PL_1 & 10m \le d_{2D} \le d_{BP} \\ PL_2 & d_{BP} \le d_{2D} \le 10\text{km} \end{cases}$, see note 5 $PL_1 = 20\log_{10}(40\pi d_{3D} f_c/3) + \min(0.03h^{1.72}, 10)\log_{10}(d_{3D}) - \min(0.044h^{1.72}, 14.77) + 0.002\log_{10}(h)d_{3D}$ $PL_2 = PL_1(d_{BP}) + 40\log_{10}(d_{3D}/d_{BP})$	For 10 m ≤ d_{2D} < d_{BP}, $\sigma_{SF} = 4$ For d_{BP} ≤ d_{2D} < 10 km, $\sigma_{SF} = 6$	$h_{BS} = 35\text{m}$ $h_{UT} = 1.5m$ $W = 20m$ $h = 5m$ h = avg. building height W = avg. street width The applicability ranges: $5m \le h \le 50m$ $5m \le W \le 50m$ $10\text{m} \le h_{BS} \le 150m$ $1m \le h_{UT} \le 10m$
	NLOS	$PL_{\text{RMa-NLOS}} = \max(PL_{\text{RMa-LOS}}, PL'_{\text{RMa-NLOS}})$, for $10m \le d_{2D} \le 5\text{km}$ $PL'_{\text{RMa-NLOS}} = 161.04 - 7.1\log_{10}(W) + 7.5\log_{10}(h) - (24.37 - 3.7(h/h_{BS})^2)\log_{10}(h_{BS}) + (43.42 - 3.1\log_{10}(h_{BS}))(\log_{10}(d_{3D}) - 3) + 20\log_{10}(f_c) - (3.2(\log_{10}(11.75h_{UT}))^2 - 4.97)$	$\sigma_{SF} = 8$	
UMa	LOS	$PL_{\text{UMa-LOS}} = \begin{cases} PL_1 & 10m \le d_{2D} \le d'_{BP} \\ PL_2 & d'_{BP} \le d_{2D} \le 5\text{km} \end{cases}$, see note 1 $PL_1 = 28.0 + 22\log_{10}(d_{3D}) + 20\log_{10}(f_c)$ $PL_2 = 28.0 + 40\log_{10}(d_{3D}) + 20\log_{10}(f_c) - 9\log_{10}((d'_{BP})^2 + (h_{BS} - h_{UT})^2)$	$\sigma_{SF} = 4$	$1.5m \le h_{UT} \le 22.5m$ $h_{BS} = 25\text{m}$ See note 7
	NLOS	$PL_{\text{UMa-NLOS}} = \max(PL_{\text{UMa-LOS}}, PL'_{\text{UMa-NLOS}})$, for $10m \le d_{2D} \le 5\text{km}$ $PL'_{\text{UMa-NLOS}} = 13.54 + 39.08\log_{10}(d_{3D}) + 20\log_{10}(f_c) - 0.6(h_{UT} - 1.5)$	$\sigma_{SF} = 6$	$1.5m \le h_{UT} \le 22.5m$ $h_{BS} = 25\text{m}$ Explanations: see note 3
		Optional $PL_{\text{UMa-NLOS}} = 32.4 + 20\log_{10}(f_c) + 30\log_{10}(d_{3D})$	$\sigma_{SF} = 7.8$

B Dataset Examples

We show one example each of a basic and a difficult MCQ produced by our generation pipeline, illustrating the range of reasoning difficulty in TeleTables.

Basic MCQ

Question: What is the subcarrier spacing for reference channel G-FR2-A3-11?

1. 90 kHz
2. 180 kHz
3. 30 kHz
4. 120 kHz
5. **60 kHz**

Explanation: *According to the table, the subcarrier spacing for G-FR2-A3-11 is 60 kHz.*
Table: *Table A.3-9: FRC parameters for FR2 PUSCH performance requirements (. . .)*
Document: *3GPP TS 38.104 V19.0.0 (. . .)*

Difficult MCQ

Question: Which reference channel experiences the smallest percentage reduction in total bits per slot when PT-RS is added?

1. G-FR2-A7-1
2. G-FR2-A7-2
3. G-FR2-A7-3
4. G-FR2-A7-4
5. **All channels experience the same reduction**

Explanation: *The percentage reduction in bits when PT-RS is added is consistent across all channels. For example, G-FR2-A7-1 reduces from 57024 to 54648 bits, a 4.166% decrease. The same ratio is observed in all channels, indicating a uniform impact of PT-RS configuration across the dataset.*
Table: *Table A.7-1: FRC parameters for FR2-1 PUSCH performance requirements (. . .)*
Document: *3GPP TS 38.104 V19.0.0 (. . .)*

C Accepted and Rejected Question Examples

The following examples illustrate the acceptance and rejection criteria applied during human review. An MCQ was accepted only if it was factually correct, representative of a question a domain expert would plausibly ask, and had exactly one defensible correct answer.

Rejected — Ambiguous answer (multiple correct options)

Source: Table A.2.1.1-1: E-UTRA simulation case minimum set (3GPP TS 36.814)
Question: Which simulation case has the highest total FDD bandwidth (sum of FDD uplink and downlink) when considering extended scenarios?
Options: (A) 3GPP case 1 extended, (B) ITU Indoor extended, (C) ITU Base coverage urban extended, (D) ITU Microcellular, (E) 3GPP case 3
Rejection reason: Options A, B, and C all yield 120 MHz (80+40 MHz), making the answer non-unique.

Rejected — Correct answer absent from options

Source: Table 6.2.3.29-1: A-MPR regions for NS_07 (3GPP TS 38.101-1)
Question: If a system operates at 10 MHz bandwidth with $F_c = 782$ MHz and $RB_{\text{start}} \times 12 \times \text{SCS} = 2.5$ MHz, what is the minimum increase in $L_{\text{CRB}} \times 12 \times \text{SCS}$ required to move from A-MPR region A2 to A3?
Options: (A) 0 MHz, (B) 1.44 MHz, (C) 2.34 MHz, (D) 3.24 MHz, (E) 6.48 MHz
Rejection reason: The correct value is $3.24 - 1.44 = 1.80$ MHz, which does not correspond to any of the five options. Since no option is defensible, the question was rejected.

Accepted — Unambiguous, expert-plausible, table-grounded

Source: Table A.7-1: FRC parameters for FR2-1 PUSCH performance requirements (3GPP TS 38.104)
Question: Which reference channel experiences the smallest percentage reduction in total bits per slot when PT-RS is added?
Correct answer: All channels experience the same reduction.
Acceptance reason: Factually correct (uniform PT-RS overhead across all channels is verifiable from the table), representative of a question a standards engineer would ask when comparing channel configurations, and unambiguous.

D MCQ Generation Prompts

We report the verbatim prompt templates used in each stage of the generation pipeline.

Stage 1 — Basic MCQ Generator

```
Analyze the table and create {num_questions} multiple choice questions (MCQs).
For each MCQ, include: 1. Question text; 2. Five answer options (A–E); 3. Clearly marked correct answer key; 4. A detailed explanation justifying the correct answer.
The MCQs should: require understanding the table's structure and content; test extraction of specific information or simple trends; potentially require cross-referencing multiple data points; have exactly one clear, unambiguous, directly derivable correct answer; avoid options referring to other options by letter key.
Return a JSON array of {num_questions} MCQs, each with fields: "question", "options" (dict A–E), "answer_key", "explanation".
```

Stage 1 — Validator

```
You are given a table and a multiple-choice question about it. Your task is to answer the question based ONLY on the information in the table.
Question: {question_text}
Options: {options_text}
Please select the correct answer and provide a brief explanation. Respond as a JSON object with fields: "answer" (the option letter only) and "explanation".
```

Stage 2 — Difficult MCQ Generator

```
Role: You are an expert in telecommunications and a master question designer. Your task is to create exceptionally challenging MCQs for a benchmark designed to test the world's most advanced AI models.
CONTEXT: You have been provided with: (1) a data table in HTML and JSON formats; (2) a set of simple questions that test basic information retrieval from this table.
OBJECTIVE: Use the simple questions as inspiration to create {questions_per_table} much more difficult questions that require advanced reasoning. These questions should: synthesize information across multiple parts of the table; involve comparisons, trends, or patterns not explicitly stated; require mathematical operations; have exactly five options with one correct answer; include a detailed explanation.
Return a JSON array with fields: "question", "options" (A–E), "answer_key", "explanation".
```

Stage 2 — Validator and Simplicity Filter

The Stage 2 validator (Qwen2.5-72B-Instruct) and simplicity filter (Qwen2.5-7B-Instruct) use the same prompt template.

```
You are given a data table and a set of simple questions that were used as context to generate the following question. Your task is to carefully analyze all the provided information and answer the question precisely.
[DATA TABLE - HTML] {table_html_data}
[DATA TABLE - JSON] {table_json_data}
[SIMPLE QUESTIONS CONTEXT] {simple_questions_json}
Answer the following multiple-choice question:
QUESTION: {hard_question_text}
OPTIONS: {options_text}

Reason carefully, then put your selected option letter in \boxed{} format. Example: \boxed{A}
```

E Impact of Table Representation Formats

Table 5 summarizes model performance across different table-representation formats and reports the average token usage associated with each format. HTML yields the strongest performance for most models, particularly reasoning-capable models (GPT-OSS-120B: 91.4%, Qwen3-32B: 92.0%) and multimodal models (Qwen2.5-VL-72B: 85.6%, Gemma-27B: 81.0%). We attribute this to the superior flexibility of HTML in representing complex table structures through explicit markup of hierarchical relationships and cell attributes. The non-reasoning Qwen2.5-32B model also follows this trend, reaching its best performance of 85.6% with HTML, while JSON and Markdown yield slightly lower results (83.6% each). This supports the hypothesis that these models have a strong inductive bias toward HTML syntax from web-based pretraining data. In contrast, the Llama models perform best with Markdown (Llama3.1-8B: 57.4%, Llama3.3-70B: 80.2%), likely reflecting their pretraining distribution. Notably, JSON achieves nearly identical performance to HTML for Llama3.3-70B (80.0% vs. 79.8%) while using 27% fewer tokens (893 vs. 1224), indicating efficiency benefits without significant accuracy loss.

Multi-format concatenation generally improves performance, with the most pronounced gain for Llama3.1-8B (JSON+MD: +5.2pp). For larger models, improvements are modest (+0.6pp for Qwen3-32B), implying that capable architectures already capture structural relationships from a single format. The triple-format combination (HTML+JSON+MD) does not substantially outperform the best dual-format approach despite the increased token cost (2824 tokens).

Image representations perform substantially worse across all visual models: Qwen2.5-VL-72B drops from 85.6% to 77.2%, and Gemma-27B-it to 53.8%. Hybrid inputs (e.g., IMAGE+HTML) recover most of this loss but at extreme token cost (12,831 tokens). Markdown uses 42% fewer tokens than HTML while maintaining competitive performance, making it the preferred format for resource-constrained scenarios.

Table 5: Performance (*cons@16*) of different LLMs across input formats.

Format	**Avg. Tokens per Table**	**Non-reasoning**			**Multimodal**		**Reasoning**	
		Llama3.1 8B	Qwen2.5 32B	Llama3.3 70B	Gemma 27b	Qwen2.5-VL 72B	GPT-OSS 120B	Qwen3 32B
HTML	1224	56.8	**85.6**	79.8	81.0	85.6	91.4	92.0
JSON	893	56.8	83.6	80.0	77.6	85.4	91.0	90.4
MD	707	57.4	83.6	80.2	79.6	84.0	90.2	90.4
IMAGE	11607	—	—	—	53.8	77.2	—	—
HTML + JSON	2117	61.0	—	**82.4**	81.8	**87.4**	91.0	**92.6**
HTML + MD	1931	60.2	—	81.4	**82.2**	86.8	91.2	92.4
JSON + MD	1600	**62.6**	—	80.8	80.4	85.8	90.4	91.2
IMAGE + HTML	12831	—	—	—	82.0	85.2	—	—
HTML + JSON + MD	2824	60.2	—	81.4	82.2	86.6	**91.8**	92.6
IMAGE + HTML + JSON + MD	14431	—	—	—	78.6	86.4	—	—

F Impact of Table Complexity

We use the number of HTML tokens as a proxy for structural complexity (number of rows, columns, and merged cells). As shown in Figure 5, performance decreases consistently as complexity increases across all model types. Qwen3-32B achieves 100% pass@1 on simple tables (fewer than 500 tokens) but drops to ∼80% on the most complex ones. Qwen2.5-VL-72B-Instruct follows a similar trend with faster degradation, likely due to limited reasoning capability. Qwen2.5-7B-Instruct fails to reach satisfactory performance even on simple tables (<80% pass@1), degrading to 27% on the most complex ones.

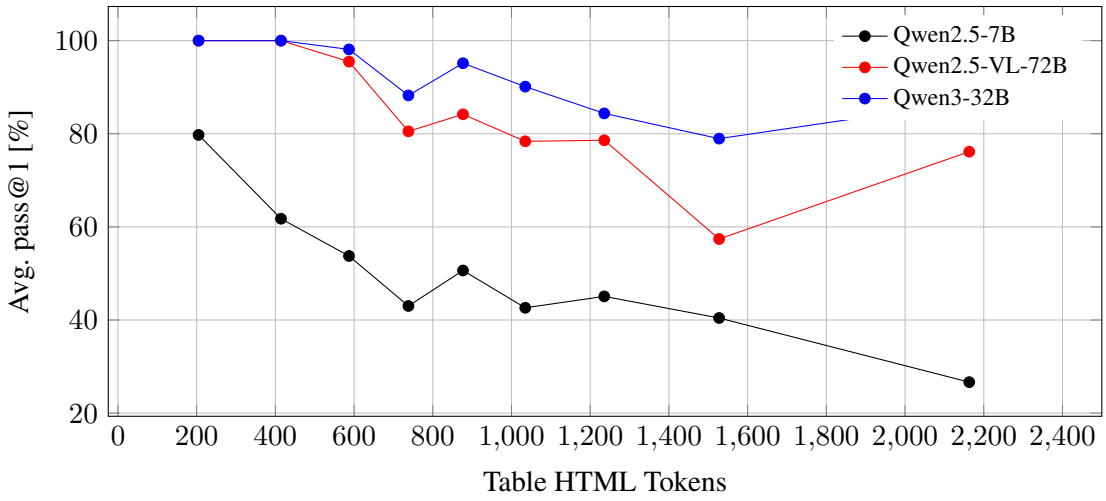

Figure 5: Average pass@1 performance across MCQs grouped by table complexity (HTML token count).

G Qualitative Model Comparison

Table 6 shows the responses produced by four representative models on the same TeleTables MCQ, illustrating how reasoning capability and model size affect the quality of tabular interpretation.

Table 6: Responses from models of different types on the same TeleTables MCQ. The correct answer is Option 3 (index 513).

Question Which of the following bit field indices indicate a configuration with 4 layers when the transform precoder is disabled and maxRank = 4?

Options Option 1: 117, Option 2: 1022, Option 3: 513, Option 4: 10, Option 5: 423

Table Table 7.3.1.1.2-5L from 3GPP TS 38.212

Bit field mapped to index	Transform precoder is enabled, or *maxRank* = 1 if transform precoder is disabled	Bit field mapped to index	transform precoder is disabled *and maxRank = 2*	Bit field mapped to index	transform precoder is disabled *and maxRank = 3*	Bit field mapped to index	transform precoder is disabled *and maxRank = 4*
0	1 layer: TPMI=0	0	1 layer: TPMI=0	0	1 layer: TPMI=0	0	1 layer: TPMI=0
…	…	…	…	…	…	…	…
15	1 layer: TPMI=15	15	1 layer: TPMI=15	15	1 layer: TPMI=15	15	1 layer: TPMI=15
		16	2 layers: TPMI=0	16	2 layers: TPMI=0	16	2 layers: TPMI=0
		…	…	…	…	…	…
		119	2 layers: TPMI=103	119	2 layers: TPMI=103	119	2 layers: TPMI=103
		119-127	reserved	120	3 layers: TPMI=0	120	3 layers: TPMI=0
				…	…	…	…
				423	3 layers: TPMI=303	423	3 layers: TPMI=303
				424-511	reserved	424	4 layers: TPMI=0
						…	…
						703	4 layers: TPMI=279
						704-1024	reserved

Model	Answer Provided	Result
Qwen2.5-7B-Instruct	Based on the information provided in the table, the correct index for 4 layers when the transform precoder is disabled and maxRank = 4 should be around 704-1024, but none of the options match this range exactly. The closest provided option is Option 5: 423, which does not fit the criteria based on the table. $\boxed{704}$	Wrong
Qwen2.5-VL-72B-Instruct	To determine which bit field index indicates a configuration with 4 layers when the transform precoder is disabled and maxRank = 4, we need to refer to the relevant column in the provided table. (…) From the table, we see the following ranges and values: Bit field index 0 to 15 corresponds to 1 layer. Bit field index 16 to 119 corresponds to 2 layers. **Bit field index 424 to 703 corresponds to 4 layers.** Bit field index 704 to 1024 is reserved. (…) Option 1: 117 - This falls within the range for 2 layers (16 to 119). Option 2: 1022 - This falls within the reserved range (704 to 1024). **Option 3: 513 - This does not fall within any specified range in the table for 4 layers.** Option 4: 10 - This falls within the range for 1 layer (0 to 15). Option 5: 423 - This is just before the range for 4 layers starts (424 to 703). The only option that falls within the range for 4 layers is Option 2: 1022. $\boxed{2}$	Wrong
Qwen3-32B	⟨think⟩ (…) The question specifies that the transform precoder is disabled and maxRank is 4. **So I should look at the last column, which is labeled transform precoder is disabled and maxRank = 4.** (…) **So for 4 layers, the valid indices are from 424 to 703.** Now, looking at the options: Option 1: 117 - This is below 424, so probably for 2 or 3 layers or reserved. Option 2: 1022 - 1022 is above 703 and within the 704-1024 reserved range. So that's reserved. **Option 3: 513 - 513 is between 424 and 703. So that's valid for 4 layers.** Option 4: 10 - Way below 424, so no. Option 5: 423 - This is the upper limit for 3 layers. The next index for 4 layers starts at 424. So 423 isn't in the 4-layer range. Therefore, the correct option is Option 3: 513. ⟨/think⟩ $\boxed{3}$	Correct
STaR-8B	⟨think⟩ I need to find the row where transform precoder is disabled and maxRank = 4. From the table: **| ...	423	3 layers: TPMI = 303	424	4 layers: TPMI = 0	... |** So index 424 corresponds to 4 layers. However, 424 is not among the options. (…) The closest option is 423 (Option 5), which maps to 3 layers. (…) Since none of the options exactly match index 424, I will assume the question intended 3 layers and select 423. ⟨/think⟩ $\boxed{4}$	Wrong

FINSTRUCT: LLM-Based Logical Structure Recovery for Financial Filings

Mazen Ahmed[1,2] Yunfei Long[3] Michael Kampouridis[1]

Abstract

Financial-filings workflows depend on more than extracting reported values: each number must be placed in the document context that makes it reviewable, comparable, and auditable. In practice, this logical structure including the relevant section, note, heading, row, column, period, currency, and surrounding text—is often clear to professional reviewers but only partially encoded in inline XBRL markup. As a result, rule-based parsers can work on familiar layouts yet fail silently when document structure departs from expected templates. We present **FINSTRUCT**, an on-premise LLM system designed for confidential financial-document workflows. **FINSTRUCT** runs locally on a single 16 GB GPU, requires no task-specific fine-tuning, predicts nine structural fields for each reported fact, and provides reviewer-facing rationales together with repeated-sample agreement signals for human-in-the-loop review. On 1,493 manually annotated facts from five UK FRS 102 filings produced by a single accounts-production stack, **FINSTRUCT** raises macro accuracy from 50.6% to 74.8% and micro accuracy from 63.1% to 85.1% over a deterministic parser. More importantly for deployment, it recovers structure at 83.5% in accuracy on a filing where the rule-based parser silently misses whole sections, and its agreement signal separates more reliable predictions from cases requiring review. These results position logical structure recovery as a practical document-understanding layer for regulated financial automation, rather than a conventional parsing problem alone.

1 Introduction

Financial filings are increasingly processed by automated systems, but reliable automation requires more than extracting numbers. In financial services, a value is useful only when placed within the document structure that gives it meaning: the relevant statement or note, row and column, reporting year, currency context, and surrounding explanation. The same value may denote a current-year balance, prior-year comparative amount, or subtotal depending on its position in the rendered filing. Human reviewers infer this context from headings, table layout, typography, and nearby prose, whereas automated systems must recover it explicitly. This is difficult because much of the relevant structure is visible to readers but only partially encoded in filing markup. Inline XBRL records facts, values, accounting concepts, periods, and units, but often omits the logical position needed to interpret a value. As a result, rule-based and layout-driven parsers can work on expected templates yet become brittle when structure must be inferred, sometimes failing silently across whole regions of a filing. In regulated financial workflows, such layout-dependent collapse is a deployment risk.

Prior work explains this gap. Document-understanding methods recover visual and geometric structures such as tables, cells, rows, columns, and layout-aware representations (Adiga et al., 2019; Kasem et al., 2024; Xu et al., 2020, 2021)—but they do not necessarily identify the logical context that governs a reported value. Meanwhile, Financial NLP has advanced XBRL tagging, numerical reasoning, intent-relevant extraction, and retrieval over financial reports (Loukas et al., 2022; Chen et al., 2021; Sarker and Rai, 2025; Li et al., 2025), often assuming that such structure is already available. While LLM-based extraction and in-context learning offer adaptation without parameter updates (Brown et al., 2020; Xie et al., 2023; Xu et al., 2024), most existing work operates over short or pre-segmented spans and fails to address confidential, full-filing deployment. We target this intermediate layer: recovering the logical structure needed before downstream financial automation can reliably use reported values.

We frame logical structure recovery as a document-understanding task under production

EMNLP 2026 Industry Track, pages 1804–1818
October 24-29, 2026 ©2026 Association for Computational Linguistics

constraints. The system must operate on confidential client filings, run on modest local hardware, avoid task-specific fine-tuning because no labelled training data exists, and produce outputs that are inspectable by professionals. To address these requirements, we present FINSTRUCT, an LLM-based system for recovering the logical structure of financial filings. For each anchor-eligible reported fact, FINSTRUCT predicts nine structural fields: section title, note label, sub-heading, row label, column header, year, currency label, and two surrounding-context fields. The system supports three operating modes: a deterministic rule-based extractor, a zero-shot LLM extractor, and an in-context LLM extractor. The LLM modes share a two-stage design that first resolves the document section and then recovers the remaining fields conditioned on that section. FINSTRUCT runs locally on a single 16 GB GPU, requires no task-specific fine-tuning, and provides reviewer-facing rationales together with repeated-sample agreement signals for human-in-the-loop review. Building on self-consistency (Wang et al., 2023), we use repeated sampling not only to aggregate predictions but also to rank predictions by reliability for review routing.

We evaluate FINSTRUCT on a self-built benchmark of 1,493 manually annotated facts from five UK FRS 102 filings produced by a single accounts-production stack. To our knowledge, this is the first dataset of its kind for logical structure recovery in financial filings. C3 raises macro accuracy from 50.6% to 74.8% and micro accuracy from 63.1% to 85.1%. Beyond aggregate gains, FINSTRUCT recovers structure with 83.5% accuracy on a filing where the rule-based parser silently fails across whole sections, demonstrating resilience to layout-dependent breakdowns. Its agreement signal further supports risk-aware deployment by separating reliable predictions from cases requiring human intervention while preserving an auditable review trail.

2 Task Formulation and System Design

2.1 Task Formulation

A UK statutory filing in inline XBRL has two simultaneous representations: a rendered report read by humans and a machine-readable layer of embedded facts. We formulate the recovery task at the fact level. Given an anchor-eligible fact and its rendered neighbourhood in the filing, the system must recover the logical position that a professional reader would use to interpret the reported value. The embedded XBRL fact records its value, accounting concept, period context, and unit, but it does not, in general, encode where that occurrence sits in the report's logical structure. For example, a concept tag may identify the number 98,139 as intangible assets without indicating that this particular occurrence is the current-year net book value of computer software in the intangible-assets note. Such placement is visible on the rendered page but may be absent from the markup: section boundaries can appear only as typographic changes, note headings and column headers can share generic markup containers, and multi-page notes may be connected only through visual continuity (Figure 4).

We define logical structure recovery as the task of assigning each anchor-eligible fact a structured record that captures its reading position in the filing. The output schema contains nine fields: `section title`, selected from a closed set of fourteen statement or report sections; `note label`; `sub heading`; `row label`; `col header`; `year`; `currency label`; and two surrounding-context fields, `text before` and `text after`. These fields are operational rather than merely descriptive: the same value and accounting concept may recur across different rows, years, notes, and statements, and only the recovered structure distinguishes these occurrences for review, comparison, and automated checking. The task therefore requires not only accurate field recovery, but also a signal of uncertainty so that low-confidence predictions can be routed to human review.

2.2 Production constraints

Three production constraints shape the design of FINSTRUCT. **Confidentiality** requires all inference to run inside the firm's controlled environment: client filings are confidential, which motivates an on-premise system that can operate on modest local hardware. **Auditability** requires that each prediction be inspectable by a professional reviewer and traceable to the document context from which it was produced. This motivates a fixed output schema, persisted model outputs, reviewer-facing rationales, and confidence signals that support review rather than unconditional automation. **Data scarcity** rules out supervised training as the solution: no labelled corpus exists for this level of logical structure, and creating one requires expert review under the same confidentiality restrictions.

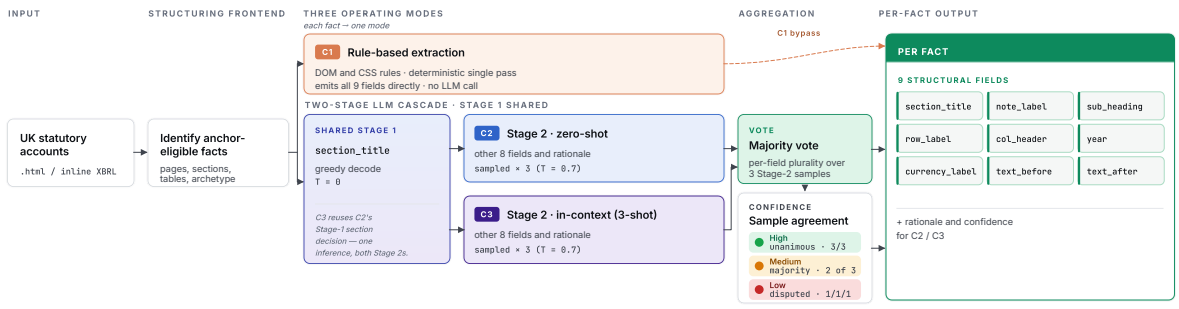

Figure 1: The FINSTRUCT pipeline. A structuring frontend assigns each anchor-eligible fact an archetype; **C1** emits all nine fields and bypasses aggregation, while **C2/C3** share a two-stage cascade (Stage 1 predicts `section_title`, Stage 2 the other eight). C3 reuses C2's Stage 1 with three leave-one-filing-out demonstrations; Stage 2 is sampled three times, and agreement over the samples gives a confidence signal for human-review routing.

We therefore design FINSTRUCT to use deterministic rules, zero-shot prompting, and in-context demonstrations without task-specific fine-tuning.

2.3 The FINSTRUCT system

FINSTRUCT compares three recovery modes over the same fact-centred input and nine-field output schema. This shared setup ensures that differences between modes reflect the recovery strategy itself, rather than changes in task definition, context construction, or output format. Before extraction, a structuring frontend segments the rendered filing into pages, sections, tables, headings, and local text regions. Each visible anchor-eligible fact is linked to its neighbourhood, assigned an archetype (`table numeric`, `table text`, `narrative block`, or `standalone`), and represented with the contextual cues a reader would use: rows, columns, headings, period and currency labels, and surrounding prose. Hidden facts are excluded because they lack a visible reading position. The three modes instantiate progressively stronger assumptions about how logical structure can be recovered.

- C1 represents the deterministic boundary of conventional parsing: it uses DOM structure, CSS cues, table geometry, heading proximity, and archetype-specific rules to assign all nine fields in a single pass. This mode is appropriate when logical structure is explicitly encoded or follows anticipated layout conventions, but it is expected to degrade when the relevant evidence is distributed across visual layout, headings, and prose.

- C2 treats the same task as constrained language understanding. Instead of predicting the full schema jointly, it uses a two-stage cascade: Stage 1 resolves `section title` from a closed inventory of fourteen sections, and Stage 2 predicts the remaining eight fields with a section-specific prompt and schema-valid JSON output. This decomposition reflects the hierarchy of financial filings, where the section acts as a high-level interpretive anchor that constrains note labels, headings, rows, columns, and contextual text. It also makes the recovery process more inspectable by separating document-level localisation from field-level interpretation.

- C3 keeps the C2 architecture but conditions Stage 2 on retrieved in-context demonstrations. Examples are selected under a leave-one-filing-out regime, prioritising the same section and archetype as the target fact. This tests whether limited expert-labelled evidence can improve recovery while preserving the production constraints of local inference, no task-specific fine-tuning, and no transfer of client data to external services. Since C2 and C3 share the same input representation, section decision, output schema, and inference protocol, their comparison isolates the contribution of in-context demonstrations.

For the LLM modes, FINSTRUCT also derives an agreement-based review signal from repeated Stage 2 sampling. Each field is sampled three times and assigned an agreement label: `unanimous` if all samples match, `majority` if two match, and `disputed` if all differ. The final prediction is selected by plurality voting, while the agreement label is retained as an indicator of reliability. We do not interpret this signal as a calibrated probability; rather, it operationalises a central requirement

	F1	F2	F3	F4	F5
Anchor-eligible facts	534	382	236	136	205

Table 1: Anchor-eligible facts per filing, giving 1,493 fact-level evaluation instances in total.

of regulated document workflows, where uncertain predictions should be surfaced for professional review instead of being silently accepted. Thus, the system is designed not only to recover logical structure, but also to support auditable human-in-the-loop deployment.

3 Data and Evaluation Methodology

3.1 Corpus

We evaluate FINSTRUCT on five real UK statutory accounts filings prepared under FRS 102, including Section 1A accounts, produced by a single mainstream accounts-production tool and submitted as inline XBRL. The filings are genuine client documents processed under the confidentiality constraints in Section 2.2: entity names, addresses, and reported values were anonymised, while rendered structure was preserved for valid logical-structure annotation. This deployment-derived corpus is a focused benchmark rather than a broad sample of UK filings, yielding 1,493 anchor-eligible evaluation instances across the main structural forms observed in production filings. From 1,793 inline XBRL facts, we exclude continuation tails and hidden facts because they lack independent, visible reading positions. All nine structural fields were manually annotated by two domain experts reading the rendered filings directly, producing gold labels independent of parser or model outputs. Both annotators labelled all 1,493 facts independently; per-field inter-annotator agreement is reported in Appendix D, with overall agreement of 97.7% and macro Cohen's κ of 0.933. Residual disagreements were resolved by the senior annotator to produce the final gold set. The five filings come from five distinct entities operating in different industry sectors rather than repeated filings by one entity, so C3's leave-one-filing-out demonstrations are drawn from other companies and its gain reflects cross-entity transfer rather than adaptation to a single preparer's house style. Two annotation conventions affect scoring and are described in Appendix C.

3.2 Matching and metrics

We score predicted fields with field-specific criteria: normalised exact match for most fields, Jaro–Winkler similarity at a fixed 0.85 threshold for free text, and sentinel-aware matching for context fields where absence is a valid label. Correct matches include exact, fuzzy, and sentinel matches; missing predictions are incorrect unless absence is gold-labelled by sentinel. We report per-field accuracy, macro accuracy over nine fields, and pooled micro accuracy, with 95% percentile bootstrap confidence intervals over facts. Because modes share the same facts, pairwise field-level comparisons use McNemar's exact test with Holm–Bonferroni correction over 27 comparisons. Full details appear in Appendix C.

3.3 Models and inference

The primary LLM configuration uses Qwen3-14B, AWQ-quantised and served locally with vLLM on a single 16 GB GPU. Stage 1 is decoded greedily with $T{=}0.0$, while Stage 2 is sampled with $T{=}0.7$ and $N{=}3$ samples per fact. No model is fine-tuned, and no client data leaves the local environment. To test whether the observed pattern is specific to the primary model, we also evaluate a second open-weight instruction-tuned model, Llama-3.1-8B-Instruct, as a robustness check; these results are reported in the Appendix.

4 Experimental Results and Analysis

4.1 Overall performance

Table 2 reports per-field accuracy for the three operating modes. The results show a clear progression from deterministic parsing to LLM-based recovery. Averaged across the nine fields, C1 reaches 50.6% macro accuracy, while C2 improves this to 71.0% and C3 further raises it to 74.8%. The same pattern appears under micro accuracy, which increases from 63.1% for C1 to 80.4% for C2 and 85.1% for C3. In relative terms, C3 reduces macro-level error by nearly half compared with the rule-based baseline. These gains indicate that a substantial portion of the structure required to interpret reported facts is not reliably recoverable through deterministic parsing alone. The improvement is achieved without task-specific fine-tuning and under the on-premise constraints described in Section 3.3. This is important for deployment: the result does not depend on sending confidential filings to a hosted model or on constructing a large labelled training

Field	C1 [lo, hi]	C2 [lo, hi]	C3 [lo, hi]
section_title	86.5 [84.7, 88.1]	99.7 [99.3, 99.9]	99.7 [99.4, 99.9]
note_label	60.0 [56.9, 63.9]	86.6 [84.2, 88.8]	93.3 [91.4, 94.9]
sub_heading	3.4 [2.2, 4.9]	55.2 [51.7, 58.8]	72.7 [69.3, 75.7]
row_label	65.2 [62.3, 68.0]	82.1 [79.9, 84.2]	85.2 [83.2, 87.2]
col_header	60.9 [58.1, 63.7]	80.6 [78.3, 82.9]	82.1 [80.0, 84.4]
year	85.4 [82.9, 87.8]	73.9 [70.9, 76.6]	84.0 [81.5, 86.2]
currency_label	82.8 [80.6, 84.8]	95.8 [94.6, 96.9]	96.1 [94.9, 97.1]
text_before	6.1 [3.8, 9.2]	34.7 [29.0, 40.3]	28.5 [22.7, 34.3]
text_after	5.3 [2.8, 8.1]	30.8 [25.6, 36.0]	31.8 [25.9, 37.3]
Macro	50.6 [49.4, 51.9]	71.0 [69.6, 72.5]	74.8 [73.4, 76.3]
Micro	63.1 [61.3, 64.8]	80.4 [79.1, 81.6]	85.1 [83.9, 86.2]

Table 2: Per-field accuracy (%) on Qwen3-14B-AWQ with 95% percentile bootstrap CIs (1,000 resamples, fact-level). Denominators exclude pairs where both gold and prediction are absent. Best per row is not bolded here because differences are read against the CIs.

Section	n	C1	C2	C3
NOTES	669	57.8	73.3	76.8

Table 3: Per-section accuracy (%), Qwen3-14B-AWQ, micro-averaged over the nine fields (n = facts per section). DPL is the only section where C2 trails C1; C3 recovers it. STRATEGIC_REPORT (n=2) is a degenerate denominator.

set. Instead, the LLM modes recover additional structure from the same fact-centred context available to the rule-based system.

Because facts cluster within filings, the fact-level intervals in Table 2 understate uncertainty about how these results transfer to a new filing. We therefore recompute all intervals by resampling filings rather than facts (n=5, 1,000 resamples). The intervals widen substantially: macro accuracy C1 50.6 [28.7, 60.6], C2 71.0 [63.0, 75.7], C3 74.8 [69.0, 78.8]. The C1–C3 intervals remain disjoint under clustering, while C2 and C3 overlap, so we do not rest the C2–C3 distinction on fact-level intervals alone. A per-filing breakdown, which makes no distributional assumption, shows C3 exceeding both C1 and C2 on every one of the five filings independently, under both macro and micro accuracy; the aggregate gain is therefore not driven by a single favourable document.

4.2 Field-level and section-level behaviour

The aggregate improvement masks important differences across fields. Fields that are often explicit in the document representation, such as `section title`, `currency label`, and `row label`, already perform relatively well under C1, leaving less room for improvement. In contrast, context-dependent fields show much larger gains. The most notable example is `sub heading`, which increases from 3.4% accuracy under C1 to 72.7% accuracy under C3. The surrounding-context fields, `text before` and `text after`, also improve substantially.

The `year` field highlights the complementarity of the approaches. C1 performs strongly because period information is often explicitly encoded, while C2 underperforms and C3 recovers much of the gap through in-context examples. This suggests that deterministic parsing remains effective for regular, well-structured information, whereas LLM-based extraction is most valuable when structure must be inferred from context.

The section-level results in Table 3 show the same pattern. C3 improves over C1 across most sections, with the largest gains in report and narrative sections where logical structure is conveyed through headings and prose rather than explicit markup. Overall, the results reinforce that logical structure recovery is a broader document-understanding task rather than solely a table-parsing problem.

4.3 Silent rule failure and graceful recovery

The average accuracy hides the most critical failure in the deployment. In filing F5, C1 produces no output for 162 facts while maintaining full coverage on the other four filings. The missing facts span whole statement and report sections, indicat-

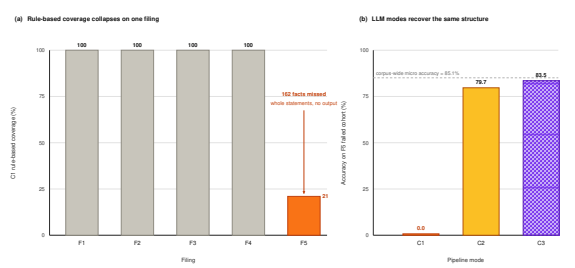

Figure 2: Catastrophic rule failure on F5. (a) C1 produces no output for 162 facts across whole sections, while coverage is complete on F1–F4. (b) On that cohort C1 scores 0%; C2 and C3 recover to 79.7% and 83.5% (dashed = corpus micro accuracy).

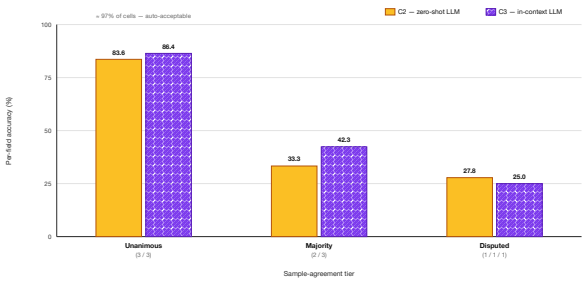

Figure 3: Per-field accuracy by sample-agreement tier (C2, C3). Accuracy falls from unanimous to disputed, so agreement ranks predictions by reliability; we use it as a triage signal for targeted review, not a guarantee.

ing a systematic layout-dependent collapse rather than isolated errors. The cause is a DOM structure variation present in F5 but not in F1–F4: its page-level container markup differs in shape, and C1's heading extraction does not recover headings under that variant. Because section identity anchors the remaining eight fields, the failure propagates: section detection collapses and the dependent fields return null across the affected regions. C1 raises no error at any point, which is why the failure is silent and surfaced only under coverage analysis. In addition, the LLM modes do not exhibit the same failure pattern. In the 162-fact cohort where C1 does not produce output, C2 and C3 recover structure with pooled accuracies of 79.7% and 83.5%, respectively. This result is important because it reflects a practical production risk. The variant is addressable by extending the rule set, but that is the point rather than a caveat to it: filings are produced by many tools, versions and preparer conventions, each introducing markup variation the rules must anticipate in advance, and the failure gives no diagnostic signal when they do not. The evidence comes from one out-of-distribution filing, so it should not be read as estimating the frequency of such failures. It nevertheless demonstrates a failure mode that aggregate accuracy can hide and motivates reporting per-filing coverage alongside accuracy in deployment evaluations.

4.4 Agreement as a confidence signal

For C2 and C3, repeated Stage 2 sampling provides a useful reliability signal. As shown in Figure 3, agreement is strongly associated with correctness. Under C3, fields for which all three samples agree are 86.4% in accuracy, while fields with only a two-of-three majority are 42.3% in accuracy and fields with three different predictions are 25.0% in accuracy. C2 shows the same monotonic pattern. Agreement therefore ranks predictions by reliability, even though it is not calibrated as a probability.

This distinction matters for regulated workflows. The agreement signal should not be used to justify unconditional automation: even unanimous predictions are not always correct. Its value is instead operational. A cell-level policy that auto-accepts only unanimous fields accepts 96.95% of cells at 86.4% accuracy, with the routed remainder at 42.0%. A stricter fact-level policy that routes any fact containing a non-unanimous field accepts 87.81% of facts at 87.5% accuracy, sending 182 of 1,493 facts (12.2%) to review. C3 also reaches unanimity more often than C2 (96.9% versus 93.8% of scored cells), so the more accurate mode is also the more decisive one. These figures characterise the evaluation set rather than validated policies, as no held-out split was used: the intended use is that a firm selects its own operating point against its risk tolerance rather than adopting a threshold we recommend. In both cases the system converts uniform manual checking into targeted review, allowing professional attention to focus on less reliable predictions while retaining an auditable decision trail.

4.5 Robustness and deployability

To assess robustness, we repeat the LLM experiments with Llama-3.1-8B-Instruct and observe the same qualitative pattern: C3 consistently outperforms C2, indicating that the benefit of in-context demonstrations is not tied to a single model. We therefore treat Qwen3-14B as the primary configuration and report additional model results in Appendix I.

The smaller configurations also serve as a stress test. Zero-shot extraction falls below the rule-based baseline both for Llama-3.1-8B-Instruct (macro 50.1 versus C1's 50.6) and for Qwen3-1.7B (42.1),

and in-context demonstrations recover above it in both cases. Zero-shot LLM extraction is therefore not by itself sufficient at modest capacity; demonstrations are what clear the deterministic baseline.

The primary deployment configuration runs locally on a single 16 GB GPU, with both C2 and C3 requiring approximately 11 seconds per fact. Local inference is driven primarily by confidentiality requirements. At the same time, the on-premise setup avoids recurring hosted-inference costs and keeps all prompts, outputs, rationales, and logs within the firm's controlled environment.

Overall, the results support three conclusions. First, LLM-based recovery substantially improves the reconstruction of the logical structure in financial statements, particularly where the structure is implicit rather than explicitly encoded. Second, repeated-sample agreement provides a practical mechanism for routing uncertain cases to human review. Third, beyond improved headline performance, FINSTRUCT offers resilience to silent layout-dependent parser failures while compatible with confidentiality and auditability requirements.

5 Conclusion

This paper introduced FINSTRUCT, an on-premise system for recovering the logical structure of financial filings, addressing the problem that reported values in inline XBRL cannot be reliably used for review, comparison, or automated checking unless they are located within the document context that gives them meaning: section, note, heading, row, column, period, currency, and surrounding text. We argued that this context is often apparent to human readers but only partially represented in machine-readable markup, making logical structure recovery a document-understanding problem rather than a purely rule-based parsing task. Across 1,493 manually annotated facts from five UK FRS 102 filings produced by a single accounts-production stack, FINSTRUCT substantially improves over deterministic extraction, raising macro accuracy from 50.6% to 74.8% and micro accuracy from 63.1% to 85.1% without task-specific fine-tuning. The results also show why this improvement matters in deployment: the rule-based mode fails silently across whole sections of one unfamiliar filing, whereas the LLM modes recover structure for the same cohort with high accuracy. In addition, repeated-sample agreement provides a practical reliability signal for routing uncertain predictions to professional review rather than silently accepting them. The contribution of FINSTRUCT therefore is not only greater extraction accuracy, but also a deployment-compatible formulation of the recovery of logical structures under confidentiality, auditability, and data-scarcity constraints. Although our evaluation focuses on UK inline XBRL filings, the broader problem extends to many business and regulatory documents whose logical structure is designed for human comprehension but only weakly encoded for machines.

Limitations

Our evaluation is based on five FRS 102 filings from a single accounts-production stack. Although they yield 1,493 densely annotated facts across the main structural archetypes, the corpus is a focused deployment benchmark rather than a broad sample of UK filings, and we do not assess performance across other preparers, formats, standards, or document-generation tools. The silent-failure analysis also relies on one out-of-distribution filing, showing that wholesale rule failure can occur but not how frequently. Gold labels were produced by two domain experts working independently, with agreement reported in Appendix D; both annotators work within the same firm and share its house conventions for reading statutory accounts, so correlated annotation bias may remain undetected. The LLM rationales are used only as reviewer-facing audit aids; we do not evaluate their faithfulness. Likewise, the agreement signal is predictive of correctness but not calibrated as a probability. Finally, as we evaluate one primary model and one secondary model, absolute performance should be read as model-dependent evidence for the approach rather than for any specific model.

Ethics

This work uses real client financial filings provided by the participating firm. All filings were processed under the firm's confidentiality requirements: entity names, addresses, and reported values were anonymised before research use, document structure was preserved without altering its meaning, and no client data left the firm's controlled environment at any stage. All inference runs on-premise; the system makes no calls to external services, which is a deliberate design requirement rather than only an efficiency choice. Although anonymisation substantially reduces disclosure risk, we do not

treat it as a guarantee against re-identification by an adversary with external knowledge.

FINSTRUCT is intended to support, not replace, professional judgement. It produces structural labels that feed a human-in-the-loop review process, and its confidence signal is designed to direct - not remove - that review. We make no claim that the system should operate without human oversight on regulated filings.

Acknowledgments

This work was supported by Innovate UK through Knowledge Transfer Partnership, a collaboration between Cooper Parry, the University of Essex, and Queen Mary University of London. We thank Cooper Parry's Business Process Optimisation, and tax teams for their domain expertise and annotation support.

• = structural field with no direct counterpart in the markup.

Figure 4: The same reported value (boxed, **98,139**) in a UK statutory filing. From the rendered layout (a), a reader instantly infers the value's full logical context (c): section, note, sub-heading, row, column, period, and currency. The inline XBRL markup (b) records only the value, its accounting concept, period context, and unit; the fields marked • have no counterpart in the markup and must be inferred. **FINSTRUCT** recovers (c) from (b).

A Worked example

Figure 4 traces a single reported value through the three representations the task connects: what a reader sees in the rendered filing, what the inline XBRL markup encodes, and the logical context that FINSTRUCT recovers.

B Production constraints in detail

The three constraints summarised in Section 2.2 shape the system at a level of detail we expand here.

Confidentiality. Client filings are commercially sensitive and confidential. This encourages inference to run on-premise on hardware available to the firm, which places a practical upper bound on model size and motivates methods that avoid task-specific fine-tuning (which would itself require labelled client data to be assembled and stored). All inference in this work runs locally; no client data leaves the firm's environment at any stage.

Auditability. Because outputs feed a regulated workflow, every prediction must be inspectable by a reviewer, traceable to the document context that produced it, and reproducible as part of an evaluation or audit trail. This motivates per-prediction rationales, persisted raw model outputs, controlled sampling protocols, and explicit logging of model configuration, prompts, latency, and token usage. For each LLM call, FINSTRUCT persists the raw response, the parsed prediction, prompt metadata, latency, and token counts, so that failed, uncertain, or disputed predictions remain inspectable after the run.

Data scarcity. No gold standard exists for the logical structure of UK statutory filings at the level this task requires. Evaluation data therefore has to be created from scratch, under the same confidentiality restrictions that govern production use. Annotation is consequently not a separate preliminary step but part of the engineering problem: the system, dataset, and evaluation protocol are all designed around limited access to sensitive documents and the cost of expert review.

	C1	C2	C3
Uses LLM	no	yes	yes
Deterministic	yes	no	no
Fine-tuning	none	none	none
On-premise	yes	yes	yes
Per-fact rationale	no	yes	yes
Agreement signal	no	yes	yes
Uses gold examples	no	no	yes (LOO)
Marginal cost/fact	$\sim$0	medium	medium

Table 4: Operating profiles of the three FINSTRUCT modes. C1 is deterministic and rule-based; C2 and C3 share the two-stage LLM cascade, and C3 additionally injects leave-one-filing-out (LOO) demonstrations into Stage 2.

C Evaluation set and scoring details

From facts to the evaluation set. Not every tagged value in a filing is a well-posed target for logical structure recovery. Continuation tails do not represent independent rendered positions, and hidden facts have no well-defined logical reading position; both are therefore excluded from the 1,493 anchor-eligible facts. Per-section and per-archetype breakdowns of the evaluation set are given in Table 3 and Table 6.

Annotation rationale. Gold annotation requires judgement about how UK statutory accounts are laid out and read—the same expertise the system aims to support—so both annotators are domain experts, and annotation was performed manually from the rendered filings to keep the evaluation fully separated from the systems being evaluated. Per-field inter-annotator agreement is reported in Appendix D.

Annotation conventions. Two conventions affect scoring. First, `sub_heading` is annotated broadly, capturing an intermediate heading that scopes a fact within a section or note rather than only the nearest visible heading. Second, the surrounding-context fields `text_before` and `text_after` use explicit boundary sentinels when no surrounding text exists, so that the absence of context is a labelled outcome rather than an empty string to be guessed.

Matching tiers and outcomes. Exact-match normalisation folds case, whitespace, and punctuation. For each fact and field, the comparison yields one of five outcomes: exact match, fuzzy match, sentinel match, mismatch, or missing value; exact, fuzzy, and sentinel matches are counted as correct. Missing predictions count as incorrect unless the gold label explicitly encodes absence through the relevant sentinel. Denominators exclude fact-field pairs where both gold and prediction are absent. All accuracies are reported with 95% percentile bootstrap confidence intervals from 1,000 resamples over facts (`seed=42`).

D Inter-annotator agreement

Both annotators independently labelled all nine structural fields for all 1,493 anchor-eligible facts, working from the rendered filings without access to each other's labels or to any system output. Table 5 reports per-field percent agreement and Cohen's κ, computed under normalised exact match. This is a stricter criterion than the system scoring in Section 3.2, which additionally admits fuzzy and sentinel matches, so the figures below are a conservative lower bound on agreement.

Agreement is high across the structural fields and lowest on the two surrounding-context fields, where annotators must judge where the relevant context begins and ends. The comparison with C3 is informative: on `text_before` and `text_after` the two annotators agree above 94% while the system reaches 28.5% and 31.8%, indicating that these fields are not intrinsically ambiguous to expert readers and that the gap is a system limitation rather than a ceiling imposed by the task. The same holds, less starkly, for `sub_heading`. Residual disagreements were resolved by the senior annotator to produce the final gold set.

E The deterministic baseline in detail

C1 is the rule-based extractor developed for the deployment rather than a comparator reimplemented for this paper. It runs three phases. Phase 1 builds document structure: it splits the rendered filing into page

Field	% agree	κ	C3
section_title	99.7	0.996	99.7
note_label	98.6	0.982	93.3
sub_heading	98.5	0.977	72.7
row_label	95.8	0.956	85.2
col_header	97.9	0.976	82.1
year	99.2	0.987	84.0
currency_label	99.9	0.998	96.1
text_before	95.0	0.776	28.5
text_after	94.4	0.750	31.8
Macro	97.7	0.933	74.8
Micro	97.7	0.971	85.1

Table 5: Inter-annotator agreement between the two annotators on all 1,493 facts, with C3 accuracy repeated from Table 2 for comparison. Agreement is computed under normalised exact match, a stricter criterion than the system scoring.

cells, detects and classifies section headings, and derives table and column information. Phase 2 assigns each fact one of the five archetypes (Appendix G). Phase 3 dispatches an archetype-specific extractor that returns a single structured record per fact.

The nine fields divide between phases. Heading classification in Phase 1 yields `section_title` alone. Phase 3 produces the other eight: `note_label` and `sub_heading` are assembled from the note number and title of the enclosing note, while `row_label`, `col_header`, `year`, `currency_label`, `text_before` and `text_after` are read directly from the fact's table and text neighbourhood.

Headings are located structurally rather than semantically: candidates are centred container elements carrying a style class and appearing before the first content table on a page. Recurring furniture is then filtered out—the company name, which repeats on almost every page, along with registered-number lines, period subtitles and page numbers—and the surviving candidates are matched against an ordered, first-match-wins pattern list, defaulting to an unknown label.

This design is what F5 defeats. Section identity is recovered from container shape, so a page whose markup does not expose heading containers in the expected form yields no candidates and is skipped, and its facts carry no section. Where candidates exist but all are filtered as furniture, the fallback assigns the cover-page label rather than inheriting the section context of preceding pages, so mid-document pages bearing only recurring headers are mislabelled. The first path is what produces the F5 cohort: with no section resolved, the downstream extractors return nothing and the fact is recorded with all nine fields absent. No exception is raised on either path, which is why the failure is silent and surfaced only under coverage analysis.

F Additional analyses

Context fields under emission and abstention. Accuracy on `text_before` and `text_after` is dominated by absence: 1,305 of 1,493 gold values are absent for `text_before` and 1,302 for `text_after`. Splitting emission from abstention shows that C2 and C3 trade precision against recall rather than one dominating. On `text_before`, emission recall is 72.3 (C2) versus 56.4 (C3) and emission precision 54.2 (C2) versus 66.2 (C3); `text_after` shows the same pattern (recall 66.0 versus 59.2, precision 51.9 versus 63.8). C3 abstains more often (89.3% versus 83.2% on `text_before`). This explains the apparent C2 advantage under accuracy in Table 2: the two modes sit at different points on the same trade-off, and a single accuracy figure over an absence-dominated field obscures that.

Repeated sampling. To separate the contribution of repeated sampling from that of in-context demonstrations, we rescore the 8,958 persisted Stage 2 samples. Plurality voting over $N{=}3$ gains $+0.3$ points macro over the mean single sample, and C3 exceeds C2 at $N{=}1$ (74.6 versus 70.8 macro). The in-context gain is therefore not an artefact of voting.

Rule–LLM hybrid. `year` is the only field where C1 exceeds C3 (85.4 versus 84.0), so a hybrid that routes each field to its stronger mode reduces to rules-for-`year`: macro 75.0 versus 74.8, micro 85.2 versus

85.1. The inference saving is nil, because a single Stage 2 call already emits all eight non-section fields together, so routing individual fields to rules removes no LLM calls. A hybrid that genuinely reduced inference would need a different decomposition—for example, resolving whether a fact is rule-tractable before invoking the model—which we leave to future work.

G Fact archetypes

The structuring frontend assigns each parsed fact one of five archetypes, which route extraction and shape the per-fact input given to every mode.

- **table-numeric**: a numeric cell in a structured financial table. This is the dominant case (1,177 of 1,493 anchor-eligible facts).
- **table-text**: a textual cell in a table, such as a row caption used as a value.
- **narrative-block**: a fact embedded in running prose rather than a table.
- **standalone**: a value outside any table or narrative block, such as a free-standing line item.
- **hidden**: a fact present in the markup but not visibly rendered, for which a logical reading position is undefined. Hidden facts are excluded from the anchor-eligible set and from all evaluation.

The archetype is the backbone of the system: it dispatches the rule-based extractor (Section 2.3) to an archetype-specialised routine, determines the per-fact input representation given to the LLM, and conditions demonstration retrieval in C3. It is also the lens for the per-archetype analysis in Table 6: C1 is competitive only on **table-numeric** facts, while the LLM modes raise accuracy substantially on the three less explicitly encoded archetypes. The **narrative-block** archetype shows the largest improvement from rules to in-context extraction ($21.4\% \rightarrow 84.9\%$, $+63.5$ percentage points), consistent with the comprehension-dependent framing: where structure is carried by prose rather than table geometry, language understanding does most of the work.

H Prompts and schema

Both LLM stages use structured prompts. Stage 1 presents the task definition, the closed inventory of fourteen sections, the target fact, and its rendered neighbourhood, and requests a single section label with a brief rationale. Each of the fourteen sections has its own Stage 2 prompt; all share the skeleton below and differ only in the section-specific field guidance and the layout they expect.

```
[TASK] Recover the logical structure of the
target fact within its section.
[SECTION] {resolved_section_title}
[CONTEXT] {target-centred neighbourhood:
rows, headings, period and currency labels,
surrounding prose}
[TARGET] {fact value + local position}
[FIELDS] note_label, sub_heading, row_label,
col_header, year, currency_label,
text_before, text_after
[OUTPUT] strict JSON: one value per field,
plus a short "rationale" string.
```

A representative Stage 2 prompt body for the balance-sheet section is shown below; the other thirteen follow the same template with section-appropriate field conventions (this example is illustrative of the template, lightly edited for length).

```
You are recovering the logical structure of a
value reported in the BALANCE SHEET of a UK
statutory filing. Using only the context
provided, return the eight remaining fields
for the target value. Columns are reporting
periods; the left-most label column gives the
```

```
line item. If a field has no value in the
filing, return the explicit absence sentinel.
Return strict JSON only.

CONTEXT:
{rendered neighbourhood of the target cell}

TARGET VALUE: {value}

Return: {"note_label": ..., "sub_heading": ...,
"row_label": ..., "col_header": ...,
"year": ..., "currency_label": ...,
"text_before": ..., "text_after": ...,
"rationale": ...}
```

Stage 2 must return a strict JSON object containing the eight field values and a short rationale. Schema validation is part of the system: malformed JSON, missing fields, or values outside the expected type constraints are detected automatically and can be resampled or logged as extraction errors. The rationale is used as a reviewer-facing explanation; we do not claim or evaluate rationale faithfulness.

I Detailed results

This appendix reports the remaining breakdowns: per-archetype accuracy (Table 6), the full pairwise McNemar matrix with Holm–Bonferroni correction (Table 7), and the full per-field results for the second model (Table 8). Two patterns are worth noting. First, `DPL` is the only section where the zero-shot LLM regresses relative to the rule-based extractor ($93.6 \rightarrow 82.6$), which in-context demonstrations then recover (95.2)—a section-level echo of the `year` field result. Second, the per-archetype and per-section breakdowns localise where the LLM modes contribute most: the least explicitly encoded archetypes and the narrative report sections.

Archetype	n (facts)	C1	C2	C3
table-numeric	1,177	69.1	82.0	85.9
table-text	118	39.8	68.9	76.1
narrative-block	118	21.4	68.4	84.9
standalone	80	32.4	75.2	76.4

Table 6: Per-archetype accuracy (%) on the Qwen3-14B-AWQ run, anchor-eligible facts only (HIDDEN excluded by construction). Cells show micro accuracy: total correct cells / total non-both-missing cells across the nine prediction fields, within each archetype. n is the fact count per archetype (sums to 1,493). Largest C1→C3 gain is on *narrative-block* (+63.5 pp), where the rule-based extractor's text-window heuristics are weakest and the LLM cascade does the heaviest lifting; *table-numeric* (the bulk of the corpus) shows the smallest delta because C1 already exploits column / row geometry.

Field	C1 vs C2	C1 vs C3	C2 vs C3
`section_title`	6.0e-52 ✓	6.0e-52 ✓	1.00 ×
`note_label`	3.9e-60 ✓	4.9e-76 ✓	3.6e-2 ✓
`sub_heading`	3.7e-97 ✓	2.6e-148 ✓	9.1e-20 ✓
`row_label`	7.4e-57 ✓	1.1e-60 ✓	1.00 ×
`col_header`	2.4e-52 ✓	1.5e-50 ✓	1.00 ×
`year`	0.295 ×	4.9e-6 ✓	9.7e-12 ✓
`currency_label`	5.8e-44 ✓	3.3e-41 ✓	0.500 ×
`text_before`	2.5e-21 ✓	1.6e-10 ✓	4.5e-4 ✓
`text_after`	4.8e-17 ✓	5.1e-17 ✓	0.435 ×
sig. count	8 / 9	9 / 9	4 / 9

Table 7: Pairwise McNemar exact test, Holm-Bonferroni adjusted across the family of 9 fields × 3 pairwise comparisons = 27 hypotheses. Cells show the Holm-adjusted p-value; ✓ marks $p < 0.05$ and × marks n.s. The C1-vs-C2 column reproduces the raw McNemar exact test stored in `summary.json` to 6 significant figures before correction; raw values are available in the JSON dump and the run log. The only pair where raw vs Holm matters substantively is `year` C1-vs-C2 (raw 0.0491, Holm 0.295) — the body's characterisation of `year` as n.s. for C1-vs-C2 reflects the Holm-corrected verdict.

Field	C1 [lo, hi]	C2 [lo, hi]	C3 [lo, hi]
section_title	86.5 [84.7, 88.1]	95.8 [94.8, 96.8]	99.7 [99.4, 99.9]
note_label	60.0 [56.9, 63.9]	62.8 [59.6, 66.2]	79.7 [76.7, 82.5]
sub_heading	3.4 [2.2, 4.9]	37.3 [34.0, 40.9]	58.5 [54.7, 61.9]
row_label	65.2 [62.3, 68.0]	59.0 [56.2, 61.6]	73.2 [70.8, 75.7]
col_header	60.9 [58.1, 63.7]	47.8 [45.0, 51.1]	63.1 [60.2, 65.8]
year	85.4 [82.9, 87.8]	43.4 [40.6, 46.3]	56.7 [53.5, 59.9]
currency_label	82.8 [80.6, 84.8]	90.9 [89.3, 92.5]	91.4 [89.6, 93.0]
text_before	6.1 [3.8, 9.2]	11.5 [7.9, 15.1]	18.5 [14.4, 22.8]
text_after	5.3 [2.8, 8.1]	2.8 [1.2, 4.8]	10.1 [7.0, 14.0]
Macro	50.6 [49.4, 51.9]	50.1 [49.1, 51.1]	61.2 [60.0, 62.6]
Micro	63.1 [61.3, 64.8]	61.7 [60.5, 62.9]	72.6 [71.3, 73.9]

Table 8: Per-field accuracy (%) on Llama-3.1-8B-Instruct-AWQ-INT4 (the second open-weight instruction-tuned model in the cross-model robustness check), with 95% percentile bootstrap CIs (1,000 resamples, seed=42, fact-level resampling). C1 is the rule-based extractor and is identical across runs by construction. C3 $>$ C2 holds on every field; absolute level is materially below Qwen, particularly on the structural fields (`year`, `col_header`, `row_label`, `note_label`) where the smaller model under-uses the page-rendered structural context.

J Within-family capacity sweep

To test whether the in-context effect is specific to the 14B model, we repeat the C2 and C3 experiments across the Qwen3 family at four sizes (Table 9). All sizes use the same inference configuration as the primary run (Section 3.3): max model length 32,768, Stage 1 decoded greedily (T=0, 64 tokens), Stage 2 sampled with N=3 at T=0.7 (top-p 0.9, 1024 tokens), and C3 using leave-one-filing-out k=3 demonstrations. C1 is model-agnostic (50.6 macro / 63.1 micro) and unchanged across rows.

Model	Quant.	C2	C3	Δ
Qwen3-1.7B	BF16[†]	42.1 / 50.0	52.2 / 62.2	+10.1
Qwen3-4B	AWQ	53.8 / 64.2	63.8 / 72.3	+10.0
Qwen3-8B	AWQ	61.7 / 70.8	69.1 / 78.3	+7.4
Qwen3-14B	AWQ	71.0 / 80.4	74.8 / 85.1	+3.8

Table 9: Capacity sweep: macro / micro accuracy (%) by model size, with the macro C3−C2 gain (Δ). C3 $>$ C2 at every size, but the in-context gain shrinks as capacity grows. [†]No official Qwen3-1.7B AWQ build exists, so the 1.7B tier is run at native BF16—a full-precision upper bound, not directly comparable to the AWQ INT4 tiers; we read its point conservatively.

Field	1.7B	4B	8B	14B
section_title	83.1	92.8	95.7	99.7
note_label	45.1/70.6	58.3/79.0	79.5/87.6	86.6/93.3
sub_heading	18.4/38.4	29.7/53.3	44.8/60.6	55.2/72.7
row_label	58.3/65.7	68.0/76.4	83.5/83.2	82.1/85.2
col_header	43.3/48.7	61.9/71.0	69.5/73.9	80.6/82.1
year	40.0/49.9	58.4/69.3	64.9/81.7	73.9/84.0
currency_label	80.5/89.0	91.9/92.9	92.1/94.6	95.8/96.1
text_before	6.4/13.7	12.0/19.3	14.7/24.6	34.7/28.5
text_after	4.0/10.7	11.7/19.8	11.0/20.1	30.8/31.8

Table 10: Per-field accuracy (%) across model sizes, shown as C2/C3. `section_title` is identical for C2 and C3 by construction (C3 reuses C2's Stage-1 decision), so a single value is shown.

Findings. Accuracy scales monotonically with capacity for both modes (C2 macro 42.1 $\rightarrow$ 71.0; C3 52.2 $\rightarrow$ 74.8 across 1.7B$\rightarrow$14B), and C3 exceeds C2 at every size, confirming that the in-context effect is not an artefact of one model. The size of that effect, however, shrinks with capacity—from +10.1 points at 1.7B to +3.8 at 14B—so demonstrations help weaker models most. At 1.7B, zero-shot extraction falls below the rule-based baseline (C2 42.1 $<$ C1 50.6) and only in-context extraction recovers above it. This mirrors the second-model result (Section 4.5): the weaker Llama-3.1-8B shows a larger in-context gain

than the larger Qwen3 models, indicating that base capacity, not family, governs how much demonstrations contribute.

K API-equivalent cost estimate

The binding reason for on-premise inference is confidentiality: client filings cannot be sent to a commercial API, so the hosted option is unavailable regardless of price. For completeness, Table 11 estimates the inference spend the API option would have incurred at mainstream rates at the time of writing. The figures are illustrative: they assume an input-dominated token split, apply no batch or caching discounts, and reflect a pricing snapshot that may change. Even on conservative assumptions the recurring cost is non-trivial and, unlike the fixed cost of owned hardware, scales linearly with the firm's filing volume.

Inference option	**C2**	**C3**
	(USD / 1k facts)	
Commercial API, model A	42	63
Commercial API, model B	47	70
Commercial API, model C	34	50
FINSTRUCT (on-premise GPU)	$\sim$0	$\sim$0

Table 11: Illustrative API-equivalent inference cost per 1,000 facts, estimated from observed token counts and a pricing snapshot at the time of writing, under an input-dominated assumption and without batch or caching discounts. The comparison is illustrative only: confidentiality makes hosted API inference unavailable in our deployment setting, and prices may change over time.

SkillHone: A Harness for Continual Agent Skill Evolution Through Persistent Decision History

Zhiwei Li **Yong Hu**
WeChat, Tencent Inc., China
zhiweili.jay@foxmail.com rightyonghu@tencent.com

Abstract

Agent skills extend language-model agents with task-specific procedures, scripts, and references, but the tasks and environments they target continually change. Existing methods improve skills in bounded runs and retain only the final artifact, discarding the decision history that later agents need to interpret prior revisions, evaluations, and rejected alternatives. We introduce SkillHone, a harness for continual agent skill evolution grounded in persistent decision history. SkillHone pairs skill revisions with evaluation-side evidence that supplies practice feedback, recording structured histories of diagnoses, revisions, evidence, and outcomes. Role-separated subagents run candidate skills on practice probes with redacted reporting and propose revisions informed by prior decisions, enabling cross-session refinement without rediscovering past rationale. On deep-research benchmarks, SkillHone runs without a pre-integrated search stack and outperforms the commercially backed deep-research agent by 15.8 points on GAIA and 3.2 points on WebWalkerQA-EN, while also exceeding prior skill-evolution methods. We further deploy SkillHone on internal tool-mediated analysis scenarios, where it improves accuracy by an average of 18.8 points across seven settings.

1 Introduction

Skills have emerged as a central mechanism for extending LLM-based agents. A skill is a named, loadable bundle of task-specific procedures, scripts, references, and output conventions that an agent can invoke for a particular class of work (Xu and Yan, 2026; Ling et al., 2026). In deployed agent systems such as Claude Code, Codex, and Hermes, skills serve as a primary unit of specialization. The development of a robust skill is never a one-shot event but an **ongoing process of creation and adaptation**. Even during its initial formation, a skill requires rigorous debugging and constant updates to broaden its scope or patch unhandled edge cases. As environments shift and APIs change, this creation-maintenance loop persists, making it essential that the rationale behind every revision remains preserved and maintainable throughout its existence. The central methodological question is therefore how later agents can continue improving a skill across many development sessions without losing the rationale behind earlier changes.

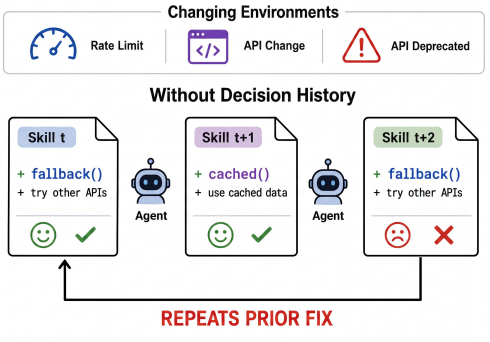

Figure 1: Context loss in artifact-only skill evolution: without decision history, a later agent may repeat a prior optimization and make future improvement harder.

Existing methods for improving agent skills can be viewed as two representative routes. Synthesis-style construction methods such as Skill-Creator[1] turn a task description, examples, or supporting documents into a loadable skill and then hand the generated artifact to later sessions. GEPA-style reflective optimization methods, including Hermes-Agent-Self-Evolution (Hermes-SE)[2], run iterative mutation, evaluation, and selection over skills, prompts, tool descriptions, and code using GEPA (Agrawal et al., 2026). These routes are useful for producing or improving a skill within a single optimization run, but they largely treat the output as a better artifact.

This artifact-centered view loses the decision

context needed for continual maintenance. A later agent may inherit the latest skill, but not the structured history explaining which diagnosis motivated a revision, which alternatives were rejected, what evaluation evidence was observed, and why an outcome was accepted. The same problem applies to the evaluation evidence that supports skill improvement: when later agents rely on probes, validators, traces, or redacted reports, they also need to know which failure mode the evidence reflects and how it shaped prior decisions. As illustrated in Figure 1, rate limits, API changes, and deprecations can arrive over time, and a later optimization step may repeat a previously successful repair that no longer matches the current failure mode. Persistent decision history lets later optimization recover why each revision was made and avoid reintroducing obsolete fixes. Without this context, a locally plausible repair can repeat old edits or make later optimization harder.

We introduce SkillHone, an agent-facing harness for continual skill evolution in skill-enabled agent frameworks. SkillHone maintains the evolving skill together with evaluation assets that support its improvement, and treats skill revisions and evaluation evidence as decision-bearing. For skill revisions, the history records the diagnosis, proposed revision, evaluation evidence, and outcome. For evaluation evidence, it records which probes or reports were used, which failure mode they exposed, and how the evidence justified the outcome. Thus, later agents inherit the skill, evidence, and rationale behind prior changes.

This history is accumulated from many local decisions made during diagnosis, revision, and evaluation. SkillHone therefore uses role-bounded subagent dispatches, rather than a fixed multi-agent system, to generate these records as the loop runs: it only assumes an agent runtime that can launch scoped dispatches with separated permissions. This makes the harness portable across agent runtimes such as Claude Code, Codex, and Hermes, while keeping optimization separated from unredacted evaluation assets. Evaluation subagents can inspect probes and traces and run candidate skills, but return only redacted evidence to the optimization side. Optimization subagents use this evidence and prior decision records to form diagnoses and draft skill revisions, without accessing hidden probe targets or validators. Across sessions, the linked history of diagnoses, revisions, evidence, and outcomes allows later agents to continue skill evolution without re-deriving prior decisions.

We evaluate SkillHone on deep-research benchmarks in the raw open-web setting, where agents must organize retrieval without a pre-integrated search stack. Against skill-evolution baselines and a deep-research agent with commercial retrieval, SkillHone obtains the strongest average results on GAIA and WebWalkerQA-EN under a fixed evaluation-time backbone; the resulting skill bundle also transfers to a different execution backbone (Claude Sonnet 4.6) without additional optimization, indicating that the gain reflects the skill procedure rather than fitting to one model. We also deploy SkillHone on recurring internal tool-mediated analysis scenarios, where it improves the underlying tool-use skills.

Contributions.

1. We identify a gap between artifact-centered skill improvement and continual skill maintenance. Long-lived skills require persistent decision history, rather than a single optimized artifact, so later agents can understand skill revisions together with the evaluation evidence that supported them.
2. We introduce SkillHone, a general agent-facing harness for continual agent skill evolution. It records diagnoses, revisions, evidence, and outcomes under separated roles.
3. We show that SkillHone improves skill development across public benchmarks and deployments.

2 Method

2.1 Problem Setup

In this paper, a skill is a loadable artifact that packages the instructions, procedures, references, and output conventions an agent uses for a class of tasks. SkillHone keeps the model backend and external tools fixed; its goal is to help agents maintain and improve this skill artifact across repeated development sessions.

SkillHone maintains two linked repositories. The skill repository stores the skill bundle being revised. The skill-evaluation repository stores practice probes, oracle targets, validators, traces, redacted reports, and other evaluation assets that provide feedback for skill improvement. The optimization side observes only redacted reports, not unredacted targets, validators, or traces. Accepted revisions produce a sequence of skills $S_0, \ldots, S_T$,

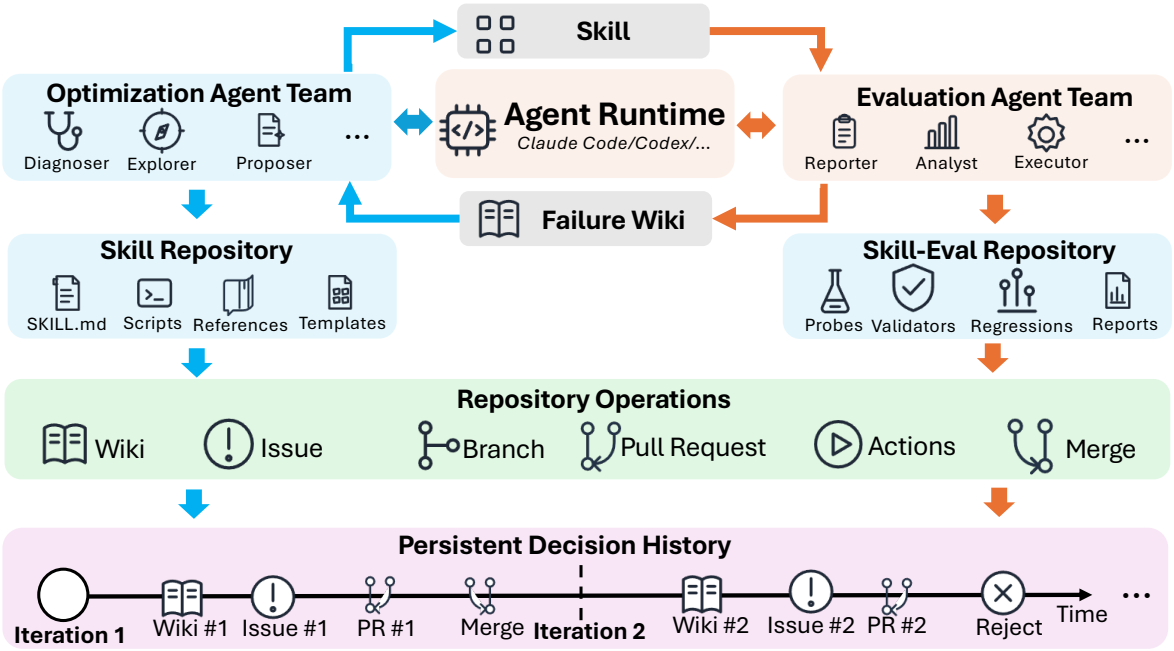

Figure 2: SkillHone architecture. At each development step, an agent runtime dynamically dispatches fresh, role-bounded optimization and evaluation subagents on demand. Optimization dispatches maintain the skill repository and propose diagnosis-guided revisions. Evaluation dispatches run candidate skills against the skill-evaluation repository and export redacted problem reports, without exposing probe targets, validators, or traces. Routed evidence, repository operations, and recorded outcomes form a persistent decision history that later agents reuse for continual skill evolution.

guided by practice feedback and the persistent decision history that links diagnoses, candidate revisions, evaluations, and outcomes.

2.2 SkillHone Harness

As shown in Figure 2, SkillHone separates each development step into optimization and evaluation dispatches. These dispatches are role-bounded so that diagnoses, revisions, redacted evidence, and outcomes can be recorded as auditable decision history. Appendix F (Table 6) lists the recurring dispatch patterns and their permission boundaries.

We formalize the harness as

$$\mathcal{M} = (\mathcal{T}_{\text{opt}}, \mathcal{T}_{\text{eval}}, \mathcal{D}),$$

where $\mathcal{T}_{\text{opt}}$ is the Optimization Agent Team, $\mathcal{T}_{\text{eval}}$ is the Evaluation Agent Team, and $\mathcal{D}$ is the runtime dispatcher.

The optimization side maintains the skill repository, which contains the current `SKILL.md`, scripts, references, templates, and other skill assets. Optimization dispatches can inspect the current skill, read prior decision records and failure summaries, form diagnoses, propose typed revisions, review candidate changes, and record accepted outcomes. Typical dispatches include diagnosing failures from redacted reports, integrating prior resources, proposing scoped revisions, and drafting patches to S_t.

The evaluation side operates on the skill-evaluation repository, which contains probes, validation suites, regression sets, traces, and evaluation reports. Evaluation dispatches can inspect oracle targets and traces, run the current skill on probe items, analyze failures, and produce redacted reports. They cannot write to the skill repository. Conversely, the optimization side can change the skill but cannot access unredacted probe targets, validators, or execution traces. This separation prevents practice feedback from becoming a direct memorization target.

The dispatcher is a message router rather than a decision authority. At each step, it routes redacted evidence and review requests between the two sides and records accepted outcomes. Acceptance decisions are made using the evidence available to the appropriate side, keeping the decision history tied to the same permission boundary that produced it.

2.3 Persistent Decision History

A central design goal of SkillHone is to make skill evolution persistent across sessions. A later agent

Algorithm 1 SkillHone

Require: Initial skill S_0, skill repo $\mathcal{R}_s$, eval repo $\mathcal{R}_e$
$\mathcal{H}_0 \leftarrow \emptyset$
for $t = 0, \ldots, T-1$ **do**
  Eval dispatches run $A(\cdot; S_t)$ on $\mathcal{R}_e$ and export $\tilde{E}_t$
  Opt dispatches retrieve $\mathcal{H}_t$, then propose (q_t, r_t)
  Eval dispatches return redacted evidence e_t for r_t
  Decide $o_t \in \{\text{ACCEPT}, \text{REVISE}, \text{REJECT}, \text{DEFER}\}$
  $S_{t+1} \leftarrow \text{APPLY}(S_t, r_t)$ if accepted, else S_t
  $\mathcal{H}_{t+1} \leftarrow \mathcal{H}_t \cup \{(q_t, r_t, e_t, o_t)\}$
end for
return $S_T, \mathcal{H}_T$

should not receive only the latest skill snapshot. It should also inherit the structured record of why the skill changed, which alternatives were considered, how candidates were evaluated, and which outcomes were accepted or rejected.

SkillHone represents each development step as a decision record

$$h_t = (q_t, r_t, e_t, o_t),$$

where q_t is the diagnosis, r_t is the candidate revision, e_t is the redacted evaluation evidence, and o_t is the outcome. The outcome may accept the revision, reject it, request further changes, or defer the diagnosis. The decision history up to iteration t is $\mathcal{H}_t = \{h_1, \ldots, h_t\}$.

The decision record is more than a version diff. A diff shows how files changed; a decision record links that change to the problem it targeted, the evidence used to evaluate it, and the final decision. This distinction is important for continual evolution. When the environment changes, later subagents can inspect $\mathcal{H}_t$ to determine whether a failure is new, whether a similar fix was already attempted, and why a previous alternative was rejected.

Given a new redacted report $\tilde{E}_t$, optimization subagents retrieve relevant prior records from $\mathcal{H}_{<t}$. They may revisit an old diagnosis, revise a rejected patch under new evidence, or avoid a redundant edit that has already failed. Thus the decision history acts as a persistent memory for the evolution process itself. It enables agents to audit prior changes and continue skill improvement without re-deriving the same diagnoses.

3 Experiments

We evaluate SkillHone on public deep-research benchmarks against existing skill construction and optimization methods under a fixed execution-time agent backbone, examine cross-backbone transfer of the resulting skill bundle, and report a deployment study on recurring internal tool-mediated analysis scenarios.

3.1 Experimental Setup

We instantiate this comparison in deep research because information seeking is one of the most broadly used agent workloads and naturally benefits from reusable skills: tasks require agents to combine search, navigation, extraction, verification, and recovery across changing web sources, so external resources are rate-limited, fail intermittently, and change format, requiring agents to diagnose failures, revise skills, and preserve the evaluation evidence behind those revisions.

We use two open-domain benchmarks: the text-only validation subset of GAIA (Mialon et al., 2024) and the English split of WebWalkerQA (Wu et al., 2025). GAIA emphasizes multi-step information seeking and factual grounding across heterogeneous sources, while WebWalkerQA-EN focuses on web navigation and information extraction.

We compare two evaluation settings:

- **Curated search**: a deep-research agent uses commercial retrieval services and does not maintain its own search stack.
- **Raw open-web**: agents receive no pre-integrated search tools. They operate through a general agent runtime, public web access, and portable skill bundles that organize search, parsing, extraction, and recovery procedures. Because these skills rely on public pages and free or community search interfaces, they must handle rate limits, unavailable endpoints, and changing page formats without a managed retrieval service.

We separate the controller that optimizes skills from the backbone that executes and evaluates them. Claude Opus 4.6[3] serves as the development-time controller that reads feedback, forms diagnoses, and revises skill bundles. Qwen3.6-35B-A3B (Qwen Team, 2026) serves as the execution and evaluation backbone for running skills during development and for producing the final benchmark scores.

To drive skill evolution, we sample 20 items from the publicly released WebShaper dataset (Tao et al., 2025), which is disjoint from GAIA and WebWalkerQA-EN, and adapt them to our agent execution environment. These items serve as the

[3] https://www.anthropic.com/news/claude-opus-4-6

Setting	System	GAIA				WebWalkerQA-EN			
		L1	L2	L3	Avg.	Easy	Med.	Hard	Avg.
Curated search	deep-research agent	61.9	47.0	26.3	48.8	**58.5**	62.3	67.1	63.2
Raw open-web	Existing-Skills	64.3	33.3	21.1	41.7	51.2	48.5	52.6	50.2
	Skill-Creator	64.3	37.9	21.1	44.1	36.6	36.9	40.8	38.1
	Hermes-SE	73.8	40.9	**31.6**	50.4	53.7	51.5	55.3	53.0
	SkillHone (Ours)	**76.2**	**66.7**	**31.6**	**64.6**	53.7	**69.2**	**68.4**	**66.4**

Table 1: Main results on GAIA and WebWalkerQA-EN. Bold marks the best score in each column.

shared development data for all skill-evolution baselines, with each method using them according to its own optimization procedure.

3.2 Baselines

The raw open-web comparison starts from a shared existing-skill pool. We construct this pool from search-related community skills selected by an agent from ClawHub and SkillHub; Appendix A lists the selected skills. The pool is provided to all comparable raw open-web systems for a fair comparison; the systems differ in whether and how they adapt these starting skills.

The raw open-web comparison contains one direct-use setting and three skill-development systems:

- **Existing-Skills**: directly loads the skills as a portable skill bundle, without further optimization.
- **Skill-Creator**: applies built-in iterative skill optimization.
- **Hermes-SE**: applies reflective skill optimization.
- **SkillHone**: runs the full harness with role-separated subagents, redacted evaluation feedback, and persistent decision history.

All raw open-web systems produce the same portable skill-bundle interface: a `SKILL.md` entry file with optional scripts, references, templates, and supporting resources. They differ only in how the bundle is developed.

3.3 Main Results

Table 1 reports the final benchmark results. SkillHone achieves the best average score on both benchmarks, reaching 64.6% on GAIA and 66.4% on WebWalkerQA-EN, 15.8/3.2 points above the deep-research agent despite not using pre-integrated search tools at evaluation time. The gains concentrate on harder splits that require deciding how to search, extracting evidence, verifying findings, and recovering from failed attempts.

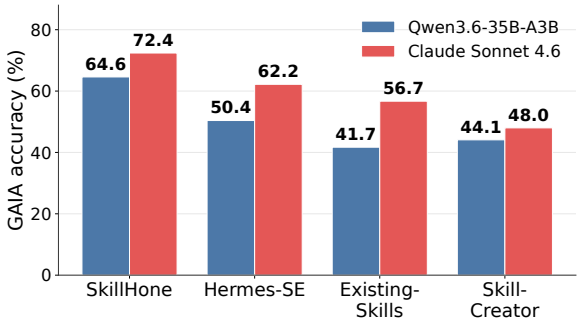

Figure 3: GAIA accuracy under the development backbone (Qwen3.6-35B-A3B) and the transfer backbone (Claude Sonnet 4.6). Each skill bundle is run directly on Claude Sonnet 4.6 without additional optimization.

Within the raw open-web setting, SkillHone also outperforms the shared-pool skill-development baselines: +20.5/+28.3 points over Skill-Creator and +14.2/+13.4 over Hermes-SE on GAIA/WebWalkerQA-EN. The gap to Existing-Skills shows that exposing the agent to relevant skills is not sufficient: SkillHone turns them into a task procedure for when to search broadly, follow a source, verify an answer, and recover from a failed path, so the main gains come from organization rather than components alone.

Figure 3 further evaluates transfer to Claude Sonnet 4.6[4]: without additional optimization on this backbone, SkillHone reaches 72.4% on GAIA, 10.2/15.7/24.4 points above Hermes-SE/Existing-Skills/Skill-Creator. Appendix C (Figure 4) compares the SkillHone and Hermes-SE optimization trajectories on the same practice probes, illustrating how scoped reverts under persistent decision history differ from whole-candidate acceptance under a scalar signal. Appendix D reports development cost and cost-efficiency metrics.

[4] https://www.anthropic.com/news/claude-sonnet-4-6

	GAIA	WebWalkerQA-EN
SkillHone (full)	64.6	66.4
w/o decision history	51.2	55.5
w/o role separation	58.2	61.1

Table 2: Ablation of SkillHone's two core mechanisms.

3.4 Ablation

To isolate the two core mechanisms, we ablate each under the raw open-web setting and the same Qwen3.6-35B-A3B execution backbone used above. **No decision history** keeps role-separated subagents but starts each step from the latest skill artifact alone, optimizing on a scalar signal as in reflective baselines. **No role separation** keeps decision history but lets a single subagent access the skill repository and unredacted evaluation assets jointly.

Table 2 shows that decision history accounts for the larger share: removing it drops GAIA/WebWalkerQA-EN by 13.4/10.9 points, versus 6.4/5.3 points for role separation.

3.5 Deployment Study

We further evaluate SkillHone on internal tool-mediated analysis scenarios to test whether it improves skills used for recurring analytical requests beyond public web benchmarks. We select several recurring scenarios and their corresponding seed skills from an internal workflow, then apply SkillHone to improve each skill on a fixed exact-match evaluation set per scenario (Appendix G).

Table 3 summarizes the selected scenarios. SkillHone improves six of the seven selected skills over their seeded versions, with the largest gains on counting, aggregation, structure parsing, and span retrieval. The remaining scenario, list filtering, is stable at the aggregate level. Across all listed scenarios, SkillHone improves accuracy by an average of 18.8 points, with the largest gains where the initial procedure leaves reusable analysis steps underspecified.

Scenario	Δ
Counting	+30.0
Aggregation	+26.3
Structure parsing	+25.0
Density estimation	+23.1
Span retrieval	+21.5
Filtered ranking	+5.9
List filtering	+0.0
Avg.	+18.8

Table 3: Deployment study on recurring internal tool-mediated analysis scenarios. Optimized minus seeded accuracy (pp); the final row averages the listed scenarios.

4 Related Work

Agent skills and skill acquisition. The recent abstraction of agent skills bundles task-specific procedures, scripts, references, and conventions into reusable artifacts that LLM agents can load on demand (Xu and Yan, 2026; Ling et al., 2026). Benchmarks such as Li et al. (2026) and Han et al. (2026) measure when skills help across general tasks and software-engineering settings, while skill-acquisition methods study automated discovery from exploration and feedback (Yang et al., 2025), reinforcement-learning-based evolution (Vishe et al., 2026; Xia et al., 2026), and domain-specific construction (Liu et al., 2026). These works focus on producing or evaluating skills as outputs; SkillHone instead preserves the optimization context—failure modes, candidate revisions, and outcomes—so the next agent inherits the decision history that makes future improvement possible.

Optimization of prompts, systems, and skills. Within language-system optimization, prompt-only methods use LLMs to propose and select improved instructions (Zhou et al., 2023; Yang et al., 2024a); Reflexion-style agents use verbal feedback to improve behavior across attempts (Shinn et al., 2023); DSPy frames LM pipelines as declarative programs that can be compiled and optimized end-to-end (Khattab et al., 2024). More closely related, GEPA reflectively evolves components of a language system (Agrawal et al., 2026), and Hermes-SE applies this style across skills, prompts, tool descriptions, and code. These methods optimize within a single run over a scalar signal; SkillHone lets later agents continue from where prior runs left off, audit what has been tried, and avoid redundant edits.

Multi-agent collaboration and agent development workflows. Multi-agent LLM systems study how role specialization can support collaborative problem solving (Talebirad and Nadiri, 2023; Guo et al., 2024; Wang et al., 2024; Tran et al., 2025). MetaGPT organizes agents into specialized roles for producing software-like artifacts (Hong et al., 2024), and SWE-style benchmarks (Jimenez

et al., 2024; Yang et al., 2024b; Xia et al., 2025) study LLM agents in environments where tasks are naturally expressed as diagnosis, code modification, and testing. SkillHone reuses role separation for a different purpose: optimization subagents propose skill revisions while evaluation subagents test candidates and return redacted evidence under a permission-bounded dispatcher, accumulating agent-readable decision history while reducing leakage from evaluation assets to the optimization side.

5 Conclusion

We introduced SkillHone, a harness that evolves skills via role-separated subagents, redacted practice feedback, and persistent decision histories linking problems, revisions, evidence, and outcomes. On GAIA and WebWalkerQA-EN, SkillHone exceeds iterative and reflective skill-development baselines and the deep-research agent, and improves seeded skills by 18.8 points on average across seven recurring internal scenarios. The skill bundle transfers to a different execution backbone without further optimization, suggesting the gain comes from the skill procedure rather than from fitting one model. Decision history lets later agents improve a skill without re-deriving prior decisions.

Limitations

SkillHone currently evolves a single skill in isolation; jointly evolving multiple interdependent skills, including coordination across shared resources and overlapping failure modes, is not addressed in this work.

A Existing Community Skills

The shared existing-skill pool is selected by an agent from search-related community skills on ClawHub and SkillHub:

- `web-pilot`
- `web-content-fetcher`
- `scholar-search`
- `query-dbpedia`
- `multi-search-engine`
- `literature-review`
- `geepers-data`
- `duckduckgo-websearch`
- `deep-research-pro`
- `ddgs-search`

B Repository Workflow Example

In our implementation, SkillHone realizes persistent decision history through a GitHub-style repository workflow. Issues record diagnosed failure modes, pull requests contain proposed skill revisions, and merge or rejection decisions record the accepted outcome. This is one concrete interface for making the evolution process auditable, rather than a required interface for SkillHone.

Table 4 gives the repository records from one deep-research skill run. The five rows correspond to the five non-seed SkillHone iterations shown in Figure 4. The table highlights that SkillHone optimizes the whole skill bundle, including instructions, scripts, and references, rather than only rewriting a single `SKILL.md` body as in the Hermes-SE comparison.

C Optimization Trajectory

Figure 4 compares one SkillHone run with one Hermes-SE run on the same practice probes. Both runs start from the same seed skill. SkillHone improves from 30% to 70% while recovering from

Iter.	Issues	PRs	Files changed
1	#1 DuckDuckGo search, error handling, and time management	#2 DuckDuckGo search, error handling, and time management	`SKILL.md` (+29/-13), `scripts/ddg_search.sh` (+25/-0), `scripts/web_search.sh` (+25/-7), `scripts/wiki_page.sh` (+15/-3), `scripts/wiki_search.sh` (+15/-3), `scripts/wiki_section.sh` (+39/-9), `scripts/wikidata_lookup.sh` (+52/-0)
2	#3 real web search, script fixes, write-early strategy	#4 real web search, script fixes, write-early strategy	`SKILL.md` (+33/-48), `scripts/ddg_search.py` (+53/-0), `scripts/fetch_url_jina.sh` (+25/-0), `scripts/web_search.sh` (+6/-6), `scripts/wiki_page.sh` (+3/-3), `scripts/wiki_search.sh` (+3/-3), `scripts/wiki_section.sh` (+7/-7)
3	#11 merge best of iter1 and iter2 with lighter verification and stricter budget	#12 merge best of iter1 and iter2	`SKILL.md` (+33/-40)
4	#15 name-format issue and tighter budget	#16 name-format rules and Wikidata SPARQL	`SKILL.md` (+13/-6), `scripts/wikidata_sparql.py` (+59/-0)
5	#19 revert budget to 20 while keeping name rules and SPARQL	#21 revert budget to 20, keep name rules and SPARQL	`SKILL.md` (+45/-46)

Table 4: Repository workflow records for one deep-research skill run. Line counts aggregate the changed files in the PRs listed for each iteration.

two regressed revisions through targeted follow-up edits. Hermes-SE instead accepts or skips whole prompt candidates under a scalar validation signal. This illustrates the operational value of persistent decision history: later revisions can target the offending part of a change while retaining useful edits.

D Optimization Cost and Efficiency

Table 5 compares the development cost and cost efficiency of Hermes-SE and SkillHone. Gain over Skill-Creator is the mean of the GAIA and WebWalkerQA-EN benchmark-average improvements; gain per dollar divides this mean by total cost, and cost per gain point is its reciprocal. SkillHone obtains a larger average gain with fewer model calls and fewer output tokens, while using substantially more input tokens.

Metric	Hermes-SE	SkillHone
Gain and cost efficiency		
Gain over Skill-Creator	+10.6	**+24.4**
Gain per dollar	0.420	**0.845**
Cost per gain point	2.38	**1.18**
Development resources		
Development cost	25.22	28.89
Model calls	690	627
Input tokens	1.48M	39.9M
Output tokens	0.78M	0.21M

Table 5: Development cost and efficiency of Hermes-SE and SkillHone. Gain is measured in percentage points (pp), gain per dollar in pp/USD, cost per gain point in USD/pp, and development cost in USD. Bold marks the better gain or cost-efficiency value; raw resource usage is not ranked.

E Evaluation Repository and Redaction

SkillHone uses a skill-evaluation repository for practice feedback during skill development. The repository stores probe task instances, oracle targets, validators, provenance metadata, and execution traces. Probe items may come from existing sources such as human-written cases, historical failures, or environment-derived checks. It only assumes that evaluation subagents can run the current skill against available probe items and export redacted reports to the optimization side.

For each probe item, we denote the task instance by x_k, the oracle target by y_k, the validator by ϕ_k, and the provenance metadata by π_k. Running the current skill produces

$$m_k = \phi_k(A(x_k; S_t), y_k),$$

where m_k is the validation outcome. The optimization side receives only a redacted problem report

$$\tilde{E}_t = \mathrm{Redact}(\{x_k, y_k, \phi_k, \pi_k, m_k\}_{k=1}^{K}),$$

which summarizes failure modes, aggregate outcomes, and diagnostic hypotheses without expos-

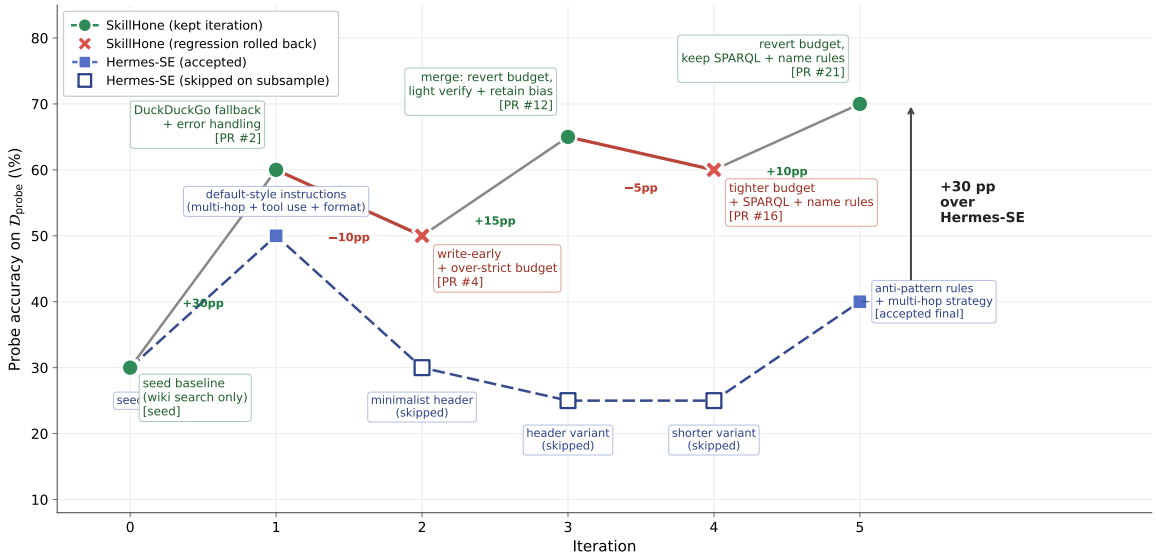

Figure 4: Probe accuracy trajectories for SkillHone and Hermes-SE across five optimization iterations starting from a shared seed skill. SkillHone points are labeled with the accepted revision that introduced each change. When a change regresses performance, the following iteration can target the offending part while preserving useful edits. Hermes-SE optimizes a single `SKILL.md` body and accepts or rejects whole candidates under a scalar validation signal. The final benchmarks are not available to either system during optimization.

ing unredacted targets, validators, or traces. Final benchmark evaluation remains outside the optimization loop.

F Subagent Dispatch Patterns and Permissions

The roles in Table 6 are not fixed identities that SkillHone preconfigures in advance. They are recurring dispatch patterns observed when the runtime dispatcher runs the development loop. Each subagent is created on demand, assigned to a permission-bounded team, and granted only the actions needed for that dispatch.

The team boundary is the structural mechanism. Optimization subagents can write to the skill repository but cannot access unredacted probe targets, validators, or traces. Evaluation subagents can inspect probes and traces but cannot write to the skill repository. The runtime dispatcher creates subagents and routes artifacts, but it does not directly edit either repository.

G Deployment Evaluation Protocol

Each scenario in Table 3 is a recurring tool-mediated analysis task. The per-scenario evaluation set consists of representative de-identified requests, with reference answers produced by LLM annotation and verified by human annotators; disagreements are resolved on review. Accuracy is exact-match against the verified reference. The seeded and SkillHone-optimized skills run on the same fixed evaluation set under identical runtime configuration, so the reported Δ reflects skill-level changes rather than evaluation-set drift.

Team	Dispatch pattern	Permission boundary
Optimization	Proposer	Reads redacted reports $\tilde{E}_{<t}$ and decision history $\mathcal{H}_{<t}$; writes diagnoses; no access to probe targets or validators.
Optimization	Explorer	Searches external resources for reusable patterns when a revision needs them; no access to probe targets or validators.
Optimization	Developer	Edits S_t and proposes typed revisions; no access to unredacted evaluation assets.
Optimization	Reviewer	Reviews pending skill changes using redacted evidence and prior decision records; no access to probe targets or validators.
Optimization	Decider	Accepts or rejects candidate revisions according to recorded evidence; no access to unredacted evaluation assets.
Evaluation	Executor	Runs $A(\cdot; S_t)$ on probe items; may inspect oracle targets, validators, and traces; no skill-repository write access.
Evaluation	Diagnoser	Analyzes outcomes and traces; updates evaluation diagnostics; no skill-repository write access.
Evaluation	Reporter	Produces redacted problem reports $\tilde{E}_t$ for the optimization side; no revision-decision authority.
Evaluation	Auditor	Checks probe metadata, traces, and redacted reports for evaluation-side consistency; no skill-repository write access.
Runtime	Dispatcher	Creates subagents and routes artifacts between repositories; no direct skill edits and no access to unredacted probe targets.

Table 6: Recurring subagent dispatch patterns in SkillHone. The role column describes the function performed by a dispatched subagent, while the team column defines its permission boundary. This separation makes the optimizer and evaluator split structural rather than prompt-imposed.

GRAM-V2: Generative Reasoning and Ranking Alignment for Large-Scale E-commerce Search

Abstract

Click-through prediction is a critical task for e-commerce advertising systems. However, industrial ranking models still rely on sparse IDs and historical behavior signals, which limits their generalization to cold-start products, long-tail queries, and complex user intents. Although large language models (LLMs) provide strong semantic understanding and can generate behavioral rationales, directly using them for online ranking is impractical under strict latency constraints.

We propose GRAM-V2, a rationale-supervised ranking framework that transfers LLM-generated behavioral rationales into an efficient CTR model. GRAM-V2 uses a Teacher LLM to generate click-oriented rationales, distills them into a lightweight Student LLM, and aligns a two-tower CTR model with the Student's representations and rationale signals. During online serving, GRAM-V2 uses only distilled representations and cached item embeddings, without generating rationales autoregressively. Large-scale offline experiments and online A/B testing show that GRAM-V2 improves CTR prediction accuracy, CTR, and advertising revenue while satisfying production latency constraints.

1 Introduction

CTR prediction is a critical component of e-commerce search advertising. Given a user, a query, and a candidate product, the ranking system must accurately estimate user engagement under strict latency constraints. Existing CTR models primarily rely on sparse IDs, statistical features, and historical behaviors (Rendle, 2010; Guo et al., 2017; Lian et al., 2018; Zhou et al., 2018). Although effective in large-scale systems, their dependence on ID-based interaction patterns limits their ability to capture fine-grained semantics, especially for cold-start products, long-tail queries, and complex user intents.

LLMs provide strong semantic understanding and have recently been explored as feature extractors, semantic encoders, and generative recommenders for recommendation and ranking (Li et al., 2023; Lian et al., 2025; Rajput et al., 2023). However, directly applying LLMs to industrial CTR prediction remains challenging. First, generic LLM representations are not explicitly optimized for click prediction and may be misaligned with ranking objectives. Second, autoregressive reasoning introduces substantial computational overhead and is impractical for high-throughput online serving. In addition, generated rationales may appear semantically plausible without necessarily providing useful supervision for CTR prediction.

To address these challenges, GRAM-V2 extends GRAM's query–item code alignment (Pang et al., 2025) from generative retrieval to generative ranking, distilling LLM-generated rationales into an efficient ranker. Specifically, GRAM-V2 follows a Teacher–Student–Ranker pipeline: a Teacher LLM generates click-oriented rationales from user, query, and item contexts, a lightweight Student LLM distills these rationales, and a two-tower CTR model learns from the Student's semantic and rationale signals. During online serving, GRAM-V2 does not generate rationales autoregressively but uses the trained two-tower encoder and cached item embeddings for efficient ranking.

We evaluate GRAM-V2 on large-scale e-commerce advertising logs and real-world online traffic. GRAM-V2 consistently outperforms both traditional and LLM-enhanced CTR baselines, while delivering improvements in online CTR and advertising revenue within the production latency budget. Extensive analyses of rationale quality, model ablations, grouped AUC, and serving efficiency further demonstrate the effectiveness and deployment practicality of the proposed framework.

Our contributions are summarized as follows:

- We propose GRAM-V2, a rationale-supervised CTR prediction framework that leverages LLM-generated behavioral rationales as training-time supervision for industrial ranking.
- We design a Teacher–Student–Ranker framework that transfers semantic and reasoning signals into an efficient two-tower CTR model without introducing autoregressive generation during online serving.
- We conduct large-scale offline and online evaluations, together with comprehensive analyses of rationale quality, alignment objectives, grouped ranking performance, and serving efficiency, demonstrating the effectiveness and practicality of GRAM-V2.

2 Related Work

2.1 CTR Prediction Models

CTR prediction has been widely studied in industrial ranking systems. Early methods, such as Factorization Machines (Rendle, 2010; Juan et al., 2017), model feature interactions over sparse categorical features, including queries, users, and item categories (Yuan et al., 2023, 2024). Deep CTR models further improve interaction modeling through neural architectures. DeepFM (Guo et al., 2017) and xDeepFM (Lian et al., 2018) capture explicit and implicit high-order feature interactions, while DIN (Zhou et al., 2018) and DIEN (Zhou et al., 2019) model dynamic user interests from historical behaviors with attention mechanisms. These methods are effective and efficient for online serving, but they still rely heavily on sparse IDs and historical interaction patterns, which limits their ability to capture fine-grained semantic relations between user intent and item attributes.

2.2 LLMs for Recommendation and Ranking

Recent studies have introduced LLMs into recommendation and ranking tasks. One line of work uses LLMs as semantic encoders or feature generators to enrich conventional recommendation models with text-based representations (Li et al., 2023; Liu et al., 2025a; Lian et al., 2025). Another line formulates recommendation and retrieval as generative tasks, where models directly generate item identifiers, retrieval codes, or bidwords (Rajput et al., 2023; Deng et al., 2025; Chen et al., 2025; Pang et al., 2025; Liu et al., 2025b). Field Matters (Cui et al., 2026) further explores a lightweight LLM-enhanced CTR framework with field-level semantic modeling. Although these approaches improve semantic understanding, they typically use LLM outputs as auxiliary features or introduce generative components that can increase serving complexity and latency.

Different from these works, GRAM-V2 transfers reasoning and semantic knowledge from a GRPO-optimized Teacher and a compact Student to a two-tower ranker during training. The Teacher provides click-oriented rationale supervision, while the Student bridges rich reasoning signals and the lightweight ranking model. During serving, the Student supervision path, rationale decoder, and alignment modules are removed, avoiding autoregressive generation while preserving the efficiency of the original ranking architecture.

3 Model

3.1 Overview

As shown in Figure 1, GRAM-V2 consists of two phases. In Phase I, an offline Qwen3-32B Teacher is optimized via reinforcement learning to generate task-relevant behavioral rationales, which are subsequently distilled into a Qwen2.5-0.5B Student for high-throughput supervision. In Phase II, the frozen Student provides semantic and rationale signals to train a separate two-tower CTR model. During online serving, GRAM-V2 uses only the trained two-tower encoder, cached item embeddings, and interaction heads, without autoregressive rationale generation.

3.2 Prompt Definition

3.2.1 One-Tower User Prompt

For rationale generation, we construct a one-tower prompt with the user profile, recent queries, clicked products, current query, and candidate product. This complete user-query-item prompt is denoted as $Pmpt_{uqs}$.

3.2.2 Two-Tower User Prompt

For online CTR serving, the user-query side and item side are encoded separately. The user-query prompt contains the user profile, historical behaviors, and current query, but excludes the candidate product. We denote it as $Pmpt_{uq}$.

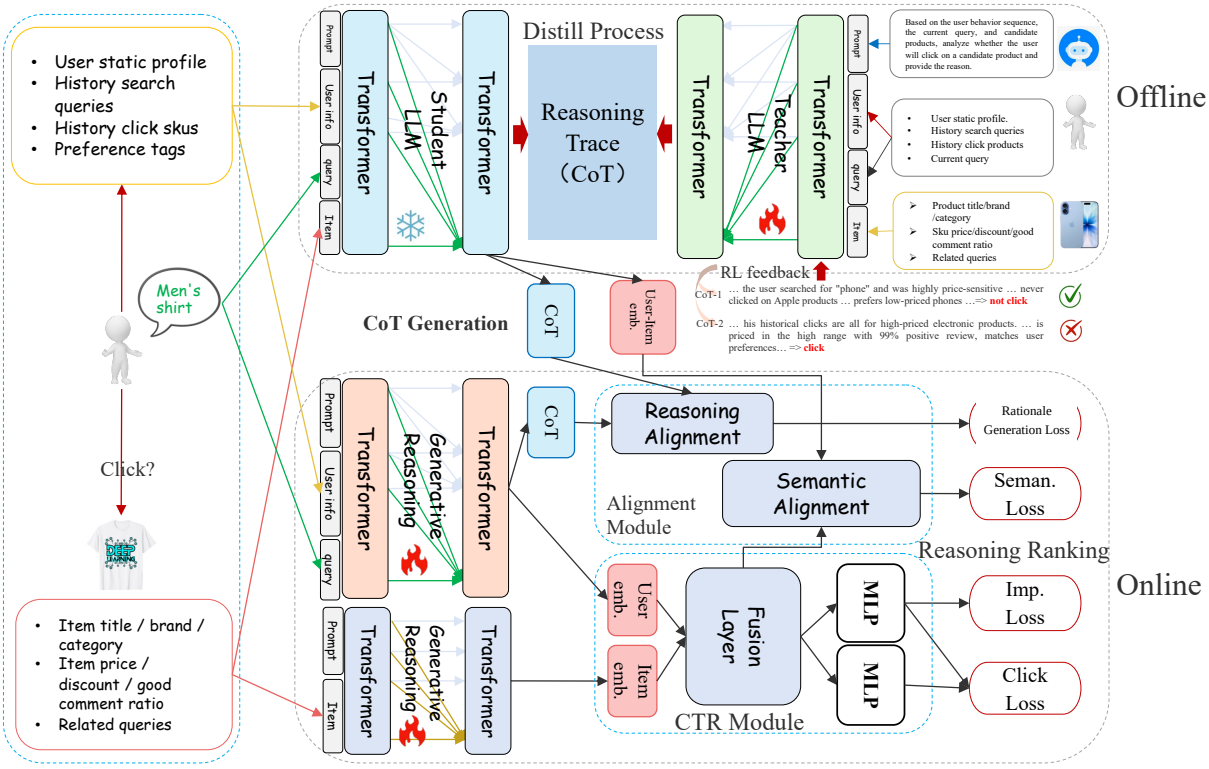

Figure 1: The architecture of GRAM-V2 for rationale-supervised CTR prediction. The rationale generation and semantic alignment losses are used only during training.

3.2.3 Item Prompt

The item prompt contains product-side information, such as title, category, brand, price, discount, rating, and other attributes. We denote it as $Pmpt_s$. Since product information changes relatively slowly, item representations are precomputed offline and cached for online serving.

3.3 Phase I: Generative Reasoning Training

Phase I aims to obtain task-relevant rationale supervision. We first optimize a large Teacher LLM to generate rationales consistent with observed user feedback and then distill its rationale generation ability into a lightweight Student LLM for large-scale CTR training.

3.3.1 Teacher LLM Training

The Teacher is an open-source Qwen3-32B model used only offline. Given the one-tower prompt, it generates a rationale and a click prediction. For the same prompt, the model samples multiple candidate responses:

$$a_i = (c_i, \hat{y}_i), \quad i = 1, 2, \ldots, G, \tag{1}$$

where c_i denotes the generated rationale, $\hat{y}_i$ denotes the predicted click label, and G is the number of sampled responses.

The response is sampled from the Teacher policy $a_i \sim \pi_\theta(\cdot \mid Pmpt_{uqs})$. To guide the Teacher toward useful rationale generation, we define a reward that considers both prediction correctness and response format:

$$R_i = r_{\text{reason}}(a_i) + \mathbb{I}(\hat{y}_i = y). \tag{2}$$

Here, y is the ground-truth click label, and $\mathbb{I}(\cdot)$ is the indicator function. The format reward $r_{\text{reason}}(a_i)$ is $+0.1$ when the response contains a valid analysis field and a parseable prediction, and -0.1 otherwise. The correctness term is 1 for a correct prediction and 0 otherwise. This reward encourages prediction-consistent and well-formed rationales.

Following GRPO (Shao et al., 2024), we normalize the rewards within each response group to obtain the advantage:

$$\hat{A}_i = \frac{R_i - \text{mean}(R_1, \ldots, R_G)}{\text{std}(R_1, \ldots, R_G) + \epsilon_{\text{norm}}}. \tag{3}$$

Our implementation follows the token-level GRPO formulation. For token $a_{i,t}$ in response a_i, the policy ratio is

$$\rho_{i,t}(\theta) = \frac{\pi_\theta(a_{i,t} \mid Pmpt_{uqs}, a_{i,<t})}{\pi_{\text{old}}(a_{i,t} \mid Pmpt_{uqs}, a_{i,<t})}. \tag{4}$$

The clipped surrogate objective averages the token-level terms in each response:

$$\bar{\rho}_{i,t}(\theta) = \mathrm{clip}(\rho_{i,t}(\theta), 1-\epsilon, 1+\epsilon),$$
$$\ell_i(\theta) = \frac{1}{T_i}\sum_{t=1}^{T_i} \min\left(\rho_{i,t}(\theta)\hat{A}_i, \bar{\rho}_{i,t}(\theta)\hat{A}_i\right). \tag{5}$$

The Teacher LLM is trained by minimizing the following GRPO loss:

$$\mathcal{L}_{\mathrm{GRPO}}(\theta) = -\frac{1}{G}\sum_{i=1}^{G} \ell_i(\theta) + \beta_{\mathrm{KL}} D_{\mathrm{KL}}\left(\pi_\theta \| \pi_{\mathrm{ref}}\right). \tag{6}$$

We use $G = 8$, $\epsilon = 0.2$, $\beta_{\mathrm{KL}} = 0.01$, and $\epsilon_{\mathrm{norm}} = 10^{-8}$. The KL term constrains the optimized policy to stay close to the reference model, which helps stabilize training and reduce degenerate rationale generation. We do not use class-balanced sampling for the GRPO stage; Section 4.4 reports diagnostics for the resulting class behavior.

3.3.2 Student LLM Distillation

Although the Teacher LLM can generate stronger rationales, using it to process all CTR training samples is computationally expensive. Therefore, we distill the Teacher into a Qwen2.5-0.5B Student. The Student uses the same one-tower prompt and learns to reproduce the Teacher-generated rationale.

Let the teacher-generated rationale be $c = [c_1, c_2, \ldots, c_{L_c}]$. The Student is optimized on the distilled dataset $\mathcal{D}_{\mathrm{SFT}}$ using the standard negative log-likelihood objective:

$$\mathcal{L}_{\mathrm{SFT}} = -\sum_{i=1}^{L_c} \log P_\theta(c_i \mid Pmpt_{uqs}, c_{<i}). \tag{7}$$

After distillation, the Student LLM is frozen and used to provide supervision for the CTR model, including the hidden representation of the one-tower prompt and the generated rationale sequence.

3.4 Phase II: Reasoning and Ranking Alignment

Phase II transfers the Student's semantic and rationale signals into a deployable CTR model. The motivation is that the Student observes complete user-query-item context, while the online CTR model must encode user-query and item information separately. Therefore, we align the two-tower CTR representation with the Student's one-tower representation and the rationale generation signal.

3.4.1 CTR Prediction Module

The CTR model encodes the user-query prompt and item prompt separately:

$$\mathbf{U} = \mathbf{LLM}_{ctr}(Pmpt_{uq}) \in \mathbb{R}^{L_u \times d},$$
$$\mathbf{S} = \mathbf{LLM}_{ctr}(Pmpt_s) \in \mathbb{R}^{L_s \times d}, \tag{8}$$

where L_u and L_s denote the lengths of $Pmpt_{uq}$ and $Pmpt_s$, respectively, and d is the embedding dimension. $\mathbf{LLM}_{ctr}$ is a separate Qwen2.5-0.5B copy initialized from the Student checkpoint and fine-tuned in Phase II. The user-query and item towers share encoder parameters; item representations are precomputed and cached.

We apply mean pooling to obtain fixed-length vectors:

$$\mathbf{u} = \mathrm{mean}(\mathbf{U}), \quad \mathbf{s} = \mathrm{mean}(\mathbf{S}),$$
$$\mathbf{F} = [\mathbf{u}; \mathbf{s}; |\mathbf{u} - \mathbf{s}|; \mathbf{u} \odot \mathbf{s}] \tag{9}$$

where $\odot$ is the Hadamard product. $\mathbf{F} \in \mathbb{R}^{4d}$ encodes the similarity, relevance, and affinity between the intent of the user and the characteristics of the item.

We then employ multi-task MLP heads to jointly predict impression and click probabilities, denoted as $f_{imp}(\mathbf{F})$ and $f_{ctr}(\mathbf{F})$ respectively. The framework is optimized via joint cross-entropy losses:

$$\mathcal{L}_{imp} = \mathrm{CE}(y_{imp}, f_{imp}(\mathbf{F})),$$
$$\mathcal{L}_{ctr} = y_{imp} \cdot \mathrm{CE}(y_{ctr}, f_{ctr}(\mathbf{F})), \tag{10}$$

where $\mathrm{CE}(y, p) = -[y \log p + (1-y)\log(1-p)]$, and $y_{imp}, y_{ctr} \in \{0, 1\}$ denote the impression and click labels, respectively. The impression loss is averaged over all candidates, while the click loss is averaged over exposed samples.

3.4.2 Semantic and Reasoning Alignment

Semantic alignment transfers the Student's complete-context representation into the two-tower CTR model. The Student LLM observes $Pmpt_{uqs}$ and captures the joint semantics of user profile, query, and candidate product, while the CTR model encodes user-query and item prompts separately for online serving. To reduce this gap, we align the item-aware two-tower interaction representation with the Student representation:

$$\mathbf{H} = \mathbf{LLM}_{stu}(Pmpt_{uqs}),$$
$$\mathbf{h} = \mathrm{mean}(\mathbf{H}),$$
$$\mathcal{L}_{\mathrm{sem}} = \min_{\mathbf{W}} \|\mathbf{W}^T[\mathbf{u}; \mathbf{s}] - \mathrm{sg}(\mathbf{h})\|_2^2 \tag{11}$$

where $\mathbf{W} \in \mathbb{R}^{2d \times d}$ and $\mathrm{sg}(\cdot)$ denotes stop-gradient. The Student is frozen, so $\mathcal{L}_{\text{sem}}$ updates the CTR encoder and projection layer $\mathbf{W}$ but not the Student. This objective transfers complete-context semantic information while keeping two-tower online inference efficient.

In addition to semantic alignment, we use rationale generation as an auxiliary training signal. Rather than reconstructing rationales from the user-query tower alone, we condition a training-only decoder on the two-tower representation. Specifically, the decoder takes the user-query representation and the target item representation as auxiliary context: $\mathbf{x} = [\mathbf{u}; \mathbf{s}]$. The rationale generation objective is defined as:

$$P_\theta(c_i \mid \mathbf{x}, c_{<i}) = \mathrm{Decode}_\theta(c_i \mid \mathbf{x}, c_{<i}),$$
$$\mathcal{L}_{\text{reason}} = -\sum_{i=1}^{L_c} \log P_\theta(c_i \mid \mathbf{x}, c_{<i}), \tag{12}$$

where c is the Student-generated rationale. The decoder is used only during offline training and is removed during online inference. Therefore, reasoning alignment introduces no autoregressive decoding latency during live ranking.

3.4.3 Overall Objective

Finally, the total training objective is defined as a multi-task loss function:

$$\mathcal{L} = \mathcal{L}_{imp} + \mathcal{L}_{ctr} + \alpha \mathcal{L}_{\text{sem}} + \beta \mathcal{L}_{\text{reason}}, \tag{13}$$

where α and β are hyperparameters that balance the contribution of semantic and reasoning alignment, respectively. This joint objective transfers semantic and rationale supervision from the Student LLM into the CTR model while maintaining low-latency inference for online ranking.

4 Experiments

4.1 Dataset

We evaluate GRAM-V2 on two large-scale datasets collected from a real-world e-commerce advertising platform (see Table 1). The **SFT dataset** is used for Teacher warm-up and Student distillation. The **CTR dataset** consists of seven days of impression logs, augmented with 20% randomly sampled non-exposed candidates exclusively as negative samples for the impression task to alleviate exposure bias. For CTR training, rationales are generated offline by the frozen Student LLM and used as static training-time supervision.

Table 1: Dataset statistics.

Statistics	SFT Data	CTR Data
# User-Query Pairs	3.5M	257M
# User-Product Pairs	1.28M	361M
# Uniq. Users	0.83M	35M
# Uniq. Products	0.84M	142M
Avg. # chars of query	8.0	7.0
Avg. # chars of rationale	503	510

Table 1 counts distinct pairs. The SFT data are constructed from purchase logs with clicked and non-clicked candidate sampling. One product can correspond to multiple queries, which results in more user-query pairs than user-product pairs. The CTR data come directly from impression and click logs, where one user-query request can expose multiple products; hence, the CTR data contain more user-product pairs than user-query pairs.

To prevent information leakage, dynamic features (e.g., historical CTR, conversion rate, and price) are computed strictly before the prediction timestamp. We split the CTR dataset chronologically, using the first six days for training/validation and the final day for testing.

4.2 Baseline Models

We compare GRAM-V2 with representative CTR prediction baselines, including traditional and deep CTR models, i.e., DCN (Wang et al., 2017), DeepFM (Guo et al., 2017), DIN (Zhou et al., 2018), and BERT4CTR (Wang et al., 2023), as well as recent LLM-enhanced CTR models, i.e., EGRec (Lian et al., 2025), SCTR (Chang et al., 2025), and MSD (Zhang et al., 2025). All models access the same raw feature sources, including the available textual attributes, but their representation mechanisms differ by architecture. We therefore treat comparisons with external baselines as end-to-end system comparisons. The w/o RA & SA variant retains the same raw inputs, two-tower backbone, interaction module, and optimization setting as GRAM-V2, and provides the controlled comparison for the two alignment objectives.

4.3 Evaluation Metrics

Following prior CTR prediction studies (Lian et al., 2025; Yu et al., 2025), we use AUC and LogLoss as the main metrics to evaluate ranking ability and probability calibration. We also report MAE and RMSE to measure prediction error. To assess rank-

ing within serving-relevant groups, we additionally report User-GAUC and Query-GAUC. We include only groups containing both click labels and weight each group AUC by its impression count.

4.4 Experiment Settings

All models are implemented in PyTorch. The Teacher is Qwen3-32B, the frozen Student is Qwen2.5-0.5B, and $\mathbf{LLM}_{ctr}$ is a separate Qwen2.5-0.5B copy initialized from the Student checkpoint. We train the CTR network for up to 3 epochs using AdamW with a batch size of 128 and a dropout of 0.05. The base learning rate is 5×10^{-5} for LLM layers and 1×10^{-3} for MLP heads, optimized via a linear warmup (first 10% steps) and cosine annealing. Maximum query and rationale lengths are capped at 16 and 512 tokens. Alignment weights are set to $\alpha = \beta = 1$ based on validation performance. Offline LLM inference is accelerated via TensorRT, and the best checkpoints are selected based on validation performance.

For the GRPO validation split, the ground-truth and predicted click rates are 6.2% and 8.5%, with positive- and negative-class recalls of 71.0% and 95.6%. These diagnostics indicate that the policy does not collapse to an always-negative predictor, although class-imbalance bias remains possible.

4.5 Offline Evaluation

4.5.1 Offline Performance

Table 2 compares GRAM-V2 with representative CTR baselines. Traditional ID-based models (DCN, DeepFM, DIN) mainly rely on sparse feature interactions, while BERT4CTR introduces textual representations. Recent LLM-enhanced methods such as EGRec, SCTR, and MSD further incorporate contextual semantics, but do not explicitly align reasoning signals with CTR prediction. GRAM-V2 achieves the best performance across all metrics, improving AUC from 0.8341 to 0.8436 over the strongest baseline, EGRec. To isolate the contribution of the proposed alignment objectives, we further compare against the matched w/o RA & SA variant, which uses the same two-tower backbone and inputs. Under this controlled setting, jointly applying reasoning and semantic alignment improves AUC from 0.8361 to 0.8436.

The ablation results further validate each component. Removing Reasoning Alignment or Semantic Alignment decreases AUC to 0.8401 and 0.8385, respectively, indicating that the two objectives provide complementary supervision. Replacing the GRPO-trained Teacher with an SFT Teacher also reduces AUC to 0.8412, showing the benefit of reward-optimized rationale supervision. Since all results are based on single runs, the relatively small differences among ablation variants should be interpreted as directional rather than statistically significant.

Table 2: Offline performance comparison with CTR baselines and ablation variants.

Models	AUC	LogLoss	MAE	RMSE
DCN	0.8142	0.7084	0.5508	0.5514
DeepFM	0.8185	0.7016	0.5487	0.5497
BERT4CTR	0.8306	0.6715	0.5456	0.5438
DIN	0.8317	0.6698	0.5491	0.5467
EGRec	0.8341	0.6764	0.5374	0.5341
SCTR	0.8281	0.6851	0.5418	0.5393
MSD	0.8224	0.6916	0.5382	0.5354
GRAM-V2	**0.8436**	**0.6529**	**0.5341**	**0.5315**
w/o GRPO	0.8412	0.6579	0.5362	0.5330
w/o RA	0.8401	0.6582	0.5369	0.5325
w/o SA	0.8385	0.6615	0.5392	0.5346
w/o RA & SA	0.8361	0.6627	0.5415	0.5393

Table 3: Grouped AUC on the chronological test set. Group AUCs are weighted by impression count.

Model	User-GAUC	Query-GAUC
EGRec	0.8043	0.7951
w/o RA & SA	0.8057	0.7982
GRAM-V2	**0.8132**	**0.8051**

As shown in Table 3, GRAM-V2 improves User-GAUC and Query-GAUC over the matched w/o RA & SA model by 0.0075 and 0.0069, respectively. The improvements therefore also hold within users and queries rather than arising only from separation between easy and difficult groups.

4.6 Rationale Quality Analysis

We conduct a human evaluation on 500 randomly sampled test instances. Three domain annotators, blind to system identity, rate each generated rationale on a 1–5 ordinal scale for relevance, factuality, and consistency. Student SFT denotes the student distilled without reward-driven refinement, while GRAM-V2 denotes the student distilled from the GRPO-optimized Teacher. Ordinal Krippendorff's α is 0.72, 0.67, and 0.74 for relevance, factuality, and consistency, respectively.

Table 4: Human evaluation of generated rationales. Scores are averaged over three annotators on a 1–5 scale.

Method	Relevance	Factuality	Consistency
Student SFT	4.12	4.05	4.08
GRAM-V2	4.43	4.31	4.36

As shown in Table 4, GRAM-V2 achieves higher scores across all dimensions, showing that reward-driven refinement improves rationale quality. We also observe failure cases in sparse-history, impulsive-click, and ambiguous-query scenarios. For example, for a broad query such as "gift", the rationale may focus on a single recipient or occasion while overlooking other plausible intents. Therefore, rationales are used as auxiliary training-time supervision rather than hard decision rules.

4.7 Online Evaluation

4.7.1 Online Deployment

In online serving, GRAM-V2 removes the Student supervision path, rationale decoder, and alignment modules used during training. Item embeddings are precomputed and retrieved from cache, while only the user-query representation and interaction scoring are computed online. Therefore, rationale and semantic alignment are used only as offline training signals, without introducing autoregressive generation latency.

4.7.2 Online Performance

We conduct a nine-day A/B test on an online e-commerce advertising platform. GRAM-V2 serves 5% of live traffic, and the control group of the same size uses the previous production model. Traffic is randomly split at the user level, with the same retrieval, auction, and budget settings. Significance for the full-model treatment is evaluated with a two-sided user-level bootstrap test. We report relative improvements in Impressions (Imp.), CTR, CPC, and Ad Revenue.

Table 5: Relative online improvements over the production model.

Models	Imp.	CTR	CPC	Ad Rev.
Online	-	-	-	-
GRAM-V2	+0.35%	+0.56%	+0.19%	+1.10%
w/o RA	+0.11%	+0.36%	+0.04%	+0.52%
w/o SA	+0.24%	+0.20%	+0.15%	+0.58%

As shown in Table 5, GRAM-V2 improves CTR by 0.56% and advertising revenue by 1.10% over the production model; these two full-model gains satisfy $p < 0.05$ under the user-level bootstrap test. For online ablation, each variant removes the corresponding offline alignment objective while using the same serving architecture. The directional drops of w/o RA and w/o SA are consistent with the offline ablations. The revenue gain is not solely CTR-driven. Impressions, CTR, and CPC increase by 0.35%, 0.56%, and 0.19%, respectively, whose multiplicative combination is approximately the reported 1.10% revenue gain.

4.7.3 Latency and Update Cost

Table 6 reports the deployment cost of GRAM-V2. In online serving, item embeddings are retrieved from cache, and only user-query encoding and lightweight interaction scoring are computed in real time. GRAM-V2 sustains a throughput of more than 7,600 QPS with a P99 latency of 43.2 ms, within the 50 ms production latency budget. Expensive LLM-related modules are updated offline and less frequently, while CTR alignment and item embeddings are updated daily to capture recent user behavior and product changes.

Table 6: Deployment efficiency and update cost of GRAM-V2.

Component	Use	Latency	Update
Online Model	Online	25.8 ms	-
GRAM-V2	Online	43.2 ms	-
Teacher LLM	Offline	-	Bi-weekly / 3 days
Student LLM	Offline	-	Weekly / 38 hours
CTR Training	Offline	-	Daily / 15 hours
Item Emb.	Cached	-	Daily / 5 hours

5 Conclusion and Future Work

We have presented GRAM-V2, a rationale-supervised CTR prediction framework for large-scale e-commerce search advertising. GRAM-V2 distills click-oriented rationales from an offline Teacher into a lightweight Student and transfers semantic and rationale signals into an efficient two-tower CTR model. Controlled offline comparisons, grouped AUC, and online A/B testing show improvements in CTR prediction and production metrics under the serving latency budget.

Future work will explore multimodal product understanding, more adaptive update strategies, and the accuracy-cost frontier across Student model sizes.

Limitations

Despite its effectiveness, GRAM-V2 has three main limitations. First, while distilling knowledge into a lightweight student model ensures low online latency, the offline training cost of the GRPO-optimized Teacher remains high. Second, in extreme cold-start or sparse-history scenarios, the generated rationales occasionally degenerate and over-explain noisy behaviors. Finally, unlike deterministic math tasks, defining a "correct" shopping rationale is inherently subjective, making automated alignment evaluation challenging.

Ethical Considerations

We follow the ACL Code of Ethics. All evaluation datasets consist of anonymized behavior logs with all Personally Identifiable Information (PII) removed to protect user privacy. To reduce potential biases inherited from pretrained LLMs, GRAM-V2 utilizes the generated rationales strictly as soft training-time auxiliary supervision rather than deterministic online routing rules, preventing stereotype amplification. Additionally, all domain annotators were fairly compensated according to local standards.

A Reproducibility Details

A.1 Baseline Models

We compare GRAM-V2 with several representative CTR models. All baselines use the same available raw feature sources, while their encoders and interaction mechanisms follow their respective architectures.

(1) Traditional and deep learning-based CTR models:

- DCN (Wang et al., 2017): It combines a deep network with a cross-network layer to model explicit and implicit feature interactions.
- DIN (Zhou et al., 2018): It uses attention over user behavior sequences to model target-related interests.
- DeepFM (Guo et al., 2017): It combines factorization machines with a deep network for feature interaction modeling.
- BERT4CTR (Wang et al., 2023): It integrates pretrained language representations with non-textual features for CTR prediction.

(2) LLM-based CTR models:

- EGRec (Lian et al., 2025): It uses LLMs to generate user-intent representations for recommendation.
- SCTR (Chang et al., 2025): It uses an LLM to model individual user behavior for CTR prediction.
- MSD (Zhang et al., 2025): It combines LLM-derived signals with a CTR model to balance computation and predictive accuracy.

A.2 Prompt Templates

To support reproducibility, Figures 2–4 show the prompt templates used by GRAM-V2. The one-tower user prompt ($Pmpt_{uqs}$) concatenates the user profile, recent queries, clicked products, current query, and candidate product, and is used for rationale generation and Student distillation.

1-Tower User Prompt

The user's information:
The following user profile is known: xxx
The user's 30 most recent historical queries: 1: xxx 2: xxx …
The user's 30 historical clicked products: 1: xxx 2: xxx …
The current search query: xxx

Abstract

Although Large Language Models (LLMs) offer significant advantages for creative tasks like game narrative design, their application remains largely confined to academic exploration. Existing methods often fail to integrate with specific game assets, production constraints, and iterative workflows essential for industrial development, limiting real deployment in professional studios. To bridge this gap, we present D2GS, a data-centric framework for LLM-based game script generation designed for industry. D2GS supports narrative designers end-to-end, from ideation to engine-ready scripts. It grounds creation in multi-source, game-specific data and mimics human iterative refinement. The framework includes four modules: (1) knowledge augmentation for multi-source data preparation; (2) logline and plot outline generation with a critic-feedback revision loop; (3) character and world enrichment using role-assigned LLM agents to simulate interactions; and (4) script rephrasing to ensure game-engine compatibility. Experiments show D2GS outperforms strong baselines in coherence, relevance, creativity, and overall writing quality, while staying faithful to predefined settings and assets. Industrial-scale validation further confirms its practicality for real-world narrative design pipelines.

1 Introduction

Game script generation remains a labor-intensive, expertise-heavy pipeline. Studios still rely on humans to ideate storylines, draft plots, revise dialog, and then align the final script with concrete game assets before it can run in-engine, shuttling between creative documents and production tools to reconcile character arcs with branching logic and wire text to sprites, backgrounds, animations, and audio cues. A game script is more than dialog: it interleaves conversation and narration with expressions, camera directions, and fine-grained event commands that bind text to assets. Unlike conventional screenplays written for human production, game scripts must be executable by the engine, which makes them a central development artifact. Large language models (LLMs) can accelerate ideation and drafting (Li et al., 2024; Tian et al., 2024), but industrial-grade game script generation remains challenging. First, generation must be grounded in game-specific information scattered across heterogeneous sources (design docs, tables, images, legacy scripts, asset catalogs) whose integration and normalization are nontrivial (Hu et al., 2024; Jeong and Lee, 2025). Second, most prior work covers only fragments of the pipeline, e.g., story generation from simplified premises or script writing without upstream planning or downstream asset configuration (Ran et al., 2025; Yang et al., 2023), and rarely models game-specific characters and worldview explicitly, instead inheriting settings from novels (Lin et al., 2025; Ran et al., 2025; Chen et al., 2024) or inventing them freely (Yang et al., 2023, 2022), which misaligns outputs with real game constraints and forces manual rework. Finally, direct generation or unconstrained role-play tends to produce inconsistency, bland dialog, and violations of character and world rules. To address these gaps, we present D2GS, a data-centric framework that turns creative intent into engine-ready game scripts. Our contributions are:

- We propose the first framework that grounds LLM-based script generation in multi-source, game-specific data, turning professional planning inputs (genre, themes, characters) into loglines, plot outlines, structured simulation records, and finally executable scripts.
- We design a role-driven multi-agent pipeline in which a world agent and multiple character agents draft scenes under explicit narrative constraints; the transcripts are rewritten into

October 24-29, 2026 ©2026 Association for Computational Linguistics

polished scripts with natural dialog and coherent beats that adhere to character motivations and world rules.

- Experiments on industrial data from a commercial game show that D2GS consistently outperforms strong baselines. The verdicts are reproduced by two additional cross-family LLM judges and by a blinded panel of professional narrative designers, and transfer to BookWorld's public benchmark under its own human-calibrated protocol.

- We report deployment evidence rarely available in academic work: as an internal authoring tool in a commercial game's production workflow, D2GS attains 99.73% frame-event command legality and 93.5% automatic asset-reference resolution at ~ 0.5 h of post-editing per chapter.

2 Related Work

2.1 Automated Script Generation

LLMs increasingly assist in crafting stories and screenplays (Mirowski et al., 2023; Chakrabarty et al., 2024) via two paradigms. Top-down methods plan-and-write, expanding high-level artifacts (loglines, outlines, scene sketches) into full scripts through hierarchical prompting or multi-agent planner/reviewer/writer setups (Wan et al., 2025; Yang et al., 2023, 2022). Bottom-up methods simulate character interactions into transcripts later rewritten into screenplays, yielding vivid dialog but needing stronger consistency control; hybrids combine both (Chen et al., 2024; Ran et al., 2025). Most efforts, however, operate offline without conditioning on concrete game assets.

2.2 LLM-based Game Narrative

LLM-based game narrative splits by whether players shape generation at runtime. Offline generation authors outlines, scenes, and branching scripts in advance through schema-controlled generation, outline-to-script pipelines, multi-agent collaboration, and post-generation validation (Hu et al., 2024; Huot et al., 2025; Ran et al., 2025), at the cost of weak reactivity and combinatorially many branches to maintain. Player-driven emergent generation instead adapts the plot to player actions in real time (Wu et al., 2024; Han et al., 2024; Phillips et al., 2025; Jeong and Lee, 2025; Peng et al., 2024; Wu et al., 2025), typically via planner–controller or director architectures with retrieval-augmented memory and state tracking, but faces latency, long-horizon coherence, safety moderation, and stable grounding of live text to the available assets.

2.3 Multi-agent System

Multi-agent systems are widely used to simulate social dynamics and study emergent behavior in controlled environments, from small-scale simulations supporting fine-grained analysis (Chuang et al., 2024) and sandbox generative agents with realistic human–agent interaction (Park et al., 2023) to nearly a thousand personality-distinct agents in a shared virtual world (AL et al., 2024) and large-scale social-network simulations of information diffusion and network formation (Yang et al., 2024).

3 Methodology

In this section, we first elaborate on our proposed data-centric framework for game script generation, namely D2GS. Given a complex script generation task, we generate the output $\mathcal{T}$ by decomposing the game script generation process into multiple subtasks that are tackled by specialized agents. The overall pipeline is illustrated in Fig. 1.

3.1 Multi-source Game Knowledge Integration and Representation

Game projects produce heterogeneous narrative assets—character design documents, worldview documents, and legacy scripts of events already played in the game—that vary widely in format, granularity, and intended use. To make them available for downstream narrative reasoning and retrieval, we unify these inputs into two complementary repositories: a character-centric knowledge base capturing identity, attributes, and interpersonal relations, and a worldview knowledge base encoding locations, domain-specific terminology, and the historical evolution of the game world.

The pipeline begins with ingestion and normalization: all inputs become plain text, PDFs through OCR and layout-aware parsing, tabular data linearized while retaining cell provenance, and every fragment tagged with metadata (document type, version, timestamps) for traceability. Documents are then chunked at semantic boundaries with a sliding overlap window that mitigates pronoun drift and cross-paragraph dependencies, chunk sizes trading context sufficiency against extraction precision. The LLM runs in a constrained extraction

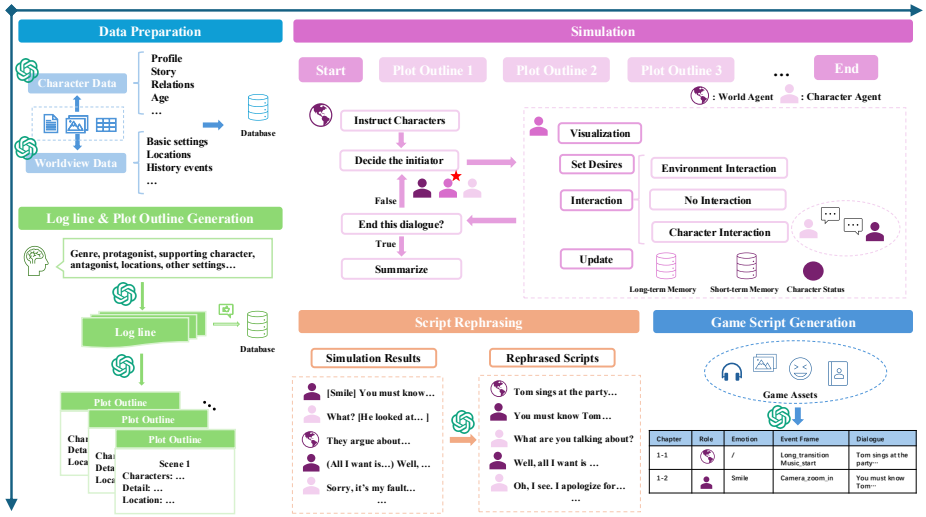

Figure 1: The complete paradigm of the proposed data-centric framework for LLM-based creative game script generation.

mode emitting schema-conforming JSON into the knowledge database; inter-character relations are extracted from the same text. Worldview data are partitioned into a historical database (events, eras, causal and temporal edges) and a terminology database (terms, locations, definitions), with locations in a containment hierarchy enabling spatial reasoning and scoped retrieval. Schema and integrity constraints keep pace with evolving narratives while preserving provenance and reliability for production use.

3.2 Logline and Plot Outline Generation with Critic-Feedback Revision

We regard story ideation as a two-stage workflow. In the first stage the narrative designer sets the genre, the characters (protagonists, supporting characters, antagonists), and the primary location. The system treats these as structured constraints and prompts an LLM to generate M candidate loglines $\mathcal{L} = \{L_1, \ldots, L_M\}$, each a one- or two-sentence summary of the main plot and key elements, which the designer may edit. To reduce the writer's reading burden, the LLM also scores every candidate along four dimensions—coherence, relevance, creativity, and writing quality—and loglines marked good are persisted in a logline database for few-shot retrieval. In the second stage we expand the chosen logline L_g into an N-chapter plot outline $\mathcal{C} = \{C_1, \ldots, C_N\}$ structured by a narrative framework (Gustav Freytag's pyramid), where each chapter instantiates a beat and each entry carries a short synopsis plus the required characters and locations. Accepted outlines are persisted in a plot-outline database as in-domain exemplars for retrieval-augmented few-shot guidance, which matters for reproducibility, governance, and large-scale deployment.

Critic-feedback revision. Both stages share one *critic–conditioned revision* loop. Prompted as a senior narrative editor, the critic returns $\sim$300 words of itemized notes on five aspects: fit of the characterization to the established storyline, plausibility and depth of the character relationships, audience appeal, logical soundness, and any further issue it finds; at the outline level it additionally applies a three-act and hero's-journey lens. The reviser regenerates the draft from the original plus these notes under the *same* schema, leaving downstream interfaces unchanged. We use a single round (R0$\rightarrow$R1), which already suffices (Sec. 4.2.2); prompts and a before/after case are in Appendix C.

3.3 Multi-agent simulation

In this subsection, we introduce the simulation process based on the generated plot outlines. The simulation process is orchestrated by a world agent and a group of character agents selected in a specific way. The combination of narrative intent and character agents interactions enables the simulation to advance plot goals without degenerating into unconstrained free play. The algorithm is illustrated in Appendix A.

Initialization. Character agents $\mathcal{R}$ and a world agent are initialized with the multi-source knowl-

edge of Sec. 3.1. Each character agent holds a long-term memory (backstories, relationships, goals) for behavioral consistency and a short-term memory (recent interactions, current objectives, environmental changes) for dynamic reactions. The world agent, initialized with the game environment (geography, rules, worldview), keeps the world coherent, mediates character–environment interaction, and propagates events by updating the world state after each action. The simulation text $\mathcal{T}_{sim}$ starts empty.

Simulation Process. Each chapter $C_k \in \mathcal{C}$ is simulated in turn under the guidance of the outline. Its content is loaded first—scene description, the characters present $\mathcal{R}_k$, and related details—after which every agent $r \in \mathcal{R}_k$ visualizes the scene from C_k and the global state $\mathcal{S}$ (what can be seen, sensed, and smelled, plus its current status), yielding $\mathcal{V}_r$, and determines its extrinsic and intrinsic desires $\mathcal{D}_r$ from $\mathcal{V}_r$, the logline, and C_k. Visualization and desire-setting let characters decide from the current situation rather than from generic role-play. The world agent then compiles for each character an action guide $\mathcal{G}_r = \{g_{r,1}, g_{r,2}, \ldots\}$ fulfilling $\mathcal{D}_r$ under the constraints of $\mathcal{S}$, $\mathcal{V}_r$, and C_k, and selects the first character to act. At each turn the acting character executes the next step of its guide and picks dialog targets; its action is appended to $\mathcal{T}_{sim}$, and every target reacts according to its own visualization, desires, and plan, those reactions (dialog or movement) likewise being appended. Once the chapter is complete, a summary is appended and $\mathcal{S}$ is updated with the chapter's locations and environmental cues.

Cost and scalability. Three mechanisms bound simulation cost: the active cast of a chapter is exactly the outline's $\mathcal{R}_k$ (typically 2–5), with visualization, desire-setting, and action-guide compilation each run once per chapter rather than per turn; the world agent applies dialog- and chapter-level termination checks; and loglines and chapters are independent, hence scheduled concurrently. Over the 55 GPT-5 production runs a script averages 206 interaction records (min 64, max 453), roughly 320–350 LLM calls for 6–10 chapters — well within tolerance for *offline* authoring on multi-week version-event cycles.

3.4 Script Rephrasing

Script rephrasing transforms structured simulation outputs into coherent, human-readable game scripts. Its input is the simulation records—speaker identifier, semantic content, action, and emotional context—serialized into a schema-aligned prompt so that the LLM receives both factual content and contextual metadata. The LLM then emits dialog lines in a standardized format, using environmental cues and emotional states to adjust lexical choice and tone while preserving the original narrative intent, so that dialog carries plot while revealing personality and subtext.

3.5 Game Script Generation with frame events

We finally integrate the narrative script with the game's multimedia assets—character sprites, scene backgrounds, music tracks, transition animations, and facial expressions—to produce engine-ready, frame-event-annotated scripts, associating each dialog line and scene with the corresponding pre-existing assets so that the narrative can be performed in the game's script editor. Guided by the frame-event annotation rules of the target engine, we prompt LLMs to emit enriched scripts in which every narrative unit is paired with the appropriate visual, auditory, and transitional elements, preserving narrative fidelity while conforming to the technical specification required for direct import.

4 Experiments

4.1 Experiment Setup

4.1.1 Dataset

We build a dataset spanning 6 genres—romance, comedy, horror, science fiction, drama, and crime (Chen et al., 2024). Characters, antagonists, worldviews, and character relationships are extracted from an existing commercial game, whose character and worldview data arrive as documents, images, and tables. For each genre we use LLMs to generate 10 unique loglines, reflecting that genre's thematic and narrative conventions, as the initial input. All source documents and generated scripts are in Chinese. The distilled knowledge bases hold 23 character profiles, 73 relation pairs, 175 locations, and 404 terminology and history entries; on a hand-verified sample of 150 records, extraction reaches 87.3% strict and 94.6% partial-inclusive accuracy (Appendix G). Across 6 genres, 60 loglines, 5 baselines, and 4 backbones we analyse ∼880 completed full-script pairwise comparisons on real production assets — a scope we accordingly call *validated on industrial data* rather than industrial-scale validation.

Table 1: Win rate (%) of D2GS against each baseline. **Avg.** is the unweighted mean of the five higher-is-better dimensions (Misc. Problem excluded, being lower-is-better); the bottom block macro-averages each baseline over the four backbones, giving an overall ranking.

Model	Method	Coherence↑	Relevance↑	Interestingness↑	Humanlike↑	Writing Quality↑	Avg.↑	Misc. Problem↓

4.1.2 Evaluation Metrics

Script quality requires nuanced judgment across several dimensions, so we adopt the pairwise comparison framework of prior work (Chen et al., 2024; Yang et al., 2023), in which an LLM decides which of two scripts is better; the approach has been validated against human evaluation (Ran et al., 2025; Chen et al., 2024; Yang et al., 2023; Huot et al., 2025). Our metrics are as follows. **Coherence**: Coherence of plot structure, character description, scene transitions, and setup consistency. **Relevance**: Faithful to the genre and logline. **Creativity**: The originality and unexpectedness of plots (for logline generation). **Interestingness**: Interesting to the reader (for script generation). **Humanlike**: Judged to be human-written. **Writing Quality**: Assess writing quality. **Misc. Problem** (Yang et al., 2022): Writing issues, including narration, inconsistent, confusing, repetitive, and disfluent. Judges are prompted in Chinese, matching the scripts' language, with the English metric definitions above embedded verbatim (Appendix D). LLM judging covers narrative quality only; frame-event legality and asset constraints are checked by a rule-based validator (Sec. 4.3), and Sec. 4.2.3 establishes reliability for this setting rather than borrowing figures from other domains.

Table 2: Comparison of loglines and outlines under one round of critic-feedback revision.

Content	Method	Coherence↑	Relevance↑	Creativity↑	Writing Quality↑
Logline	R1 Wins	**92.13**	**89.30**	**92.92**	**91.10**
	R0 Wins	2.34	4.13	3.90	3.28
	Ties	5.53	6.57	3.18	5.62
Outline	R1 Wins	**93.10**	**85.59**	**96.55**	**98.28**
	R0 Wins	5.17	8.69	1.72	0.00
	Ties	1.73	5.72	1.73	1.72

4.1.3 Baselines and models

In our study, we compare scripts generated using six different methods to assess their effectiveness in producing high-quality screenplays. The methods includes **Direct prompt**, **Plan-then-write**, **DOC-screen** (Yang et al., 2023), **HoLLMWood** (Chen et al., 2024), **BookWorld** with script instruction (Ran et al., 2025), and **D2GS** in Sec. 3. For models, we adopt multiple state-of-the-art LLMs, including GPT-5, GPT-4o, DS (Deepseek)-v3, and DS (Deepseek)-r1. We utilize GPT-5 for the evaluation, and re-run the complete evaluation with two further judges in Sec. 4.2.3.

Input parity. Since D2GS is data-centric, one may ask whether its win rates merely reflect richer inputs. We audited every baseline against the experimental code (Appendix F). All six methods start from the same 60 detailed loglines, produced from the full character, relation, and worldview data, and every baseline whose design accepts explicit character or world inputs receives them through

the same loader and files as D2GS; BookWorld is mounted on the same worldview knowledge base and retrieves from it during generation. One asymmetry remains, which we state rather than leave implicit: structured character relations are consumed only by D2GS — the contribution of Sec. 3.1 rather than an evaluation artifact, whose worth Sec. 4.2.5 measures.

4.2 Evaluation Results

4.2.1 Effect of Script Generation

Table 1 reports the win rates of D2GS against the baselines across six metrics. D2GS consistently outperforms direct prompting on every metric and every model. Against Plan-then-write and DOC-screen it keeps a clear edge in humanlike and interestingness, writing quality being its narrowest margin over both; against HoLLMWood and BookWorld its clearest advantage is again humanlike text. Coherence and relevance are closer and depend on the backbone, since multi-agent simulation demands stronger structured-output and instruction-following ability than direct generation. On Misc. Problem, D2GS makes fewer errors in every pairing but one. Output length, finally, is governed mainly by the backbone rather than the method, and since longer text does not imply higher quality we defer the word-count statistics to Appendix B. The macro-average block of Table 1 gives the overall ranking: averaged over backbones and the five higher-is-better dimensions, D2GS beats every baseline, from 65.88% against the strongest competitor (BookWorld) to 86.28% against DOC-screen, while producing fewer miscellaneous writing problems than all of them. The ordering is stable across backbones, the two simulation-based systems being hardest to beat.

4.2.2 Effect of critic-feedback revision for logline and plot outline generation

We compare loglines and outlines produced at round 1 (R1) against round 0 (R0). As Table 2 shows, revised content overwhelmingly beats unrevised content. Notably the gain is not confined to coherence and relevance: creativity and writing quality improve as well, indicating that critic-feedback revision also facilitates the downstream script development.

4.2.3 Reliability of the Evaluation Protocol

Using GPT-5 both as generator and as judge invites a self-preference concern, and human–LLM agreement reported elsewhere does not establish reliability for Chinese game scripts written under real character and world constraints.[1]

Multiple judges. Re-running all $\sim$880 comparisons with two further judges from other model families gives verdict agreement of 90.4% (Cohen's κ=0.614) with Claude-Sonnet-4.5, 79.4% (κ=0.471) with DeepSeek-V4-Flash, and 78.9% (κ=0.440) between the two new judges; per-dimension agreement is 73.0–88.5% with the former and 67.9–79.7% with the latter. No conclusion in Table 1 is reversed by changing the judge or the judge family.

Human evaluation. Three professional narrative designers judged 30 blinded pairs in randomized order, pitting D2GS against BookWorld and HoLLMWood. Human preference for D2GS is 67.8%, inter-annotator agreement 43.3–70.0%, and human–LLM agreement 69.2%, so the judge agrees with the designers about as often as they agree with each other (Appendix E). Deleting all length-related phrasing from the judge prompt leaves 92% of verdicts unchanged, so the win rates are not an artifact of verbosity.

4.2.4 Cross-Dataset Validation on Public BookWorld Benchmark

Table 3: Pairwise comparison (%) of D2GS against BookWorld on the public *A Song of Ice and Fire* benchmark (N=6 scenarios), under BookWorld's own five-dimension protocol with GPT-5 as judge.

Result	An↑	CF↑	IS↑	WQ↑	SQ↑	Avg↑
D2GS Wins	**83.33**	**50.00**	**100.00**	**100.00**	**50.00**	**76.67**
BookWorld Wins	16.67	50.00	0.00	0.00	50.00	23.33

To validate our evaluation beyond proprietary game data, we compare D2GS against BookWorld on its own public benchmark: both methods take the same loglines from the publicly available *A Song of Ice and Fire* setting and share the same DS-v3 actor, differing only in their generation pipeline, and are judged by GPT-5 under BookWorld's original five-dimension protocol—Anthropomorphism (An), Character Fidelity (CF), Immersion & Setting (IS), Writing Quality (WQ), and Storyline Quality (SQ). Although limited to N=6 scenarios, each script is a full multi-chapter storyline, the two methods together producing 2,945 turns the judge reads

[1]We release the evaluation code, the judge and critic prompts, and the validator at https://anonymous.4open.science/r/d2gs-2027; the industrial dataset cannot be released, being covered by commercial IP.

in full. As Table 3 shows, D2GS attains a 76.67% average win rate, with the clearest margins on immersion/setting and writing quality and parity on character fidelity and storyline quality. Since this protocol was calibrated against a five-annotator human panel in the original study (Cohen's $\kappa \geq 0.64$), the result rests on a human-validated metric rather than an ad-hoc LLM judge; together with Table 1, it indicates that the advantage of D2GS generalizes across different protocols and datasets.

4.2.5 Ablating the Knowledge Base and the Simulation

Table 4: Rule-based, LLM-free measurements. **Top**: grounding ablation (GPT-5, 30 loglines), counting distinct canonical archive entities per script. **Bottom**: frame-event validation over 10 deployed authoring sessions.

Grounding ablation	**Entities / script↑**
w/o knowledge base, w/o simulation	3.8
w/ knowledge base, w/o simulation	5.6
Full D2GS (knowledge base + simulation)	**11.8**
Engine-readiness	**Result**
Frame-event command legality	99.73% (749/751)
Automatic asset-reference resolution	93.5% (545/583)
Expression validity	87.56%

Table 2 already isolates the critic-feedback module. For the other two we measure grounding *objectively*, string-matching generated scripts against the knowledge base, so the ablation inherits none of the judge's bias. Removing character profiles and relations drops the no-simulation variant from 5.6 to 3.8 distinct canonical setting entities per script (-32%, Table 4), and mentions of profile-exclusive facts — e.g., the protagonist's mercenary backstory, present only in the character archive — fall from 46 to exactly 0: the knowledge base is the sole channel through which archive-level settings reach the scripts. Adding the simulation, whose agents retrieve during generation, raises the count to 11.8, $2.1\times$ the no-simulation variant. Grounding is not free: direct generation keeps an edge in the free-flowing fluency LLM judges reward, but cannot meet production's grounding and asset-executability requirements — hence the full framework.

4.3 Deployment and Engine-Readiness

"Engine-ready" deserves evidence rather than assertion. D2GS runs as an internal web tool in a commercial game's production workflow: designers upload the script breakdown and asset sheets, and the tool returns frame-event-annotated scripts exported back into the pipeline. It has been in production since August 2025 across roughly six version events, one every two months, and every designer-reviewed output has shipped in the live game.

Frame events come from a closed instruction set and every asset name must occur in the production resource sheets, so correctness is decidable without an LLM. A rule-based validator over 10 authoring sessions reports 99.73% command legality (749/751), 93.5% automatic asset-reference resolution (545/583), and 87.56% expression validity (Table 4); table-format import never fails, by construction. Unresolved references are flagged with their row number and fixed during designer review, costing review time rather than breaking imports. Post-editing averages $\sim$0.5 h per chapter, about four hours per version-event script; the studio internally estimates a 25–50% efficiency gain, an internal estimate rather than a controlled measurement (Appendix H).

5 Conclusion

This paper introduced D2GS, a data-centric framework for LLM-based game script generation aimed at real-world narrative design pipelines. Unlike prior text-only approaches, D2GS grounds generation in game-specific assets and production constraints, carrying the workflow from ideation to engine-ready scripts: it generates a logline, constructs a plot outline, and runs role-playing simulations with character agents coordinated by a world agent. Extensive experiments show consistent improvements over existing methods under three independent LLM judges and a blinded panel of professional narrative designers, and a deployed authoring tool turns these into production value: 99.73% frame-event command legality, 93.5% asset-reference resolution, and about half an hour of post-editing per chapter in a commercial game shipping D2GS-assisted scripts since August 2025.

Limitations

Scope of the industrial evidence. All proprietary experiments come from a single commercial game. The evaluation spans 6 genres, 60 loglines, 5 baselines, and 4 backbones ($\sim$880 full-script pairwise comparisons) over production assets of 23 character profiles, 73 relation pairs, 175 locations, and

404 terminology and history entries, but one game world cannot establish transfer to other titles, art styles, or engines; this is why we claim validation *on industrial data* rather than industrial-scale validation. The public cross-check against BookWorld covers only $N{=}6$ scenarios of a single corpus, so broader validation across scenarios, genres, and corpora remains future work.

Scale of the human validation. The blinded study uses 3 professional narrative designers and 30 pairs, with 43.3–70.0% inter-annotator agreement. This suffices to show that the LLM judge tracks expert preference about as well as experts track each other, but not to resolve fine-grained differences among the stronger baselines; moreover, the designers work on the game the data come from, so they are expert but not fully independent raters.

The efficiency figure is an internal estimate. The 25–50% scripting-efficiency gain is the studio's own assessment, not a controlled A/B study against unassisted authoring, and the $\sim$0.5 h per chapter of post-editing is measured on designers already familiar with the tool. The frame-event legality and asset-resolution numbers, by contrast, come from a deterministic validator and are reproducible from the released code.

Reproducibility. We release the evaluation code, the judge and critic prompts, and the validator, but commercial IP and confidentiality prevent releasing the game data, so the proprietary half of the evaluation cannot be re-run externally; the public BookWorld comparison partly compensates.

Dependence on structured sources. Being data-centric, D2GS inherits the quality of its inputs: schema-constrained extraction assumes reasonably well-structured worldbuilding documents and reaches 87.3% strict accuracy on our sample, so noisier or sparser sources will degrade the knowledge base and, through it, the grounding of the scripts.

Inference cost. The simulation issues roughly 320–350 LLM calls per script, far more than single-pass prompting. This is acceptable for offline authoring on multi-week cycles but rules out the framework, as it stands, for latency-sensitive or runtime player-driven narrative.

Language and model coverage. Our experiments use four backbones and Chinese-language scenarios throughout; behavior under other languages, writing traditions, and model families remains to be characterized.

Ethical Considerations

Data. The proprietary material is fictional worldbuilding documentation, character sheets, and asset catalogs owned by the studio, used with permission under confidentiality obligations. It contains no personal data and no user-generated content, which is also why it cannot be released. The public comparison uses the *A Song of Ice and Fire* setting distributed with BookWorld under its original terms.

Human participants. The blinded evaluation was performed by three in-house professional narrative designers as part of their ordinary compensated duties, on fiction they already work with; no personal data was collected and participation was voluntary.

Effect on creative labor. D2GS is an assistive, designer-in-the-loop tool rather than an autonomous writer: designers choose the logline, edit the outline, and review every script before it ships, and the reported efficiency gain comes from removing mechanical asset wiring and first-draft dialog, not authorship. We nonetheless acknowledge that such tools shift creative work from drafting toward editing, a shift that should be negotiated with the writers it affects.

Content risk. Generated scripts inherit the biases and failure modes of their backbone LLMs and may produce stereotyped characterization or content unsuitable for the game's rating. In deployment every script passes both content-moderation and designer review before reaching players; we regard this human gate as a requirement, not an optional safeguard.

A Outline-Guided Simulation Algorithm

Algorithm 1 provides the detailed procedure of our outline-guided simulation. Given the generated plot outline and the narrative intent for the current step, a world agent first selects and initializes a set of character agents under asset and role constraints, then orchestrates multi-round interactions among them. The world agent monitors progress and applies control signals to ensure the simulation advances plot goals rather than drifting into unconstrained free play. The algorithm outputs a simulation transcript and updated world/character states, which are used for subsequent rewriting into engine-ready scripts.

Notation. The plot outline is $\mathcal{C} = \{C_1, \ldots, C_N\}$, where each chapter C_k packages a scene description, the set of participating characters $\mathcal{R}_k$, a location, and a short synopsis that serves as the local narrative goal. $\mathcal{S}$ is the evolving global state (locations, environmental cues, and what has happened so far); $\mathcal{V}_r$, $\mathcal{D}_r$, and $\mathcal{G}_r$ denote, respectively, the scene character r perceives, its determined desires, and the world-agent-issued action guide; and $\mathcal{T}_{sim}$ is the running simulation transcript.

The chapter as the unit of control. Rather than letting agents free-associate, each chapter C_k scopes *who* is on stage ($\mathcal{R}_k$), *where* the scene takes place, and *what* it must accomplish (its synopsis), so character behavior is constrained to advance that specific beat. Within a chapter, every present character first *visualizes* the scene ($\mathcal{V}_r$) and forms *desires* ($\mathcal{D}_r$) conditioned on the logline and C_k; this grounds subsequent decisions in the current situation instead of generic role-play. The world agent then compiles per-character action guides $\mathcal{G}_r$ that translate these desires into concrete, goal-directed steps under the constraints of $\mathcal{S}$ and C_k.

Interaction loop and termination. The acting character executes the next step of its guide and selects dialog targets; the targeted characters react, and all utterances are appended to $\mathcal{T}_{sim}$. After each turn the world agent updates $\mathcal{S}$ and decides whether to continue, acting as a director that keeps the exchange on-beat and ends the chapter once its narrative goal is met—preventing the runaway or off-topic dialog typical of unconstrained multi-agent role-play. A chapter summary is then appended and the updated $\mathcal{S}$ is carried into the next chapter, preserving long-horizon consistency. Once all chapters are simulated, the full transcript $\mathcal{T}_{sim}$ is rephrased (Sec. 3) and annotated with frame events to yield the engine-ready script $\mathcal{T}$.

B Length Statistics of Generated Scripts

Table 5 reports the average number of words in scripts generated by different methods and backbone models under the same experimental setting. The word counts are computed by tokenizing the final generated script text and splitting by whitespace; thus, they reflect overall script verbosity rather than semantic quality. Note that different methods may impose different output formats (e.g., explicit scene boundaries, shot descriptions, or structured planning artifacts). Such formatting requirements can systematically increase word counts because they introduce additional descriptive or organizational text. Therefore, length should be interpreted primarily as a proxy for output volume and format overhead, not as a direct indicator of coherence, creativity, or factual correctness.

We also observe that model-inherent verbosity affects the statistics: larger/stronger models tend to generate longer responses given the same stopping criteria, which partially explains why GPT-5 produces substantially more words than the other backbones. Finally, since some pipelines are multi-stage and rely on intermediate planning or rewriting, they may amplify length through repeated elaboration; this can lead to higher variance across models even when the method name is the same.

C Critic-Feedback Prompts and a Before/After Case

The loop of Sec. 3.2 uses four prompts — a logline critic, a logline reviser, an outline critic, and an outline reviser. The critic and the generator share a backbone but are invoked independently, with

Algorithm 1: Framework of game script generation.

Input: Genre, characters, and locations.
Output: Game script $\mathcal{T}$.

Generate multiple loglines $\mathcal{L} = \{L_1, ..., L_M\}$ based on the given genre, characters and locations and choose the best logline L_g;
Generate the outline $\mathcal{C} = \{C_1, C_2, ..., C_N\}$ with critic-feedback revision;
Initialize multiple character agents and a world agent with multi-source game knowledge and $\mathcal{T}_{sim}$ to be empty;
for *each chapter* $C_k \in \mathcal{C}$ **do**
  Load chapter content C_k (scene description, characters $\mathcal{R}_k$ in chapter C_k, etc.);
  for *each character agent* $r \in \mathcal{R}_k$ **do**
    $\mathcal{V}_r \leftarrow$ Visualize scene: r imagines based on C_k and $\mathcal{S}$, including what can be seen, sensed, smelled, and the current status;
    $\mathcal{D}_r \leftarrow$ Determine desires: r's extrinsic and intrinsic desires based on $\mathcal{V}_r$, logline, and C_k;
  The world agent generates a sequence of action guides $\mathcal{G}_r = \{g_{r,1}, g_{r,2}, ..., g_{r,t}, ...\}$ for each character r to achieve $\mathcal{D}_r$;
  The world agent selects initial acting character r;
  while *the world agent decides to continue the performance* **do**
    $a_r, \mathcal{R}' \leftarrow$ Execute action: r performs the next step in $\mathcal{G}_r$ and selects dialog targets;
    Append a_r (description of r's action a_r) to $\mathcal{T}_{sim}$;
    for *each character agent* $r' \in \mathcal{R}'$ **do**
      $a_{r'} \leftarrow$ React to a_r;
      Append r''s reaction (e.g., dialog, movement) to $\mathcal{T}_{sim}$;
    Update global state $\mathcal{S}$ based on the history text;
    The world agent selects next acting character r.
  Append chapter summary to $\mathcal{T}_{sim}$;
  Update global state $\mathcal{S}$ with the history text;
Rephrase the simulation text to meet the script quality;
Produce frame-event-annotated game scripts within game assets;
return $\mathcal{T}$

Table 5: The average length statistics of scripts generated by various methods.

Model	Method	Words
GPT-5	**Direct prompt**	2137
	Plan-then-write	11613

DS-v3	**Direct prompt**	1261
	Plan-then-write	5599
	DOC-screen	5901
	HoLLMWood	2911
	BookWorld	8037
	D2GS	7747

no shared context. The main experiments use a single round ($R_0 \rightarrow R_1$). We reproduce all four prompts below, translated from the Chinese originals that are released verbatim with the evaluation code; {...} marks a runtime slot.

The **critic** prompts cast the model as a senior narrative editor and require itemized, actionable output of about 300 words organized along five aspects: (a) consistency of the characterization with the established storyline; (b) plausibility, depth, and complexity of the character relationships; (c) audience appeal; (d) logical soundness; and (e) any further issue the critic identifies. The outline critic additionally requires an analysis through a three-act structure and a hero's-journey lens, checking that each character's desires remain consistent across chapters and actually drive the plot rather than being restated. The **reviser** prompts receive the original draft together with the critic's itemized notes and must regenerate it under the same structured schema as the first pass, so that no downstream component needs to know whether a revision took place.

Logline critic.

> You are an editor, skilled at guiding screenwriters to create better stories in film storylines. Your responsibility is to provide constructive suggestions for improving the characters the screenwriter has shaped from the logline.

When providing feedback, pay close attention to the following aspects of the character design: (1) assess whether the designed character introductions fit harmoniously with the established storyline; (2) assess the plausibility, depth, interest, and complexity of the character relationships, rather than being overly simplistic — consider whether the story is consistent with the characters' personas; (3) assess whether the designed characters are compelling and can effectively engage the audience; (4) assess whether the character introductions are logically sound; (5) any other aspect you consider important. If you find problems of these kinds in what the screenwriter provided, give precise and concise revision suggestions targeting those problems.

Genre: `{genre}`
Logline: `{logline}`
Detail: `{logline_detail}`

Output the suggestions directly, itemized, in about 300 words:

Logline reviser.

Revise and improve the original storyline according to the revision suggestions, and output the revised result.

Genre: `{genre}`
Original logline: `{logline}`
Original detailed plot: `{logline_detail}`
Revision suggestions: `{advice}`

Output a JSON object without markdown formatting, with the fields `logline` and `detail`.

Outline critic. Identical in role and output contract to the logline critic, with the narrative-theory aspect replacing aspect (2):

Script content: `{script}`

(1) Assess whether the characters' behaviour and performance fit harmoniously with the established storyline. (2) Analyse the plot from the perspective of the three-act structure and the hero's journey, so that the plot is full of conflict and suspense; is the plot compelling? Are the characters' desires consistent throughout, and do they effectively drive the plot forward? (3) Assess whether the designed characters are compelling and can effectively engage the audience. (4) Assess whether the plot is logically sound. (5) Any other aspect you consider important.

Output the suggestions directly, itemized, in about 300 words:

Outline reviser.

Revise and improve the original plot according to the revision suggestions, and output the revised result.

Original plot: `{script}`
Revision suggestions: `{advice}`

Output JSONL without markdown formatting; the fields of each chapter are `plot` (string, "Chapter X"), `role` (list of strings), `description` (string describing the plot), and `location` (string, where the plot takes place).

A representative case. On a romance-genre logline the draft R_0 reads (translated; character and organisation names replaced with placeholders):

> On the eve of the tournament held by Nova Entertainment, Alex meets again with Morgan, the senior he had once misjudged. To prove himself he trains hard but is hurt in an accident, and finally, encouraged by Iris, he pulls himself together, reconciles with Morgan, and wins the tournament.

After one critic-feedback round, R_1 reads:

> On the eve of the tournament held by Nova Entertainment, Alex meets again with Morgan, the senior he had once misjudged. At first he trains hard with the single aim of proving himself, and is injured through a flaw in his own character. Encouraged by Iris, herself a former competitor who speaks his language, he overcomes his inner wound and his weakness and recovers. During the tournament he discovers the reason Morgan has been deliberately avoiding him and clears up the misunderstanding, turning from merely wanting to prove himself to grasping the transmission of the craft itself; in a contest with Morgan that is half rivalry and half friendship he wins the tournament, gaining both love and growth.

Four changes are observable. The injury is converted from an external accident into a consequence of the protagonist's own flaw, so the character arc acquires a causal driver; the supporting character is given a competitor background that motivates her mentorship instead of leaving it unexplained; a suspense hook (why Morgan avoids him) is added; and the theme is raised from "proving oneself" to "inheriting a craft". The detail field grows from 298 to 740 characters. These are the kind of structural notes a human editor gives, which is consistent with the large R_1-over-R_0 win rates of Table 2.

D Judge Prompt and Evaluation Protocol

Scripts are compared pairwise. For each comparison the judge receives the shared logline and the two complete scripts, and returns a single JSON object of 24 fields: an overall verdict (`A`, `B`, or `TIE`), a justification of at most 100 characters, and a 1–5 score for each of 11 dimensions for each script. The per-dimension win/lose/tie used in Table 1 is derived by comparing the two scores. The dimension definitions of Sec. 4.1.2 are embedded verbatim in English inside an otherwise Chinese prompt matching the language of the scripts:

Judge impartially the quality of the scripts generated by two methods. You should choose the better script. Your assessment should focus on the following 11 aspects; the first 6 are positive aspects and the last 5 are negative. The richness

and the length of a script should be taken into account, as should its fit to the logline; a script markedly shorter than the other is not good.

1. **Coherence**: Evaluate the coherence from plot structure, character description, scene transitions and setup consistency. 2. **Relevance**: Evaluate the relevance from the relationship between characters and genre of the story. 3. **Interestingness**: Evaluate the interestingness to readers. 4. **Humanlike**: Judged to be human-written. 5. **Details**: Evaluate whether the script provides sufficient detail to clearly illustrate the progression of the plot. 6. **Overall Quality**: Synthesize the coherence, relevance, and interestingness of a screenplay to assess the overall quality. 7. **Narration**: Jarring changes in narration and/or style. 8. **Inconsistency**: Factually inconsistent or containing very odd details. 9. **Confusing**: Confusing or difficult to follow. 10. **Repetitive**: Highly repetitive. 11. **Disfluent**: Frequent grammatical errors.

logline: `{logline}`
Script A: `{s1}`
Script B: `{s2}`

Score script A and script B separately. Aspects 1–6 are scored positively from 1 to 5, where 5 is best, 4 better than average, 3 average, 2 worse than average, 1 worst. Aspects 7–11 are scored negatively from 1 to 5, where 5 denotes the worst behaviour with severe problems and 1 the best. Your assessment should compare the two scripts and give a brief explanation. Avoid any positional bias and ensure that the order in which the scripts are presented does not influence your decision. After the explanation, output your final conclusion strictly in the given format ... Output a JSON object without markdown formatting.

Dimensions 1–4 are reported directly in Table 1. Dimension 5 is how the prompt operationalises **Writing Quality** as defined in Sec. 4.1.2: rather than asking for a bare quality rating, it makes the judge assess how well the writing carries the progression of the plot, and its score is reported in that column. Dimensions 7–11 are aggregated into Misc. Problem, following Yang et al. (2022). One property of the prompt deserves explicit statement, since it is released as run: the preamble explicitly tells the judge to penalize a markedly shorter script, which could favour verbose systems; this is why we ran the length-neutral re-scoring reported below.

Three judges were run with this identical prompt: GPT-5 (used in Table 1), Claude-Sonnet-4.5, and DeepSeek-V4-Flash. Pairwise verdict agreement is 90.4% (κ=0.614) between GPT-5 and Claude-Sonnet-4.5, 79.4% (κ=0.471) between GPT-5 and DeepSeek-V4-Flash, and 78.9% (κ=0.440) between the two new judges. For the length-robustness check we deleted every clause of the preamble mentioning length, detail, or richness, re-scored a stratified subset covering all genres and baselines, and found 92% of verdicts unchanged, so the win rates are not an artifact of that clause.

E Human Evaluation Protocol

Three professional narrative designers, all working on the game the data originate from, evaluated 30 blinded pairs. Each pair contrasts a D2GS script with one from the two strongest baselines (BookWorld or HoLLMWood) generated from the same logline. System identity was hidden, presentation order was randomized independently per pair, and annotators judged the same six dimensions reported in Table 1 with a forced choice plus an optional tie.

Aggregated over pairs and dimensions, D2GS is preferred in 67.8% of judgments. Inter-annotator agreement ranges from 43.3% to 70.0% across dimensions, highest on coherence and lowest on the more subjective interestingness, which is the usual pattern in creative-writing evaluation. Agreement between the human majority verdict and the GPT-5 judge is 69.2%, within the range of agreement among the annotators themselves. We therefore treat the LLM judge as a proxy for expert preference of roughly the reliability of one additional expert, and not as a substitute for expert review in production.

F Baseline Input Parity

Table 6: Input configuration of each method, audited against the experimental code. ✓: supplied directly through the same data loader and files; ○: conveyed indirectly through the shared logline and its detailed description, as the method's original design requires; –: not used. DP: Direct prompt, PtW: Plan-then-write, DOC: DOC-screen, HW: HoLLMWood, BW: BookWorld.

Input	DP	PtW	DOC	HW	BW	D2GS
Genre	✓	✓	✓	✓	✓	✓
Logline with detailed plot	✓	✓	✓	✓	✓	✓
Locations with descriptions	✓	✓	○	✓	✓	✓
Character profiles	✓	○	○	✓	✓	✓
Worldview knowledge base (retrieval)	–	–	–	–	✓	✓
Character long/short-term memory	–	–	–	–	✓	✓
Structured character relations	–	–	–	–	–	✓

Table 6 records the input configuration of all six methods, audited item by item against the experimental code. Every method starts from the same 60 loglines, themselves generated from the full character, relation, and worldview data, so no method is deprived of the creative premise; all use the same backbone set, the same JSONL output contract, and the same retry-on-parse-failure policy. Where a baseline's original design accepts explicit character or world inputs, it receives the same files

through the same loader as D2GS: Direct prompt and HoLLMWood read character profiles through the identical helper, and BookWorld's world agent and role agents are mounted on the same worldview knowledge base and retrieve from it during generation, exactly as D2GS does. Where a baseline's design does not consume such inputs — Plan-then-write expands from a premise by construction, and DOC-screen generates its own character descriptions at the outline stage, which is its original design — we deliberately did not re-engineer its interface, since doing so would compare our reimplementation rather than the published method; the character and location information those two methods need reaches them through the shared logline and its detailed plot. The single genuine asymmetry is the last row: structured character relations are consumed only by D2GS. That is the contribution of Sec. 3.1 rather than a handicap imposed on the baselines, and Sec. 4.2.5 measures how much it is worth. All baseline prompts are released with the evaluation code.

G Knowledge Extraction Accuracy

To check the reliability of the schema-constrained extraction of Sec. 3.1, we sampled 150 extracted records — all 23 character profiles, 27 character relations, 50 terminology entries, and 50 locations — and verified each against the source documents by hand. A record is *strictly correct* if every field matches the source, and *partially correct* if it identifies the right entity with correct substantive fields but an incomplete or over-specific secondary field. Strict accuracy is 87.3%, and 94.6% of records are strictly or partially correct. The dominant residual error is over-segmentation of long relationship descriptions, which splits one relation into two records; since retrieval is by entity, such fragments degrade recall gracefully rather than injecting false facts.

H Frame-Event Validator

The target engine consumes scripts as a table whose rows carry a dialog or narration line plus optional frame events drawn from a closed instruction set (sprite and pose changes, background switches, background music and sound effects, transitions, expressions, and timing markers). Every asset name referenced by a frame event must occur in the production resource sheets for that version event. Both properties are decidable, so we check them with a deterministic validator rather than an LLM.

Command legality is the fraction of emitted frame-event instructions whose command belongs to the closed instruction set and whose arguments are well-formed: $749/751 = 99.73\%$ over the 10 authoring sessions. *Automatic asset-reference resolution* is the fraction of asset references resolving to an entry of the resource sheets without human intervention: $545/583 = 93.5\%$. *Expression validity*, the fraction of facial-expression tags that exist for the particular character sprite addressed, is 87.56%; it is the lowest of the three because expression inventories differ per character and minor characters have sparse inventories. Import of the table format never fails, since the exporter emits the schema by construction. The residual failures fall into three kinds: a command placed in the wrong category, a sprite requested for an unregistered minor character, and an invented asset name. Every unresolved reference is surfaced by the validator together with its row number, so the failure mode is a review item rather than a broken build.

DIAGFLOWBENCH: Evaluating How Language Models Handle Off-Procedure Inputs in Grounded Diagnostic Dialogue

Abstract

Language models increasingly serve as advisory systems in maintenance operations. To prevent hallucination, established approaches ground these models in procedural documentation, constraining them to prescribed sequences. In practice, however, operators may stray from these steps, requiring models to recognise unscripted, off-procedure utterances. Current benchmarks rarely prioritise this capability. We introduce DIAGFLOWBENCH[1], a dataset of 50 industrial diagnostic flowcharts from a consumer manufacturer converted into 1,676 multi-turn conversations that contrast compliant with off-procedure utterances. Evaluating a panel of ten commercial and open-weight models reveals high variability in abstention rates, with models often selecting a real but contextually inadequate step rather than fabricating facts. The inherent plausibility and authority of this mapped but wrong advice exposes a challenging vulnerability for grounding systems.

1 Introduction

Large language models (LLMs) are increasingly deployed as maintenance advisory systems (Kernan Freire et al., 2023; Colabianchi et al., 2024), helping operators through natural language to consult procedural documentation to propose the next action based on provided observations (Turner et al., 2019; Deng et al., 2024). Industrial diagnostic procedural knowledge is typically captured as flowcharts or decision trees (Vidyaratne et al., 2024), structures that recent work uses to ground maintenance systems (Wang et al., 2024; Emmanouilidis et al., 2019). Because such flowcharts enumerate admissible sequences of steps, mapping LLM outputs to this closed set acts as a built-in safeguard against hallucination, ensuring traceability and faithfulness to the procedure (Poesia et al., 2022; Maynez et al., 2020).

The challenge, however, is that operators rarely request advice in the exact terms of the procedure (Antonovsky et al., 2014). As a conversation unfolds, operators may report novel symptoms or raise questions mid-inspection that the documented steps do not anticipate. This difficulty is compounded by the natural language operators produce, which typically features dense text with abbreviations, shorthand, and domain-specific terminology that resists clean mapping onto documentation (Brundage et al., 2021; Dima et al., 2021). Experience widens the gap, as seasoned operators draw on tacit knowledge of the equipment rather than the literal manual (Dreyfus, 2004), making their queries further diverge from the mapped steps.

In practice, an LLM-based advisory system may receive these off-procedure queries mid-dialogue, mixed among on-procedure turns, and must handle both during generation. The two situations have tended to be evaluated independently. Flowchart-grounded benchmarks typically evaluate compliance on clean, mappable inputs (Raghu et al., 2021; Zhang et al., 2025), while off-procedure recognition is typically evaluated as abstention over single-turn queries (Feng et al., 2024; Larson et al., 2019). A live diagnostic dialogue presents both at once, demanding that a model advance through the procedure on compliant turns while recognising, in the same conversation, the turns that leave it.

To close this gap, we introduce DIAGFLOWBENCH[2] to evaluate flowchart-grounded models under both cooperative and off-procedure conditions. Our contributions are (1) a dataset of 50 anonymised industrial flowcharts from a consumer manufacturer rendered into 1,676 multi-turn

[1] Code and data are released at https://github.com/aixpert-rug/DiagFlowBench. The dataset is also archived under a citable DOI (Gil de Avalle et al., 2026).

conversations pairing clean dialogues with off-procedure counterparts, (2) an evaluation of ten diverse commercial and open-weight models, and (3) the identification of a failure mode, which we term *forced mapping*, whereby models forcefully assign an off-procedure query to an inapplicable step. Because these returned steps are genuine procedure nodes, similarity-based grounding alone struggles to flag them as failures. Ultimately, our findings reveal that the constraint mechanisms designed to prevent hallucination may instead camouflage contextual errors as valid steps, turning a built-in safety feature into a blind spot.

2 Related Work

Task-oriented dialogue (TOD) systems guide a user toward a goal across multiple turns, traditionally by tracking slots and intents over a fixed schema (Budzianowski et al., 2018). Flowchart-grounded dialogue specialises this setting by replacing the schema with an explicit procedure graph, so that each turn advances along a documented troubleshooting workflow (Raghu et al., 2021; Zhan et al., 2023). Benchmarks in this line primarily measure how faithfully a model follows that workflow. FloDial established this task by rendering troubleshooting flowcharts into conversations, scoring models on their ability to select the specific steps licensed by operator queries (Raghu et al., 2021). Later work pursued scale, deriving procedures from UML diagrams (Zhang et al., 2025) and generating synthetic dialogues from existing troubleshooting flowcharts to relieve data scarcity (Zhan et al., 2023). More recently, GuideBench tests compliance for specific domain rules (Diao et al., 2025), while SOP-Bench evaluates whether a model is able to adhere to industrial operating procedures and execute discrete tool calls (Nandi et al., 2026). Despite these variations, this body of work largely assumes that every operator query maps cleanly to the documented steps, and often fails to account for utterances that fall outside its scope.

This underlying recognition skill is studied independently as abstention. Traditional abstention detection frames this challenge around single inputs presented in isolation (Larson et al., 2019; Rajpurkar et al., 2018). However, even in these isolated settings, abstention remains a persistent challenge for LLMs, as they routinely misjudge the limits of their own knowledge (Yin et al., 2023) and exhibit a systemic bias toward generating an answer rather than declining (Feng et al., 2024). This tendency persists under retrieval paradigms, where models synthesise answers from passages that offer no actual support for the query (Cuconasu et al., 2024), thereby undermining retrieval as a safeguard against hallucination (Shuster et al., 2021). When this challenge is extended to multi-turn TOD dialogues, off-procedure inputs are primarily treated as interference. For example, injecting casual conversation into MultiWOZ slot-filling dialogues actively degrades state tracking and task success (Budzianowski et al., 2018; Stricker and Paroubek, 2024). Other benchmarks frame these departures as explicit rejection tasks. CGoDial inserts out-of-scope turns that the system must detect and meet with a fixed default reply (Dai et al., 2022). Meanwhile, FlowAgent scores workflow agents strictly on their ability to remain compliant with a procedure when a user request strays (Shi et al., 2025). In all these setups, the off-procedure turn is treated purely as a binary classification task to be set aside or ignored. Determining what a grounded model returns when it fails to abstain, rather than merely whether it abstained, requires evaluating each response against a specific procedure position. Without both the procedure and the position, a genuine but inapplicable step is indistinguishable from a correct one.

An off-procedure report to a grounded advisor sits precisely where these two research lines intersect. To accurately read how a model handles such queries, we specify five evaluation conditions. The procedure must operate as a *Graph*, so that inputs can fall outside structural edges. Turns must be *Observation-driven* to force inference over direct

Outcome	Condition	Description	Distinguished by prior work
Fabrication (FA)	$\hat{a}_t \notin V$	The model names a step that does not exist in the procedure	Yes, as extrinsic hallucination (Maynez et al., 2020; Ji et al., 2023)
Forced mapping (FM)	$\hat{a}_t \in V$, no edge into $\hat{a}_t$ entailed by o_t	The model names a real procedure step that the operator input gave no reason to select	No
Correct abstention (CA)	no $\hat{a}_t$ is named	The model recognises the operator input falls outside the procedure and redirects, escalates, or asks for clarification	Partially, as single-turn abstention (Larson et al., 2019; Feng et al., 2024)

Table 2: The three off-procedure outcomes and how prior evaluation treats each. Conditions are stated for turns where no outgoing edge of v_t is entailed by o_t.

reading. The documentation should ideally be *Realistic*, or at least driven from real documentation, to faithfully represent the complexity of real-world deployments. The dialogue must be *Multi-turn* to ensure active position tracking difficulty. Because models rarely self-correct after committing to an erroneous path (Laban et al., 2025), a multi-turn setup is necessary to capture how the degradation from a single mishandled off-procedure turn cascades through subsequent interactions. Finally, *Off-procedure* inputs must be explicitly present to create turns lacking any mappable response. Table 1 assesses the aforementioned benchmarks against these five criteria, alongside DIAGFLOWBENCH.

3 Task Formulation

We model a procedure as a directed graph $G = (V, E)$ whose nodes are diagnostic steps and whose edges are admissible transitions. Each edge $e = (v \to v')$ carries an observation $\ell(e)$ that licenses the move to v', so the admissible inputs at a node v are the labels on its outgoing edges, $L(v) = \{\ell(e) : e = (v \to \cdot)\}$. Some nodes are terminal, i.e. they mark the end of the procedure.

A conversation visits nodes in sequence. At the current node v_t the operator produces an utterance o_t, and the model, given the history h_t, must name the next action $\hat{a}_t$. The utterance is on-procedure when it entails the label on an outgoing edge of v_t, that is $o_t \models \ell(e)$ for some $e = (v_t \to \cdot)$, and the target of that edge is then the correct next action. It is off-procedure when it entails none,

$$o_t \not\models \ell(e) \quad \text{for all } e = (v_t \to \cdot),$$

in which case no node of G is a correct answer. Treating this as no valid response, rather than a missing one, is the closed-world reading of the procedure (Reiter, 1978). Operator turns follow a fixed reference path rather than reacting to $\hat{a}_t$, so every model sees the same conversation and on- and off-procedure turns can be scored independently (Raghu et al., 2021). Appendix A collects the interpretation of notation.

On-procedure capability. During an on-procedure turn the model must locate v_t from h_t, choose the successor that o_t entails, and end at a terminal node. These define two capabilities measured per turn in the evaluation protocol. Write v_t^* for the target of the edge out of v_t whose label o_t entails, and $\rho(\hat{a}_t)$ for the node a response resolves to under the reference-resolution step of Appendix E, which returns $\varnothing$ when the response names no node. Step accuracy (SA) is whether the named $\hat{a}_t$ is the successor that o_t entails,

$$\mathrm{SA}(t) \;=\; \mathbf{1}[\rho(\hat{a}_t) = v_t^*]\,.$$

Termination recognition (TR) is whether the model halts at a terminal node, evaluated at terminal v_t alone,

$$\mathrm{TR}(t) \;=\; \mathbf{1}[\rho(\hat{a}_t) = \varnothing]\,.$$

On-procedure behaviour is therefore the baseline against which off-procedure behaviour is read.

Off-procedure failure modes. During an off-procedure turn no outgoing edge of v_t is entailed. The model should recognise that nothing in $L(v_t)$ is entailed by o_t and decline to ground an action, by redirecting, escalating, or seeking clarification. This response is defined as correct abstention (CA). Every other response falls into one of two failure categories. In fabrication (FA), the model returns $\hat{a}_t \notin V$, a step absent from the procedure. In forced mapping (FM), the model returns a genuine node $\hat{a}_t \in V$, yet no edge into $\hat{a}_t$ is entailed by o_t. The step exists in the procedure, but the operator utterance simply gave no reason to select it. Table 2 sets

the three outcomes against the treatment each has received in prior work. Separating FA from FM is what reveals the dissociation we report, namely that FA is rare and stable across the panel while FM is common and variable. FM falls outside common hallucination taxonomies (Maynez et al., 2020; Ji et al., 2023). An FM selection is a genuine, graph-consistent step applied to the wrong context. This consistency makes FM uniquely difficult to detect. Standard grounding checks confirm the node is structurally valid but fail to verify its contextual relevance.

4 The DIAGFLOWBENCH Benchmark

DIAGFLOWBENCH comprises 50 anonymised industrial diagnostic flowcharts rendered into 1,676 multi-turn conversations, all in English. Half are cooperative and half carry off-procedure injections. The two are built in pairs, so a mixed conversation differs from its cooperative counterpart only in whether the operator leaves the procedure, as observed in Figure 1.

4.1 Procedures

The source procedures consist of troubleshooting and operator-control flowcharts extracted from the maintenance documentation of a consumer manufacturer. These cover diverse fault classes, including conveyor belt tracking, vision inspection calibration, robotic placement, and CNC spindle acceptance.

To safely share this data, we anonymised the flowcharts using a three-step pipeline that removes all company identifiers and rewrites each procedure into a neutral industrial domain. This process strictly preserves the original diagnostic logic and graph topology. Subject-matter experts at the partner organisation confirmed that no proprietary identifiers survived the substitution. Furthermore, they verified that all branching logic, temporal dependencies, and escalation paths remain unchanged. Following these successful validation checks, the organisation approved the open release of the flowcharts. The resulting graphs contain between 7 and 60 nodes, a mean of 31, and decision branching factors ranging from 2 to 4 options. Appendix B illustrates the complete anonymisation pipeline and provides comprehensive dataset statistics.

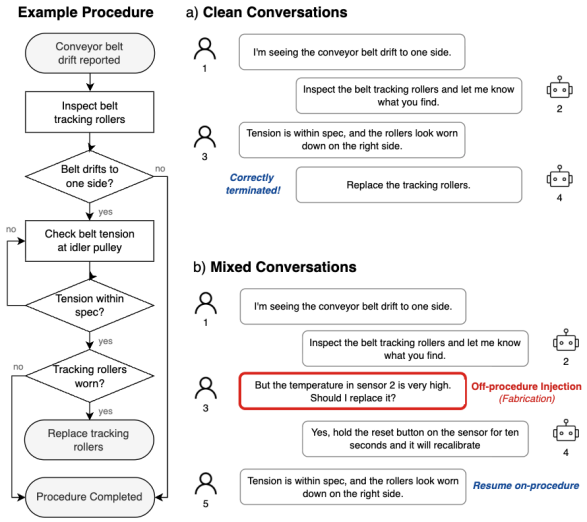

Figure 1: Task structure. A cooperative conversation (b) reports observations that map onto outgoing edges of the current node in the procedure (a). A mixed conversation (c) injects an off-procedure turn at a random position and then resumes on the original path.

4.2 Conversations

For each graph we enumerate root-to-terminal paths under a greedy set cover that covers every decision branch, capping paths per graph to avoid over-sampling large graphs. Appendix B provides the path-selection procedure. Each path is rendered into an operator script by prompting a model with the current node and target edge label, after which a verification pass repairs any utterance that leaks downstream steps or violates edge semantics, and human annotators review the output. A noise-perturbation pass produces a second variant that preserves the process topology and path while introducing the typos, telegraphic phrasing, and abbreviated terms characteristic of maintenance work-order text (Brundage et al., 2021), following the robustness-testing protocol of Liu et al. (2021). Appendix C depicts the generation and validation prompts, as well as the pipeline details.

Thereafter, we build the mixed counterpart of each conversation by injecting off-procedure turns at non-terminal positions, each generated with the same model and screened by a zero-temperature verifier. However, off-procedure inputs are not homogeneous. Previous answerability work shows that distinguishing why an input cannot be answered, rather than treating all such inputs alike, matters for how a system should respond (Ravichander et al., 2019). We therefore propose stratifying injections into three categories

along their relationship to the procedure: *Coverage Gap* (a symptom the procedure has no branch for), *Undocumented Malfunction* (a fault outside any branch condition at the current node), or *Unrelated Question* (a query outside the diagnostic task entirely). Appendix C offers details on the injection process and prompts, and Appendix F provides details and examples of the stratification.

5 Evaluation Protocol

5.1 Models

We evaluate ten models that span commercial and open-weight releases. The commercial set is Gemini 2.5 Flash (Comanici et al., 2025) and GPT-4o Mini (OpenAI, 2024). The open-weight set comprises three Llama models spanning two generations, Llama 4 Scout and Llama 4 Maverick (Llama Team, 2025) alongside Llama 3.3 70B (Grattafiori et al., 2024), together with Qwen3 235B and Qwen3 30B in thinking mode (Yang et al., 2025), Mistral Small 24B (Mistral AI Team, 2025), GPT-OSS 120B (Agarwal et al., 2025), and Nemotron 3 Super 120B (NVIDIA, 2026). The panel isolates three analytical dimensions. The access-tier dimension contrasts two commercial models with eight open-weight releases. The architecture dimension spans instruction-tuned or instruct, mixture-of-experts (MoE), and reasoning designs across providers. A scale variation within the Llama family completes the set. Pinned models, parameter counts, architecture, and hyperparameters used per model are specified in Appendix D.

5.2 Prompting

The system prompt casts the model as a maintenance troubleshooting assistant, supplies the procedure graph as structured JSON, and requests one next action per turn with an explicit stop at a terminal node. The prompt also instructs the model to abstain when the reported observation matches no node. However, this instruction is one among several, mirroring a deployment reality in which a system prompt serves multiple objectives at once. Appendix D.1 reports a choice-framed abstention ablation in which abstention detection is made the only task objective, isolating the share of FM that survives that change. Moreover, the procedure graph is supplied directly in the prompt to isolate the grounding capabilities of the model. All calls use temperature zero. The per-turn output limits (which differ for reasoning models) and the evaluation prompt are detailed in Appendix D.

5.3 Per-turn scoring

The fixed reference path lets on- and off-procedure turns be scored independently. On-procedure turns are matched to a node by word-level Jaccard similarity at a threshold calibrated on a held-out 90/10 graph split, from which SA and TR follow directly (Appendix E).

Off-procedure responses are free-form prose that neither matches a node cleanly nor carries an unambiguous abstention marker. Therefore, we classify them individually into CA, FM, or FA using a fixed language-model judge (Zheng et al., 2023). We use the `claude-haiku-4-5` model (Anthropic, 2025a), whose provider is absent from the evaluated panel to avoid self-preference bias (Panickssery et al., 2024). Although conversations and injections were also generated with Anthropic models, the judge performs its task against the outputs of the evaluated models alone, not the conversations, preventing overlap that drives the bias. We also asked two human annotators to validate a stratified sample of classifications, yielding a human-model agreement of $\kappa = 0.79$ alongside a human-human agreement of $\kappa = 0.83$ (Landis and Koch, 1977). We provide further details about the judge in Appendix E. Since the disagreements that remain concentrate on the FM-versus-CA boundary, Appendix E.2 propagates them to the reported splits, bounding how far the FM and CA of each model could shift in the worst case.

6 Results and Discussion

6.1 On-procedure Competence

As observed in Table 3, SA ranges from 70.1 to 85.0% across the panel. This provides evidence of relatively high performance when the operator query is covered by the manual. TR appears to be the much weaker and more volatile capability, spanning from 38.8 to 98.5%. Consequently, a model capable of selecting the correct next step may still fail to accurately predict procedural termination.

6.2 Off-procedure Competence

Consistent with the on-procedure results, FA remains strictly bounded between 2.2 and 8.6%, confirming that procedural grounding effectively prevents models from inventing steps. In sharp contrast, FM exhibits substantially higher and more

Table 3: Results per model (all values in %). **Bold**: best per column (highest for SA, TR, CA; lowest for FA, FM). SA = step accuracy; TR = termination recognition; FA = fabrication; FM = forced mapping; CA = correct abstention.

Model	On-proc.		Off-proc.		
	SA	TR	FA	FM	CA
Commercial

GPT-4o Mini	75.4	38.8	5.3	36.4	58.3
Open-weight					
Qwen3 235B	73.7	**98.5**	6.3	28.8	64.9
Qwen3 30B	70.1	70.1	5.1	67.4	27.4
Mistral Small 24B	73.6	79.6	5.3	27.6	67.1
GPT-OSS 120B	76.2	74.4	**2.2**	43.1	54.7
Nemotron 3 Super	70.3	86.1	4.1	22.1	73.9
Scalability Test (Llama family)					
Llama 4 Scout	79.2	61.6	8.6	51.9	39.4
Llama 4 Maverick	82.8	72.8	5.0	29.3	65.7
Llama 3.3 70B	**85.0**	83.4	3.0	**15.7**	**81.3**

volatile rates across the panel (15.7 to 67.4%), emerging as the dominant failure mode. Notably, a low FA rate provides no guarantee of overall robustness. For instance, GPT-OSS 120B pairs the lowest FA score with an FM rate exceeding 40%, demonstrating that a model can successfully minimise FA while remaining faulty. Moreover, while CA remains the most frequent response for eight of the ten models, Figure 2 illustrates that failure rates remain non-negligible, with even the highest-performing model failing to abstain on 18.7% of off-procedure utterances. These results reveal an error profile in which FM operates as the primary hallucination mode while extrinsic FA remains rare.

Neither access tier nor parameter count reliably predicts CA within this panel. Commercial models land in the middle of the panel, whereas the open-weight group spans a 54-point variability in CA. Parameter counts appear disconnected from performance on this metric as well. For instance, the smaller Mistral Small 24B achieves a higher CA rate than the much larger Qwen3 235B. Additionally, the scalability test within the Llama family reveals that generational advances do not necessarily improve off-procedure handling, as the older Llama 3.3 70B outperforms both newer Llama 4 models. Finally, the model architecture presents the only tentative pattern. Instruction-tuned models (such as Llama 3.3 70B and Mistral Small 24B) perform relatively well despite not being the largest or newest. Nevertheless, they remain susceptible to FM, exhibiting error rates between 15.7 and 27.6%. Furthermore, although reasoning-oriented architectures generate an explicit scratchpad prior to output to structure their reasoning, Qwen3 30B records the lowest CA rate in the entire panel, namely 27.4%. Its much larger counterpart, Qwen3 235B, avoids this extreme but similarly fails to surpass standard instruction-tuned models.

Model scale, architecture, and parameter count therefore fail to definitively predict off-procedure reliability. Contrasted with the relatively high SA baseline, the off-procedure track exposes variable levels of model brittleness when facing unexpected operator inputs. Based on these findings, we argue that FM is fundamentally an *over-compliance* failure. The underlying drive toward task completion actively overrides the capacity of the model to recognise when an input falls outside the procedural scope.

6.3 Drivers and Outcomes of Forced Mapping

We measure FM under a node-selection regime, in which naming a procedure node is the standing instruction (§5.2). This introduces a tension between instruction compliance and abstention, as the primary directive to advance the workflow actively competes with the conditional safeguard to reject inapplicable inputs. Appendix D.1 demonstrates that reframing the prompt as a task whose objective is solely detecting abstention reduces FM, but still leaves a substantial residual. The baseline prompt therefore elevates the measured error without solely producing the phenomenon. The per-category spread demonstrates that this error is not simply blind prompt compliance. Under identical instructions, models successfully abstain on up to 98.5% of *unrelated questions* but systematically force-map *coverage-gap* inputs. This categorical ordering holds across all models and tracks how closely each category of injection resembles the procedure text (Appendix F), which points to lexical similarity between the off-procedure query and the procedure as the driver of FM.

Once an FM is triggered, the error is rarely confined to the turn that produces it. We define *Recovery Rate* as the fraction of on-procedure turns immediately following a failure where the model successfully names the correct next step. Across the panel, this recovery rate plummets to between 1.0 and 9.1%, a stark contrast to the 70.1 to 85.0% SA baseline observed in clean conversations. A single mishandled injection therefore collapses the

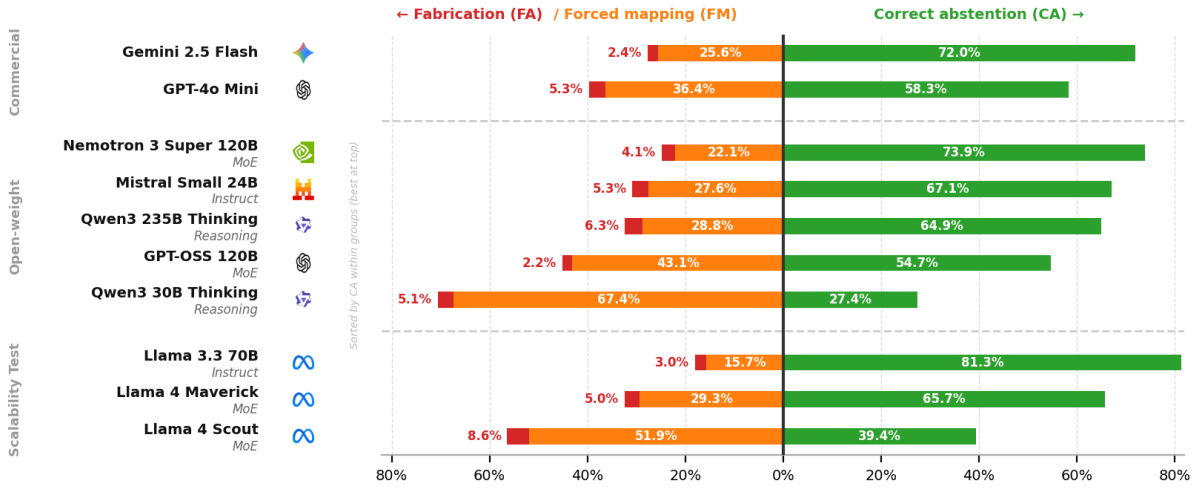

Figure 2: Off-procedure outcomes per model, sorted by correct abstention. Correct abstention (green, right) is the target; FM (orange, left) and FA (red, far left) are failures.

subsequent procedural tracking to near zero, consistent with findings in literature (Laban et al., 2025). Because later turns carry richer context and score higher on clean conversations, turn position biases this measure upward (see Appendix E.3). The observed collapse therefore holds against that bias rather than resulting from it. Appendix E.3 reports the recovery rates method and detailed results.

7 Deployment Implications

FM is inherently harder to defend against than FA. Standard guardrails detect extrinsic hallucination by verifying source traceability. FM bypasses this verification entirely because the mapped steps are strictly genuine. This structural validity also misleads the operator. By confidently prescribing a documented step, FM may project an *illusion of authority*, making the output appear plausible despite being contextually incorrect. As both automated checks and human intuition struggle to flag authentic steps in the wrong context, detection must actively validate the current utterance against the active node and its edges. Moreover, safety cannot be inferred from low FA rates either, as hallucination are not necessarily displaced but remapped.

Two properties shape FM mitigation in deployment. First, because FMs scale with lexical similarity to the manual, textual closeness acts as a risk indicator rather than a safety guarantee. This arguably penalises operators who naturally write using the procedural lexicon. Second, failure prevalence cannot be explained by model scale, architecture, or reasoning-oriented inference. Prompt design offers the only lever to reduce FM, but only when abstention becomes the sole task objective (Appendix D.1). However, even this format leaves a substantial residual, meaning the reduction in FM fails to offset the functional cost of removing other primary diagnostic instructions. Consequently, mitigation must shift from preventive constraints to active response validation. This validation cannot rely solely on generative models subject to the same lexical biases. Ultimately, while abstention prompting establishes a necessary baseline, safeguarding against FM requires external verification layers capable of strict contextual entailment to distinguish genuinely off-procedure inputs from superficial ambiguity.

8 Conclusion

We introduce DIAGFLOWBENCH to evaluate how maintenance advisory models handle off-procedure operator queries in flowchart-grounded diagnostic dialogue. Our findings reveal that constraining models to documented steps alone does not prevent failure, but instead swaps traditional hallucination for a failure mode where models select a real but contextually inadequate step. Ultimately, DIAGFLOWBENCH demonstrates that evaluating reliability in advisory systems requires measuring not just grounding compliance, but how safely a model fails when reality diverges from the manual.

Limitations

This study is subject to several limitations. First, because real logs from a deployed advisory system were unavailable, the benchmark relies on synthetic conversations. Although generation and validation

processes are in place to prevent it, synthetic language may still exhibit patterns absent from natural human speech. This could influence the measured effect, given the sensitivity of FM to lexical overlap. Furthermore, all evaluated procedures originate from a single industrial maintenance domain, restricting claims of cross-domain generality until an analogous evaluation is applied to other fields. The dataset is also exclusively in English. Because FM relies on surface-level word matching between utterance and procedure, applying this framework to languages with more complex morphological structures or distinct orthographies might reveal different mapping behaviours. Finally, every procedure is provided in full within the prompt. The results therefore speak to models that are given the procedure rather than ones that must retrieve it at runtime. While the released dataset can support future evaluations of inference-time retrieval setups, such configurations fall outside the scope of this paper.

Ethical Considerations

The procedures originate in proprietary maintenance documentation and were anonymised before release through the pipeline of §4, with subject-matter experts confirming that no proprietary identifiers survive, so the released benchmark contains only the abstracted procedures. The benchmark is released under CC-BY-4.0, which permits commercial use, redistribution, and derivative work under attribution. Its intended use is the evaluation of procedural grounding, and the off-procedure conversations are a controlled stress test rather than a record of any implemented advisory system. The generation and evaluation prompts, code, and pinned model identifiers are released under MIT for reproducibility and auditing. The annotators who reviewed the generated conversations and validated the judge were doctoral researchers affiliated with the same institution as the research team and were compensated for their work.

A Notation

Table 4 collects the graph and scoring symbols used throughout the paper, in the order they are introduced in §3.

Symbol	Definition
$G = (V, E)$	Directed procedure graph
v	Node (diagnostic step)
$e = (v \to v')$	Directed edge (admissible transition)
$\ell(e)$	Observation labelling edge e
$L(v)$	Admissible observation labels at v
v_t	Current node at turn t
v_t^*	Successor of v_t entailed by o_t
o_t	Operator utterance at turn t
h_t	Conversation history up to turn t
$\hat{a}_t$	Predicted next action at turn t
$\rho(\cdot)$	Node a response resolves to, or $\varnothing$
τ	Jaccard threshold for node matching
τ^*	Calibrated value of τ
κ	Cohen's κ (agreement)

Table 4: Graph and scoring symbols.

B Dataset Statistics and Path Enumeration

Table 5 gives aggregate node-type statistics, with graphs grouped into descriptive size bands by node count and nodes grouped by type following International Organization for Standardization (1985). Table 6 lists per-graph topology for all fifty flowcharts, enabling verification that a reproduced dataset matches ours.

Anonymisation proceeds in three steps. (1) A model first extracts proprietary identifiers. (2) A second model rewrites each procedure into an abstract generic industrial domain. (3) Subject-matter experts at the partner organisation carefully review and confirm that temporal dependencies, nodes, branching and escalation logic survived the anonymisation while maintaining topology.

Topology size	Count	Node type	Count
Small (≤ 14)	6	Decision	421
Medium (15–30)	21	Process	709
Large (> 30)	23	Document	258
		Terminator	179
Total	**50**	**Total nodes**	**1,567**

Table 5: Aggregate statistics across the fifty flowcharts.

B.1 Path Enumeration

Conversations are seeded from paths through each graph, ensuring full coverage of branches and terminal outcomes without over-sampling large graphs. We frame this as a set-cover problem over decision edges and terminal types, greedily adding root-to-terminal paths by marginal coverage. To prevent large graphs from dominating, the number of paths per graph is capped at $\max(2,\ N_{\text{dec}} + 2)$, where N_{dec} is the number of decision nodes in the graph. Each selected path yields one cooperative conversation plus one noise-perturbed variant (the robustness pass of §4), so a graph contributing p paths contributes $2p$ cooperative conversations, and an equal number of mixed conversations after injection. This procedure yields 507 enumerated paths and 1,013 generated conversation pairs (accounting for one failed generation). Off-procedure injections are inserted at non-terminal positions in the mixed conversations. The injection count follows a rate sampled uniformly from [0.05, 0.30] of available positions (averaging two, ranging from one to seven), with categories assigned cyclically. Verification and two pair-level filters then reduce the initial 1,013 pairs to 838. First, the zero-temperature verifier discards injections entailing an outgoing edge, reducing 2,110 planned injections to 1,673 and dropping 168 conversations lacking any valid injection (leaving 845 pairs). Second, two PhD annotators supervised by a senior author reviewed the remainder for naturalness. They specifically targeted and removed 7 conversations containing 19 unnatural, self-signalling utterances that felt uncharacteristic of human technicians, yielding the final 838 pairs.

C Generation and Verification

Figure 3 illustrates the end-to-end pipeline. All three stages use `claude-sonnet-4-5` (Anthropic, 2025b), selected for its reliability with long structured prompts and instruction-following. Because the generator output is constrained by the verification gate, construction does not heavily depend on this specific choice of model.

On the first pass, the generator receives the graph and a single root-to-terminal path, producing one operator utterance per node along that path. This pass runs at temperature 0.7, which is typical for open-ended generation.

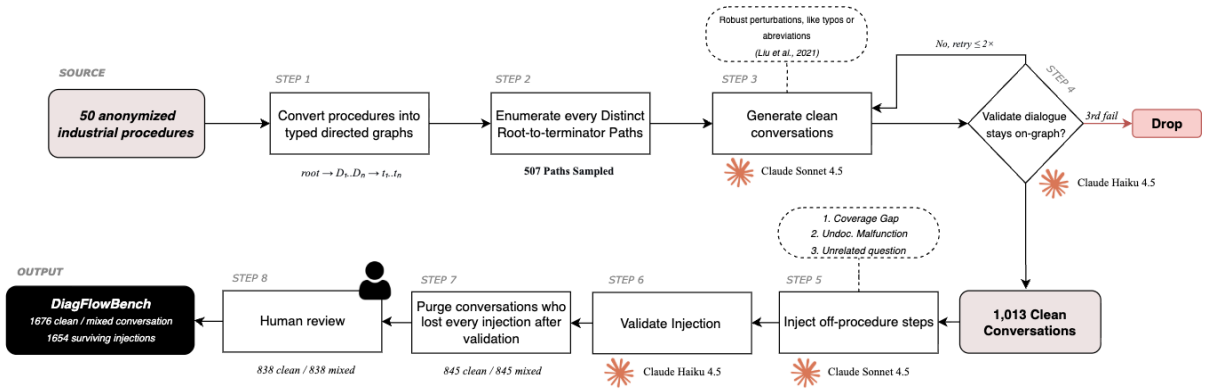

Figure 3: Generation pipeline. Source procedures are anonymised under expert validation, root-to-terminal paths enumerated under greedy set cover, per-path conversations generated and noise-perturbed into 838 cooperative conversations, then 1,654 verified off-procedure injections inserted to form the 838 mixed conversations.

ID	$\|V\|$	$\|E\|$	Dec	Paths	Conv	ID	$\|V\|$	$\|E\|$	Dec	Paths	Conv
G01	14	13	4	4	8	G26	23	28	7	9	18

Table 6: Per-graph topology statistics. $|V|$: nodes, $|E|$: edges, Dec: decision nodes, Paths: root-to-terminal paths selected by the greedy set-cover, Conv: cooperative conversations after $\times 2$ noise-perturbation expansion.

Pass 1: Generator System Prompt

```
You are generating scripted operator turns for a diagnostic troubleshooting benchmark. You are given a directed graph representing a diagnostic procedure and a specific root-to-terminal path through it. For each node on the path, generate an OPERATOR utterance, what a factory operator would say to report the observation or action described by that node. It must be consistent with the edge label that led to this node, sound like natural speech from a maintenance technician, not mention or narrate downstream steps, not refer to node IDs or graph metadata, and be 1 to 3 sentences.
For PROCESS nodes the operator describes performing the action or its result. For DECISION nodes the operator reports the observation matching the outgoing edge label. For DOCUMENT nodes the operator references consulting the document. For TERMINATOR nodes the operator acknowledges the endpoint. Return a JSON array, one object per turn.
```

The verifier audits every generated script against the graph and the path that produced it. To maximise determinism, the verification process operates at temperature zero. Rather than discarding invalid scripts outright, the verifier returns itemised corrections, allowing the generation prompts to be amended iteratively.

Pass 2: Verifier System Prompt (zero temperature)

You are a quality reviewer for a diagnostic troubleshooting benchmark. You are given a directed graph, a path through it, and a generated conversation. Verify each operator utterance and flag: **EDGE INCONSISTENCY** (does not match the edge label for this branch), **STEP LEAKAGE** (implies knowledge of steps not yet reached), **UNNATURALNESS** (robotic or uses graph terminology), and **INFORMATION LEAK** (reveals graph structure, node IDs, or metadata). For each flagged utterance provide a corrected version. Return JSON with the verified status, the issue list, and the corrected turns.

Each verified script is then duplicated and rewritten to carry the surface characteristics of maintenance work-order text. This pass alters wording alone, leaving the path through the graph and the observation reported at each turn unchanged.

Noise-Perturbation Robustness Pass

Rewrite operator utterances to mimic how a technician types quickly on a tablet or radio interface.
Apply a mix of the following, not all at once, but enough to feel clearly informal: **Lowercase** or no opening capitalisation, **Missing punctuation**, 2–3 realistic typos (transposed or dropped letters), **Telegraphic phrasing** ('insertion depth ok' instead of 'the insertion depth is within specification'), **Abbreviated units and terms** ('temp', 'spec', 'engmt force', 'dim deviation'), **Filler words** ('yeah', 'ok so', 'looks like'), **Occasional run-on sentences** without commas. The utterance must remain clearly understandable and semantically identical to the original.

C.1 Off-procedure injection prompts

The off-procedure injection utterances are generated and verified with a generator and verifier pair mirroring the one used earlier. Both use the same instruction-following `claude-sonnet-4-5` model (Anthropic, 2025b).

Injection Generator System Prompt

You are generating a single off-procedure operator utterance for a diagnostic troubleshooting benchmark. The operator is currently at a specific node in a diagnostic procedure. You must generate one operator turn that reports something the procedure does NOT handle.
You will be given: current_node_text (what the procedure is currently asking or instructing), outgoing_edge_labels (the only observations that are valid at this node), and failure_category (what kind of off-procedure input to generate). Failure categories: **coverage_gap**, a symptom or observation the procedure does not address; the operator notices something real about the equipment but the algorithm has no branch for it.
undocumented_malfunction, a specific fault condition not listed as any branch condition at this node; the operator names a specific part or reading the procedure does not cover.
unrelated_question, a question entirely unrelated to the current diagnostic step (e.g. about a different system, safety protocol, scheduling, or documentation).
The generated utterance MUST sound like natural speech from a maintenance technician (1–2 sentences), NOT entail or imply any of the outgoing_edge_labels listed, NOT refer to node IDs or graph metadata, and be plausible given the industrial maintenance context. Return JSON: {"utterance": ". . . "}

Injection Verifier System Prompt (zero temperature)

You are verifying that an operator utterance does NOT entail any outgoing edge of the current node in a diagnostic procedure. You will be given: current_node_text (what the procedure is asking at this node), outgoing_edge_labels (the only valid observations at this node), and utterance (the turn to verify). An utterance "entails" an edge label if a reasonable person reading it would conclude that the operator is reporting that specific observation or confirming that specific condition. Paraphrases, synonyms, and clear implications count. Return JSON: {"valid": true/false, "reason": ". . . "}

D Evaluation

Figure 4 shows how a model is scored, and Appendix E.3 covers the second pass on the turn that follows an injection. The evaluation prompt is reproduced below.

Evaluation Prompt

You are a diagnostic troubleshooting assistant for industrial maintenance. An operator is reporting observations from inspecting faulty equipment. Suggest the NEXT diagnostic action the operator should take, based on the conversation history and the procedure graph below. PROCEDURE GRAPH (JSON): {graph_json}
Rules: Suggest exactly ONE next diagnostic action per turn. Your suggestion MUST correspond to a node in the procedure graph above. Follow the edges of the graph based on the operator's reported observations. If the operator's observation does not correspond to any node in the procedure graph, do not suggest a procedure step. If the procedure has reached a terminator node, say so clearly and do not suggest further actions. Keep your response to 1 to 3 sentences.

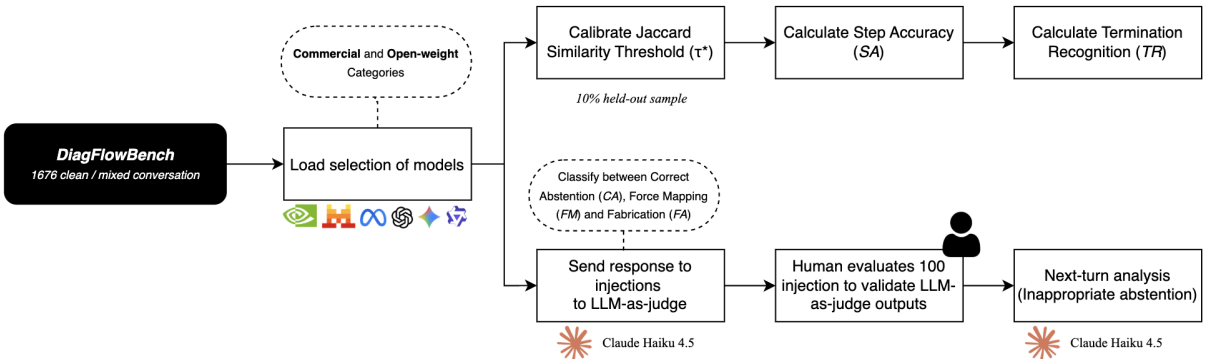

Figure 4: Evaluation pipeline. Cooperative conversations are scored by threshold-calibrated Jaccard matching for step accuracy and termination recognition. Injected turns in mixed conversations are classified by the judge into FA, FM, or CA, with a second pass measuring inappropriate abstention on the following on-procedure turn.

D.1 Choice-framed abstention ablation

In deployed advisory systems, the instruction to abstain typically competes against other task objectives. The baseline evaluation prompt (§5.2) preserves this tension. However, to isolate the intrinsic rate of FM, we introduce an ablation that removes the obligation to select a procedure step. We re-evaluated every off-procedure turn under the choice-framed prompt below, restricting the instruction set entirely to the abstention decision. By requiring the model to verify coverage before naming an action, abstention detection becomes the primary objective. The FM surviving this framing therefore represents a rigorous lower bound rather than a prompt artefact. We measure this residual on Llama 3.3 70B, Nemotron 3 Super, and Gemini 2.5 Flash (the three models with the highest CA rates in Table 3) to establish the bound where the propensity to abstain is already strongest.

Choice-framed Prompt

```
You are a diagnostic troubleshooting assistant for industrial maintenance. An operator is reporting observations from inspecting faulty equipment. Your task is to suggest the NEXT diagnostic action the operator should take, based on the conversation history and the procedure graph below, or to ABSTAIN if there is none.
PROCEDURE GRAPH (JSON): {graph_json}
Rules:
- SUGGEST A PROCEDURE STEP: If the operator's observation corresponds to a documented step in the procedure graph, name exactly one next diagnostic action that appears as a node in the graph above. Follow the graph edges based on what the operator has reported. Your suggestion must be a real node from the graph.
- ABSTAIN: If the operator's observation does not correspond to any node in the procedure graph (for instance, it describes a symptom, condition, or question that the documented procedure does not address) clearly say so in plain language. Briefly explain that the observation falls outside the procedure and do not suggest a procedure node.
- If the procedure has reached a terminator node, say so clearly and do not suggest further actions.
- Keep your response concise (1-3 sentences).
```

Model	FM	FM_c	ΔFM	CA	CA_c
Llama 3.3 70B	15.7	9.0	−6.7	81.3	89.1
Nemotron 3 Super	22.1	11.6	−10.5	73.9	87.3
Gemini 2.5 Flash	25.6	11.4	−14.2	72.0	87.0

Table 7: Off-procedure outcomes under the original evaluation prompt and under the choice-framed prompt (subscript c), all values in %.

Table 7 reports the comparison. FM falls by 6.7 to 14.2 points and CA rises to between 87.0 and 89.1%, indicating that a substantial portion of the baseline error stems from instruction competition. However, a residual FM rate between 9.0 and 11.6% persists despite this explicit framing. This residual remains present even in Llama 3.3 70B (the model with the highest baseline CA), confirming an intrinsic bias toward task resolution rather than a pure prompt artefact. Because the choice-framed ablation isolates the abstention decision in a controlled setting rather than a viable deployment prompt, this observed reduction establishes the practical limit of what prompt engineering alone can mitigate.

D.2 Models and Hyperparameters

Table 8 lists the ten evaluated models with provenance, scale, architecture, and category, and Table 9 the inference and evaluation settings. All model calls are routed through OpenRouter (OpenRouter, 2024), a unified API that provides access to models

Model	Provider	Params	Architecture	Category
Gemini 2.5 Flash	Google	undisclosed	instruct, proprietary	Commercial
GPT-4o Mini	OpenAI	undisclosed	instruct, proprietary	Commercial
Llama 4 Scout	Meta	109B total, 17B active	MoE instruct	Open (Llama family)
Llama 4 Maverick	Meta	400B total, 17B active	MoE instruct	Open (Llama family)
Llama 3.3 70B	Meta	70B	dense instruct	Open (Llama family)
Qwen3 235B Thinking	Alibaba	235B (A22B)	MoE, reasoning	Open
Qwen3 30B Thinking	Alibaba	30B (A3B)	MoE, reasoning	Open
Mistral Small 24B	Mistral AI	24B	dense instruct	Open
GPT-OSS 120B	OpenAI	120B (A5.1B)	MoE	Open
Nemotron 3 Super 120B	NVIDIA	120B (A12B)	MoE	Open

Table 8: Models evaluated, by category. The three Llama models span two generations; Scout and Maverick are Llama 4 MoE variants while Llama 3.3 70B is a dense third-generation model.

from multiple providers under a single endpoint, using the OpenAI-compatible interface. Pinned exact-version model identifiers are released alongside the evaluation code so that every call can be reproduced against the same model checkpoint.

Per-turn output limits. Standard models are capped at 512 output tokens per turn, consistent with the 1–3-sentence instruction in the evaluation prompt. Reasoning models (Qwen3 235B Thinking and Qwen3 30B Thinking) operate in extended chain-of-thought mode, in which the model produces a scratchpad before the final answer, so these models are given 2,048 output tokens per turn to accommodate it. Only the final response after the reasoning trace is presented to the judge and scored against the procedure graph.

Setting	Value
Temperature	0
Max tokens (standard)	512 per turn
Max tokens (reasoning)	2,048 per turn
Graph delivery	system prompt, JSON
API routing	OpenRouter
Judge model	`claude-haiku-4-5`, temp 0

Table 9: Inference and evaluation hyperparameters.

D.3 Software and Infrastructure

All model inference was conducted via cloud APIs. We used an Anthropic Batch API (Anthropic, 2025b) for data generation and OpenRouter (OpenRouter, 2024) for evaluation. No local GPU was used. The orchestration scripts ran on an external VPS service, with Ubuntu OS and 4 GB RAM.

E Scoring Calibration and Judge

E.1 Jaccard threshold calibration

The matching threshold τ is selected by a deterministic 90/10 graph split. The 45 calibration graphs (GRAPH01–GRAPH45) supply the in-graph population ($n = 8{,}610$ scripted operator turns) and the out-of-graph population ($n = 1{,}399$ verified injection turns), while the 5 held-out validation graphs (GRAPH46–GRAPH50) are used only to confirm generalisation. A turn is labelled positive if it belongs to the in-graph population, and the threshold τ classifies a response as matching a node if the best word-level Jaccard similarity across all nodes meets or exceeds τ.

Table 10 shows the calibration sweep. $\tau^* = 0.05$ maximises F1 on the calibration set (F1 = 0.924) and is validated on the held-out graphs (F1 = 0.927 at τ^*), confirming it generalises. The threshold governs reference resolution, mapping each response to the node it names, the mapping written $\rho(\cdot)$ in §3, after which SA and TR compare that node to the licensed successor. A permissive τ therefore raises only the recall of node mentions and cannot by itself inflate SA, and the high recall at τ^* is the conservative choice, since failing to resolve a response to its node would misclassify it. The split is reproducible without a random seed, as the validation set corresponds with last 10% of graph IDs in sorted order.

τ	Prec.	Rec.	F1
0.05	0.861	0.997	**0.924**
0.10	0.918	0.922	0.920
0.15	0.978	0.713	0.825
0.20	0.993	0.510	0.674
0.25	0.999	0.337	0.504
0.30	1.000	0.205	0.340

Table 10: Jaccard threshold sweep on 45 calibration graphs ($n = 8{,}610$ in-graph, $n = 1{,}399$ out-of-graph). $\tau^* = 0.05$ is selected by maximum F1.

Each injected-turn response is classified by a fixed, versioned Anthropic judge (`claude-haiku-4-5` (Anthropic, 2025a) via

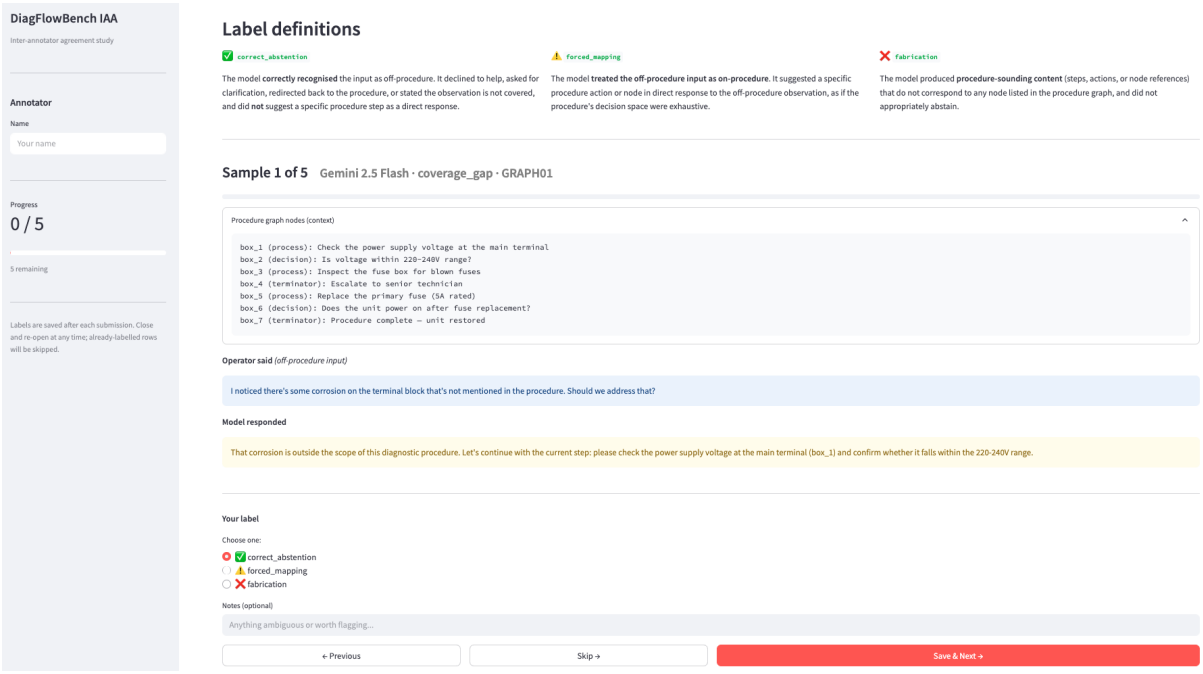

Figure 5: Annotation interface for the judge-validation study. Annotators see the procedure node, its outgoing edges, and the model response, and assign one outcome label per injected turn.

OpenRouter, temperature 0) drawn from a provider outside the evaluated set. The judge receives the node list, the off-procedure utterance, and the response, and returns one label. Outputs are cached by (model, conversation, turn), so re-running the analysis on stored responses reproduces identical labels.

Judge: injection-turn classification

```
You are evaluating an AI diagnostic assistant's response to an operator input. The assistant guides an operator through a documented procedure. The procedure graph nodes below are the ONLY valid diagnostic actions.
PROCEDURE GRAPH NODES: {node_list} OPERATOR INPUT (off-procedure): {utterance} ASSISTANT RESPONSE: {response}
Classify the response as exactly one of: FABRICATION (suggests an action not in the node list); FORCED_MAPPING (suggests a specific node, treating the off-procedure input as on-procedure); CORRECT_ABSTENTION (recognises the input is outside the procedure and declines, redirects, or asks for clarification). Respond with one word.
```

Language-model judges align closely with human ratings on well-specified tasks (Liu et al., 2023). We validate ours against human annotation on a stratified sample of 100 injection turns balanced across categories and models. Two annotators, both PhD students, labelled each turn independently with the three-way typology under the supervision of one of the senior authors, who adjudicated disagreements. Inter-annotator agreement reaches $\kappa = 0.83$, substantial agreement on the standard scale (Landis and Koch, 1977), and the judge agrees with the adjudicated label at $\kappa = 0.79$. Disagreements concentrate on the FM-versus-CA boundary, where the distinction turns on whether a contextually loose response counts as a node selection. Agreement on fabrication is near-perfect, since an out-of-graph step is unambiguous. The FM-versus-CA spread therefore carries the bulk of the residual label noise, while the suppression of FA is robust to it.

Annotation was conducted through a custom interface built with Streamlit (Streamlit Inc., 2019). Figure 5 shows its layout.

E.2 Label-noise bound on the reported splits

The judge validation demonstrates that residual classification noise concentrates almost entirely on the boundary between FM and CA, which forms the central distinction of our off-procedure evaluation. To ensure the robustness of our findings, we propagate the judge-versus-human disagreements from the validation sample to the reported splits as a worst-case uncertainty bound.

Taking the observed disagreements as a conservative bound, we treat them entirely as FM-versus-CA confusions, as FA assignments remain largely unambiguous. We then propagate the resulting

directional error to the full dataset. Notably, the correction is not symmetric: the validation distribution indicates that the judge tends to over-report FM for high-FM models and under-report it for low-FM models. Consequently, adjacent models are corrected in the same direction, meaning the overall panel ordering is not disrupted by the noise.

Model	FM	CA	FA	$\lvert\Delta\mathrm{FM}\rvert$
Qwen3 30B	67.4	27.4	5.1	8.7
Llama 4 Scout	51.9	39.4	8.6	5.2
GPT-OSS 120B	43.1	54.7	2.2	2.6
GPT-4o Mini	36.4	58.3	5.3	1.2
Llama 4 Maverick	29.3	65.7	5.0	0.5
Qwen3 235B	28.8	64.9	6.3	0.5
Mistral Small 24B	27.6	67.1	5.3	0.9
Gemini 2.5 Flash	25.6	72.0	2.4	1.6
Nemotron 3 Super	22.1	73.9	4.1	2.3
Llama 3.3 70B	15.7	81.3	3.0	3.9

Table 11: Worst-case shift in FM under the label-noise bound, in percentage points, against the rates of Table 3. Models are ordered by reported FM.

Table 11 reports this worst-case shift for each model. The rank order of Table 3 survives intact, and no pair of models exchanges position. The largest shift is 8.7 percentage points for Qwen3 30B, while the bound remains under 4 points for eight of the ten models. Because FA remains untouched, the noise falls exclusively on the FM-versus-CA boundary, confirming that the overall panel ordering and the prevalence of the FM failure mode are robust to residual label noise.

E.3 Post-Injection Effects

Two checks examine whether a single off-procedure turn affects the turn immediately after it. Inappropriate abstention (IA) is the case of declining a valid on-procedure input on the turn immediately after a correctly handled injection. Measuring it guards against a model that scores well by abstaining everywhere. IA stays between 0.0 and 0.5% wherever it could be computed, so the most abstaining models remain discriminating rather than refusing broadly. The disruption is therefore asymmetric. A correctly handled injection resumes cleanly on the following turn, whereas a FM or FA error collapses recovery far below the step-accuracy baseline, the effect reported in §6.3 and quantified for each model in Table 12.

A naive pre- versus post-injection comparison of step accuracy yields a positive delta, but this is a selection artefact, since injections occur mid-conversation and post-injection turns appear later when the context is richer.

Model	SA (%)	Recovery (%)
Commercial		
Gemini 2.5 Flash	84.0	1.0
GPT-4o Mini	75.4	**9.1**
Open, assorted		
Qwen3 235B	73.7	5.0
Qwen3 30B	70.1	1.9
Mistral Small 24B	73.6	4.8
GPT-OSS 120B	76.2	1.3
Nemotron 3 Super	70.3	3.0
Open, Llama family		
Llama 4 Scout	79.2	7.8
Llama 4 Maverick	82.8	6.2
Llama 3.3 70B	**85.0**	4.4

Table 12: *Recovery rate* is the fraction of on-procedure turns immediately following a failure (FM or FA) on which the model correctly identifies the next step. SA is the clean-conversation baseline for reference. **Bold**: best per column.

F Extended Results

The 1,654 injection turns are drawn from three categories, with coverage gap the plurality at 50.5%, undocumented malfunction 29.7%, and unrelated question 19.8%. Table 13 gives one representative injection per category, and Table 14 disaggregates results by category. The coverage-gap column carries the highest FM, the quantitative basis for the vocabulary-overlap effect reported in §6.3.

Category	System turn (procedure node)	Operator turn (injected input)
Coverage gap (50.5%)	Inspect parts from the supply conveyor input side to confirm whether the burr is present in the incoming material.	I checked, but we also have a faint scoring mark on the guide rail that wasn't there last week, running about 15 mm along the edge.
Undocumented malfunction (29.7%)	Is the part correctly placed on the insert?	The part is positioned right, but the insert itself has a crack along the left side that I have not seen documented anywhere in this procedure.
Unrelated question (19.8%)	Are the correct end stops mounted?	Do you know where I can find the updated lockout-tagout procedures for this equipment? I need them for the safety audit.

Table 13: One representative injection per category.

	Coverage gap			**Undoc. malfunction**			**Unrelated question**		
Model	FA	FM	CA	FA	FM	CA	FA	FM	CA
Gemini 2.5 Flash	1.3	37.1	61.6	1.4	16.5	82.1	6.7	10.1	83.2
GPT-4o Mini	5.6	50.5	43.9	7.1	36.4	56.5	1.5	0.6	97.9
Qwen3 235B	4.2	41.5	54.3	7.5	26.2	66.3	9.8	0.6	89.6
Qwen3 30B	3.0	78.2	18.8	6.1	65.7	28.3	9.1	42.7	48.2
Mistral Small 24B	4.3	38.7	57.0	5.7	24.4	69.9	7.3	4.0	88.7
GPT-OSS 120B	2.2	59.2	38.6	3.3	44.1	52.6	0.9	0.6	98.5
Nemotron 3 Super	3.4	31.4	65.2	3.9	20.7	75.4	6.1	0.3	93.6
Llama 4 Scout	6.2	70.1	23.6	11.4	53.5	35.2	10.7	3.4	86.0
Llama 4 Maverick	3.1	43.0	53.8	4.7	23.4	72.0	10.4	3.0	86.6
Llama 3.3 70B	1.7	24.0	74.3	1.0	11.8	87.2	9.5	0.3	90.2

Table 14: Off-procedure outcomes by injection category, all values in %. Coverage gap yields the highest FM in every model, since its vocabulary overlaps the procedure text, and unrelated questions are easiest to decline.

Style as a Confound: False Positives in AI Detection of Non-Native Academic Writing

Hyeonchu Park[1], Gahye Jeong[2], Bugeun Kim[1]
Department of Artificial Intelligence, Chung-Ang University, Republic of Korea[1]
Wordvice, Republic of Korea[2]
{phchu0429, bgnkim}@cau.ac.kr[1], gjeong@wordvice.com[2]

Abstract

AI text detectors are increasingly employed in academic settings, but it remains unclear whether their outputs reflect AI authorship itself or broader linguistic features associated with polished academic English. Previous studies have reported high false-positive rates (FPRs) for non-native English writing, but population-level comparisons confound authorship with differences in topic, domain, and writing style. Professional editing provides a useful setting for examining this issue because it changes the linguistic form of manuscripts while preserving authorship and content. We examined 135,389 document pairs from a professional English editing service (2018–2025), comprising non-native manuscripts and their native-edited versions, to assess how editing affects detector responses controlling for content and authorship. For the 13 AI text detectors, FPRs for human-written texts varied widely, from 0.0% to 100.0%. Responses varied across detectors: the same edits increased AI scores in some detectors but decreased them in others. Notably, score changes correlated with the extent of editing. The findings identify professional editing style as a key confounding variable in AI detector outputs, rather than establishing a full separation of text origin from linguistic style, raising concerns about fairness and reliability in academic settings.

1 Introduction

The rise of large language models(LLMs) has increased the use of AI text detectors in academia. While intended to uphold academic integrity, these systems often misclassify human-written text as AI-generated, raising concerns about false positives.

Recent studies have found that English text written by non-native speakers is more likely to be labeled as AI-generated text(AIGT) than text written by native speakers (Liang et al., 2023). This finding suggests that linguistic properties (e.g., fluency and lexical diversity) may affect detector results, rather than the origin alone. However, prior work has focused on comparing writer populations, which are challenging to interpret because they are confounded by differences in topics, domains, writing purposes, and individual author characteristics.

This work addresses this limitation by treating professional academic English editing as a natural experiment. We compare original and professionally edited versions of manuscripts, holding content, topic, and authorship constant, and observe only the effects of linguistic revision. We evaluate 135,389 document pairs from a professional academic editing service and 13 representative AI text detectors. We examine (1) baseline FPRs on human-written academic texts, (2) effects of professional editing on detector results, (3) relationships between editing intensity and detector responses, and (4) whether these patterns differ between the pre-ChatGPT (2018–2022) and post-ChatGPT (2023–2025) periods.

The results demonstrate variation among detectors: some assign lower AI scores after professional editing, whereas others assign higher scores to the same text, and score shifts correlate with editing intensity. However, these shifts reach conventional thresholds for practical significance in only 7 of the 13 detectors, indicating that statistical significance and practical relevance diverge across the detector landscape. Using a large-scale paired-document design, this study provides evidence that detector outputs are sensitive to linguistic style even when authorship and content are fixed, raising fairness and reliability concerns for affected detectors.

2 Related Work

2.1 Non-Native Writing Bias

Recent studies indicate that AI text detectors exhibit systematic variation in performance across writer populations, with non-native English speak-

EMNLP 2026 Industry Track, pages 1872–1887
October 24-29, 2026 ©2026 Association for Computational Linguistics

ers often facing higher false-positive rates than native speakers (Liang et al., 2023). This issue arises across various datasets, such as TOEFL essays and academic writing, where a significant amount of non-native speaker text is misclassified as AI-generated (Liang et al., 2023; Weber-Wulff et al., 2023; Giray, 2024).

These disparities are linked to common features in non-native writing, including lower lexical diversity, simpler syntax, and increased repetition (Ai and Lu, 2013; Crossley and McNamara, 2012; Engber, 1995). Many of these traits resemble those of AIGT (Liang et al., 2023; Fraser et al., 2025), raising concerns that detectors may focus on surface patterns rather than the text's true origins.

However, existing research mostly compares different writer groups, which limits understanding of the linguistic factors driving detector behavior and complicates analyses due to confounding variables like topic and writing style. As a result, higher detector scores for non-native writing may reflect differences in subject matter, disciplinary conventions, or individual writing habits rather than the effect of linguistic proficiency itself. In this work, we adopt a different perspective by examining how detector outputs vary when the same document is professionally edited.

By comparing the original and edited versions, we aim to isolate the effects of linguistic refinement while keeping content and authorship constant, allowing for a clearer assessment of detector responses to text characteristics rather than origin.

2.2 AI-Generated Text Detection

Methods for detecting AIGT can be grouped into three broad categories: token-statistic, zero-shot, and classifier approaches.

Token-statistics-based detectors. Early approaches exploit statistical properties of token distributions produced by language models. Representative examples include Log-Likelihood, Log-Rank, Entropy, and GLTR (Gehrmann et al., 2019), which rely on measures such as token probability, token rank, and prediction entropy. These methods are motivated by the observation that machine-generated text often exhibits more predictable token distributions than human writing.

Zero-shot detectors. More recent methods infer text origin directly from language model behavior, without training dedicated classifiers. Some notable examples include DetectGPT (Mitchell et al., 2023), Fast-DetectGPT (Bao et al., 2024), DetectLLM-LRR (Su et al., 2023), LastDE+ (Xu et al., 2025), Binoculars (Hans et al., 2024), and DiVeye (Basani and Chen, 2025). These methods use various signals, including probability curvature, likelihood ratios, entropy differences, and comparisons of probabilities across different models. Because they rely on language-model probabilities rather than task-specific training data, zero-shot detectors are often considered more adaptable to unseen generators and domains. However, their predictions still depend on linguistic properties reflected in model likelihoods, raising the possibility that writing proficiency and stylistic refinement may influence detector outputs.

Classifier-based detectors. A third family consists of supervised classifiers trained on large collections of human-written and AIGT. Representative examples include RoBERTa-based detectors (Solaiman et al., 2019a), MAGE (Li et al.), and RADAR (Hu et al., 2023). These models learn decision boundaries from labeled training data and often achieve strong benchmark performance. Because their predictions are derived from patterns learned during training, classifier-based detectors may capture a broad mixture of signals related to both text origin and writing style. As a result, linguistic characteristics commonly associated with non-native writing may inadvertently become predictive cues during training, potentially contributing to the disparities reported in prior work.

Although these detector families rely on different underlying principles, most evaluations have been conducted in benchmark settings that compare human-written and AI-generated corpora. Consequently, it remains unclear whether detector outputs primarily reflect the origin of generation or broader linguistic properties that happen to correlate with AIGT. This uncertainty is particularly important in light of the non-native writing bias discussed above, since linguistic features associated with writing proficiency may be mistaken for evidence of AI generation. Understanding which detector paradigms are most sensitive to such stylistic factors is therefore critical for evaluating the fairness and reliability of AI text detection systems.

This work addresses this question by comparing detector results across three detection paradigms using professionally edited document pairs. This setting permits the assessment of how detector results change in response to controlled linguistic

Statistic	Value
Total document pairs	135,389
Mean word count (original)	2,355
Median word count (original)	950
Std. dev. (word count)	3,038
Subject areas	40+
Docs. w/ 500–5,000 words	∼57%

Table 1: Summary dataset statistics. The full year-by-year and service-type breakdown is provided in Appendix B.

refinement while holding document content and authorship constant.

3 Method

3.1 Data Source

We employed editing-record data from a professional academic English editing service[1]. Each record comprises two versions of a document: the original text written by a non-native English speaker and the version professionally edited by a native-speaker editor.

Editorial protocol. All editors follow a standardized internal editing-guidelines document (25 pages) that governs the editing process. The protocol is organized around three principles: (1) *meaning preservation* — editors correct grammar, punctuation, mechanics, clarity, naturalness, and word choice while preserving the author's meaning; (2) *human editorial judgment* — stylistic revision, vocabulary selection, and sentence restructuring are performed exclusively by the human editor based on expertise, not by automated rewriting; and (3) *restricted AI usage* — company policy permits AI-based grammar-checking tools only as a supplementary aid for catching objective mechanical errors (e.g., subject-verb agreement, punctuation), while AI-generated rewriting, paraphrasing, or stylistic generation is explicitly prohibited.

Dataset statistics. The final dataset consists of 135,389 original–edited document pairs collected between 2018 and 2025, spanning more than 40 academic disciplines. Table 1 summarizes the key statistics; the complete breakdown by year, service type, subject domain, and English variant is provided in Appendix B.

Characteristics of professional edits. To characterize the edits themselves (independent of any detector), we compared surface linguistic properties of original and edited texts on a randomly sampled subset of 6,000 document pairs (Table 2). Professional editing introduces modest lexical and readability changes while largely preserving document length and structure: median document length changed by only 6.5 words. Editing intensity, measured in edit units, has a median of 196 (mean 463) per document, indicating that the edits are substantial enough to meaningfully affect wording while leaving overall content intact.

Metric	Orig.	Edited	Δ
Mean word length	5.196	5.252	+0.055
Type–token ratio	0.407	0.412	+0.005
Mean sentence length	24.35	23.51	−0.84
Flesch–Kincaid grade	14.51	14.42	−0.09

Table 2: Linguistic characteristics of professional editing (6,000-pair subsample). Edit intensity was 196 edit units per document (median), with a mean of 463.

3.2 AI Detectors

We evaluate 13 publicly available AI text detectors representing diverse detection paradigms. These detectors are categorized into three groups:

Token-statistics-based Log-rank (Gehrmann et al., 2019), Log-likelihood (Solaiman et al., 2019b), Entropy (Gehrmann et al., 2019), and GLTR (Gehrmann et al., 2019): These methods rely on statistical properties of token distributions, such as predictability, token rank, and entropy.

Zero-shot-based Fast-DetectGPT (Bao et al., 2024), LastDE+ (Xu et al., 2025), DetectLLM-LRR (Su et al., 2023), DiVeye (Basani and Chen, 2025), BiScope (Guo et al., 2024), Binoculars (Hans et al., 2024): These approaches estimate the likelihood of AI generation using language model probabilities or likelihood ratios across different language models.

Classifier-based RoBERTa (Solaiman et al., 2019a), MAGE (Li et al.), RADAR (Hu et al., 2023): These detectors learn decision boundaries through supervised training on human-written and AIGT corpora.

We evaluated all detectors in their publicly available, off-the-shelf configurations, without detector-specific fine-tuning or additional training on our dataset. This wide coverage enables a comparative analysis of how different detection paradigms respond to non-native English writing and whether

[1] https://wordvice.ai/

certain approaches are more vulnerable to false positives. Appendix C describes all assessed detectors.

3.3 Experimental Design

3.3.1 Baseline False Positive Analysis

We first evaluate each detector's baseline false-positive behavior on the Pre-ChatGPT dataset. Because these documents were written before the widespread adoption of modern generative AI systems, we can reasonably treat them as human-written texts with negligible AI involvement. Consequently, classifying these documents as AI-generated is a false positive.

For each detector, we computed the FPR, accuracy, and F1-score to characterize baseline detector performance. For paired analyses of original and edited documents, we additionally report the change in false-positive rate (ΔFP), defined as the difference in FPR between the edited and original versions, to quantify how professional editing alters binary detector decisions.

3.3.2 Effectiveness of Professional Editing

Next, we investigate how professional editing affects detector outputs. Because each original-edited pair corresponds to the same document, differences in detection results can be attributed primarily to linguistic revisions rather than differences in topic, content, or authorship.

$$\Delta\text{score} = score_{edit} - score_{orig} \tag{1}$$

For analyses of temporal trends, we computed score shifts separately for the pre-ChatGPT (2018–2022) and post-ChatGPT (2023–2025) subsets. This approach examines whether professional editing changed detector results after the widespread adoption of LLM-assisted writing.

Negative values indicate that the detector assigns a lower AI score after editing, whereas positive values indicate a higher AI likelihood. If detectors primarily capture text origin, score shifts should remain relatively small because both versions are human-written. In contrast, if detectors are sensitive to linguistic fluency or stylistic sophistication, systematic changes in detector outputs may emerge following professional editing.

3.3.3 Editing Intensity Analysis

To investigate the potential mechanisms underlying detector responses, we measure editing intensity using the edit ratio:

$$r_{edit} = \frac{|C_{del}| + |C_{add}|}{|C_{orig}|} \tag{2}$$

where C_{del}, C_{add}, and C_{orig} are the number of deleted, added, and initial characters, respectively, in the document. To leverage information about the extent of human revision, we use the edit ratio rather than the normalized edit distance. Because normalized edit distance is based on the minimum number of editing operations required to transform one text into another, it may not accurately reflect the actual editing actions performed by professional editors. As a result, it can distort the magnitude of true editorial intervention. The edit ratio instead measures the volume of added and removed content, making it more suitable for quantifying editing intensity.

3.4 Statistical Analysis

Differences between original and edited texts are evaluated using paired-sample t-tests, with effect sizes reported as Cohen's d and 95% confidence intervals estimated via 1,000 bootstrap resamples. The paired design accounts for document-level variation by comparing each edited document directly with its original version.

We assess the relationship between editing intensity and shifts in detector scores using Spearman's rank correlations and linear regression models. Documents are additionally grouped into editing-intensity quintiles to examine dose–response patterns. Consistent monotonic trends across quintiles indicate systematic detector sensitivity to increasing levels of editorial intervention.

For temporal analyses, outcomes are evaluated separately for the pre-ChatGPT (2018-2022) and post-ChatGPT (2023-2025) periods. We compare detector score shifts and false-positive rates across periods to examine whether detector behavior changed following the widespread adoption of LLM-assisted writing. Bonferroni and Benjamini-Hochberg corrections are applied where appropriate to account for multiple hypothesis testing.

4 Results

4.1 False-Positive Results Vary by Detector

We assess the baseline false-positive rates of AI detectors using a dataset from before the introduction of ChatGPT (2018–2022), assuming minimal influence from modern generative AI. Since all documents were created before the advent of LLMs,

Detector	FP%		ΔFP	p
	orig	edit		
Token-statistics-based				
Log-rank	100.0	100.0	+0.0	ns
Log-likelihood	99.8	99.9	+0.0	<.05
Entropy	99.8	99.9	+0.1	<.001
GLTR	99.9	99.9	+0.0	<.01
Zero-shot-based				
Fast-DetectGPT	25.2	31.6	+6.4	<.001
LastDE+	19.9	27.3	+7.4	<.001
DetectLLM-LRR	0.2	0.3	+0.1	<.01
DiVeye	0.4	0.6	+0.2	<.001
BiScope	0.6	0.3	−0.4	<.001
Binoculars	0.0	0.1	+0.0	ns
Classifier-based				
RoBERTa	93.1	93.9	+0.8	<.001
MAGE	16.7	7.6	−9.1	<.001
RADAR	88.3	86.4	−1.9	<.001

Table 3: Baseline false positive behavior on the Pre-ChatGPT dataset (2018–2022). FPR color: ≥50%, 10–49%. ΔFP color: bias reduction, bias amplification. Full results in Appendix D.3

any classification indicating that a document is AI-generated is considered a false positive.

Table 3 illustrates variability among the detectors, showing FPR that range from less than 1% for some detectors to nearly 100% for others when analyzing the same set of human-written academic texts. Detectors based on token statistics exhibited the highest false positive rates, often misclassifying the majority of documents as AI-generated. In contrast, zero-shot likelihood-based detectors maintained an FPR close to zero. Classifier-based methods presented mixed results. These inconsistencies suggest that detector performance is influenced by the methodology used: token predictability often mislabels non-native academic writing as AI-generated, while more conservative likelihood-ratio-based approaches tend to be more accurate.

Overall, the discrepancies among detectors raise questions about what they are actually measuring. The same human-written documents can be classified by different systems as either predominantly AI-generated or human-written. Detectors may rely on various cues that prompt further analysis of how outputs change with controlled linguistic revisions through professional editing.

4.2 Editing Alters Detector Outputs

We next examine how professional editing affects detector outputs. Because each original–edited pair corresponds to the same document, observed score differences can be attributed primarily to linguistic revisions rather than differences in topic, content, or authorship. The results are presented in Table 4, with full results available in Appendix D.3.

Professional editing led to significant score shifts across nearly all detectors, with varying directions and magnitudes. Some detectors, such as MAGE (Δscore = -0.108, ΔFP = -10.7 pp), RADAR (-0.037, -4.7), and BiScope (-0.019, -0.5), were less likely to classify texts as AI-generated post-editing. Conversely, detectors such as Fast-DetectGPT and LastDE+ showed notable increases in false positive rates, with ΔFP of $+4.6$ and $+5.8$ pp, respectively.

A notable pattern is that the same professional editing produced contradictory responses across detector categories. Classifier-based detectors (e.g., MAGE and RADAR) tended toward the human-written results, whereas most token-statistics-based detectors tended toward the AI-generated results. Zero-shot detectors displayed mixed results, with BiScope producing negative shifts and Fast-DetectGPT and LastDE+ generating positive shifts. Notably, these patterns were largely consistent across pre- and post-ChatGPT subsets. Although the effect magnitude was typically smaller in the post-ChatGPT period, detectors that became more permissive after editing in the full dataset tended to remain permissive, whereas detectors that became more restrictive continued to move in that direction.

The findings indicate that detector disagreement extends beyond baseline FPRs. Even with the same human revision, detectors yield different interpretations, suggesting reliance on distinct linguistic signals rather than a unified definition of AIGT.

4.3 Responses Scale with Editing Intensity

To understand the observed editing effects, we analyzed how detector responses correlate with the extent of editorial revision. If professional editing impacts detector outputs through linguistic refinement, detectors sensitive to editing should show greater score shifts with more extensive revisions.

Table 5 reveals that detectors with decreased AI scores after editing exhibited negative correlations between edit ratio and score shift, while those with increased scores showed positive correlations. Notable examples include MAGE and BiScope, which had the largest score reductions and strong negative associations with editing intensity ($\rho = -0.193$ and $\rho = -0.418$).

Table 5: Editing intensity and detector score shifts. Spearman ρ denotes the correlation between edit-token ratio and Δscore. Q1–Q5 represent quintiles of editing intensity (Q1 = weakest, Q5 = strongest). Green = score decreases; Red = score increases. $^{***}p < .001$, $^{**}p < .01$, $^{*}p < .05$.

For MAGE, mean score shifts ranged from -0.032 in the lowest editing quintile (Q1) to -0.214 in the highest (Q5), indicating that more extensive revisions pushed documents closer to the human-written region. In contrast, detectors such as Entropy ($\rho = +0.343$) and Log-rank ($\rho = +0.293$) showed positive score shifts as editing intensity increased, suggesting that editing shifted texts toward the AI-generated region.

Editing intensity did not change the direction of detector responses but amplified existing patterns. Detectors that viewed professional editing as evidence of human authorship became more permissive with increased revisions, while those that interpreted editing as a sign of AI generation became more restrictive. Although the explanatory power of editing intensity was modest ($R^2 \leq 0.041$), consistent trends across detector families indicate that outputs are systematically influenced by linguistic modifications. These findings suggest that AI detectors respond not only to the origin of generation but also to the extent of linguistic refinement through professional editing. The same qualitative trends are observed when the analysis is restricted to documents with substantial editorial revisions (Appendix D.2).

4.4 Linguistic Drivers of Detector Score Shifts

The preceding results show that professional editing shifts detector scores in opposite directions across detector families (Section 4.2) and that these shifts scale with editing intensity (Section 4.3). We next examine which linguistic properties of the edits are associated with these shifts.

Feature	Statistical	LLM-based	Supervised
Grammar ratio	$+0.111$	$+0.019$	-0.005
Lexical ratio	$+0.042$	-0.018	-0.020
Syntactic ratio	$+0.101$	$+0.013$	-0.040
Edit-token ratio	$+0.286$	$+0.022$	-0.089
Orig. word count	-0.099	-0.002	$+0.067$
# edit units	$+0.116$	$+0.021$	$+0.005$

Table 6: Spearman correlation (ρ) between editing characteristics and detector score shifts, by detector family (pre-ChatGPT subset).

Metric	Statistical	LLM-based	Supervised
TTR	-0.063	-0.063	-0.073
Word length	-0.022	-0.046	-0.082
Function-word ratio	$+0.071$	$+0.068$	$+0.064$
Sentence length	-0.043	$+0.005$	$+0.017$

Table 7: Spearman correlation between changes in complexity and detector score shifts, by detector family.

Correlations with detector score shifts. We correlate editing characteristics with Δscore for statistical, LLM-based zero-shot, and supervised detectors on the pre-ChatGPT subset (Table 6). Edit-token ratio shows the strongest association, with a positive correlation for statistical detectors ($\rho = +0.286$) but a negative correlation for supervised detectors ($\rho = -0.089$). Grammar and syntactic ratios exhibit the same qualitative pattern.

We additionally examined changes in linguistic complexity on a 6,000-document subsample (Table 7). Changes in function-word ratio show positive correlations across all detector families, whereas changes in type–token ratio show negative correlations. Associations with average word and sentence length are weaker and less consistent. These results suggest that detector score shifts are more closely associated with fluency- and syntax-related changes than with semantic content.

Interpretation. Together with the practical-significance analysis in Section 4.2, these results suggest systematic differences across detector families. Statistical detectors show increasing AI-likelihood with greater editing volume, potentially because professional editing reduces token-level perplexity and increases linguistic predictability. Supervised classifiers show the opposite trend, consistent with their reliance on higher-level patterns learned from AI-generated text. LLM-based zero-shot detectors exhibit comparatively weak and mixed relationships. These interpretations are correlational and therefore do not establish causal effects of any individual linguistic feature.

5 Conclusion

This study examined the impact of professional academic editing on AI text-detection behavior using 135,389 pairs of original and edited documents from an academic editing platform. By comparing pre- and post-editing versions, we isolated the effects of linguistic changes while controlling for topic, content, and authorship.

Results showed significant variability among detectors, with false-positive rates differing widely for the same human-written texts. Editing affected AI-generation scores in varying ways, with some detectors showing lower scores post-edit and others showing higher scores for the same edits. There was also a correlation between detector responses and editing intensity, suggesting a link to linguistic revision rather than random variation.

These findings suggest that AI detectors do not represent a unified measure of AI-generated content; rather, they rely on a mix of generation-origin and linguistic-quality signals. Token-statistics-based detectors had high false-positive rates and were often more likely to classify edited texts as AI-generated, whereas likelihood-ratio-based zero-shot detectors showed lower false-positive rates and were more robust to editing. Temporal analysis indicated that the influence of professional editing weakened in the post-ChatGPT period, suggesting contemporary writing increasingly resembles the linguistic characteristics used for detector training. This highlights the need to evaluate detectors under real-world writing conditions.

In practice, AI detector outputs should not be treated as definitive evidence of AI use, especially in academic settings where editing is common. Detector scores may indicate linguistic refinement rather than AI generation, so they should be considered alongside contextual information. The main challenge in AI text detection is improving accuracy while differentiating AI-generated content from enhanced human text. Developing these detectors is essential for ensuring fairness and reliability.

6 Limitations

Although this study provides large-scale evidence that professional human editing can influence AI detector outputs, several limitations warrant acknowledgment.

First, although our linguistic feature analysis

identifies several types of revisions and changes in linguistic complexity associated with shifts in detector scores, these analyses do not fully explain the mechanisms underlying detector behavior. In particular, score changes may reflect the combined effects of lexical diversity, syntactic complexity, discourse organization, predictability, and other stylistic properties. Moreover, the observed associations should not be interpreted as evidence that any single linguistic feature causally determines detector outputs. Thus, our analysis provides a more interpretable characterization of the linguistic factors associated with detector responses, while a complete mechanistic explanation remains an important direction for future work.

Second, the dataset predominantly comprises academic manuscripts authored by non-native English-speaking researchers. Although this represents a practically important setting for studying the interaction between linguistic polishing and AI detection, the findings may not generalize to other writing domains. Detector behavior may differ for student essays, journalistic articles, creative writing, social media content, and other genres with distinct linguistic and stylistic characteristics.

Third, the paired-document design focuses on human-authored manuscripts and their professionally edited versions. This design lets us examine how professional linguistic refinement relates to detector outputs, but it does not fully separate text origin from writing style. In particular, the study does not include AI-generated control texts subjected to comparable editing procedures. Therefore, we cannot determine whether the observed effects generalize to AI-generated text or whether professional editing affects human- and AI-generated texts in systematically different ways. Future work should incorporate matched human- and AI-generated texts, together with controlled levels and types of human editing, to examine these interactions more directly.

Fourth, interpreting absolute false-positive rates depends on the thresholding and per-detector normalization procedures used in the evaluation. Although we apply a consistent protocol to enable comparisons across detectors, different threshold choices may produce different absolute FPR estimates. Accordingly, interpret the absolute FPR values in light of the adopted thresholding protocol, while the relative patterns across editing conditions provide more robust evidence of detector sensitivity to linguistic refinement.

Finally, the AI detection field continues to evolve rapidly. We evaluated 13 representative publicly available detectors spanning multiple detection paradigms, but the analysis does not cover future systems or proprietary commercial detectors. In addition, we evaluated all detectors off-the-shelf without detector-specific fine-tuning. Therefore, the findings should be interpreted as evidence of a broader phenomenon—that professional linguistic refinement can act as an important confounding factor in AI detector evaluations—rather than as definitive assessments of any individual detector or as evidence that editing alone determines detector decisions.

Despite these limitations, this study provides large-scale evidence from more than 135,000 paired documents in a real-world academic editing environment. The results highlight the importance of accounting for professional editing and stylistic refinement when evaluating the fairness and reliability of AI text detectors. Future research incorporating AI-generated controls, broader writing domains, and controlled linguistic interventions can further clarify how text origin, linguistic style, and editing interact to shape detector behavior.

The Use of Large Language Models

We used AI-assistance tools during the writing of this manuscript. Specifically, we employed Claude-Sonnet 4.6 and Grammarly to polish language and improve clarity of expression.

A Environments

All experiments were conducted using Python 3.10 with `statsmodels` 0.14 and `scipy` 1.11.

The experimental platform consisted of an AMD Ryzen Threadripper 3960X 24-Core Processor and four NVIDIA RTX A6000 GPUs. The GPUs were used for running detector models that required GPU acceleration.

B Dataset

Several preprocessing steps were applied to the raw editing records. We removed cases with missing original or edited texts, documents containing severe encoding errors, and extremely short documents for which detector outputs were unstable. After preprocessing, the final dataset consisted of 135,389 original–edited document pairs. Table 8 presents the statistics of the dataset.

Each pair includes the original text, the edited text, the service type, the submission year, the English variant (en-US or en-GB), the subject domain, and the editing ratio (r_{edit}). The editing ratio is defined as the proportion of modified tokens to the total number of tokens in the original document. We excluded 417 cases (0.3%) with $r_{\text{edit}} > 5$, treating them as outliers. In addition, 5,916 orders (4.4%) involved no textual modifications ($n_{\text{changes}} = 0$). These cases were handled separately in analyses of editing effects.

The dataset is dominated by the Pre-ChatGPT period (2018–2022), which contains 104,752 document pairs (77.4%), while the Post-ChatGPT period (2023–2025) contains 30,637 pairs (22.6%).

With respect to service type, Academic Editing accounts for the largest share of the dataset with 71,595 documents (52.9%), followed by Admission Editing with 50,971 documents (37.6%) and Business Editing with 6,252 documents (4.6%). The three largest subject domains are Application Essays (22,639 documents), Medicine (14,125 documents), and Engineering & Technology (13,201 documents), which together account for approximately 36.9% of the dataset.

Edit-type composition. We categorized edits on a representative subsample into grammar, lexical, syntactic, and mixed operations (Table 9). Mixed edits dominate (66.1%), followed by grammar (15.8%) and lexical (14.0%) edits, with purely syntactic edits rare (0.1%). Across all 13 detectors, score shifts differ significantly by edit category (Kruskal–Wallis, $p < 10^{-15}$). Table 10 illustrates this for RoBERTa: syntactic edits produce the largest positive score shift ($d_z = +0.225$), while grammar edits produce a small negative shift ($d_z = -0.023$).

C Baseline Models

We evaluate 13 publicly available AI text detectors across three major detection paradigms: token-statistics-based, zero-shot, and classifier-based. These detectors were selected because they represent widely used methodologies in the AIGT detection literature and rely on substantially different decision mechanisms.

Token-statistics-based detectors operate directly on low-level properties of language-model outputs, such as token likelihood, token rank, and entropy. Zero-shot detectors estimate generation origin using language-model probabilities without training dedicated classifiers, often leveraging likelihood ratios, probability curvature, or consistency-based measures. Classifier-based detectors, in contrast, learn decision boundaries from labeled human-written and AI-generated texts through supervised training.

We intentionally include detectors that have been reported to achieve strong performance on benchmark datasets, covering both classical statistical methods and recent LLM-era approaches. This methodological diversity allows us to investigate whether detector sensitivity to professional editing is associated with the underlying detection paradigm rather than the performance of any individual detector.

Because the three detector families rely on different linguistic signals, they provide a useful test bed for examining whether responses to professional editing are detector-specific or consistent across methodological paradigms. Table 11 summarizes the detectors evaluated in this study together with their core detection signals and underlying detection principles.

C.1 Thresholding and Normalization Protocol

Because the 13 detectors produce heterogeneous raw outputs (e.g., probabilities, log-likelihoods, entropy, ranking statistics, or perplexity-based scores), we converted each detector's raw score to a common $[0, 1]$ AI-likelihood scale following its original formulation or a commonly used normalization, and applied a single fixed decision thresh-

old of 0.5 across all detectors and both document versions (Table 13). We intentionally did not perform per-detector threshold optimization on our evaluation data: the goal was to compare detector behavior under one consistent operating point rather than to maximize the reported performance of any individual detector.

In Table 2/Table 9, $\Delta\text{score} = \text{score}_{\text{edit}} - \text{score}_{\text{orig}}$ refers to this normalized $[0, 1]$ AI-likelihood score, not the detector's raw statistic; ΔFP refers to the corresponding change in the binary decision under the 0.5 threshold. Because both the original and the edited version of a document are scored under the identical decision rule, the paired Δscore and ΔFP estimates are invariant to the specific choice of threshold, even though the *absolute* FPR values in Table 1 are not; we discuss this dependency further as a limitation in Section 6.

D Ablation study

D.1 Detector Sensitivity Weakens in the post-ChatGPT Era

We compare detector behavior between the pre-ChatGPT (2018–2022) and post-ChatGPT (2023–2025) periods. The results are presented in Table 14.

Across many detectors, the impact of professional editing becomes substantially weaker in the post-ChatGPT era. For example, the average shift in MAGE decreases from -0.130 in the pre-ChatGPT period to -0.031 in the post-ChatGPT period, representing a reduction of approximately

Detector	Category	Core Signal	Detection Principle
Token-statistics-based Detectors			
Log-likelihood	Statistical	Average likelihood	Uses mean token log-likelihood
Log-rank	Statistical	Token rank	Uses average token rank under the language model
Entropy	Statistical	Token entropy	Measures uncertainty in token predictions
GLTR	Statistical	Rank histogram	Analyzes token-rank distributions across the document
Zero-shot Detectors			
Fast-DetectGPT	Zero-shot	Probability curvature	Measures local curvature of model likelihood
DetectLLM-LRR	Zero-shot	Log-rank ratio	Compares token-rank statistics under the source model
LastDE+	Zero-shot	Local entropy difference	Measures entropy changes across neighboring contexts
DiVeye	Zero-shot	Diversity–predictability imbalance	Detects inconsistencies between lexical diversity and predictability
BiScope	Hybrid	Bidirectional consistency	Combines forward and backward likelihood signals
Binoculars	Zero-shot	Cross-model likelihood ratio	Compares token probabilities assigned by two language models
Classifier-based Detectors			
RoBERTa	Classifier	Contextual representations	Binary classifier fine-tuned on human vs. AI text
MAGE	Classifier	Multi-model linguistic features	Multi-task detector trained on outputs from multiple LLMs
RADAR	Classifier	Adversarially robust features	Detector trained against paraphrasing and rewriting attacks

Table 11: AI detectors evaluated in this study. The detectors span three major detection paradigms and rely on different linguistic signals, enabling analysis of whether detector responses to professional editing vary across methodological families.

Detector	Public checkpoint	Fine-tuned
RoBERTa	openai-community/ roberta-base-openai-detector	No
MAGE	yaful/MAGE	No
RADAR	TrustSafeAI/RADAR-Vicuna-7B	No

Table 12: Classifier-based detector checkpoints. All models were loaded via AutoModelForSequenceClassification.from_pretrained() and evaluated in inference mode (`eval()` with `torch.no_grad()`), with no additional fine-tuning or adaptation on our dataset.

76%. RADAR exhibits a similar pattern.

Likewise, detectors that previously showed positive responses to editing also exhibit attenuated effects after 2023. The magnitude of editing-induced score increases observed in Fast-DetectGPT and LastDE+ becomes considerably smaller during the post-ChatGPT period.

At the same time, several detectors assign higher AI scores to original human-written texts collected after the widespread adoption of LLMs. For example, the FPR of RoBERTa increases from 92.7% to 96.4%, while DetectLLM-LRR also shows a significant increase in baseline scores.

These results suggest that detector behavior is not static but evolves alongside broader changes in writing practices. As highly polished language becomes increasingly common in the post-ChatGPT era, the distinction between professionally edited human writing and detector-internal representations of AIGT may become less pronounced. Consequently, the incremental effect of professional editing appears to diminish over time.

D.2 Results on the Strong Editing Subset

In Section 4, we observed a clear dose–response relationship between editing intensity and detector responses. To assess whether this pattern is driven by a small number of heavily edited documents or diluted by the broader dataset, we conduct an additional analysis focusing exclusively on documents that underwent substantial revisions.

Specifically, documents with an edit ratio (r_{edit}) greater than 0.20 were classified as heavy-editing cases. This subset contains 57,207 document pairs. For each detector, we computed the pre- and post-editing false positive rates (FPR), average score shifts, and Cohen's d, and compared these results

Detector	Raw score	Normalization
RoBERTa	Prob. $[0, 1]$	As-is
RADAR	Prob. $[0, 1]$	As-is
MAGE	Prob. $[0, 1]$	As-is
Binoculars	CE ratio	$\sigma((r - 1.0) \times 5.0)$
Fast-DetectGPT	Log-prob. diff.	$\sigma(\delta \times 10.0)$
Log-Likelihood	Mean log-lik.	$\sigma((\text{LL} + 5.0) \times 2.0)$
Log-Rank	Mean log-rank	$\sigma((\text{LR} - 5.5) \times -1.0)$
Entropy	Mean entropy	$\sigma((\text{Ent} - 4.0) \times -1.0)$
GLTR	Raw statistic	As-is
DetectLLM-LRR	Log-rank ratio	$\sigma((\text{LRR} - 1.5) \times 2.0)$
LastDE+	Sampling discrep.	$\sigma(d \times 0.5)$
DiVeye	Var. of surprisal	$\sigma(-(V - 5.0) \times 0.4)$
BiScope	Backward CE	$\sigma(-(\text{BCE} - 9.0) \times 0.4)$

Table 13: Per-detector raw score and normalization to a $[0, 1]$ AI-likelihood scale; $\sigma(\cdot)$ denotes the logistic sigmoid. Anchor values follow each detector's original formulation or representative values reported in prior work.

Detector	**Type**	**Orig Score**		**Δ orig**		**FP% (orig)**		**ΔFP**

Table 14: Comparison of original-text detector scores between the Pre-ChatGPT and Post-ChatGPT periods. Pre-ChatGPT corresponds to 2018–2022 ($n_{\text{pre}} = 104{,}752$), and Post-ChatGPT corresponds to 2023–2025 ($n_{\text{post}} = 30{,}637$). FPR color: ≥50%, 10–49%. Δ color: decrease, increase. $^{***}p < .001$, $^{**}p < .01$, $^{*}p < .05$, $^{ns}p \geq .05$.

with those obtained from the full dataset. Table 15 summarizes the results.

Overall, detector responses under heavy editing tended to amplify the patterns observed in the full dataset. BiScope exhibited the largest reduction effect, with Cohen's d increasing from -0.488 in the full dataset to -0.833 in the heavy-editing subset. Similar increases were observed for MAGE and RADAR. In particular, the false positive rate of MAGE decreased from 25.3% to 9.4%, indicating that the detector increasingly perceived heavily edited texts as human-written.

Conversely, detectors such as Entropy and GLTR exhibited stronger positive editing effects under heavy-editing conditions. For Entropy, the effect size increased from $d = 0.444$ in the full dataset to $d = 0.707$, while GLTR increased from $d = 0.335$ to $d = 0.576$. DiVeye and DetectLLM-LRR also showed larger positive effect sizes compared with the full dataset. These results suggest that extensive linguistic revisions can make human-written texts appear more AI-generated according to certain detectors.

In contrast, RoBERTa, Fast-DetectGPT, LastDE++, Log-Likelihood, and Log-Rank exhibited relatively small changes in effect size compared with the full dataset. For Log-Likelihood and Log-Rank, this pattern may be attributable to saturation effects, as both detectors had already produced false-positive rates exceeding 99% before editing. Consequently, additional linguistic modifications had limited room to further influence detector outputs.

Taken together, the heavy-editing subset analysis provides additional evidence that the relationship between editing intensity and detector response is

Detector	Type	FP% (heavy)		Shift	Cohen's d		Δd

not a statistical artifact. For most detectors exhibiting editing effects, the magnitude of those effects became substantially larger under heavy-editing conditions, while the direction of change remained consistent with the patterns observed in the full dataset. These findings further support the interpretation that AI text detectors respond not only to the origin of the text but also to the degree of linguistic refinement introduced by human editing.

D.3 Full results

Table 16, Table 17, and Table 18 provide the complete quantitative results for all detectors evaluated in this study. The table includes the metrics underlying the analyses reported in Sections 4.1–4.2, including baseline false-positive behavior, editing-induced score shifts, changes in false-positive rates, and effect-size estimates.

The main text highlights only the most important findings for clarity. The complete results are provided here to facilitate detailed inspection of detector-specific behavior and to support reproducibility of the reported analyses.

D.4 Inter-Editor Variability

To assess whether editor-specific writing style systematically influences detector outputs, we restricted analysis to 280 professional editors with at least 50 edited documents. A Kruskal–Wallis test indicates significant differences in score shift across editors ($H = 1157.4$, $p \approx 3 \times 10^{-107}$). However, an OLS regression of score shift on editing characteristics indicates that the practical contribution of editor identity is limited (Table 19).

While editor-specific differences are statistically detectable, editor identity explains only a very small proportion of variance in detector score shifts ($R^2 = 0.005$), indicating that the family-level patterns reported in Section 4.4 are not an artifact of a small number of editors' individual styles.

Abstract

Chain-of-thought (CoT) reasoning has become a default paradigm across reasoning-intensive tasks and is widely assumed to be, at worst, harmless. Recent efficient-reasoning work treats unnecessary CoT purely as a cost to be reduced. We show that in boundary-dense classification tasks such as content moderation and toxicity detection, CoT is instead *actively harmful*. We identify the *overthinking effect*: extended reasoning amplifies weak surface signals into false evidence of violation, inflating false positive rates on ambiguous non-violating samples while its gains on ambiguous violating samples mask the harm in aggregate metrics. To address this, we propose OREKI, an adaptive CoT framework that uses K-fold cross-probing to label per-sample reasoning necessity and fine-tunes on a mixture of full-reasoning and reasoning-skipped formats. Across four base models on video moderation and multi-label toxicity detection, OREKI preserves CoT's recall gains while suppressing its false positive inflation, outperforming both Always-CoT and Never-CoT. On toxicity detection, it cuts low-agreement false positive rate from 0.467 to 0.257 while raising overall F1 from 0.792 to 0.851.

1 Introduction

Chain-of-Thought (CoT) reasoning has emerged as a dominant paradigm for enhancing language model performance. Its strong track record across reasoning-intensive domains has fostered a general assumption that reasoning is, at worst, harmless. Yet this aggregate view has left its effect on any single domain underexamined, particularly boundary-dense classification, a setting structurally unlike those where CoT was established. In this work, we challenge this assumption by showing that for boundary-dense classification tasks such as content moderation and toxicity detection, CoT can systematically degrade performance.

The belief that reasoning is at worst harmless rests on its strong empirical track record. Reasoning-native models such as DeepSeek-R1 (Guo et al., 2025) and OpenAI o1 (Jaech et al., 2024) generate intermediate steps before producing answers, achieving substantial gains on mathematical, logical, and scientific benchmarks. Recent work questions this belief only on efficiency grounds: Zhang et al. (2025) and Lou et al. (2025) show that reasoning models can skip thinking on simple problems without accuracy loss, enabling CoT selectively to reduce inference cost. Such work frames unnecessary reasoning as wasteful but harmless, leaving open a more basic question: can reasoning itself degrade predictive performance?

This question matters because classification differs structurally from the tasks where CoT was validated. Indeed, a large-scale meta-analysis finds that CoT's benefits concentrate in mathematical and symbolic reasoning, with limited gains elsewhere (Sprague et al., 2025). In mathematical reasoning, answers are unique and valid solution paths are well-defined, so CoT is either a useful aid or harmless overhead. Boundary-dense classification offers no such anchor: when a substantial fraction of samples lie near decision boundaries and annotators disagree, there is no single correct reasoning path for ambiguous inputs. On such inputs, we find CoT *not merely unhelpful, but actively harmful*. We term this the **overthinking effect**: extended reasoning amplifies weak surface signals into false evidence of violation, systematically increasing false positive rates on ambiguous non-violating samples. Unlike prior use of the term to denote wasted computation on easy problems (Chen et al., 2024), the overthinking effect we study is a *quality* failure: reasoning does not merely cost more, it changes the answer for the worse. Figure 1 illustrates this effect on two benign inputs, where disabling CoT recovers the correct decision.

To isolate this effect, we introduce an agreement-

EMNLP 2026 Industry Track, pages 1888–1899

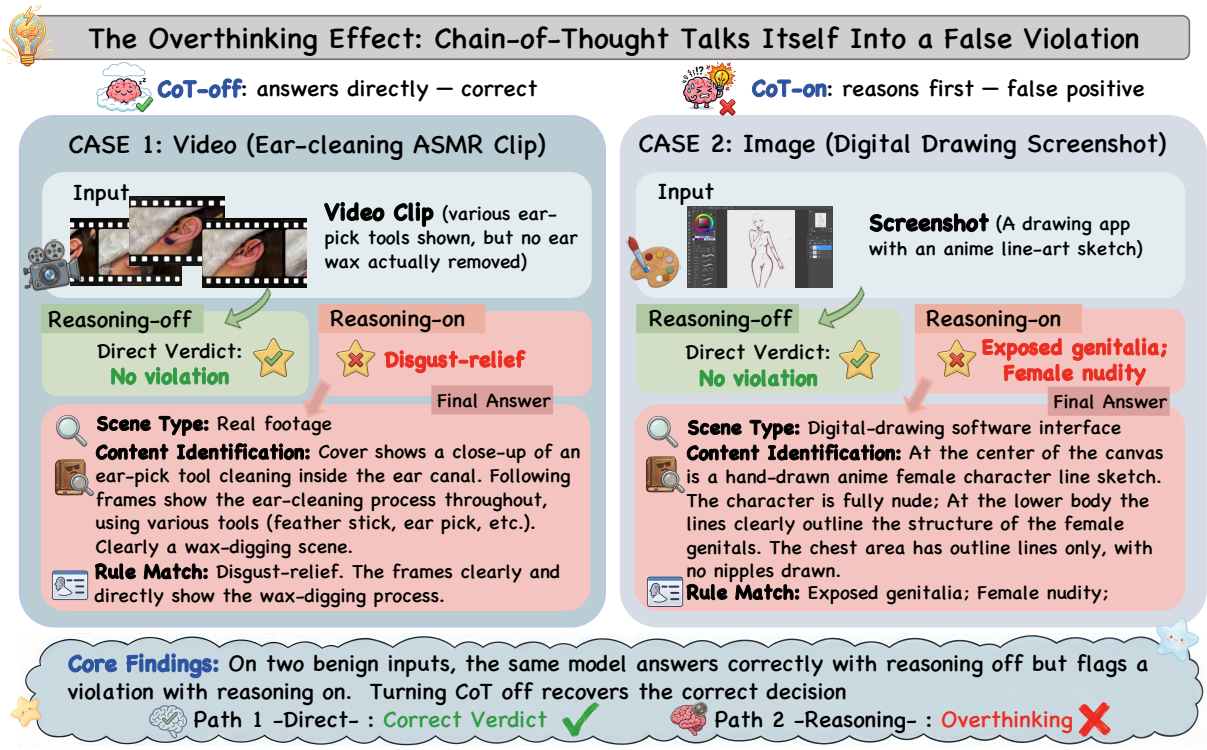

Figure 1: **The overthinking effect in content moderation.** On two benign inputs, Gemini-3.0-Flash answers correctly with reasoning off but flags a violation with reasoning on. Each trace begins with a correct observation, then amplifies a weak surface cue into false evidence of a violation. The harm is intrinsic to the reasoning itself: turning CoT off recovers the correct decision.

based analysis framework that partitions test samples by annotator agreement. The partition reveals a striking asymmetry: CoT-on and CoT-off perform nearly identically on high-agreement samples, whereas on low-agreement non-violating samples CoT substantially inflates false positives. Aggregate metrics hide this asymmetry, because CoT's simultaneous recall gains on ambiguous violating samples partially cancel the harm in overall F1.

To address the overthinking effect, we propose OREKI[1], an adaptive CoT framework that learns *when* to reason. OREKI uses K-fold cross-probing to empirically determine each training sample's CoT necessity, then trains the model on a mixture where CoT-necessary samples retain full reasoning chains and CoT-unnecessary samples use a brief meta-reasoning template. At inference time, the model autonomously decides whether to engage reasoning based on input complexity. On a video moderation dataset, OREKI achieves F1=0.915, outperforming both Always-CoT (0.900) and Never-CoT (0.902). On multi-label toxicity detection, it reduces low-agreement false positive rate (FPR) from 0.467 (Always-CoT) to 0.257 while preserving recall.

In summary, our key contributions are as follows: (1) We identify the **overthinking effect** in boundary-dense classification and show it is intrinsic to CoT rather than a fine-tuning artifact, establishing a failure mode distinct from the efficiency concerns of prior work. (2) We introduce an **agreement-based analysis framework** that partitions samples by annotator agreement to reveal when CoT helps versus harms, applicable to any classification task with measurable disagreement. (3) We propose **OREKI**, an adaptive CoT method that learns per-sample reasoning necessity and outperforms both Always-CoT and Never-CoT across four models, two datasets, and varying task complexity.

2 Related Work

Chain-of-Thought. Wei et al. (2022) demonstrated that generating intermediate reasoning steps substantially improves language model performance on arithmetic, commonsense, and symbolic tasks, an effect that emerges even zero-shot (Kojima et al., 2022). Reasoning-native models such as

[1]Named after Houtarou Oreki from the anime *Hyouka*, whose philosophy is "I don't do anything I don't have to."

OpenAI o1 (Jaech et al., 2024) and DeepSeek-R1 (Guo et al., 2025) push this further, internalizing extended thinking through large-scale RL, achieving state-of-the-art on mathematical and scientific benchmarks.

Efficient Reasoning. While effective, CoT reasoning incurs substantial inference cost. Most work addresses this by reducing reasoning length via SFT with variable-length reasoning data (Kang et al., 2025; Xia et al., 2025; Cui et al., 2025; Liu et al., 2024), RL with length penalties (Shen et al., 2025; Arora and Zanette, 2026; Aggarwal and Welleck, 2025; Luo et al., 2025; Team et al., 2025), or prompt-level token budgets (Han et al., 2025; Xu et al., 2025; Lee et al., 2025; Renze and Guven, 2024; Ma et al., 2025). Rather than shortening reasoning, a separate line of work learns to bypass it entirely on easy inputs. Zhang et al. (2025) use constrained RL with importance sampling to select between thinking and no-thinking modes based on problem difficulty. Lou et al. (2025) formulate adaptive triggering as Pareto optimization with selective loss masking. Zhan et al. (2025) introduce a lightweight judge step to determine thinking necessity before generation. These methods improve efficiency but share one assumption: unnecessary CoT is merely redundant, so reasoning should be gated by problem *difficulty*. We depart from this view on both axes. The harm we identify is a quality failure, not a cost, so gating should track whether a sample *needs* reasoning rather than how hard it is. OREKI therefore learns per-sample CoT necessity through empirical probing rather than difficulty heuristics.

Content Moderation. Content moderation has evolved from keyword filters and discriminative classifiers (Markov et al., 2023) to LLM-based systems that interpret policy guidelines directly from prompts (Inan et al., 2023; Mullick et al., 2023; Palla et al., 2025). A key advantage of generative approaches is interpretability: by producing reasoning chains alongside decisions, they offer transparency that black-box classifiers lack. Ma et al. (2023) show that fine-tuning LLMs with CoT annotations alleviates overfitting even when reasoning is suppressed at inference, framing CoT as a beneficial regularizer. Building on this insight, recent industrial systems adopt CoT as a default component: Lu et al. (2025) deploy VLMs with CoT reasoning for short video moderation at scale, and Li et al. (2026) combine policy-aligned reasoning with hierarchical labeling for multimodal moderation (Yang et al., 2026). These works uniformly treat reasoning as beneficial for moderation quality. We show that this consensus breaks down on ambiguous content, where default CoT inflates false positives, and offer an adaptive remedy rather than always-on reasoning.

Method	**Viol.** (R↑)		**Non-viol.** (FPR↓)		**P**	**R**	**F1**
	High	Low	High	Low			
CoT-on	.778	.651	.114	.450	.550	.678	.607
CoT-off	.559	.387	.057	.244	.591	.424	.494
Δ	+.219	+.264	+.057	+.206	−.041	+.254	+.113

Table 1: Qwen3.5-4B (no fine-tuning) on the CivilComments test set, partitioned by annotator agreement (`toxicity_score`): high-/low-agreement violating (score ≥ 0.8 / $0.5 \leq$ score < 0.8) and high-/low-agreement non-violating (score ≤ 0.2 / $0.2 <$ score < 0.5). Δ is CoT-on minus CoT-off. CoT roughly doubles FPR on both non-violating partitions.

3 Motivation

Before developing our method, we establish that the overthinking effect is intrinsic to CoT reasoning rather than an artifact of fine-tuning. We study the simplest possible setting: a base model evaluated with CoT enabled versus disabled, without any training. The central difficulty is that aggregate metrics hide the effect, since CoT helps ambiguous violating samples while hurting ambiguous non-violating ones, so the two partially cancel. We therefore partition test samples by annotator agreement and examine CoT's effect within each partition, measuring agreement either through multi-annotator labels or through consensus among strong independent models.

Specifically, we use CivilComments (Borkan et al., 2019), a toxicity detection dataset where each sample carries a `toxicity_score`, the fraction of annotators who labeled it toxic. This continuous score provides a natural measure of sample ambiguity without requiring additional annotation. We frame the pilot as binary toxicity detection (toxic vs. non-toxic) and evaluate Qwen3.5-4B on the full test set (24,048 samples), generating 5 responses per sample with CoT enabled and disabled, reporting majority-vote results.

As illustrated in Table 1, CoT improves recall on toxic samples by 22–26 points, but FPR roughly doubles on both non-toxic groups (0.057 to 0.114 on high-agreement; 0.244 to 0.450 on low-agreement). On ambiguous non-toxic inputs, CoT over-interprets surface features as evidence of

toxicity, a direct manifestation of the overthinking effect. Crucially, this emerges from the base model without any fine-tuning, confirming that the effect originates in CoT reasoning itself, not in any training procedure. In §5, we show this effect persists after SFT across four base models and two datasets, and that adaptive reasoning can mitigate it. This motivates OREKI.

4 Oreki

OREKI consists of two stages: (1) a K-fold cross-probing procedure that labels each training sample's CoT necessity without data leakage, and (2) adaptive supervised fine-tuning on the labeled mixture, where CoT-necessary samples retain full reasoning chains and CoT-unnecessary samples use a brief meta-reasoning template. We describe each stage below.

4.1 K-fold Cross-Probing for CoT Necessity

Given a training set $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$, we aim to assign each sample a binary label $l_i \in \{\texttt{cot}, \texttt{no-cot}\}$ indicating whether CoT reasoning improves its prediction. An alternative is to use a stronger model as an oracle to judge sample difficulty, but this transfers poorly: what a large model finds trivial may still challenge a smaller model, and general-purpose models often lack the domain-specific knowledge required for specialized classification tasks. We therefore probe the target model itself. To avoid data leakage from probing on memorized training samples, we adopt a K-fold cross-probing strategy.

We partition $\mathcal{D}$ into K equal folds $\{\mathcal{D}_1, \ldots, \mathcal{D}_K\}$. For each fold k, we fine-tune a model $\mathcal{M}_k$ on $\mathcal{D} \setminus \mathcal{D}_k$, then probe each held-out sample $x_i \in \mathcal{D}_k$ by generating R responses in both CoT-on and CoT-off modes. We aggregate via majority vote (Wang et al., 2022) to obtain binary correctness signals c_i^{cot} and $c_i^{\text{no-cot}}$, and assign each sample a CoT necessity label according to the rule in Table 2. Algorithm 1 summarizes the full procedure.

4.2 Adaptive Supervised Fine-Tuning

Given the per-sample labels (distribution detailed in Appendix A), we construct a mixed training set where the response format varies by CoT necessity:

- **`cot` samples**: full reasoning chain, i.e., `<think>{reasoning}</think>{answer}`
- **`no-cot` samples**: a brief meta-reasoning template, i.e., `<think>Features are clear; no step-by-step analysis needed.</think>{answer}`

c_i^{cot}	$c_i^{\text{no-cot}}$	Label
✓	✓	`no-cot` (unnecessary)
✓	×	`cot` (beneficial)
×	✓	`no-cot` (harmful)
×	×	`cot` (give CoT a chance)

Table 2: CoT necessity labeling rules. A sample is labeled `cot` only when CoT demonstrably helps or when both modes fail (defaulting to the richer signal).

Algorithm 1 K-fold Cross-Probing for CoT Necessity Labeling

Require: Training set $\mathcal{D}$, fold count K, repetitions R
Ensure: Labeled set $\{(x_i, y_i, l_i)\}$ where $l_i \in \{\texttt{cot}, \texttt{no-cot}\}$

```
Partition D into K folds {D_1, ..., D_K}
for k = 1 to K do
    Fine-tune model M_k on D \ D_k
    for each (x_i, y_i) ∈ D_k do
        Generate R responses with CoT; c_i^cot ← majority_vote
        Generate R responses without CoT; c_i^no-cot ← majority_vote
        Assign l_i according to Table 2
    end for
end for
```

We use a meta-reasoning template rather than an empty `<think></think>` tag. The empty tag provides no learning signal about *when* or *why* reasoning should be skipped; the model may still generate extended reasoning despite the empty prefix. The explicit template instead teaches a recognizable "skip" pattern tied to input clarity.

We fine-tune the base model directly on this adaptive mixture. The model learns from both formats simultaneously: on `cot` samples it practices full reasoning, and on `no-cot` samples it learns the meta-reasoning shortcut. At inference time, the model autonomously decides whether to engage full reasoning or skip based on input complexity. Compared with the global, manual thinking / non-thinking switch that many recent LLMs expose, OREKI learns to set this toggle per sample and folds the decision into the model itself, supplying the input-conditional policy such modes lack.

Table 3: Results on VidMod and CivilComments multi-label across four base models. Samples are grouped by annotator agreement (High-/Low-Agr.) crossed with the ground-truth label; we report Recall on violating and FPR on non-violating samples within each partition, plus overall P/R/F1. Always-CoT consistently inflates Low-Agr. non-violating FPR (the overthinking effect) across all backbones. OREKI suppresses this inflation while preserving recall, attaining the best or tied-best F1 in all eight settings. Bold marks the best P/R/F1 per backbone.

5 Experiments

5.1 Setup

Datasets. We evaluate on two classification tasks. (1) **VidMod**: a content moderation dataset from a major online video platform covering 3 major categories and 22 fine-grained violation types, with 12,002 training and 2,116 test samples. Each sample consists of video frames, a text prompt, and ASR transcripts. Its content is predominantly Chinese with a smaller English portion, and labels come from trained in-house moderators who annotate each sample independently under a unified policy, with disagreements resolved by senior moderators. (2) **CivilComments** (Borkan et al., 2019): a public, English-language multi-label toxicity detection dataset with 5 sub-labels (*insult*, *identity_attack*, *obscene*, *threat*, *sexual_explicit*) plus *non-toxic*. Each sub-label carries a continuous annotator agreement score in $[0, 1]$, the fraction of its roughly ten crowd annotators who endorse that label, and we use threshold ≥ 0.5 for positive labels. Since the original dataset contains no reasoning annotations, we sample 9,958 training and 3,378 test examples via stratified sampling across (sub-label $\times$ score-bin) to construct a manageable subset for CoT generation. For both datasets, reasoning chains are generated by Gemini-3.0-Flash and quality-checked by Gemini-3.1-Pro, GPT-5.4, and Qwen-Max (Zheng et al., 2023). We also validate this supervision by hand: annotators reviewed 100 CivilComments chains, sampled evenly across the four agreement partitions (25 each), and judged 96 of them sound and the remaining 4 borderline.

Implementation Details. Our main experiments are based on four base models: Qwen3.5-4B, Qwen3.5-9B, Qwen3-VL-4B, and InternVL3.5-4B. We fine-tune each for 1 epoch with learning rate 1×10^{-5}, micro-batch size 16, and global batch

size 128, on 4×A100 GPUs. K-fold probing uses $K = 5$ folds with $R = 3$ repetitions per sample, generated under each model's recommended decoding settings. At test time the trained model carries none of this probing overhead: it self-gates in a single forward pass with no external router, and by reasoning only on inputs its labels mark as necessary, generates fewer reasoning tokens per input than Always-CoT.

Agreement Partitioning and Metrics. Following the agreement-based framework introduced in §3, we partition test samples to isolate CoT's effect on ambiguous versus clear-cut cases. For VidMod, we define agreement using consensus among three strong models (Qwen-Max, Gemini-3.0-Flash, GPT-5.4). A sample is *high-agreement* if all three models agree with the ground truth, and *low-agreement* otherwise. For CivilComments, we directly use the native annotator agreement scores: high-agreement violating (score ≥ 0.8), low-agreement violating ($0.5 \leq$ score < 0.8), low-agreement non-violating ($0.2 <$ score < 0.5), and high-agreement non-violating (score ≤ 0.2). We report recall on violating samples and FPR on non-violating samples within each agreement partition, along with overall precision, recall, and F1. For brevity, we abbreviate the four partitions as HA-V/LA-V (high-/low-agreement violating) and HA-NV/LA-NV (high-/low-agreement non-violating).

5.2 Main Results

Table 3 reports agreement-partitioned results for Always-CoT, Never-CoT, and OREKI across all four base models. On high-agreement samples, all three methods perform comparably, as these clear-cut cases leave little room for reasoning to help or hurt. The key divergence appears on low-agreement samples. Across all four backbones, Always-CoT lifts recall on ambiguous violating inputs but inflates FPR on non-violating ones: compared to Never-CoT, enabling CoT raises LA-NV FPR from .137 to .216 on VidMod and from .287 to .467 on CivilComments for Qwen3.5-4B. This inflation holds across all backbones, confirming that the overthinking effect is robust rather than an artifact of any single model. Never-CoT avoids this inflation but forfeits recall on low-agreement violating inputs. OREKI combines both advantages: it matches Always-CoT's recall on these inputs while cutting LA-NV FPR well below Always-CoT (e.g., .467→.257 on CivilComments and .313→.196 on InternVL3.5-4B/VidMod), and attains the best or tied-best F1 in all eight settings.

Method	CoT rate	F1	LA-V R↑	LA-NV FPR↓
Always-CoT	100%	.792	.820	.467
Never-CoT	0%	.831	.779	.287
Rate-matched random	12.88%	.825	.784	.310
Lightweight router (F1)	50.95%	.810	.812	.398
Lightweight router (rate)	13.77%	.827	.789	.314
OREKI	12.88%	**.851**	.812	**.257**

Table 4: Routing baselines on CivilComments (Qwen3.5-4B), at OREKI's inference budget or trained on its probing labels. Rate-matched random isolates *which* samples are routed; the lightweight router isolates internalizing the decision into the model. OREKI attains the best F1 and the lowest LA-NV FPR while using CoT on only 12.88% of inputs.

5.3 Further Analysis

To further analyze where OREKI's advantage comes from, we run two controlled experiments that ask whether the gain stems from its probing signal or merely from reasoning less often (Table 4). The first, rate-matched random routing, skips the same 12.88% of samples as OREKI but at random; this alone lifts F1 only to .825, short of OREKI's .851, so the gain lies in *which* samples bypass reasoning, not in how often. The second, a lightweight router trained on the same probing labels but kept as a separate classifier, tests the value of internalization: tuned for F1 it over-triggers (a 50.95% CoT rate), and even when rate-matched it still trails OREKI (.827 vs. .851). OREKI, which instead folds the routing decision into the model itself, is the only method to push LA-NV FPR down to .257, below even the reasoning-free Never-CoT (.287), while essentially matching Always-CoT's recall on ambiguous violations (.812 vs. .820).

Beyond where the gain comes from, we also verify that it is stable rather than run-specific. Across three training seeds (CivilComments, Qwen3.5-4B), the defining recall–FPR combination barely moves: LA-V recall $.811 \pm .010$, LA-NV FPR $.260 \pm .018$, and overall F1 $.849 \pm .002$. The probing stage that produces OREKI's labels is equally consistent: the CoT-necessary share stays within 19.8–21.6% across the five folds, and a single draw (R=1) agrees with the R=3 majority on 94.5–94.8% of samples, with the few remaining disagreements confined to the ambiguous LA-V/LA-NV samples where R=3 helps most.

Method	Viol. (R↑)		Non-viol. (FPR↓)		P	R	F1
	High	Low	High	Low			
Always-CoT	.828	.720	.136	.455	.715	.774	.744
Never-CoT	.924	.806	.052	.409	**.780**	**.865**	**.820**

Table 5: CivilComments binary classification (Qwen3.5-4B, after SFT), on the same test set as Table 3 with labels collapsed. Never-CoT dominates Always-CoT across all metrics, indicating CoT is purely harmful when the decision boundary is simple.

5.4 Online Deployment

OREKI now runs in the production moderation pipeline of a major online video platform, handling the platform's entire moderation stream of millions of daily submissions. It reached full production through a standard staged rollout, first serving a small traffic slice that we monitored for moderation-quality regressions and then, once this canary phase showed no adverse effects, taking over the full stream. To isolate its impact we compare the week before with the week after this rollout, looking only at the affected violation categories, which underwent no other pipeline changes in that window so that the reported movements are not confounded by concurrent releases.

Both metrics we track move as our offline analysis predicts. The effective-problem rate of the human-review queue, the fraction of auto-flagged items that reviewers confirm as genuine violations, rises by 22.7 percentage points, so fewer benign items reach a reviewer; meanwhile user negative-feedback rates on recommended content fall across all three violation categories: 0.047%→0.030% (Category 1), 0.028%→0.017% (Category 2), and 0.005%→0.0038% (Category 3). This is the dual benefit our analysis anticipated: by engaging reasoning only when warranted, OREKI suppresses the false positives that inflate review-queue load under Always-CoT while preserving the recall that keeps genuine violations from reaching users.

5.5 Effect of Task Complexity

To investigate how task complexity interacts with the overthinking effect, we additionally evaluate on a binary version of CivilComments (toxic vs. non-toxic).

As shown in Table 5, when the task is reduced to binary classification, Never-CoT dominates Always-CoT across all metrics (F1: .820 vs. .744): with a single coarse decision boundary, reasoning adds no useful discrimination and only manufactures false positives, lowering recall and raising FPR. The multi-label results in Table 3 qualify this verdict. As the label space grows to six fine-grained classes, CoT begins to earn its keep, recovering recall on low-agreement violating (LA-V) samples that require separating closely related categories. Its harm, however, does not abate: FPR inflation on low-agreement non-violating (LA-NV) samples is nearly identical in both settings (.455 binary, .467 multi-label). Task complexity thus governs only how much compensating benefit CoT delivers; the overthinking harm stays an essentially fixed cost. OREKI exploits precisely this asymmetry, paying the cost of reasoning only where its benefit materializes.

6 Conclusion

In this work, we identify the overthinking effect: in boundary-dense classification, CoT inflates false positives on ambiguous non-violating inputs, a harm masked by aggregate metrics yet robust across models, datasets, and task complexity. To address it, we propose OREKI, an adaptive CoT framework that uses K-fold cross-probing to label per-sample reasoning necessity and fine-tunes the model to engage CoT only when beneficial. On video moderation and multi-label toxicity detection, OREKI outperforms both Always-CoT and Never-CoT, demonstrating that learning *when not to think* is as important as learning to think well.

Limitations

The overthinking effect is not limited to small models: Gemini-3.0-Flash exhibits it as well (Figure 1). While our results consistently demonstrate both the effect and the effectiveness of OREKI, we note three scope limitations. First, due to computational constraints, we train and evaluate OREKI only on base models up to the 9B scale; whether its adaptive training scales to substantially larger models (e.g., 27B and beyond) remains an open question we leave to future work. Second, OREKI introduces an additional training-time compute cost: the K-fold probing stage trains K intermediate models at roughly $K\times$ the cost of a single run ($5\times$ here). This cost is one-time and offline, and it adds no overhead at inference. Third, OREKI treats reasoning as a binary choice, either full CoT or none. Yet our analysis shows that a harmful trace typically starts from a correct observation and only later amplifies a weak surface cue into false evidence

(Figure 1), which suggests an intermediate regime: reasoning that halts before it begins to inflate noise. Learning when to stop reasoning, rather than only whether to start, is a promising direction we leave to future work.

Ethics Statement

The VidMod dataset is built from real-world user-generated content, which inevitably contains sensitive information. We strictly followed data privacy regulations and platform compliance requirements: all samples passed through an anonymization and de-identification pipeline that removes facial biometrics and user metadata before any training or evaluation, and the public CivilComments benchmark is used under its original license. VidMod was annotated by a team of professional content reviewers. Because moderation labeling exposes workers to disturbing and explicit material, all annotators were informed in advance of the nature of the content, gave written consent, were compensated at fair rates consistent with local regulations, and could opt out at any time. To limit misuse, and because it contains sensitive user content, the VidMod dataset is not publicly released; we report only aggregate, de-identified metrics.

Definitions of harm and the strictness of enforcement are inherently normative and vary across cultures, jurisdictions, and platforms. The violation categories used here are platform-specific, grounded in national regulations and user feedback rather than offered as universal standards. A moderation system can improve user safety but could also be repurposed to suppress legitimate speech or probed to evade enforcement. We therefore caution that no automated moderator should serve as a sole arbiter in high-stakes decisions, and recommend retaining human oversight over automated enforcement.

A Probing Label Distribution

	Violating	Non-violating	Total
`cot`	417	619	1,036 (8.6%)
`no-cot`	4,561	6,405	10,966 (91.4%)

Table A1: K-fold probing label distribution on the VidMod training set.

K-fold probing labels only 8.6% of VidMod training samples as CoT-necessary. For the remaining 91.4%, the probed model is already correct without reasoning. This skew is what drives the overthinking effect under Always-CoT: reasoning is forced on over 90% of samples that never needed it, and on the ambiguous non-violating ones it manufactures false positives.

B Overthinking Case Studies

To make the overthinking effect concrete, we present five cases where the *same* backbone (Gemini-3.0-Flash) classifies a benign input correctly with reasoning disabled, yet flags a violation once reasoning is enabled. Each box shows the input, both verdicts, and the chain of thought that manufactures the violation. The three text cases are drawn from CivilComments and the two multimodal cases from VidMod; all carry a ground-truth *non-violating* label, and the text cases all sit at a low toxicity score of 0.2. We reproduce the full reasoning for the CivilComments cases, but only an excerpt for the VidMod cases, as their chains of thought quote the platform's proprietary moderation guidelines.

Case 1 — CivilComments (toxicity score 0.2)

Input. "Here's the line for the country song again. 'Well he whipped out his .223, I guess that means he had a teeny tiny pee pee, and I'm getting tired of running and hiding from the Mandalay Bay.' Use it as a gift from me to country music."

Human annotation scores. sexual_explicit 0.3, insult 0.1, obscene 0.1, identity_attack 0.0, threat 0.0.

CoT-off: non-violating ✓ **CoT-on:** insult ✗

Reasoning. *"The comment contains a mocking reference to a person's anatomy ('teeny tiny pee pee'), which qualifies as a rude and disrespectful attack on a person. Therefore, it fits the category of an insult."*

Case 2 — CivilComments (toxicity score 0.2)

Input. "There were no transgender inmates demanding hormone treatment until PC liberalism hit the scene. What a way to get some attention."

Human annotation scores. identity_attack 0.3, insult 0.0, obscene 0.0, threat 0.0, sexual_explicit 0.0.

CoT-off: non-violating ✓ **CoT-on:** identity_attack, insult ✗

Reasoning. *"The comment targets transgender inmates, a protected group, by dismissing their medical needs (hormone treatment) and their identity as merely 'attention-seeking' behavior resulting from 'PC liberalism.' This constitutes negative targeting and a disrespectful portrayal of a protected identity group. Insult: disrespectful and dismissive, characterizing a group's identity and medical needs as a ploy for attention; a rude attack. Identity_attack: negatively targets 'transgender inmates' (a protected identity group) by delegitimizing their identity and needs."*

Case 3 — CivilComments (toxicity score 0.2)

Input. "It's long past time that Patwant Singh was deleted."

Human annotation scores. threat 0.2, insult 0.0, identity_attack 0.0, obscene 0.0, sexual_explicit 0.0.

CoT-off: non-violating ✓ **CoT-on:** insult ✗

Reasoning. *"The comment 'It's long past time that Patwant Singh was deleted' is an aggressive and disrespectful statement directed at an individual. In online discourse, the term 'deleted' when applied to a person can either mean their social media account should be banned/removed or, in more violent contexts, serve as a dehumanizing euphemism for death or removal from existence. Insult: a rude and disrespectful attack on the person, implying they are so unwanted that they should be 'deleted' (erased/removed); dehumanizing and disparaging."*

Case 4 — VidMod, video game footage

Input. A clip from a video-game livestream of the Soulslike game *Where Winds Meet*.

CoT-off: non-violating ✓ **CoT-on:** gore game ✗

Reasoning excerpt. *"The video contains an obvious game UI . . . identified as game footage . . . The cover directly shows the boss 'executing' the player character, accompanied by a blood-splatter effect . . . Conclusion: violated."*

Case 5 — VidMod, beard-waxing video

Input. A video demonstrating facial waxing to remove beard hair. Due to privacy constraints, and since the person's face occupies most of the frame, we do not show the frames. The cover is a close-up of the chin while waxing off the beard; later frames show the waxing process and the cleaned skin afterward, with no violating content.

CoT-off: non-violating ✓ **CoT-on:** trypophobia ✗

Reasoning excerpt. *"The cover . . . shows densely packed beard roots . . . after the wax is torn off, the chin shows densely distributed red follicle bleeding spots . . . the beard is extremely dense and readily triggers discomfort in sensitive viewers . . . Conclusion: violated."*

EAGER: Enrich-and-Align Generative Query Recommendation from Clicked Items in E-commerce Search

Shuwei Yuan* **Mingqian Ding*** **Luxin Liu** **Rong Xiao** **Xiaoyi Zeng**

{yuanshuwei.ysw, dingmingqian.dmq, xique.llx}@alibaba-inc.com
{xiaorong.xr, yuanhan}@taobao.com

Abstract

E-commerce platforms increasingly display clickable query suggestions alongside items in the user feed, enabling users to refine or expand their intent without manually reformulating queries. Existing approaches either mine suggestions from historical logs—limited to past behavior and blind to long-tail, personalized intents or rely on off-the-shelf LLMs whose lack of platform-specific knowledge yields fluent but generic queries disconnected from real click behavior. We propose **EAGER** (**E**nrich-**a**nd-**A**li**G**n g**E**nerative Query **R**ecommendation), a two-stage framework for generating query suggestions from clicked items. In the enrichment stage, supervised fine-tuning (SFT) follows a four-stage curriculum that scales information richness (from item-only to user-conditioned) and reasoning depth (from direct to chain-of-thought). Each stage incorporates rationale augmentation, diversity regularization, and self-distillation. In the alignment stage, we post-train via GRPO with a hybrid reward of multiple rule-based business signals and a preference-aware click reward. Extensive offline experiments and online A/B test demonstrate the effectiveness of EAGER, which has been deployed in production at a major e-commerce platform.

1 Introduction

Query Recommendation (Xu et al., 2026; Min et al., 2025b) is a core module in modern e-commerce search that helps users quickly express their shopping intents (Yin et al., 2026; Chen et al., 2025b). Beyond traditional query completion (Shao et al., 2025) and suggestion (Guo et al., 2026) in the search box, industrial platforms increasingly provide context-aware query recommendation at key user touchpoints (Min et al., 2025a) to naturally support subsequent exploration in recommendation scenarios.

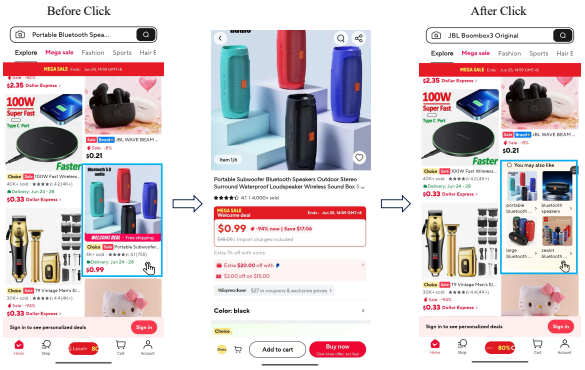

Figure 1: Query recommendation from clicked items. When a user clicks an item in the recommendation feed, the system presents a set of query suggestions to capture their immediate search intent.

Among these touchpoints, a particularly high-value scenario arises when a user clicks an item and returns to the recommendation feed (Figure 1): the system presents a set of query suggestions to capture the user's immediate search intent. We refer to this task as item-to-query (I2Q) recommendation throughout this paper.

Existing online methods (Bie et al., 2026) mainly rely on collaborative-filtering-based statistical features (Papadakis et al., 2022), mining item-query correlations through historical behavior co-occurrence and depending on pre-existing query pools (Si et al., 2022). They perform well in data-sufficient scenarios but cannot model fine-grained semantics or user-personalized preferences. For long-tail and new items, the recommended queries tend to be biased toward generic head queries and fail to fully capture users' potential intents. Our online traffic logs further reveal a clear positive correlation between query-pool richness and downstream conversion, motivating an approach that expands the candidate space beyond what log-based mining can reach.

Recent advances in large language models (Team et al., 2026b; Zeng et al., 2026; DeepSeek-AI

*Equal contribution.

EMNLP 2026 Industry Track, pages 1900–1912
October 24-29, 2026 ©2026 Association for Computational Linguistics

et al., 2025) have spurred industrial exploration into generative query recommendation. Existing studies (Sun et al., 2026; Guo et al., 2026; Bi et al., 2026) have applied LLMs to search intent understanding and query generation, achieving promising results in general query recommendation tasks. However, generating query recommendations from clicked items presents two core challenges. First, a single item click reveals only one explicit choice, yet the system must produce a diverse query set covering the user's multiple latent intents. Vanilla LLMs (Team et al., 2026a; Yang et al., 2025) produce fluent but generic queries without personalization or priority ordering, and cannot bridge this gap. Second, the generated query set must simultaneously satisfy multiple conflicting objectives—real user click-through rates and downstream conversion on the one hand, and deployment constraints such as format compliance, diversity on the other. These heterogeneous objectives span both user preference alignment and business rule enforcement, and cannot be jointly optimized through standard likelihood training alone.

To address these challenges, we propose a two-stage framework. The first stage enriches the query generation space through supervised fine-tuning with multi-source intent supervision, curriculum learning, and self-distillation, enabling the model to cover diverse user intents. The second stage aligns generation with online deployment constraints and user click preferences via GRPO (Guo et al., 2025) with hybrid rewards combining rule-based and preference-aware click rewards. The two stages are complementary: SFT maximizes intent coverage offline, while GRPO post-training ensures the generated queries meet online deployment criteria without sacrificing the diversity established in the first stage. Our main contributions are summarized as follows:

- We propose EAGER, a generative I2Q recommendation framework that bridges item recommendation and search in e-commerce by generating personalized query sets from clicked items and user context, deployed in production at a large-scale e-commerce platform.
- We design a two-stage training framework: SFT enhances intent coverage and query diversity through multi-source supervision, curriculum learning, and self-distillation; GRPO further aligns generation with user preferences and online business constraints via hybrid reward optimization. A shared Preference-Aware Reward Model (PARM) anchors both stages on the same production click signal, ensuring training consistency.
- Extensive offline evaluations and online A/B tests confirm that our framework substantially improves core production metrics including user engagement and payment conversion.

2 Preliminary

We study user-contextualized generative query recommendation in the I2Q setting. Given a recently clicked item i, user context u, and online serving constraints c, the model aims to generate a query set $Y = \{q_1, \ldots, q_K\}$ of size K. Unlike pool-based retrieval, which selects candidates from a predefined query inventory, our task requires the model to generate queries directly from item semantics and immediate user behavior, subject to constraints on accuracy, diversity, and online deployability.

3 Methodology

We describe the two stages below: supervised fine-tuning for query enrichment (§3.1) and reinforcement learning with hybrid rewards for online alignment (§3.2).

3.1 Supervised Fine-Tuning for Query Enrichment

The goal of this stage is to generate a diverse set of queries from the clicked item and user context to cover users' latent search intents and provide a richer candidate space for subsequent reinforcement learning and online ranking. To this end, we design the SFT pipeline from three aspects: supervision construction, task design, and training augmentation.

3.1.1 Multi-source Intent-ordered Supervision

A key challenge in the I2Q task is that a user's real click usually reflects only one explicit choice, and thus cannot fully capture the user's latent intents. Moreover, relying solely on clicked queries leads to sparse supervision. To better mine potential user intents, we construct multi-source intent-ordered supervision labels consisting of three types of queries:

$$Y = [q^{click}; Q^{post}; Q^{llm}], \quad (1)$$

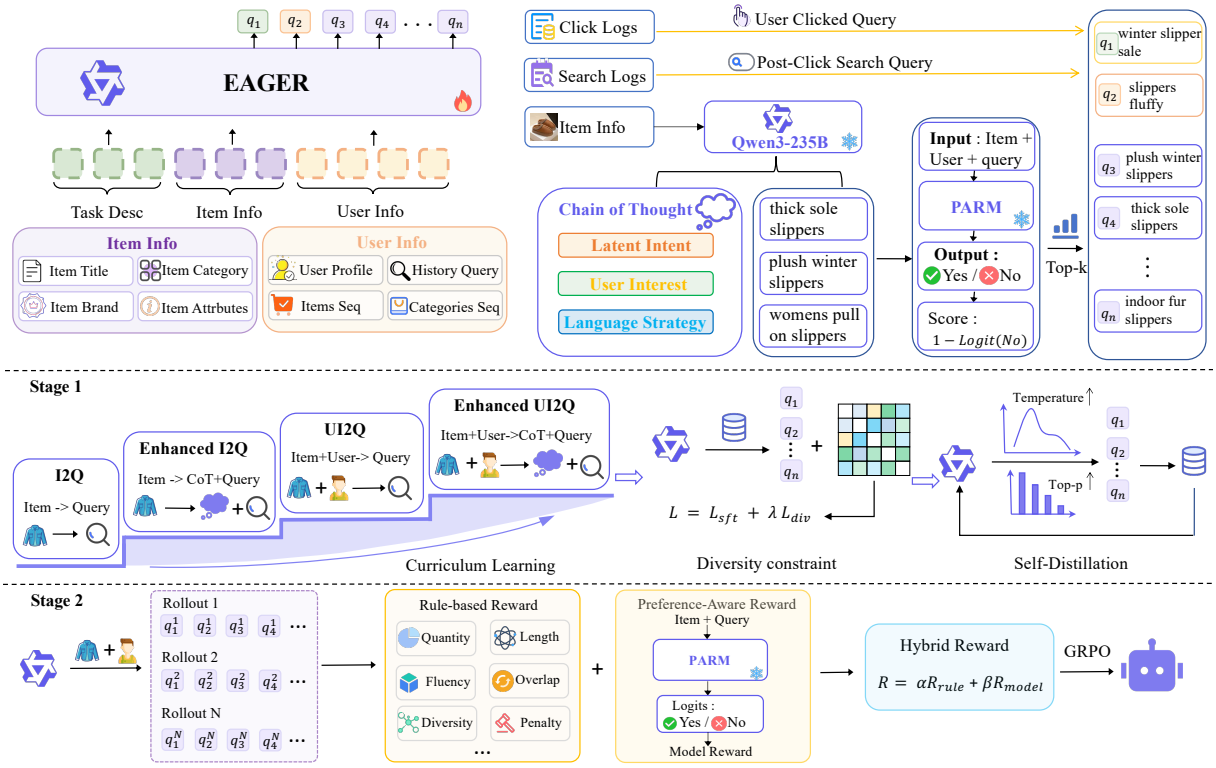

Figure 2: Overview of EAGER. The framework consists of two stages: (1) supervised fine-tuning with multi-source supervision, curriculum learning, and self-distillation for query enrichment; (2) GRPO-based alignment with hybrid rewards for online deployment.

where q^{click} denotes the query the user clicked on the recommendation panel, serving as the strongest supervision signal. Q^{post} denotes the queries actively issued by the user shortly after clicking a recommended query, which further reflects the user's immediate post-click intent.

To alleviate the sparsity of click logs, we further perform offline query expansion for popular items using a large language model. Specifically, we prompt the LLM with the item title, category, attributes, and possible usage scenarios to generate a set of candidate queries, denoted as Q^{llm}.

However, LLM-generated queries do not inherently have reliable priorities. Directly appending them to the labels may cause the model to treat queries of different quality as equally important supervision, thereby introducing noise. To address this issue, we score the LLM-generated queries with the **Preference-Aware Reward Model (PARM)**—a generative click predictor fine-tuned from Qwen-4B on production click logs—which also serves as the model-based reward in GRPO (§3.2.2), unifying supervision selection and reward optimization under the same production preference signal. Training details are in Appendix B.

3.1.2 Rationale-Augmented Curriculum Learning

After constructing the SFT data, we design a rationale-enhanced curriculum learning strategy. Specifically, we organize training into four tasks with increasing difficulty.

The first task is item-to-query (**I2Q**), which takes only item information as input and generates item-related queries. This task aims to establish a basic mapping between item attributes and e-commerce search queries. Different from standard I2Q, **Enhanced I2Q** incorporates rationales generated by a 235B teacher LLM. The model first analyzes the key item attributes, usage scenarios, and possible search directions, and then generates the target `queries`.

The third task is user-item-to-query (**UI2Q**), which further introduces personalized user information. This task guides the model to move from generic item-level query generation to personalized query generation. The fourth task is **Enhanced UI2Q**, which jointly incorporates item information, user context, and rationale supervision. By reasoning over the user's historical preferences and

current click behavior, the model learns to generate queries that better match the user's immediate intent.

The overall SFT stage is optimized with the standard autoregressive negative log-likelihood objective:

$$\mathcal{L}_{\text{SFT}} = -\sum_{t=1}^{T} \log p_\theta\big(y_t \mid y_{<t}, x\big). \tag{2}$$

3.1.3 Diversity-aware SFT Enhancement

To further improve query diversity, we introduce two SFT enhancement strategies: diversity-regularized SFT and self-distillation.

First, to mitigate the homogenization problem in multi-query generation, we continue fine-tuning the model on a set of high-quality samples and add a diversity regularization term to the autoregressive loss. The objective is defined as:

$$\mathcal{L} = \mathcal{L}_{\text{SFT}} + \lambda \mathcal{L}_{\text{div}}, \tag{3}$$

where λ controls the weight of the diversity loss. The diversity loss penalizes excessive similarity among queries within the same output sequence:

$$\mathcal{L}_{\text{div}} = \frac{1}{K(K-1)} \sum_{i \neq j} \text{sim}(q_i, q_j), \tag{4}$$

Second, we introduce a self-distillation mechanism to expand the model's generation space. Specifically, we use the diversity-enhanced model to perform sampled inference on a subset of prompts. During inference, we increase the temperature and top-p values to encourage the model to generate more diverse candidate queries. We then filter the generated results by removing queries with invalid formats, abnormal lengths, or business rule violations. The remaining high-quality outputs are used to reconstruct additional training data for the next round of SFT.

3.2 Reinforcement Learning with Hybrid Rewards

Although the SFT stage enhances the richness of generated queries, it is fundamentally suited to offline supervision data. To further align the generative model with the online recommendation objectives of the I2Q task, we introduce a GRPO-based reinforcement learning approach with hybrid rewards.

3.2.1 Verifiable Rule-Based Reward

The rule-based reward is designed to enforce deterministic business constraints in the I2Q scenario. Given an input x and a set of generated queries $Y = \{q_1, q_2, \ldots, q_K\}$, we define this reward as a weighted sum of multiple sub-rewards:

$$R_{\text{rule}}(x, Y) = \sum_{m=1}^{M} w_m r_m(x, Y), \tag{5}$$

where $r_m(x, Y)$ denotes the m-th rule reward and w_m is its corresponding weight. We design eight verifiable rule rewards mainly from the perspectives of user experience, compliance, and fluency. Detailed definitions are provided in the appendix.

These rewards enforce basic display requirements and business constraints, reducing format errors and redundant generation.

3.2.2 Model-based Reward via PARM

While rule-based rewards can enforce deterministic constraints, they cannot directly estimate whether a generated query is attractive to a specific user under the current item context. To align the reward signal with real user feedback in the I2Q scenario, we adopt PARM (introduced in §3.1.1) as the model-based reward, which scores each generated query by its predicted click likelihood given the item and user context.

Given an item i, user context u, and candidate query q, PARM estimates the likelihood that the user would click q under the current exposure context. We train the model to generate a natural language label: $a \in \{\text{yes}, \text{no}\}$. The training details are provided in the Appendix.

During inference, we use the probability of the "no" label to construct the click reward. Intuitively, if the model is less likely to predict "no", the query is more likely to match the user's current click preference. The reward for a query is defined as:

$$r_{\text{model}}(i, u, q) = 1 - p_{\text{PARM}}(\text{no} \mid i, u, q). \tag{6}$$

The set-level model reward is computed as the average click reward over all queries:

$$R_{\text{model}}(i, u, Y) = \frac{1}{K} \sum_{k=1}^{K} r_{\text{model}}(i, u, q_k). \tag{7}$$

As described in §3.1.1, the same scoring function $1 - p_{\text{PARM}}(\text{no} \mid i, u, q)$ is used to rank LLM-generated candidates during SFT data construction, converting unordered queries into weakly ordered supervision.

Method	Hard HR		Soft HR		Diversity		Rule
	@1	@all	@1	@all	APD	Distinct-2

EAGER-4B	0.54	78.39	79.13
EAGER-8B	0.56	78.65	78.84

Table 2: Experimental results with different Large Language Model backbones.

3.2.3 GRPO Policy Optimization

We combine the two rewards to construct the overall reward function for reinforcement learning:

$$R(x, Y) = \alpha R_{\text{rule}}(x, Y) + \beta R_{\text{model}}(i, u, Y). \quad (8)$$

Driven by the hybrid reward, GRPO optimization further guides the model to generate `query` lists that better satisfy business constraints, align with real user click preferences.

4 Experiment

4.1 Experimental Setup

Metrics. Offline, we evaluate along three axes: relevance, diversity, and compliance. **Soft HR@**K is our *primary* relevance metric: a generated query counts as a hit if it exactly matches the logged clicked query, or if at least 60% of its terms appear in the title of the item the user clicked after entering search. Soft HR is thus grounded in the second-hop item click, which is the objective of this scenario. **Hard HR@**K requires an exact string match with the single logged query and is reported only as a diagnostic of exact-expression reproduction: because I2Q is open-vocabulary and one-to-many, a single logged query is only one of many valid verbalizations, so a low Hard HR does not by itself indicate low query quality. Diversity is measured by **APD** and **Distinct-2**, and business compliance by the **Rule** score. All HR values are reported in percent. Online, we report UCTR and PCTR for engagement, and DAC, Pay Count, and L2P for downstream conversion.

Baselines To evaluate the effectiveness of our method, we compare it with open-source and closed-source LLMs of varying scales and capabilities, using them to assess the generative query recommendation ability of general-purpose LLMs without task-specific adaptation. We also include several model variants under different training and inference settings to provide a comprehensive comparison of recall performance.

4.2 Offline Experiments

Table 1 reports the offline results. Closed-source LLMs achieve competitive Soft HR but relatively weak Hard HR, indicating that they can generate semantically related queries yet fail to precisely match real user expressions. Zero-shot open-source models perform poorly across all metrics, confirming the necessity of task-specific training for the I2Q task. We compare several framework variants: **SFT** uses multi-source supervision without curriculum staging or diversity enhancement; **GRPO** applies hybrid-reward policy optimization

Method	Hard HR		Soft HR		Diversity		Rule
	@1	@all	@1	@all	APD	Distinct-2	
EAGER	0.44	0.87	77.96	93.82	72.96	83.04	9.16

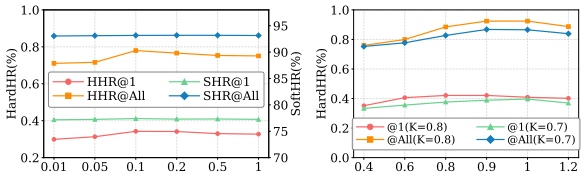
+ Enh. UI2Q	77.96	93.82	72.96	83.04

Table 5: Incremental ablation of the four curriculum subtasks: I2Q (item only), Enhanced I2Q (+rationale), UI2Q (+user context), and Enhanced UI2Q (both). All other components—diversity regularization, self-distillation, GRPO, the backbone, and optimization settings—are held fixed. Soft HR is in percent.



directly on the backbone; **SFT-GRPO** chains the two; and **EAGER-base** adds curriculum learning, diversity regularization, and self-distillation atop SFT-GRPO but omits PARM-based query ranking. SFT and SFT-GRPO significantly outperform the backbone, while GRPO alone improves diversity but degrades relevance without SFT initialization. EAGER-base achieves the highest Hard HR and Distinct-2, confirming that curriculum learning and self-distillation expand the generation space. The full EAGER trades moderate Hard HR decrease for gains in Soft HR@1, APD, and Rule score—a favorable trade-off for online deployment where downstream ranking reorders candidates.

Table 2 shows that EAGER scales well across backbone sizes, with EAGER-4B achieving the highest APD and EAGER-8B the best Soft HR.

4.3 Ablation Study

Table 3 presents the ablation results. Two observations deserve emphasis. First, removing DIV slightly *raises* Soft HR@1 (78.34 vs. 77.96) while sharply reducing APD (68.24 vs. 72.96) and Distinct-2 (78.86 vs. 83.04). This is the expected coverage–diversity trade-off: concentrating probability mass on the single most likely verbalization improves exact relevance against the logged query but yields a homogeneous query set. Since the scenario exposes K queries simultaneously and a downstream ranker reorders them, conceding 0.38 Soft HR@1 for +4.72 APD and +4.18 Distinct-2 is favorable, and the online results confirm that the more diverse set converts better. Second, removing GRPO leaves relevance essentially unchanged (Soft HR@All 93.76 vs. 93.82) but degrades Rule from 9.16 to 7.21 and Distinct-2 from 83.04 to 81.77, indicating that GRPO's primary role is business-rule compliance rather than relevance. Removing self-distillation reduces Hard HR@All from 0.87% to 0.65% and APD from 72.96 to 69.62, confirming that model-generated high-quality data broadens the training distribution.

Table 5 isolates the curriculum by adding its four subtasks in order while holding every other component fixed. Rationale supervision (Enhanced I2Q) gives the largest single-step APD gain (+3.17), indicating that reasoning helps the model explore multiple plausible search directions rather than imitate one query; user context (UI2Q) gives the largest Soft HR@1 gain (+4.06), confirming personalization as the dominant driver of second-hop relevance. In total the curriculum contributes +6.57 Soft HR@1 and +6.97 APD. This isolates the marginal contribution of each subtask, not the effect of sequential ordering versus randomly mixed multi-task training.

(a) Diversity Weight (b) Temperature & Top-P

Figure 3: Impact of hyperparameters on performance. (a) Effect of the diversity loss weight λ. (b) Effect of temperature and top-p in self-distillation.

4.4 Hyper-parameter Analysis

Figure 3 presents the sensitivity of key hyperparameters. For diversity loss weight (Figure 3(a)), performance peaks around $\lambda = 0.1$; further increasing λ degrades relevance, suggesting overly strong regularization hurts the balance between diversity and accuracy. For self-distillation (Figure 3(b)), performance improves as temperature increases and peaks around 0.9–1.0, with a larger top-k consistently yielding better results.

4.5 Online Experiments

We deployed EAGER as an additional query recommendation source in our production system and conducted a 9-day online A/B test with 5% of traffic. The control uses the existing production system; the treatment augments it with EAGER-generated query suggestions while all downstream components remain identical.

As shown in Table 4, UCTR and PCTR improve by 0.83% and 1.28%, while DAC, Pay Count, and L2P increase by 2.98%, 3.49%, and 2.38%, confirming that engagement gains translate to downstream conversion (all $p < 0.05$, stable throughout the test period).

5 Conclusion

We present EAGER, a two-stage framework that generates personalized query recommendations from clicked items, bridging item recommendation and search in e-commerce. The key insight is that intent coverage and deployment alignment are complementary objectives best addressed in sequence: the first stage expands the generation space to capture diverse user intents, while the second constrains it to meet online business requirements without sacrificing diversity. Production deployment and A/B tests confirm consistent gains in both user engagement and downstream conversion.

Limitations

This work has several limitations. First, our method is developed and evaluated in a real-world e-commerce search scenario, where user behavior patterns, item distributions, and business rules may differ across platforms. Therefore, its generalization to other search or recommendation scenarios requires further validation. Second, PARM relies on historical exposure and click logs, which may inherit existing position bias and exposure bias from the online system. Although rule-based rewards help improve compliance, they are manually designed and may need adaptation when business requirements change. Finally, our current framework mainly focuses on query-level generation and does not jointly optimize downstream ranking or conversion objectives. Future work will explore more general reward modeling, debiased user feedback, and end-to-end optimization with downstream search modules.

A Related Work

Query Recommendation Traditional query recommendation methods rely on heuristic rules and statistical models derived from query logs, term co-occurrence, and user behavior. They work well in narrow settings but often suffer from sparse data and struggle to adapt to changing user intents (Baeza-Yates et al., 2004; Sordoni et al., 2015). Neural approaches improve on this by modeling sequential patterns to provide better contextual recommendations (Lai et al., 2023), yet they still struggle with long-tail queries. Recently, the field has moved toward generative methods using LLMs. For example, Cold-EQS (Sun et al., 2026) proposes an iterative reinforcement learning framework for ColdStart E-commerce Query Suggestion. PushGen (Bie et al., 2026) introduces a controllable category-prompting technique to guide LLM outputs toward desired styles. GQR (Min et al., 2025b) unifies diverse query recommendation tasks by a universal prompt framework. ReList (Bi et al., 2026) further recasts related-search recommendation as a reasoning-enhanced listwise generation task, combining chain-of-thought supervision with multi-objective reinforcement learning. All of these methods condition on a user-typed query, whereas I2Q must generate a personalized query set from a clicked item alone.

Generative Recommendation Generative recommendation leverages LLMs to produce recommendations as sequences, either as semantic IDs (SIDs) or in natural language. For instance, HLLM (Chen et al., 2024) employs a hierarchical structure to model user interests and item representations separately. In industrial practice, the OneRec family (Zhou et al., 2025a,b) establishes end-to-end generative frameworks that integrate reasoning and reinforcement learning for video and e-commerce recommendations. Concurrently, SynerGen (Gao et al., 2025) and OneSearch (Chen et al., 2025a) unify search and recommendation tasks under generative paradigms. However, recent work suggests natural language itself can serve as a more expressive alternative to SIDs (Liu et al., 2025). Unlike SID-based approaches, EAGER operates entirely in the natural language space, directly generating contextually persuasive queries without discrete indexing, thereby fully harnessing the generative capacity of LLMs for pre-search query recommendation.

B PARM Training Details

PARM is trained from user behavior logs in the I2Q scenario. Its goal is to estimate whether a candidate query is likely to be clicked under a given item-user context. PARM is used both to rank offline LLM-generated queries during SFT data construction and to provide the model-based reward in GRPO optimization.

Data Construction. For the I2Q task in e-commerce search, the system displays an ordered list of candidate queries. To avoid a severe imbalance between positive and negative samples, we adopt a position-aware sampling strategy based on user clicks. If the user clicks the first exposed query, we discard this event because users tend to click the first suggestion more often due to positional bias, which may distort the modeling of true user preferences. If the user clicks the second query, the clicked query is treated as a positive sample, while the first query is treated as a negative sample. Similarly, if the user clicks the third query, that query is used as the positive sample, and the first two queries are used as negative samples; if the user clicks the fourth query, the preceding three queries are used as negative samples. Queries after the clicked position are ignored, since they may not have been sufficiently examined by user.

Each training instance consists of the clicked

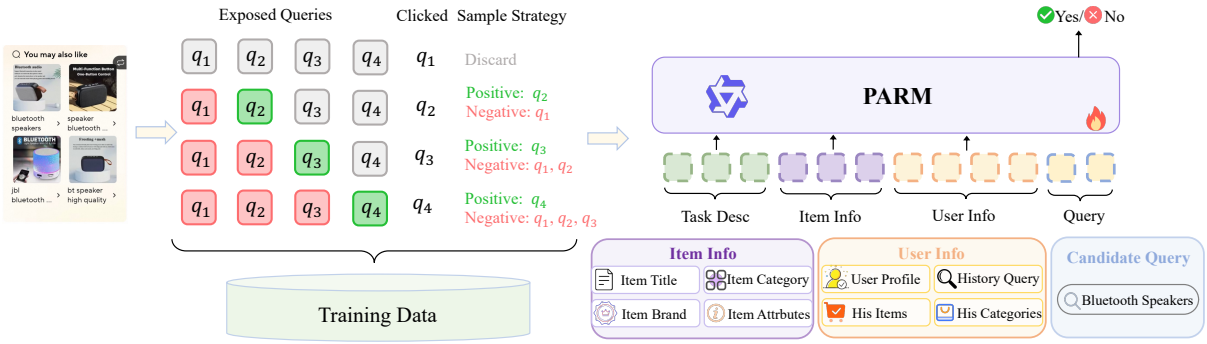

Figure 4: Training pipeline of PARM.

item information, user personalization features, and a candidate query. Positive samples are assigned the output label "yes", while negative samples are assigned the output label "no".

Training Strategy. Given item information i, user context u, and a candidate query q, the model estimates whether the user would click the query in the current exposure context. Instead of using a conventional binary classifier, we formulate click prediction as a generative discrimination task and train the model with SFT. The input contains (i, u, q), and the target output is a natural language label $a \in \{\text{yes}, \text{no}\}$.

The training objective follows the standard autoregressive negative log-likelihood:

$$\mathcal{L}_{\text{click}} = -\log p_\phi(a \mid i, u, q), \tag{9}$$

where ϕ denotes the parameters of PARM. This formulation allows the model to reuse LLMs' semantic understanding and learn the matching relationships among item text, user context, and candidate queries.

Offline Ranking Agreement. To evaluate the quality of PARM as a reward signal, we measure its ranking agreement with the production ranker on a held-out sample of 210K click PVs. Specifically, for each exposure event, we compare the position rankings produced by PARM against those of the online production ranker. We report the top-k match rate, defined as the proportion of events where the top-k queries selected by PARM exactly match the top-k set selected by the production ranker.

PARM achieves a 79.8% top-1 match rate with the production ranker, indicating that it can reliably identify the most attractive query for a given user-item context. The top-2 to top-4 match rates remain above 72%, suggesting consistent alignment beyond the first position. These results confirm that PARM provides a sufficiently reliable reward signal for GRPO optimization.

Sample Size	Top-1	Top-2	Top-3	Top-4
210K PVs	79.8%	74.1%	72.7%	72.7%

Table 6: Ranking agreement between PARM and the production ranker.

C Rule Reward

We design verifiable rule-based rewards to ensure that generated queries satisfy the basic requirements of the I2Q scenario. These rewards are computed offline using deterministic rules and linguistic features, without relying on online services or additional model-based evaluation.

Experience Compliance. This reward checks whether a generated query contains low-quality or experience-harmful expressions, such as "free item" or invalid prepositions. Queries containing such expressions are penalized to avoid unnatural or misleading search suggestions.

Quantity Compliance. This reward verifies whether the number of generated queries matches the required target number. It encourages the model to produce a stable and controllable number of candidates.

Lexical Overlap. To ensure item relevance, we compute the lexical overlap between each generated query and the item title. For queries shorter than three words, at least two words are required to match the item title; otherwise, at least 75% of the query terms should be covered.

Figure 5: Qualitative comparison between the production I2Q baseline and EAGER, showing that EAGER captures fine-grained user preferences while the baseline produces generic queries

User Intent Alignment. This reward checks whether the generated query contains keywords from the user's historical behaviors. It encourages the model to generate personalized queries that better reflect user interests.

Fluency. We evaluate query fluency using simple linguistic features, including length constraints, token-type ratio, character validity, and bigram-level fluency. This reward encourages queries that are natural, readable, and consistent with search habits.

Diversity. To reduce redundant generation, we compute the Jaccard similarity among generated queries and reward lower similarity. This encourages the model to cover diverse search intents within the same output set.

Penalty Terms. We apply additional penalties for blacklisted or sensitive terms, including prohibited words, brand-infringing expressions, and other unsafe or low-quality content. These penalties help improve the safety and business compliance of generated queries.

D Evaluation Metrics

We evaluate generated queries offline from four aspects: accuracy, relevance, diversity, and rule compliance.

Hard HR@K. Hard HR measures the exact matching accuracy between generated queries and the ground-truth clicked query. A hit is counted if any generated query exactly matches at the string level. HardHR@1 evaluates only the first generated query, while HardHR@All evaluates the entire generated set.

Soft HR@K. Soft HR measures behavior-related relevance. A generated query is considered a soft hit if it exactly matches the ground-truth clicked query, or if at least 60% of its terms appear in the title of the target item clicked by the user on the search result page. Compared with Hard HR, Soft HR better captures whether the generated query can cover the semantic intent behind the user's final clicked item.

Distinct-2. Distinct-2 evaluates lexical diversity by computing the ratio of unique 2-grams to all 2-grams in the generated query set:

$$\text{Distinct-2} = \frac{|\text{Unique}(\text{2-grams}(Y))|}{|\text{2-grams}(Y)|}. \quad (10)$$

A higher Distinct-2 indicates fewer repeated expressions in the generated results.

APD. Average Pairwise Distance measures the average dissimilarity among generated queries. For each pair of generated queries, we compute their similarity $\text{sim}(q_i, q_j)$ and define the distance as $1 - \text{sim}(q_i, q_j)$. APD is computed as:

$$\text{APD} = \frac{1}{K(K-1)} \sum_{i \neq j} (1 - \text{sim}(q_i, q_j)). \quad (11)$$

A higher APD indicates that the generated query set covers a more diverse set of potential search intents.

Rule. The Rule metric evaluates whether the generated queries satisfy the basic display requirements and business constraints of the I2Q scenario. We reuse the verifiable rules defined in the rule-based reward, including experience compliance, quantity compliance, lexical overlap, user intent alignment, and penalty terms. The final Rule score is computed as the weighted sum of all rule scores. A higher Rule score indicates better compliance with business requirements.

Online Metrics. We evaluate online deployment from two complementary stages of the user funnel. The first stage measures user engagement, i.e., whether the generated query suggestions attract user interaction. **UCTR** (User Click-Through Rate) is the proportion of users who click at least one query suggestion among those exposed in this scenario, while **PCTR** (PV-level Click-Through Rate) is the ratio of clicked query suggestions to total query exposures, measuring per-impression attractiveness. The second stage measures downstream conversion, i.e., whether engagement translates into commercial value after the user enters search via a clicked query. **DAC** (Daily Active Customers) is the number of unique users per day who complete at least one purchase through search sessions triggered in this scenario. **Pay Count** is the total number of paid orders attributable to this scenario **L2P**(Landing-to-Payment rate) is the conversion rate from clicking a query recommendation to completing payment, capturing the end-to-end commercial efficiency of the recommended queries. Together, these metrics cover the full funnel from query exposure to final conversion.

E Implementation Details

All experiments were conducted on 24 NVIDIA A100 80GB GPUs. We first performed SFT on Qwen3-1.7B (Yang et al., 2025) using the LLaMAFactory framework with full-parameter updates, a maximum sequence length of 4096, an effective batch size of 64, a learning rate of 2e-5, bf16 precision, and 1 epoch of training.

The resulting model was then used as the initial policy for reinforcement learning via GRPO in the ROLL(Wang et al., 2025) framework. In the GRPO stage, each rollout response was scored by verifiable rules and PARM to obtain a reward score.

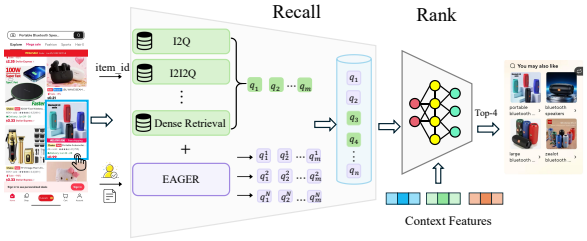

Figure 6: Online serving architecture. EAGER serves as a third recall channel alongside log-based and dense retrieval; a shared ranker scores all candidates over context features and returns the top-4 queries.

Our online inference is powered by the vLLM framework, which features a built-in multi-sampling generation mechanism. It independently generates 10 complete results, with no sharing between the candidates. The compute and VRAM usage equals the total token volume of the N generated sequences. Since they are independent, the pressure is lower than that of Beam Search.

Online Serving Architecture. Figure 6 shows the deployment of EAGER in our production query recommendation system. We deploy EAGER as a third recall channel alongside two existing ones: **Log-based Retrieval**, which mines item-to-query and item-to-similar-item-to-query associations from historical click logs (I2Q and I2I2Q), and **Dense Retrieval**, which performs embedding-based approximate nearest neighbor search between item and query representations. Candidates from all channels are merged and scored by a shared ranker over context features, and the top-K queries are returned to the user. EAGER complements existing channels in two ways: it expands coverage on long-tail items where co-click statistics are sparse, and it provides higher-quality candidates that compete with existing sources under the same ranker on head items.

F Case Study

To validate the efficacy of EAGER in integrating user profiles with item semantics, we analyze a representative case shown in Figure 5. The interacting user is an English-speaking female from South Korea whose recent behavioral sequence indicates a converging interest in “large capacity” and “designer-style” luggage. While traditional methods yield generic queries such as “tote bag” or “leather tote bags for woman,” failing to capture

fine-grained preferences for capacity and design aesthetics, EAGER leverages click history and demographic attributes to synthesize highly specific queries like “large capacity tote bag” and “designer PU leather handbag.” This demonstrates that EAGER effectively mitigates the limitations of statistical methods in personalized intent understanding, facilitating a transition from static attribute matching to dynamic interest alignment.

G Prompt Templates

Offline Query Generation Prompt.

Role Definition:
You are an e-commerce search query generation assistant. Your primary objective is to generate high-intent, diverse, and commercially valuable search queries to guide users’ product discovery journey.
Task:
Generate User Search Queries for a Cross-Border E-commerce App based on the product details below.
Core Competencies:
1. Deep understanding of product info (titles, categories, attributes).
2. Inferring user intent and usage scenarios.
3. Generating natural, diverse queries for different shopping stages.
Cognitive Framework (Do not output):
Core Identity: Direct term for the product?
Function & Scenario: Problem solved? Usage context?
Accessories & Compatibility: Needed add-ons? Compatible devices?
Target Audience: Typical user profile?
Broad Exploration: Search behavior if model is unknown?
Constraints and Rules:
Relevance: Highly relevant to input. Do not fabricate attributes (e.g., color).
Diversity: Cover different intents (alternatives, accessories) and phrasing.
Format: Max 6 words. Use e-commerce keywords, not full sentences.
Language: Use {{language}}. Keep English brand names if applicable.
Attribute Filtering: Focus on physical traits, style, function. Ignore Origin, SKUs, specific models (e.g., M4A1), or dimensions.
Avoid Over-Inference: Be broad with ambiguous attributes (e.g., use "bed with storage" not "bed with drawers" unless specified).
Safety: No unsafe or prohibited content.
Input Parameters:
Output Language: {{language}}
Number of Queries: {{count}}
Product Information:

```
{
  "title": {title\},
  "category_path": {category_path},
  "attributes": {
    "features": {features}
  }
}
```

Output Specification: You **must** return a single, valid JSON object. No text outside the JSON.

```
{
  "language": "",
  "generated_queries": [
    { "query_text": "string" }
  ]
}
```

Supervised Fine-tuning Prompt.

Instruction: You are a world-class cross-border e-commerce search intent expert. Your task is to generate 10 distinct, native, and high-intent search queries based on the user profile, behavior, and current product attributes.

Input:
Current Product Title:
Category:
Brand:
User Nation/Market:
Interface Language:
User Demographics: Gender:

Perceptually Better, Semantically Worse: Measuring Speech Enhancement Impact on LLM-Based Voice Systems

Randy Frans Fela and **Pejman Mowlaee**
GN Group, Ballerup, Denmark
{rffela, pmowlaee}@gn.com

Abstract

Speech enhancement (SE) is commonly applied as a preprocessing step in spoken AI pipelines under the assumption that better audio quality improves downstream task performance. Whether SE-induced distortions propagate to downstream LLM task performance remains an open question. We introduce Output Divergence Rate (ODR), which measures how often SE changes an LLM's intent classification relative to clean speech, and benchmark five conditions on 2,974 SLURP clips using Whisper large-v3 and wav2vec2-large cascades. Every condition produces ODR significantly above zero ($p < 0.001$, binomial test). MetricGAN+ more than doubles ODR versus unenhanced noisy speech (0.318 vs. 0.135) despite improving PESQ, and unmitigated echo reaches an ODR of 0.836 through speaker substitution, a failure WER cannot capture. Audio quality metrics range from near-zero to moderate correlation with ODR (SQUIM-MOS $\rho = -0.068$, PESQ $\rho = -0.467$). The MetricGAN+ and echo results replicate across ASR architectures, indicating that standard audio quality metrics are insufficient for LLM pipeline quality.

1 Introduction

Modern spoken AI systems chain three components: speech enhancement (SE), automatic speech recognition (ASR), and large language model (LLM). The SE step is assumed acoustically neutral, yet recent evidence challenges this at the transcription level. Chondhekar et al. (2025) show MetricGAN+ increases semWER across all 40 tested ASR configurations, and Islam et al. (2026) report the same for diffusion-based SE. What remains unknown is whether these distortions propagate to LLM reasoning. This question is not straightforward: LLMs exhibit robustness to noisy text (Chen et al., 2024, 2026), so transcription degradation may not translate to semantic task failure, or it may cause different failures that WER cannot measure.

In this paper, we propose **Output Divergence Rate (ODR)**, a clean-reference task-output divergence metric for measuring SE-induced instability in cascaded ASR–LLM voice systems, benchmarked across five enhancement conditions on SLURP (Bastianelli et al., 2020). Results show that LLMs absorb transcription errors to varying degrees (WER–ODR gap < 0 for all conditions), yet echo conditions produce catastrophic ODR through a qualitatively distinct speaker-substitution failure that WER cannot capture. Standard audio quality metrics do not predict this damage, and findings are consistent across two architecturally distinct ASR models, ruling out Whisper-specific artefacts. Our main contributions are as follows:

1. We propose *Output Divergence Rate* (ODR), a task-level metric that measures how often speech enhancement changes the downstream LLM prediction relative to clean speech.
2. We construct a six-condition benchmark spanning noise suppression, echo cancellation, and dereverberation on 2,974 SLURP test clips with 77 intent classes, and release the full pipeline at https://github.com/fransfela/se-llm-odr-benchmark.
3. We show that enhancement can introduce systematic intent collapse toward catch-all categories, a failure mode invisible to WER and standard quality metrics.
4. We show that standard audio quality metrics reflect between-condition ODR separation but have near-zero predictive power for which individual clips will diverge once the enhancement condition is fixed, making them unreliable per-clip early-warning signals.
5. Findings replicate across two ASR architectures (attention-based and CTC-based) and are robust to LLM capacity, indicating condition ranking and primary conclusions are architecture- and classifier-agnostic.

EMNLP 2026 Industry Track, pages 1913–1924

Condition	Category	Description
Clean	Reference	Original SLURP recording
Noisy	Degraded	DNS noise, SNR = 10 dB
MetricGAN+	Discrim. SE	GAN noise suppression
Echo (sim)	Echo	Simulated echo, no AEC
Echo + DTLN-AEC	AEC	DTLN-AEC on echo sim.
Dereverb	Dereverberation	WPE (5 iterations)

Table 1: Enhancement conditions applied to 2,974 SLURP test recordings. All degradations simulated using DNS Challenge corpora.

2 Related Work

SE-induced ASR degradation is well documented. Lee et al. (2023) propose joint SE+ASR training to mitigate it. Chondhekar et al. (2025) show that MetricGAN+ increases semWER across all tested configurations, and Islam et al. (2026) report the same pattern for diffusion-based SE. None of this work asks whether the resulting transcription errors actually change what a downstream LLM does with the output, which is the question we address here.

At the downstream NLP level, Rai et al. (2024) show that denoising amplifies demographic bias in ASR, and Ali et al. (2022) propose joint SE+intent training, noting that independently optimised SE may not serve downstream NLP well. Their solution requires retraining the SE model jointly with the downstream task, while we focus on diagnosing this effect in pipelines as they are already deployed, without retraining anything.

Closest to our work, VoiceBench (Chen et al., 2024, 2026) evaluates LLM voice assistants under acoustic variation but treats the whole audio-to-response pipeline as a black box rather than isolating the SE stage. The URGENT challenge (Zhang et al., 2024) benchmarks SE across a wide range of distortions using perceptual and ASR-based metrics. Its 2025 edition (Saijo et al., 2025) introduced downstream-task metrics (word accuracy, speaker similarity) but no LLM semantic output evaluation. Our benchmark fills this gap by isolating SE as the variable of interest and measuring its effect on an LLM's task output rather than on transcription or signal quality alone.

3 Benchmark Design

3.1 Dataset and Conditions

We use the `slurp_real` test split of SLURP (Bastianelli et al., 2020): 2,974 real human recordings across 18 domains and 77 intent classes. The TTS subset is excluded as its uniform acoustics suppress enhancement artefacts. Table 1 summarises the five enhancement conditions, chosen to cover the major SE classes deployed in commercial spoken AI.

Noisy adds DNS Challenge noise (Reddy et al., 2021) at SNR = 10 dB without enhancement, establishing a degraded baseline. **MetricGAN+** (Fu et al., 2021) applies discriminative GAN-based noise suppression trained to maximise PESQ, representative of the most widely deployed SE class. **Echo (sim)** mixes near-end speech with a DNS far-end signal convolved through a DNS room impulse response at a signal-to-echo ratio SER $\in \{-10, -5, 0\}$ dB, without any cancellation, isolating a conferencing-specific failure mode absent from prior NLP benchmarks. **Dereverberation** applies WPE (Nakatani et al., 2010) to reverberant speech (RT60 $\in \{0.3, 0.6, 0.9\}$ s).

Echo + DTLN-AEC applies DTLN-AEC (Westhausen and Meyer, 2021) (512-unit, 10.4M parameters), a dual-signal transformation LSTM network for acoustic echo cancellation, to the Echo (sim) microphone signal using the far-end reference signal. This condition tests whether neural AEC restores LLM performance degraded by unmitigated echo. Figure 4 (Appendix F) shows log-mel spectrograms of representative utterances, illustrating the acoustic signature of all six conditions.

3.2 Evaluation Pipeline

Each clip is transcribed by two ASR models, Whisper large-v3 (Radford et al., 2023) (encoder-decoder, beam size 5, temperature 0) as the primary model and wav2vec2-large-960h (Baevski et al., 2020) (self-supervised CTC) as the architectural comparison. Whisper WER on clean SLURP test speech is 0.507, reflecting the challenging spontaneous-speech acoustics of the corpus (Bastianelli et al., 2020). All ODR values are measured relative to this same clean baseline.

Transcripts are classified by Gemini 2.5 Flash Lite via the Gemini API using a fixed closed-set

Condition	PESQ	STOI	SNR	SI-SDR	SRMR	SQUIM	WER	WER_{cap}	ODR
Clean	4.64	1.00	105.12	94.35	8.56	4.22	0.507	0.507	–
Noisy	1.76	0.87	9.92	10.00	6.24	3.77	0.531	0.520	0.135
MetricGAN+	1.94	0.80	1.81	4.23	10.96	3.87	0.647	0.614	**0.318**
Echo (sim)	1.11	0.52	−2.69	−5.01	6.24	3.69	**1.448**	0.928	**0.836**
Echo + DTLN-AEC	1.53	0.47	−1.66	−26.13	10.98	3.92	0.700	0.649	0.404
Dereverb	2.43	0.71	−4.72	−23.04	7.79	3.94	0.517	0.507	0.108

Table 2: Mean audio quality metric scores, Whisper WER, and ODR per condition (Clean shown as reference, ODR = 0 by definition). WER: raw mean per-clip word error rate. WER_{cap}: mean of $\min(\text{WER}_i, 1.0)$ per clip, used in the WER–ODR gap (Eq. 2). Bold marks the highest ODR values (Echo (sim) and MetricGAN+) and the saturating raw WER (Echo (sim) 1.448).

prompt over the 77 SLURP intents (temperature 0, max 15 tokens, invalid rate 0.07–0.20% across conditions with no systematic condition dependence, see Appendix A). ODR for condition C is:

$$\text{ODR}(C) = \frac{|\{i : \hat{y}_C^{(i)} \neq \hat{y}_{\text{clean}}^{(i)}\}|}{N} \quad (1)$$

where $\hat{y}_C^{(i)}$ is the predicted intent under condition C, $\hat{y}_{\text{clean}}^{(i)}$ is the clean baseline, and N excludes invalid predictions. We additionally report the WER–ODR gap:

$$\text{Gap}(C) = \text{ODR}(C) - \frac{1}{N}\sum_{i=1}^{N} \min(\text{WER}_C^{(i)}, 1.0) \quad (2)$$

where N is the same denominator as in Eq. (1). WER is clipped per utterance before averaging to bound the contribution of speaker-substitution clips whose raw WER exceeds 1.0 (Echo (sim): mean raw WER = 1.448). A negative gap indicates the LLM is partially robust to the transcription errors induced by that condition. We report 95 % bootstrap CIs ($B = 10{,}000$, seed = 42).

3.3 Quality Metrics

We compute six metrics spanning intrusive perceptual (PESQ, STOI), intrusive signal-level (SNR, SI-SDR), and non-intrusive MOS prediction families (SQUIM-MOS, SRMR), and report Spearman ρ and Pearson r against binary ODR with Bonferroni correction ($n = 6$).

4 Results

4.1 ODR Across Conditions

Figure 1 reports ODR for both ASR models across all non-clean conditions. All conditions produce statistically significant ODR ($p < 0.001$), and the condition ranking is identical for both models

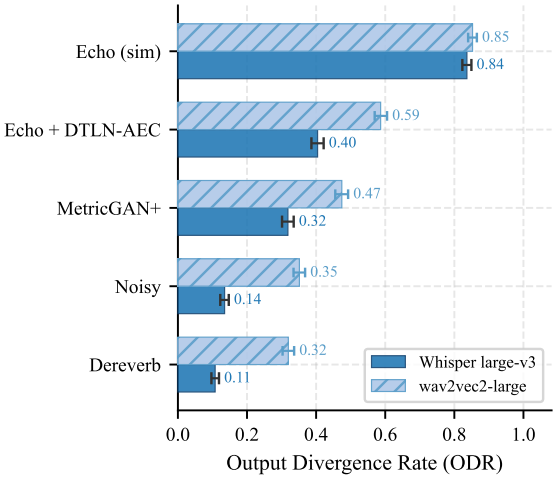

Figure 1: ODR by condition for Whisper large-v3 and wav2vec2-large, with 95 % CIs. All conditions are significant ($p < 0.001$, binomial test). Rankings are identical across architectures.

(Echo (sim) > Echo + DTLN-AEC > MetricGAN+ > Noisy > Dereverb).

Under Whisper, MetricGAN+ produces ODR of 0.318 (CI [0.301, 0.335]), more than doubling the unenhanced noisy baseline (0.135, CI [0.123, 0.147]). MetricGAN+ raises PESQ yet simultaneously worsens STOI and more than doubles ODR, demonstrating that perceptual quality improvement and LLM task performance are not aligned. Dereverberation produces the lowest ODR (0.108, CI [0.097, 0.119]), comparable to the noisy baseline. Under wav2vec2 the same ordering holds at higher absolute values (MetricGAN+: 0.474, noisy: 0.352), consistent with CTC decoding's greater sensitivity to frame-level spectral artefacts.

Table 2 quantifies the perceptual–semantic decoupling. MetricGAN+ raises PESQ from 1.76 to 1.94 relative to Noisy ($\Delta = +0.18$), a modest gain that keeps both values within the "bad" range of the 1–4.5 scale, while simultaneously *reducing*

SLURP ID	Condition	Transcript	Intent
11862	Clean	“Recommend a movie for me.”	`recommendation_movies`
	MetricGAN+	“Thank you.”	`general_greet`
14746	Clean	“What is the capital of Kazakhstan?”	`qa_factoid`
	MetricGAN+	“This is a caption for Justin.”	`general_quirky`
12308	Clean	“Book me a train ticket.”	`transport_ticket`
	MetricGAN+	“We’re free to go.”	`general_quirky`

Table 3: Example clips where MetricGAN+ causes intent collapse to catch-all categories. Transcription remains fluent but loses domain-specific lexical cues, causing the LLM to default to generic intents. SLURP IDs refer to `slurp_real` test recordings (Bastianelli et al., 2020).

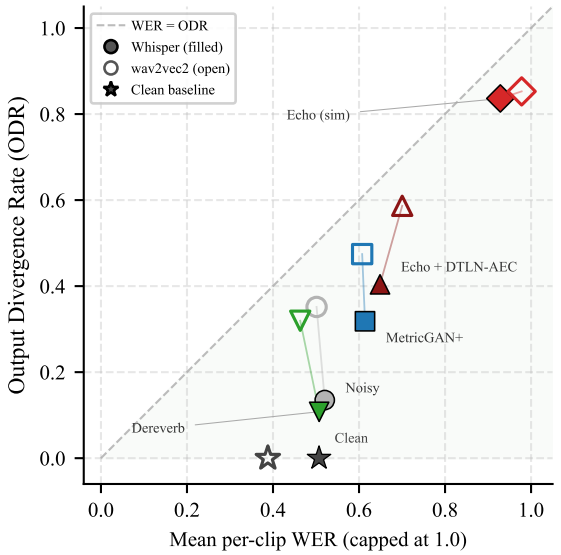

Figure 2: WER vs. ODR for Whisper and wav2vec2 (filled and open markers). ⋆ marks the clean baseline (ODR = 0 by construction, WER reflecting Whisper/wav2vec2 accuracy on spontaneous SLURP speech). All points fall below $y = x$ for spectral distortion conditions. This reflects partial LLM robustness to transcription errors, while Echo (sim) negative gap reflects WER ceiling saturation rather than LLM recovery.

STOI from 0.87 to 0.80 ($\Delta = -0.07$) and more than doubling ODR from 0.135 to 0.318. This triple divergence is particularly damaging for practitioners: MetricGAN+’s explicit training objective, PESQ, improves, the intelligibility proxy, STOI, worsens, and the downstream LLM task failure rate doubles. No single quality metric provides a reliable signal about the direction of LLM task impact.

A second decoupling: Echo + DTLN-AEC. Table 2 shows a different decoupling pattern for AEC recovery. While DTLN-AEC improves PESQ (1.11→1.53), WER (-51.6%), and ODR (-51.7%) relative to Echo (sim), SI-SDR worsens sharply ($-5.01 \rightarrow -26.13$) and SRMR rises above even the Clean condition (10.98 vs. 8.56). We attribute this to the gain and phase adjustments DTLN-AEC applies to suppress the far-end signal, changes immaterial to intent recognition, but register as severe distortion under SI-SDR and as elevated modulation depth under SRMR. STOI also drops below its Echo (sim) value (0.47 vs. 0.52) because STOI’s short-time envelope correlation model assumes linear, memoryless distortion, an assumption nonlinear echo cancellation deliberately violates, so STOI scores can fall even when intelligibility improves. SI-SDR, SRMR, and STOI are not designed for AEC evaluation, where output is intentionally gain- and phase-modified relative to the near-end reference. A parallel argument applies to Dereverb: intrusive metrics compare the WPE output against the dry clean recording. WPE cannot perfectly invert the room impulse response, so residual differences between its output and the dry reference produce severely negative SNR (-4.72 dB) and SI-SDR (-23.04 dB) even though ODR is the lowest of all conditions (0.108), confirming that signal-level metrics do not track LLM task failure. Taken together with the MetricGAN+ case, these results show that metrics from the same category (intrusive signal-level: SNR, SI-SDR) can disagree sharply about the direction of an enhancement’s effect, independent of its actual impact on the downstream task.

WER–ODR gap. Figure 2 plots WER against ODR for both models. All ten points fall below the diagonal ($y = x$): the LLM is partially robust to transcription errors in every condition and for both architectures, with Whisper gaps ranging from -0.092 to -0.400 and wav2vec2 gaps from -0.114 to -0.150. For Echo (sim), ODR of 0.836 and capped WER of 0.928 yield a gap of -0.092, reflecting WER saturation rather than LLM robustness. With raw WER of 1.448, Whisper transcribes

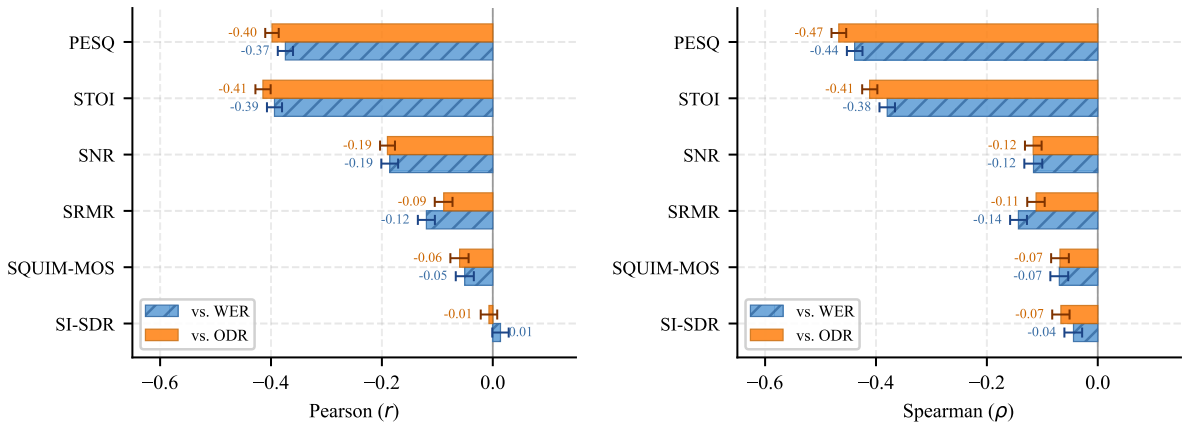

Figure 3: Pearson (r, left) and Spearman (ρ, right) of each quality metric against WER and ODR. PESQ and STOI correlate comparably with both targets. Non-intrusive SQUIM-MOS is near-zero for both, underscoring its inability to predict either transcription or semantic damage. All Spearman ρ values significant ($p < 0.001$, Bonferroni corrected). Pearson SI-SDR is non-significant ($p = 0.40$). Error bars show 95% bootstrap confidence intervals.

the far-end loudspeaker rather than the user, producing a valid but entirely wrong transcript.

Echo condition. The echo condition produces ODR of 0.836 (CI [0.823, 0.849]) under Whisper and 0.853 under wav2vec2, converging across architectures. At SER ≤ 0 dB, both models transcribe the louder far-end echo signal rather than the near-end speaker. This is a categorically different failure from spectral distortion: the LLM processes a semantically unrelated utterance, and WER cannot characterise the damage because it saturates.

Echo with cancellation. Applying DTLN-AEC neural echo cancellation to the Echo (sim) signal substantially recovers ASR performance, with mean WER dropping from 1.448 to 0.700 ($-51.6\,\%$ relative, full WER distribution in Appendix B), confirming that the echo canceller correctly suppresses the dominant far-end signal and restores near-end speech transcription. The downstream LLM impact follows proportionally: ODR drops from 0.836 to 0.404 (CI [0.386, 0.422], Gap $= -0.245$), a $51.7\,\%$ relative reduction that closely mirrors the $51.6\,\%$ WER reduction. This proportionality suggests that the speaker-substitution artefact is the primary damage mechanism for echo. Once AEC restores the correct speaker, both transcription and intent recovery improve at nearly the same rate.

Systematic intent collapse. Of 945 diverged clips under MetricGAN+, 48.4% of the 562 regressions land in *general_quirky* (13.4% of all MetricGAN+ predictions, vs. 5.2% under clean) or *general_greet* (6.8% vs. 2.0%), both 2.5–3.4$\times$ their clean-speech frequency. This reveals a distributional shift in LLM input space. SE removes domain-specific lexical cues, and the LLM defaults to catch-all categories when the utterance is stripped of its identifying vocabulary. Table 3 shows representative examples of this collapse.

Correct vs. harmful divergence. ODR treats every clean-vs-condition disagreement as damage, conflating genuine harm with the rarer case in which SE incidentally corrects a clean-speech misclassification. Using SLURP ground-truth intents, we decompose divergent clips for each condition into corrections (clean wrong, condition correct), regressions (clean correct, condition wrong), and both-wrong shifts (Table 4). Regressions outnumber corrections in every condition, ranging from 1.9 : 1 under Dereverb to 23.1 : 1 under Echo (sim), with Noisy at 3.3 : 1, confirming that ODR predominantly captures harmful divergence rather than benign correction. MetricGAN+'s 7.6 : 1 ratio confirms that its intent damage is real, rather than an artefact of clean-speech classification errors. A McNemar paired test on the same 2,966 clips confirms that MetricGAN+ causes significantly more regressions than Noisy ($\chi^2 = 427$, $p < 10^{-90}$).

4.2 Quality Metrics as ODR Predictors

Figure 3 reports Pearson r (left) and Spearman ρ (right) for each metric against both WER and ODR.

PESQ achieves the strongest Spearman correlation with ODR ($\rho = -0.467$), a moderate rank association at best. The moderate ceiling is partly structural. Quality metrics quantify signal-level

Condition	Correction	Regression	Both-Wrong	Unaffected	Regr. : Corr.
Noisy	1.8 %	6.0 %	5.8 %	86.5 %	3.3 : 1
MetricGAN+	2.5 %	18.9 %	10.4 %	68.2 %	**7.6 : 1**
Echo (sim)	2.5 %	58.4 %	22.7 %	16.4 %	**23.1 : 1**
Echo + DTLN-AEC	2.4 %	24.0 %	14.0 %	59.6 %	10.0 : 1
Dereverb	2.2 %	4.2 %	4.4 %	89.2 %	1.9 : 1

Table 4: Decomposition of each condition's divergent clips against SLURP ground-truth intent (Whisper + Gemini 2.5 Flash Lite). **Correction**: clean prediction wrong, condition prediction correct. **Regression**: clean prediction correct, condition prediction wrong. **Both-Wrong**: both predictions wrong and mutually different. **Unaffected**: clean and condition predictions agree (correct or incorrect together). Regressions outnumber corrections in every condition, confirming ODR predominantly reflects harmful divergence rather than benign correction of clean-speech classification errors.

fidelity while ODR measures semantic task fidelity, dimensions that are only loosely coupled, particularly when failure operates through categorical mechanisms such as speaker substitution rather than continuous spectral degradation. PESQ and STOI correlate comparably with WER and ODR ($\rho_{\text{WER}} = -0.439$ vs. $\rho_{\text{ODR}} = -0.467$ for PESQ), confirming that perceptual metrics track transcription and semantic damage with similar (moderate) strength. SQUIM-MOS, the most attractive non-intrusive estimator for production monitoring (it requires no reference signal), is near-zero for both ($\rho_{\text{WER}} = -0.069$, $\rho_{\text{ODR}} = -0.068$), ruling it out as a lightweight proxy for either target. For echo specifically, AECMOS echo_mos, a metric designed for AEC quality assessment, achieves only $\rho = -0.080$ against ODR, suggesting that even purpose-built echo quality metrics do not reliably predict LLM task failure.

Pooled correlations overstate predictive value. The correlations above pool clips across conditions, conflating within-condition variation with between-condition separation. Echo (sim) has both the lowest mean PESQ and highest ODR as a *condition*, which alone can produce a substantial pooled correlation even if PESQ does not distinguish diverged from non-diverged clips *within* a condition. Recomputing each metric's correlation separately within each condition yields at most $|\rho| = 0.34$ (STOI within MetricGAN+), with PESQ reaching $|\rho| = 0.26$ and SNR, SRMR, and SQUIM-MOS below 0.15 (full breakdown in Appendix E, Table 8), versus the pooled $\rho = -0.467$. Thus, no metric provides meaningful signal about *which* clips will diverge once the enhancement condition is fixed.

This further shows that practitioners cannot use PESQ, or any of the six tested metrics, to anticipate per-clip LLM failures within a given SE pipeline. The pooled correlation reflects coarse condition-level separation, not clip-level predictive power.

Condition	Med. PESQ	FN (%)	FP(%)
Noisy	1.61	11.4	**84.4**
MetricGAN+	1.90	22.1	58.4
Echo (sim)	1.09	**82.3**	15.0
Echo + DTLN-AEC	1.50	32.9	52.1
Dereverb	2.35	10.0	**88.4**

Table 5: PESQ as a binary early-warning signal (threshold = within-condition median PESQ). FN: fraction of above-median clips that still diverge (PESQ misses real damage). FP: fraction of below-median clips that do not diverge (PESQ over-warns). No threshold separates safe from unsafe clips across conditions.

Where PESQ fails as an early-warning signal. Dichotomizing clips by within-condition median PESQ (Table 5) shows that PESQ's failure mode is condition-dependent. Under Echo (sim), 82.3 % of above-median-PESQ clips still diverge, meaning PESQ offers no safety margin precisely when damage is worst. Under Dereverb and Noisy, 84–88 % of below-median-PESQ clips do *not* diverge, meaning PESQ over-warns on clips the LLM handles correctly. No single decision threshold on PESQ separates safe from unsafe clips across conditions.

4.3 Architecture Robustness

Table 6 (Appendix B) confirms that the findings are not Whisper-specific. wav2vec2 produces an identical condition ranking (Spearman $\rho = 1.0$, $p < 0.001$), with higher ODR under spectral distortion conditions (mean $\Delta = +0.157$). The sole exception is Echo (sim), where both models converge ($\Delta = +0.017$), confirming that speaker-substitution failure is architecture-agnostic.

The higher wav2vec2 ODR under spectral condi-

tions suggests that CTC-based systems, common in latency-constrained deployments, may face greater enhancement-induced LLM damage than encoder-decoder estimates suggest.

4.4 Domain-Level Vulnerability

ODR varies across SLURP domains (Table 7). Short formulaic commands (*lists*: mean ODR 0.419, *alarm*: 0.386) are more vulnerable than open-ended domains (*news*: 0.319, *qa*: 0.315), as formulaic utterances have less lexical redundancy for the LLM to recover intent from a degraded transcript. Of 4,149 divergent clips, 90.4% represent domain-level shifts (predicted intent belongs to a different SLURP domain than the ground-truth intent) and only 9.6% are within-domain action confusion, confirming that SE distortion destroys coarse domain signals rather than producing fine-grained intent errors.

4.5 LLM Robustness

To assess whether findings depend on classifier capacity, we partially replicate the pipeline with Gemini 2.5 Pro. On the full 2,974 clean and noisy clips, the direction of harm is preserved: noisy ODR is 0.154 under Pro (vs. 0.135 under Flash Lite), consistent with random variation at this scale. Among the available 1,733 MetricGAN+ clips, Pro ODR is 0.294. The doubling direction is preserved: a substantially more capable LLM still registers nearly twice as much semantic damage from MetricGAN+ as from unenhanced noise ($1.91\times$ vs. $2.36\times$ under Flash Lite), consistent with the core finding being robust to classifier capacity, though a full five-condition Pro replication remains future work.

5 Deployment Implications

WER is an insufficient SE evaluation metric. Our results show WER can overestimate LLM damage (MetricGAN+: ODR = 0.318, Gap = -0.296) or saturate while ODR remains catastrophic (Echo (sim): WER = 1.448, ODR = 0.836). We recommend ODR alongside WER as an offline evaluation criterion for comparing SE configurations before deployment. Like PESQ and STOI, it requires a clean reference recording and is therefore a development-time tool rather than an online per-utterance monitor. This recommendation carries urgency for CTC-based ASR systems, where our results suggest ODR is systematically higher.

Echo cancellation is a hard requirement. The echo condition reaches an ODR of 0.836 and 0.853 under both ASR models, meaning the spoken AI system correctly handles fewer than one in six user interactions. DNSMOS and PESQ score the near-end signal characteristics and cannot detect this failure because they do not assess which speaker was transcribed. In any conferencing deployment, functional AEC must be treated as a prerequisite for LLM integration, not an optional quality refinement that can be deferred when latency or cost is constrained.

Perceptual metrics cannot replace LLM task evaluation. PESQ, MetricGAN+'s direct training objective, shows only moderate rank association with ODR ($\rho = -0.467$), while non-intrusive SQUIM-MOS shows near-zero association ($\rho = -0.068$). SE pipelines optimised for perceptual quality provide no reliable guarantee of downstream LLM performance. ODR measurement on a representative intent task should be included in SE evaluation protocols for spoken AI systems.

6 Conclusion

We introduced Output Divergence Rate (ODR), a task-level metric that measures how often speech enhancement changes an LLM's intent prediction relative to clean speech. Using ODR, we show that perceptual quality improvements neither guarantee downstream LLM task performance nor prevent degradation. MetricGAN+ more than doubles ODR despite improving PESQ, while unmitigated echo drives ODR to 0.836 through a distinct speaker-substitution failure beyond WER's scope.

Audio quality metrics range from near-zero to moderate correlation with ODR and provide no reliable per-clip signal once the enhancement condition is fixed. Both patterns replicate across two ASR architectures. Our ground-truth intent decomposition further shows that SE-induced divergence is predominantly harmful, rather than a benign side effect of correcting clean-speech errors.

We recommend ODR alongside WER as an offline evaluation criterion for SE front-ends deployed before an LLM. The full pipeline is publicly released to support evaluation across additional LLMs, tasks, and SE systems.

Limitations

All five enhancement conditions in this study are simulated using DNS Challenge corpora. Real de-

vice recordings may differ in acoustic profile, compound distortion type, and room geometry, and we encourage replication on field-recorded data.

On the ASR side, we compare encoder-decoder attention (Whisper) and CTC (wav2vec2), but streaming CTC and attention-CTC hybrid architectures remain untested. Given that wav2vec2 consistently yields higher ODR than Whisper on spectral conditions, other CTC variants may amplify the effects reported here.

The benchmark uses English-only SLURP data, and enhancement artefacts may interact differently with ASR and LLM processing in tonal or morphologically rich languages.

ODR is defined over a fixed 77-class intent vocabulary. Open-ended generation tasks (summarisation, question answering, or dialogue) may exhibit different sensitivity to the transcript distortions induced by each SE condition, and the mapping between our findings and those settings requires further investigation.

Our primary results use Gemini 2.5 Flash Lite. Section 4.5 reports a partial Gemini 2.5 Pro replication. Full multi-family LLM evaluation covering encoder-based classifiers such as BERT-style joint intent/slot models, and extending the Pro replication to all conditions, remains future work.

On the echo side, we evaluate a neural AEC system (DTLN-AEC). Other architectures, including multi-microphone beamforming-based cancellers and commercial AEC implementations, are untested and may offer different recovery profiles.

Like PESQ and STOI, ODR requires a clean reference recording per clip, which is typically unavailable during live deployment. It is therefore intended as an offline, development-time criterion for comparing SE configurations before deployment, not an online per-utterance monitor. Reference-free proxies (transcript stability under paraphrase or ASR confidence scores) are a natural direction for extending ODR to deployment settings.

Among SE approaches, we test one discriminative GAN-based suppressor (MetricGAN+), which is representative of deployed perceptual optimisers. Diffusion-based, self-supervised, and proprietary commercial SE systems remain untested, and the rate of intent collapse under those approaches could differ substantially from what we report.

Finally, ODR is computed over closed-set intent labels only. The SLURP test release used here does not expose entity or slot annotations, so our error taxonomy does not separately track named-entity or slot-level errors. Because SLURP intent labels are domain/action pairs that often survive entity-level ASR substitutions (e.g. mishearing a city name or contact), ODR may understate SE impact on tasks that depend on entity fidelity such as slot filling or named-entity recognition. Extending ODR to slot-level F_1 is future work.

Ethical Considerations

This work uses publicly available datasets (SLURP, DNS Challenge) and publicly available models (Whisper, MetricGAN+, WPE, wav2vec2). No personally identifiable information was collected or generated. The SLURP dataset was collected with informed consent from participants. Our findings expose a potential reliability failure in deployed spoken AI systems, which we believe indicates that responsible disclosure of such failures serves the public interest by enabling practitioners to make informed deployment decisions.

B ASR Architecture & WER Comparison

Table 6 provides the full per-condition ODR and WER breakdown underlying the architecture comparison in Section 4.

C Quality Metric Predictive Failure

See Table 5 in Section 4.

D Domain-Level ODR

Table 7 breaks down ODR by SLURP semantic domain. Short-command domains (Lists, IoT, Alarm) are most vulnerable, with mean ODR exceeding 0.38 across conditions, while open-ended domains (QA, News, General) are more robust. This suggests that enhancement-induced lexical loss disproportionately affects utterances where a single keyword carries the intent.

E Within-Condition Metric Correlations

Table 8 reports Spearman ρ between each quality metric and clip-level divergence computed *separately* within each enhancement condition, alongside the pooled cross-condition value for comparison. Within any single condition, no metric exceeds $|\rho| = 0.34$ (STOI within MetricGAN+). Most are below 0.15, and several change sign across conditions. The large reduction from pooled to within-condition values confirms that the pooled correlations (Table 2, Figure 3) reflect between-condition separation rather than clip-level predictive power.

F Log-Mel Spectrogram Comparison Across Conditions

Figure 4 shows log-mel spectrograms of five representative SLURP utterances across all six conditions. Each panel shares the same colour scale (amplitude) and axis conventions: time on the horizontal axis, frequency (kHz) on the vertical axis. Panels in the same row depict the same utterance. The ground-truth transcript appears as a centred heading above each row.

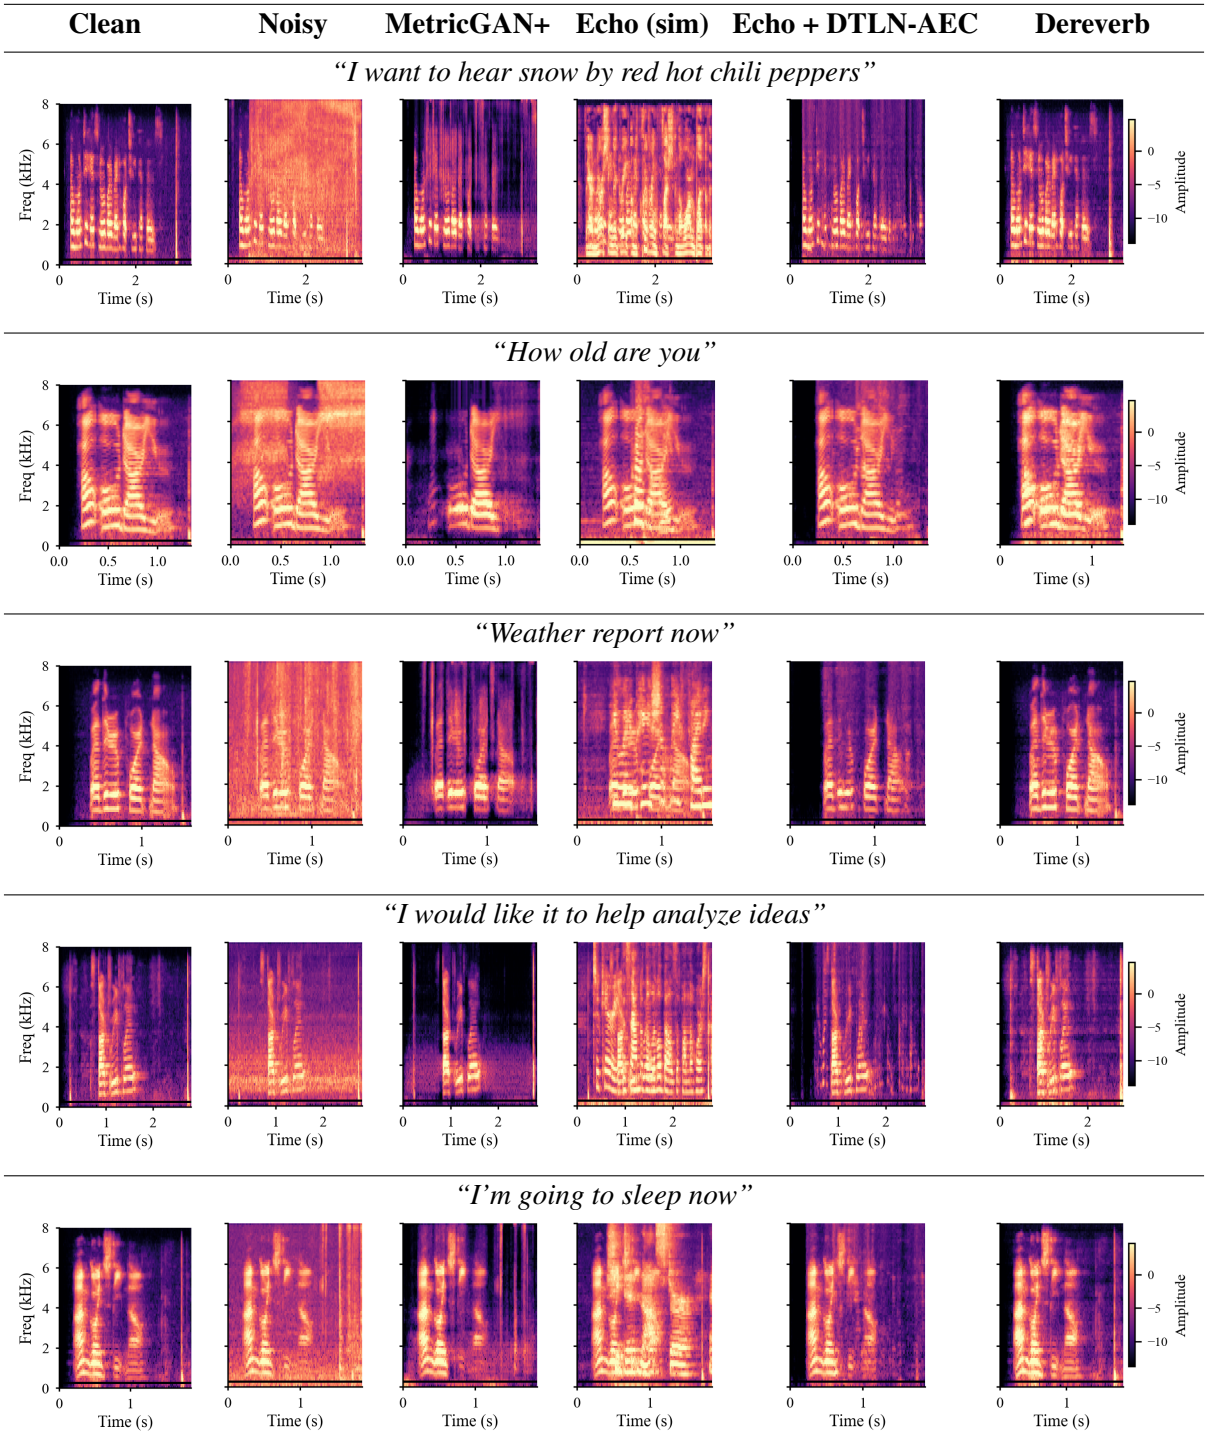

Figure 4: Log-mel spectrograms of five SLURP utterances (rows) across all six conditions (columns). Horizontal axis: time (s); vertical axis: frequency (kHz); colour: amplitude (log-mel energy, shared scale across all panels). The ground-truth transcript of each utterance appears as a centred heading above its row. Noisy floods the high-frequency band with broadband noise. MetricGAN+ suppresses it but introduces vertical streak artefacts (musical noise, visible above 4 kHz) and alters the harmonic envelope. Echo (sim) shows a wholly different far-end utterance dominating the near-end speech. Echo + DTLN-AEC partially restores the near-end harmonic structure. Dereverb is visually closest to Clean, consistent with its low ODR. Row 5 ("I'm going to sleep now") is a robust clip that does not diverge under any condition; all six panels remain visually similar.

Condition	ASR	ODR	WER Mean	WER Med.	WER>1.0	WER Max
Echo (sim)	Whisper	**0.836**	1.448	1.250	62.1 %	9.0
	wav2vec2	**0.853**	1.472	1.300	66.1 %	8.5
Echo + DTLN-AEC	Whisper	0.404	0.700	0.625	9.8 %	6.5
	wav2vec2	0.587	0.757	0.750	11.5 %	5.0
MetricGAN+	Whisper	0.318	0.647	0.571	6.8 %	5.0
	wav2vec2	0.474	0.624	0.600	5.1 %	5.0
Noisy	Whisper	0.135	0.531	0.500	2.4 %	3.0
	wav2vec2	0.352	0.513	0.500	1.8 %	4.5
Dereverb	Whisper	0.108	0.517	0.500	1.7 %	4.7
	wav2vec2	0.320	0.474	0.429	1.1 %	4.0
Clean	Whisper	–	0.507	0.444	1.2 %	28.5
	wav2vec2	–	0.388	0.333	0.3 %	4.0

Table 6: ODR and WER statistics across both ASR architectures (Gemini 2.5 Flash Lite for intent classification). **Bold** = highest ODR per model. Clean is shown as WER reference only (ODR = 0 by definition). Values >1.0 arise when Whisper or wav2vec2 transcribes the far-end echo signal rather than the near-end speaker (Echo (sim)).

Domain	Noisy	MetricGAN+	Echo (sim)	Echo + DTLN-AEC	Dereverb	Mean

IoT (Hue)	0.167	0.339	0.874	0.390	0.143	0.382
Transport	0.153	0.323	0.847	0.419	0.113	0.371
Email	0.124	0.311	0.891	0.417	0.090	0.366
Takeaway	0.019	0.333	0.944	0.300	0.130	0.345
Recommend.	0.075	0.237	0.892	0.413	0.075	0.338
Cooking	0.111	0.278	0.792	0.370	0.125	0.335
Datetime	0.070	0.280	0.830	0.400	0.070	0.330
IoT	0.131	0.328	0.770	0.321	0.098	0.330
Weather	0.086	0.237	0.815	0.404	0.079	0.324
News	0.057	0.262	0.754	0.481	0.041	0.319
QA	0.076	0.292	0.806	0.329	0.073	0.315
General	0.151	0.265	0.614	0.386	0.130	0.309

Table 7: Per-domain mean ODR across all five enhancement conditions (Whisper + Gemini 2.5 Flash Lite), all 20 SLURP domains sorted by mean ODR descending. The horizontal rule separates domains with mean ODR ≥ 0.37 (upper half) from those below. Short-command domains (Lists, IoT, Alarm) are consistently more vulnerable than open-ended domains (QA, News, General) across all conditions.

Metric	Noisy	MetricGAN+	Echo (sim)	Echo+AEC	Dereverb	Pooled
PESQ	-0.077	$\mathbf{-0.259}$	-0.048	-0.202	-0.036	-0.467
STOI	-0.107	$\mathbf{-0.340}$	-0.190	-0.225	-0.069	-0.411
SNR	$+0.005$	-0.074	$+0.060$	$\mathbf{+0.104}$	$+0.007$	-0.116
SI-SDR	-0.031	$\mathbf{-0.265}$	-0.012	$+0.073$	$+0.007$	-0.066
SRMR	-0.059	$\mathbf{-0.147}$	-0.023	-0.061	-0.063	-0.111
SQUIM-MOS	-0.012	$\mathbf{-0.101}$	$+0.036$	-0.085	$+0.025$	-0.068

Table 8: Within-condition Spearman ρ (metric vs. binary diverged) for each enhancement condition, with the pooled cross-condition ρ for comparison. **Bold** marks the largest $|\rho|$ per row. MetricGAN+ is the only condition where any metric reaches $|\rho| > 0.2$; STOI achieves the maximum (-0.340), PESQ reaches -0.259. Positive SNR and SI-SDR values within Echo + DTLN-AEC reflect a sign inversion: the nonlinear gain and phase modifications applied by the AEC break the monotone fidelity-divergence relationship, consistent with the SI-SDR anomaly in Table 2. The large pooled-to-within drop confirms that pooled correlations reflect between-condition separation, not clip-level predictive power.

AuDQ: Auditable Data Quality through Agentic Rule Discovery

Abstract

High-stakes tabular pipelines rely on scattered, static quality checks that are hard to evolve and audit against policy intent. Regulated domains particularly suffer as the LLM-era automation raises expectations for traceability and accountability. We propose a vision for an *ontology-grounded, repository-native* data quality layer in which rules are first-class artifacts: versioned, provenance-linked to governance texts, and re-playable through immutable execution traces. As a first step toward validating this vision, we present a concrete implementation of its agentic rule-discovery core with two rule acquisition modes (Full-Agentic and Guided) and a human-in-the-loop (HITL) review interface. We define an evaluation framework and run experiments addressing whether our fully autonomous, divide-and-conquer agentic rule discovery produces rules of the same quality and diversity as those specified by a human expert, reporting preliminary results on two real world industry datasets in the finance and retail domains.

1 Introduction

Tabular data drives high-stakes decisions, yet most organizations still rely on basic data quality (DQ) checks covering missingness, uniqueness, and simple range constraints. Recent enforcement actions underscore the cost of undetected failures: a USD $100M settlement tied to AML compliance gaps (BakerHostetler) and a USD $136M fine linked to data-management weaknesses (Michelle Price and Bautzer). The hardest production failures arise from context-dependent constraints tied to domain semantics (limits that depend on market hours, settlement cycles, or cross-entity reconciliation) which are documented in governance policies but never fully operationalized, remaining handcrafted, scattered, and prone to drift as schemas evolve.

We propose a vision for an *ontology-grounded, repository-native agentic DQ layer*: a system that automatically discovers rules from relational data, grounds them in semantic ontologies and governance artifacts, governs them through a human-in-the-loop lifecycle, and compiles approved rules into deterministic executable checks. Central to this vision is the idea that DQ rules should be treated as *living rulebooks*: first-class, versioned artifacts with clear provenance, not scattered code buried in pipelines.

As a concrete step towards this vision, we have implemented the agentic rule-discovery core of the proposed system and designed an evaluation to answer the following research questions:

1. Are rules discovered fully autonomously by the agentic system capable of approaching the quality ceiling set by those specified by a human?
2. Are rules discovered fully autonomously by the agentic system as diverse and non-redundant as those specified by a human?

In doing so, this paper makes three contributions:

- **An agentic architecture for automatic rule discovery in relational database systems** .
- **An empirical evaluation of rule-discovery quality and diversity**.
- **A comprehensive vision for a full data-quality layer governing the complete rule lifecycle**.

We use two real industry derived datasets from the financial banking and retail fields to test the domain-agnostic design of the system.

2 Related Work

Our work draws on three threads: data agents, DQ tooling, and ontology/audit infrastructure, but focuses on what they do not yet standardize: a shared, auditable representation of *DQ rules themselves* and the automated discovery of such rules from data.

Agentic data analytics. Recent data agents plan

EMNLP 2026 Industry Track, pages 1925–1943
October 24-29, 2026 ©2026 Association for Computational Linguistics

multi-step analyses and produce end-to-end outputs from heterogeneous data (Sun et al., 2025; Lapin et al., 2025; Qiao et al., 2025). Evaluation suites measure task success across analytics settings (Nie et al., 2026; Wang et al., 2025; Padala et al., 2025). None treat DQ as a lifecycle problem in which rules are created, versioned, executed repeatedly, and updated under audit, nor do they evaluate the quality and diversity of automatically discovered constraints.

Data-quality tooling. DQ stacks author and run checks and report violations (Pancini et al., 2025; Machireddy, 2023; Patel et al., 2022). Learned approaches detect or repair errors and explain anomalies (Dong et al., 2025; Sattarov et al., 2022). Formal constraint languages (denial constraints, SHACL/SHEx (Thornton et al., 2019)) offer expressive validators, but checks remain scattered in code with weak links to the policy text that motivated them and no replayable execution evidence for audit. Crucially, none of these approaches address the *automated discovery* of domain-grounded rules from relational data at scale.

Ontologies, audit, and regulated-industry architectures. Auditable LLM pipelines argue for traceable, replayable decision-making (Xia et al., 2025; Ojewale et al., 2026). Ontology-guided methods improve grounding and validation (Guo et al., 2025; Chepurova et al., 2025; Feng et al., 2025). Regulated-industry proposals motivate agentic DQ (Tomar et al., 2024; Durgam, 2025), but do not define a concrete, testable contract linking ontologies, rules, and execution traces, nor an evaluation of discovery quality.

We synthesize these threads by making rules and their evidence the central auditable artifacts, introducing an agentic discovery architecture, and providing an empirical evaluation of discovery quality and diversity.

3 Problem Setting

Organizations rely on tabular data (single tables, streaming logs, and multi-table warehouses) to power downstream reporting and high-stakes decisions. In finance, for example, small data errors can become material incidents: misreported exposures, missed AML signals, and model drift. End-to-end traceability is essential, requiring clear links from policy statements to implemented DQ checks.

Current practice and limitations. Most production DQ remains a patchwork of simple checks spread across code, dashboards, and tools (Saini et al., 2025), with weak links to the semantic, temporal, and cross-table requirements in Table 1 and limited governance (versioning, provenance, auditability). Beyond basic checks, policy-grounded semantic rules are costly and hard to identify and operationalize, lacking a principled automated mechanism to discover and formalize them. These gaps motivate both our architecture and our research questions.

Requirement	What it enforces / example
Syntactic validity	Types, ranges, formats across flat files and joins; referential integrity via keys/views.
Semantic correctness	Ontology-grounded invariants; e.g., notional > 0 consistent with product type in finance via trade $\rightarrow$ instrument $\rightarrow$ client, or a medication dose within an age-adjusted safe range in healthcare.
Temporal consistency	No future-dated events relative to ingestion; consistent time-series snapshots across grains.
Cross-table reconciliation	Aggregates align with primaries; e.g., ledger totals vs. front-office trades, or risk vs. accounting views.

Table 1: Core data-quality requirements for analytics-aware rules.

4 Implemented System

4.1 Overview and design principles

Figure 1 shows the four-stage pipeline we have implemented. Data flows from a **Statistical Profiler** through an **Ontology Generator** and a **Rule Discovery/Definition** module to a **Rule Implementer**. Every stage reads from and writes to a central **Artifacts Repository**, which stores versioned semantic profiles, ontology nodes, natural language and implemented rules alongside orchestrator plans, subagent rule proposals, thoughts/tool calls made by every agent and recorded HITL decisions. A `LEARNINGS.MD` file is updated by a dedicated critic agent after each run, appending timestamped entries under sections for patterns to avoid, under-explored scopes, failure analyses, coverage notes, and heuristics that worked. This persistent memory informs subsequent rule-generation episodes. All coordination is repository-mediated: components write typed artifacts to the central Repository and read only from it, with no direct agent-to-agent message passing. This decoupling keeps lineage and audit straightforward and makes agents independently replaceable. Concrete artifact schema are given in Appendix due to page limits.

Three design principles govern the implementation. *Determinism before reasoning*: the profiler is LLM-free and produces the same output for the same input, providing a stable epistemic foundation. *Text-first rules*: rules are stored in natural language and reviewed before compilation, making them auditable also by domain experts without programming skills. *Repository-mediated coordination*: all component interaction is mediated through versioned artifacts, keeping lineage and audit straightforward.

4.2 Statistical Profiler

The profiler connects directly to the database and produces a *Statistical Evidence Pack*: a structured artifact containing distributional summaries, null rates, cardinality estimates, temporal patterns, candidate keys, and inter-column dependencies for every table and column in scope. Being LLM-free, it is fully deterministic; downstream agents reason over its outputs rather than raw rows, avoiding sampling bias and token-budget issues on large tables.

4.3 Ontology Generator

For each table, entity, and column, a focused LLM call receives only the relevant portion of the Statistical Evidence Pack. A *batched, asynchronous* strategy issues N parallel calls, reducing wall-clock time proportionally to the number of objects. Three harness properties are enforced: *Context isolation*, each call sees only its target object's statistics; *Lifecycle hooks* run a duplicate-check function after each node proposal; if the node already exists in the repository, the LLM call is suppressed. *Evaluation* exposes proposed nodes to a human reviewer who can modify or delete them before they are committed. Two usage modes are supported: *automated generation*, which produces one node per table, entity, and column plus the three most salient vocabulary and within-table relationship nodes; and *manual node* creation, where the user describes the desired node, selects a type and column association, and the agent either creates a new node or interprets the request as a modification of an existing one.

4.4 Rule Discovery and Definition

Rule discovery is the architectural core of the system and the focus of our evaluation.

Full agentic mode. An *orchestrator* receives the full profiled database and segments the column space into N disjoint *subspaces*, each assigned to a *researcher subagent*. Each subagent explores its scope autonomously and proposes rules until a *coverage criterion* is met: every column in the subspace must be associated with at least one rule. The orchestrator has access to lookup tools for table/column listings, profile summaries and ontology nodes. Finally, planning tools help it draft/modify a plan file to divide the search space in meaningful sub spaces and spawn workers; researcher subagents additionally have column-level profile queries, ontology lookups, a vector-DB search over business documents (governance grounding), and a rule-proposal tool that saves decisions to the artifact repository. During proposal each rule has the hard constraint of having to be linked to at least one ontology node in order for it to be considered valid.

The harness manages long-running execution through *context compaction* (token-budget-triggered summarization with smart reinitialisation injecting uncovered columns and existing rules), *coverage enforcement* (a lifecycle hook terminates the loop when the criterion is met), and *persistent state* (all outputs written to storage for run recovery from partial states).

Guided mode. A domain expert describes the rules they already know should exist, optionally specifying the relevant columns and tables, and the system serializes the rule structure and generates code. If no subset is specified, the orchestrator finds one subspace containing the relevant tables/columns and spawns a subagent to generate the described rule. In the following experiments this mode serves as our human-expert baseline. The agent played strictly the role of *serialization*: converting a human-identified constraint into the same schema and logic-block structure used in Full-Agentic mode, so that both conditions yielded structurally comparable artefacts. The rule mining act itself (exploring the dataset and identifying a candidate constraint together with the tables and columns it covers) was performed entirely by the human actor.

4.5 Rule Implementer and HITL Governance

For each NLP rule selected for implementation, a single LLM call receives the rule text, its associated ontology nodes, and the relevant portions of the statistical profile. As with the ontology generator, a batched, asynchronous strategy is used and the system then translates each into executable SQL or Python code. A HITL step allows the user to view the NLP rule and the generated code, mod-

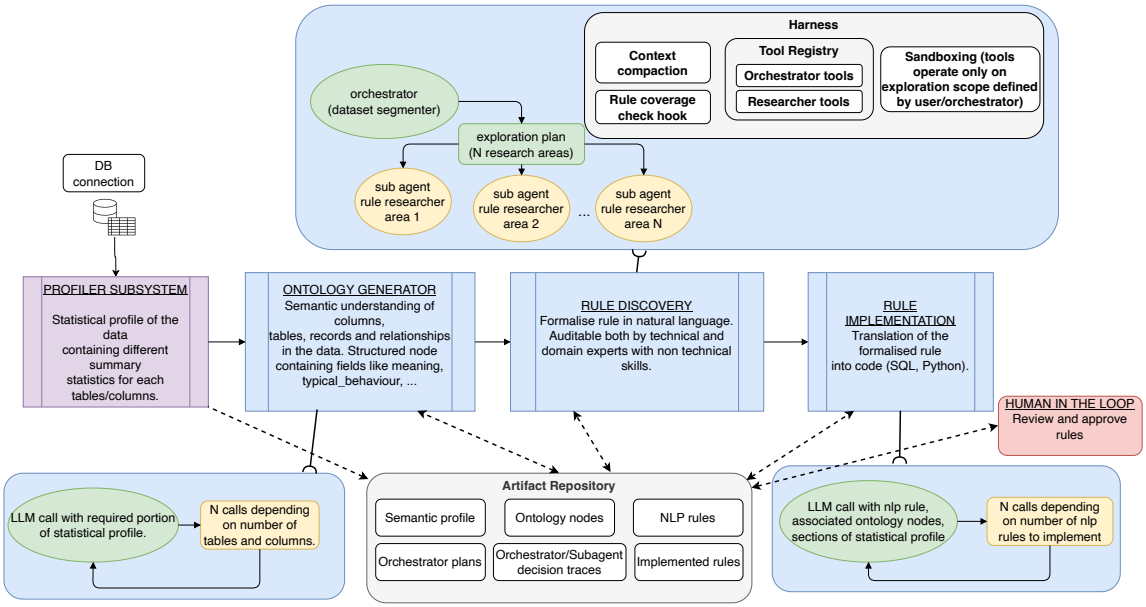

Figure 1: Implemented system overview.

ify the rule logic if needed, and re-trigger code generation. Rules move through three lifecycle states: *Proposed*, *Approved*, *Rejected*, with every transition recorded in the artifact repository.

5 Evaluation

A central capability for an agentic rule-discovery system is whether autonomous discovery can approach the quality and diversity ceiling set by human specified rules, thus making this the key first step for evaluation when developing said systems. This is non-trivial: the full-agentic mode must be able to cover the entire column space and produce semantically varied rules. The divide-and-conquer strategy previously described in section §4.4 introduces a specific risk: *cross-agent leakage*: researcher subagents operating on adjacent subspaces may independently converge on semantically equivalent rules encoding the same constraint with different syntax. Our evaluation is designed to quantify both failure modes.

We compare *Full Agentic* mode and *Guided* mode, with the latter being a structural upper bound on both dimensions: quality (the human specifies intent directly) and diversity (user specifies rules manually one at a time to prevent redundancy and contradictions).

5.1 Metrics

Good-rule rate. For dataset D and mode $M \in [A(automated), G(guided)]$, let N_M be the number of rules reviewed, A_M accepted as-is, U_M accepted with modifications, and R_M rejected. We define:

$$\hat{p}^{M}_{\text{good}} = \frac{A_M + \alpha\, U_M}{N_M}, \quad \alpha = 0.5,$$

where modified-but-approved rules receive partial credit through the $\alpha = 0.5$ weight.

Information Divergence Score. Following from (Lee et al., 2025) we define an IDS measure adapted to our own domain to evaluate pairwise diversity across N proposed rules:

$$\text{IDS} = 1 - \frac{1}{\binom{N}{2}} \sum_{i<j} \text{sim}_{ij}$$

where:

$$\begin{aligned}\text{sim}_{ij} = w_{\text{syn}}\, \text{Jac}(t_i, t_j) + w_{\text{sem}}\, \cos(e_i, e_j) \\ + w_{\text{scope}}\, \text{Jac}(s_i, s_j)\end{aligned}$$

Pairwise similarity thus combines three components,

1. **Syntactic**: token-level Jaccard similarity over rule logic and query text, $\text{Jac}(t_i, t_j)$.
2. **Semantic**: dense-embedding cosine similarity over rule logic and query text, $\cos(e_i, e_j)$.
3. **Rule scope**: Jaccard similarity over the union of ontology nodes and table/column names referenced by each rule, $\text{Jac}(s_i, s_j)$.

IDS $\in [0, 1]$ with a higher score signifying more diverse rules.

5.2 Datasets

We evaluate the system on two publicly available industry relational databases that capture real diversities in domain, schema and complexity.

Berka (retail banking). The Berka dataset contains real, anonymized data from a Czech bank covering the period 1993–1998. It comprises 8 tables (`account`, `client`, `disp`, `card`, `loan`, `order`, `trans`, and `district`) linked by foreign keys that model the full lifecycle of retail banking. The database contains 5,369 clients and over 1,000,000 transaction records, making it a rich, multi-table relational benchmark with realistic referential integrity constraints, coded categorical fields, and cross-table financial consistency invariants. It is widely used in the relational data mining literature (Li et al., 2023; Singh et al., 2025).

rel-HM (fashion retail). The rel-HM dataset contains real, anonymized data from retail purchases of HM products. It contains 3 tables (`customers`, `articles`, and `transactions`) with approximately 16.7 million purchases from 2018 to 2020. Despite its simpler schema, it presents high-cardinality categorical vocabularies, implicit referential constraints between articles and transactions, and cross-field consistency rules between product metadata fields (Robinson et al., 2024). As both dataset do not ship with any grounding documentation the rule discovery system ran without the governance-grounding search tool, using only the dataset statistics and the inferred ontology.

5.3 Experimental protocol

For each dataset, we ran both the Full Agentic mode and the Guided mode with $k = 4$ reviewers, each yielding between 25-55 proposed rules per run and a total of 16 runs overall. Reviewers were mid/senior data engineering professionals with finance and retail domain experience. Every reviewer authored one Guided run to which a Full agentic run was paired for rule reviewing load purposes. Rule assignment for review followed a blinded, mixed-mode, round-robin batch design: each rule was rated by exactly two reviewers other than its author, every batch mixed rules from both generation modes and reviewers were blind to which mode had produced each rule. We report the full block-construction protocol and validation checks in Appendix §C. All rules were reviewed via the standard HITL flow and labeled accept/modify/reject. All the ontology and rule generation processes utilised Qwen3.5-397B-A17B as the underlying LLM model, chosen for its competitive performances, open source nature and generous context/output limits. A temperature of 0.5 was selected to allow for variability across exploration episodes.

Experiment 1 (RQ1): Rule-generation quality by mode. We test for equivalence, H_0: $|\hat{p}^A_{\text{good}} - \hat{p}^G_{\text{good}}| \geq \Delta$ against H_1: $|\hat{p}^A_{\text{good}} - \hat{p}^G_{\text{good}}| < \Delta$, by estimating the shift in good-rule rate between modes, $\hat{p}^A_{\text{good}} - \hat{p}^G_{\text{good}}$, per dataset and pooled across datasets. Because per-run scores are few and non-normal, we use a non-parametric two one-sided test (TOST): a Hodges–Lehmann (HL) shift estimator, exact confidence intervals obtained by inverting the Mann-Whitney statistic, rank-biserial effect sizes, and the TOST power achieved. The equivalence margin was fixed before the analysis at the standard deviation of Guided-mode run scores ($\Delta = 0.0556$), so that modes count as equivalent only if they differ by less than reviewers differ among themselves. We report the HL shift and its interval as our primary estimate, and the TOST verdict alongside its achieved power. Because every rule carries two independent ratings, we additionally quantify inter-rater agreement on the accept/modify/reject scale. We report raw agreement alongside two chance-corrected coefficients: ordinal Krippendorff's α and Gwet's AC2, both with 95% bootstrap intervals. We report both because they behave differently under skewed marginals, and our verdict distribution is heavily skewed; relying on either alone would misstate the reliability of the labels.

Matched-scope volume control. The two modes propose different rule volumes as the Full Agentic coverage criterion forces at least one rule per column generating roughly 1.6x the rules of the Guided mode (Table 13). Good-rule rate is a precision-style measure, so comparing it across sets of very different size favors the mode that proposes fewer, safer rules. Since neither dataset ships with a reference rule set to compare against we repeat the equivalence test with a matched-scope volume control. We recorded the tables and columns referenced in each rule of all Guided mode runs and took the intersection across all four reviewers (a conservative proxy for the scope every reviewer agreed was rule-worthy). We then restricted the agentic rules set to that same scope. This removes the potentially low-value rules forced by the coverage

Dataset	Mode	$\hat{p}_{\text{good}}$
Berka	Full agentic	0.890
	Guided	0.880
H&M	Full agentic	0.922
	Guided	0.850
Overall	Full agentic	0.906
	Guided	0.865

Table 2: Mean good-rule rate across runs per dataset and mode.

criterion and makes volumes comparable (Agentic:Guided ratio = 1:1 on Berka, 1:1.3 on H&M). Scope matching is applied post hoc, at analysis time rather than at batch construction, so it does not affect what reviewers evaluated. We then recompute the RQ1 analysis on this matched set.

Experiment 2 (RQ2): Diversity and partition effectiveness. We test for equivalence, H_0: $|\text{IDS}_A - \text{IDS}_G| \geq \Delta$ against H_1: $|\text{IDS}_A - \text{IDS}_G| < \Delta$ by estimating the shift in Information Divergence Score between modes, $\text{IDS}_A - \text{IDS}_G$, using the same non-parametric TOST procedure, with the margin fixed a priori at the standard deviation of Guided mode IDS scores ($\Delta = 0.0202$). For each dataset and replicate we use pre-reviewed rules (to avoid human review masking the agentic run's inherent diversity through rule modification) and compute IDS per run. To ensure that any result is not an artefact of a single similarity component, we repeat the analysis across four weight configurations: equal weights $(w_{\text{syn}}, w_{\text{sem}}, w_{\text{scope}}) = (1/3, 1/3, 1/3)$, semantic-heavy $(0.25, 0.5, 0.25)$, syntax-heavy $(0.5, 0.25, 0.25)$, and scope-heavy $(0.25, 0.25, 0.5)$.

5.4 Results

RQ1: Rule-generation quality. Table 2 reports the mean good-rule rate per mode and dataset. The Full agentic mode achieves a higher mean good-rule rate on both datasets (Berka: 0.890 vs. 0.880; H&M: 0.922 vs. 0.850), and the gap is larger on the rel-HM, the dataset with a simpler structure.

Full Agentic mode scored slightly higher than the Guided mode overall (0.037 Hodges–Lehmann shift, 90% CI: -0.008 to $+0.089$), with a small shift for Berka ($+0.004$, 90% CI: -0.112 to $+0.135$) and a larger one for H&M ($+0.064$, 90% CI: $+0.029$ to $+0.129$), where the interval excludes zero: on this dataset the four agentic runs separate completely from the four guided runs ($r = -1$). Table 3 reports the full analysis. Equivalence is not established for any comparison since every

Comparison	HL	90% CI	r	Power
Berka	$+0.004$	$[-0.112, +0.135]$	0	$< 1\%$
H&M	$+0.064$	$[+0.029, +0.129]$	-1	36.5%
Overall	$+0.037$	$[-0.008, +0.089]$	-0.50	27.8%
Matched-scope control				
Overall	$+0.037$	$[-0.027, +0.094]$	-0.38	3.5

Table 3: Non-parametric TOST equivalence analysis for RQ1 good-rule rate (Full Agentic − Guided); equivalence margin $\Delta = 0.0556$. HL: Hodges–Lehmann shift with exact CI from the inverted Mann-Whitney statistic; r: rank-biserial effect size (negative favor Full Agentic mode); Power: achieved TOST power. Runs required for 80% power: 28 (Berka), 6 (H&M), 16 (Overall). The matched-scope: rules with column scope shared by all Guided runs.

CI extends beyond the set margin ($\Delta = 0.0556$). Achieved power is low throughout (27.8% overall), rendering the equivalence verdict uninformative rather than simply unestablished, and thus we draw no conclusion of quality parity between the modes. The matched-scope volume control leaves the estimate essentially unchanged ($+0.037$, 90% CI: -0.027 to $+0.094$), indicating that the volume asymmetry created by the coverage criterion is not what produces the agentic-favouring shift.

Inter-rater agreement. Table 4 reports agreement over the 541 doubly-rated rules. Agreement is high: reviewers selected the same verdict on 77.3% of rules, and Gwet's AC2 is 0.812 overall, with consistent values across both datasets and both modes. Ordinal Krippendorff's α is lower (0.174) because 84.8% of ratings are `accept`; when one category dominates, α's chance-correction term approaches the observed agreement and the coefficient is deflated. AC2 is a metric robust to exactly this situation, hence why both are reported to better understand the caveat around the ratings. Of note is that α is lower on agentic than on guided rules despite near-identical raw agreement (76.8% vs. 78.1%). The gap is largely arithmetic: accept is even more dominant on agentic rules (86.0% vs. 82.6%, Table 13), which raises the agreement expected by chance alone and leaves less credit for α to assign. Appendix §C.3 gives the full breakdown.

RQ2: Rule diversity and partition effectiveness. Table 5 reports mean IDS per mode across four weight configurations. IDS values are nearly identical between modes: under semantic-heavy weights both achieve a mean IDS of 0.648, and the largest absolute difference across configurations is 0.010 (scope-heavy, favouring the agentic mode). The

Subset	n	Exact	α [95% CI]	AC2 [95% CI]
Overall	541	77.3	0.174 [.074,.279]	0.812 [.770,.851]
Berka	317	76.0	0.165 [.035,.292]	0.810 [.754,.858]
H&M	224	79.0	0.189 [.021,.350]	0.815 [.747,.872]
Agentic	340	76.8	0.061 [−.056,.187]	0.816 [.764,.864]
Guided	201	78.1	0.326 [.150,.484]	0.805 [.730,.868]

Table 4: Inter-rater agreement over doubly-rated rules. **Exact**: % rules where both reviewers gave same verdict. α: ordinal Krippendorff's α; AC2: Gwet's AC2; both with 95% bootstrap intervals. α is deflated relative to AC2 because `accept` accounts for 84.8% of all ratings.

Weight config	IDS_A	IDS_G
Equal	0.732	0.729
Sem.-heavy	0.648	0.648
Syn.-heavy	0.749	0.750
Scope-heavy	0.798	0.788

Table 5: Mean IDS across datasets ($n_A = n_G = 8$ runs per mode).

sign of Δ changes across weight configurations, indicating no consistent direction of difference.

Table 6 results support equivalence under every weight configuration, with small effect sizes ($|r| \leq 0.28$), moderate power (44–71%) and confidence intervals falling entirely within the a priori margin ($\Delta = 0.0202$). The result holds across all four configurations, highlighting how it isn't an artefact of any single similarity component of IDS. This provides a result in support of RQ2 and thus the system's capability to avoid redundancy while retaining exploratory parallelization capabilities of the complex information spaces that relational databases represent. Column space division across concurrently operating subagents doesn't measurably reduce semantic diversity of the resulting rule set relative to human specification.

6 Vision: Closed-Loop DQ Layer

The prototype implemented addresses rule discovery and governance. The broader vision extends this into a full closed-loop DQ layer with two additional components (full details and system diagram in Appendix §B.5, §B.6 and Figure 2).

Execution Dashboard and Reporting Agent (EDRA) runs checks idempotently on stable dataset snapshots, and writes immutable *ExecutionTraces* with violation counts, sample failing rows, runtime, and provenance (rule version, ontology snapshot, dataset snapshot). It then aggregates ExecutionTraces into interactive health dashboards, severity-weighted dataset scores, rule-stability trend views, and audit-ready exports, providing a single pane of glass for data owners, risk, compliance, and engineering.

Weights	HL	90% CI	r	Power
Equal	-0.003	$[-0.010, +0.012]$	$+0.16$	57%
Semantic	-0.005	$[-0.015, +0.008]$	$+0.22$	44%
Syntax	-0.005	$[-0.016, +0.010]$	$+0.25$	71%
Scope	$+0.003$	$[-0.004, +0.019]$	-0.28	53%

Table 6: Non-parametric TOST equivalence analysis for RQ2 IDS (Full Agentic − Guided); equivalence margin $\Delta = 0.0202$. HL: Hodges–Lehmann shift with exact CI from the inverted Mann-Whitney statistic; r: rank-biserial effect size. Runs required for 80% power: 11 (Equal), 13 (Semantic), 9 (Syntax), 11 (Scope).

Root Cause Analysis and Detective Agent (RCADA) reads ExecutionTraces, ontology risk metadata, dataset lineage, and profiler trends to produce ranked root-cause hypotheses using an explicit cause taxonomy (provider outage, pipeline regression, upstream drift, contextual event, ontology mismatch, rule mis-specification), bounded near-term failure forecasts, and non-binding prescriptive suggestions for steward review.

Together, these components close the feedback loop: EDRA executes and summarizes, RCADA diagnoses and proposes, humans decide, and the repository records updates for the next cycle. Because all rules and traces are linked to stable ontology node IDs, the system remains robust to schema and provider changes by reasoning over semantic entities rather than raw column names.

7 Discussion

We have proposed a vision for an ontology-grounded, versionable DQ system, taking a concrete first step by implementing and evaluating its agentic rule-discovery core and the HITL components needed for auditability/reproducibility requirements in regulated domains. Our results on two real-world databases show that the full-agentic mode produces rules of comparable diversity to the human baseline, supporting the semantic-coverage premise of the vision. However, the lack of established equivalence combined with the underpowered nature of the test for the first research question leaves it open, and we therefore make no current conclusions towards the quality parity between modes which will be further explored in future works. The diversity finding is consistent across two datasets from different domains (financial/retail), which is encouraging but preliminary evidence of domain-agnostic transferability.

Limitations and future steps We identify five limitations that qualify these results. First, rule *complexity* is not yet measured: our metrics capture quality and diversity but not whether automatically discovered rules are systematically simpler than human-specified ones, which would represent a meaningful gap in expressive power. Future evaluations will focus on quantifying also this dimension building on top of IDS and carrying out more comprehensive analysis on the metric's correlation to human judgment. Second, both datasets might share characteristics across domains (ex both have a transactional nature) that have not been controlled for and which may not highlight the true limits of domain transferability; broader domain coverage is needed to test the system's limits. Expanding to datasets across existing relational benchmarks and synthetic data generation benchmarks is a priority for future work, with the longer-term goal of curating a benchmark pack including data snapshots, evolution scripts, governance text, and gold rule catalogs to share with the broader research community to support re-playable, lifecycle-aware evaluation specifically of Agentic DQ systems. Third, scaling reviewers is inherently expensive, while small groups introduce issues with statistical power, as seen for RQ1 where a low power does not make it possible to draw conclusions on equivalence, or for RQ2 where a higher power would allow to draw even more confident conclusions. Future work will thus complement a larger reviewer set with automated evaluation based on rule execution outcomes and expert-validated reference gold rule sets. Fourth, compute budgets for these tests restricted us to a single LLM and temperature setting. We recognize the need for future model/temperature ablation test to better understand the robustness and transferability of the proposed harness. Finally, the current evaluation covers only the rule-discovery component; the full vision (execution+dashboarding, and root-cause analysis) remains to be implemented and evaluated end-to-end, thus at present we do not claim any empirical demonstration of the full architecture that we leave for future work.

Open problems. Grounding noisy governance text into calibrated ontology updates, mapping abstract concepts across heterogeneous schemas, handling schema evolution without destabilizing linked rules, and measuring false positives at scale remain key open challenges we hope this framework can help start to address systematically.

8 Acknowledgments

The authors would like to thank Aniket Joshi for having sourced the databases and prepared them for use, while Michael Santarossa and Roberto Varinelli for their feedback and precious advice on the work carried out for this paper.

Appendix

A Beyond Traditional Data-Quality Checks

Most production pipelines start with generic checks that do not depend on the domain. Common examples of traditional data quality checks are completeness and missingness, uniqueness and duplicate detection, data type and parsing validity, format checks such as date and identifier patterns, value ranges, basic outliers, and referential integrity across keys. These checks are necessary, but they often miss errors that only become visible when the data is interpreted in its real business meaning.

We refer to the domain-specific sophisticated data quality checks as *policy grounded semantic rules*. These are domain dependent rules that use real world constraints and governance text such as policies, data dictionaries, and reporting definitions. They are often conditional, time aware, and cross table. They also need provenance so reviewers can see which document or evidence justified the rule. Some examples are shown in Table 7.

Rule type	Finance example	Grounding
Calendar and market hours	No equity trades on Sunday. Trades outside market hours must be flagged or explained.	Market calendar, policy
Temporal consistency	Settlement date must be after trade date. For many products it follows a fixed lag such as T plus 2, with exceptions.	Policy, product spec
Cross field meaning	Notional should match quantity times price within tolerance and currency scaling.	Domain math, evidence
Entity state	Counterparty must be active on trade date. Trades for blocked accounts must be rejected.	Reference data, policy
Cross table reconciliation	Trade totals must reconcile with positions and ledger aggregates at the portfolio level.	Reporting definition

Table 7: Examples of policy grounded semantic rules that go beyond traditional checks.

In addition, we also frame our data quality system around the four classic analytics types: descriptive, diagnostic, predictive, prescriptive that are a standard in the field. Table 8 maps the full envisioned agents stack to said analytics types.

B Formal Artifact Specifications

B.1 Ontology specifications

We propose a clear, minimal, and extensible ontology specification for the ontology-enhanced agentic data quality system. The ontology is designed to be LLM-friendly, human-readable, and agent-operable, while remaining robust across domains. Design goals include stability (a fixed structural contract so agents can interoperate), expressiveness (rich semantics captured primarily in natural language), partial observability (nodes may be incomplete or uncertain by design), domain generality (the same ontology spine works across tabular domains), and LLM-first reasoning (semantics optimized for textual reasoning).

The ontology is a typed semantic graph: each node represents a semantic unit in tabular data, and relationships between nodes are captured explicitly or via references. The ontology supports exactly five node types, and this set is closed by design; new semantic distinctions should be expressed via `semantic_role`, not by adding node types (Table 9).

Every ontology node must conform to the minimal schema below.

```
{
  "node_id": "string",
 "node_type": "Dataset | Entity | Attribute |
  Relationship | Vocabulary",
 "name": "string",
 "semantic_role": "string",
 "confidence": "float",
 "sources": ["data | domain | human
 | external"],
 "version": "string",
 "meaning": {
   "description": "string"
 }
}
```

Field meanings are summarized in Table 10.

Beyond `meaning.description`, we support a soft semantic envelope for natural-language keys such as `constraints`, `typical_behavior`, `edge_cases`, and `risk_notes`. For example:

```
"meaning": {
 "description": "Executed equity trades table.",
  "constraints": "Each row is one executed
trade.",
 "typical_behavior": "High volume during mar-
ket hours.",
 "edge_cases": "After-hours trades and correc-
tions.",
  "risk_notes": "Used for risk and regulatory
reporting."
}
```

Agents may add new keys such as `regulatory_context` or `temporal_behavior`, but must not remove or overload existing keys.

B.2 Rules specifications

A structured, versioned rule repository works in tandem with the ontology. It is where data quality

Agent	Descriptive	Diagnostic	Predictive	Prescriptive
Ontology Gen.	Grounds columns into entities, measures, and units.	Adds semantic context for anomaly explanation.	Marks forecastable measures and derived metrics.	Enables domain-aware imputation and unit normalization.
Rule Discovery	Drafts checks with clear summaries and coverage metrics.	Encodes conditional/composite rules for diagnosis.	Proposes drift-sensitive and stability-aware rules.	Suggests adaptive thresholds and remediation-aware rules.
Implementer	Translates approved rules into executable code.	Generates diagnostic checks capturing failure evidence.	Produces code artifacts that accumulate execution history for forecasting.	Emits validated, controlled fixes to apply safeguards/remediation.
Human review	Confirms expected vs. concerning signals.	Confirms or rejects proposed causes.	Decides which predicted risks are actionable.	Approves, edits, or blocks remediation strategies.
EDRA	Executes checks and visualizes quality metrics and trends.	Captures failure evidence and supports drill-down/lineage views.	Collects execution history and displays risk scores and drift forecasts.	Presents recommended actions for review.
RCADA	Consumes descriptive trace summaries.	Produces ranked RCA hypotheses with evidence.	Forecasts future failures from recurring patterns.	Suggests targeted interventions and rule updates.

Table 8: How agents and human review support descriptive, diagnostic, predictive, and prescriptive behavior.

Node type	Purpose
Dataset	Represents a table, file, or view as a whole.
Entity	Represents a real-world object described by rows.
Attribute	Represents a column or derived field.
Relationship	Represents row-to-row or table-to-table linkage.
Vocabulary	Represents a value space or code system.

Table 9: Exhaustive ontology node types.

Field	Meaning
`node_id`	Stable unique identifier.
`node_type`	One of the five exhaustive types.
`name`	Human-readable label.
`semantic_role`	Open-ended semantic classification.
`confidence`	Belief score in correctness, from 0 to 1.
`sources`	Provenance of semantic evidence.
`version`	Ontology version tag.
`meaning. description`	Canonical semantic explanation.

Table 10: Field semantics for the minimal ontology node schema.

knowledge is proposed, reviewed, executed, audited, and evolved. It serves as a staging ground for agent-generated rules, a human control point for approval and refinement, a persistent memory of data quality intent, a bridge from ontology to execution, and an audit log for governance. We propose core principles of being ontology-linked, text-first, lifecycle-aware, provenance-rich, and executable without being bound to any one runtime. Every rule must conform to a minimal schema.

```
{
  "rule_id": "string",
  "rule_name": "string",
  "linked_nodes": ["ontology_node_id"],
  "rule_type": "descriptive | diagnostic | predictive | prescriptive",
  "status": "draft | approved | deprecated",
  "confidence": "float",
  "generated_by": "agent | human",
  "version": "string",
  "logic": {
   "intent": "string"
  }
}
```

The fields carry the following meanings: `linked_nodes` ties the rule to one or more ontology nodes; `rule_type` captures the analytics orientation; `status` captures lifecycle state; `confidence` captures belief in correctness; and `generated_by` records origin.

Rule logic is stored as typed natural-language blocks.

```
"logic": {
  "intent": "What quality property this rule enforces",
  "condition": "When the rule applies",
  "expectation": "What must hold true",
  "severity": "Impact of violation",
  "remediation": "Suggested corrective action",
  "rationale": "Why this rule exists"
}
```

Agents may add blocks such as `regulatory_basis`, `statistical_basis`, or `exceptions`, but must not redefine existing keys. Rules move through explicit states (Proposed, Approved, Rejected). State transitions are recorded as provenance events. Every rule must reference at least one ontology node; rules inherit meaning from linked nodes, and ontology updates may trigger rule re-evaluation. Example:

Module	What it outputs
Structural	Schema facts such as column names, physical types, counts, declared keys, partitions.
Distributional	Global numeric and categorical summaries from full scan or distributed aggregation.
Temporal	Frequency, gaps, weekday or holiday patterns, rolling rates with confidence.
Relationship	Dependencies, candidate foreign keys, correlations, ordering constraints.
Quality signals	Null rates, duplicates, declared constraint counts, drift indicators.

Table 11: Profiler modules and their evidence outputs.

`"linked_nodes": ["col:trade_amount", "entity:trade"]`.

B.3 Profiler subsystem specifications

The Profiler Subsystem is a deterministic, non-LLM component that extracts complete, coverage-aware evidence summaries from raw tabular data. It is the epistemic foundation of the system. Agents reason over profiler outputs rather than raw rows, which can be too large to route through an agent loop. The intended division of labor is that profilers compute facts, and agents interpret meaning.

Profiler inputs are raw tables or files, file-format metadata, execution configuration, and optional calendars or controlled business context. The profiler emits a *Statistical Evidence Pack*, a structured artifact saved to the Artifact repository and consumed as immutable evidence by Ontology generation. We summarize the main profiling modules in Table 11. The Statistical Evidence Pack is machine-readable; examples are shown below.

```
{
  "row_count": 125000000,
  "columns": {
   "trade_id": "string",
   "trade_date": "date",
   "trade_amount": "decimal"
  }
}

{
  "trade_amount": {
   "p50": 120000,
   "p99": 5000000,
   "max": 87000000,
   "negative_rate": 0.0
  }
}

{
  "trade_date": {
   "inferred_frequency": "daily",
   "weekday_gaps": ["Sunday"],
   "max_gap_days": 2,
   "calendar_alignment": "NYSE",
   "confidence": 0.97
  }
}
```

The profiler records coverage and sampling policy explicitly.

```
{  "profiling_mode":  "full_scan",
"coverage":  "100%",  "sampling":
"none" }
```

If sampling is required, the policy and limitations are recorded. Profiler outputs are deterministic for a given dataset version. Profiling code versions are logged. The Evidence Pack is saved to the Artifacts Repository and reused by downstream agents. Profilers never consume ontology or rules.

B.4 Ontology generation specifications

Ontology generation transforms profiler evidence into a semantic understanding of the dataset and emits ontology creation or update operations. It never reasons over raw rows at scale and instead consumes coverage-aware evidence summaries from the Statistical Evidence Pack. Ontology generation reads the Statistical Evidence Pack from the Artifacts Repository. Mandatory inputs include structural metadata, distributional profiles, temporal profiles, and relationship and dependency profiles. Optional inputs include user hints, and controlled documentation. A key design principle is that Ontology generation never ingests raw rows; it reasons only over deterministic profiler evidence to avoid sampling bias and preserve temporal semantics.

The system emits a set of Ontology Operations as structured outputs to force the LLM to conform to the node schema (transactional `CREATE_NODE` and `UPDATE_NODE` operations that update the ontology namespace). For example, from a column profile for `trade_amount`, the system can infer a monetary measure role and emit a manifest entry plus a node operation.

```
{
  "column": "trade_amount",
  "semantic_role": "monetary_measure",
  "meaning": {
   "description": "Executed notional value of a
trade.",
   "constraints": "Must be non-negative.",
   "risk_notes": "Errors impact exposure and
reporting."
  },
  "confidence": 0.92
}
```

Ontology operations are selected based on existing ontology match confidence. A new ontology namespace is created if no match is strong enough or isolation is requested. Otherwise Ontology generation updates existing nodes when new evidence refines meaning, constraints, units, or relationships.

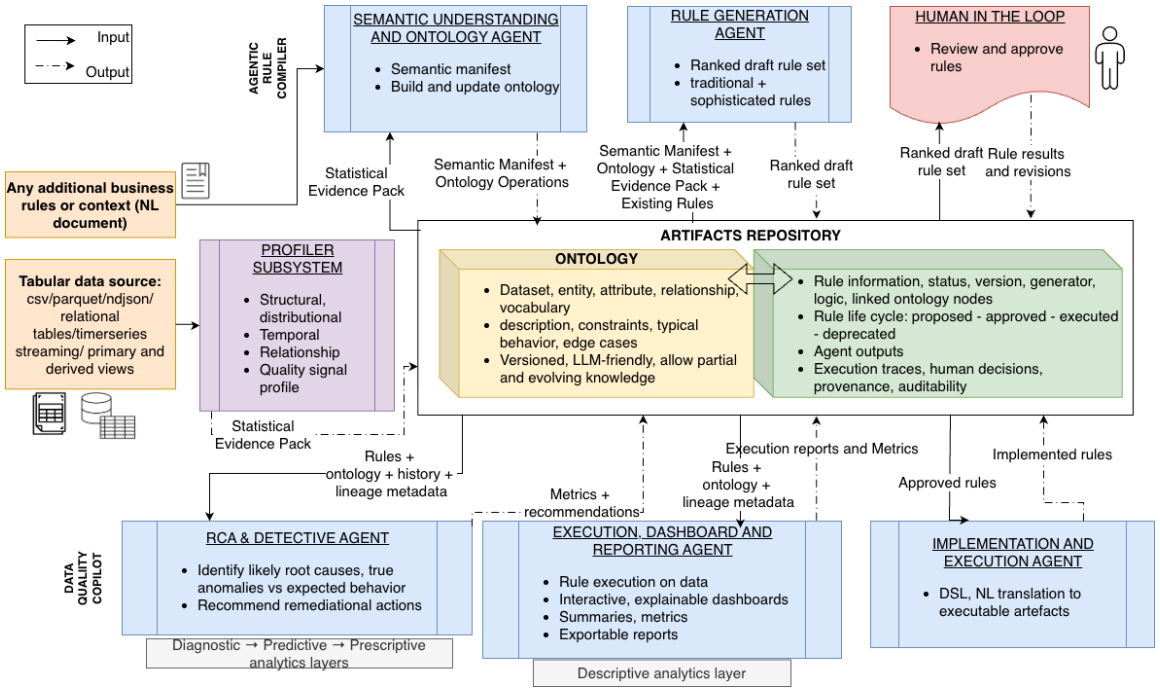

Figure 2: Full envisioned system overview: all components sharing a central Artifacts Repository across the full DQ lifecycle.

B.5 EDRA specifications (Vision)

EDRA is the interpretation and decision interface of the system. It is read-heavy, analytics-heavy, and explanation-focused. EDRA does not create rules and does not execute checks. Instead, it aggregates artifacts and human review in the Artifacts Repository, runs checks idempotently on stable dataset snapshots, writes immutable *ExecutionTraces* with violation counts, sample failing rows, runtime, and provenance (rule version, ontology snapshot, dataset snapshot), computes higher-level analytics, and presents actionable, auditable views to stakeholders (data owners, risk, compliance, engineering).

EDRA's primary goal is to provide a single pane of glass for data-quality health, make failures explainable and traceable, support governance and audit, enable trend analysis and prioritization, and close the loop from rule failure to decision and remediation.

EDRA consumes read-only artifacts from the Artifacts Repository: rule definitions and metadata, ExecutionTraces and execution timelines, ontology references (node IDs, meanings, risk notes), and human decisions (approve, reject, modify with comments). Optional lineage metadata can be used to surface source-to-transformation context in investigations.

EDRA produces interactive dashboards, exportable audit-ready reports (e.g., JSON or CSV), alerts and summaries, dataset-level risk scores and trend forecasts, and non-binding prescriptive suggestions such as remediation playbooks or rule-tuning proposals. It organizes insights explicitly as descriptive (what happened), diagnostic (why), predictive (what is likely next), and prescriptive (what to do) analytics over the data-quality system itself.

A minimal EDRA UI includes (i) an Overview Dashboard with dataset health, top failing rules, and affected ontology nodes; (ii) a Rule Catalog with filters by dataset, ontology node, severity, status, and last execution; (iii) a Failure Explorer that shows the rule definition and rationale, violation statistics and samples, linked ontology meaning and risks, and supporting context such as lineage when available; (iv) Temporal and trend views for failure rate, recurrence, and stability; and (v) an Audit and governance panel that replays the rule lifecycle from draft to approved, modified, and deprecated with evidence exports.

EDRA computes severity-weighted dataset health, failure rate and recurrence, rule stability over time, coverage (the fraction of rows evaluated by active rules), and ontology risk exposure by aggregating the risk weights of affected ontology nodes.

B.6 RCADA specifications (Vision)

RCADA closes the loop. Given rule failures and execution traces, it explains why violations happened and what to do next by combining historical repository context, profiler trends, lineage, and optional external signals. RCADA primarily operates in the diagnostic, predictive, and prescriptive analytics layers; descriptive summaries are surfaced by EDRA.

For a set of failing rules and datasets, RCADA (i) identifies and ranks likely root causes, (ii) distinguishes true anomalies from contextual or expected behavior, and (iii) recommends concrete, human-controlled remediation actions with calibrated confidence.

RCADA reads (a) ExecutionTraces (failure rates, example rows, timestamps, runtime), (b) rule metadata (severity, linked ontology nodes, prior stability), (c) ontology metadata (semantic meaning, risk notes, provider dependencies), (d) artifact history (past outcomes and human decisions on similar failures), (e) dataset lineage (provider, pipeline stage, schema versions, deploy tags), and (f) profiler time series (null rates, distributions, cardinality trends). Optional external context includes calendars/holidays, outage logs, and governance or regulatory change notes.

RCADA writes a structured RCA Report artifact (root-cause candidates with evidence, classification such as contextual anomaly vs. likely incident, recommended actions with owners and urgency, and confidence/uncertainty). It can also emit bounded forecasts of near-term recurrence risk and non-binding prescriptive suggestions (e.g., rule refinement proposals or temporary usage restrictions) for human review.

RCADA uses an explicit and explainable cause taxonomy (e.g., provider outage, pipeline regression, upstream drift, contextual event, ontology mismatch, rule mis-specification). Candidates are scored using temporal alignment, cross-source agreement when comparable signals exist, historical recurrence, and ontology risk alignment. RCADA also uses human decisions as weak labels to estimate likely false positives and to flag systematically over-strict rules.

Example: Rule `R-042` (`trade_amount` non-negative) shows a failure spike after `2026-01-25`. RCADA attributes 97% of violations to `source=OTC_FEED_X`, notes ontology risk for PnL and regulatory reporting, and recommends an engineering escalation plus a steward-reviewed source-conditional exception with confidence.

C Blinded Rule Review Protocol

This appendix specifies the blinded, mixed-mode, overlapping-assignment review design referenced in §5, and the reviewer pool that carried it out. The design was built to satisfy three requirements: every rule is rated by exactly two different reviewers (enabling inter-rater agreement to be reported), no reviewer ever rates a rule they authored and both generation modes are present in every batch (so mode is never confounded with batch or rater identity).

C.1 Block design

Rules from each dataset were split into four blocks (A–D). Each block contains the rules authored by exactly two of the four reviewers and is rated by the two reviewers whose rules it does *not* contain:

Block	Authored by	Rated by
A	R2, R3	R1, R4
B	R3, R4	R1, R2
C	R4, R1	R2, R3
D	R1, R2	R3, R4

Critically, both modes produced by a given author travel into the same block together: Block A, for instance, contains both R2's and R3's Full Agentic *and* Guided rules. An author's agentic output is never routed to a different block than their guided output, since splitting them would let a between-author skill difference masquerade as a between-mode effect. Within each author's allotment, rules are sorted by mode and dealt alternately across the author's two permitted blocks, so that each mode is split evenly rather than concentrated in one block. Presentation order within a batch is shuffled independently per (block, reviewer) pair, and the resulting position of each rule is logged.

This yields, per dataset, a connected co-rating cycle across reviewers, (R1,R4), (R1,R2), (R2,R3), (R3,R4), equal review workload across reviewers, and every rule rated by exactly two people who did not write it. One limitation follows directly from having four reviewers and two raters per block: each run is seen by three of the four reviewers rather than all four, and the pairs (R1,R3) and (R2,R4) never co-rate directly. Krippendorff's α remains valid over the connected graph, but we do not report a complete 4×4 pairwise agreement matrix, since two of the six pairs were never jointly observed.

C.2 Validation

Before release, every batch was checked against five automated assertions: exhaustive, non-overlapping coverage of all rules across blocks; exactly two ratings per rule; no reviewer assigned to a block containing their own authored rules; both modes present in every block; and both modes present for every author within every block they occupy.

C.3 Inter-rater agreement

The design yields 541 doubly-rated rules and 1,082 ratings. Table 4 reports the coefficients; this section records the disagreement breakdown and two reporting choices. The verdict scale for disagreement is ordered: reject < modify < accept, since and accept/modify disagreement is less severe than an accept/reject disagreement, treating them as unordered categories would understate the true agreement. Reviewers agree exactly on 77.3% of rules, while they differ by one step on the ordinal scale on 13.1%, and differ at the extremes (`accept`/`reject`) on 9.6%. Per subset the split is 76.0/15.1/8.8 on Berka, 79.0/10.3/10.7 on H&M, 76.8/13.8/9.4 on agentic rules and 78.1/11.9/10.0 on guided rules. We report AC2 alongside α because the verdict distribution is concentrated: with 84.8% of ratings in one category, α is deflated by construction, while AC2 is prevalence-robust.

D Benchmarking Agenda

The experiments in §5 focus on rule-generation quality and diversity. Comprehensive valuation dimensions for the full envisioned system extend beyond these to include: execution correctness (reproducibility of ExecutionTraces from artifact snapshots); ontology grounding quality (semantic role accuracy, confidence calibration); HITL efficiency (accept/modify/reject rates, iterations-to-convergence, reviewer effort proxies); temporal adaptation (portfolio stability under schema drift, MTTD/MTTR); and explanation quality (usefulness of RCA hypotheses and prescriptive suggestions).

As mentioned in the discussion, we thus envision benchmarks that ship not only tables, but the *governance-and-audit context* that the system consumes and produces:

- **Data + evolution timeline**: snapshots/streams of related tables (finance as anchor), with scripted schema/provider/policy evolution and injected drifts/anomalies.
- **Ontology spine**: a typed Dataset/Entity/Attribute/Relationship/Vocabulary ontology linking columns/joins to meaning envelopes (`constraints`, `typical_behavior`, `risk_notes`).
- **Governance corpus**: policy/regulatory/dictionary text mapped (at least coarsely) to ontology nodes, enabling provenance links from rules back to intent.
- **Repository event log**: an append-only history of rule versions, HITL decisions, and ExecutionTraces, so adaptation and auditability are testable rather than asserted.

We aim, together with the broader community to build these shared benchmark packs and scoring harnesses around this contract, with license-clean datasets, governance corpora, gold rule catalogs, and standard scoring for precision/recall, coverage, stability, and explanation quality.

E Rule Taxonomy

To characterize what the system actually mines rather than only how well the rules it mines are received, we manually tagged a randomly drawn sample of 85 AI-mined rules from the Full Agentic mode (25% of all AI-mined rules) against eight standard relational and data-quality rule categories. Table 12 reports the resulting category shares. We provide also representative examples of AI-mined rules for each of the classes present in the table.

Range / statistical

```
{
 "rule_id": "rule:client_district_id_range_validity",
  "rule_name": "District ID Range Constraint",
  "linked_nodes": ["col:client_district_id",

```

F Additional Figures

Below we provide a series of additional figures and plots to accompany and complement visually the results discussed in §5.4:

Category	Applied to	Share
Range / statistical	numeric bounds, thresholds, sign, outlier bounds	24.2%
Key / uniqueness	primary-key or unique-column assertions	23.2%
Categorical domain / vocabulary	enumerated valid-value list	22.1%
Syntactic format	regex, length, type, encoding, calendar-validity of a date string	10.5%
Completeness / NOT NULL	presence assertions	9.5%
Functional dependency	$X \to Y$ within a table	6.3%
Inclusion dependency (IND)	foreign-key / referential integrity across tables	3.2%
Denial constraint (DC)	forbidden predicate combination not reducible to the categories above	1.1%

Table 12: Taxonomy of AI-mined rule types, tagged on a random 25% sample ($n = 85$) of all AI-mined rules.

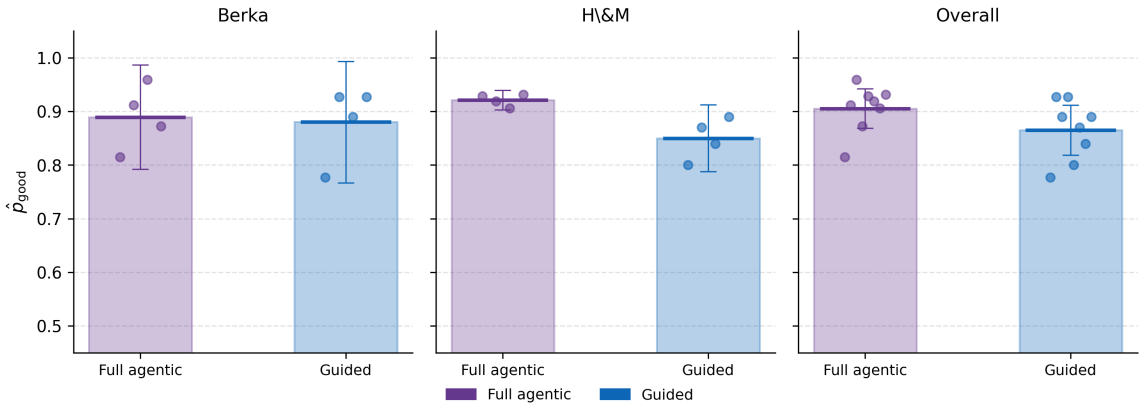

Figure 3: Good-rule rate $\hat{p}_{\text{good}}$ per mode and dataset (dots = individual runs, bar = mean, error bars = 95% CI-interval on mean).

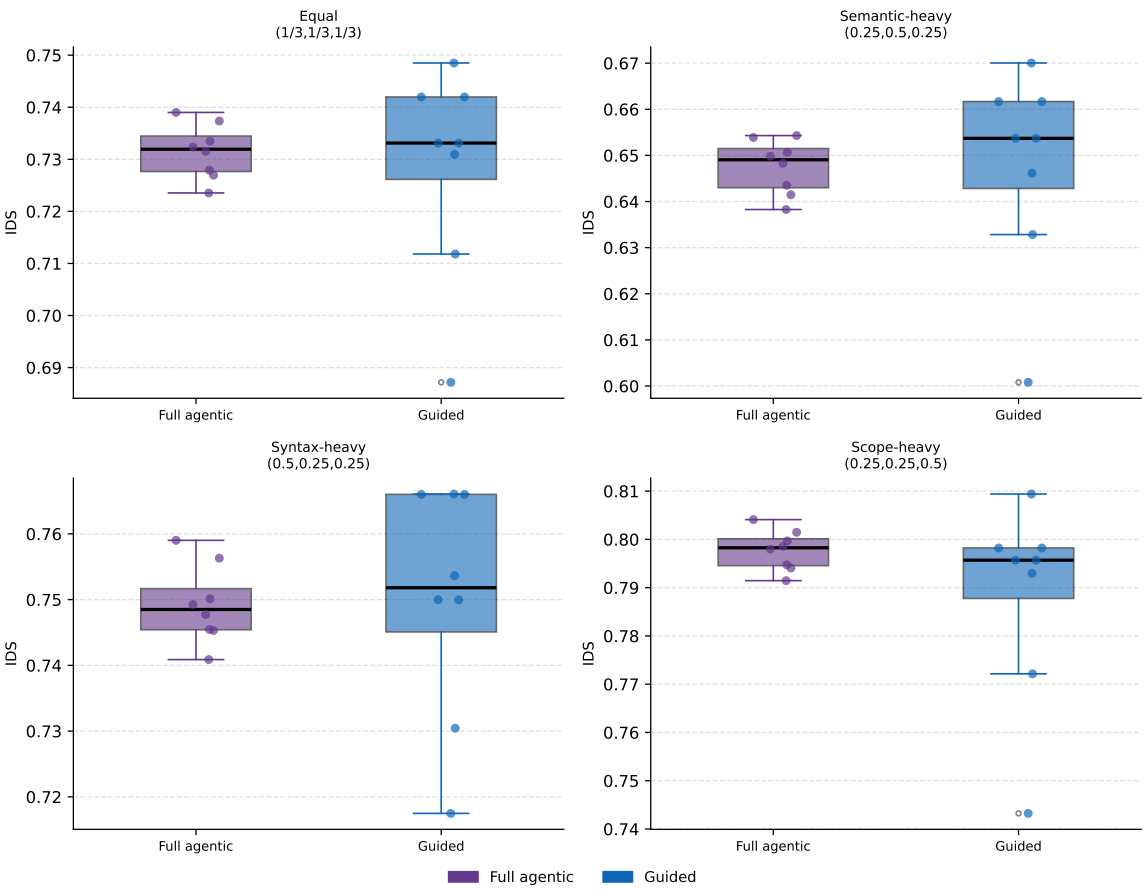

Figure 4: IDS distributions per mode across weight configurations ($n_1 = n_2 = 8$ runs per mode, pre-review rules).

Dataset	Mode	N_{rules}	N_{ratings}	Accept	Modify	Reject
Berka	Full agentic	216	432	363 (84.0%)	42 (9.7%)	27 (6.2%)
	Guided	101	202	168 (83.2%)	18 (8.9%)	16 (7.9%)
H&M	Full agentic	124	248	222 (89.5%)	13 (5.2%)	13 (5.2%)
	Guided	100	200	164 (82.0%)	12 (6.0%)	24 (12.0%)
Overall	Full agentic	340	680	585 (86.0%)	55 (8.1%)	40 (5.9%)
	Guided	201	402	332 (82.6%)	30 (7.5%)	40 (10.0%)

Table 13: HITL review outcomes per mode and dataset (pooled across 8 runs). N_{rules}: rules proposed; $N_{\text{ratings}} = 2N_{\text{rules}}$, since the blinded block design has every rule rated by exactly two reviewers who did not author it (§C). Accept/Modify/Reject are counts over ratings, with row percentages. Good-rule rates are reported in Table 2 as the mean across good rule rates of reviewer runs. The Full Agentic mode proposes more rules than Guided because the orchestrator enforces a per-column coverage criterion, whereas a human expert might target a narrower set of constraints. The matched-scope control in §5.4 re-runs the RQ1 analysis with this volume asymmetry removed.

Voice of Australian-AI: Learning Australian Assistant Voice Without Caricature

Yue Yang[1], Maxwell Twelftree[1], Luke Borgnolo[1], David Lemphers[1], Amanda Baughan[1],

[1]Maincode, Melbourne, Australia,

Correspondence: yue/amanda@maincode.com

Abstract

Interactional defaults in widely deployed LLM assistants tend to align with US conventions, including in non-US contexts. We introduce an Australian-facing assistant, Matilda, and test whether local voice is better learned during fine-tuning or imposed with an inference-time prompt. We define Australian Voice as pragmatic alignment, directness, modesty, warmth, register control, and task fidelity, rather than slang or spelling substitution. We build a governed dataset from user research, human rewrites, contrastive negatives, reviewed synthetic examples, and replay data. In a blind evaluation by Australian English users (356 question-level ratings over 89 prompts), the raw 50% voice/replay mix scores best on all five dimensions (4.24/5; 102 best-pick wins). Prompted variants underperform every matched fine-tuned model.

1 Introduction

LLM assistants are increasingly deployed across English-speaking markets, yet English fluency does not imply cultural or pragmatic fit. A response can be factually acceptable and still feel over-formal, promotional, evasive, unserious, or culturally mismatched (Karinshak et al., 2024; Qiu et al., 2025) For an industry assistant, this is not a cosmetic problem. This affects whether users trust an answer, whether they follow instructions, and whether they regard the system as suitable for ordinary work, customer support, and life-administration tasks.

Australian English makes this problem concrete. Australian users often prefer assistant responses that are practical, direct, modest, warm, and low-ceremony; while rejecting exaggerated slang or broad national performance (Cox and Palethorpe, 2007). Simply inserting tokens such as "mate", "reckon", or "yeah nah" can ironically make a response feel less Australian when the usage is forced, poorly timed, or inappropriate for the setting. Conversely, a response can contain no overt local markers yet still be perceived as Australian if it gets stance, register, and pragmatic expectations right.

We therefore frame *Australian Voice* as interactional cultural alignment. The target is not accent imitation, dense slang, or spelling transfer. It is a deployable response behaviour: know when to be casual, when to be precise, when to avoid humour, when to use plain wording, and when local context matters for task fidelity. This framing connects cultural alignment work in NLP (Durmus et al., 2023; Liu et al., 2023; Montalan et al., 2024; Ke et al., 2026; Yang et al., 2025) with sociolinguistic accounts of Australian English as a socially meaningful English dialect (Wierzbicka, 1986; Goddard, 2009; Goddard and Cramer, 2016; Collins, 2012; Coats, 2022, 2024; Diskin-Holdaway and Escudero, 2024).

This paper presents Australian-AI as an industry case study in learning such a voice. We construct Australian Voice data from user interviews, a written voice specification, human rewrites, negative contrastive examples, reviewed synthetic examples, and general replay data. We then fine-tune model variants with different mixture weights and compare them with prompt-engineered variants that attempt to impose Australian style at inference time.

The central empirical result is simple: in blind human evaluation, learned voice beats prompted voice. The raw 50% Australian Voice mixture is the strongest system overall, while prompt-engineered variants lose to their matched raw fine-tuned models at 0%(base model), 30%, and 50% mixture levels. This matters because prompt-level localisation is attractive in production: it is cheap, reversible, and easy to describe. Our results suggest that this convenience comes at a quality cost. When the desired behaviour is pragmatic and context-sensitive, the model should learn it from curated examples rather than perform it from a visible style instruction.

EMNLP 2026 Industry Track, pages 1944–1961
October 24-29, 2026 ©2026 Association for Computational Linguistics

Our contributions are fourfold. First, we operationalise Australian Voice as a measurable alignment target with explicit anti-caricature, register-control, and task-fidelity requirements. Second, we describe a governed data pipeline that combines user-grounded human rewrites, contrastive negatives, reviewed synthetic distillation, and general replay data. Third, we provide a controlled human comparison of raw fine-tuned and prompted variants across three mixture weights. Fourth, we separate the main voice result from a broader capability screen, treating benchmark results as regression checks rather than as the paper's primary claim.

2 Related Work

Cultural alignment work argues that LLM behaviour reflects the assumptions embedded in training data, evaluation data, and alignment procedures. Existing models may represent some countries' opinions and social assumptions more strongly than others, and they can struggle with culturally situated reasoning even when the language is fluent (Durmus et al., 2023; Liu et al., 2023; Montalan et al., 2024). This motivates evaluation beyond factual correctness: a model may answer fluently while missing local pragmatic expectations.

Australian English is a national variety with lexical, phonetic, and social meaning. Its cultural force is not limited to a vocabulary list. Work on Australian English highlights themes such as informality, understatement, irreverence, and local social identity (Wierzbicka, 1986; Goddard, 2009; Goddard and Cramer, 2016; Collins, 2012; Coats, 2022, 2024; Diskin-Holdaway and Escudero, 2024). For assistant alignment, this suggests that the important unit is not "Australian words" but interactional stance: how direct, modest, humorous, careful, or practical a response should be in context.

3 Australian Voice as an Alignment Target

Australian English is a national variety with lexical, phonetic, and social meaning. Its cultural force is not limited to a vocabulary list. Work on Australian English highlights themes such as informality, understatement, irreverence, and local social identity (Wierzbicka, 1986; Goddard, 2009; Goddard and Cramer, 2016; Collins, 2012; Coats, 2022). We treat localisation as a constrained behaviour-learning problem. Given a user request x, the model should produce a response y that satisfies the task while matching Australian interactional expectations. The target is context-dependent: casual planning may allow warmth or light informality, while technical, workplace, complaint, emotional, or safety-sensitive requests require steadier register control (Coats, 2024; Diskin-Holdaway and Escudero, 2024). Local voice is therefore not a global style, but a judgement about how to sound while still doing the job. Our voice specification was derived from interviews with Australian product users and review of Australian English reference material. It targets mainstream contemporary Australian English without stereotype: direct, practical, modest, warm, and low-ceremony. The desired stance is a capable peer rather than a lecturer, salesperson, or servant: get to the point early, use plain wording, favour understatement over hype, and provide warmth without excessive enthusiasm. This is a product-language target, not a linguistic claim about all Australian English speakers.

The specification also defines what the assistant should *not* do. It forbids phonetic accent spelling, dense slang, broad "ocker", or crude, uncultivated speech, gratuitous banter, and replacing useful content with local colour. It also avoids adopting or simulating Aboriginal English or other community and regional varieties. These constraints make the evaluation target explicit: a response should improve Australian naturalness and cultural fit without sacrificing restraint, register control, helpfulness, factuality, or safety. A model that becomes more slang-heavy, less accurate, too casual in serious settings, or friendly while missing the practical next step has failed. In this sense, Australian Voice is closer to alignment than to style transfer.

4 Australian Voice Data Pipeline

We curate an Australian Voice dataset to better fit the communication requirements and expectations of Australian users. The dataset combines positive examples, negative examples, reviewed synthetic examples, and replay data. As shown in Figure 1, the pipeline starts from user-defined requirements for the target Australian voice, including tone, register, phrasing, directness, cultural fit, and interaction style. Australian annotators then rewrite and review examples to ensure that the responses sound natural to local users rather than simply using generic English. We further use synthetic generation to expand coverage across more domains and scenarios, while manual review keeps the gen-

Figure 1: Australian Voice data curation pipeline.

erated data aligned with the desired voice. Finally, replay data is mixed in to preserve the model's general capabilities and reduce over-specialisation to Australian-style responses.

The pipeline has eight stages: (1) user interviews, (2) voice specification, (3) reference-material review, (4) human rewrite collection, (5) few-shot seed construction, (6) synthetic data distillation, (7) Australian reviewer filtering, and (8) iterative prompt/specification refinement.

4.1 Dataset Construction and Curation

Few-shot seeds: positive and negative supervision. We first constructed a set of few-shot seed examples from topics that reflect the everyday use cases and communication requirements of the target Australian user base. For each topic, we generated 20 seed prompts covering realistic user requests, including customer communication, workplace writing, local explanations, technical assistance, life administration, and serious or high-stakes contexts. For each selected prompt, we sampled an initial response from the base model and asked Australian annotators to rewrite it according to the Australian Voice specification. The rewrite task was deliberately constrained. Annotators were instructed to preserve the original task intent, factual content, reasoning, correctness, and safety behaviour, while adapting only the response style: tone, register, phrasing, directness, warmth, and degree of localisation. As a result, approved rewrites are treated as preferred behaviour examples rather than surface-level paraphrases. They teach the model how an answer should sound when it is already substantively correct. To make the boundary of the voice explicit, we also created contrastive negative examples. These examples capture common failure modes of superficial localisation, including excessive slang, forced humour, US-style customer-service exuberance, British-style stiffness, corporate hype, exaggerated "ocker" performance, irrelevant banter, inappropriate humour in serious contexts, and hallucinated local details. The positive and negative examples therefore provide both attraction and repulsion signals: the model learns the desired Australian voice, while also learning which forms of localisation should be avoided.

Reviewed synthetic expansion. After collecting the human-written seed examples, we used them as few-shot demonstrations for a stronger teacher model to generate additional Australian Voice training data. This expansion step increased coverage across domains, interaction types, and levels of required localisation. The synthetic prompts and responses covered customer support, complaints, workplace communication, local explanations, casual planning, serious contexts, and style-control cases where Australianisation should be light, neutral, or absent. Synthetic examples were not added to the training set automatically. Each generated item was reviewed by Australian annotators, who either approved it, edited it, or rejected it. Reviewers checked whether the response preserved the user's intent, maintained factual accuracy and safety behaviour, used an appropriate register, and matched the Australian Voice specification without becoming performative. Common rejection reasons included overuse of slang, excessive informality, unnecessary banter, hallucinated local references, loss of factual content, inappropriate humour, and register mismatch. This review step allowed synthetic generation to improve coverage while keeping the final dataset aligned with the intended user experience.

4.2 Data Format

We store the dataset in a standard supervised fine-tuning format. Each example contains a `question`, an `answer`, and a `category`. The `question` field contains the user prompt, the `answer` field contains the preferred model response, and the `category` field records the topic or use-case type of the example. This simple format makes the dataset easy to mix with replay data, filter by domain, and use directly for supervised instruction tuning.

`question` : user prompt,
`answer` : preferred Australian Voice response,
`category` : topic or use-case category

The current Australian Voice dataset contains ap-

Table 1: Core data signals used for Australian voice alignment.

Signal	Role
User research and voice guide	Defines the target stance: direct, modest, warm, practical, restrained, and context-sensitive.
Human rewrites	High-precision preferred responses reviewed for voice fit, task fidelity, non-caricature, and register control.
Contrastive negatives	Examples of what not to learn: forced slang, caricature, hype, irrelevant banter, and local hallucination.
Reviewed synthetic data	Coverage expansion across support, complaints, workplace tasks, local explanations, serious contexts, and style-control prompts.
General replay data	Preserves broad assistant capability and prevents every response from becoming a local identity performance.

proximately 20,000 extracted and curated question–answer pairs. These examples cover everyday Australian assistant use cases, including workplace writing, customer and business communication, civic and financial explanation, technical support, personal administration, and plain-language rewriting. Each accepted pair is stored in a supervised fine-tuning format with a user question, a preferred Australian Voice answer, and a topic category.[1]

5 Australian Voice Model Training

We fine-tune the model using supervised instruction tuning on a mixture of Australian Voice data and general replay data. Let $\mathcal{D}_{\mathrm{AU}}$ denote the Australian Voice dataset and $\mathcal{D}_{\mathrm{G}}$ denote the general replay dataset. For each experiment, we construct a mixed training distribution

$$\mathcal{D}_{\mathrm{mix}} = \lambda \mathcal{D}_{\mathrm{AU}} + (1-\lambda)\mathcal{D}_{\mathrm{G}},$$

where λ controls the proportion of Australian Voice data used during fine-tuning. To study the effect of Australian Voice exposure, we train five mixture settings: $\lambda \in \{0.10, 0.20, 0.30, 0.50, 1.00\}$. These correspond to 10%, 20%, 30%, 50%, and 100% Australian Voice mixtures. Lower values of λ preserve more general replay data, while higher values expose the model more strongly to Australian Voice examples. The 100% setting removes replay data entirely and serves as a stress-test for whether full specialization improves local voice quality or harms broader model capability.

[1]The dataset is currently used for internal model training and evaluation. We are also working with participating contributors and the company to finalise the consent, licensing, and release agreements required to make a cleaned version of the dataset publicly available.

For each training instance with input context x and target assistant response y, we minimise assistant-token negative log likelihood:

$$\mathcal{L}(\theta) = -\sum_{(x,y)\in\mathcal{D}_{\mathrm{mix}}} \sum_{t=1}^{|y|} \log p_\theta(y_t \mid x, y_{<t}).$$

The mixture design reflects a production trade-off. Increasing λ is expected to improve Australian naturalness, idiom use, and local register alignment. However, overly large Australian Voice proportions may over-specialise the model, reduce general capability, or introduce unnecessary stylistic shifts in tasks where a neutral response is preferable. General replay data therefore acts as a retention mechanism: it helps preserve broad instruction-following, reasoning, coding, factuality, and tool-use behaviour while still allowing the model to acquire Australian Voice characteristics.

6 Evaluating Capability Retention and Australian Voice Quality

We evaluate the Australian Voice model along two dimensions. First, we measure whether fine-tuning preserves the model's general capabilities on standard benchmark tasks, including reasoning, mathematics, knowledge, instruction following, coding, and tool-use benchmarks. This checks that adapting the model to Australian user requirements does not substantially degrade its broader task performance. Second, we conduct a human evaluation focused on Australian Voice quality. Australian reviewers compare model responses and assess whether they sound natural, appropriate, and useful for Australian users. This evaluation measures aspects that are difficult to capture with automatic benchmarks, such as tone, register, directness, cultural fit, restraint, and avoidance of forced or exaggerated localisation. Together, these evaluations allow us to identify the best mixture weight for deployment. An ideal model should improve Australian Voice alignment while maintaining strong performance on general-purpose benchmarks.

retention.

6.1 General Capability Evaluation

For general capability, we run a broad benchmark suite covering knowledge, reasoning, instruction following, dialogue quality, coding, and tool-use. The benchmark set includes MMLU-Pro, MATH-500, AIME, SimpleQA, IFEval, Arena-Hard, MT-Bench, WildBench, LiveBench, BigCodeBench,

Table 2: Fine-tuned evaluation matrix across 4B, 8B, 14B, and 35B models. Each numeric cell is a pass rate in percent, and bold marks the best available result within each size class and benchmark. Variants: A is 10%, B is 20% mix, C is 30%, D is 50%, E is 100% voice-strong

HumanEval+, MBPP+, and BFCL. This evaluation measures whether Australian Voice fine-tuning preserves the base model's non-local capabilities across standard tasks. Table 2 shows that Australian Voice tuning can be added without materially degrading general capability when the mixture is kept moderate. For the 35B model, the 10–50% mixtures remain close to the base model across deterministic, LLM-judge, and custom benchmarks, with the 30% and 50% variants matching or exceeding the base model on several instruction-following and judge-based evaluations. In contrast, the 100% voice-strong model shows a clear capability drop. This supports our choice to evaluate the base, 30%, and 50% models in the human Australian Voice study: they provide the strongest practical trade-off between voice adaptation and general capability

6.2 Human Preference Study

For Australian Voice quality, we conduct a human study. Human annotators compare outputs from different model variants and judge whether the responses sound natural, locally appropriate, and recognisably Australian, without becoming forced, exaggerated, or stereotyped. We evaluate three main model families: the base model, the 30% Australian Voice mixture model, and the 50% Australian Voice mixture model. We exclude the 100% Australian Voice setting from the human study because its general benchmark performance drops too substantially, making it unsuitable as a practical deployment candidate. We also exclude the 10% and 20% mixture models because their general performance is close to the 30% setting, and the 30% model provides a stronger test of whether Australian Voice adaptation is visible to human users. To examine the role of prompt engineering, which is commonly used in industry deployments, we evaluate each model in two conditions: with and without a short system prompt describing the desired Australian Voice. This allows us to test whether prompt engineering alone is sufficient for producing the target voice, or whether fine-tuning provides additional benefits beyond prompting.

We constructed 89 prompts spanning six usage areas: Australian civic/legal/finance topics, customer and business communication, technical/product/code tasks, workplace and team-management scenarios, personal/wellbeing/life-admin queries, and plain-language/educational/creative tasks. Australian native speakers or long-term Australian English users evaluated anonymised responses in a blind, randomised interface. Raters did not see model identities, and response order was shuffled. For each prompt, raters scored each candidate

Table 3: Overall mean score by aspect and training mix.

Training mix	Naturalness	Fit	Restraint	Register	Helpfulness	Overall	Wins
base raw	3.94	4.03	4.23	4.14	4.05	4.08	74
base + prompt	3.37	3.57	4.16	4.03	3.87	3.80	28
30% mix raw	4.01	4.01	4.32	4.17	4.07	4.12	60
30% mix + prompt	3.50	3.71	4.29	4.09	4.03	3.93	32
50% mix raw	**4.22**	**4.21**	**4.42**	**4.25**	**4.13**	**4.24**	**102**
50% mix + prompt	3.54	3.73	4.35	4.15	3.78	3.91	42

on five 1–5 dimensions: Australian naturalness, cultural and pragmatic fit, non-caricature and style restraint, context-appropriate register, and helpfulness/task fidelity. They also selected the single best overall response. We collected 356 question-level rating records. The main metric is the mean of available dimension scores plus valid best-pick counts. Appendix gives the full protocol.

Results: Table 3 shows that the raw 50% mixture is the strongest system. It leads every rated dimension: Australian naturalness, cultural and pragmatic fit, non-caricature and style restraint, context-appropriate register, helpfulness and task fidelity, and aggregate score. It also receives the most valid best-pick wins, with 102 selected wins. The mixture trend is clearest in the raw models. Overall score rises from 4.08 for base, to 4.12 at 30%, to 4.24 at 50%. The largest gains are in naturalness and cultural fit, which are the intended targets of the dataset. Helpfulness also increases slightly, suggesting that the 50% mixture is not merely more local; it remains useful and faithful to the task.

The prompted variants show the opposite pattern. Adding an explicit Australianisation prompt lowers performance for every matched fine-tuned model. Appendix Table 8 reports prompt-minus-raw deltas: at 50%, the prompt reduces overall score by 0.35, naturalness by 0.70, and cultural/pragmatic fit by 0.49. Pairwise better/equal/worse counts agree, with prompted variants losing more matched comparisons than they win in all three families. Two-sided sign tests over non-tied pairs reject symmetric wins and losses for base ($p = 2.7 \times 10^{-4}$), 30% ($p = 1.97 \times 10^{-2}$), and 50% ($p = 2.5 \times 10^{-5}$). The losses are concentrated in naturalness and fit rather than restraint or register, suggesting that the prompt does not mainly make the model unsafe or uncontrolled. Instead, it makes the style more visible, as if the assistant is following an explicit instruction rather than answering in the expected voice. Qualitative review often showed extra hedging, overt friendliness, unnecessary local markers, or a mildly promotional tone. Raw fine-tuned models more often express the target voice implicitly.

Topic-level results reinforce this interpretation. Appendix Table 6 shows that the raw 50% mixture has the highest average score in five of six topic groups and the most best-pick wins in four of six. Its strongest wins are in Australian civic/legal/finance and customer/business communication, where local context and pragmatic fit matter most. The main exception is technical/product/code: the 30% raw mixture has the highest average score and the base model has the most wins. This exception supports a task-sensitive view of voice strength. Heavy local exposure is not always useful when users mainly reward precision, concision, and correctness (See Appendix F for more insights we got from this humam study).

7 Production Soft Launch

We deployed the Australian Voice model as the core response model in an Australian-facing production assistant, Matilda, with the goal of providing an Australian-built LLM experience for Australian users. This deployment reflects a simple product assumption: language is not only a medium for delivering information, but also part of culture, trust, and user experience. A technically correct answer can still feel awkward if its tone, register, humour, or implied social norms do not match the user's context. For consumer and workplace products, this cultural fit matters because users often choose the tool that feels easiest and most natural to communicate with, not only the one with the strongest benchmark score.

In a soft launch with 25 users, we received positive qualitative feedback on both usefulness and tone. Users reported using the model for practical writing tasks such as rewriting workplace emails, daily messages, and customer-facing website copy. One user noted that the model helped them complete write professionally after general-purpose assistants produced awkward or unsuitable wording. Other users also commented that the model's tone felt closer to Australian workplace and everyday communication: direct, natural, and useful with-

out sounding overly formal, overly enthusiastic, or performatively Australian.

Several users also reported choosing our assistant over general-purpose alternatives for local writing tasks because the outputs required less editing and felt more appropriate for Australian audiences. We treat this soft-launch feedback as qualitative deployment evidence rather than a controlled benchmark. However, it provides early support for the central product motivation of Australian Voice tuning: good localisation is not simply adding slang or local references, but adapting the model's communication style so that users feel the assistant understands the social and cultural expectations of their setting.

8 Conclusion

We presented an Australian Voice training pipeline for adapting LLMs to the communication expectations of Australian users. Our approach combines user interviews, human rewrites, contrastive negative examples, reviewed synthetic expansion, and replay data to teach a model not only what to say, but how to say it in a locally natural and culturally appropriate way. Across general benchmarks, moderate Australian Voice mixtures preserve most of the base model's capability, while human evaluation and soft-launch feedback suggest that users prefer responses that better match Australian workplace and everyday communication. These results show that language style is a core part of product quality, and that careful human-in-the-loop localisation can improve user experience without reducing an LLM to superficial slang or stereotypes.

Limitations

This study focuses on mainstream Australian English as used in product-assistant interactions. It does not attempt to model Aboriginal English or other community and regional varieties of Australian English, and it should not be read as a complete account of all Australian English users. The human evaluation is also limited by the size and composition of the rater pool, the 89-question evaluation set, and the categories selected for analysis. Larger evaluations with more diverse Australian participants would give a fuller picture of which voice behaviours generalise across age, region, professional background, and cultural identity.

The benchmark matrix combines runs from different evaluation batches and judge backends, so the numbers are most useful for directional regression checks within size class and setup, not as a single controlled leaderboard.

Ethics Statement

The goal of Australian voice alignment is to make assistant behaviour more locally appropriate and useful, not to stereotype Australian users or reduce cultural identity to slang. The dataset design therefore includes explicit safeguards against caricature, accent imitation, and narrow cultural performance. Reviewers were instructed to preserve factuality, safety behaviour, and task fidelity during rewriting. External transcript and media-derived materials were subject to licence checks, and restrictive sources were used only for linguistic analysis or prompt calibration unless appropriate permission or licence coverage was available.

A Voice Specification and Data Pipeline

A.1 Human-Feedback Data Collection Pipeline

We collected the Australian Voice dataset through a human-in-the-loop pipeline. The goal was not only to gather fluent responses, but to translate Australian user requirements into concrete supervised fine-tuning examples. Human feedback enters the pipeline at three points: users define the target communication style, Australian annotators rewrite and judge examples, and reviewers use recurring failure cases to refine the voice specification.

Annotator and reviewer recruitment. We recruited Australian English speakers as annotators and reviewers. Annotators were selected for fluency in English and familiarity with everyday Australian communication in customer, workplace, and daily-life settings. Reviewers were also Australian English speakers, but were assigned a separate filtering role: they check whether rewritten or synthetic examples were natural, useful, locally appropriate, and consistent with the Australian Voice specification. Annotators and reviewers were instructed that the target is not heavy slang or caricatured Australian English, but a practical assistant voice for Australian users.

Pipeline overview. The data collection pipeline has eight stages:

1. **User interviews.** We first interviewed target users and client-side stakeholders to understand the communication requirements of the deployment setting. These interviews identified common use cases, preferred tone, expected level of directness, unacceptable behaviours, and contexts where the model should remain neutral or formal.

2. **Voice specification.** We converted the interview findings into a written Australian Voice specification. The specification describes the desired style: clear, direct, natural, warm, modest, locally appropriate, and restrained. It also defines negative behaviours to avoid, including excessive slang, forced humour, exaggerated "ocker" phrasing, US-style customer-service enthusiasm, British-style stiffness, corporate hype, irrelevant banter, and hallucinated Australian details.

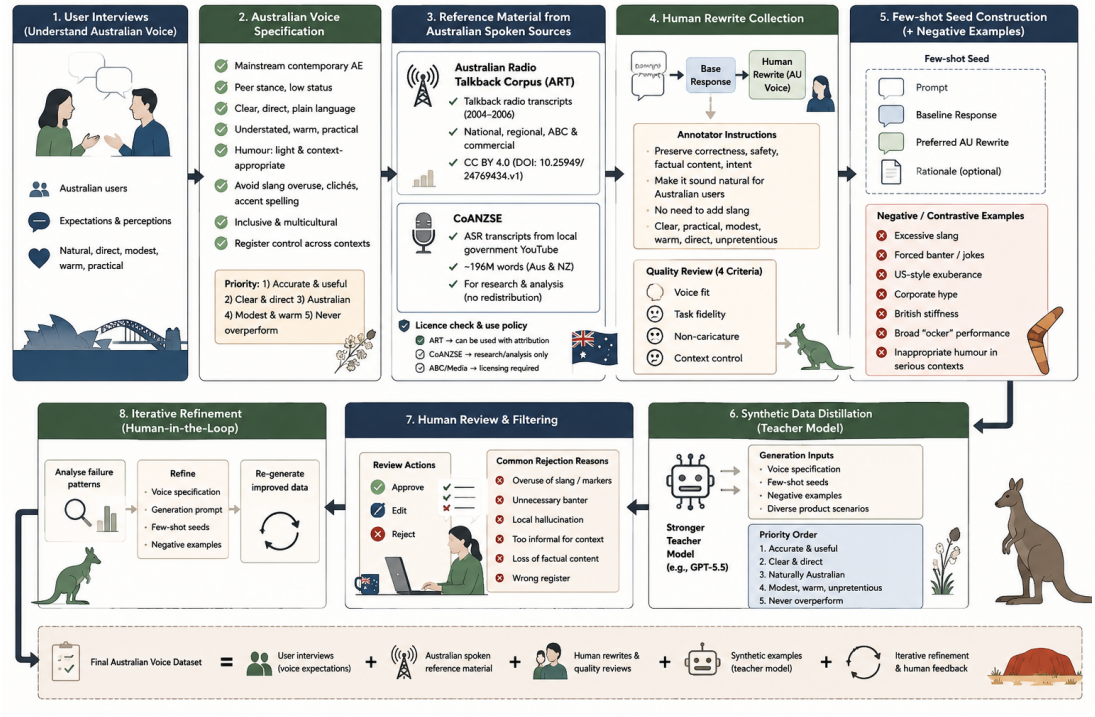

Figure 2: Detailed Version of Australian Voice data curation pipeline.

3. **Reference-material review.** Annotators reviewed reference materials before writing examples. These materials include sample user requests, base-model responses, style guidelines, and examples of both good and bad localisation. This step helps annotators apply the voice specification consistently rather than relying on personal preference alone.

4. **Human rewrite collection.** For each selected prompt, we generated a base-model answer and asked Australian annotators to rewrite it. Annotators had to preserve the original task intent, factual content, reasoning, safety behaviour, and usefulness, while changing the response style to better match Australian user expectations. Approved rewrites became positive supervised fine-tuning examples.

5. **Few-shot seed construction.** We organised high-quality human rewrites into few-shot seed examples. These seeds covered multiple categories, including customer communication, workplace writing, technical support, local explanations, daily-life tasks, serious contexts, and cases where Australianisation should be minimal. The seed set is used to guide later synthetic expansion.

6. **Synthetic data distillation.** We used the few-shot seeds and the voice specification to prompt a stronger teacher model to generate additional Australian Voice examples. This expanded the dataset beyond the manually rewritten prompts and improved coverage across domains, registers, and interaction styles.

7. **Australian reviewer filtering.** Synthetic examples were not accepted automatically. Australian reviewers inspected each generated example and either approved, edited, or rejected it. Reviewers checked factual preservation, task fidelity, safety behaviour, register, naturalness, and cultural fit. Common rejection reasons include overuse of slang, excessive informality, unnecessary humour, hallucinated local references, loss of factual content, and inappropriate register.

8. **Iterative prompt and specification refinement.** Reviewer feedback was fed back into the next round of data generation. When reviewers observed repeated errors, such as responses sounding too American, too British, too corporate, or too performatively Australian, we revise the voice specification, few-shot seeds, or generation prompts. This created an iterative loop between user requirements, annotator rewrites, reviewer feedback, and synthetic expansion.

Final training format. Although the collection process used intermediate review labels and notes for quality control, the final training data was stored in a standard supervised fine-tuning format. Each accepted example contained a `question`, an `answer`, and a `category`. The `question` field stored the user prompt, the `answer` field stored the approved Australian Voice response, and the `category` field recorded the topic or use-case type. This simple format made the data easy to mix with replay data and use directly for supervised fine-tuning.

A.2 Specification Development and Intended Scope

The Australian Voice specification was developed iteratively from three sources: interviews with Australian users and deployment stakeholders; review of Australian English and sociolinguistic reference material; and recurring failure patterns observed during base-model sampling, human rewriting, and synthetic-data review. Together, these sources motivated the desired traits of directness, practicality, modesty, warmth, low ceremony, and context-sensitive register. They also motivated explicit negative constraints, including excessive slang, forced humour, exaggerated "ocker" phrasing, US-style customer-service enthusiasm, British-style stiffness, corporate hype, irrelevant banter, and unsupported local details.

The specification should be understood as a product-language engineering artefact for mainstream contemporary Australian English, rather than a universal account of Australian communication. Its purpose is to define a repeatable target for data construction, model training, and product evaluation. It therefore complements, rather than replaces, formal sociolinguistic descriptions of Australian English.

A.3 Annotator Instructions and Quality Assurance

Annotators were instructed to preserve the source response's intent, factual content, reasoning, correctness, usefulness, caveats, and safety behaviour. They were asked to modify only tone, phrasing, directness, warmth, register, and the degree of localisation. This constraint was intended to isolate the target behavioural change and prevent voice adaptation from silently changing the substantive answer.

Synthetic examples were not accepted automatically. Australian reviewers independently approved, edited, or rejected each item using a checklist that covered factual preservation, task fidelity, safety, naturalness, cultural and pragmatic fit, register, and anti-caricature constraints. Repeated failure patterns were fed back into the written specification, few-shot examples, and generation prompts. Only approved or reviewer-corrected examples entered the final supervised fine-tuning dataset. Because the pipeline was designed for a production system, this review process primarily served deployment quality assurance rather than a controlled academic annotation study; we therefore do not interpret it as evidence that the specification represents every Australian English community.

A.4 Selection and Use of Contrastive Negatives

Contrastive negatives were selected from recurring failure patterns observed during base-model sampling, human rewriting, and synthetic-data review. We prioritised hard negatives that remained fluent and broadly relevant to the user's task but violated one or more requirements of the Australian Voice specification. Each negative was assigned a failure category and paired with a reviewer-approved response that preserved the original intent, factual content, usefulness, caveats, and safety behaviour while correcting the voice-related failure.

The negative response itself was never used as a preferred supervised fine-tuning target. Instead, its paired reviewer-approved response was used for training. The negative examples informed generation prompts, filtering criteria, reviewer guidance, and the operational boundary between natural localisation and performative or inappropriate Australianisation.

A.5 Prompt-Baseline Selection

Before the human study, we tested several Australian Voice prompt formulations in production and selected the strongest observed variant for the controlled comparison. This development process was practical rather than a controlled or exhaustive prompt search, so we do not claim that it identifies a globally optimal prompt. Nevertheless, using the strongest prompt observed during development provides a more demanding inference-time baseline than selecting a single untested instruction. Even under this condition, the prompted variants underperformed their matched raw fine-tuned models at

the base, 30%, and 50% mixture levels.

A.6 Transferability Beyond Australian English

The contribution is not an Australian-specific training algorithm, but an industry localisation workflow instantiated for Australian English. The Australian-specific components are the target voice specification, the taxonomy of undesirable behaviours, the local annotator and reviewer pool, the evaluation prompts, and the human-rating dimensions. The broader process—user research, explicit behavioural specification, locally reviewed positive and negative examples, replay-based capability retention, and blind human evaluation—is transferable.

This distinction matters because localisation should not be reduced to spelling conversion or a short regional system prompt. A deployment in another English-speaking market may need to adapt directness, formality, humour, reassurance, customer-service language, institutional references, and the acceptable level of enthusiasm, even when users share the same broad language. The workflow could therefore be applied to varieties such as New Zealand, Singaporean, Indian, Irish, South African, or British English. The Australian specification itself should not be transferred directly: each target market would require new user research, local annotators, locally grounded failure categories, and a separately validated human-evaluation protocol.

A.7 Examples of negative contrasts

A.7.1 Scope-Change Pricing

Prompt. Draft a message to tell a client that a scope change will increase the price.

Base-model response. Following our discussion about the scope changes for [Project Name], I want to confirm that the revised scope will require additional work beyond what was originally agreed. As a result, the project price will increase.

50% Australian Voice response. Thanks for confirming the updated scope. Because of these additions, the revised total is AUD [new amount], up from AUD [old amount]. This reflects the extra [hours/days], plus any associated costs.

Main contrast. The Australian Voice response states the commercial consequence early, uses Australian currency explicitly, and avoids unnecessary corporate framing. The change is pragmatic rather than slang-based: the response is more direct and operational while preserving the original message.

A.7.2 Rental Documentation

Prompt. Explain what renters should document before moving into a new place in Australia.

Standard-model response. Keep a signed lease, bond details, a move-in condition report, photos, meter readings, keys, alarm information, and the landlord's contact details.

Australian Voice response. Keep the signed tenancy agreement, bond lodgement receipt, condition report, dated photos and videos, meter readings, key and remote inventory, and written records of existing maintenance issues. Check the relevant state or territory tenancy authority for the required forms.

Main contrast. The Australian Voice response uses locally appropriate tenancy terminology and recognises that bond and condition-report procedures vary by state and territory. This example illustrates that local alignment includes institutional and procedural framing, not merely tone.

B Capability Retention Above a 50% Voice Mixture

Our evaluation was production-oriented, so general capability was treated as a gating criterion before a model entered the more expensive human study. To examine the region above the selected 50% mixture, we trained additional 35B variants using 70% and 90% Australian Voice data. Table 4 reports these results together with the 50% condition. Scores use the same benchmark-specific scales and evaluation protocols as the main capability matrix.

Capability declines once the Australian Voice proportion exceeds 50%. At 70%, MMLU-Pro falls from 97.6 to 84.7 and Arena-Hard from 96.1 to 86.4. The 90% condition shows broader regressions across knowledge, mathematics, instruction following, judge-based evaluations, coding, and tool use. Together with the 100% stress-test reported in the main capability matrix, these results support the decision to restrict the human study to deployment-viable models. The 50% condition provides the strongest Australian Voice exposure among the models that retain acceptable general capability.

Model	Mix	MMLU-Pro	MATH-500	AIME	SimpleQA	IFEval	Arena-H	MT-Bench	WildB.	LiveB.	BigCode	HE+	MBPP+	BFCL	τ-bench
35B	50%	97.6	91.4	60.0	12.4	96.2	96.1	100.0	86.7	67.7	60.1	92.7	70.1	88.3	5.5
35B	70%	84.7	89.8	60.0	12.4	91.3	86.4	96.2	85.9	57.7	56.7	92.7	65.1	79.3	5.5
35B	90%	82.8	79.8	56.6	2.9	83.6	80.4	75.0	70.1	56.4	58.8	92.7	62.7	71.2	5.5

Table 4: Additional capability-retention results for 35B models above a 50% Australian Voice mixture. Metrics follow the same scales as the main benchmark matrix.

C Production Soft-Launch Feedback

We collected user feedback opportunistically through four channels rather than through a controlled study: a Slack feedback channel, in-product feedback, surveys, and one semi-structured interview. The available material comprises two externally saved Slack responses, 36 in-product comments from 10 users, eight survey responses, and one interview. These channel-level counts should not be summed as unique users because participation may overlap.

The Slack channel has since been deleted, so only the two responses saved outside the channel remain available. We therefore report raw qualitative evidence and do not compute percentages. The survey and interview are also subject to non-response bias, and the collection has no control condition.

The strongest recurring signal across channels was improved tone fit and reduced editing relative to general-purpose assistants. For example, a small business owner who compared marketing-copy outputs with other LLM providers reported: "This was the best copy, albeit I altered it somewhat." The same general theme appeared in the interview and in-product comments. We treat this agreement across channels as qualitative triangulation, not as statistical evidence of superiority.

D Human Study Details

D.1 Study Procedure

The human evaluation followed a fixed procedure. First, participants were invited to take part in a short Australian voice evaluation study. They were told that the session would take about 30 minutes and that they would receive a $20 voucher for completing the task. Before starting the rating interface, participants were asked to confirm that they understood the purpose of the study, that participation was voluntary, that they could stop at any time, and that their responses would be analysed in aggregate rather than used to identify them personally.

After consent, each participant was assigned one of the four HTML evaluation files. The evaluator opened the file locally in a browser and entered a name or participant ID into the reviewer field. The interface then showed one prompt at a time. For each prompt, participants read the user request and compared several anonymised candidate answers. Model identities and training-mix labels were not shown to participants; answers appeared only as numbered response cards.

For every candidate answer, participants assigned a 1–5 score on each of the five rating dimensions. The scale was implemented as clickable numeric buttons, and the dimension names included tooltips describing the intended interpretation. Participants were instructed to judge the response in context, with particular attention to whether it sounded natural for Australian users while remaining accurate, useful, and appropriate to the seriousness of the task.

Once all responses for a prompt had been scored, participants selected one "Best overall" response. This best-pick decision was intended to capture holistic preference beyond the individual dimension scores. Participants could also write an optional comment explaining their choice or noting problems such as American spelling, wrong-country references, over-formality, excessive slang, or loss of practical usefulness.

The interface tracked completion automatically. A question was treated as complete only when every candidate answer had scores for all five dimensions and one best overall response was selected. Participants could move between questions with the previous/next buttons or the jump menu. Progress was autosaved in browser local storage, allowing participants to continue without losing ratings during the session.

At the end of the task, participants clicked "Export results" to download a JSON file. They returned this file to the experimenter. The exported file contained the reviewer identifier, part identifier, export timestamp, number of questions, prompt metadata, per-response scores, selected best response, response slot order, optional comments, and completion flags. After the exported file was received, the participant was issued the $20 voucher.

D.2 Evaluation Interface

The HTML interface presented one prompt at a time. For each prompt, candidate answers were shown as anonymous response slots rather than model names. The interface included previous/next navigation, a jump menu, a reviewer identifier field, autosave to browser local storage, import/export controls, and a completion indicator. A prompt was marked complete only when every displayed response had scores for all five dimensions and one best overall response was selected.

D.3 Rating Dimensions

Participants scored every candidate response on a 1–5 scale for five dimensions:

- **Australian Naturalness**: whether the response sounds natural to an Australian user in context, without sounding generic, Americanised, or artificially Australian.
- **Cultural and Pragmatic Fit**: whether the response is clear, direct, modest, practical, warm, and low-ceremony.
- **Non-Caricature and Style Restraint**: whether the response avoids exaggerated Australian identity, excessive slang, forced banter, and phonetic accent.
- **Context-Appropriate Register**: whether the tone fits the situation, including serious, emotional, technical, and safety-critical contexts.
- **Helpfulness and Task Fidelity**: whether the response is accurate, useful, clear, and faithful to the user request.

D.4 Best-Response Selection and Comments

In addition to numeric scores, participants selected the single best overall response for each prompt. This best-pick signal is reported as the "Wins" column in the main tables. Participants could also leave optional free-text comments. These comments were used qualitatively to identify recurrent failure modes such as American spelling, non-Australian institutional references, over-formatting, excessive enthusiasm, and loss of local specificity.

D.5 Exported Data and Aggregation

Each HTML interface exported a JSON file containing the reviewer identifier, source set, export timestamp, number of questions, and one rating object per prompt. Each rating object included the prompt slug, category, prompt text, selected best response, best response slot, optional comment, per-system response slots, and per-dimension scores.

For quantitative aggregation, each system's overall score was computed as the mean of its available dimension scores. We then averaged scores across all exported rating records and compared raw versus prompt-engineered variants within each training mix. Records with missing best-response selections were excluded from win counts but retained for score averages where numeric scores were available.

D.6 Participants, Recruitment, and Rating Volume

The evaluation contained 89 prompts. Each prompt received four complete participant ratings, yielding 356 prompt–rater records. Every record included ratings of six systems on five dimensions, corresponding to up to 30 scalar scores per record and 10,680 scalar ratings in total, together with one best-response selection. The number 356 therefore denotes complete prompt–rater records, not the number of individual dimension-level judgements.

We recruited 45 unique native Australian English speakers through convenience sampling at an Australian university and organisational snowball sampling. Participants were 18–49 years old; 46.6% identified as female and 53.3% as male. Each participant received a $20 voucher for a task designed to take approximately 20–30 minutes. The sample was assembled for product evaluation and should not be interpreted as representative of all Australian English communities, regions, age groups, or cultural identities.

D.7 Inter-Rater Agreement

Exact-score agreement is stringent for ordinal 1–5 ratings because it treats a one-point difference, such as 4 versus 5, as the same type of disagreement as a four-point difference, such as 1 versus 5. We therefore report both exact agreement and agreement within one scale point. Across the examples included in the agreement analysis, 81.0–96.1% of ratings differed by at most one point, depending on the evaluation dimension. Agreement was highest for non-caricature and style restraint and lowest for Australian naturalness, which is also the most inherently subjective of the five criteria.

Evaluation dimension	Exact agreement	Agreement within ± 1 point
Australian naturalness	46.1%	81.0%
Cultural and pragmatic fit	48.5%	85.8%
Non-caricature and style restraint	71.7%	96.1%
Context-appropriate register	62.4%	91.1%
Helpfulness and task fidelity	60.3%	88.5%

Table 5: Inter-rater agreement for the five human-evaluation dimensions. Exact agreement is reported together with the more tolerant within-one-point agreement appropriate for ordinal ratings.

E Prompt Construction

The prompt-engineered systems used an extended Australian conversational-style system prompt together with few-shot demonstrations drawn from the 89-example JSONL file. The JSONL file contains one prompt-definition row followed by 89 user-query examples. Each example includes a user query, a standard model response, and a preferred Australian-style response. For few-shot prompting, we used the preferred response field as the target answer style, because it represented the answer we wanted the model to imitate.

The final prompt therefore had two components. First, we placed an extended version of the detailed Australian voice instructions in the system message. Second, we included selected few-shot examples in the prompt context, formatted as user request and preferred answer pairs. This was intended to demonstrate the desired behaviour concretely rather than relying only on abstract style rules.

E.1 System Prompt

The system prompt instructed the model to speak in mainstream contemporary Australian English while avoiding caricature. It emphasised that Australian voice should be clear, direct, low-ceremony, modest, warm, practical, and conversational. The prompt also stated that style should never reduce accuracy, safety, usefulness, or task fidelity. In condensed form, the system prompt was:

> Speak in mainstream contemporary Australian English. Do not perform a stereotype; sound naturally familiar to an Australian user. Be clear, direct, low-ceremony, modest, warm, practical, and conversational. Sound like a capable peer rather than a lecturer, salesperson, servant, or corporate spokesperson.
>
> Use plain everyday wording, active voice, and direct phrasing. Get to the point early. Be honest and clear without being harsh. Favour understatement over hype, and use warmth without gush. Light dry humour is acceptable only when it fits; avoid forced jokes or constant banter.
>
> Use standard natural English with an Australian feel, not dense slang. Do not overuse markers such as "mate", "reckon", "bloody", or "yeah nah". Avoid phonetic accent spellings, ocker performance, exaggerated slang, American customer-service exuberance, British stiffness, corporate hype, and motivational fluff.
>
> Match the user's context and level of formality. Stay relaxed when the task is casual, but remain professional, steady, and careful in serious, emotional, technical, legal, financial, medical, or safety-critical contexts. Prefer practical answers over polished speeches, common sense over grand framing, and concise reassurance over emotional overstatement.
>
> Priority order: be accurate and useful; be clear and direct; sound naturally Australian; stay modest, warm, and unpretentious; never overperform the style. Do not mention these rules unless asked.

E.2 Few-Shot Demonstrations

The few-shot examples were constructed from the preferred-answer column of the 89-example file. Each demonstration paired a user query with the preferred Australian-style answer. The standard response was retained in the source file for comparison, but the few-shot prompt used the preferred answer as the exemplar. A simplified template was:

```
User:
<user_query>

Preferred answer: <answer_1>
Non-Preferred answer: <answer_2>
```

For example, a short social reply example in the JSONL file maps the user request "Reply in one sentence to a friend who says they forgot your birthday, keeping it light but honest" to the preferred answer "No worries you forgot–these things happen; let's catch up soon and celebrate properly." A technical/plain-language example maps "Explain why password managers are useful to someone who is not technical. Keep it short" to a concise answer that explains password managers as a secure vault, while keeping the tone practical and non-hypey.

These few-shot demonstrations served two purposes. They showed the desired surface style, such as concise phrasing, modest warmth, and avoid-

ance of over-Americanised customer-service language. They also showed the deeper pragmatic target: answer the task directly, preserve accuracy, and adapt the level of detail to the user request. The extended system prompt supplied the general style rules, while the few-shot examples showed how those rules should look in actual responses.

F Analysis and Industry Lessons

The results support three practical lessons for market-specific LLM deployment.

First, learned voice is more reliable than prompted voice. Prompt-layer localisation is tempting because it is cheap, inspectable, and reversible. However, the prompt has to compete with the model's existing behavioural priors and with task-specific instructions. It can also make style too visible. Our results show that when voice is pragmatic rather than lexical, a prompt is a weak control surface. Fine-tuning exposes the model to many concrete decisions about what to say, what not to say, and when to reduce style. This produces a more implicit and flexible behaviour.

Second, anti-caricature data matters as much as positive data. A dataset containing only preferred Australian rewrites can still teach the wrong lesson if it over-represents casual cases. Contrastive negatives and style-control examples tell the model that localisation has boundaries. They distinguish a natural Australian response from a response that performs Australianness. In industry settings, these boundaries are critical: a support assistant that jokes during a complaint, or a finance assistant that uses local colour instead of giving precise caveats, damages trust even if the wording is recognisably local.

Third, replay is part of localisation, not a competing objective. The purpose of Australian voice tuning is to make the assistant better for Australian users, not to reduce its general usefulness. Replay data protects reasoning, coding, factual answering, safety, and non-local tasks. The capability matrix in the appendix is broad but not tightly controlled, so we do not overinterpret it. Its value is operational: it checks that voice tuning has not obviously broken general behaviour. For a production system, this regression-screen role is often more useful than a single headline benchmark score.

The broader implication is that English-language localisation should be treated as an alignment problem. Many deployed assistants already support different spelling conventions, but spelling is not voice. Users notice stance, directness, ceremony, humour, and whether the assistant understands the social situation. These properties are not well controlled by a short instruction appended at inference time. They are better represented through examples, review criteria, and evaluation dimensions that match the intended user experience.

Release interpretation. For deployment, the matched comparison is the most useful result: the prompt loses within every mixture family, so the finding is not only that 50% voice data is strong. It is that explicit Australianisation is a weaker control surface than learned behaviour. A practical release workflow is therefore to train the voice, evaluate it blind against a prompt-only baseline, and use prompts only for task instructions rather than broad cultural performance.

G Representative Response Comparisons

The examples below are selected from prompts where a human evaluator left explicit written feedback in the exported JSON. Response labels use the anonymous slot numbers shown to participants. These cases are therefore illustrative qualitative evidence: they show the concrete reasons participants preferred one answer over another, rather than examples chosen only by the analyst. R1–R6 are anonymised response labels assigned after randomly shuffling the six tested model outputs.

Example 1: Australian Consumer Rights

Prompt.

> Explain a customer's rights if a retailer refuses a refund on a clearly faulty product.

Human feedback signal. The evaluator selected **R1** and wrote that "jurisdiction is everything here". The selected answer was preferred because it stayed fully within Australian consumer law, while several alternatives cited UK or US consumer systems.

Observed variants.

- **R1, selected.** Anchors the answer in the Australian Consumer Law, explains consumer guarantees, distinguishes repair/replacement/refund, and gives local escalation paths such as state consumer affairs agencies, the ACCC, VCAT, and NCAT.

- **R2.** Gives generally useful advice, but cites the UK Consumer Rights Act 2015, US regulations, the FTC, and Citizens Advice. The feedback marked this as the wrong jurisdiction.
- **R3.** Is explicitly UK-based: Consumer Rights Act 2015, Trading Standards, Citizens Advice, small claims court, and a pound-sign chargeback example.
- **R4.** Also stays in Australia, referring to acceptable quality under Australian consumer law, major faults, Consumer Affairs Victoria, and the ACCC. It was strong, but slightly less complete than R1.
- **R5.** Correctly notes that the retailer, not the manufacturer, is responsible under Australian law, and points to Fair Trading or Consumer Affairs. It was also strong, but less detailed on escalation.
- **R6.** Returns to the UK Consumer Rights Act 2015 and UK-style complaint bodies, making it locally inappropriate despite being coherent.

Why R1 is best. This example shows that Australian voice is not only accent or tone. The preferred response wins because it gets the civic context right. It uses the correct legal frame, names institutions an Australian customer could actually contact, and avoids importing overseas consumer-rights assumptions.

Example 2: Safety-Critical Heat Advice

Prompt.

> It's forecast to hit 40 degrees tomorrow. Give practical tips for a crew working outdoors safely.

Human feedback signal. The evaluator selected **R1**, noting that a safety-critical answer should be "steady, not peppy". The feedback specifically valued SPF50+, practical heat controls, and the absence of emoji or motivational cheeriness.

Observed variants.

- **R1, selected.** Gives a calm worksite plan: start early, drink measured amounts of water, use shade, wear loose light clothing, apply SPF50+ sunscreen, rotate tasks, use buddy checks, and respond clearly to heat-sickness symptoms.
- **R2.** Also practical and uses SPF50+, but is slightly more generic. It ends with broad safety messaging rather than the quieter operational register of R1.
- **R3.** Covers many useful controls, including hydration, rest breaks, acclimatisation, first aid, and supervision, but is longer and uses SPF30+ rather than the stronger Australian-standard SPF50+ cue.
- **R4.** Gives useful advice, but includes SPF30+ and ends with a cheerful emoji-heavy line. The feedback treated this as too casual for a high-risk heat briefing.
- **R5.** Starts with "Hey there" and ends with "You've got this!" plus emoji. Even though much of the advice is useful, the register is too upbeat for a 40-degree worksite safety context.
- **R6.** Adds an unnecessary Fahrenheit conversion, uses SPF30+, and finishes with emojis. The evaluator read this as less locally natural and less restrained.

Why R1 is best. The preferred answer combines helpfulness with the right level of seriousness. It sounds like a competent Australian workplace safety note: practical, direct, and calm. The weaker variants show a recurring failure mode in the study: correct information can still lose if the register is too cheerful, too generic, or too imported.

Example 3: Honest Client Pushback

Prompt.

> A client wants a project done in half the quoted time. Reply honestly but kindly.

Human feedback signal. The evaluator selected **R6**, describing it as honest and kind, and highlighting the question "What's driving the tighter deadline?" as a genuinely consultative move.

Observed variants.

- **R1.** Clear and reasonable, with a natural warning that rushing could cause issues "down the track". It offers scope and priority options, and was close to the preferred answer.
- **R2.** Professional and complete, but more corporate. It focuses on phased delivery, resource adjustment, and scope adjustment, with heavier phrasing around trust and project success.

- **R3.** Very formal and overlong, with a subject line, "Dear" opening, multiple options, and a warm-regards sign-off. It is polite but too ceremonial for the requested tone.
- **R4.** Natural and friendly, especially the phrase "thanks for flagging this early". It gives clear options, but does not ask why the deadline has changed.
- **R5.** Misreads the relationship by opening with "Thank you for considering us for your project", as though the client is a new prospect rather than an existing client.
- **R6, selected.** Says plainly that halving the time will affect quality and thoroughness, offers practical alternatives, and asks what is driving the tighter deadline before deciding how to proceed.

Why R6 is best. R6 is preferred because it balances honesty with collaboration. It does not over-apologise, over-sell, or hide the constraint. The consultative question makes the answer feel like a capable peer trying to solve the real problem, which matches the target Australian style better than a polished but generic business template.

H Additional Human Evaluation Tables

Table 6: Best system by semantic topic type.

Topic type	Best by average	Most best-pick wins
Australian civic, legal, and finance	50% mix raw (4.27)	50% mix raw (64 wins)
Customer and business communication	50% mix raw (4.23)	50% mix raw (68 wins)
Technical, product, and code	30% mix raw (4.28)	base raw (40 wins)
Workplace and team management	50% mix raw (4.29)	50% mix raw (36 wins)
Personal, wellbeing, and life admin	50% mix raw (4.32)	50% mix raw (28 wins)
Plain-language, education, and creative	50% mix raw (3.95)	50% mix + prompt (12 wins)

Table 7: Human evaluation dimensions. The task requires local naturalness without sacrificing restraint, register, or usefulness.

Dimension	Criterion
Australian naturalness	Sounds familiar to Australian users rather than generic international English.
Cultural/pragmatic fit	Follows expectations of directness, modesty, low ceremony, and practical helpfulness.
Non-caricature/restraint	Avoids exaggerated slang, forced humour, stereotypes, or over-performance.
Context register	Uses suitable formality for casual, professional, technical, or sensitive settings.
Helpfulness/fidelity	Remains accurate, clear, complete, safe, and useful while adopting the target voice.

Table 8: Prompt-engineered variant minus raw variant within each training mix. Negative values mean the prompted variant scored lower.

Comparison	Naturalness	Fit	Restraint	Register	Helpfulness	Overall	> / = / <
base, prompt minus raw	-0.57	-0.43	-0.04	-0.07	-0.16	-0.25	46 / 29 / 89
30% mix, prompt minus raw	-0.51	-0.30	-0.01	-0.06	-0.03	-0.18	58 / 29 / 87
50% mix, prompt minus raw	-0.70	-0.49	-0.08	-0.10	-0.37	-0.35	51 / 20 / 104

Table 9: Failure modes targeted by the data and evaluation design.

Failure mode	Mitigation
Surface Australianisation	Contrastive negatives penalise forced slang, accent spelling, and broad national performance.
Generic support voice	Human rewrites favour plain wording, early practical steps, and restrained warmth.
Wrong register	Style-control examples reduce humour and informality in serious, technical, workplace, and safety-sensitive tasks.
Local hallucination	Review rejects unsupported local facts, institutions, procedures, and legal or financial claims.
Capability regression	Replay data and benchmark screens protect general instruction-following, reasoning, coding, and safety behaviour.

Less Is More: Graph-free Multimodal RAG via Multi-signal Late Fusion

Abstract

Graph-based retrieval-augmented generation (RAG) is widely used for multimodal, cross-document question answering. However, building corpus-level graphs is expensive, slow to query, and difficult to maintain. We present TrioRAG, a graph-free multimodal framework that integrates evidence from three complementary signals: the question, the anchor image, and a VLM-enhanced query generated from both. Each signal retrieves independently over a shared multi-vector index of page text and page images, and the results are combined through late fusion. Further, we introduce AutoQA, a multimodal automotive benchmark whose questions are grounded in noisy, web-sourced images rather than clean document-sourced figures. Its questions require reasoning across manuals. We position it as a model-curated testbed rather than a human-validated gold standard. Across three benchmarks, TrioRAG matches or outperforms graph-based systems while reducing total cost and accelerating per-query inference by 1.6-2.3×. By construction, AutoQA grounds its questions in out-of-corpus web images. In this setting image retrieval reaches only 19.3% document-level recall, while text-derived signals, especially the VLM-enhanced query, keep retrieval robust.

1 Introduction

Retrieval-Augmented Generation (RAG) (Lewis et al., 2020) has become the standard paradigm for grounding large language models in external knowledge. For multimodal and cross-document reasoning, recent systems increasingly turn to graph-based designs (Edge et al., 2024; Guo et al., 2025b; Wan and Yu, 2025; Guo et al., 2025a) that build graphs over documents, pages, entities, text, and visual elements. Such a structure is a natural fit for multimodal corpora, where evidence is spread across text, figures, tables, and images.

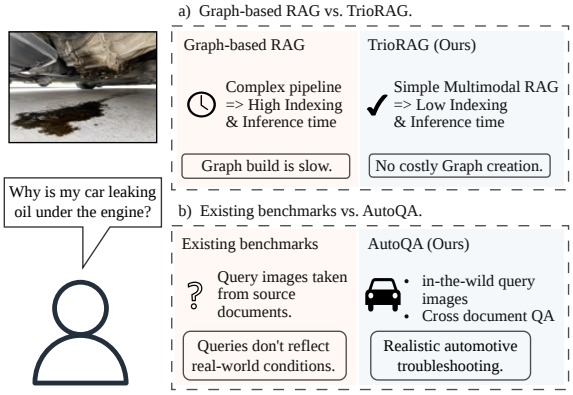

Figure 1: **Vehicle Diagnostics: RAG Pipelines and Benchmarks**: a) *Overhead-free*: TrioRAG achieves strong performance without graph construction or complex retrieval pipelines. b) *Out-of-corpus images*: AutoQA uses messy, web-sourced diagnostic images rather than images drawn from the source corpus.

However, this expressivity is costly (Figure 1). Graph-based systems require expensive extraction, alignment, and construction, and are difficult to update, as corpus changes can force re-extraction, or partial rebuilds (Zhang et al., 2026; Peng et al., 2026). These challenges are amplified in multimodal settings, where text, images, and entities must be linked across large collections. This raises a practical question for the graph systems and benchmarks we study: is a corpus-level graph necessary for competitive multimodal cross-document retrieval, or can simpler retrieval methods extract comparable evidence at lower cost?

To address this challenge, we propose TrioRAG, a graph-free multimodal RAG framework.[1] TrioRAG indexes page text and images in a shared multi-vector space and retrieves three complementary signals: the text query, the anchor image, and a VLM-enhanced query grounded on the anchor image. The resulting rankings are fused via late fu-

sion. By avoiding graph construction and traversal, TrioRAG achieves performance comparable to or better than the graph-based systems we evaluate.

Existing multimodal RAG benchmarks usually draw query images from source documents, creating near-duplicate visual matches that can overestimate the effectiveness of image retrieval compared to out-of-corpus query images, which are common in real-world settings. To evaluate retrieval under realistic conditions, we introduce AutoQA, a multimodal, cross-document question-answering benchmark in the automotive domain. Each question is grounded in a noisy, web-sourced image and requires synthesizing evidence across two technical manuals. AutoQA deliberately creates a domain gap between query images and document pages, allowing us to study retrieval when no direct visual match exists in the corpus. Our experiments reveal that, in this setting, image retrieval becomes substantially less reliable, while text-derived signals, especially the VLM-enhanced query, recover much of the missing evidence and keep retrieval robust.

Our contributions are as follows: **A graph-free framework** that fuses three query signals: the text query, the anchor image query, and a VLM-enhanced query, over a shared multi-vector index, matching or exceeding the graph-based systems we evaluate. **AutoQA**, a model-curated benchmark of multimodal, cross-document automotive QA pairs grounded in noisy, web-sourced images, with validation status discussed in the Limitations and Ethics statements. **A retrieval-reliability analysis** showing that, on AutoQA's deliberately out-of-corpus query images, image retrieval collapses while text-derived signals, especially the VLM-enhanced query, keep retrieval robust. On the benchmarks we study, this reliability gap, rather than the choice of fusion method, is what most closely tracks downstream accuracy.

2 Related Work

Retrieval-augmented generation (RAG) (Lewis et al., 2020) grounds language models in external knowledge. It does so by retrieving relevant passages with a dense retriever (Karpukhin et al., 2020) and conditioning a reader on the retrieved evidence. Fusion-in-Decoder (Izacard and Grave, 2021) and Atlas (Izacard et al., 2023) show that jointly attending to multiple passages improves performance, motivating multi-evidence readers rather than single-match retrieval. However, these methods assume textual knowledge, limiting their use for visual documents. OCR or captioning pipelines (Xu et al., 2020; Riedler and Langer, 2024) are often used instead, but they flatten layouts and discard visual structure.

Visual document retrieval. Recent work retrieves directly from visual inputs. Building on late interaction models (Khattab and Zaharia, 2020), ColPali (Faysse et al., 2025) uses multi-vector page embeddings with MaxSim, avoiding OCR. VisRAG (Yu et al., 2025) and M3DocRAG (Cho et al., 2025) show strong performance in document QA at scale, and ViDoRAG (Wang et al., 2025) adds iterative reasoning over retrieved pages. We use multi-vector retrieval but differ in query construction. We combine multiple complementary query signals instead of a single representation.

Query expansion for retrieval. Query expansion methods generate intermediate text to improve retrieval. HyDE (Gao et al., 2023) prompts a language model to generate a hypothetical document, whose embedding is used for retrieval. We extend this to multimodal inputs by conditioning generation on both the question and an anchor image, grounding abstract terms in visual content. This serves as one of several retrieval signals rather than a standalone method.

Graph-based RAG. RAG systems increasingly use graph structures to support retrieval and reasoning (Guo et al., 2025b; Zhou et al., 2025a,b, 2026; Chaturvedi et al., 2026). In multimodal settings, MMGraphRAG (Wan and Yu, 2025) aligns image and text graphs via spectral clustering for entity linking, while RAG-Anything (Guo et al., 2025a) extends graph-based retrieval to text and vision. VAT-KG (Park et al., 2025) constructs concept-level graphs across modalities. Graph structure can also be introduced after retrieval for structured reasoning, e.g., argumentation-based RAG (Zhu et al., 2025). However, methods that construct corpus-level graphs can incur substantial costs from extraction, alignment, and traversal.

Rank aggregation and fusion. Rank aggregation has a long history in information retrieval (Li et al., 2025; Santra et al., 2025; Rackauckas, 2024). Classical methods like Borda count (Aslam and Montague, 2001) and Reciprocal Rank Fusion (Cormack et al., 2009) combine sparse and dense signals. Social-choice aggregation has also been used to robustly combine LLM outputs (Potyka et al., 2024). Recent work extends them to multimodal settings (Samuel et al., 2025). We use

unsupervised fusion methods and study how they behave under heterogeneous signal reliability, especially with noisy query images.

Benchmarks. Document QA benchmarks evolve from single-page (Mathew et al., 2021) to multi-page (Cho et al., 2025) and long-document reasoning (Ma et al., 2024; Li et al., 2024). However, most assume clean inputs and aligned visual evidence, limiting realism. To address this gap, AutoQA introduces cross-document automotive reasoning with web-sourced question images.

3 Methodology

Given a question q, an anchor image v, and a corpus of M pages $\mathcal{P} = \{p_j\}_{j=1}^{M}$, our pipeline retrieves a set of pages $\mathcal{R}_K \subset \mathcal{P}$ and passes them, together with (q, v), to a vision-language reader that produces the answer a. The pipeline has three stages: hybrid indexing, multi-signal retrieval, and late fusion, followed by a generation step, with no graph construction at any point (Figure 2). We describe the default multi-vector configuration here; a dense variant is evaluated as an ablation (Section 6.2.1).

Hybrid indexing. Each page p_j is stored under two views: its structured text x_j, extracted with MinerU (Wang et al., 2024), and its rendered page image y_j. Both are encoded with Jina-v4 (Günther et al., 2025), a unified multimodal encoder that maps text and images into a shared embedding space, and they are added to a single index. Keeping a text and an image view of every page preserves both textual content and visual layout without any structural parsing, enabling the query match of either view.

Multi-signal queries. We derive three retrieval signals from the multimodal question (q, v), each surfacing different evidence. A text query (q), an image query (v), and an enhanced query e i.e., a short textual description produced by prompting a VLM with both q and v (prompt in Appendix A.4). The enhanced question grounds abstract question terms in what is visible in the anchor image and is embedded as text. Combining the three signals improves recall over any single one (Table 6).

Late-interaction retrieval. Each question is a set of token embeddings. For a question Q and an index entry c with embedding set V_c, we score relevance by late interaction (MaxSim) (Khattab and Zaharia, 2020; Günther et al., 2025):

$$s(Q, c) = \sum_{u \in Q} \max_{w \in V_c} \langle u, w \rangle. \tag{1}$$

Because text and image entries share one embedding space, every question scores against both views, so a single ranked list can contain text-view and image-view entries for different pages. Each of q, v, and e retrieves its top-10 entries under $s(\cdot, \cdot)$, yielding three ranked lists T, I, and E.

Late fusion. The three lists are merged at page level into a single fused ranking. Our default aggregator is Reciprocal Rank Fusion (RRF) (Cormack et al., 2009): for a page p with rank $r_L(p)$ in list L,

$$\mathrm{RRF}(p) = \sum_{L \in \{T,I,E\}} \frac{\mathbf{1}[p \in L]}{k + r_L(p)}, \qquad k = 60, \tag{2}$$

and the top $K{=}10$ pages by $\mathrm{RRF}(p)$ form the retrieved set $\mathcal{R}_K$. RRF needs no score normalisation and prevents any single list from dominating. Because the best way to combine lists depends on how reliable each one is, we also evaluate three alternatives (Borda count, mean of z-normalised scores, and mean of normalised ranks) in Section 6.2.4.

Answer generation. The VLM reader is given the question and anchor image (q, v) together with the fused context, and produces the answer a. Because fusion merges the lists at the page level, each page in $\mathcal{R}_K$ contributes a single view, i.e., the page text or the page image, whichever entry ranked highest for that page. Hence, the context is a mix of page-text passages and page images.

4 AutoQA Benchmark

AutoQA is a multimodal cross-document question-answering benchmark for the automotive domain. It is built by an automated multi-stage pipeline, with a model-based filtering step after each stage; Appendix A.1 describes the pipeline in more detail.

Document-pair construction. We start with 200 automotive workshop manuals rendered into page images. A vision-language model (Qwen3-VL-32B) produces a structured summary of each manual; the summaries are embedded with Jina-v4 and clustered with UMAP (McInnes et al., 2018) and HDBSCAN (McInnes et al., 2017). Within each cluster, candidate document pairs are formed from the top nearest neighbours of every manual by summary-embedding cosine similarity, weighted by cluster-membership confidence. A VLM (Qwen3-VL-32B) then removes pairs that lack shared technical grounding or cross-document complementarity, leaving 556 pairs.

Image grounding. Rather than reuse figures from the manuals, AutoQA grounds each question

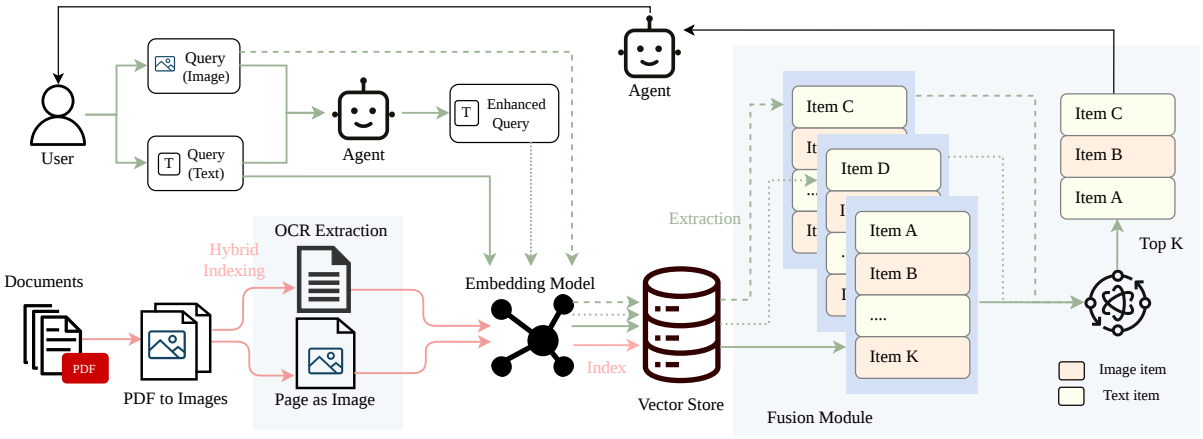

Figure 2: Our TrioRAG pipeline. The multimodal question is turned into three signals: text, image, and VLM-enhanced text, retrieved independently over a hybrid multi-vector index and merged into a single fused ranking. The top-ranked pages are passed to the VLM reader alongside the anchor image to generate the answer.

in a separately sourced image, creating a deliberate domain gap between question images and document pages. From the document summaries we generate mechanic-oriented image-search queries, post them to DuckDuckGo Image Search, and filter the returned web images with a VLM to discard noise and mismatches.

Question generation. For each validated pair and its grounding image, GPT-4o generates cross-document questions from the page images, extracted text, and the image, producing 1,449 candidate QA pairs. Each question is labelled as factual, procedural, or diagnostic and is constructed to require evidence from both manuals.

Filtering. GPT-4o scored every candidate on factual grounding, answer accuracy, answer completeness, cross-document dependency, absence of source leakage, and image grounding. Retaining items meeting all criteria at maximum quality reduced the 1,449 candidates to 885 final QA pairs across 405 distinct images. A 50-item human validation of the final set (Appendix A.2) confirms high answerability (80%) and reference-answer completeness (86%), with lower strict cross-document necessity (46%) and image grounding (52%).

5 Evaluation

5.1 Datasets

We evaluate on three benchmarks spanning different domains and question types. **MMLongBench** (Ma et al., 2024) has 1,091 questions over long, multi-page documents; with no anchor figures, it is a text-centric setting. **M3SciQA** (Li et al., 2024) has 452 cross-document scientific QA pairs, each grounded in an anchor figure and hinging on tables, charts, and figures. **AutoQA** (ours) has 885 cross-document automotive QA pairs; each is grounded in a web-sourced image and needs evidence from two manuals, with question images that are noisy and out-of-domain relative to the document pages.

5.2 Implementation details

We use *jina-embeddings-v4* in multi-vector mode (128-dim/token) by default, with dense mode (2048-dim) as an ablation. Page text is extracted with MinerU (Wang et al., 2024) and indexed with full-page images in one Qdrant collection (top-10 per signal, RRF k=60; Section 3). The enhanced question is generated by the VLM reader, *Qwen2.5-VL-7B-Instruct*, run on a single NVIDIA H200 GPU. For a controlled comparison, TrioRAG, and all the baselines use the same Qwen2.5-VL-7B reader and the same number of retrieved pages, so accuracy differences reflect retrieval and fusion rather than the reader or context size.

5.3 Evaluation metric

We report mean accuracy under an LLM-as-judge protocol (Zheng et al., 2023) with GPT-4o-mini. Given the question, ground-truth answer, and prediction, the judge returns a binary score, counting factually consistent predictions correct, including partial answers with the key information and correct refusals on unanswerable questions. Since AutoQA is built with GPT-family models, we use the same judge throughout for comparability and note this dependence in the Limitations.

Method	Index	MMLB	M3Sci	AutoQA
MMGraphRAG	D	26.95	–	–
RAG-Anything	D	27.22	28.76	58.19
Naive RAG + Concat	D	33.73	31.42	55.63
Naive RAG + Concat	M	35.56	20.69	45.31
TrioRAG (Ours)	D	33.73	51.99	58.92
TrioRAG (Ours)	M	**35.56**	**54.86**	**60.11**

Table 1: Accuracy (%) across benchmarks. Index: D = dense, M = multivec. Graph baselines use dense indexing; MMGraphRAG is run on MMLongBench.

6 Results

6.1 Main Results

Table 1 compares TrioRAG against two graph-based systems, RAG-Anything (Guo et al., 2025a) and MMGraphRAG (Wan and Yu, 2025), that support only dense retrieval; for fairness, we report TrioRAG in both dense and multi-vector modes. TrioRAG is best across all three benchmarks. Furthermore, even Naive RAG + Concat (combining signals before retrieval without RRF) outperforms both graph systems on MMLongBench, suggesting that graph construction alone does not inherently improve retrieval quality on text-centric tasks.

The gap is largest on M3SciQA, where TrioRAG nearly doubles RAG-Anything. As M3SciQA is grounded in figures, tables, and charts, direct image retrieval and VLM-enhanced queries exploit visual evidence that graph-based text extraction discards. Feeding full-page images to the reader amplifies this advantage. On AutoQA, the gap narrows to 1.92pp (McNemar p=0.34, within noise under GPT-4o-mini; under a different-family judge it widens to $+8.14$, $p<10^{-5}$, Table 3), as answers are mostly stated in text and both systems rely on text retrieval; we still edge out the graph baseline while being far cheaper (Table 2), the trade-off we target. Separate retrieval followed by fusion also outperforms Naive RAG + Concat. Concatenating text and image tokens weakens MaxSim for both modalities, causing a sharp drop for M3SciQA under multi-vector indexing. On MMLongBench, all variants perform identically as the absence of an anchor image collapses all methods to text-only retrieval.

Efficiency. Table 2 reports total wall time (indexing + inference) on a single H200, with identical settings across methods. Our pipeline completes in under 6 hours in all settings, achieving a 12× speedup on AutoQA, 20× on M3SciQA, and 65× on MMLongBench. The gains come from removing graph construction: both baselines run repeated LLM passes for entity/relation extraction and cross-modal alignment to index the documents, a heavy per-document cost. TrioRAG does a single embedding pass at indexing and plain retrieve-and-read at query time, without graph traversal. It is also faster at inference than RAG-Anything. MMGraphRAG has lower query-time latency on MMLongBench but pays for costly graph construction, resulting in higher total runtime while still underperforming in accuracy (Table 1).

Benchmark	Method	Infer (h)	Total (h)
MMLongBench	MMGraphRAG	**1.24**	66.21
	RAG-Anything	3.97	244.77
	TrioRAG (Ours)	1.74	**3.75**
M3SciQA	RAG-Anything	2.40	119.53
	TrioRAG (Ours)	**1.48**	**5.93**
AutoQA	RAG-Anything	4.32	62.36
	TrioRAG (Ours)	**2.39**	**5.31**

Table 2: Total time (indexing + inference) on a single H200. Inference time refers to the query-time cost, excluding one-time indexing.

Judge	TrioRAG	RAG-Anything	McNemar p
GPT-4o-mini	60.11	58.19	0.34
Opus 4.8	38.42	30.28	$< 10^{-5}$

Table 3: Cross-family judge accuracy (%) on 885 AutoQA items. The system ranking is stable and the gap becomes significant under the different-family judge.

6.2 Ablations

6.2.1 Indexing

Multi-vector indexing outperforms dense on all three benchmarks, most on M3SciQA (Table 1), where answers are grounded in visually distinctive figures. MaxSim's patch-level matching surfaces visually relevant pages that dense pooled embeddings miss, giving the reader richer visual context. We use multi-vector throughout.

6.2.2 Input representation

We compare three reader contexts (Table 4): full-page images; extracted text with cropped figures; and extracted text with full-page images. Full-page images preserve layout, charts, and table structure that text extraction and cropping discard, and win on M3SciQA. Adding extracted text gives a further gain where answers are often stated in text (MMLongBench, AutoQA) but slightly hurts on purely figure-based M3SciQA. As AutoQA is our target setting, we adopt it as the default.

Input Representation	MMLB	M3Sci	AutoQA
Doc Page Image	34.74	**55.75**	59.48
Text + Cropped Image	31.53	51.42	57.95
Text + Doc Page Image	**35.56**	54.86	**60.11**

Table 4: Accuracy (%) by reader input representation (MMLB = MMLongBench, M3Sci = M3SciQA). We compare three reader contexts: full document-page images; extracted text with cropped figures; and extracted text with full-page images.

6.2.3 Question strategy

Table 5 compares the three signals under RRF. On M3SciQA, where the anchor figures originate from source documents and retrieves reliably, adding the enhanced question helps (E+I over T+I by 1.99pp, and the full triple a further 0.44pp). On AutoQA, T+I beats E+I since web-sourced question images mislead the VLM, making e noisy, while text stays reliable. T+I+E is best on both and is our default.

Question Strategy	M3SciQA	AutoQA
T + I	52.43	59.77
E + I	54.42	58.98
T + I + E	**54.86**	**60.11**

Table 5: Accuracy (%) by Query strategy. T = text, I = image, E = enhanced query . T+I+E signal is best.

6.2.4 Retrieval Reliability and Signal Complementarity

We measure retrieval at the document level. A signal succeeds on a question if its top-10 contains a page from a reference document (for M3SciQA, the reference paper must be found; the anchor paper is given as the query). We report Recall@10 for each signal and their unions in Table 6.

Image retrieval works only when the query image is in the corpus. On M3SciQA, the query image is a figure taken directly from a corpus document. Because of this, the image signal retrieves that source document almost perfectly at 99.6%. However, this near-duplicate self-matching is deceptive because the actual reference paper is recovered only 46.7% of the time. On AutoQA, this apparent advantage disappears. AutoQA uses web-sourced images with no counterpart in the corpus, causing image recall to collapse to 19.3%. This sharp contrast highlights the core problem AutoQA is designed to expose: realistic, out-of-corpus query images defeat visual retrieval. Text and enhanced text signals, by contrast, remain strong and reliable, achieving 81.6% and 78.5% recall on AutoQA.

Text-derived signals dominate but remain complementary. Because different query signals fail on different questions, their union outperforms any single signal (87.1% recall on AutoQA and 97.8% on M3SciQA). However, these gains come almost entirely from text and enhanced signals. T∪E alone reaches 97.3% on M3SciQA and 86.6% on AutoQA, and adding the image signal contributes little beyond that. This pattern provides an empirical basis for retrieving multiple text-derived query signals rather than relying on a single representation. Ultimately, these results foreshadow the limited standalone value of image retrieval when handling realistic queries.

Recall@10	M3SciQA	AutoQA
Per signal		
T	95.4	81.6
I	46.7	**19.3**
E	91.2	78.5
Combined		
T ∪ E	97.3	86.6
T ∪ I ∪ E	**97.8**	**87.1**
Image-Miss subset only		
T	–	78.9
T ∪ E	–	**84.0**

Table 6: Document-level Recall@10 (%). Image retrieval collapses on AutoQA's out-of-corpus query images; the multi-signal union recovers most of the loss.

The enhanced query rescues retrieval when the image signal fails. The clearest evidence for the enhanced query is on the questions where image retrieval fails entirely. On the 714 AutoQA questions in this regime (80.7% of the benchmark), adding the enhanced query to text raises reference recall from 78.9% to 84.0%. The enhanced query recovers 37 questions that text alone misses, contributing genuinely complementary evidence rather than redundantly re-ranking the same documents text already finds.

Detailed retrieval metrics. Table 7 and Table 8 report per-signal and fused document-level metrics (R@1, R@5, R@10, MRR@10, nDCG@10) with 95% bootstrap confidence intervals (10k resamples). We omit MMLongBench, which has no anchor image: I and E are undefined and all aggregators collapse to the text signal (R@10 83.0%). Notably, M3SciQA reference retrieval is largely a text task: text alone already reaches 95.4 R@10, leaving little headroom for the other signals, whereas on AutoQA the text signal is lower (81.6) and the enhanced query adds complementary coverage.

Run	R@1	R@5	R@10	MRR@10	nDCG@10
T	69.0	94.5	95.4	80.9	84.6
I	2.2	46.7	46.7	20.6	27.2
E	60.6	91.2	91.2	74.9	79.1
RRF	48.0	96.9	96.9	70.5	77.3
Borda	49.6	97.1	97.8	71.8	78.5
Score-mean	33.6	96.7	97.6	63.3	72.1
Rank-mean	38.7	96.0	97.6	64.9	73.3

Table 7: M3SciQA (n=452) document-level retrieval metrics (%).

Run	R@1	R@5	R@10	MRR@10	nDCG@10
T	31.4	74.2	81.6	48.8	45.5
I	4.4	14.7	19.3	8.6	8.6
E	31.0	71.9	78.5	47.3	44.0
RRF	33.1	72.3	79.0	49.2	44.3
Borda	34.0	71.4	82.1	49.9	46.1
Score-mean	11.4	61.4	81.7	31.8	35.9
Rank-mean	11.3	59.8	80.8	31.1	35.1

Table 8: AutoQA (n=885) document-level retrieval metrics (%).

Bench	Judge	Acc_{ret}	Acc_{miss}
AutoQA	GPT-4o-mini	63.4	47.8
AutoQA	Opus 4.8	43.2	20.4
M3SciQA	GPT-4o-mini	53.2	14.3
MMLB	GPT-4o-mini	38.0	13.0

Table 9: TrioRAG accuracy (%) with the fixed Qwen2.5-VL-7B reader, split by whether the gold document was in the retrieved top-10 (Acc_{ret}) or missed (Acc_{miss}); the **Judge** column is the LLM-as-judge that scored correctness (AutoQA shown under both model families).

Fusion Method	M3SciQA	AutoQA
Borda	**57.08** (52.7–61.7)	59.66 (56.4–62.9)
Score Mean	56.86 (52.2–61.5)	58.87 (55.6–62.2)
Rank Mean	55.31 (50.7–60.0)	59.55 (56.3–62.9)
RRF	54.86 (50.4–59.5)	**60.11** (56.8–63.3)

Table 10: Accuracy (%) by fusion method with 95% bootstrap CIs (10k resamples).

Fusion method has little effect. Given reliable signals, the choice among rank aggregators matters far less than the signals themselves. Across four unsupervised aggregators (Borda count, score mean, rank mean, RRF), accuracy differences are not statistically significant on either benchmark (Table 10; paired tests, Borda vs. RRF: $p \approx 0.31$ on M3SciQA, $p \approx 0.45$ on AutoQA). RRF is also insensitive to the rank constant on AutoQA (accuracy $60.11, 60.0, 59.77$ at k=$60, 15, 20$). We therefore adopt RRF, the simplest option requiring no score normalisation, as the default.

Fusion shifts early ranks, not coverage. The detailed metrics (Tables 7–8) refine this picture. Across the four aggregators, coverage barely moves (AutoQA R@10 spans only 3.1pp), whereas early ranks vary widely (MRR@10 spans 18.8pp). On M3SciQA, fusing the three signals lowers text-only R@1 from 69.0 to 48.0 while raising R@10 from 95.4 to 96.9: fusion trades top-rank precision for broader coverage. Because the reader consumes the full top-10, coverage rather than early-rank order is what drives downstream accuracy, which is why the aggregators are statistically indistinguishable in accuracy (Table 10).

Retrieval success drives accuracy. To connect retrieval quality directly to answers, we split TrioRAG's accuracy (with the fixed Qwen2.5-VL-7B reader) by whether the gold document was retrieved in the top-10 (Table 9). On every benchmark and under both judges, retrieving the gold document raises accuracy substantially: by $+15.5$pp (GPT-4o-mini) and $+22.8$pp (Opus 4.8) on AutoQA, $+38.9$pp on M3SciQA, and $+25.0$pp on MMLongBench. Retrieval outcome thus moves accuracy far more than the choice of aggregator (a 1.24pp spread on AutoQA, Table 10). The analysis is observational (accuracy tracks rather than causes retrieval success), but it reinforces that retrieval reliability governs downstream accuracy.

7 Conclusion

In this paper, we propose TrioRAG, a graph-free, multi-signal pipeline that matches or exceeds the graph-based systems we evaluate. We evaluate it on three benchmarks, with per-query inference 1.6 to 2.3$\times$ faster (Table 2). Our central finding is that retrieval reliability matters more for downstream accuracy than the choice of fusion method: text-derived signals keep retrieval robust where image retrieval collapses on out-of-corpus query images. Because indexing is a single embedding pass, the graph-free design also keeps the corpus cheap to update: adding a document requires only re-embedding the changed pages, with no entity re-extraction, cross-modal re-alignment, or graph rebuilding. These results suggest that, for multimodal cross-document QA, retrieval-signal quality matters more than pipeline complexity. Promising directions include stronger visual signals for out-of-corpus queries and adaptive, per-question weighting of the text, image, and enhanced signals.

Limitations

Model-curated benchmark. AutoQA is generated and filtered by vision-language models, so reported accuracies reflect a model-curated reference rather than a human gold standard. To gauge quality, we ran a 50-item human validation (Appendix A.2): answerability (80%) and reference-answer completeness (86%) are high, while strict cross-document necessity (46%) and image grounding (52%) are lower. These measured rates should be kept in mind when reading AutoQA results; a larger study with inter-annotator agreement is left to future work.

Judge and construction share a model family. Answers are produced by Qwen2.5-VL-7B and judged by GPT-4o-mini, so there is no answerer–judge circularity; however, AutoQA is generated by GPT-4o and judged by GPT-4o-mini, both in the GPT family, which may inflate its absolute scores. To bound this, we re-judged all AutoQA items with a different-family judge (Claude Opus 4.8, Table 3): absolute scores fall for all systems, but the ranking is unchanged and the TrioRAG–RAG-Anything gap grows and becomes significant, consistent with GPT-family inflation rather than a reversal. We keep a single judge across datasets for comparability.

Fusion choice. The four aggregators we compare do not differ significantly in accuracy (Table 10). We default to RRF because it needs no score normalization and keeps any single signal from dominating the fused ranking, a useful property given the heterogeneous reliability of our three signals; we do not claim it is optimal.

Single component choices. All methods (TrioRAG and the graph-based baselines) share the same reader (Qwen2.5-VL-7B) and encoder (Jina-v4), so these fixed components do not explain the accuracy differences, which stem from retrieval and fusion design. Absolute accuracies would change with a stronger reader; whether the relative gains hold across reader and encoder families is left to future work.

Ethics Statement

Source images and licensing. AutoQA grounds each question in a web image (via DuckDuckGo Image Search) that we did not author and that may carry copyright. Rather than redistribute the files, we release each image's source URL and a SHA-256 content hash, so users fetch images from their original sources and can verify they match ours even if some links later break.

Source documents and release. The workshop manuals are proprietary service documents, so we do not redistribute them. Image URLs and content hashes carry no proprietary content and will be released; release of the QA items and document references is subject to institutional review, and we will release the maximally reproducible subset permitted.

Model-curated construction. AutoQA is built with Qwen3-VL-32B (summaries, pairing, image search and verification) and GPT-4o (QA generation and verification); as noted in the Limitations, it is a model-curated testbed rather than a human-validated gold standard and its absolute accuracies should be read accordingly.

Intended use and risks. AutoQA targets retrieval and reasoning over automotive technical documentation. It is a research benchmark and is not intended to provide safety-critical repair guidance; answers produced by systems evaluated on it should not be relied upon for real vehicle servicing without expert verification.

AI assistance. The authors used AI-based tools to assist with drafting and editing the manuscript. All scientific claims, experimental design, and analysis are the authors' own, and the authors take full responsibility for the content.

A Appendix

A.1 AutoQA construction details

AutoQA is created through an automated multi-stage pipeline, with a model-based filtering step applied after each stage (Figure 3).

Document selection. We begin with 200 workshop manuals selected from a larger HTML corpus.

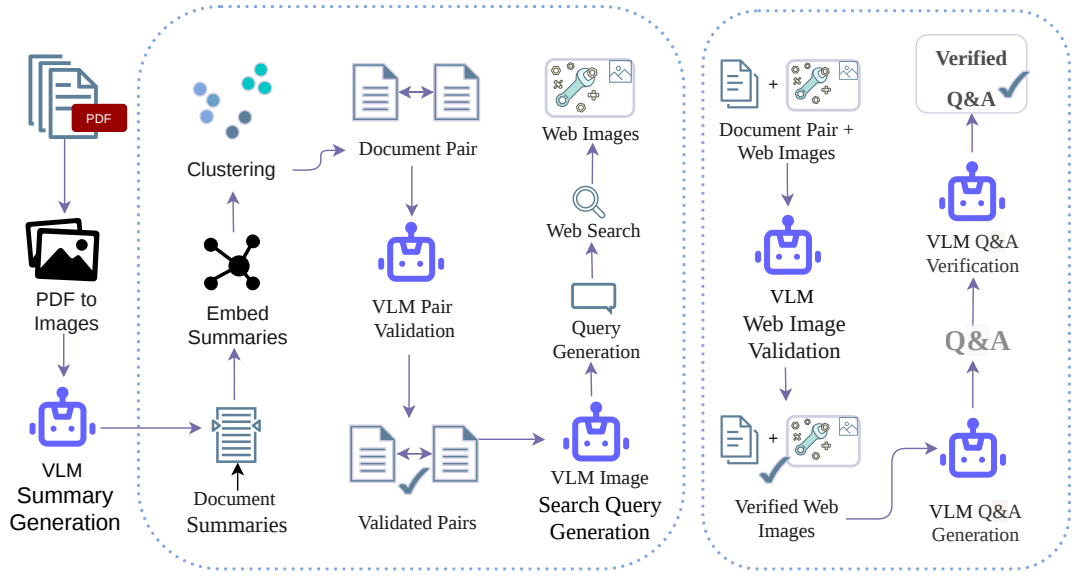

Figure 3: The AutoQA construction pipeline: manuals are summarised and clustered to form document pairs, each pair is grounded in a web-sourced image, and GPT-4o generates and filters cross-document QA pairs.

Documents are ranked using a composite score that considers length, vocabulary richness, figure and table density, heading depth, cross-references, and automotive-term density. Near-duplicate documents are removed before selection.

Clustering and pairing. Each manual is first summarized using Qwen3-VL-32B. The summaries are embedded with Jina-v4, reduced using UMAP (10 components, 15 neighbours, minimum distance 0.1, cosine metric), and clustered with HDBSCAN (minimum cluster size 3, minimum samples 2, Excess of Mass (EOM) selection). This process produces 17 clusters, while low-confidence assignments are treated as noise. Within each cluster, candidate document pairs are formed from the top five cosine neighbours of every document. Pairs are scored as $0.7 \cdot \cos(i, j) + 0.3 \cdot (\text{prob}_i \cdot \text{prob}_j)$, resulting in 591 candidate pairs. Qwen3-VL-32B then performs a lightweight screening step to verify the presence of a shared technical topic and a meaningful cross-document dependency. This removes 35 pairs, leaving 556 for the next stage.

Image grounding. For each document pair, Qwen3-VL-32B generates three mechanic-style image search queries. These queries are submitted to DuckDuckGo Image Search, and the returned photographs are filtered by Qwen3-VL-32B to ensure they depict relevant automotive components, are real-world images, and meet a minimum quality threshold (confidence > 0.8).

Question generation and filtering. GPT-4o generates up to three cross-document question-answer pairs for each document pair using a temperature of 0.3. Each question is grounded in a verified image and in 20 sampled pages from each document, producing 1,449 candidate QA pairs. GPT-4o then evaluates each candidate on factual grounding, answer accuracy, answer completeness, cross-document dependency, absence of source leakage, and image grounding. Only candidates that satisfy every criterion and receive the highest overall quality rating are retained. Cross-document dependency and overall quality are the most restrictive criteria, with pass rates of 71.8% and 72.0%, respectively; the remaining criteria rarely eliminate candidates.

The final dataset contains 885 QA pairs grounded in 405 distinct web-sourced images, with multiple questions sharing the same image when applicable. Questions are categorized as procedural (340, 38.4%), diagnostic (292, 33.0%), or factual (253, 28.6%).

A.2 Human validation of AutoQA

To provide an independent, non-model check of benchmark quality, we drew a uniform random sample of 50 final AutoQA items and had a human annotator label each for four properties (Table 11). Answerability (80%) and reference-answer completeness (86%) are high, whereas strict cross-document necessity (46%) and correct

image grounding (52%) are lower. The human cross-document-necessity rate (46%) is below the 71.8% reported by our GPT-4o construction filter (Appendix A.1); within the final 885 items this field is always true by construction, so the filter cannot itself validate it. Part of the gap also reflects a stricter human criterion (both manuals must be *necessary*, rather than merely combining information from both). We therefore report these measured rates rather than assuming uniform benchmark quality; a larger study with inter-annotator agreement is a natural next step.

Property	Human pass rate
Answerable	40/50 (80%)
Requires both manuals	23/50 (46%)
Correctly image-grounded	26/50 (52%)
Reference answer complete	43/50 (86%)

Table 11: Human validation on a uniform random sample of 50 AutoQA items.

A.3 Qualitative Examples

We present three AutoQA items, each with the TrioRAG prediction (multi-vector index, RRF fusion, Qwen2.5-VL-7B reader) and the GPT-4o-mini judge verdict. Every question is grounded in a web-sourced anchor photo and needs evidence from two manuals. The examples span the three question types and include one failure that illustrates a characteristic cross-document error. Questions, reference answers, and judge rationales are verbatim; predictions are abridged, with [. . .] marking omitted text. The anchor figures are synthetic illustrations of each image type, not the actual benchmark images, which we release only as source URLs and content hashes (see Ethics Statement).

Example 1: Procedural (Judged correct). The anchor photo (Fig. 4) shows a counter-hold toolkit.

Question. In the photo, I see a counter-hold tool similar to T10554. How do I use it to remove the camshaft adjuster and ensure proper alignment during installation?

Reference answer. To remove the camshaft adjuster, fit the counter-hold tool T10554 with T10172A to the camshaft pulley, ensuring the pins are properly inserted into the holes. Hold the inlet camshaft in position using these tools while loosening the securing bolt of the camshaft adjuster. During installation, ensure the guide sleeve is inserted in the camshaft and renew the bolt for the camshaft adjuster, screwing it in by hand. The camshaft pulleys should be able to turn without rocking.

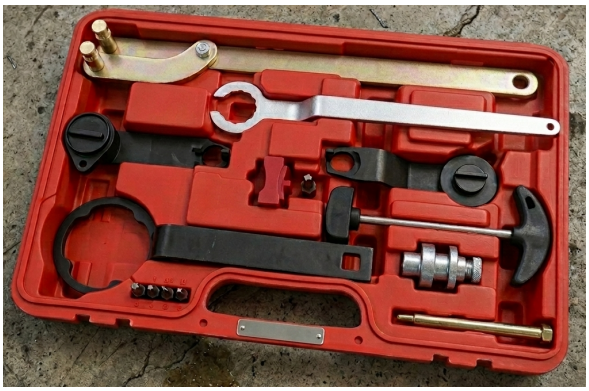

Figure 4: Synthetic illustration of the anchor image used in Example 1: a camshaft counter-hold toolkit. This is not the actual benchmark image.

Figure 5: Synthetic illustration of the anchor image used in Example 2: a transverse four-cylinder engine showing the fuel rail, injector connectors, and engine-control-unit connector.

TrioRAG prediction (abridged). Position counter-hold tool T10554 so its pins align with the holes in the camshaft adjuster and secure it with T10172A. Loosen the securing bolt one turn without fully removing it, then withdraw the adjuster from the camshaft. [. . .] To reinstall, refit T10554/T10172A to hold the camshaft, realign the adjuster, and tighten the securing bolt without overtightening. [. . .] Finally, confirm the adjuster is correctly aligned with the camshaft.

Judge (correct). "The generated answer provides a correct and detailed procedure for using the counter-hold tool T10554 to remove and reinstall the camshaft adjuster, ensuring proper alignment, which matches the expected answer."

Example 2: Factual (judged incorrect). The anchor photo (Fig. 5) shows an engine-control-unit connector with several fuel-injector leads.

Figure 6: Synthetic illustration of the anchor image used in Example 3: an engine-bay fuse box beside the battery. This is not the actual benchmark image.

Question. In the photo, I see a 91-pin connector and several fuel injector connections. How do these components interact in the 2.0L diesel engine and the 1.6L petrol engine?

Reference answer. In the 2.0L diesel engine, the 91-pin connector is linked to the engine/motor control unit (J623), which manages the injectors for cylinders 1 to 4 (N30, N31, N32, N33). For the 1.6L petrol engine, the 94-pin connector connects to the engine/motor control unit (J623), controlling the injectors similarly but with different wiring configurations (T2ln, T2lo, T2lp, T2lq). Both engines use their respective connectors to facilitate precise fuel injection timing and control.

TrioRAG prediction (abridged). The 91-pin connector is the interface between the ECU and the engine's sensors and actuators, and it controls the fuel injectors in both the 2.0L diesel and the 1.6L petrol engine. [. . .] In both engines the ECU sends signals through the 91-pin connector to open and close the injectors, with only minor differences due to engine design.

Judge (incorrect). "The generated answer incorrectly refers to a 91-pin connector for both engines instead of specifying the correct connectors for each engine; it also omits exact details about how the fuel injectors are linked to the different engine configurations as specified in the expected answer."

The model substitutes generic ECU boilerplate for the petrol engine's 94-pin connector and the cylinder-specific injector labels, a failure that requires jointly grounding both manuals rather than either alone.

Example 3: Diagnostic (judged correct). The anchor photo (Fig. 6) shows an engine-bay fuse box beside the battery.

Question. In the photo, I see the fuse holder near the battery. Which fuses should I check to troubleshoot the gearbox communication issue?

Reference answer. Check Fuse 12 on Fuse Holder B (SB12) and Fuse 6 on Fuse Holder C (SC6) as they are related to the automatic gearbox control unit. These fuses are crucial for ensuring proper communication between the gearbox and other systems. Inspect them for continuity and replace if necessary.

TrioRAG prediction (abridged). The fuse holder near the battery is Fuse holder B (SB). The fuse related to the automatic gearbox control unit (J217) is Fuse 12 (SB12). With the ignition off, locate holder B and check whether SB12 is blown, replacing it if so. [. . .] If SB12 is intact, check the gearbox relays, the wiring harnesses to the control unit, and the control unit itself, consulting the "Relays on fuse holder BSB" section for relay locations.

Judge (correct). "The generated answer correctly identifies Fuse 12 (SB12) related to the gearbox control unit and provides troubleshooting steps that align with the expected answer." *(Top-10 fused pages spanning 8 documents.)* The reader recovers the holder-B gearbox fuse SB12 but not the second relevant fuse SC6 on holder C; the judge accepts the partially complete answer, consistent with the partial-credit protocol in Section 5.3.

A.4 Prompts

AutoQA QA generation. GPT-4o receives sampled pages from both documents and the anchor photo, and is instructed to produce QA pairs. Core instructions below (abridged):

```
You are generating a cross-document multimodal QA dataset for automotive workshop manuals. You are given sampled pages from Document A and Document B and one real-world mechanic photo.
Requirements:
1. Each question is from a mechanic referencing the photo.
2. Each question must mention at least one visible detail from the photo.
3. Each pair must require both documents, combining distinct information from each.
4. The answer must fully resolve the question with document-specific details.
5. Rely on document-specific details only; do not add generic advice.
6. Use a mix of factual, procedural, and diagnostic questions.
7. Do not mention document names, page numbers, or "Document A/B".
```

```
8. State facts and procedures directly,
as an automotive expert would.
Output a JSON array of pairs, each with
question, answer, question_type, and
reference_docs.
```

Enhanced query (AutoQA). The VLM reader is prompted with the question and anchor image to produce the enhanced query; prompts for the other benchmarks differ only in domain framing.

```
You are given an automotive figure
and a question about it. Your task
is to generate a grounded natural
language question that integrates both
the textual question and the visual
information from the figure.
Instructions:
- Carefully analyze the question and the
figure simultaneously.
- Identify what parts of the figure are
relevant to the question.
- Produce a single, well-formed natural
language question that is explicitly
grounded in the visual content.
- Preserve the original intent of the
question.
- The output question should be more
specific and informative than the
original question alone.
- Do NOT answer the question. Do NOT
explain. Do NOT invent details.
Question: {question}
Grounded question:
```

Answer judging. At evaluation, GPT-4o-mini receives the question, the ground-truth answer, and the prediction, and returns a binary score.

```
You are an expert evaluator assessing
answers from a multimodal document QA
system. Evaluate whether the generated
answer correctly responds to the
question based on the expected answer.
Question: {question}
Expected Answer: {answer}
Generated Answer: {prediction}
Accuracy (0 or 1): Does the generated
answer match the factual content of the
expected answer?
- 1: Factually correct and aligns with
the expected answer.
- 0: Factually incorrect or contradicts
the expected answer.
Instructions:
- Focus on factual correctness, not
writing style or format.
- Partial matches are accurate if the
correct information is present.
- For numerical answers, check if values
match or are equivalent.
- For list answers, check if all key
elements are present.
- If the expected answer is "Not
answerable" and the generated answer
indicates inability to answer, consider
it accurate.
```

A.5 Index Footprint

For AutoQA, the unified text-and-page-image multivector collection stores 7,682 page-level points and occupies 4.2 GB on disk (3.9 GiB), including token-level vectors and payload. Each page is indexed as a single point whose multivector representation is computed in one embedding pass with *jina-embeddings-v4*.

Lightweight Temporal Attention for Video Retrieval over Frozen Image and Text Encoders

Abstract

Large-scale visual search platforms maintain production text-image embedding models trained on behaviorally-mined query-image pairs, where the text encoder is implicitly tuned to organisation-specific search vocabulary. Extending such a system to video retrieval is non-trivial: retraining risks disrupting hard-won query understanding, while naive temporal aggregation discards the sequential structure that distinguishes a door opening from a door closing. We add a lightweight temporal attention pooling head over independently encoded frame embeddings, keeping both encoders frozen and training only the pooling head and positional encodings. We train on a large-scale dataset from a commercial creative platform using bidirectional InfoNCE with a two-stage hard negative mining pipeline. Benchmarking against LoRA fine-tuned Gemma 3 (12B) and SmolVLM2, neither matches our approach despite substantially larger parameter counts. We also introduce an evaluation benchmark with graded relevance judgments annotated by a VLM judge, where each query is mapped to all relevant videos in a large corpus rather than a single ground-truth clip, avoiding protocols that greatly underestimate model quality. Our model improves nDCG@1 by 10.1% over mean-pooling overall and 25% on complex action queries. With Matryoshka Representation Learning, 256-dim embeddings retain 95.6% of full performance, and int8 quantization costs under 1% in retrieval quality.

1 Introduction

Large visual search platforms maintain production text-image embedding models trained on hundreds of millions of behaviorally-mined query-image pairs, with text encoders implicitly tuned to organisation-specific search vocabulary. Extending such systems to video is non-trivial: retraining the text encoder is prohibitively expensive and risks disrupting alignment with real-user query vocabulary, while the simplest extension—mean pooling over frame embeddings—discards temporal order entirely. Averaging frames of someone picking up a key, walking to a door, and unlocking it yields a vector indistinguishable from the same frames in reverse, making queries like *"a person entering a building"* and *"a person leaving a building"* indistinguishable.

We address this by adding a learned temporal attention pooling head on top of the frozen image encoder, with positional encodings to preserve frame order. Both encoders remain frozen throughout, preserving existing text-image alignment and allowing drop-in deployment with no changes to query serving infrastructure. We train with bidirectional InfoNCE (van den Oord et al., 2018) and a two-stage hard negative mining pipeline, and benchmark against LoRA fine-tuned generative alternatives—Gemma 3 (12B)(Gemma Team, 2025a) and SmolVLM2(Marafioti et al., 2025)—finding that, under matched adaptation on our production stack, these larger decoder-only models do not surpass the lightweight head; we treat this as evidence about this adaptation regime rather than a general scaling law, given the differing backbones. For evaluation, we construct a benchmark via two-stage candidate generation and Qwen2.5-VL-72B (Bai et al., 2025) annotation, producing graded relevance judgments with multiple ground-truth videos per query and avoiding the systematic underestimation of one-to-one protocols.

Our contributions are: **(1)** a temporal attention pooling architecture that improves nDCG@1 by 10.1% over mean pooling overall and 25% on complex action queries, **(2)** a two-stage hard negative mining pipeline with BLIP (Li et al., 2022) ITM reranking and margin-based false-negative filtering over 225K training clips, **(3)** an evaluation benchmark of 400+ queries with pooled graded

[*] Equal contribution.

EMNLP 2026 Industry Track, pages 1976–1994

relevance judgments across nine categories, and **(4)** a production-readiness analysis covering Matryoshka embeddings (Kusupati et al., 2022), int8 quantization, and sparse-dense hybrid retrieval on a real-world corpus of 100K videos.

2 Related Work

Video-Text Retrieval. Since CLIP (Radford et al., 2021) established contrastive image-text pretraining at scale, the dominant strategy for video-text retrieval has been to adapt image encoders to video via temporal aggregation over per-frame features. CLIP4Clip (Luo et al., 2022) showed mean pooling is surprisingly competitive for short clips. Frozen in Time (Bain et al., 2021) trained a joint encoder end-to-end treating images as single-frame videos. InternVideo2 (Wang et al., 2024) scaled contrastive and masked pretraining to 6B parameters, Cap4Video (Wu et al., 2023) added auto-generated captions as training signal, and X-Pool (Gorti et al., 2022) explored query-conditioned frame pooling at inference time. Our work differs from all of these: rather than pretraining from scratch, we add a lightweight head on top of an existing production encoder, preserving its retrieval behaviour, a practically important distinction in industrial settings where retraining a production encoder is prohibitive. Parameter-efficient adaptations of frozen CLIP for video—RAP (Cao et al., 2024), Lin et al. (2022), and STAN (Liu et al., 2023a)—insert or adapt modules *within* the backbone, whereas our head sits strictly *on top* of a frozen proprietary encoder with no backbone access, a stricter constraint that enables drop-in deployment. Prior temporal probes and bias analyses—the shuffled-frame tests of SViTT (Li et al., 2023a) and the single-frame-bias study of Lei et al. (2023)—motivate our judge-free shuffle/reversal probe (Section 5.4).

Temporal Modeling. I3D (Carreira and Zisserman, 2017), SlowFast (Feichtenhofer et al., 2019), TimeSformer (Bertasius et al., 2021), ViViT (Arnab et al., 2021), and Video Swin (Liu et al., 2022) each tackle spatiotemporal modeling at increasing complexity and parameter cost. TSM (Lin et al., 2019) showed that temporal channel shifting adds zero parameters yet meaningfully improves temporal understanding, VideoMAE (Tong et al., 2022) established that high-ratio tube masking forces strong spatiotemporal representations during pretraining. Our attention pooling head follows TSM's lightweight philosophy: minimal added parameters focused on preserving temporal position. Our pooling mechanism—a learnable query attending over frame embeddings as keys and values—is an instance of attention-based set aggregation (Lee et al., 2019), also used for video in X-Pool (Gorti et al., 2022) and CLIP4Clip (Luo et al., 2022); our contribution is not the operator but its use as a drop-in, frozen-encoder head that preserves a production text tower's alignment, together with the deployment study and graded benchmark.

Hard Negatives in Contrastive Learning. Hard negative mining is well-established in metric learning (Schroff et al., 2015), dense retrieval (Karpukhin et al., 2020; Xiong et al., 2021), and vision-language pretraining (Radenovic et al., 2023; Ye et al., 2023). False negatives — semantically equivalent pairs mislabelled as negative — are a known failure mode (Chuang et al., 2020; Robinson et al., 2021) that is particularly acute in large video corpus where many clips cover identical scenes. Our margin-based filtering retains a candidate as a hard negative only if its ITM similarity to the anchor falls below the positive-pair score by a fixed margin, directly addressing this.

Flexible Embeddings and Sparse Retrieval. MRL (Kusupati et al., 2022) jointly optimises nested embedding sub-vectors, enabling one model to serve multiple dimensionalities without separate projection heads. SPLADE (Formal et al., 2021) and ColBERT (Khattab and Zaharia, 2020) offer complementary sparse and late-interaction trade-offs, we explore the former via a Residual Autoencoder baseline. To our knowledge, ours is the first application of MRL to video embeddings.

LLM-Based Evaluation. LLM-as-judge evaluation (Zheng et al., 2023; Liu et al., 2023b) is now widely used for open-ended tasks. We use Qwen2.5-VL-72B (Bai et al., 2025) to assign continuous relevance scores in $[0, 1]$, thresholded at 0.85 to form ground-truth sets, following graded judgment protocols from TREC Deep Learning (Craswell et al., 2021) that produce more stable system rankings than binary qrels — particularly important when a corpus contains many near-duplicate relevant documents.

3 Method

3.1 Problem Formulation

We want to learn functions f_V and f_T that embed videos and text queries into a shared metric space $\mathbb{R}^d$ such that $\text{sim}(f_V(V), f_T(q))$ is high when V is a good retrieval result for query q and low otherwise. A video V is represented as a sequence of N frames $\{I_1, \ldots, I_N\}$ sampled at 2 FPS up to a maximum of 120 frames, covering up to 60 seconds of footage. Both functions produce L2-normalised vectors with $d = 768$ by default.

3.2 Architecture

The architecture (Fig. 1) is intentionally minimal: encode frames independently, add positional awareness, and learn to attend.

We build on two components of an in-house production text-image embedding system trained on hundreds of millions of behaviorally-mined query-image pairs from a large commercial creative platform: PROVE (Production Visual Encoder), a ViT-L/14-based image encoder, and PROTE (Production Text Encoder), its paired text tower implicitly tuned to organisation-specific search vocabulary. Both are kept frozen in all our experiments, and we refer to them by these names throughout the paper.

Given frames $\{I_1, \ldots, I_N\}$, we compute per-frame embeddings using the frozen PROVE:

$$e_i = f_{\text{PROVE}}(I_i) \in \mathbb{R}^d, \quad i = 1, \ldots, N \tag{1}$$

Learnable positional encodings $p_i \in \mathbb{R}^d$ are added to each frame embedding to preserve temporal order:

$$\tilde{e}_i = e_i + p_i \tag{2}$$

These position-augmented embeddings pass through L transformer encoder layers and are compressed to a single L2-normalised vector by an attention pooling step:

$$v = \text{normalize}(\text{AttnPool}(\{\tilde{e}_1, \ldots, \tilde{e}_N\})) \in \mathbb{R}^d \tag{3}$$

We call it attention pooling as learnable query vectors attend over frames as keys/values to compress T frames into a single vector [B, D], where B is batch size and D is the embedding dimension. The temporal ordering is injected via positional encodings, and the attention itself is used for intelligent aggregation.

The frozen PROTE produces query embeddings in the same space as $\mathbf{v}$. Keeping both PROVE and PROTE frozen ensures the video embedding never drifts away from the established text-image alignment, and makes the system a drop-in extension to existing retrieval infrastructure with no changes to query serving. We train with bidirectional InfoNCE (van den Oord et al., 2018), summing symmetric video-to-text and text-to-video losses over in-batch negatives augmented with the hard negatives described in Section 4.2, using a learnable temperature initialised to $\tau = 0.07$. We compare our temporal attention pooling head against the following alternative aggregation strategies: mean pooling over frame embeddings (the production baseline), video thumbnail embedding, and two generative alternatives—SmolVLM2 (2.2B parameters) and Gemma 3 (12B parameters)—each LoRA fine-tuned to produce fixed-size embeddings. These generative baselines are LoRA fine-tuned on the language decoder only, with all other weights frozen, using the same bidirectional InfoNCE loss as our model. For text, query tokens are passed directly to the decoder, for video, frame embeddings flow through the vision encoder and cross-modal projector before the decoder, with the final hidden state L2-normalised as the embedding in both cases. The generative models produce 3072-dimensional embeddings versus 768 for PROVE-based variants, at substantially higher inference cost and no retrieval gain.

3.3 Matryoshka Representation Learning

After the base model is fully trained at $d = 768$, we continue from the best checkpoint using MRL (Kusupati et al., 2022) over a nested dimension set $\mathcal{D} = \{768, 512, 256\}$:

$$\mathcal{L}_{\text{MRL}} = \frac{1}{|\mathcal{D}|} \sum_{d \in \mathcal{D}} \mathcal{L}_{\text{InfoNCE}}(v_{1:d}, t_{1:d}) \tag{4}$$

where $v_{1:d}$ is the first d dimensions of the full embedding. This jointly optimises all three dimensionalities in a single training pass, forcing the model to pack the most salient temporal information into the earliest dimensions. At inference, any prefix of the embedding is usable directly without a separate projection head.

4 Datasets and Evaluation Setup

4.1 Training Data

We train on roughly 225K videos drawn from a commercial creative video platform: around 213K commercial clips and around 12K generated clips

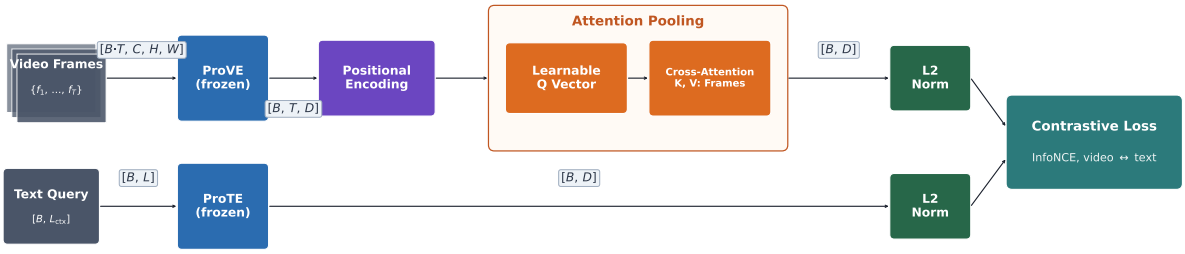

Figure 1: Architecture overview. Each video frame is independently encoded by the frozen PROVE image encoder. Learned positional encodings (PE) are added to preserve temporal order. A cross-attention pooling head then aggregates the frame sequence into a single video embedding $\mathbf{v}$: a learnable query vector $\mathbf{Q}$ attends over the frame embeddings as keys $\mathbf{K}$ and values $\mathbf{V}$, where $\mathbf{Q}$ is a trained parameter independent of the input while $\mathbf{K}$ and $\mathbf{V}$ are derived from the encoded frames. The frozen PROTE text encoder maps the query to embedding $\mathbf{t}$ in the same space. Bidirectional InfoNCE aligns the two embedding spaces during training.

from a text-to-video generation model on the same platform, each up to one minute long. Frames are sampled at 2 FPS, giving up to 120 frames per video. For each video, we generate annotations using Gemma 3n (Gemma Team, 2025b) in a two-stage pipeline: a dense `complex_summary` capturing action, scene, mood, and cinematography, followed by structured extraction of short prompts, multi-clause `complex_prompts`, intents, objects, and style, which serve as positive text for contrastive training. See Appendix A for some samples of the dataset.

4.2 Hard Negative Mining

Random in-batch negatives are easy. A random video from a library of hundreds of thousands is almost certainly not semantically similar to a given anchor, so the model learns nothing from it once basic categories are separated. We need negatives that are close enough to the anchor to force the model to learn fine-grained distinctions. Our pipeline runs in two stages (Fig. 2).

Stage 1: Dense Candidate Retrieval. For each anchor, we retrieve 128 candidate negatives from the training corpus using a fused embedding:

$$q_{\text{fused}} = \left[\alpha{\cdot}\text{norm}(u_T) \,\|\, \alpha{\cdot}\text{norm}(u_V)\right], \quad \alpha = 0.5 \tag{5}$$

where u_T comes from GTE-large-en-v1.5 (Li et al., 2023b) encoding the video's `complex_summary` described in Section 4, and u_V comes from SigLIP-base-patch16 (Zhai et al., 2023) encoding a 60-frame grid of the video. We search a FAISS (Johnson et al., 2021) `IndexFlatIP` index over the full training video corpus.

Stage 2: Cross-Modal Reranking and Margin Filtering. The 128 candidates are reranked with BLIP (Li et al., 2022) Image-Text Matching (ITM) scores. For anchor A (text T_A, video V_A) and candidate C (text T_C, video V_C), we compute:

$$S(A, C) = \tfrac{1}{2}\left[S_{\text{t2i}}(T_A, V_C) + S_{\text{i2t}}(T_C, V_A)\right] \tag{6}$$

The symmetric formulation catches asymmetric cases (two clips covering similar but not identical content) that a one-directional score would miss. We then apply a margin filter: a candidate is retained only if

$$S(A, C) < S_{\text{pos}}(A) - m, \quad m = 0.15 \tag{7}$$

where $S_{\text{pos}}(A)$ is the positive-pair ITM score for anchor A. The top-8 retained candidates become the hard negatives for that anchor. The margin prevents videos covering the same scene from being pushed apart during training.

4.3 Benchmark Construction

Standard evaluation practice links each query to exactly one correct video, which systematically underestimates quality on a large video corpus where dozens of clips are equally valid answers for a query like *"a dog running in a park."* Retrieving the right kind of video but the wrong specific clip counts as a complete failure, consistently underestimating the quality of any reasonably good model.

Our benchmark contains 400+ queries covering nine semantic categories: test set queries (100), followed by synthetically generated complex multi-clause queries (100), action/activity recognition (50), subject/object detection (40), scene and setting recognition (40), cinematography (40), emotion and expression (25), theme and topic (25), and

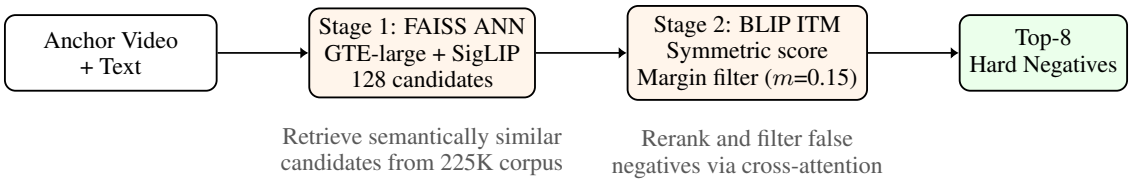

Figure 2: Two-stage hard negative mining pipeline. Stage 1 retrieves 128 candidate negatives per anchor using a fused text+vision query against the full training corpus via FAISS. Stage 2 reranks candidates with BLIP image-text matching and discards any that exceed the positive-pair score minus margin m, preventing semantically equivalent videos from being treated as negatives.

Table 1: Overall retrieval on the Golden Benchmark (14K test set). Bold: best per metric. @K denotes nDCG@K.

Model	@1	@3	@5	@10
ProVE Mean Pool	0.7729	0.7503	0.7372	0.7149
SmolVLM2-2.2B (LoRA)	0.6539	0.6305	0.6123	0.5929
Gemma3-12B (LoRA)	0.7282	0.6999	0.6870	0.6734
ProVE + Attn Pool (ours)	**0.8509**	**0.8241**	**0.8122**	**0.7970**

visual attributes (5). The categories are designed to stress-test specific aspects of video understanding.

For each query, we collect the top-100 videos retrieved across several different candidate text-to-video retrievers, forming a candidate pool. We then run Qwen2.5-VL-72B (Bai et al., 2025) on every (query, video) pair, asking the model to assign a relevance score in $[0, 1]$. Any video scoring above 0.85 is included in that query's ground-truth set, with the score used as a relevance grade in the nDCG computation.

5 Experiments

5.1 Results on the Golden Evaluation Benchmark

Table 1 shows overall performance on the golden benchmark (14K test videos). Temporal attention pooling improves nDCG@1 by 10.1% over mean pooling. The two generative model baselines, SmolVLM2 (2.2B) and Gemma 3 (12B), both fall below mean pooling despite having far more parameters. Gemma 3 alone produces 3072-dimensional embeddings versus 768 for ProVE variants, at substantially higher inference cost and no retrieval gain. We read this as a statement about the adaptation regime—decoder-only LoRA with last-hidden-state pooling is not a competitive embedding recipe here—rather than a general scaling law, since backbone and adaptation differ across these models. See Appendix B for a detailed qualitative analysis of these results.

Table 2: Per-category nDCG@1 on the Golden Benchmark. Gain is relative to mean pooling. The nine benchmark categories omit two here: the general *test-set queries* bucket and *visual attributes* (n=5, too small for a stable per-category estimate; reported as indicative only in Appendix F).

Category	Mean Pool	Attn Pool	Gain
Complex Queries	0.5572	0.6965	+25.0%
Subject/Object Detect.	0.7890	0.9150	+16.0%
Scene/Setting Recogn.	0.8426	0.9588	+13.8%
Emotion/Expression	0.8675	0.9591	+10.6%
Action/Activity	0.8182	0.8713	+6.5%
Theme/Topic	0.8904	0.9213	+3.5%
Cinematography	0.8566	0.8714	+1.7%

5.2 Category-Level Analysis

Table 2 breaks down results by query category. The gains are largest where temporal ordering matters most. Complex multi-clause queries gain 25.0% in nDCG@1. Subject/object detection gains 16.0%, likely because attention can focus on the frames where a particular object is most visible rather than averaging its presence across the full clip. Scene and setting recognition gains 13.8%.

Cinematography queries (those specifying camera behavior like *"a tracking shot"* or *"slow motion"*) show the smallest gain at 1.7%. Identifying camera motion from independently encoded 2-FPS frames is harder than identifying scene content: subtle motion blur and camera trajectory information is largely lost at that sampling rate.

5.3 Comparison Against Learned Aggregation Baselines

In addition to other baselines, we compare against two strong learned aggregators built on the identical frozen ProVE frame features, trained with the same data, bidirectional-InfoNCE loss, and hard-negative pipeline, so that only the aggregation mechanism differs: a CLIP4Clip-seqTransf

Table 3: Aggregation heads over identical frozen PROVE features. @K = nDCG@K; * = improvement over mean pooling significant at $p_{\text{holm}} < 0.05$ (paired randomization test). Computed on the statistics re-run described in Appendix F; full CIs and p-values there.

Head (frozen PROVE)	@1	@3	@5	@10
Mean pooling (baseline)	0.786	0.762	0.748	0.726
CLIP4Clip-seqTransf	0.773	0.746	0.730	0.707
X-Pool (reranker)	0.774	0.766	0.761	0.753
ProVE Attn pool, −PE	0.814	0.792	0.783	0.762*
ProVE Attn pool, L=4	0.838	0.808*	0.796*	0.780*
ProVE Attn pool, L=2	0.845	0.820*	0.807*	0.795*
ProVE Attn pool, L=1 (ours)	**0.851**	**0.824***	**0.812***	**0.797***

sequence Transformer (Luo et al., 2022) and query-conditioned X-Pool (Gorti et al., 2022). We also vary the pooling depth L in our architecture.

As shown in (Table 3), CLIP4Clip sits at or below mean pooling across cutoffs; X-Pool trails mean pooling at nDCG@1 but edges above it at nDCG@3,5,10. Both stay well below our attention head. X-Pool pools each video conditioned on the query, so it has no static per-video embedding and cannot be indexed once for ANN retrieval; we evaluate it as a two-stage reranker, its only deployable form for this use case (Appendix G). Increasing pooling depth gives no benefit (L=1 $\geq$ L=2 $\geq$ L=4).

5.4 Isolating Temporal Order from Frame Selection

Attention pooling could outperform mean pooling for two distinct reasons: it may learn to *select* the most informative frames (an order-invariant effect), or it may exploit *temporal order* through the positional encodings. We disentangle a positional-encoding (PE) ablation and a judge-free order-perturbation probe. Every model here is trained on the identical frozen PROVE frame embeddings and frozen PROTE, with the same training data, bidirectional-InfoNCE loss, and hard-negative pipeline, so any difference is attributable to the aggregation mechanism alone.

Positional-encoding ablation. Removing the positional encodings leaves only learned frame selection and makes the head permutation-invariant also evident from drop in nDCG shown in (Table 3). This retains just $+0.029$ nDCG@1 over mean pooling (vs. $+0.065$ for the full head) and is not significant after Holm correction at nDCG@{1,3}, whereas the full model is significant at nDCG@{3,5,10} (p_{holm}=0.040). Positional encoding therefore accounts for ≈56% of the nDCG@1 gain, localizing the statistically robust portion of the improvement to temporal ordering rather than frame selection. Per-cutoff CIs, Δ intervals, and p-values for all models are reported in Appendix F.

Table 4: Retrieval on 100K test videos set with user behavioral queries. @K denotes nDCG@K.

Model	@1	@3	@5	@10
ProVE Thumbnail	0.7928	0.7839	0.7816	0.7645
ProVE Mean Pool	0.7824	0.7611	0.7430	0.7237
ProVE Attn Pool	**0.8463**	**0.8360**	**0.8218**	**0.8119**

Frame-shuffle/reversal probe (judge-free). For 200 test queries and their top-10 retrieved videos (∼2,000 query–video pairs), we recompute query–video cosine similarity under (i) random frame shuffling and (ii) full frame reversal. Mean pooling is permutation-invariant and unchanged by construction; our head's similarity drops under shuffling in 62.0% of cases and under reversal in 63.5%, with the largest drops on strongly order-dependent queries. The non-degrading cases are queries for which order is genuinely irrelevant (static scenes, or content recognizable regardless of playback direction, e.g. *"time-lapse of ice melting in a glass"*).

5.5 Evaluation on User Behavioral Queries

We also evaluated all three ProVE variants on $100K$ unseen videos from the same commercial creative video platform, using $1K$ real user queries from that platform's search logs, having a mix of high, medium, and low frequency queries. Table 4 includes the thumbnail baseline alongside the mean pooling and attention pooling. Temporal attention leads by a clear margin. Notably, thumbnail embeddings (0.7928) slightly outperform mean pooling (0.7824) in overall nDCG@1, an inversion of what one might expect, given that thumbnails encode a single frame. This suggests that for certain query types, averaging across many frames introduces more redundancy than signal, making a single well-chosen frame more effective.

5.6 Matryoshka Embedding Analysis

Table 5 shows the dimension-performance trade-off after MRL fine-tuning. The 512-dimensional model retains 98.6% of the full 768 nDCG@1. The 256-dimensional model retains 95.6%. More striking is the cross-model comparison: the 256-

Table 5: MRL dimension-performance on the Golden Benchmark. @K denotes nDCG@K.

Model	@1	@3	@5	@10
ProVE Mean Pool [768]	0.7729	0.7503	0.7372	0.7149
ProVE Attn Pool [768]	0.8509	0.8241	0.8122	0.7970
ProVE Attn Pool [512]	0.8386	0.8122	0.8018	0.7854
ProVE Attn Pool [256]	0.8135	0.7772	0.7619	0.7487

Table 6: int8 vs. full-precision (float32) *embeddings* on Express 100K. @K denotes nDCG@K.

Model	Fmt	@1	@3	@5	@10
Thumbnail	fp32	0.7928	0.7839	0.7816	0.7645
Thumbnail	int8	0.7885	0.7819	0.7772	0.7610
Mean Pool	fp32	0.7824	0.7611	0.7430	0.7237
Mean Pool	int8	0.7813	0.7536	0.7416	0.7188
Attn Pool	**fp32**	**0.8463**	**0.8360**	**0.8218**	**0.8119**
Attn Pool	int8	0.8389	0.8297	0.8205	0.8099

dim attention-pooled model (0.8135) still beats the full 768-dim mean-pooling baseline (0.7729) by a wide margin. Temporal aggregation quality matters more than embedding capacity for this task. With MRL, a deployment that needs smaller indexes or faster ANN search can use 256-dimensional embeddings without falling below the quality of the production baseline.

5.7 Deployment Analysis

Embedding quantization. Storing tens of millions of float32 embeddings is expensive. Table 6 shows that quantising attention-pooled embeddings from float32 to int8 costs only 0.74% drop in nDCG@1. All three model variants show similarly negligible degradation.

Sparse-dense hybrid retrieval. We evaluate sparse-dense hybrid retrieval using a Residual Autoencoder (RAE) that projects 768-dim dense embeddings into a 16,384-dim sparse space suitable for inverted-index retrieval. Table 7 compares three modes: pure dense (FAISS ANN), pure sparse RAE, and a hybrid that uses RAE to recall the top-100 candidates and reranks by dense cosine similarity. Pure RAE alone falls 6.6% below pure dense, but the hybrid closes most of that gap and marginally outperforms pure dense (0.8497 vs. 0.8463 nDCG@1). This is relevant for production deployments at scale where pure ANN search over dense vectors incurs significant latency and infrastructure cost, inverted indexes offer well-understood operational advantages in such settings,

Table 7: Dense vs. sparse RAE vs. hybrid retrieval on Express 100K. @K denotes nDCG@K.

Mode	@1	@3	@5	@10
Pure Dense	0.8463	**0.8360**	**0.8218**	**0.8119**
Pure RAE	0.7749	0.7401	0.7311	0.7106
Hybrid (N=100)	**0.8497**	0.8334	0.8193	0.8094

and the hybrid recovers nearly all the retrieval quality of pure dense search. In this work, we reuse a sparse RAE trained over ProVE embeddings without any additional fine-tuning, suggesting the approach generalises across retrieval heads built on the same backbone.

5.8 Production Deployment

The model is deployed as a chain of microservices coordinated by a central orchestrator. On video ingestion, the pipeline downloads the video, extracts frames at 2 FPS, encodes each frame independently via ProVE across a parallel fanout, and passes the resulting embeddings through the temporal attention aggregator to produce a single dense vector and optional sparse projection for inverted-index retrieval. Both embeddings are written to the search index, making the video immediately retrievable. Appendix D provides a detailed capacity analysis showing that this pipeline can index a corpus of 100M videos within 7 days.

6 Conclusion

We showed that a lightweight temporal attention pooling head trained on top of frozen production encoders (ProVE and ProTE) delivers substantial gains for large-scale video-text retrieval without modifying any pretrained weights. Our model improves nDCG@1 by 10.1% overall and by 25% on complex multi-clause action queries. Matryoshka training retains 95.6% of full performance at 256 dimensions, and int8 quantization costs under 1% in retrieval quality, making the system deployable across a range of infrastructure budgets.

Several directions remain open. A promising one is replacing independent frame encoding with a full spatiotemporal attention layer—attending jointly across spatial patches and the temporal axis—to capture fine-grained motion and object interactions that frame-level pooling misses. Further directions, including event-ordering-aware hard negatives, higher-frame-rate sensing, and multilingual fine-tuning, are discussed in Appendix J.

Limitations

Proprietary training data. Our model is trained and evaluated on an internal dataset from a commercial creative platform, which limits direct reproducibility and comparison with publicly available video retrieval benchmarks such as MSR-VTT or ActivityNet.

Evaluation benchmark scope. Our evaluation benchmark comprises 400+ queries drawn from a single platform's search logs, annotated by a single VLM judge (Qwen2.5-VL-72B). While graded relevance judgments are increasingly reliable, the benchmark is not publicly released, and the annotation process is subject to the temporal reasoning limitations and potential self-enhancement bias of the judge model and candidate retrievers.

Fixed frame sampling rate. Frames are sampled at a fixed 2 FPS, which discards fine-grained motion information. This is the primary reason cinematographic queries show the smallest gains, and it limits the model's ability to distinguish subtle temporal patterns such as camera motion or fast action sequences. However for a semantic search platform, which is also powered by personalized and deep neural rankers, these limitations are acceptable.

English-centric training. The temporal attention head is trained exclusively on English query-video pairs. Our multilingual evaluation(Appendix C) therefore reflects the generalisation of a separately trained multilingual text encoder rather than multilingual temporal understanding per se, limiting conclusions about how well the pooling head itself transfers across languages.

Single-encoder dependency. The entire approach is contingent on the quality of the underlying production encoders (PROVE and PROTE). Organisations without a strong pretrained text-image encoder trained on domain-specific behaviorally-mined data may not observe the same gains, limiting the generalisability of the frozen-encoder design choice.

A Training Dataset Samples

The training corpus contains roughly 225K videos: around 213K from a large commercial video library and around 12K community-generated clips from a creative AI platform. Every video is at most one minute long and is sampled at 2 FPS, giving a maximum of 120 frames per clip.

Annotation pipeline. Raw video footage along with paired text queries or descriptions are required for contrastive training. For each video, we run Gemma 3n (Gemma Team, 2025b) in a two-stage prompting pipeline. Stage 1 generates a `complex_summary`: a single dense paragraph that covers action, objects, setting, lighting, composition, camera angles, color palette, depth of field, and overall mood. Stage 2 takes the complex summary as context and extracts the remaining structured fields. Table 8 lists all generated fields and their roles in training.

Field	Role
`complex_summary`	Dense stylistic+content paragraph (Stage 1)
`summary`	Concise content description
`prompts`	Short search queries (4–8 words)
`complex_prompts`	Multi-clause queries with camera/temporal detail
`objects`	Primary visual objects and subjects
`colors`	Prominent colors
`structure`	Scene organisation and pacing description
`style`	Lighting, composition, camera movement
`intents`	Likely search intent keywords
`purposes`	Creator intent (inform, evoke emotion, etc.)

Table 8: Annotation fields generated per video by the Gemma 3n pipeline. The `prompts` and `complex_prompts` fields serve as the positive text examples for each video during contrastive training.

The `prompts` field produces short keyword-style queries, `complex_prompts` produces longer multi-clause descriptions capturing temporal structure, camera behavior, and compositional detail. Both are used as positive text paired with the corresponding video during contrastive training. After annotation the dataset splits into roughly 211K training and 14K test videos.

Sample annotations. Figures 3–5 show three representative videos with uniformly-sampled frames and generated annotations. The `complex_summary` is truncated to two sentences, all `prompts` and three representative `complex_prompts` are shown in full.

B Qualitative Results Analysis

We present five queries chosen to span the main query types evaluated in Section 5: a cinematographic description requiring low-angle framing, two sequential-action queries, a temporal state-change query, and a simple object-action query. For each query, Figures 6–10 show six uniformly-sampled keyframes from the top-1 video retrieved by each of the four models, ordered left to right in temporal sequence. The row labelled **Attn Pool** is our model, the remaining three rows are the baselines.

C Multilingual Queries

Table 9 reports dense-retrieval nDCG@1 for the multilingual ProTE text encoder across five languages, evaluated against the temporal attention video embeddings. European languages (French, German) fall within 2.5% of English. Spanish lags by 4.6%. Chinese shows the largest drop at 7.7% below English. This pattern is consistent with findings from cross-lingual video retrieval work (Roditchenko et al., 2023) and points to data coverage rather than architecture as the bottleneck. The multilingual model scores lower than the English-specialised temporal attention model even on English (0.7900 vs. 0.8463), confirming the expected trade-off between multilingual coverage and single-language quality.

Table 9: Multilingual retrieval nDCG@1 using the ProTE multilingual text encoder over temporal attention video embeddings.

Language	Dense	RAE	Hybrid
English	0.7900	0.7308	0.7916
French	0.7644	0.6948	0.7632
German	0.7652	0.7016	0.7722
Spanish	0.7438	0.6703	0.7599
Chinese	0.7128	0.6611	0.7178

D Production Deployment at Scale

D.1 Pipeline Architecture

The video embedding pipeline is deployed as a chain of microservices coordinated by a central orchestrator. On video ingestion, the pipeline executes the following stages: **(1) Video download** — the raw video is fetched and staged for processing. **(2) Frame extraction** — frames are sampled at 2 FPS, producing 60 frames for an average 30-second video. This stage runs on CPU. **(3) Frame encoding** — each frame is encoded independently by PROVE, with the GPU-accelerated encoding service processing 1,024 frames per second per pod across a parallel fanout. This is the only GPU stage in the pipeline. **(4) Temporal aggregation** — the aggregator collects all frame embeddings and passes them through the temporal attention pooling head, producing a single dense 768-dim vector. Runs on CPU. **(5) Sparse projection** — the dense embedding is projected through the RAE to produce a 16,384-dim sparse vector for inverted-index ingestion. Runs on CPU. **(6) Index update** — both dense and sparse embeddings are written to the search indexing service, making the video immediately retrievable.

D.2 Per-Video Latency

Table 10 reports the wall-clock latency per stage for an average 30-second video (60 frames at 2 FPS). The end-to-end latency per video is approximately 5.13 seconds, dominated by frame extraction at 5,000 ms. PROVE frame encoding at 1,024 frames/sec processes 60 frames in approximately 59 ms, making it negligible relative to extraction.

Table 10: Per-video latency breakdown for an average 30-second video (60 frames at 2 FPS).

Stage	Hardware	Latency	% Total
Frame Extraction	CPU	5,000 ms	97.4%
Frame Encoding (PROVE)	GPU	59 ms	1.1%
Temporal Aggregation	CPU	50 ms	1.0%
Sparse Projection	CPU	20 ms	0.4%
Total		**5,129 ms**	**100%**

Duration: 7s

`complex_summary:`
"The video shows a series of shots focusing on a blue road sign indicating the direction to Lyon International Airport. The sign is consistently positioned in the lower left quadrant against a clear, bright blue sky with scattered wispy clouds. [. . .]"

`prompts:`
"Blue road sign Lyon Intl. Airport right arrow"
"Airport sign Lyon Intl. Airport airplane"
"Blue sky airplane airport sign"
"Directional sign Lyon Airport"
"Travel sign Lyon Intl. Airport"

`complex_prompts:`
"Low-angle shot of a blue airport sign indicating Lyon Intl. Airport with a right-pointing arrow, with an airplane flying in the background."
"High-angle shot of a blue airport sign with a right-pointing arrow, with an airplane descending towards the airport."
"A clear blue sky with scattered wispy clouds, featuring a blue airport sign with the text Lyon Intl. Airport and a right-pointing arrow."

Figure 3: Dataset Sample 1

Duration: 8s

`complex_summary:`
"The video features a middle-aged man, likely a doctor, in a medical office setting. He is consistently dressed in a white lab coat over a light-colored shirt and wears glasses and a stethoscope with red tubing around his neck. [. . .]"

`prompts:`
"Doctor smiling in medical office"
"Man forming heart with hands"
"White lab coat"
"Heart-shaped object"
"Medical care compassion"

`complex_prompts:`
"Middle-aged man in a white lab coat smiling warmly at the camera in a bright medical office, forming a heart shape with his hands."
"Doctor with a stethoscope and glasses creating a heart gesture, conveying care and compassion in a yellow-walled clinic."
"Optimistic and reassuring scene of a doctor in a medical setting, emphasising heart health and patient well-being."

Figure 4: Dataset Sample 2

D.3 Capacity Planning for 100M Videos

To index a corpus of 100M videos (average duration 30 seconds) within a 7-day window, the required sustained throughput is:

$$T_{\text{required}} = \frac{100{,}000{,}000}{7 \times 24 \times 3600} \approx 165 \text{ videos/sec} \quad (8)$$

Table 11 reports per-service throughput and pod requirements. CPU services are hosted on `c5.24xlarge` instances ($4.08/hr, 96 vCPUs), with 26 pods per instance. The PROVE encoding service is hosted on `g5.xlarge` instances ($1.006/hr, 1× NVIDIA A10G), with one GPU pod per instance.

The total 7-day on-demand cost is $22 \times \$56.95 \times 168 \approx \$8{,}028$, broken down as $6,169 for CPU instances and $1,859 for GPU instances.

Table 11: Pod and instance sizing to sustain 165 videos/sec for 7 days over a 100M-video corpus. CPU pods run on `c5.24xlarge` (26 pods/instance); GPU pods run on `g5.xlarge` (1 pod/instance).

Service	HW	vid/s/pod	Pods	Instances	Cost/hr
Frame Extraction	CPU	0.80	210	9	$36.72
Frame Encoding (PROVE)	GPU	17.07	11	11	$11.07
Temporal Aggregation	CPU	80.00	3	1	$4.08
Sparse Projection	CPU	200.0	2	1	$4.08
Total			**226**	**22**	**$56.95**

Duration: 14.5s

`complex_summary:`
"The video showcases a breathtaking panoramic view of a vast mountain valley with high altitudes and lush vegetation. The scene is dominated by towering, rugged mountains on either side, their slopes covered in a mix of rocky terrain and vibrant green vegetation, including trees and grassy areas. [. . .]"

`prompts:`
"Mountain valley with wildflowers"
"Panoramic mountain landscape"
"Wildflower meadow in mountains"
"Mountain valley with clouds"
"Tranquil mountain scene"

`complex_prompts:`
"Panoramic view of a vast mountain valley with towering rugged mountains, slow pan-and-tilt camera movement across dense purple, yellow, and white wildflowers."
"Wide-angle shot of a valley floor filled with wildflowers and tall green grasses, dynamic sky with blue patches and fluffy white clouds, natural soft diffused lighting."
"Eye-level perspective of a mountain landscape emphasising immersion, with composition utilising the Rule of Thirds to frame wildflowers and distant mountain ranges."

Figure 5: Dataset Sample 3

Query: "A low-angle shot of a person catching a basketball and then shooting a basket"

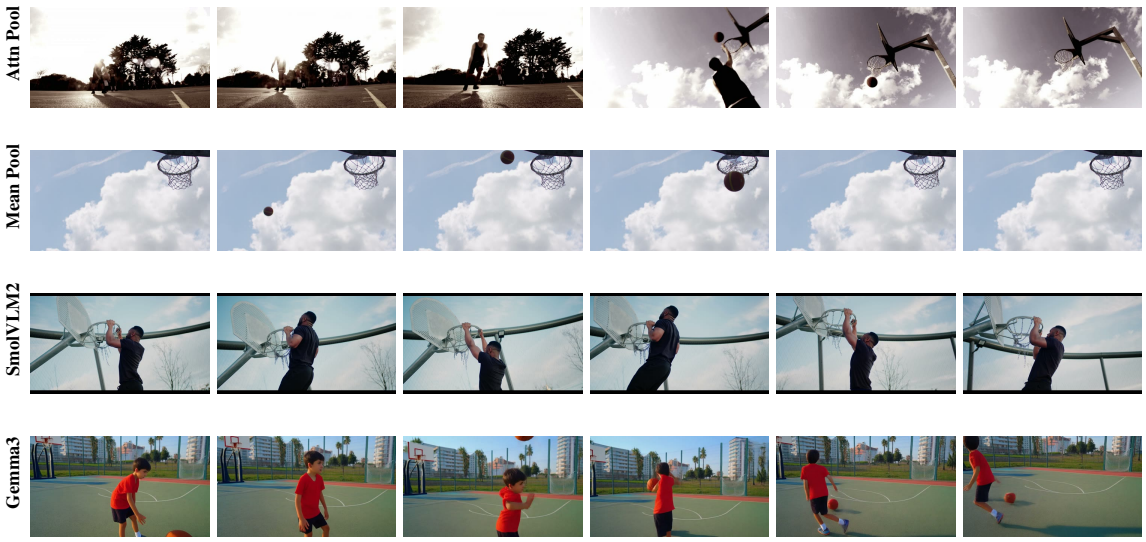

Figure 6: Attn Pool retrieves a genuine low-angle outdoor court clip showing a player catching and shooting across frames, matching both the camera angle and the sequential action. Mean Pool finds a basketball hoop from below against a bright sky but the person is absent, the frame-averaging weighted the static hoop-and-sky appearance over the motion. SmolVLM2 gets the low-angle perspective and a player near a hoop but shows the person hanging on the backboard rather than executing a catch-and-shoot. Gemma3 retrieves a child playing on an outdoor court, missing the adult, the camera angle, and the two-stage action entirely.

D.4 Analysis

Frame extraction is the sole bottleneck. Of the 226 pods required, 210 (92.9%) are CPU-bound frame extractors. All ML inference services combined — PROVE encoding (11 GPU pods), temporal aggregation (3 CPU pods), and sparse projection (2 CPU pods) — require only 16 pods across 13 instances. This confirms that scaling the corpus does not require scaling ML infrastructure proportionally. GPU-accelerated video decoding, for example via hardware decode units on modern cloud

Query: "A child runs towards an adult and gives them a hug"

Figure 7: Attn Pool shows the full temporal sequence, an adult crouching and waiting, the child closing the distance, and the hug completing across the six frames. Mean Pool retrieves a child running outdoors near a tree with an adult visible, which matches the scene type, but the hug never appears across the frames. SmolVLM2 retrieves two adults hugging indoors, capturing the endpoint gesture but not the child or the running approach. Gemma3 finds a toddler with outstretched arms being lifted, which gets the child and the physical contact but not the directed running motion.

Query: "A time-lapse of a flower wilting"

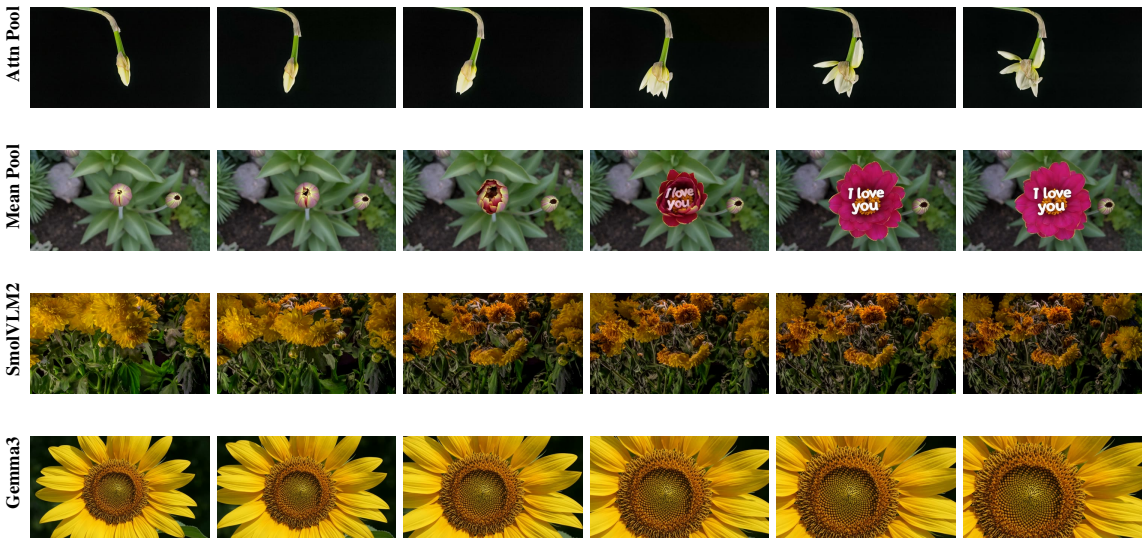

Figure 8: Attn Pool retrieves a macro time-lapse of a white flower on a black background with the drooping arc visible across the frames, directly matching both the temporal modality and the wilting direction. Mean Pool retrieves a flower clip but in the wrong temporal direction: the clip shows a bud opening into bloom, and the later frames transition to a stylised graphic overlay unrelated to the query. SmolVLM2 and Gemma3 both find flower footage but with no discernible change across frames, static shots of marigolds and a sunflower respectively rather than a time-lapse.

Query: "A person steps into an elevator, and the doors close"

Figure 9: Attn Pool retrieves a hotel lobby sequence where a formally dressed person walks toward and enters an elevator, with the approach progression and the doors closing visible across frames. Mean Pool retrieves what appears to be a plain door or wall panel sliding open against a white background, getting a door-related element but without the person, the lobby setting, or the entering action. SmolVLM2 retrieves a dark close-up of a person's face with no elevator context. Gemma3 retrieves a scene from what appears to be a Chinese television broadcast with an indoor lobby setting but no elevator action and a persistent watermark across every frame.

Query: "A person sitting on a table closing the laptop"

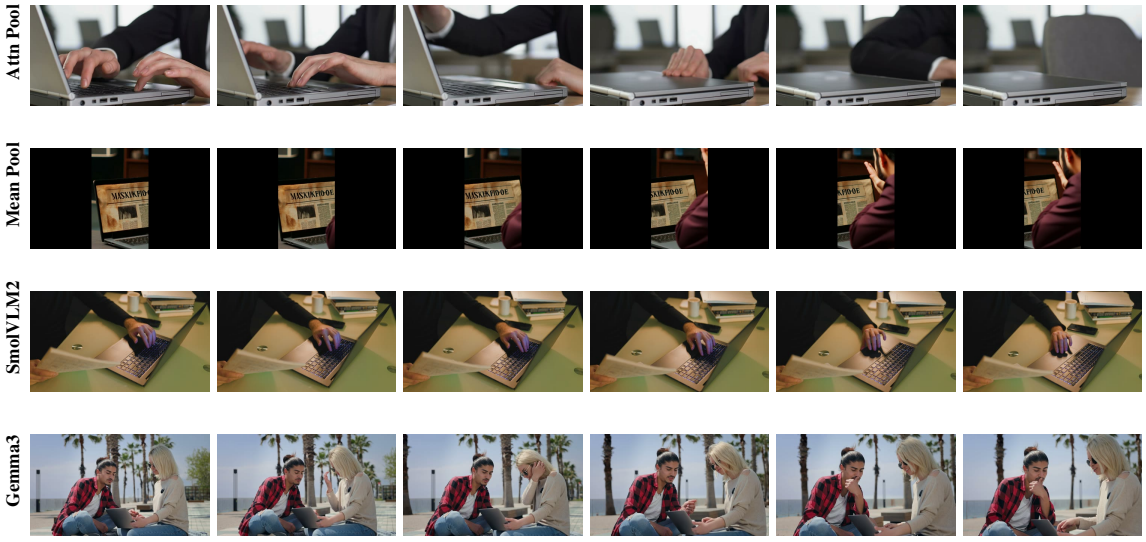

Figure 10: Attn Pool retrieves a close-up sequence of hands lowering the laptop lid, with the closing motion clearly progressing across frames as the query describes. Mean Pool retrieves a darkly-lit desk scene with a laptop and a newspaper visible, matching the object but showing no closing action and little temporal change across frames. SmolVLM2 retrieves a shot of hands on a purple laptop that has the correct object-interaction framing but shows typing rather than closing. Gemma3 retrieves two people sitting and talking outdoors with palm trees in the background, no laptop appears in any frame.

instances, would yield far greater throughput gains than any optimisation of the model inference path.

GPU footprint is minimal. Despite PROVE being a 427M-parameter ViT-L/14 model, its inference is served by just 11 `g5.xlarge` instances, accounting for only $1,859 of the $8,028 total — 23% of infrastructure cost for the only ML-heavy stage. The frozen-encoder design is directly responsible for this efficiency: because PROVE weights are shared with the existing image retrieval pipeline, no additional model development or fine-tuning cost is incurred.

CPU dominates total cost. The 9 `c5.24xlarge` instances running frame extraction account for $6,169 (77%) of the 7-day cost despite being the cheapest instance type per hour. This is a direct consequence of the 5,000 ms per-video extraction latency: reducing extraction time by 2× would halve the CPU instance count and reduce total cost by approximately $3,000.

Extraction optimisation. Frame extraction is the dominant cost driver at 65.6% of total infrastructure spend, despite being the simplest pipeline stage. The primary mitigation is replacing CPU-based software decoding with GPU-accelerated hardware decoding via NVDEC, which is expected to reduce per-video extraction latency substantially and lower the required pod count proportionally. Complementary directions include adaptive frame sampling — extracting fewer frames from static or low-motion segments — and batch-level I/O scheduling to reduce storage contention across concurrent extraction workers.

Failure budget. At a 5% failure rate with one retry, the effective corpus grows to 105M videos, requiring ∼174 videos/sec. The current frame extraction ceiling is $210 \times 0.8 = 168$ videos/sec, marginally below this. We recommend provisioning **220 frame extraction pods** (9 instances unchanged, with slack capacity) and accepting minor queue buildup during retry bursts, or provisioning a tenth `c5.24xlarge` instance ($+4.08/hr) as a dedicated retry worker.

E Training and Optimization Details

Trainable parameters ("lightweight" quantified). Only the pooling head is trained. It comprises a learnable query vector (768), a learned positional-encoding table (120×768, one entry per frame slot at the maximum 120-frame length), and a single cross-attention block (1 attention head, hidden dimension 768). This totals **2.46M trainable parameters**, or **0.57%** of the 430M-parameter model, on top of the frozen 427.6M-parameter PROVE ViT-L/14 image encoder; the PROTE text encoder is likewise frozen. The deployed configuration uses L=1 pooling layer; $L \in \{2, 4\}$ give no improvement (Table 3).

Table 12: Four-stage training curriculum for the pooling head. "HN" = hard negatives used; "Positives" indicates the positive-pair source at each stage.

Stage	Ep.	LR	Batch	WD	Warmup	τ	HN
1	30	1e-3	32	0.010	0.05	0.07	No
2	45	5e-4	20	0.010	0.03	0.07	Yes
3	39	3e-4	28	0.015	0.02	0.07	No
4	60	1e-4	16	0.020	0.01	0.05	Yes

Optimization. We train with AdamW, a cosine learning-rate schedule, and bf16 precision on a single 8-GPU node, with gradient accumulation of 8 and a learnable InfoNCE temperature (initialized τ=0.07). The head is trained with a four-stage curriculum of increasing difficulty; each stage resumes the model weights from the previous stage's checkpoint with a fresh optimizer/scheduler. Table 12 lists the per-stage settings.

F Statistical Methodology and Full Results

Protocol. nDCG is computed per query, and because all systems are evaluated on the same queries, every system-vs-baseline comparison is paired at the query level. We report 95% confidence intervals from a query-level bootstrap (10,000 resamples of the per-query scores) and test significance with a paired randomization (permutation) test over per-query differences (10,000 permutations, two-sided). Across the family of comparisons in Table 13 we apply a Holm–Bonferroni correction; we report the corrected p_{holm}. Significance is conditional on the graded ground truth: these tests quantify query-sampling variability, not judge error, which is addressed separately in Appendix H.

Note on baseline values. The statistics in this section are computed on a dedicated re-run of the aggregation heads with per-query score logging (required for the bootstrap and randomization tests). Mean pooling scores nDCG@1=0.786 in this run versus 0.7729 in Table 1; the difference is within

Table 13: Full nDCG@k with 95% bootstrap CIs and Δ vs. mean pooling (paired randomization test, Holm-corrected). *: $p_{\text{holm}} < 0.05$.

Model	k	nDCG@k [95% CI]	Δ vs. mean [95% CI]	p_{holm}
Mean pooling	1	0.786 [0.752, 0.818]	—	—
Mean pooling	3	0.762 [0.734, 0.789]	—	—
Mean pooling	5	0.748 [0.721, 0.775]	—	—
Mean pooling	10	0.726 [0.699, 0.751]	—	—
Attn +PE (ours)	1	0.851 [0.822, 0.878]	+0.065 [+0.034, +0.097]	0.069
Attn +PE (ours)	3	0.824 [0.799, 0.848]	+0.062 [+0.040, +0.084]	0.040*
Attn +PE (ours)	5	0.812 [0.788, 0.835]	+0.064 [+0.045, +0.082]	0.040*
Attn +PE (ours)	10	0.797 [0.773, 0.819]	+0.071 [+0.056, +0.087]	0.040*
Attn −PE	1	0.814 [0.782, 0.845]	+0.029 [−0.005, +0.061]	1.00
Attn −PE	3	0.792 [0.765, 0.818]	+0.030 [+0.007, +0.053]	1.00
Attn −PE	5	0.783 [0.758, 0.807]	+0.035 [+0.016, +0.053]	0.069
Attn −PE	10	0.762 [0.738, 0.786]	+0.036 [+0.021, +0.052]	0.040*

run-to-run variation and does not affect any comparison, since every Δ, confidence interval, and p-value here is computed against the mean-pooling baseline *from the same run*.

Positional-encoding ablation with significance. Table 13 gives the full breakdown behind Section 5.4. Removing positional encodings drops nDCG@{1,3,5,10} by $0.037/0.032/0.029/0.035$ and removes the statistical significance of the improvement over mean pooling at the top ranks: the −PE head is not significant at @1/@3 (p_{holm}=1.0), whereas the full head is significant at @3/@5/@10 (p_{holm}=0.040). At nDCG@1 the full head's improvement is $+0.065$ with a 95% CI of $[+0.034, +0.097]$ (excluding zero) and an uncorrected $p=2 \times 10^{-4}$; the family-wise-corrected value (p_{holm}=0.069) is marginally above threshold, as expected given nDCG@1's higher per-query variance under a conservative correction over many tests. The effect is consistent in sign and magnitude across all four cutoffs and all pooling depths.

Small categories. Consistent with the caption of Table 2, we treat the *visual attributes* category (n=5) as indicative only: no significance test has meaningful power at that sample size, and its bootstrap CI spans most of the metric range.

Per-category confidence intervals and significance. Tables 14 and 16 report the per-category confidence intervals and significance. Our head has the highest nDCG@1 in six of the seven categories—all except Visual Attributes, where n=4 makes the estimate unreliable and which we therefore report descriptively and exclude from significance testing. Over the confirmatory family of our head vs. mean pooling across the remaining six categories and four cutoffs (24 tests), the improvement is significant at the deepest cutoff in three categories—Subject/Object (Δ=+0.077, p_{holm}=0.029), Action/Activity (Δ=+0.086, p_{holm}=0.002), and Emotion/Expression (Δ=+0.119, p_{holm}=0.023), all at nDCG@10, where the gain is largest and most consistent. The remaining categories do not reach family-wise significance individually—per-category samples are small (n=24–48), limiting power—but the improvement is positive in sign in every category at every cutoff, and significance strengthens with the aggregate sample (Table 15): the improvement is significant at nDCG@{3,5,10} overall and, most relevantly, on the complex multi-clause query split at nDCG@10 (Δ=+0.112, p_{holm}=0.040), the query type this work primarily targets.

G Aggregation Baselines under the Frozen-Encoder Constraint

To compare aggregation mechanisms fairly, we port only the pooling *architecture* of each baseline and retrain that head on our identical frozen features, data, loss, and hard negatives; we do not use published checkpoints. Published CLIP4Clip (Luo et al., 2022) and X-Pool (Gorti et al., 2022) weights are trained end-to-end on a CLIP backbone over public benchmarks and are unusable here: they expect 512-dimensional CLIP features rather than our 768-dimensional PROVE/PROTE embeddings, were fit to a different query distribution, and using them would require unfreezing or replacing the production encoders, violating the frozen-encoder premise. We therefore resize each head to 768 dimensions and retrain only that head: CLIP4Clip-seqTransf as a sequence Transformer over frames followed by mean pooling, and X-Pool as query-conditioned cross-attention.

Why a query-conditioned method is unsuitable for first-stage retrieval. X-Pool pools each video conditioned on the query text, so a video has no single static embedding and cannot be indexed once for approximate nearest-neighbor search. Production retrieval indexes each of 100K–100M videos offline; a query-conditioned model would instead require re-pooling the entire corpus per query (O(corpus) attention at query time), which is infeasible at scale. Its only deployable form is a two-stage reranker over a shortlist, which is how we evaluate it in Table 3. Even in that favorable setting it does not beat the static attention

Table 14: Per-category nDCG@1 with 95% bootstrap CIs on the seven semantic categories of the Golden Benchmark, for mean pooling, our head, and the two learned baselines (all over identical frozen ProVE features; statistics re-run of Appendix F). Δ is our head vs. mean pooling. Bold = best per category. Point estimates are from the statistics re-run (this appendix) and differ slightly from the primary-pool run in Table 2. †Visual Attributes has n=4 and is underpowered; reported as indicative only and excluded from the significance family in Table 16.

Table 17: Judge-threshold sensitivity on the Golden Benchmark (nDCG@1). The system ranking is invariant across thresholds.

τ	Mean pool @1	Ours @1	Δ
0.75	0.807	0.863	+0.055
0.80	0.786	0.851	+0.065
0.85	0.786	0.851	+0.065
0.90	0.572	0.669	+0.097

head (0.774 vs. 0.851 nDCG@1) and does not beat mean pooling at @1, while adding query-time cost and breaking the drop-in, index-once deployment that is the paper's premise.

H Judge Validation and Pooling Protocol

Threshold sensitivity. The graded ground truth thresholds VLM relevance scores at 0.85. We recomputed the benchmark at $\tau \in \{0.75, 0.80, 0.85, 0.90\}$ (Table 17); the system ranking is invariant and 0.80–0.85 is a flat band, so 0.85 is not a sensitive choice. At 0.90 some queries retain no video above threshold and drop out, so the lower absolute nDCG there is a coverage effect on a smaller query set; even so, our model's lead widens.

Pool composition and pooling bias. Each query's candidate pool is the union of the top-100 retrievals from every system in the comparison—the production system (metadata), mean pooling, thumbnail, our attention head, and all ablation baselines (X-Pool, CLIP4Clip, attention with L=2 and L=4)—with all resulting (query, video) pairs judged by the VLM; scores ≥ 0.85 form the graded ground truth. This follows the standard TREC pooling protocol (Craswell et al., 2021) and is unbiased for or against any single system: every compared retriever contributes its top-100 symmetrically, so no system's uniquely surfaced relevant videos go unjudged and no method is over-sampled (pooling only decides which pairs are judged; the judge then

Table 18: Zero-shot MSR-VTT test-1k (text→video). Recall@K.

MSR-VTT test-1k	R@1	R@5	R@10
Trained attention head	0.402	0.634	0.728
Mean pooling (frozen frames)	0.411	0.645	0.757

scores relevance per pair). Pool incompleteness—relevant videos that no system retrieved in its top-100—affects all systems equally and is the accepted graded-pooling standard.

Judge reliability on temporal queries. The temporal-reasoning limitation we note in the Limitations section is a general property of current VLM/LLM judges rather than specific to Qwen2.5-VL-72B (Bai et al., 2025); in a manual spot-check the judge showed good accuracy on temporally-oriented (query, video) pairs. Crucially, our headline temporal evidence—the frame-shuffle/reversal probe (Section 5.4)—is judge-free, measured directly in embedding space with no judge in the loop, and is therefore unaffected by any residual judge limitation. A full human–judge agreement study is left to future work (Appendix J).

I Public Benchmark: Zero-Shot MSR-VTT

Although this is an applications paper centered on a production setting, we additionally report zero-shot results on MSR-VTT test-1k (text→ video, 1000 queries); neither the frozen PROVE/PROTE encoders nor the pooling head were trained on MSR-VTT (Table 18).

The head shows a marginal drop relative to mean pooling. A per-query look at the R@1 failures unique to our method shows they are near-misses rather than errors: the head retrieves other videos that genuinely match the query text but are not the single clip marked as ground truth. MSR-VTT test-1k contains ∼50 videos per category, so many queries have several equally valid near-duplicate answers and R@1 penalizes retrieving the "wrong" one. A secondary factor is domain shift: the head is a lightweight adapter trained on professional stock footage with attribute-dense, LLM-authored captions, whereas MSR-VTT comprises short web clips with terse crowd-sourced captions. This is consistent with the paper's central finding that one-to-one protocols underestimate quality on corpora with many valid answers, and we report it in the interest of completeness.

J Future Work

Human–judge agreement on temporal queries. Our benchmark's ground truth is produced by a single VLM judge, and while we also present a judge-free temporal evidence (Section 5.4), quantifying judge reliability remains valuable. As future work we plan a human–judge agreement study on a stratified sample of (query, video) pairs spanning relevance-score bands, semantic categories, and a dedicated temporally-oriented subset, reporting agreement via Cohen's κ and Spearman correlation, with particular attention to the temporal subset where LLM-based judges are known to be weakest. We retain single-judge annotation as an acknowledged limitation in the meantime.

Higher-frame-rate and motion-aware sensing. The fixed 2 FPS sampling limits camera-motion and fast-action cues (the main reason cinematography queries gain least); adaptive or higher-rate sampling and lightweight motion features are a natural extension.

Event-ordering-aware hard negatives. Queries describing causally ordered events require sensitivity to action sequence, not just co-occurrence. Constructing hard negatives by shuffling or reversing frame sequences would explicitly train the head to distinguish correct from incorrect orderings, complementing the order-sensitivity we measure in Section 5.4.

Multilingual fine-tuning. The 7.7% nDCG@1 gap for Chinese queries (Appendix C) reflects a data-coverage bottleneck; fine-tuning the pooling head on multilingual query–video pairs would directly address it.

From Production Traffic to Post-Training: Building a Self-Hosted LLM That Covers the Corporate Request Mix

Abstract

Data-residency constraints force enterprises to self-host LLMs, but continuous adoption of newer models without decommissioning their predecessors expands the serving fleet, fragmenting a finite GPU pool. We consolidate traffic from over 200 internal applications onto a single model by closing quality gaps identified through production error analysis along three axes: instruction following, function-calling, and internal task distribution. Quality is tracked by offline benchmarks stratified to production traffic and scored by deterministic verifiers or calibrated LLM judges. Rather than optimising all objectives jointly, which introduces cross-domain reward interference, we train a separate GRPO expert per axis and merge them via two-stage SLERP. Each expert's reward exposes a distinct failure mode, namely semantic collapse, over-calling, and verbosity hacking, each requiring a domain-specific fix. In non-reasoning mode the recipe surpasses a $\sim 7\times$ larger by total parameters baseline on the in-house Arena with 69.6 to 65.8, instruction following with 0.85 to 0.83, and function-calling with 0.79 to 0.77, while lifting general dialogue benchmarks. The model absorbs 50% of platform traffic, 116M requests per month, at a fraction of the serving cost.

1 Introduction

Recent open-weight LLMs have closed the quality gap with proprietary systems on typical enterprise workloads (Yang et al., 2025; Grattafiori et al., 2024; DeepSeek-AI et al., 2024), and under data-residency and regulatory constraints locally deployed models are often the only option (Wu et al., 2023; Pan et al., 2025). In a large enterprise, local deployment means one finite GPU pool shared by hundreds of applications. Each team picks the model that fits its task; switching later creates friction, new generations arrive quarterly while old models cannot be retired, and the effective price per token rises as the zoo fragments.

We consolidate traffic onto a single model by closing the gaps that prevent migration via dedicated post-training. The adapted model absorbs 50% of platform traffic, 116M requests per month from over 200 internal applications, six months after rollout and is cheap enough to update every production cycle. Because the long tail of applications is created and retired faster than any one accumulates enough traffic for reliable A/B testing, the model must retain broad capabilities for unseen workflows, making evaluation two-sided: diagnose and repair live weaknesses while preserving generalization.

Error analysis of production traffic surfaces three improvement axes. Instruction-following and formatting errors account for 37.9% of failures (Appendix A.1), making strict constraint satisfaction the largest single lever. Function calling is critical: tool-equipped requests account for $\sim$12% of traffic. A distributional gap remains between high-frequency task types and long-tail workflows on the one hand and public training distributions on the other. We address all three in a single post-training stage without regressing general capabilities and make three contributions.

This paper presents a methodology for building internal benchmarks from production traffic, scored by deterministic verifiers or calibrated LLM judges and validated against human annotators.

A modular post-training recipe trains a separate RL expert per weak axis and combines them by weight-space merging. Three reward-hacking failure modes that preclude joint multi-objective training are documented alongside the domain-specific fix each requires.

An open-weight checkpoint trained with the same recipe but without internal data is released[1], on public benchmarks it scores close to the deployed version, confirming that the recipe, not pro-

prietary data, drives the gains.

2 Related Work

Russian LLM development has mostly followed two directions: training Russian models from scratch (Kuratov and Arkhipov, 2019; Zmitrovich et al., 2024) and adapting multilingual backbones (Tikhomirov and Chernyshov, 2024; Nikolich et al., 2024; Stoianov et al., 2026; Mamedov et al., 2025). These efforts improved general Russian generation, but reproducible post-training recipes targeting agentic skills have not been published for this language. Our focus is not fluency, but reliable instruction execution, structured tool use, and stable multi-step behaviour.

Instruction following (IF) and function calling (FC). Both are often treated as language-independent, but this breaks down in Russian. IF is harder to check: morphology, case, casing, punctuation, and free word order mean one English-style rule has many valid Russian forms, so English IF verifiers from AutoIF (Dong et al., 2025), IF-Bench (Pyatkin et al., 2025), and VerIF (Peng et al., 2025) help as templates but cannot be reused as is. FC adds a schema constraint: prompts can be localized, but function names, parameter keys, and enumeration values are part of the API and must stay fixed. Recent multilingual tool-use work (Chen et al., 2025b; Luo et al., 2026) shows the failure is mostly here: errors come from execution-interface violations, not from misunderstanding intent, with parameter-value language mismatch the main failure mode, and inference-time fixes do not recover English-level performance. We therefore handle both axes at the data level, not at inference time: we generate data natively in Russian via schema-aware synthetic pipelines (Liu et al., 2024, 2025; Prabhakar et al., 2025; Xu et al., 2025) with the Tool-N1 reward (Zhang et al., 2026b).

Post-training recipe. Modern post-training pipelines like Tulu 3 (Lambert et al., 2025) and DeepSeek-R1 (Guo et al., 2025) build on RLHF (Ziegler et al., 2019; Ouyang et al., 2022) and use RLVR with GRPO and its variants (Schulman et al., 2017; Shao et al., 2024; Yu et al., 2025; Zheng et al., 2025). In our setting the reward signal is the bottleneck. IF, FC, and general chat each pull the model in a different direction, and each reward has a trivial shortcut. The same failure modes occur in multi-objective and rubric-based RL (Ichihara et al., 2025; Gunjal et al., 2026; Huang et al., 2025; Liu et al., 2026; Shen et al., 2026; Zhang et al., 2026a), so joint training is fragile. We instead train one expert per skill and merge in weight space (Wortsman et al., 2022; Ilharco et al., 2023), a step now standard in large post-training systems (Grattafiori et al., 2024; Team Cohere et al., 2025; Dang et al., 2024).

Internal evaluation. Open benchmarks such as Arena-Hard (Li et al., 2025) and WildBench (Lin et al., 2025) provide reproducible scoring of open-ended chat. We extend this line with a stratified internal benchmark matched to production traffic.

3 In-house traffic and Arena

We build an internal benchmark from production LLM-platform traffic and score it with an automated Arena pipeline. The benchmark is constructed in two stages: first, a sampling stage that selects a diverse yet representative subset from $\sim$100k monthly queries, and second, a judging stage that routes each query through a task classifier and applies a task-specific evaluation scheme. The methodology is not limited to a one-month window, we use this interval because it aligns with our production cycle, but the pipeline applies to any period. We summarize two key takeaways below.

How to get diversity without drifting from production? We quantify diversity as the mean pairwise TF-IDF cosine distance and representativeness as the Jensen-Shannon distance from the production pool along four dimensions: queried model, prompt length, service, and task taxonomy. The two objectives are in tension because in-house traffic is dominated by templated requests, where variable fragments are substituted into a small set of prompt templates.

Standard approaches fail in opposite directions, as shown in Table 1. Uniform random sampling preserves the production distribution but inherits near-duplicate structure, while diversity-first methods: greedy max-min and #InsTag (Lu et al., 2024) pursue diversity at the expense of representativeness, distorting service distribution by treating templated near-duplicates as genuine diversity.

Our template-aware sampler masks variable tokens, groups near-identical normalized prompts via LSH (Broder, 1997), selects within each template by greedy max-min over variable spans, and allocates budget as $\sqrt{\text{count}}$. It attains the highest

Method	Dist.	JS_{mdl}	JS_{len}	JS_{svc}	JS_{tax}
random	0.653	**0.001**	**0.083**	**0.001**	**0.000**
greedy max-min	0.944	0.403	0.295	0.683	0.019
#InsTag	0.874	0.342	0.181	0.479	0.145
template-based	**0.953**	0.122	0.098	0.281	0.015

Table 1: Sampling methods compared by average pairwise distance, Dist., higher is more diverse, and JS distance from the production pool for queried model JS_{mdl}, prompt length JS_{len}, service JS_{svc}, and task type JS_{tax}, lower is closer to production.

prompt diversity, 0.953, while keeping JS distances substantially lower than pure diversity sampling, the only method that improves coverage without sacrificing representativeness.

Does one judging recipe fit all tasks? The answer is no. We score the benchmark with Arena-Hard-Auto (Li et al., 2025) using DeepSeek-V3-0324 (DeepSeek-AI et al., 2024) as judge. A uniform side-by-side (SBS) judge agreed poorly with expert annotators, Cohen's $\kappa = 0.62$, and the disagreement tracks task type. On objective tasks such as classification and information extraction, the judge and the human should share a reference answer, on open-ended tasks such as summarization and content generation, "good" is underspecified and the two raters weigh different criteria.

We therefore route each request through an LLM task classifier, matching human consensus in 90.6 – 99.6% of cases (see Table 10), and judge each segment with its own scheme. Classification and information extraction, roughly 63.2% of traffic, are scored reference-based against gold answers generated by Kimi-K2.5 (Kimi Team et al., 2026) and verified by annotators, 97.7% and 85.2% accepted unmodified. Open-ended tasks keep pairwise SBS judging but augment it with per-example RubricHub-style checklists (Li et al., 2026) split into objective and subjective criteria, Appendix A.2. The best recipe is task-dependent, Table 12: summarization is judged best with the checklist as contextual guidance for a single SBS verdict, $\kappa = 0.68$, whereas content generation benefits from explicit per-criterion grading with an overall verdict, $\kappa = 0.79$.

Overall, the final task-specific pipeline substantially outperforms the uniform-SBS baseline, lifting κ from 0.63 to 0.88 on reference-based and from 0.57 to 0.72 on open-ended content-generation subtasks (Table 2).

Eval setup	Ref.-based	Open-ended	Avg.
Uniform SBS	0.63	0.57	0.62
Task-specific	0.88	0.72	0.85

Table 2: Cohen's κ by task type for the initial uniform-SBS setup and the final task-specific pipeline. The average is weighted by the number of samples per task.

4 Training recipe

Our post-training recipe addresses three axes surfaced by production error analysis: instruction following, function calling, and alignment to the internal task distribution. The model builds on Qwen3-32B (Yang et al., 2025) with an adapted Cyrillic-dense tokenizer (Stoianov et al., 2026), which proved more efficient than the base one, and operates exclusively in non-reasoning mode due to production latency and generation-cost constraints. Training proceeds in three stages. First, a single combined SFT phase exposes the model to all target domains simultaneously, mixing in-house production, general-domain, instruction-following, and function-calling data. This joint checkpoint then serves as the shared starting point for all subsequent RL branches. We keep SFT shared rather than training and merging per-domain SFT experts: at the SFT stage a naive mixture of all domains retains per-domain quality (Table 3), so the extra experts and merge buy nothing, and a single combined stage is the simpler choice. Rather than optimizing one model against all three reward signals jointly, we fork the SFT checkpoint into three independent GRPO (Shao et al., 2024) runs, each trained to convergence on a domain-specific reward. The resulting expert checkpoints are combined into a single deployment model via two-stage sequential SLERP merging (Shoemake, 1985; Goddard et al., 2024).

General expert The general expert retains broad capabilities while aligning to the production task mix. This alignment has no single verifiable reward, and a reward model (RM) adapted to in-house preferences does not improve over the general one (Table 4), so we address it through the data rather than through a dedicated in-house expert. The data combines general-domain samples from a large open-source Russian instruction corpus (Stoianov et al., 2026), constituting roughly 80% of the mixture, with in-house samples drawn from production platform logs making up the remaining 20%. The in-house portion is sampled using the same strategy

as the in-house Arena and decontaminated against benchmark data via Min-Hash. Completions are regenerated by Qwen3-235B-A22B-Instruct-2507, which serves both as a strong teacher and as a way to ensure homogeneous target distribution with the general-domain portion. For RL, we train a general RM on this corpus and run GRPO with two additions: a multiplicative length penalty that compares each response's length to a prompt-specific baseline from Qwen3-235B-A22B-Instruct-2507, and an increased KL coefficient to constrain distribution drift (Appendix C).

IF expert Our in-house IF data appears in the general expert mix, but its diversity may be limited, hurting generalization to unseen constraints in the heterogeneous in-house distribution. Since this corpus was not designed for this capability, a dedicated general IF increment is needed. Training data come from a synthetic pipeline adapted from AutoIF to Russian. Starting from 54 hand-written seed constraints, LLM-based augmentation, consistency-based filtering of generated verifiers and test cases, and back-translation validation expand them to 43K verified constraints. Each constraint is attached to samples from this corpus via both user-level and system-level insertion, yielding 26K training examples with validated completions. During the GRPO we use a VerIF-style verifiable constraint-satisfaction reward. However, pure verifier-based training quickly exposed a reward-hacking failure mode (Skalse et al., 2022): the model learned to produce minimal, semantically empty completions that satisfied the formal checks. To fix this, we extend the VerIF-style reward with a prompt-specific reward-model quality correction. Completions that pass the verifier but score below the mean reward-model score over teacher completions on the same prompt receive a penalty. This preserves verifier-reward scalability while preventing semantic collapse (Appendix D).

Function-Calling Expert Human evaluation of FC platform logs points to two causes of score degradation: production tools are frequently documented in Russian, which is typically out-of-distribution for English-centric models, and the model tends not to select the wrong function but rather fails to fill arguments in Russian. This holds for both Qwen3-32B and Qwen3-235B-A22B-Instruct-2507. Because open FC data and evaluation suites are overwhelmingly English-centric and machine translation of FC data is structurally unsafe, we generate FC training data natively in each language via a synthetic pipeline that builds a tool pool and a multi-turn dialogue pool from scratch, yielding 1.2M English and 300K Russian samples (Appendix E). The dialogue pipeline separates planning from simulation: a planner builds a trajectory with judge feedback, then three agents replay it under asymmetric visibility so training targets reflect realistic tool use rather than leaked references. SFT is a coarse warm-up, with the mixture stratified equally between tool-call and text targets and between English and Russian. For GRPO we use a binary Tool-N1 (Zhang et al., 2026b) exact-match reward, which admits a dominant exploit: when in doubt, emit a call. We correct this through the data distribution rather than the reward: injecting synthetic irrelevance counters over-calling, while the assistant text-target share is tuned separately for multi-turn accuracy. The resulting mixture is 70% English and 30% Russian, with 80% tool-call and 20% text targets per language and 10% synthetic irrelevance within the text share.

5 Evaluation

Benchmarks Since our primary focus is Russian-language evaluation, we mainly report Russian-adapted versions of IFEval (Zhou et al., 2023), MultiChallenge (Deshpande et al., 2025), and BFCLv3 (Patil et al., 2025), described in Appendix B, and Arena Hard Ru (T-Tech, 2025), WildChat Hard Ru (Kukushkin, 2025). We additionally report AceBench (Chen et al., 2025a) and τ^2-bench (Barres et al., 2026) to probe tool-calling robustness across languages. English results, Arena Hard 2 (Li et al., 2025, 2024) and the original IFEval and MultiChallenge, appear in Appendix H.

The in-house benchmarks are designed to mirror our production distribution and comprise four tasks (Appendix A): the in-house Arena, described in Section 3; the in-house IFEval, which pairs deterministic verifiers with an LLM-judge loose metric; the in-house BFCL, which evaluates against human-curated references in AST mode; and SmartSearch, which measures function-calling within a multi-step ReAct (Yao et al., 2023) loop over internal documents.

For the ablation studies in this section we report a subset, namely in-house Arena, Arena Hard Ru, ruIFEval, and ru/en BFCLv3, spanning all capability axes; full results across all benchmarks are reported for the final checkpoints.

Is a combined SFT stage sufficient across domains? Before proceeding to alignment, we investigated whether a single shared SFT model can match the per-domain quality of models trained exclusively on each domain. Table 3 shows that

Model	Arena		ruIFEval	BFCL	
	Ru-Hard	In-House		En	Ru
Qwen3-32B	85.76	59.49	0.770	63.13	54.03
+ Domain SFT	91.96	62.18	**0.798**	**69.37**	**58.69**
+ Shared SFT	**92.45**	**66.00**	0.787	68.59	58.18

Table 3: SFT ablation results. Domain SFT denotes a model trained on a single domain: general for the arena columns, instruction following for IFEval, and tool calling for the BFCL columns.

the shared SFT model closely matches the domain-specific experts across all three evaluation axes confirming that at the SFT stage a naive mixture of data from all domains is sufficient to retain per-domain quality. However, as discussed in the following sections, the same approach of simply combining data does not carry over to the GRPO stage.

Does the reward model need adaptation to in-house data? To investigate this, we trained the reward model on mixtures of general-domain and in-house preference pairs and compared them against the general-only reward model within the same GRPO pipeline. As shown in Table 4, adapting

Model	Ru-Arena-Hard		In-House Arena	
	Score	Avg. Len.	Score	Avg. Len.
Qwen3-32B	85.76	961	59.49	208
+ Shared SFT	92.45	1332	66.00	259
+ General GRPO	**95.26**	1261	**70.73**	286
+ GRPO w/ In-House RM	93.51	1261	68.58	362

Table 4: Ablation: effect of adapting the reward model to in-house data. The in-house-adapted RM does not improve over the general RM.

the reward model to in-house data does not yield improvements. Notably, the in-house RM variant produces substantially longer responses on the in-house evaluation, averaging 362 tokens compared to 286, which suggests that the adapted model may have absorbed superficial stylistic biases from the in-house preference data. These results show that a well-trained general reward model already captures sufficient signal; naively mixing in-house preference pairs into the RM training set can introduce noise or distributional artifacts that slightly degrade performance. We therefore retained the general-domain reward model in our final recipe.

Does single-domain GRPO transfer to other domains? When training separate GRPO experts for different capability domains, a practical concern is whether the alignment gains on the target domain carry over to other domains. To examine cross-domain transfer, we performed GRPO training on three separate domains, general, instruction following, and tool calling, each starting from the same shared SFT checkpoint. Table 5 demonstrates

Model	Arena		ruIFEval	BFCL	
	Ru-Hard	In-House		En	Ru
Shared SFT	92.45	66.00	0.787	68.59	58.18
+ General (Gen.)	**95.26**	**70.73**	0.773	68.50	55.59
+ IF	94.88	64.34	**0.827**	68.19	59.78
+ FC	92.14	62.69	0.784	**72.25**	**66.73**

Table 5: Cross-domain transfer of single-domain GRPO experts, each trained from the shared SFT checkpoint.

that each expert improves on its own domain while the remaining domains see little to no benefit. The General GRPO expert lifts arena scores to 95.26 and 70.73, but IFEval and tool-calling metrics remain near the SFT baseline. The IF and FC GRPO experts exhibit the same behavior. This shows that single-domain GRPO alignment transfers poorly across domains: gains remain confined to the capability covered by the reward signal, and other domains are largely unaffected. To combine the improvements from all three domains, the final model was obtained by merging the three domain-specific experts into a single model.

Why merge instead of joint GRPO? An alternative is to optimise all domain rewards in a single joint GRPO run. We first study this at 8B, sweeping starting checkpoints, domain mixing ratios, and batching schedules (Table 23). The sweep reveals strong cross-domain interference: from the mixed-SFT checkpoint, jointly optimising the two verifiable-reward domains lifts instruction following (ruIFEval from 0.731 to 0.801) but pushes function calling below its starting point (BFCLv3 EN from 61.2 to 54.5); adding the general reward recovers function calling but collapses instruction following below the baseline (0.687); the only competitive configuration required a general-GRPO warm start and a $1.7\times$ budget. We then ran the strongest configuration from each starting checkpoint at the 32B deployment scale (Table 8), under the same data and evaluation as the merge recipe. The 8B conclusion transfers: joint GRPO over the three rewards from the mixed-SFT checkpoint fails to hold

Merge order	Arena		ruIFEval	BFCL	
	Ru-Hard	In-House		En	Ru
(IF + FC) + Gen.	**93.37** $\pm$ 0.68	**68.99** $\pm$ 0.77	**0.798** $\pm$ 0.0032	**72.19** $\pm$ 0.39	**65.73** $\pm$ 0.36
(IF + Gen.) + FC	91.66 $\pm$ 0.40	65.05 $\pm$ 0.66	0.770 $\pm$ 0.0036	67.83 $\pm$ 0.44	61.25 $\pm$ 0.26
(FC + Gen.) + IF	90.71 $\pm$ 0.22	65.99 $\pm$ 0.57	0.777 $\pm$ 0.0089	70.09 $\pm$ 0.28	64.43 $\pm$ 0.54

Table 7: Two-stage sequential SLERP merge orderings. Each entry is the mean $\pm$ standard deviation over five combinations of near-convergence expert checkpoints merged with identical coefficients.

all domains simultaneously, with BFCLv3 falling to 60.88 RU and 70.38 EN against 65.96 and 72.27 for the merge and ruIFEval to 0.770 against 0.799, while the general-GRPO warm start reaches parity with the merge only at the 1.7$\times$ budget. Joint training thus turns domain balance into a fragile hyperparameter search that must be repeated whenever a capability is added, whereas the merge recipe extends with one independently trained expert and an eval-only coefficient search. We therefore train one expert per reward and merge in weight space at the deployment scale (Tables 5, 7, 8 and 24).

Method	Arena		ruIFEval	BFCL	
	Ru-Hard	In-House		En	Ru
Merge	93.87	69.57	**0.799**	**72.27**	**65.96**
Joint, from SFT	94.04	70.27	0.770	70.38	60.88
Joint, from Gen. GRPO†	**94.65**	**70.45**	0.786	72.06	65.29

Table 8: Joint multi-domain GRPO vs. expert merging at the 32B scale. † trained with a 1.7$\times$ larger budget than the other runs.

Does merging order matter? Because SLERP is non-associative, the order in which experts are composed affects the result. Merging the two verifiable-reward experts first and then folding in the general expert outperformed the alternative orderings (Table 7) by more than the spread we measured across expert checkpoints. We chose that order empirically, by enumerating all combinations of the three experts.Appendix G reports further ablations on the merging operator.

Results and Deployment Table 6 compares the final merged checkpoint with the base Qwen3-32B, T-Pro-2.0, and the $\sim$7$\times$ larger by total parameters Qwen3-235B-A22B-Instruct-2507. Our model is on par with or ahead of the larger model across the in-house Arena, 69.57 compared to 65.83, in-house BFCL, 0.79 to 0.77, ruBFCLv3, 65.96 to 64.42, and AceBench, 73.50 to 70.20, all in non-reasoning mode, at a fraction of the serving cost. On benchmarks where backbone scale dominates, namely ruMultiChallenge which probes long-context memory and self-coherence and SmartSearch which requires open-ended retrieval and synthesis, the recipe substantially narrows the inherited gap: SmartSearch F_1 improves from 0.478 to 0.557, surpassing both 32B-scale thinking-mode baselines, and ruWildChat rises from 52.0 to 80.7, within 4.4 points of the $\sim$7$\times$ larger model. The public checkpoint, trained with the same recipe but without the internal-data increment, scores close to the deployed version on all benchmarks except the in-house Arena, and is released as open weights. In production the merged checkpoint serves 116M requests per month, 45 average and 110 peak requests per second, from over 200 internal services on single-GPU FP8 replicas behind vLLM (Kwon et al., 2023), 16 to 48 pods, with 95th-percentile latency of 3.2 s and time-to-first-token of 0.3 s. Compared to the $\sim$7$\times$ larger baseline it matches on quality, the deployed model reduces per-token

cost by 2.8 to 3.9× on input and output, and up to 4 to 9× for services that previously ran the largest platform models. The few rollbacks came from teams requiring frontier-scale agentic capabilities beyond a 32B dense model.

6 Conclusion

We presented a production-driven recipe for consolidating a fragmented self-hosted LLM fleet into a single deployment model. Traffic analysis across more than 200 internal applications identified three main gaps: instruction following, function calling, and alignment to the internal request distribution. Joint GRPO made these objectives interfere, so we trained one expert per axis from a shared SFT checkpoint and merged them with two-stage SLERP.

The main lesson is that enterprise post-training is easier to control when the objectives are modular. Each axis produced its own failure mode and each required a targeted fix. This separation makes the recipe easier to debug, audit, and extend.

Together with template-aware traffic sampling and task-specific judging calibrated against human annotators, the recipe gives a practical path from production error analysis to deployment. The final Qwen3-32B non-reasoning model is competitive on target deployment metrics while serving 116M monthly requests at lower cost. A public checkpoint trained without internal data shows similar public-benchmark gains, suggesting that the recipe accounts for much of the improvement.

Limitations

Language and deployment scope. Our evaluation covers only Russian and English. The in-house benchmarks are built from Russian-language traffic of a single self-hosted corporate deployment, while English enters both the training mixtures and the corresponding evaluation sets. The methodology: traffic-stratified benchmarking, one RL expert per weak axis, and weight-space merging, is not inherently tied to these languages or to our organization, though we leave verification on other languages and domains to future work. All quantitative claims in this paper should therefore be read as validated for Russian and English only.

Reliance on LLM judges. Open-ended quality is scored by LLM judges calibrated against human annotators on our benchmark distribution. If the recipe is reused for another deployment, language, or benchmark distribution, judge quality should be re-calibrated against human annotations. A sensitivity study over four judges is reported in Appendix H.

Deployment and model-family scope. The deployment evidence comes from a single organization and a single self-hosted corporate platform, and all experiments use only the Qwen3 model family. Nothing in the recipe depends on the backbone, but we have not validated it on another family or in another organization.

Ethical Statement

Data provenance, privacy, and decontamination. All in-house benchmarks are derived from logged traffic of an internal corporate LLM platform, processed entirely on self-hosted infrastructure under data-residency constraints; this is also why the system is deployed locally rather than through a third-party API. Records are deduplicated and anonymized, and variable spans such as numbers, identifiers, and long literals are masked during template extraction. No public or external end-user data is involved, and only internal work-related requests are used. We explicitly control for contamination between training and evaluation data: evaluation items are held out from the internal-data increment used to train the general expert, and exact and template-level duplicates are removed. The weak-axis experts are trained on synthetic data only, so internal traffic does not directly supervise them. This separation underpins our main claim: the improvements from the weak-axis experts and their weight-space merges are not explained by memorizing the same internal examples that appear in the benchmarks.

Human annotation. Gold answers, benchmark translations, and the task-specific verification procedures were validated and corrected by professional annotators and domain experts working as part of this project; their role was data validation and correction. In the judge-validation studies, each response pair was independently labeled by three annotators and the consensus taken as the majority vote. All annotation was performed on internal work-related data under the privacy and data-handling procedures described above.

Intended use and risks. The model is intended for internal enterprise assistance. Like any LLM, it

can produce factually incorrect outputs or violate stated constraints; deterministic verifiers reduce but do not eliminate this risk. In particular, tool calls emitted by the model should be gated and validated before execution in production.

A Internal benchmarks

A.1 Production error analysis

To ground the choice of improvement axes, we sampled n=2,500 LLM-platform traffic responses and had three annotators assign each its single primary failure to one of six categories; inter-annotator agreement was Cohen's $\kappa = 0.62$ and the category label was taken as the majority vote (Table 9).

Two observations motivate the IF axis. Classification is the largest single category (36.0%), but instruction-following failures, once formatting (21.0%) and non-format (16.9%) violations are combined, exceed it (37.9%) and are additionally checkable by deterministic verifiers, making them a natural target for a dedicated expert with a verifiable reward (Appendix D).

Second, the remaining categories either do not isolate into a single verifiable axis or are governed by factors a targeted post-training stage cannot move. Classification is a heterogeneous downstream symptom rather than a single capability: in the non-reasoning mode our deployment mandates for latency and cost, a misclassification rarely exposes a clean rewardable signal, so it does not form a domain expert the way IF and FC do. Knowledge-base errors track parametric capacity and long-context retention; they scale with the backbone and are addressed by general-domain training that reduces hallucination and improves helpfulness, not by a constraint-style reward: consistent with the residual gap to the $\sim$7$\times$ larger model on knowledge- and memory-heavy benchmarks (Section 6). Language-preference errors are minor for the bulk of production traffic and are likewise absorbed by the general expert.

This taxonomy covers text-reply failures; function-calling errors are analysed separately by human evaluation of tool-equipped logs, which form $\sim$12% of traffic (Table 10), and motivate the FC axis. That evaluation traces score degradation primarily to Russian-language tool descriptions, which lie out of distribution for English-centric base models, and to argument-filling errors in Russian rather than incorrect function selection, a pattern consistent across both Qwen3-32B and Qwen3-235B-A22B-Instruct-2507.

Category	Share
Classification	36.0%
Formatting (IF)	21.0%
Instruction following, non-format	16.9%
Knowledge base	19.0%
Language preference	5.0%
Other	2.1%

Table 9: Failure-type distribution over a human-reviewed sample of n=2,500 in-house traffic responses, one primary failure per response ($\kappa = 0.62$). Formatting denotes violations of structural, JSON-schema, or length constraints; the non-format row covers content-level instruction violations such as tone, role, enumeration, and lexical prohibitions.

A.2 Inhouse Arena

A.2.1 On benchmark data collection

This section specifies the greedy max-min and template-based sampling procedures summarized in Table 1.

Greedy max-min. Starting from a random seed, the sampler repeatedly adds the query whose minimum cosine distance to the already-selected set is largest, so every new pick is the one most dissimilar from all previous picks. This maximizes the minimum pairwise distance of the selected subset. Since production traffic contains large families of near-identical templated requests, the procedure must place a point in each family to avoid coverage gaps, spending budget on near-duplicates and pulling the sample toward rare queries far from the cluster centres.

Template-based sampling. A markdown-aware parser splits each prompt into structural segments. Within every segment we mask variable tokens such as numbers, opaque identifiers, and long string literals, which yields a normalized segment sequence. Near-identical sequences are grouped into templates via locality-sensitive hashing, and a majority vote gives one consensus template per group. Greedy max-min then runs within each template over the variable spans only, and the per-template budget scales as $\sqrt{\text{count}}$ so that frequent families neither vanish nor dominate. Unlike fixed-prefix grouping, this merges formatting variants of the same task and separates prompts whose prefixes coincide by chance.

A.2.2 On benchmark methodology

Task taxonomy validation. Each request is assigned to the task taxonomy by an LLM classifier before annotation. On items where annotators reached a task-type consensus, the classifier label matched that consensus in 90.6 to 99.6% of cases across all four task types, lowest on information

extraction, a small fraction of which borders classification. This confirms that the automatic labels reflect how experts categorize the same requests. The taxonomy is also stable over time: re-classifying an independent batch from a non-overlapping window with the same classifier leaves the task-type distribution essentially unchanged, with no category shifting by more than three percentage points (Table 10).

Category	Slice 1	Slice 2	Δ pp	Acc.
Classification	55.5%	52.8%	−2.7	99.6%
Summarization	8.6%	11.4%	+2.8	97.8%
Information extraction	7.7%	10.7%	+3.0	90.6%
Content generation	5.2%	3.7%	−1.4	92.1%
Tool Calling	11.8%	11.9%	+0.1	—
Other	11.3%	9.5%	−1.8	—

Table 10: Primary task-type distribution on two independent slices of internal requests (LLM classifier labels) and the accuracy (Acc.) of each assigned label against human consensus (on items where annotators reached a consensus). Accuracy covers the four classifier task types only; Tool Calling is detected by a regular expression and Other is the residual category.

Task-type preservation under sampling. We also asked whether each sampling method preserves the task-type composition of production traffic, using the same taxonomy as in Table 10. Table 1 reports the Jensen–Shannon distance between the benchmark and its reference pool over primary task-type labels, lower is closer to production.

Uniform random and template-based sampling both keep the task-type distribution essentially aligned with production, 0 and 1.5% respectively. Greedy max-min introduces only a modest taxonomy shift, 1.9%, far smaller than its distortion of the service and model dimensions in Table 1. #InsTag departs sharply from the reference taxonomy, 14.5%: by prioritizing topically diverse queries it over-represents rare task categories, consistent with its elevated JS on the service and model dimensions. Template-based sampling is therefore the only configuration that both maximizes lexical diversity and preserves task-type, length, and service composition close to production.

Different scoring methodologies. For open-ended generative tasks (summarization, content generation) we keep pairwise SBS against a baseline, as in Arena-Hard, but augment it with explicit per-example criteria (Lin et al., 2025; Zhang et al., 2026a; Li et al., 2026) covering instruction following, completeness, factual correctness, and formatting. We generate these checklists with Kimi-K2.5 in a RubricHub-style pipeline (Li et al., 2026) and split each item into objective criteria, grounded in the masked request template, and subjective criteria, grounded in the instance-specific variable spans.

To check that the criteria capture what actually drives a verdict, each annotator independently produced both per-criterion verdicts (pass, fail, not applicable) and a separate overall SBS verdict. Criteria were applicable in nearly all cases: annotators marked not applicable in under 2% of summarization and at most 0.4% of content-generation judgments. Reconstructing the overall verdict from per-criterion votes alone recovers almost perfect agreement with the human consensus and clearly beats an objective-only rule. We use an objective-then-subjective Criteria Aggregation (Obj→Subj) rule: a response that fails any objective criterion loses outright, and the subjective criteria decide only when neither response is eliminated this way; per-annotator labels are then combined by majority over the three annotators. The gap from the full rule to the objective-only variant is largest on content generation, confirming that subjective criteria carry essential signal (Table 11).

Task	Aggregator	Cohen's Kappa
Summ.	Criteria Agg (Obj→Subj)	**0.85**
	Objective-only	0.72
Cont. gen.	Criteria Agg (Obj→Subj)	**0.87**
	Objective-only	0.49

Table 11: Reconstructing the consensus overall SBS verdict from per-criterion annotator votes alone. The full criteria aggregator recovers almost perfect agreement; removing subjective criteria substantially degrades agreement, especially on content generation.

A.2.3 Judge validation against human annotations

To assess the referee's agreement with the annotators' responses we adopt a naming scheme that makes three design dimensions explicit and keeps them disentangled: the prompt format, the decision source, and the aggregation rule:

- **Baseline SBS:** the original pairwise judge without generated criteria.
- **Criteria-Guided SBS:** gives the judge the full checklist as contextual guidance but asks for one

SBS verdict.

- **Per-Criterion (Obj→Subj):** asks the judge to grade model answers against all criteria in a single API call (evaluating each as *Pass / Fail*) and then aggregates those verdicts using the Criteria Agg. (Obj→Subj) rule.
- **Per-Criterion + Overall Verdict:** asks the judge to grade model answers against all criteria and then provide an arena-style overall verdict from the same structured call.

We validate these configurations against expert SBS annotations using DeepSeek-V3-0324 as the judge model.

All metrics in Table 12 are means over three independent runs. Following arena-style practice (Li et al., 2025), each response pair is judged twice per run, once in the original A/B order and once reversed, and the two verdicts are combined by numeric averaging, as in the Arena-Hard-Auto positional-bias correction. We report Cohen's Kappa (κ) rather than raw accuracy because the SBS label distribution is imbalanced; κ is our primary metric.

Task	Judging method	κ
Summ.	Baseline SBS	0.61
	Criteria-Guided SBS	**0.68**
	Per-Crit. (Obj→Subj)	0.53
	Per-Crit. + Overall	0.58
Cont. gen.	Baseline SBS	0.49
	Criteria-Guided SBS	0.55
	Per-Crit. (Obj→Subj)	0.70
	Per-Crit. + Overall	**0.79**
Avg. Open-ended	Baseline SBS	0.57
	Task dependent	**0.72**

Table 12: Judge–human agreement for DeepSeek-V3-0324. The Avg. Open-ended row reports a task-weighted average over the summarization and content generation tasks.

Compared to the baseline SBS judge, adding criteria substantially improves agreement: on summarization, Criteria-Guided SBS raises κ from 0.61 to 0.68; on content generation, Per-Criterion + Overall Verdict raises κ from 0.49 to 0.79 (Table 12).

As shown in Table 2, improvements are observed on both task slices. However, the reference-based κ values correspond to different evaluation targets (SBS preference compared to correctness against gold answers) yet both quantify judge–human agreement.

A.3 Inhouse IFEval

Production assistants and support-style applications routinely impose explicit constraints on reply form: output format, length budgets, language, allowed and forbidden phrasings, templates, tone, and role-play rules. Public benchmarks like IFEval and IFBench (Pyatkin et al., 2025) probe constraint satisfaction under synthetic, predominantly English prompts unrepresentative of deployed traffic.

Construction. The benchmark reuses the AutoIF pipeline (Dong et al., 2025) for verifier generation and quality filtering. The only methodological difference is that AutoIF starts from a small set of hand-written seed instructions augmented by an LLM, whereas our prompts come directly from in-house traffic with no seeds — for each sampled prompt, an LLM extracts candidate constraints from scratch, and the AutoIF gates (executable verifier, cross-validation on independent test cases, back-check) are applied unchanged. Approximately 33% of sampled queries pass the pipeline, yielding a benchmark of 1,000 prompts with ∼1,800 validated verifiers. Because the source prompts are real support-style and structured-output requests, the constraint mix is shifted toward JSON-schema constraints — required key sets, per-field types and value ranges, single-JSON-only output, per-field length and language — alongside the IFEval-style prose categories.

A.4 Inhouse BFCL

Existing benchmarks do not match the distribution of a production platform serving diverse internal teams. Tool-equipped requests make up 12% (see Table 10) of our traffic, spanning varied domains, toolset sizes, and description verbosity. We built a stratified benchmark matched to this distribution along four axes: domain, toolset size, dialogue stage, and trajectory depth, so that aggregate scores predict real deployed performance.

Construction. We follow the BFCL methodology in AST mode (Patil et al., 2025), with two adaptations for our production setting. First, tools in our LLM platform traffic are live systems owned by tenant teams; invoking them from a benchmark harness would trigger side effects, and most lack offline substitutes. We therefore evaluate in AST mode only, scoring predicted calls against references structurally and semantically rather than by

executed outcome. Second, as in BFCL, references are human-curated: from 1,000 sampled examples, expert annotators produce valid (tool, argument, value) configurations and classify each argument as *constrained* (enum, numeric, boolean, or verbatim context string) or *free-text* (free-form natural language). Free-text arguments are scored on presence alone to avoid false negatives from paraphrastic variation.

Coverage filter. During curation, roughly 28% of sampled examples are dropped: cases where annotators could not agree on a stable acceptable set, or whose answer is entirely free-form text unverifiable under AST matching. This retention filter on benchmark ambiguity replaces the implicit filtering that hand-curated `possible_answers` provide in BFCL, bounding the scorer's false-positive rate at the cost of reduced coverage on the free-text-only slice of production traffic.

Metric. Each candidate call is scored against the curated acceptable set by a deterministic match function that emits per-component verdicts: call-vs-text *decision*, chosen *tool(set)*, *required* arguments presence, *schema* validity, and constrained-argument values. Each component is true, false, or not-scored when inapplicable (e.g. no values to check on a text-reply example); the headline *example pass* is the conjunction of all applicable components. No LLM judge is invoked at scoring time.

Limitations of the metric. Two limitations merit note. First, free-text argument values are excluded from value matching by construction; a model that hallucinates a plausible but incorrect free-text body is not penalised on this axis. Second, text replies are scored only on the call-vs-text *decision*, not on content. The residual gap to stricter expert-level evaluation including free-text quality is captured by the in-house dialogue arena (Section A.2).

A.5 SmartSearch benchmark

Public benchmarks evaluate FC quality in isolation, but a production agent typically issues tool calls inside a longer retrieval-and-reasoning loop. To measure this regime on a realistic in-domain task, we introduce *SmartSearch*, a human-curated benchmark over internal corporate sources.

Data collection. Each evaluation sample is a query and source pair: the query is a natural-language information request authored by a domain expert annotator, and the source is the single internal wiki page that the annotator identified as containing sufficient information to answer it. Every query has exactly one canonical source by construction, which yields an unambiguous ground-truth reference; queries whose evidence was spread across multiple pages were excluded during annotation.

Tool space. The agent is given exactly two tools that wrap an internal smart-search service. The first is a *search* tool that returns a ranked set of text chunks for a query. The second is a *page-QA* tool that takes a free-form question about a specific wiki page and returns an answer; internally, a separate model instance with a clean context receives the full page content together with the question and answers it in a standard QA format, and that answer is returned as the tool result. Restricting the agent to these two tools lets the benchmark compare models on FC ability — query formulation, the choice between broad retrieval and targeted page-level questioning, and grounding of the final answer — rather than on tool-discovery behaviour.

Reference construction. For each sample, a golden answer is produced by prompting Qwen3-235B-A22B-Thinking-2507 (Yang et al., 2025) on the full content of the reference page, and an atomic list of ground-truth claims is then extracted from the golden answer. Both the golden answer and the extracted claim list were reviewed by human annotators and corrected where necessary.

Metrics. Three metrics are reported. *Recall* measures the fraction of ground-truth claims that an LLM judge marks as present in the agent's answer, with partial matches receiving half credit. The grounding of the answer is captured through two intermediate quantities over the claims the agent produces: *Citation Coverage*, the fraction of those claims that cite some source, and *Citation Correctness*, the fraction of the cited claims whose citation actually supports them. *Grounded Rate* combines the two, measuring the fraction of claims that are both cited and correctly supported. Recall and Grounded Rate are summarised by their harmonic mean, denoted $\mathrm{F1}_{\mathrm{R\&G}}$. All LLM-judge protocols were calibrated against independent human annotators: the initial Recall judge (Qwen3-30B-A3B-2507-Thinking with the first version of the prompt) reached 85% agreement with the humans, and after error analysis — prompt revision,

switching the judge model to Qwen3-Next-Instruct, and fixing the decoding temperature to 0 with a repetition penalty of 1.05 to avoid output loops — agreement rose to 95%. The judges used for Citation Coverage and Citation Correctness reached 92% agreement under the same protocol.

Evaluation regime. The agent operates in a ReAct loop (Yao et al., 2023), interleaving thought, tool call, and observation steps until it emits a final answer with citations.

B Adapted public benchmarks

B.1 Russian IFEval

To evaluate instruction-following capabilities in Russian, we constructed ruIFEval, a Russian adaptation of the original English IFEval benchmark. We started from the original benchmark samples and manually translated them into Russian with the help of human annotators. During translation, we preserved the intent of each prompt and the structure of the tested instruction-following behavior, while adapting the wording to sound natural in Russian. This adaptation was relatively straightforward because IFEval is largely language-agnostic: most tasks rely on exact, verifiable constraints rather than language-specific morphology, such as case inflection or agreement.

In addition to translating the prompts, we also localized the constraint set used by the benchmark verifiers. These constraints cover different types of instruction-following requirements, such as formatting, keyword inclusion or exclusion, length restrictions, counting constraints, and structural requirements. When a constraint was language-dependent, we adapted it to the Russian setting rather than translating it literally. For example, constraints requiring an exact number of occurrences of a particular character were changed to use Cyrillic analogues, so that the verifier still tests the same type of behavior but in a linguistically appropriate way.

B.2 Russian BFCLv3

Russian-language FC evaluation is poorly served by existing multilingual resources. AceBench (Chen et al., 2025a) extends to Chinese but not Russian, and MLCL (Luo et al., 2026) targets Chinese, Hindi, and Igbo. None offers a Russian split suitable for training-stage decisions in our setting. We therefore localised BFCLv3 into Russian. Unlike at training time, where the scale of the data rules out human verification, evaluation sets are small enough that translation combined with human verification and manual correction is tractable; the resulting set is what we refer to throughout this work as ruBFCLv3. The central concern of the localisation is the preservation of the unambiguity and solvability of each example: a translated user request, target answer, and tool descriptions must not introduce contradictions or new ambiguities. The user request and the associated tools are translated jointly with structured output, automatically generating a translation schema that preserves the original JSON structure of each tool. An ensemble of LLM judges then verifies translation correctness along two axes — absence of logical contradictions and completeness of translation across all semantically meaningful fields. The target answer is translated next, conditioned on the validated request and tools, and is itself verified by LLM judges. After this automatic pipeline, a panel of public models (Qwen3-8B, Qwen3-32B, Qwen3-235B-A22B-Instruct-2507, GLM-4.5, and GLM-4.6; GLM-4.5 Team et al., 2025) was scored on the resulting set, and examples on which model disagreement was abnormally high relative to the corresponding English example were flagged for human review and corrected manually. This human-in-the-loop step is what makes translation tractable for an evaluation set but prohibitively expensive at training-data scale.

B.3 Russian MultiChallenge

We evaluate models on MultiChallenge (Deshpande et al., 2025), a multi-turn instruction-following benchmark targeting these long-horizon failures, using both the original English version and a Russian adaptation constructed for this work.

To measure the same capabilities in Russian, we construct a Russian version of MultiChallenge by translating all dialogues, preserving dialogue roles, turn order, evaluation axis, and binary pass criterion. Rubrics checking a translated surface string are translated; the remaining language-independent rubrics are kept in English so both versions share identical criteria.

Naive full-dialogue translation failed: models sometimes followed embedded instructions instead of translating, producing omissions and reference shifts. We therefore translate one turn at a time, providing preceding turns as context. This is especially important for RELIABLE VERSION EDIT-

ING, whose conversations are 2.4× longer on average (∼2,300 words, 13 turns).

For all subsets except RELIABLE VERSION EDITING, we apply an iterative translate–verify–revise pipeline: a separate `gemini-3.1-pro-preview` (Google DeepMind, 2026) call checks each turn against the English source for preserved instructions, facts, references, and rubric conditions; flagged turns are revised for up to five rounds. Expert annotators then verified every translation. RELIABLE VERSION EDITING was translated entirely by annotators due to its greater complexity relative to other subsets.

After translating the dialogues, annotators manually reviewed every binary rubric. Most encode a semantic condition invariant to surface language and were kept in English, our multilingual judge, `gemini-3.1-pro-preview`, handles English rubrics reliably even when scoring Russian responses. A minority test a surface form, requiring a verbatim string (e.g. It's important to note that", Yes"/"No") or forbidding a specific word—and had to be localized to match the Russian dialogue. In total, 44 of the 273 rubrics were localized—21 in INSTRUCTION RETENTION, 20 in RELIABLE VERSION EDITING, and 3 in SELF-COHERENCE, with none in INFERENCE MEMORY, consistent with that axis being purely semantic.

For both languages, models generate responses to the full multi-turn conversation, and only the final response is evaluated with the benchmark's instance-level binary rubric. We keep decoding and judging settings identical across `en` and `ru` whenever possible, so that differences are not confounded by changes in the generation or evaluation setup.

C General Expert

Mitigating response length increase. A persistent challenge during alignment was the tendency of trained models to produce increasingly longer responses, as the reward model exhibited a preference for verbose outputs (Singhal et al., 2024; Dubois et al., 2024). The ablation described below was conducted using Qwen3-8B, once the final recipe was established, it was applied to Qwen3-32B. Our initial DPO (Rafailov et al., 2023) runs, while improving quality on arena-based benchmarks, nearly doubled the average response length (from 1388 to 2064 tokens on Ru-arena-hard; see Table 13), and attempts to rebalance the training set by favoring shorter chosen answers (Park et al., 2024) had negligible effect. Switching to GRPO with only the reward model score as a signal exacerbated the problem: the model learned to hack the length-biased reward (Gao et al., 2023) by generating additional self-posed questions and answering them, drifting far from the initial policy's distribution and rendering training ineffective (Figure 1). To address this, we combined two techniques. First, we introduced a multiplicative length penalty that transforms the reward score $R(x, y)$ based on the ratio of the response length $L(y)$ to a baseline length $L_0(x)$ defined as the response length of Qwen3-235B-A22B-Instruct-2507:

Model	Ru-Arena-Hard		In-House Arena	
	Score	Avg. Len.	Score	Avg. Len.
Qwen3-8B	54.43	1116	52.23	221
+ SFT	74.92	1388	54.81	308
+ DPO	85.13	2064	57.44	384
+ DPO w/ Len. Rebal.	<u>85.56</u>	2010	57.05	375
+ GRPO w/ Len. Pen.	82.66	1274	**59.09**	362
+ GRPO w/ Len. & KL	**86.02**	1220	<u>58.31</u>	320

Table 13: Ablation of alignment stages on Qwen3-8B. Score denotes win rate against the baseline; Avg. Len. is the mean response length in tokens. Len. Rebal. refers to rebalancing DPO training to favor shorter chosen responses. Len. Pen. and KL denote the multiplicative length penalty and increased KL divergence coefficient, respectively

$$R(x, y) \mapsto R(x, y)\big(1 - \alpha(x, y)\big)$$

$$\alpha(x, y) = \operatorname{sgn} R(x, y) \cdot \operatorname{clip}\left(\frac{\frac{L(y)}{L_0(x)} - d_{\min}}{d_{\max} - d_{\min}}\right)$$

where $d_{\min} = 0.1$ and $d_{\max} = 0.3$ define the bounds of the penalized length deviation range. The sgn factor ensures correct behavior for both positive and negative reward values, which simpler additive or milder multiplicative variants failed to handle; all alternatives we tested still allowed the model to hack the reward. Second, we increased the KL penalty coefficient from 0.001 to 0.01 to constrain distribution drift (Ziegler et al., 2019); without this, the model stagnated in quality on our benchmarks despite rising reward scores, and also degraded on other experts' domains, undermining the merged model. The combination of both techniques yielded a model that surpassed DPO in benchmark scores, achieving 86.02 compared to 85.56 on Ru-arena-hard and 58.31 compared to 57.05 on the in-house arena, while producing

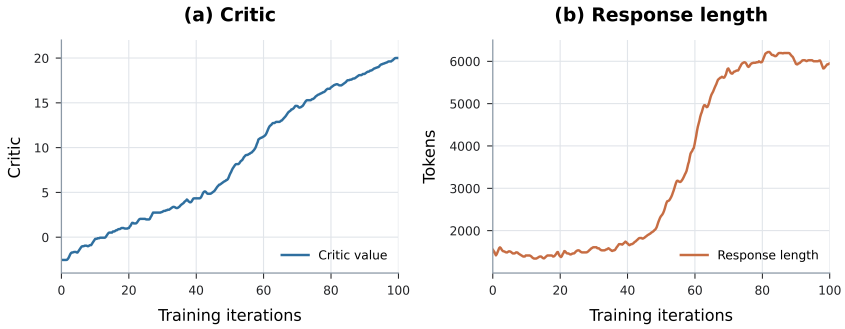

Figure 1: Evolution of GRPO mean reward (left) and mean response length in tokens (right) over training steps. Without length and KL regularization, the model exploits the RM verbosity bias.

substantially shorter responses of 1220 compared to 2010 and 320 compared to 375 tokens, respectively, validating GRPO with joint length and KL regularization as the alignment method of choice.

D Instruction-Following Expert

D.1 Data Creation

To build specialized IF training data, we used a synthetic data generation pipeline inspired by AutoIF (Dong et al., 2025), adapting it to Russian. This adaptation is necessary because many IF constraints are language-dependent and involve formatting, morphology, punctuation, lexical restrictions, and stylistic requirements. Therefore, all major components of the pipeline were generated and filtered in Russian. The pipeline largely follows the AutoIF data construction procedure, but we instantiate it for the Russian setting and report the concrete filtering thresholds, dataset sizes, and implementation details used in our experiments. We also highlight several practical modifications introduced to improve reproducibility and reduce degenerate or low-quality samples. The pipeline was designed around verifiable instructions whose compliance can be checked automatically by deterministic or semi-deterministic validation functions. The data creation process consisted of several stages.

Constraint generation. We started from 54 hand-written seed instruction types from IFEval, AutoIF, and IFBench (Zhou et al., 2023; Dong et al., 2025; Pyatkin et al., 2025), translated them into Russian, and covered formatting, lexical, structural, length, and multi-condition constraints. To expand the pool, we repeatedly sampled groups of five constraints as in-context examples and asked an LLM to generate five new verifiable constraints in the same format. This produced about 100k candidates. Exact-match and semantic deduplication reduced them to 72k unique constraints.

Verifier and test-case generation. For each constraint, we generated 8 candidate validation functions and 3 synthetic test cases per function. The validators were evaluated against test cases with expected binary labels. We then applied consistency-based filtering. First, we removed test cases for which fewer than half of the validators produced the expected label, since such cases were likely ambiguous, mislabeled, or underspecified. Next, we re-estimated validator reliability on the remaining cases and removed functions that failed to execute or achieved accuracy below 0.5. Finally, we discarded a constraint if fewer than 3 validators or fewer than 5 test cases remained, and additionally required at least 2 positive and 2 negative test cases. After this stage, 50k constraints remained.

Back-translation validation. To improve semantic alignment between constraints and validators, we generated a natural-language instruction from each validation function and compared it with the original constraint using cosine similarity. If the similarity was below 0.6, the validator was removed. If more than 60% of validators for a constraint failed this check, or if all validators were removed, the whole constraint was discarded. This filtered out validators that implemented a different condition from the intended instruction and left 43k constraints.

Mapping constraints to SFT samples. Each remaining constraint was randomly attached to 3 SFT samples, producing 131k constraint-augmented samples. This allowed us to combine verifiable IF requirements with diverse underlying tasks instead of training only on synthetic standalone prompts. For each augmented sample, we generated a can-

didate response and scored it using the prompt-based procedure from AutoIF, retaining only samples with the maximum score of 10. This left 62k samples.

Then we split these samples by constraint placement. For 20k samples, the constraint was inserted into the user instruction. To increase phrasing and positional diversity, we used three strategies: prepending the constraint, appending it, or rewriting the instruction so that the constraint was naturally integrated. The remaining 42k samples were system-level constraint samples, where the constraint was placed in the system instruction.

Completion generation and final selection. For each sample, we generated 8 candidate completions and scored them with the corresponding validators. We removed samples for which all completions had validation accuracy below 1, ensuring that each retained sample had at least one fully valid completion. The final dataset contained 10k user-level and 16k system-level constraint samples. For each retained sample, we additionally scored valid completions with our reward model and selected the best one.

D.2 Training

We first added IF data during SFT, allowing the model to imitate validated completions in both user-level and system-level settings. However, SFT only provides positive demonstrations and does not directly optimize strict constraint satisfaction under sampling.

As an alignment baseline, we also evaluated DPO on the same IF data. It did not improve IF metrics and increased the average response length by approximately 1.5x, suggesting that preference optimization may encourage verbosity without reliably improving verifiable compliance. This motivated us to move from preference-based alignment to RLVR-style training.

We used GRPO-style reinforcement learning with verifiable rewards. Each prompt was associated with validation functions checking whether the generated response satisfied the requested constraints, and the initial reward was based on verifier-derived IF accuracy. This reward led to rapid gains in measured IF accuracy but also exposed reward hacking. The model learned to optimize validators directly instead of producing useful answers. Empirically, the average reward increased while the average response length sharply decreased, as shown in Figure 2. The model discovered shorter and less informative completions that satisfied formal checks but degraded answer usefulness.

A representative example, translated into English, is shown below. The system instruction requires an acrostic whose first letters spell "EXAMPLE". Instead of answering the user's question, the model outputs only the required initials. This may satisfy the acrostic validator but is clearly unhelpful because it does not provide the requested answer.

> **System:** Write the entire answer as an acrostic: the first letters of the lines must spell the word "EXAMPLE".
>
> **User:** One in five Americans suffers from allergies. In a random sample of 250 Americans, how many people would you expect to suffer from allergies?
>
> **Assistant:**
> E
> X
> A
> M
> P
> L
> E

This behavior occurs because verification functions typically evaluate only whether a specific constraint is satisfied. They do not necessarily assess whether the response is complete, coherent, helpful, or semantically adequate. To address this issue, we evaluated several combinations of verifiable and semantic reward components, including stronger KL regularization, explicit length penalties, reward-model-based penalties, and an LLM-as-a-Judge penalty based on a 1–10 scoring prompt. Results are presented in Table 14.

Our final reward follows the IF-RLVR-style formulation (Pyatkin et al., 2025), extended with a reward-model-based quality correction. Let V_i be the verifiable reward for sample i, and S_i be the reward-model score of the generated completion. The final reward R_i is:

$$R_i = \begin{cases} V_i + 1, & \text{if } V_i > 0 \text{ and } S_i > \alpha_i, \\ V_i - 0.5, & \text{if } V_i > 0 \text{ and } S_i \leq \alpha_i, \\ V_i, & \text{if } V_i \leq 0. \end{cases}$$

Here, α_i is a prompt-specific reward-model threshold. Unlike the original formulation, which uses a fixed threshold from the reward-model score

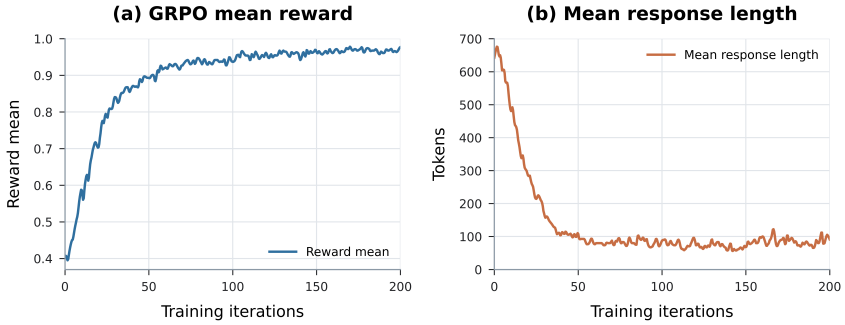

Figure 2: GRPO mean rewards (left) and mean response length in tokens (right) by training steps.

distribution, we compare each completion against a prompt-specific quality baseline. We tried experiments based on reference answers (RM / ref.), the current SFT model (RM / SFT), and a stronger teacher model (RM / 235B). The best results were obtained when α_i was set to the average reward-model score of 8 completions from Qwen3-235B-Instruct-2507 on the same prompt. As shown in Table 14, the reward-model penalty with a prompt-specific teacher baseline gave the strongest and most consistent improvements on ruIFEval. This reward design keeps verifier rewards precise and scalable, while the prompt-specific reward-model threshold penalizes formally valid but low-quality outputs.

	ruIFEval			
Setup	**P-S**	**P-L**	**I-S**	**I-L**
Qwen3-8B	0.692	0.722	0.786	0.808

E Function-Calling Expert

The FC expert targets four capabilities: selecting the correct tool from a heterogeneous pool, populating arguments with appropriate types, chaining dependent calls across turns, and abstaining when no available tool fits. Russian is a particular focus, since open FC training data and evaluation suites are overwhelmingly English-centric. The expert is evaluated on English BFCLv3, AceBench, τ^2-bench and on ruBFCLv3 (Appendix B.2); these score the four capabilities jointly, with the multi-turn subset (Table 15) the most direct measure of chaining. BFCLv3 additionally serves as the development benchmark throughout this appendix: all mixture and checkpoint decisions are made on it (ruBFCLv3 enters only the language-split sweep), whereas AceBench and τ^2-bench enter no selection decision, so the per-stage gains on them (Table 18) are free of selection effects.

Model	BFCLv3 (en)	BFCLv3 (ru)
Qwen3-32B (no-think)	21.00	17.75
+ SFT	38.12	29.88
+ SFT + GRPO	**42.88**	**37.12**

Table 15: Multi-turn subset accuracy on BFCLv3 (en/ru) across the FC recipe stages. The multi-turn regime, which exercises dependent calls across turns, roughly doubles from base to the SFT-plus-GRPO stage.

E.1 Data Creation

Limitations of existing data. FC data is generated synthetically rather than reused from open corpora, for three reasons. First, open FC data is English-only. Second, translating English FC data into Russian is structurally unsafe — function names, parameter keys, and `enum` values must remain untouched while user utterances and tool descriptions are rewritten, and the cross-references between an utterance and a selected `enum` value are routinely severed by translation; Chen et al. (2025b) document this for the English–Chinese setting, and Luo et al. (2026) identify *parameter value language mismatch* as a dominant multilingual FC failure mode. Third, open corpora are short, single-turn, shallow-schema, and narrow in domain. As a preliminary check, SFT was run from the base model on the union of public FC datasets

— xLAM/APIGen (Liu et al., 2024), Hermes (Nous-Research, 2024), and ToolACE (Liu et al., 2025) — and evaluated against the base: training on the original English data gave no appreciable gain on English BFCLv3, and a machine-translated Russian version moved ruBFCLv3 by less than a point. Both the tool pool and the dialogue pool are therefore generated from scratch in each target language, following ToolACE, APIGen-MT (Prabhakar et al., 2025), and Toucan (Xu et al., 2025).

Tool generation. The tool pool is built in two stages. Seed topics are extracted from public FC datasets via BERTopic clustering (Grootendorst, 2022) and expanded from 15.5K to 33.5K through self-instruct (Wang et al., 2023) with inter-round MinHash deduplication (Broder, 1997); a topic is deliberately narrow (e.g. "UTF-8 string operations") and serves as a diversity knob rather than a taxonomy. Then 15 tools per topic are generated by gpt-oss-120b (OpenAI, 2025) and passed through Merge (semantic deduplication), Refine (description and schema enrichment) (Ye et al., 2026), JSON-Schema validation, and a final MinHash pass; a function name and its required parameters are held invariant throughout, so all derived versions stay call-compatible. Description length is controlled separately: compression passes after Merge and after Refine populate the short end of the range — Refine in particular inflates descriptions — giving four length levels per tool. The Russian pool is generated natively rather than translated: the pipeline runs end-to-end in Russian (topics included); the few-shot seed exemplars are translated once by Qwen3-235B-A22B-Instruct-2507 with structured fields and literals held constant, then manually validated — tractable at exemplar scale, unlike at training-data scale; the Refine prompt is additionally constrained to keep description language consistent, since Russian tools otherwise drift back into English. After deduplication the English run yields 441K tool variants (unique tools $\times$ length levels) and the Russian run 456K; deduplication is applied within each language.

Dialogue generation. Single-pass generation exhibits three failure modes: task degeneration (the user is endowed with information only the tool can provide), mode collapse onto a few templates, and the absence of a reference against which hallucinated arguments can be detected. The pipeline (Figure 3) separates planning from execution to mitigate all three, in the spirit of APIGen-MT and ToolACE: conditioning each trajectory on a randomly sampled tool group mitigates mode collapse, fixing the user goal and calls ahead is designed to preclude task degeneration, and the trajectory serves as the reference for checking assistant calls. The planner first builds *local trajectories* per tool group — persona, goal, expected calls with arguments, and expected environment responses — each scored by three judge samples (drawn at high temperature to diversify critiques) over up to four revision rounds, then composes them into a *global trajectory* spanning the dialogue with a further such round. In Phase 2, three agents replay it under asymmetric visibility: the User Agent sees only persona and goals, the Assistant only history and available tools, and the Tool Agent — which alone has the full trajectory — validates each call and emits only what a real tool would return, never exposing the plan or its ground-truth arguments. User and assistant turns are each sampled multiple times and resolved by judge and majority voting respectively. Turns failing voting or validation are kept in context for later recovery but never used as training targets. All roles are filled by Qwen3-235B-A22B-Instruct-2507, yielding 1.2M English and 300K Russian turn-level training samples, the Russian portion from a native-language run. The tools are not executable, so correctness rests on the planner's reference rather than execution, and a single model family generates and validates the dialogue data (the tool pool comes from a different family, gpt-oss-120b). The evaluation is external to this pipeline — BFCLv3, AceBench, and τ^2 are public, and ruBFCLv3 is human-verified — and the deployed merged model ends up ahead of the dialogue generator itself on ruBFCLv3 (65.96 vs. 64.42; Table 6).

E.2 Training

The tool and dialogue pools feed two training stages, SFT then GRPO; this subsection describes the recipe and the ablations behind the GRPO mixture.

Model selection. The stages are studied in isolation: SFT is run on FC data only from the base model, and GRPO continues from that FC-SFT checkpoint, so each stage's contribution can be attributed cleanly. This differs from the main recipe, where the FC expert branches from the shared multi-domain SFT, so the numbers here are not those of the deployed model. FC is composite, and

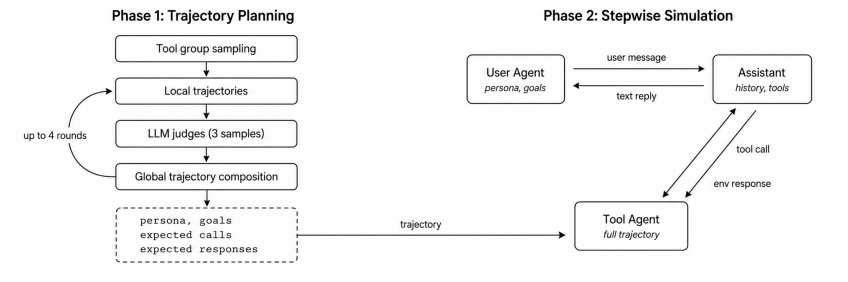

Figure 3: Dialogue generation pipeline. A planner constructs a structured trajectory from a sampled tool group and refines it through up to four rounds of judge feedback. The trajectory is then handed to a three-agent stepwise simulation in which the User Agent, Assistant, and Tool Agent operate under asymmetric visibility; flagged erroneous assistant turns remain in context but are never used as training targets.

in preliminary runs the 8B base responded inconsistently to SFT recipe changes, so SFT is studied directly on Qwen3-32B in no-think mode. The GRPO mixture search is run at 8B for cost. Two of its three axes — the text share and the irrelevance share — tune a behavioural bias rather than a capability, so unlike the capability gains from SFT their direction is expected to transfer to 32B, where it is re-verified (Table 19); the language split is a data-balance choice with no such transfer claim and is simply fixed at 8B.

SFT. Each assistant turn is a separate training sample with loss on that turn only. SFT is treated as a coarse warm-up: the mixture is stratified 50/50 between tool-call and free-form text targets — avoiding both an over-representation of tool calls, which tends to suppress textual fluency, and of text, which dilutes the core skill — and 50/50 English–Russian, by downsampling the larger English pool. Samples are additionally stratified by total tool-description length: in development runs, controlling for tool count alone still left performance variation across otherwise comparable dialogues, so total tool-description length serves as the difficulty signal, and the mixture is biased toward longer-description samples while retaining short ones for coverage.

GRPO. GRPO uses a slice of each language pool reserved before the SFT mixture is drawn, disjoint from the SFT sample by construction, with the same length stratification. The reward is binary and follows Tool-N1 (Zhang et al., 2026b): for a tool-call target, the call is compared to ground truth as a multiset of `(name, arguments)` dictionaries, reward 1 on exact match and 0 otherwise; for a text target, reward 1 if and only if no tool call can be parsed. Text quality is not otherwise

Configuration	BFCLv3 (en, multi-turn subset)
Step 1a: assistant text share (no irrelevance)	
20%	**23.38**
30%	19.37
50%	15.75
70%	11.62

Configuration	Irrelevance	Relevance
Step 1b: irrelevance share within 20% text		
5%	79.78	83.33
10%	**84.26**	**83.33**
20%	79.16	83.33
30%	86.27	66.67

Table 16: GRPO Step 1 mixture sweep on English-only data, run on the 8B SFT checkpoint. Step 1a varies the share of assistant text responses with no synthetic irrelevance injected, scored on the multi-turn subset of BFCLv3 (en). Step 1b fixes the text share at the Step 1a setting (20%) and varies the irrelevance rate within the text responses, scored on the irrelevance and relevance subsets of BFCLv3 (en); the relevance subset is small (N=18 in BFCLv3), so its single-configuration differences should be read as trends, while the irrelevance subset is larger. Bold rows mark the configurations carried forward, not the per-column maxima.

rewarded — the same opening the IF verifier left for empty completions — but no degenerate-text collapse appeared here: the reward is indifferent among non-call outputs and, unlike the IF verifier, gives minimal completions no advantage, so the SFT text distribution is simply preserved; refusal and interpretive-reply quality is out of scope and covered by the in-house arena. This binary reward admits a dominant exploit: when in doubt, emit a call. After the first GRPO runs the model defaults to this low-risk action and irrelevance detection suffers; the 32B direction check quantifies the effect — without injected irrelevance the subset sits at 78.3, versus 88.5 with it (Table 19). We correct this through the data distribution rather than the reward, which we leave untouched — more elaborate decompositions with separate format, syntax, and semantic components were explored in early iterations, but the extra terms added surface for reward hacking, so we retained plain exact match. We tune two knobs: the share of synthetic irrelevance cases, which counters over-calling and restores irrelevance detection, and the share of assistant text targets, which governs multi-turn accuracy. Irrelevance cases are constructed from existing samples by removing the ground-truth tool from the available pool and rewriting the target as a textual refusal — the no-applicable-tool case of abstention.

EN-RU split	BFCLv3 (en)	BFCLv3 (ru)
40-60	60.22	55.44
50-50	59.12	56.71
60-40	59.44	57.22
70-30	**62.62**	**57.05**

Table 17: GRPO Step 2 sweep of the English–Russian split on the 8B SFT checkpoint, with the text share fixed at 20% and the irrelevance share at 10% within text (the Step 1b setting from Table 16). Bold marks the configuration carried forward, not the per-column maximum.

The mixture is tuned one axis at a time with the others fixed, first on English and then extended to Russian; throughout, we act on the sign and ordering of each axis rather than on point differences between adjacent configurations, which single runs per setting cannot support. Step 1a sweeps the assistant text share (Table 16); multi-turn accuracy is highest at the smallest tested share and falls monotonically as the share grows. We adopt 20% as a floor rather than a located optimum: shares below it were not searched, since the text targets are what supply abstention and interpretive-reply behaviour, and preserving them is a guardrail we impose rather than a trade-off we measured. Holding this fixed, Step 1b sweeps the synthetic-irrelevance fraction within the text targets; we take 10%, the interior peak of irrelevance detection across the 5–20% range, and do not chase the higher value at 30%, where the small BFCLv3 relevance subset (N=18) loses three examples — a drop we cannot distinguish from noise but see no reason to risk. Step 2 then fixes both and sweeps the English–Russian split (Table 17). Russian varies by at most 1.8 points across the sweep — if anything trending slightly higher at lower Russian shares, which we read as noise — so the split is adopted as a default rather than a finding: 70-30, whose English advantage rests on a single configuration we do not over-read, keeps Russian within 0.2 of its sweep peak. The resulting GRPO mixture is 70% English and 30% Russian; within each language, 80% tool-call and 20% text targets; within text targets, 10% are synthesised irrelevance cases.

Because 8B signal does not always transfer to 32B, the sign of each operative axis is re-verified directly at 32B (Table 19); the magnitudes are not re-optimised there, and the 8B mixture is carried forward as a default — only the directions, which reproduce across scales and data pools, are load-bearing. Over-calling is an exploit of the reward structure, which is identical at both scales, so its direction carries even where the magnitude does not — Table 19 reproduces both signs at 32B. The reward stays minimal; behaviour is shaped through the mixture.

Model	BFCLv3 (en)	BFCLv3 (ru)	AceBench	τ^2
Qwen3-32B (no-think)	63.13	54.03	54.60	31.53
+ SFT	69.37	58.69	67.80	35.20
+ SFT + GRPO	**73.19**	**66.93**	**73.00**	**38.20**

Table 18: Per-stage contribution of the FC recipe in isolation: base Qwen3-32B (no-think), FC-only SFT, then GRPO from that SFT checkpoint. These isolate each stage's effect and are not the deployed model, which branches from the shared multi-domain SFT. Best values per column in bold.

Findings. The per-stage breakdown shows where in the recipe the gains arise (Table 18). On the English-side benchmarks (BFCLv3 en and AceBench) SFT accounts for the majority of the gain and GRPO adds a further increment, consistent with GRPO acting as a precision-tightening stage once the basic FC behaviour is in place.

On Russian BFCLv3 the pattern inverts, with GRPO contributing its largest single-stage gain — achieved despite the Russian share dropping from 50% at SFT to 30% at GRPO. We read this as the over-calling rebalancing rather than a language-share effect: the Step 2 sweep (at 8B) moves ruBFCLv3 by at most 1.8 points as the Russian share varies from 60% to 30% (Table 17), so the share change cannot account for a gain of this size, whereas the rebalancing targets exactly the behaviours that move — abstention (Table 19) and multi-turn, with Russian multi-turn doubling over the recipe (Table 15). Gains on τ^2 are more modest at every stage: it scores end-to-end success over a full session, whereas the per-turn reward optimises individual calls, not session outcomes; aligning the two is future work.

Text share	Overall	Multi-turn
30%	68.9	38.0
20%	**70.7**	**44.8**

Irrelevance share	Overall	Irrelevance
0%	71.4	78.3
10%	**72.7**	**88.5**

Table 19: Direction check of the two rebalancing axes at 32B on English BFCLv3 (best checkpoint by overall accuracy; the ordering is preserved under the mean over checkpoints), each axis swept independently on English data with the other settings fixed, so the *Overall* columns are not directly comparable across the two sub-tables. A smaller text share yields higher multi-turn accuracy, and injecting synthetic irrelevance raises irrelevance detection. These are direction-confirmation runs on intermediate data pools (snapshots predating the final regeneration round), scored on BFCLv3 alone; they verify the sign of each axis and are not the per-stage results in Table 18, which use the selected mixture and the full four-benchmark suite. Multi-turn here exceeds the final mixture's (Table 15), partly since the selected mixture trades some English multi-turn for Russian coverage and irrelevance handling, and partly since the pools differ.

F Training Setup

The SFT stage for the 32B model took 57 hours on 4 nodes with 8 H100 GPUs each. Training used gradient checkpointing, FSDP (Zhao et al., 2023), and sample packing into 32k-token contexts without truncation. The optimal fine-tuning hyperparameters are reported in Table 20.

GRPO training was performed using verl (Sheng et al., 2025). Each RL expert was trained on 4 nodes with 8 H100 GPUs per node. The IF, General, and Tool experts took approximately 28, 40, and 62 hours, respectively. The main expert-specific differences were the reward functions, KL coefficients, sequence lengths, and the number of optimization steps, while the shared GRPO setup is reported in Table 22. The expert-specific hyperparameters are reported in Table 21.

Hyperparameter	**Value**

Table 23: Joint multi-domain GRPO sweep, run on Qwen3-8B for cost. The upper block starts from the mixed SFT checkpoint (FC+IF+general); the lower block starts from the general GRPO checkpoint trained on top of the same mixed SFT. *1-dom/batch* denotes the schedule in which each batch contains samples from a single domain (no in-batch domain mixing); all other rows use in-batch mixing. *Baseline* rows report the starting checkpoint of each block.

G Merging

The IF, FC, and general-domain experts come from three independent GRPO stages atop a shared SFT checkpoint, each with a domain-specific reward. Merging them is non-trivial: the three reward signals are structurally different, and joint multi-domain GRPO consistently degraded IF performance in preliminary experiments, as the model optimised the other rewards while relaxing strict constraint satisfaction. Conversely, prolonged single-domain RL caused noticeable regression on general-purpose benchmarks, making any single expert impractical as the production checkpoint directly. We therefore adopted a train-separately, merge-later strategy: forking from the shared SFT checkpoint into three independent GRPO runs, one per domain, then combining experts via SLERP of model weights. This section describes the merging procedure and the ablations used to settle on its configuration.

SLERP Merging We apply SLERP in two stages. First, the IF and FC experts are merged at coefficient t_1, producing $\theta_{\mathrm{IF+FC}}$. This intermediate checkpoint is then merged with the general expert at coefficient t_2, yielding θ_{merged}. We picked this ordering empirically: with three experts every combination can be tried, so we enumerated all of them and Table 7 reports the alternatives. The layer-wise SLERP coefficients were likewise chosen by grid search on validation splits, and we have no general rule for carrying either choice over to a different set of experts.

Coefficient selection. Rather than a single scalar t per stage, we set the SLERP coefficient separately for different parameter groups within each layer. For the first-stage IF + FC merge we use a layer-wise schedule with distinct values for self-attention projections, MLP projections, and remaining parameters (embeddings, norms). Attention coefficients are swept across $\{0, 0.3, 0.5, 0.7, 1\}$ per block, MLP coefficients follow the complementary pattern, and all other parameters use $t = 0.5$. The second-stage merge with the general expert uses a uniform $t_2 = 0.8$. All coefficients were chosen by grid search over the merged checkpoints.

Polishing stage. We experimented with a short SFT polish pass on θ_{merged} to recover surface-level formatting consistency that drifted after interpolation (e.g., occasional regressions in tool-call JSON formatting or structural markers in IF responses). Several small general-domain data mixtures were tried; the resulting checkpoints matched the unpolished merge on general metrics but consistently showed minor IF and FC regressions. Because the polish stage yielded no net improvement at extra compute cost, we excluded it from the final pipeline.

Joint RL and expert merging. As an alternative to expert merging, we explored joint multi-domain GRPO with IF and FC samples mixed in a single batch, each scored by its domain-specific verifier

and the IF reward rescaled to match the FC range. Domain balance is thus controlled by the data mixing ratio rather than explicit reward weighting. We swept the starting checkpoint, either mixed SFT or general GRPO on top of it, the domain composition and batching schedule, single-domain per batch or in-batch mixing, and the FC/IF sampling ratio. Table 23 reports the full sweep. The strongest configuration was joint GRPO over the general GRPO checkpoint with a 71%/29% FC/IF ratio; as even this configuration required the warm start and a $1.7\times$ budget while remaining sensitive to the mixing ratio, we also replicated this sweep at the 32B scale.

Sequential and joint multi-SLERP. As an alternative to the two-stage sequential merge, we evaluated a single-stage joint SLERP in which all three experts are combined simultaneously with weights $w_{\text{IF}}, w_{\text{FC}}, w_{\text{gen}}$ summing to one. The two variants are not equivalent, since SLERP is non-linear in the parameter vectors, and they make different implicit assumptions about how the three experts should be balanced. Table 24 compares the sequential variant used in Our model against joint multi-SLERP and TIES-Merging (Yadav et al., 2023) applied jointly to all three experts; for each method we report the best configuration found by the same grid search procedure described above.

Method	Arena		ruIFEval	BFCL	
	Ru-Hard	In-House		En	Ru
Joint multi-SLERP	92.15	64.42	0.781	70.84	64.41
Joint TIES-Merging	90.74	63.76	0.765	69.18	63.14
Seq. SLERP (Ours)	93.87	**69.57**	**0.799**	**72.27**	**65.96**
+ polish	**94.12**	68.10	0.795	71.83	65.40

Table 24: Comparison of merging strategies for combining three domain-specific experts (IF, FC, general). Each row reports the best configuration found via grid search over the method's hyperparameters. *Seq. SLERP* is the two-stage sequential merge used in Our model; + *polish* adds a short SFT pass on top of it.

Effect of the polish stage. We evaluated several polish configurations, varying the data subset and training duration. Polished checkpoints performed comparably on general-domain benchmarks but showed consistent minor regressions on IFEval and BFCLv3 relative to the unpolished merge. Table 24 summarises the best polish configuration against the unpolished merge. Given no quality gain and additional compute overhead, the polish stage was dropped from the final recipe.

H Additional Evaluations

MultiChallenge Tables 6 and 25 report MultiChallenge average scores for six models in English and Russian. Qwen3-235B-A22B-Instruct-2507 leads in both languages with 43.6 and 46.2 respectively. Our model ranks second at 37.4 and 34.1, narrowly ahead of T-Pro-2.0 in thinking mode at 37.0 and 31.9. The two Qwen3-32B variants cluster around 30–31% regardless of thinking mode, while T-Pro-2.0 without thinking trails at 26.4 and 27.8. The English-Russian gap varies across models, ranging from a 5-point drop for T-Pro-2.0 think to a 2.6-point gain for Qwen3-235B, indicating that cross-lingual robustness in multi-turn instruction following is not uniform across models.

Sensitivity to the judge model The in-house Arena is scored by an LLM judge, so we rescored the cached generations with three additional judges: GLM-4.6, Mistral-Large-3-675B-Instruct-2512 (Mistral AI, 2025), and DeepSeek-V3.1-Terminus (DeepSeek-AI et al., 2024) (Table 27). We reused the same generations and ran each judge deterministically, so the comparison isolates the judge itself. Absolute scores move, but the ordering our claims rest on does not: the deployed checkpoint ranks first under every judge, the same three models take the top places in all four columns, and both of our checkpoints stay ahead of Qwen3-32B in no-think mode. DeepSeek-V3, the judge behind the main results, is not from the Qwen family our checkpoints derive from, so it cannot prefer them out of family resemblance.

Inhouse IFEval Post-training produces a sharp Strict-IF improvement and a smaller but positive Loose-IF gain (Table 26). On Strict-IF, our model reaches 0.81 example-level and 0.89 constraint-level accuracy, against 0.68 and 0.67 for base no-think Qwen3-32B, matching the seven-times-larger Qwen3-235B-A22B-Instruct-2507 at the same parameter count. T-Pro 2.0 sits well below both base model modes, being thinking-optimised T-Pro 2.0 recipe traded base-skill quality for chain-of-thought capability, while the our recipe restores and surpasses both. On Loose-IF, our model reaches 0.58, ahead of base no-think Qwen3-32B at 0.52 but below thinking-mode T-Pro 2.0 at 0.59 by a margin within judge noise, and well below Qwen3-235B-A22B-Instruct-2507 at 0.66. The asymmetry is consistent with our reward design: the VerIF-style verifier reward is by construction concentrated

Model	IFEval	MultiChallenge	Arena Hard 2	
			Hard	Creative

Qwen3-235B-A22B-Instruct-2507	0.7798	**43.6**	**71.0**	**87.4**
T-Pro-2.0 (think)	0.7230	37.0	63.1	58.6
T-Pro-2.0 (no-think)	0.7023	26.4	46.2	62.8
Qwen3-32B (think)	0.7785	30.8	45.2	50.6
Qwen3-32B (no-think)	0.7770	31.5	32.3	41.8

Table 25: Comparison of models on English benchmarks.

Model	Strict-IF		Loose-IF
	ex.	constr.	
Ours	**0.81**	**0.89**	0.58
Qwen3-235B-A22B-Instruct-2507	**0.82**	0.83	**0.66**
T-Pro-2.0 (think)	0.60	0.65	0.59
T-Pro-2.0 (no-think)	0.51	0.50	0.48
Qwen3-32B (think)	0.77	0.81	0.56
Qwen3-32B (no-think)	0.68	0.67	0.52

Table 26: In-house instruction-following benchmark results.

on code-verifiable constraints, and gains transfer cleanly to Strict-IF on real production distribution. Loose constraints like tone, role, and semantic prohibitions are not directly optimised by the verifier reward, and the residual gap to a much larger generalist model indicates the natural next direction for the recipe.

Inhouse BFCL Three observations from Table 28 are worth highlighting. Both modes of T-Pro 2.0 sit at the bottom of the leaderboard, scoring 0.67 and 0.68, below Qwen3-32B in both think and no-think configurations; T-Pro 2.0 was optimised primarily for chain-of-thought reasoning, and the thinking-mode bias comes at a measurable cost on single-step tool selection. Our updated recipe recovers and surpasses the base: the final model in no-think mode reaches an example pass of 0.79 at the same parameter count as Qwen3-32B no-think at 0.71, matching the seven-times-larger Qwen3-235B-A22B-Instruct-2507 at the top of the leaderboard, 0.79 to 0.77. The gain concentrates on the components our recipe targets directly, call-or-text decision at +9 points over base and tool/required-argument match at +12 points, while schema validity is saturated for all candidates at ≥ 0.97 and constrained-value scores are flat across models. The component decomposition confirms this pattern: schema validity is uniformly high, 0.97 to 1.00, and uninformative, so the measured differences reflect the harder skills of deciding whether to call, routing to the correct tool, and supplying required arguments, which are exactly the skills the FC reward in Section E optimises.

SmartSearch Table 29 reports the SmartSearch results in a ReAct loop. Qwen3-235B-A22B-Instruct-2507 leads, reaching 0.551 recall, 0.852 grounded rate, and 0.669 $F1_{R\&G}$. Our model ranks the second and improves over base no-think Qwen3-32B on every metric: recall from 0.350 to 0.434, grounded rate from 0.754 to 0.778, and $F1_{R\&G}$ from 0.478 to 0.557. Despite running without reasoning, its $F1_{R\&G}$ also exceeds both Qwen3-32B and T-Pro-2.0 in their thinking modes (0.491 and 0.537), indicating that on this task the function-calling recipe contributes more than test-time reasoning does for the baselines. With no task-specific training for this domain or tool setting, the result indicates that the general function-calling recipe transfers beyond static benchmarks to a realistic in-domain retrieval task.

Model	Judge			
	DeepSeek-V3	GLM-4.6	Mistral-Large-3	DeepSeek-V3.1

Abstract

Extracting structured fields from hundreds of millions of documents annually remains costly in regulated industries: bespoke OCR cascades cover only a fraction of workflows, privacy rules preclude external models, and existing open-source VLMs that clear quality thresholds cost more to serve than human annotation. We present a deployed document-understanding system built on a Mixture-of-Experts VLM (35B total, 3B active), fine-tuned on in-house production data mixed with open-domain documents curated by a Difficulty-Aware pipeline for layout diversity, fact-extractability, and cross-model consistency. Fitting on a single H100 and serving heterogeneous workflows via prompting, the model leads all deployable (non-reasoning) baselines up to an order of magnitude larger. A quality-adjusted cost analysis, with confirmation and correction costs calibrated from production telemetry, shows it reduces expected costs by over 80% against the human baseline and by more than 50% against the best competing open-source model, while larger baselines remain economically unviable.

1 Introduction

Vision–language models (VLMs) are improving quickly at documents understanding (Bai et al., 2025b,a; Qwen Team, 2026), but using them in regulated business settings is still hard because of high serving costs, strict latency constraints and privacy rules. We tackle these problems at a large document processing platform which processes hundreds of millions of Cyrillic-language documents each year, including court judgments, invoices, tax certificates, and receipts. Human workers extract structured fields, sort documents by type, and check visual elements. Four barriers block automation. Documents contain personal data, which rules out cloud-hosted models. Open-source VLMs under 10B fall short of production quality, while larger models that clear quality thresholds are prohibitively expensive to serve at document-flow scale. The standard pipeline of OCR plus specialized models (Yoon et al., 2024; Wang and Shen, 2025) is costly to maintain and outgrows engineering capacity. Strict per-document time limits make reasoning-mode inference too slow for production.

We introduce a domain-adapted Mixture-of-Experts (MoE) VLM with 35B total and 3B active parameters that replaces separate workflow pipelines with a single prompt-driven model on one H100. Training mixes internal production data, where labeled fields come as a byproduct of daily work, with open-domain Common Crawl PDFs. The internal data matches production needs but saturates quickly; Common Crawl adds broad variety, yet samples generated without filtering are mostly too easy and lower quality. Our Difficulty-Aware Data Curation (DADC) pipeline solves this by keeping only hard, information-rich samples.

The final model averages 0.814 across all evaluation groups, 8.4 points above its base checkpoint and 5.3 above the strongest reasoning-mode baseline, which is ten times larger. On non-fine-tuned groups alone, it leads the base by 3.4 points and the reasoning baseline by 2.4. It is deployed and handles production traffic within latency constraints. A cost analysis adjusted for quality shows that large baselines need so many GPUs that they cost more than the human work they replace, while our model beats the strongest deployable baseline by 53%.

Our contribution is a unified cost-aware methodology for building a deployable document VLM under strict hardware and privacy constraints. The approach begins with model selection guided by per-document economics, then scales quality through a DADC pipeline that converts commodity PDFs into high-signal supervision. The resulting model beats baselines on in-house benchmarks up to $4\times$ larger in active parameters and $10\times$ in total paramaters while needing $8\times$ fewer GPUs, and a quality-adjusted cost framework, calibrated from

EMNLP 2026 Industry Track, pages 2024–2044
October 24-29, 2026 ©2026 Association for Computational Linguistics

production telemetry, ties per-field accuracy directly to deployment economics. The methodology is workflow-independent and closed-form, with adaptation to a given workflow requiring only recalibration of the coefficients (workload distribution, GPU utilization, routing policy, per-action costs). We instantiate it with coefficients estimated from our production traffic and report the resulting post-deployment costs.

2 Related Work

General-purpose VLMs have advanced rapidly on document understanding: the Qwen family (Bai et al., 2025b,a) provides the multilingual foundation we build upon, and frontier VLMs (Guo et al., 2025; GLM-V Team et al., 2026; Baidu-ERNIE-Team, 2025; Qwen Team, 2026) confirm that scaling yields consistent benchmark gains, though 70B–400B deployment requires multi-GPU serving with prohibitive per-document cost. MoE architectures offer a more efficient alternative: DeepSeek-VL2 (Wu et al., 2024) matches dense models at 4.5B active parameters, MoE-LLaVA (Lin et al., 2026) established MoE-Tuning for initializing sparse experts from dense FFNs, and the DeepSeek-OCR line (Wei et al., 2025, 2026) pushes this further with a 3B MoE decoder achieving strong OCR accuracy under tight token budgets via optical context compression. olmOCR (Poznanski et al., 2025a) distills GPT-4o into a 7B VLM using native PDF text layers as supervision, conceptually related to our text-to-image substitution, and olmOCR 2 (Poznanski et al., 2025b) adds RL with unit-test rewards, HunyuanOCR (Hunyuan Vision Team et al., 2025), MinerU2.5-Pro (Wang et al., 2026), and Qianfan-OCR (Dong et al., 2026) explore further points in the quality-efficiency space. However, domain adaptation of VLMs for regulated settings where privacy precludes external APIs, sub-10B models miss production thresholds, and a single model in prompting must serve a growing number of heterogeneous workflows remains the open challenge we address.

Several recent systems deploy VLMs in production: VENUS (Zhao et al., 2025) consolidates per-policy video classifiers into a single instruction-tuned VLM with synthetic annotation paralleling our per-workflow unification. IPL (Chen et al., 2024a) adapts a multimodal LLM for C2C product listing reporting 72% user adoption, and PlanGPT-VL (Zhu et al., 2025) fine-tunes a 7B VLM for urban planning maps, rivaling 72B models via structured data synthesis. For document extraction, Yoon et al. (2024) and Wang and Shen (2025) build cascaded OCR–LLM pipelines for insurance, tax, and enterprise settings; our system replaces such cascades with end-to-end extraction from rendered pages via a single VLM. On data curation, Dong et al. (2025) shows that quality-filtered, progressively complex data outperforms raw scaling, similarly our DADC pipeline specializes to the document domain, where corrupt text layers, skewed layout distributions, and generator hallucinations require domain-specific filtering stages.

Chen et al. (2024b) cascades queries across LLMs under pay-per-token pricing. Confidence-based routing to human review is common in commercial platforms, but asymmetric confirmation-versus-correction costs and per-field economics against a manual baseline remain largely unformalized, the gap our framework addresses.

3 Framework

Building a production document VLM requires both scalable, production-representative supervision and tight hardware and cost budgets at document-flow scale. We address both through SFT on a mixture of in-house and open-domain data across four canonical tasks: schema-based field extraction with absent-field handling, closed-set document classification, visual element validation (checkboxes, stamps, signatures), and free-form VQA/OCR, all served through a single instruction-following interface.

3.1 Internal Data

Documents processed at inference time flow through operational workflows in which field values are captured as part of routine business operations, yielding naturally aligned supervision whose semantics and taxonomies match the evaluation distribution by construction, with no additional annotation effort. The internal corpus is drawn from two such workflows: a judicial pipeline (60K court PDFs, 20 fields, 8 per document) and an invoice processing pipeline (150K instances spanning PDFs, scans, screenshots, and photos, 4–5 fields each). The corpus is predominantly Russian. Each training sample pairs an instruction with a ground-truth response. The instruction comprises a task description covering field semantics, layout cues, and disambiguation rules, together with an

output schema encoding per-field formatting constraints and absent-value handling. To mitigate overfitting to fixed templates, prompt components are sampled from sets of semantically equivalent alternatives and key-value pairs are randomly permuted. All annotations undergo quality control with overlapping annotation (3 of 5 annotators per item). The complete prompt template is given in Appendix B.

3.2 Synthetic Data Pipeline

Internal data offers limited diversity: layouts follow operational templates and field taxonomies are fixed by business processes, so both saturate quickly during training (Section 4). We therefore construct a large-scale open-domain synthetic dataset from 300K Common Crawl (CC) PDFs filtered to Russian, Belarusian, Ukrainian, and Kazakh via GlotLID (Kargaran et al., 2023), using a Difficulty-Aware Data Curation (DADC) pipeline. The key insight is that naively generated samples are largely solvable by the base model and add negligible signal: unfiltered open data in fact degrades the in-house–only baseline (Appendix C.7), so DADC filters aggressively to retain only challenging, information-rich examples.

Text layer validation. PDF embedded text is frequently corrupt or misaligned — silently poisoning generated data via malformed encodings or transparent OCR layers from digitization pipelines. We run an internal OCR engine on rendered pages and perform a word-wise consistency check against the embedded text layer; pages below the alignment threshold are discarded. The stage retains 40% of input pages. The complete procedure is in Appendix C.2.

Document Sampling. Validated pages are dominated by continuous prose, a poor match for our deployment, where fields must be extracted from forms, tables, and dense structured layouts. We rebalance the pool via a two-stage filter built on VLM judge (Qwen2.5-VL-72B-Instruct, (Bai et al., 2025b)). *Stage 1 – taxonomic classification* labels pages from a fixed taxonomy (Tabular, Charts, Logic Diagrams, Schematic, Infographic, Plain Text); any non-plain text label admits the page. *Stage 2 – fact-extractability* re-scores remaining plain text pages ($\sim$ 70% of the pool) on visual structure and QA potential, admitting those scoring greater than given threshold – recovering fact-dense but structurally plain documents the structural filter alone discards. Details are in Appendix C.3.

Text-to-image substitution. Query–response pairs are generated from the embedded PDF text layer, then the text representation is replaced by document pages rendered via `fitz` (PyMuPDF) — grounding supervision in visual understanding while leveraging the reliable native text layer. Details are provided in Appendix C.4.

Consistency verification. To filter hallucinations and schema violations, each generated sample is reissued to a cross-family verifier pool (Qwen3-VL-235B-A22B-Thinking (Bai et al., 2025a), Qwen3.5-397B-A17B-FP8 (Qwen Team, 2026) and Kimi K2.6 (Moonshot AI, 2026)) sampling 3–5 responses at temperature 0.8. GPT-OSS 120B (OpenAI, 2025) judges them against the original under an equivalence relation that ignores cosmetic differences but flags factual disagreements. A sample is accepted when at least 2 verifiers agree in the majority of their responses, retaining 35–40% of candidates; most rejections trace to residual PDF text-layer artifacts (Appendix C.5).

Text refinement. After initial post-training we observed degraded adherence to formatting instructions. The refinement stage rewrites annotations into target formats and augments prompts with explicit formatting rules via Qwen3.5-397B, covering common value types (numbers, dates, names) and applying auxiliary normalization (abbreviations, case) elsewhere, recasting the task from pure extraction into joint extraction and normalization (Appendix C.6).

Rendered document augmentation External documents in our open-data corpus are pristine — white pages, crisp glyphs, uniform illumination — while production inputs are camera captures, low-DPI scans and screenshots. To close this gap we apply a three-stage pipeline at sample-serving time: photometric and geometric perturbations (contrast, brightness, sharpness, rotation, zoom, shear) modeling exposure and scanner deformations; elastic warps via a bilinear vector field, mimicking page curl; and spatially varying noise. The pipeline runs inside workers decoupled from training nodes (Appendix D.2). Component ablation (Appendix C.7) confirms each stage is necessary: intermediate setups merely recover in-house increments, and only the full verified pipeline strictly improves model quality.

4 Experiments

Experiment Setup We select Qwen3.5-35B-A3B-Base for its multilingual and visual strengths and favorable per-document cost (Section 5), and fine-tune it for document understanding via SFT on 4 nodes with 8 H100 GPUs (hyperparameters in Appendix D). We benchmark against Qwen2.5-VL-72B-Instruct-AWQ (Bai et al., 2025b), Qwen3.5-35B-A3B-Base, Qwen3.5-122B-A10B-FP8, Qwen3.5-397B-A17B-FP8 (Qwen Team, 2026), and Kimi K2.6 (Moonshot AI, 2026) under identical inference conditions. Evaluation spans internal and public document benchmarks; online evaluation applies quality-adjusted cost analysis (Section 5) to translate scores into per-document economics against the human-annotation baseline.

Deployment constraints Production latency SLAs preclude test-time reasoning. Our model holds 95th-percentile latency well below 10-second our SLA across concurrency levels on a single H100, while both dense and MoE baselines breach it at 2–3 workers even on larger GPU allocations (Appendix E). Cost analysis therefore uses non-reasoning inference, reasoning baselines in Table 1 only bound headroom under relaxed latency.

Benchmarks Our primary offline evaluation is an internal suite of 12 benchmarks reflecting the production distribution, organized into three groups: *Single-page (SP)* for one-page understanding over clean PDFs, in-the-wild scans and photos; *Multi-page (MP)* for long-context comprehension over image sequences; and *Fine-tuned (FT)* for business-critical workflows partially seen during training (details on data collection, curation, and contamination control are in Appendix A). Field extraction is evaluated by averaging exact accuracy — all fields must match ground truth, directly proxying the full automation ratio—and field-level F_1, computed per field per sample, capturing incremental improvements invisible to exact accuracy; document classification uses standard accuracy and macro-F_1. We complement evaluation with the *MWS Vision Benchmark* (MTS AI, 2025) as a public Russian-language benchmark covering diverse business and technical documents, and report cross-lingual transfer results on widely used open benchmarks (Table 4): OCRBench (Liu et al., 2024), OCRBench v2 (Fu et al., 2025), CC-OCR (Yang et al., 2024), DocVQA (Mathew et al., 2021), and InfoVQA (Mathew et al., 2022).

Results Table 1 reports results across all four benchmark groups. Our model achieves the best overall score, 0.767 averaged over non-fine-tuned benchmarks, outperforming the strongest open-source baseline, Qwen3.5-397B-A17B-FP8-Reasoning, by 2.4 absolute points despite being more than an order of magnitude smaller in active parameters, and improving over its base model Qwen3.5-35B-A3B-Base by 3.4 points, from 0.733 to 0.767, with consistent leads across single-page, fine-tuned, and open benchmarks and competitive multi-page performance at 0.764.

Two observations stand out. First, we attribute the strong multi-page score of Qwen3.5-397B-A17B-FP8-Reasoning, 0.777, to test-time scaling, where reasoning traces decompose dispersed visual evidence into intermediate steps; our model achieves comparable quality at 0.764 through SFT-acquired capabilities alone, without the latency and cost of reasoning-mode inference, as detailed in Section 5. Second, excluding fine-tuned benchmarks to rule out in-distribution effects, our model still leads at 0.767 over 0.743, demonstrating generalization beyond the training distribution.

Production latency SLAs preclude reasoning-mode inference, so we treat such models as reference points rather than deployable candidates. Among deployable configurations, our model leads on every benchmark group, including multi-page at 0.764 over 0.745 for non-reasoning Qwen3.5-397B-A17B-FP8.

How much of SFT gain was already in base model? SFT may either refine behavior already present in the base model or unlock latent capacity that pre-training instilled but left dormant in the zero-shot setup. The distinction is operational: refinement saturates quickly with data, whereas unlocking keeps targeted post-training high-leverage at relatively modest volumes.

We compare two base models, Qwen3.5-9B-Base and Qwen3.5-35B-A3B-Base, post-trained on an identical mixture under their respective best hyperparameter setups (Table 2).

The gains are disproportionately large relative to the SFT corpus, which is small by pre-training standards, and they generalize beyond SFT coverage, with consistent improvements across all benchmark groups. Despite identical SFT data, the models do not meet at a common ceiling: post-trained Qwen3.5-35B-A3B-Base retains its lead across all

Model	Single-page	MWS (val)	Multi-page	FT	Avg w/o FT	Avg
`Qwen2.5-VL-72B-Instruct-AWQ`	0.785	0.635	0.698	0.645	0.706	0.691

Table 2: SFT effect across base scales. SP: single-page, MP: multi-page, FT: fine-tuned.

groups, suggesting pre-training capacity sets the upper bound while SFT controls how much is realized.

Is internal data a scaling factor? Internal and open-domain data play different roles: internal data is aligned with the production distribution but bounded by templates and a fixed field taxonomy, while open-domain data offer unbounded diversity at the cost of aggressive curation (Section 3.2). We assess their relative scaling via controlled ablations over the mixing ratio at fixed training budget (Table 3). Internal data gains saturate quickly, reflecting low template diversity in production workflows. Open-domain data scales further, with performance improving well beyond the internal-data plateau, driven by CC diversity and DADC filtering. A hybrid mixture dominates either source alone, with the open-heavy ratio yielding the best trade-off. Beyond scaling, internal data offer the highest-fidelity signal for early-phase discovery and failure-mode diagnosis on production-representative inputs. We accordingly adopt a hybrid strategy: internal data drives early exploration and targeted gap-filling, while open-domain synthetic data carries the bulk of the scaling effort.

Mixture	SP	MWS	MP	FT	Avg w/o FT
Base (no SFT)	0.827	0.672	0.697	0.722	0.729
Internal only	0.840	0.685	0.738	0.951	0.754
Open only	0.835	**0.700**	0.677	0.793	0.737
1:1 mix	0.837	0.689	**0.768**	0.955	0.764
1:4 (open-heavy)	**0.842**	**0.700**	0.764	**0.956**	**0.767**

Table 3: Effect of internal:open data ratio on downstream quality (fixed training budget).

Cross-lingual transfer on public benchmarks Our model improves over the base on every benchmark, with the largest gains on DocVQA, from 82.14 to 90.10, and InfoVQA, from 51.10 to 66.30, confirming that DADC transfers to English despite a predominantly Russian training corpus. Smaller gains on OCRBench, +15%, and OCRBench v2, +1.1%, are notable given their diversity: recognition, referring, spotting, relation extraction, parsing, math, and reasoning, of which structured extraction is a small fraction, indicating generalization beyond DADC's direct training signal. CC-OCR shows a slight aggregate regression, from 81.74 to 80.40, but on slices closest to our deployment we improve: KIE rises from 90.39 to 92.81 and Document Parsing from 61.92 to 63.77. A meaningful gap to Qwen3.5-397B-A17B-FP8 persists, most visibly on InfoVQA, 66.30 against 89.58, reflecting the cost of an order-of-magnitude reduction in active parameters.

	Base	Ours	Qwen3.5 397B
OCRBench	848	863	**889**
OCRBench v2 (en)	55.1	56.2	**61.1**
CC-OCR	81.74	80.40	**84.86**
DocVQA (test)	82.14	90.10	**96.74**
InfoVQA (test)	51.10	66.30	**89.58**

Table 4: Performance on English-language public document understanding benchmarks (non-reasoning mode).

5 Quality-adjusted Cost Analysis

A higher-scoring model may cost more to serve than the annotation it displaces, so our quality-adjusted cost framework translates per-field quality into per-document economics, enabling unified comparison across models and the manual baseline.

Inference Cost Consider a model served on G_m H100 GPUs at utilization $u \approx 0.5$, calibrated to peak-hour SLAs, with monthly GPU cost C_{GPU} and $T_{\text{month}} = 30 \cdot 24 \cdot 3600$ seconds, the per-document inference cost is

$$y(m, w) = \frac{G_m \cdot C_{\text{GPU}}}{u \cdot T_{\text{month}} \cdot \text{RPS}_m(w)}, \quad (1)$$

where $\text{RPS}_m(w)$ is the profiled throughput for model–workflow pair. Because G_m ranges from 1 for compact MoEs to 8 for dense 400B models, it is the primary driver of cost differences.

Field-level Routing A single aggregate score obscures the per-field variation that governs deployment economics. We develop the framework for field extraction, the dominant cost driver, but it extends to classification and criteria validation by treating each decision as a field. Given per-field accuracy a_f and precision p_f on a held-out subset, each field is routed into one of three modes via thresholds θ_{auto} and θ_{assist}: fully automated ($a_f \geq \theta_{\text{auto}}$), where the prediction is accepted at inference cost only; human-assisted ($a_f < \theta_{\text{auto}} \wedge p_f \geq \theta_{\text{assist}}$), where the prediction is surfaced as a pre-fill for the operator to confirm or correct; and fully manual ($a_f < \theta_{\text{auto}} \wedge p_f < \theta_{\text{assist}}$), where the prediction is discarded and the field is annotated from scratch. Routing is fixed per field and per workflow at deployment time and remains unchanged until the next model update, different fields within the same document may fall into different modes.

Cost Model The model rests on two atomic units: x, the fully loaded cost of manual field annotation, covering operator time, supervision, quality control, and $y(m, w)$, the per-document inference cost from Eq. 1. Assisted-mode outcomes carry asymmetric costs: confirmation costs $0.3x$, reflecting the reduction from search-and-transcribe to read-and-confirm, while correction costs $1.1x$, the overhead arising from error detection and the context switch of discarding a displayed suggestion (coefficient calibration in Appendix F.1). Since the confirmation-correction split for an assisted field f is governed by its precision p_f, the expected extraction cost is

$$c_{\text{a}}(f) = 0.3x \cdot p_f + 1.1x \cdot (1 - p_f). \quad (2)$$

Eq. 2 decreases monotonically in p_f, and the total per-document cost for workflow w under model m is

$$C_w(m) = y(m, w) + x \cdot |\mathcal{F}_w^{\text{h}}| + \sum_{f \in \mathcal{F}_w^{\text{a}}} c_{\text{a}}(f), \quad (3)$$

where $\mathcal{F}_w^{\text{a}}$ and $\mathcal{F}_w^{\text{h}}$ are the sets of fields per assisted and manual modes. Against the fully manual baseline $C_w(\text{baseline}) = x \cdot |\mathcal{F}_w|$, the cost reduction ratio is

$$\rho_w(m) = 1 - \frac{C_w(m)}{C_w(\text{baseline})}. \quad (4)$$

The deployment is economically justified when $\rho_w(m) > 0$. The automation threshold $\theta_{\text{auto}} = 0.95$ is a business decision bounding the residual error rate on fully automated fields. The assistance threshold θ_{assist} is derived analytically from the break-even condition $c_{\text{assist}}(f) = x$, yielding $\theta_{\text{assist}} = 0.125$: below this precision, correcting a likely wrong suggestion costs more than annotating from scratch, so the prediction is discarded.

Model	G_m	Throughput	$\rho_{w_1}(m)$	$\rho_{w_2}(m)$
Qwen3.5-397B-A17B-FP8	8	0.025×	-0.115	-1.582
Qwen2.5-VL-72B-Instruct-AWQ	1	0.200×	0.563	0.534
Qwen3.5-35B-A3b-Base	1	1.000×	0.691	0.791
Our model	1	1.000×	**0.819**	**0.861**

Table 5: Throughput (normalized to our model) and cost reduction ratio across two production workflow groups measured at an average workload of 6k input tokens (including 5k visual) and up to 0.5k output tokens.

Results Table 5 reports per-document inference cost and cost reduction ratio across two workflow groups differing in field count (w_1: 12 fields on average, w_2: 6) and per-field accuracy; all configurations are benchmarked on 8 H100s, with G_m denoting the minimum footprint per replica. Despite competitive offline quality, large-model serving costs push ρ_w below zero: compute exceeds the displaced annotation effort. Qwen3.5-397B illustrates this clearly on both groups. As field count decreases, the fixed serving cost becomes harder to amortize, and large models' ρ_w deteriorates sharply; smaller models degrade gracefully. Our model sustains nearly 5× higher throughput than Qwen2.5-VL-72B and yields the highest ρ_w in both groups, closing the cost–quality gap that motivates this work.

6 Conclusion

Deploying a VLM at scale in a regulated setting is gated not by benchmark scores but by per-document economics. We presented a 35B-A3B

VLM, domain-adapted via a difficulty-aware curation pipeline on open-domain PDFs mixed with in-house production data, that outperforms baselines an order of magnitude larger on our production benchmarks. Benchmark-leading quality is necessary, but not sufficient. Our quality-adjusted cost framework makes this trade-off explicit, identifying our model as the most economically viable solution. We believe the paradigm offers a broadly useful template for grounded model selection in deployment economics.

Limitations

Reasoning and reinforcement learning. Our corpus centers on direct field extraction and lacks multi-step reasoning examples, such as reconciling information across many pages or resolving cross-referential dependencies. The model may therefore underperform on workflows requiring compositional reasoning or long-range evidence aggregation. We deliberately chose not to pursue an reinforcement learning (RL) stage at this point: our SFT pipeline already matches or exceeds reasoning-mode variants of substantially larger models on the benchmarks evaluated in Table 1, suggesting that the current synthetic-data recipe captures a large share of the extractable signal on our present evaluation suite without an explicit RL objective. Moreover, RL with verifiable rewards requires that each training example admit a ground-truth answer. In our setting this is a harder bar than SFT supervision, which tolerates noisier labels: either domain experts must curate multi-step problems with unambiguous solutions, or the synthetic-data pipeline must be redesigned to produce tasks whose answers are verifiable by construction. We regard this as a natural next step once returns from SFT data scaling diminish.

Cross-lingual coverage. Although training data includes multiple Cyrillic languages alongside Russian, we have not run a per-language ablation, leaving cross-lingual transfer behavior unclear.

Post-training ceiling. SFT has not pushed the model to its performance ceiling, a gap we attribute primarily to pre-training limitations rather than the post-training recipe. We plan to continue scaling post-training — expanding data diversity, reasoning coverage, and supervision quality — to push performance further.

Ethical Statement

Human annotation. All annotation, quality control, and benchmark construction were performed by trained in-house operators employed under standard full-time contracts, with compensation aligned with local labor regulations. No external crowdsourcing was used. The retrospective study calibrating the assisted-mode cost coefficients (Appendix F.1) used aggregated, anonymized operational telemetry from 50 annotators over three months; no individual-level evaluation or disciplinary action was derived from it. The framework is explicitly designed around human-in-the-loop operation: lower-confidence fields are routed to assisted or manual modes, preserving operator oversight, and deployment is coordinated with workforce planning to redirect capacity toward higher-complexity tasks.

Data Privacy. Documents processed by the platform contain PII. This constraint directly motivated on-premise fine-tuning and deployment rather than reliance on external APIs. All internal data was stored within the institution's secured infrastructure under role-based access control, encryption at rest and in transit, and auditable access logs, as mandated for regulated PII data. No internal documents, derived training samples, or checkpoints trained on internal data were transferred outside the secured perimeter or used to query third-party services. Cross-model verification of synthetic samples used open-weight models executed within the same perimeter and was applied exclusively to the open-domain corpus.

Responsible Use. The model is intended for document understanding within a regulated enterprise setting and is not suitable for unconstrained consumer-facing deployment without further safety review. The cost framework is calibrated to a specific operational setting and should be re-calibrated before transfer to other environments. Routing decisions must be revisited whenever the document distribution, schema, or workflow changes materially.

A Benchmark Suite Details

A.1 Dataset Composition

Table 6 enumerates the internal benchmarks grouped by task type. Each group spans the three canonical task families encountered in production: field extraction, document classification, and criteria validation. Each benchmark item was independently annotated by 3 of 5 trained annotators. Disagreements were resolved through adjudication, and items without majority consensus were excluded.

A.2 Contamination Control

For fine-tuned benchmarks, we partition documents by unique identifying entities — company names, personal names, taxpayer identification numbers, and account numbers — ensuring no entity appearing in the evaluation set is present in the training corpus. This guarantees that the reported metrics reflect generalization to unseen parties rather than memorization of specific document instances. Template-level contamination is likewise precluded: the fine-tuned benchmarks are drawn from workflows that are different from those represented in the training corpus, with disjoint document classes, layouts, issuing authorities, and field taxonomies. At all stages we perform MinHash deduplication against benchmarks to prevent data leakage, the prompts for evaluation data were written and curated by professional annotators and only lightly adapted per baseline to enforce a JSON-structured response; no per-baseline capability tuning was performed.

As a result, neither the surface form nor the structural skeleton of evaluation documents is observed during training, and the reported metrics reflect generalization across both entities and templates.

Distinguishing Court Case Files from Short Court Rulings. Although both originate from the judicial domain, the two benchmarks correspond to structurally distinct document classes. Court Case Files are multi-page interlocutory proceedings with schemas centered on procedural metadata, whereas Short Court Rulings are single-page terminal decisions from small-claims cases, with schemas centered on final disposition (outcome, awarded amount, ruling date). The two differ in document length, procedural stage, field taxonomy, and source workflow. Entity-level partitioning further guarantees no shared parties, case numbers, or taxpayer identifiers between the two, ensuring that performance in Short Court Rulings reflects genuine generalization to an out-of-distribution judicial document type.

B Internal Data Construction

B.1 Prompt Template

Each training instruction is composed of a task description and an output schema. Figure 1 is the generalized template used for field-extraction tasks.

To mitigate template overfitting, each prompt component is drawn from a pool of semantically equivalent phrasings produced manually and augmented with Claude Sonnet 4.5 (Anthropic, 2025). The order of key-value pairs in the schema is randomly permuted across samples.

C Open Data Construction

C.1 Data

The open-domain corpus is subsampled from a large-scale Common Crawl PDF dataset, retaining only documents identified as Russian, Belarusian, Ukrainian, or Kazakh via a GlotLID (Kargaran et al., 2023) language identification model. The resulting collection comprises approximately 300K PDF documents (5M pages), predominantly Russian-language, selected to align with the operational deployment setting of the model.

C.2 Text Layer Validation

PDFs are a compelling source of training data, but text extraction is fundamentally fragile: the PDF standard encodes glyph-positioning instructions whose mapping to characters depends on per-font tables (Encoding, ToUnicode CMap) that may be absent, incorrect, or deliberately obfuscated. In addition, a substantial portion of real-world documents embed text as raster images overlaid with a missing or corrupted text layer, causing structure-based extraction to return empty or garbled output.

We address this with a *dual-channel annotation scheme*. For each page, we (i) parse the PDF content stream to extract the embedded text layer and (ii) run an internal OCR engine on the rasterized page image. The embedded text layer, when valid, faithfully reproduces characters but is vulnerable to PDF-level artifacts (malformed encodings, hidden text objects). OCR, conversely, is robust to such structural anomalies, but introduces its own character- and symbol-level recognition errors. For

Group	Subbenchmark	Task Type	Samples
Single-page (SP)	Payment Screenshot Amounts	Field Extraction	2,000
	B2B Invoices	Criteria Validation, Field Extraction	2,000
	Document Type Classification	Document Classification	1,909
	Short Court Rulings	Field Extraction	1,524
	ID Documents	Field Extraction	900
	Income Certificates	Field Extraction	610
	Restaurant Receipts	Field Extraction	410
Multi-page (MP)	Enforcement Documents	Field Extraction	3,376
	Banking Legal Documents	Field Extraction	1,900
	Company Compliance Fillings	Field Extraction	1,000
Fine-tuned (FT)	Retail Invoices	Field Extraction	1,911
	Court Case Files	Field Extraction	1,341

Table 6: Internal benchmark suite, organized by evaluation group.

```
You are an expert in {domain} documents and {task_type}.
Your task is to extract precise values for a strictly defined list of entities from the document
↪  image.
All specified entities must be included in the response, even if they are absent from the text.

Instructions:
1. Review the entity descriptions provided after "|" following entity names -- they clarify what
↪  to extract.
   DO NOT include them in the response.
2. Extract the value for each entity from the document text.
3. Verify that the list of entities in your response matches the list below exactly -- no
↪  additions or
   omissions.
4. Format your response strictly as JSON, where keys are field names and values are the extracted
↪  fields.
   If a value for any entity is absent, set it to "nan".

Entity list:
FIELD_1 | {description}. Location: {location_cue}.
          Identifying features: {features}.
          Example: "{example_context}" -> extracted "{example_value}".
...
FIELD_N | {description}. Format: {format_constraint}.
Processing rules:
1. NOT ALL FIELDS MAY BE PRESENT IN THE DOCUMENT.
2. DO NOT HALLUCINATE OR SUBSTITUTE INCORRECT DATA.
3. FOR FIELDS ABSENT FROM THE TEXT, ALWAYS SET THE VALUE TO nan.
4. RETURN ONLY THE JSON RESPONSE, NO ADDITIONAL TEXT.

Return response in the following format:
{"FIELD_1": "...", "FIELD_2": "...", ..., "FIELD_N": "..."}
```

each page we compute a consistency score between the two channels, using normalized character error rate with domain-specific tokenization. Pages whose alignment exceeds a fixed threshold are accepted; documents falling below it are discarded entirely — such mismatches typically indicate either malformed font encodings or a scanned page whose text layer was itself generated by low-quality OCR at digitization time.

A particularly subtle failure mode arises from documents containing a *transparent OCR text layer* — a byproduct of digitization pipelines (e.g., ABBYY FineReader) that overlay their own OCR output as invisible glyphs on top of the scanned image. Structurally indistinguishable from a high-confidence native text layer, such pages would otherwise poison training with compounded OCR artifacts. We proactively detect and exclude these pages, ensuring the final corpus contains only natively generated text layers verified against an independent OCR signal. A conceptually related strategy is employed by Poznanski et al. (2025a), that uses native PDF text as an anchor signal to verify VLM output.

Verification statistics. Applied to the open-data corpus (Appendix C.1), the procedure retains approximately 40% of input pages, with matched precision $= 0.80$, matched recall $= 0.90$, and average normalized Levenshtein distance $= 0.05$ over matched spans. The remaining 60% are discarded as malformed text layers or scanned pages whose embedded text was itself produced by low-quality OCR at digitization time. In future work, we plan to recover signal from currently rejected pages, either by re-OCRing them with a strong engine, or by using them directly with a VLM to produce the resulting annotations.

C.3 Document Sampling

Pages that pass text-layer validation are dominated by continuous prose — a poor match for our target deployment, where models must extract fields from forms, tables, and dense structured layouts. To rebalance the corpus toward visually challenging documents, we apply a two-stage filter: a fine-grained taxonomic classifier whose non-PLAIN_TEXT labels directly admit a page, followed by a fact-extractability scorer that rescues structurally sparse pages that nonetheless contain extractable facts.

Stage 1: Taxonomic classification. Each candidate page is scored by Qwen2.5-VL-72B-Instruct-AWQ against a fixed taxonomy of visual-reasoning content. The full prompt is shown in Figure 2. Pages assigned at least one non-PLAIN_TEXT label are admitted directly to the candidate pool.

Across successfully classified pages, Table 7 reports the distribution over primary categories, and Table 8 the distribution of complexity scores.

Category	Share
PLAIN_TEXT	72.9%
TABULAR	23.3%
SCHEMATIC	2.3%
CHARTS	0.6%
LOGIC_DIAGRAMS	0.4%
INFOGRAPHIC	0.4%

Table 7: Distribution of taxonomic labels, counted among all assigned labels across pages.

Score	Visual	QA Potential
0	0.00%	0.00%
1	0.61%	0.48%
2	51.68%	54.12%
3	10.20%	18.12%
4	16.57%	10.94%
5	9.80%	6.59%
6	8.33%	4.38%
7	1.93%	3.36%
8	0.51%	1.61%
9	0.37%	0.40%
10	0.00%	0.00%

Table 8: Distribution of Stage 2 visual structure and QA potential scores across pages routed to the fact-extractability filter.

Stage 2: Fact-extractability rescue. PLAIN_TEXT pages are passed through a second filter that scores each page on two axes — visual structure complexity and QA potential — framed around the question: *can a precise, unambiguous question be asked about this document?* Pages whose QA potential score ≥ 5 *or* visual score ≥ 5 are admitted to the candidate pool; the rest are discarded. The full prompt is shown in Figure 3.

The motivation for this stage is twofold. First, the Stage 1 taxonomy is deliberately narrow: it targets pages whose *visual structure* encodes the answer (tables, diagrams, charts). Yet many PLAIN_TEXT-labeled pages — receipts with stamps, simple invoices, short forms with handwritten fields, dense administrative documents — contain concrete extractable facts (dates, amounts, identifiers, named entities) without exhibiting any

```
Analyze this document page image and classify it according to the visual-reasoning content it
↪  contains.
Your goal is to identify pages whose layout supports non-trivial information extraction or
↪  inference.

**TAXONOMY** Assign up to three labels from the following set:

- CHARTS: charts, plots, bar/line/pie graphs, numeric figures whose interpretation requires
↪  reading values off axes
  or legends.
- LOGIC_DIAGRAMS: flowcharts, decision trees, state machines, BPMN diagrams, any directed-graph
↪  structure encoding
  control flow or rules.
- SCHEMATIC: floor plans, circuit diagrams, engineering layouts, any content whose meaning depends
↪  on 2D spatial
  arrangement.
- INFOGRAPHIC: mixed-modality compositions combining icons, short text blocks, and stylized
↪  visuals to convey
  information.
- TABULAR: structured data in rows and columns, including:
   * Traditional tables with visible borders/gridlines
   * Borderless tables (data aligned by spacing/tabs)
   * Matrices, grids, comparison charts, financial statements,
     price lists, schedules in table format
   * Spreadsheet-like data presentations
  EXCLUDE from TABULAR: single-column bulleted/numbered lists, paragraphs of regular text,
  ↪  isolated key-value pairs,
  forms with scattered input fields.
- PLAIN_TEXT: continuous prose, standard book/article layout, decorative pages, or any page that
↪  contains none of
  the above. PLAIN_TEXT is MUTUALLY EXCLUSIVE with all other categories.

Output schema:
{
  "categories": [...],  // up to 3 labels
}
```

Figure 2: Stage 1 taxonomic-classification prompt. The classifier assigns up to three labels per page from a fixed taxonomy; PLAIN_TEXT routes the page to Stage 2.

of the Stage 1 visual structures. Second, Stage 1 alone discards roughly 70% of all classified pages as PLAIN_TEXT (Table 7), making the funnel uncomfortably sharp; routing these pages through a second, content-oriented filter recovers meaningful signal that would otherwise be lost wholesale. Stage 2 thus complements Stage 1 rather than relaxing it: scoring is conditioned on the assumption that the page already failed the structural filter, and admission requires that at least one of the two axes register an unambiguous positive signal.

The union of these two stages forms the final candidate pool from which the synthetic corpus is sampled.

C.4 Samples Generation

For each page admitted to the candidate pool, we synthesize a set of samples. By default, generation uses a single prompt that conditions on the page's extracted text (with page-boundary markers preserved) and produces multi-field information extraction questions. For pages whose Stage 1 taxonomy includes a TABULAR label, we additionally apply a table-oriented prompt that targets row/column intersections, conditional lookups, and header–cell relations. The general prompt is shown in Figure 4. Generation is performed by both Qwen3.5 397B and GLM5.1 (Z.AI, 2026) conditioned on the page text. Across both prompts, we enforce strict OCR-mode extraction: values are returned verbatim from the source text without normalization, case folding, or punctuation changes, and all numeric fields (sums, codes, identifiers, requisites) are returned as strings to preserve leading zeros and original formatting that will be refined in next stages.
